heart failure from those of pneumonia or bronchiolitis; indeed, many infants develop heart failure during an intercurrent pulmonary infection. Edema, if present, usually is found in the periorbital area and on the dorsa of the feet and hands. Cardiac enlargement is confirmed by chest roentgenography. Infants with malformations such as coarctation of the aorta and total anomalous pulmonary venous connection, abnormalities that usually are not characterized by an impressive murmur, sometimes are referred only after weeks of tachypnea and failure to thrive, when a chest roentgenogram taken to explore the possibility of lung disease has revealed cardiac enlargement.

When a sizable systemic-to-pulmonary communication exists in a premature infant, usually as a result of a PDA, signs of heart failure usually are associated with signs of ventilatory failure.

Hospitalization is recommended for all infants with heart failure. Elevation of the head and chest to an angle of approximately 30° and administration of humidified oxygen by techniques that do not disturb the infant help relieve dyspnea and systemic arterial hypoxia as determined by pulse oximetry. Arterial oxygen saturation levels should be monitored in newborns, particularly the premature, to avoid the risk of retrolental fibroplasia. Rest, aided by sedation, is beneficial. With severe failure, oral feedings should be suspended temporarily to prevent aspiration and fluid intake should be restricted to 65 mL/kg per day intravenously for at least the first 24 h. Anemia, acidosis, hypoxia, hypercarbia, hypoglycemia, or hypocalcemia should be corrected; serum sodium, potassium, blood urea nitrogen, and creatinine concentrations should be monitored. A low threshold for the administration of antibiotics is appropriate.

Digoxin is recommended for the management of congestive failure in infants and children, especially those with decreased ventricular systolic function, because of its excellent absorption when given orally, rapid onset of action, relatively rapid excretion, and convenience of administration. The recommended oral maintenance doses of digoxin for the different age ranges of children, expressed in μg/kg per day, are as follows: for the premature, 5; for neonates, 10; for infants between 4 and 24 months of age, 15; for older children, 10; and for adolescents, 5. The daily maintenance dose usually is given in two divided doses approximately 12 h apart. The total digitalizing dose is three times the daily maintenance dose. Parenteral doses of digoxin are approximately 75 percent of oral doses for digitalization and maintenance. Half the digitalizing dose may be given initially, followed by the remaining two quarter doses at 4-, 8-, or 12-h intervals, depending on the desired speed of total digitalization. Maintenance therapy should be started 8 to 12 h after the last digitalizing dose. In a severely ill infant with decreased perfusion and unpredictable absorption, digitalization by the intravenous route is recommended. Impaired renal function leads to digoxin accumulation and toxicity, and so the initial and maintenance doses should be adjusted accordingly. Toxicity, if it is to occur, usually appears within the first week of therapy. If anorexia, nausea or vomiting, or electrocardiographic evidence of either atrial or ventricular ectopy or AV block appears, digoxin should be stopped and the serum digoxin level should be determined. Toxicity is probable if the level exceeds 3.0 ng/mL in an infant less than 6 months of age or 2.0 ng/mL in an older infant or child. If the need for digoxin continues, the dose is adjusted as the patient grows and gains weight.

The diuretic furosemide used intravenously in doses of 1.0 to 2.0 mg/kg or orally in doses of 1.5 to 2.0 mg/kg is very effective in the acute management of congestive heart failure. With severe failure, the dose may be increased by increments of 1.0 mg/kg intravenously if no urinary response has been achieved after 45 min. For long-term oral diuretic therapy, 1.5 to 2.0 mg/kg once daily or, if necessary, twice daily is recommended. Chlorothiazide, a slightly less potent diuretic but one with a longer duration of action, may be given orally in a dose of 20 to 50 mg/kg per day. Hypokalemia and hypochloremia can be induced with these potent diuretics, and a daily oral supplement of potassium chloride in the range of 1.0 to 1.5 meq/kg, with adjustment depending on the serum level, is recommended. Spironolactone, an aldosterone antagonist, has proved useful in supplementing the diuresis and preventing the hypokalemia induced by the diuretics described above. It may be given orally in a single daily dose of 2 to 3 mg/kg. A regimen of spironolactone 2 mg/kg given every day and furosemide 1 mg/kg is usually adequate for long-

term diuretic therapy for mild to moderate heart failure and usually does not require potassium supplementation.

In emergency situations, it may be necessary to provide an immediate inotropic stimulus in the form of intravenous sympathomimetic amines administered by constant infusion pump. Isoproterenol in a dose of 0.1 μg/kg per minute exerts a powerful inotropic effect, but its usefulness may be limited by induced tachycardia and peripheral vasodilation, sometimes to the detriment of renal perfusion. Epinephrine in a dose of 0.1 to 1.0 μg/kg per minute or dobutamine or dopamine in a dose of 5 to 15 μg/kg per minute generally has been more helpful, with dopamine providing more adequate renal flow. The systemic arterial blood pressure, urinary output, and electrocardiogram (ECG) should be monitored continuously. Vasodilator therapy in the form of intravenous sodium nitroprusside may be of considerable help in patients with severe congestive failure that is not associated with large left-to-right shunts. The infusion rate at the start should be no higher than 0.5 μg/kg per minute, but it may be increased gradually to 4.0 μg/kg per minute to achieve the desired effect. Systemic arterial pressure should be monitored continuously to detect serious hypotension. The angiotensin-converting enzyme inhibitors captopril, enalapril, and lisinopril given orally have proved effective in selected patients: captopril starting at 0.1 to 0.4 mg/kg per dose in a neonate and 0.3 to 0.6 mg/kg per dose in an older child given one to four times per day, enalapril 0.16 to 0.25 mg/kg per day in two divided doses, or lisinopril 0.16 to 0.25 mg/kg per day in a single daily dose. Hypotension and/or hyperkalemia are the primary adverse effects of these agents.[25]

Infants with potentially exhausting respiratory effort or with hypoxia or hypercapnia secondary to pulmonary edema or respiratory failure benefit from endotracheal intubation and ventilation on a volume-controlled, positive-pressure respirator, usually with the addition of positive end-expiratory pressure. These measures may permit additional therapy, cardiac catheterization, and surgical intervention with a much greater margin of safety.

In newborns who have failure as a result of narrowing or closure of the ductus arteriosus in the presence of critical obstruction to flow from the left side of the heart, dramatic and lifesaving relief can be expected with reopening of the ductus by the infusion of PGE_1 at a dose of 0.1 μg/kg per minute.

Finally, infants or children in whom medical therapy is clearly inadequate or only temporarily successful may require prompt surgical intervention for control of heart failure. *As a rule, the earlier the onset of congestive failure, the more likely the need for surgery*.

Hypoxemia

The sequelae of hypoxemia are listed in Table 63-3. *Cyanosis*, a bluish tinge to the color of the skin caused by the presence of at least 3 to 5 g/dL of reduced hemoglobin, is frequently the initial sign of congenital heart disease in an infant. It also may be an early sign of pulmonary, central nervous system, or metabolic disease or methemoglobinemia. Nonsurgical palliation with PGE_1 and the rapid development of surgical techniques for infants make a prompt distinction between cardiac and noncardiac cyanosis, usually by echocardiography, extremely important.

Table 63-3: Sequelae of Hypoxemia

Cyanosis	Exercise intolerance
Clubbing	Hypoxic spells
Polycythemia	Brain abscess
Squatting	Cerebrovascular accidents

Hypoxia leading to cyanosis in congenital heart disease may be due to heart failure with pulmonary edema and pulmonary venous desaturation or to intracardiac right-to-left shunting. The hypoxia that is due either to heart failure or to lung disease with intrapulmonary shunting usually responds dramatically to oxygen administration, whereas hypoxia that is due to cyanotic defects does not. Since many infants are relatively anemic during the first few months of life (hemoglobin concentration, 10.4 to 12 g/dL), cyanosis may be subtle.

When cyanosis has been present in older children for several months, the distal tips of the fingers and toes become hyperemic. Eventually, the capillary end loop dilation causes *clubbing* of the fingers and toes with a loss of the normal angle of the base of the nail and fingers. Also, with long-standing hypoxemia, the hematocrit increases to maintain the oxygen-carrying capacity of the blood (*polycythemia*). The increased hemoglobin concentration at any given oxygen saturation will result in more reduced hemoglobin, exaggerating the cyanosis.

The central nervous system may be the target organ of cerebrovascular accidents or brain abcess. *Brain abcess* probably is due to bacteremia primarily with mouth organisms that cross from the venous system to the arterial system right-toleft from shunting. The incidence seems to be directly related to arterial saturation and occurs mostly in older children and adolescents.[26]

Cerebrovascular accidents are due directly to hypoxemia or indirectly in children who are polycythemic presumably secondary to sludging.[27] The former group usually consists of infants less than 2 years old who are anemic and thus may have markedly reduced oxygen levels. The latter group consists of children or young adults who are polycythemic and have sludging or in situ microthrombosis. Interestingly, iron deficiency leads to stiff red cells, and so sludging may occur with modest levels of polycythemia (hematocrit 55 to 60 percent) in the presence of iron deficiency. With hematocrits in the range of 65 percent or higher, increased viscocity may lead to a cerebrovascular accident. Maintaining a proper level of hemoglobin has a salutory effect on hemodynamics and oxygen delivery in the presence of significant hypoxemia.[28,29]

Other systems also may be affected by hypoxemia or polycythemia. In older adolescents, the increase in hemoglobin breakdown may result in hyperuricemia and can precipitate a secondary form of gout.[30]

Disturbances in hemostasis also occur with polycythemia. Coagulation factors are commonly abnormal in patients with hematocrits in excess of 60 percent.[31] Actual platelet counts may be normal but can be increased initially in some patients, with subsequent decreases related to persistent and worsening desaturation. There is evidence of shortened platelet survival time in patients with cyanotic heart disease.[32] Laboratory evaluation of coagulation status requires that correction be made for the diminished volume of plasma and for the volume of anticoagulant used in blood samples to avoid false results. Hematologic management of adults with cyanotic congenital heart disease requires special experience and knowledge.[33]

The major consequences of cyanosis can be avoided in many instances, although differences in intelligence have been demonstrated between cyanotic and acyanotic children.[34]

Retardation of Growth and Development

Children with severe cardiac malformations frequently exhibit retardation of growth and development, with height and weight near or below the third percentile or weight 20 percentile points below the mean percentile for height.[35]

Growth retardation is most severe among children with overt cyanosis and those with large left-to-right shunts that cause heart failure. Heart failure tends to cause a greater retardation of weight than of height. Skeletal retardation, reflected by bone age, usually occurs with height and weight retardation and, among children with cyanotic heart disease, correlates with the severity of hypoxemia.

Other factors contribute to growth retardation, including insufficient caloric intake, dyspnea, frequent infections, psychological disturbances, malabsorption, and hypermetabolism. Among infants with severe congenital heart disease recognized within the first year of life, there is a significantly increased incidence of subnormal birth weight, intrauterine growth retardation, and major extracardiac anomalies.[3] Finally, a relatively small number of children have associated syndromes known to be characterized by growth retardation, such as rubella and Noonan's, Turner's, and Down's syndromes.

Growth retardation related primarily to congenital heart disease usually responds to surgical correction or palliation, with an impressive acceleration of growth and a return to or toward normal.

Although cardiac surgery seldom is recommended on the basis of growth failure alone, decelerated growth should be recognized early and, until proved otherwise, considered an index of the severity of heart disease. In general, the more successful the surgery is, the less will be the retardation of growth and development, with its sequelae of physical, psychological, and intellectual problems.[36]

Pulmonary Arterial Hypertension and Pulmonary Vascular Obstructive Disease

Pulmonary arterial hypertension (PAH) and pulmonary vascular obstructive disease (PVOD) are serious complications of congenital heart disease. PAH usually results from direct transmission of systemic arterial pressure to the right ventricle or pulmonary arteries via a large communication. Less frequently, it is due to severe obstruction to blood flow through the left side of the heart at the pulmonary venous level or beyond. PVOD refers to a process involving structural and developmental changes in the smaller muscular arteries and arterioles of the lung that gradually diminishes and eventually destroys the ability of the pulmonary vascular bed to transport blood from the larger pulmonary arteries to the pulmonary veins without an abnormal elevation of proximal pulmonary arterial pressure.

Pulmonary resistance (R_p) may be as high as 8 to 10 Wood units immediately after birth but falls rapidly throughout the first week of life. Indexed Wood units, as a measure of resistance to flow across either the pulmonary or the systemic vascular bed, are obtained by dividing the mean pressure difference (in millimeters of mercury) across the pulmonary or systemic vascular beds by the blood flow index (expressed in liters per minute per square meter) across those respective beds. By 6 to 8 weeks, it usually has reached the normal adult level (1 to 3 Wood units). These changes are accompanied by a gradual dilatation of first the smaller and then the larger muscular pulmonary arteries and then, in the weeks and months that follow, a thinning of their muscular walls, the growth of existing arteries, and the development of new arteries and arterioles. The latter process contributes over 90 percent of the smaller or intraacinar pulmonary arterial vessels present in older children and adults.[37]

Increased pulmonary arterial pressure has an adverse effect on the normal maturation of the pulmonary vascular bed. Such pressure encourages a persistence of the thick muscular medial layer present in the smaller pulmonary arteries of term newborns, stimulates an extension of smooth muscle into smaller and more peripheral arteries than normal for age, and retards the growth of existing acinar arteries and the development of new ones.

In the presence of a large systemic-to-pulmonary communication, pulmonary arterial pressures remain at or near systemic levels, with the result that the diminution in pulmonary muscle mass and pulmonary resistance is less rapid and of a lesser magnitude than it is in a normal infant. Nevertheless, the diminution is usually sufficient to permit a large pulmonary blood flow and, as a result, congestive failure by the end of the first month. Exceptions are found among infants with a large systemic-to-pulmonary communication but with alveolar hypoxia, a stimulus for pulmonary vasoconstriction, in whom there is less than normal involution of the medial musculature and a diminution in pulmonary vascular resistance. Clinically, this is expressed by the lower incidence of congestive failure observed among infants with large VSDs born and living at high altitude and in some children with Down's syndrome and a large VSD or atrioventricular canal who may hypoventilate or have upper airway obstruction. Rarely, an infant will maintain a very high pulmonary vascular resistance in the face of an anatomically large systemic-to-pulmonary communication without evidence of significant hypoxemia or acidemia and remain free of the signs and symptoms of congestive failure. Conversely, in a premature infant in whom the medial muscle mass is less at birth than it is in a full-term infant, the fall in pulmonary vascular resistance is usually much more rapid than normal.

Chronic PAH, increased flow, or both produce a characteristic series of histologic changes in the smaller pulmonary arteries and arterioles originally described and graded by Heath and Edwards (grades I through VI below)[38] (Fig. 63-4, Plate 100) and, more recently, by Rabinovitch[37] (grades A through C below):

- Grade I-medial hypertrophy
- Grade II-concentric or eccentric cellular intimal proliferation
- Grade III-relatively acellular intimal fibrosis with occlusion of the smaller pulmonary arteries and arterioles
- Grade IV-progressive, generalized dilatation of the distal muscular arteries and the appearance of plexiform lesions, complex vascular structures composed of a network or plexus of proliferating endothelial tissue, frequently accompanied by thrombus, within a dilated thin-walled sac
- Grade V-thinning and fibrosis of the media superimposed on the plexiform lesions
- Grade VI-necrotizing arteritis within the media
- Grade A-extension of muscle into normally nonmuscular peripheral arteries with or without a mild increase in medial wall thickness of normally muscular arteries (less than 1.5 times normal)
- Grade B-extension of muscle as described above with an even greater increase in medial wall thickness of normally muscular arteries (mild, 1.5-2 × normal; severe, >2 × normal)
- Grade C-changes seen in grade B (severe) but with a decreased arterial concentration relative to alveoli (mild, ≥1/2 normal; severe, <1/2 normal)

Grades A and B are partitions of Heath-Edwards grade I and may be seen with large left-to-right shunts with (B) or without increased pressure (A). Grade C criteria may be found with grades I and II, are invariable with grade III, and usually preclude a complete return to normal of pulmonary arterial pressures and resistance despite successful surgical correction of the systemic-to-pulmonary communication.

Estimation of pulmonary vascular resistance from data obtained at cardiac catheterization remains the most widely used means of assessing the state of the pulmonary vascular bed.

Hypoxemia from oversedation, atelectasis, or pneumonitis at the time of study should be avoided scrupulously. If pulmonary vascular resistance is elevated, its responsiveness to vasodilation induced by the inhalation of 100% oxygen, the pulmonary arterial administration of prostacyclin, or the inhalation of nitric oxide should be tested.[39]

Values of $R_p \leq 3$ Wood units are considered normal. The status of the pulmonary vasculature also can be expressed as a ratio of pulmonary vascular resistance to systemic vascular resistance (R_p/R_s). *Pulmonary/systemic resistance ratios less than 0.2:1 are considered normal.*

As pulmonary vascular resistance increases, pulmonary blood flow generally decreases. Eventually, a point is reached where surgical closure of the defect will produce only a small diminution of blood flow, a proportionately small decrease in pulmonary arterial pressure, and no significant change in the factors contributing to the progression of vascular disease. At this point surgery usually is not recommended, since the benefits are minimal and closure of the defect may eliminate a useful "blow-off" for increasing resistance. *An R_p/R_s ratio of 0.7:1 or an R_p of 11 Wood units with a pulmonary/systemic blood flow ratio of 1.5:1 is the criterion generally used to define this situation.* Without surgery, these patients survive as examples of the Eisenmenger syndrome, in which $R_p \geq R_s$ and at least some right-to-left shunting occurs at rest or with exercise. Some of these patients can survive for several decades and lead productive lives, with relatively mild symptoms and few limitations.[40]

The decision regarding surgery for patients with less severe PVOD is a clinical one. The higher the calculated resistance is and the greater the structural changes in the pulmonary vasculature are, as judged by lung biopsy or quantitative pulmonary arterial wedge angiography, and the older the patient is with any given level of elevated resistance or grade of structural change, the less likely it is that the outcome will be satisfactory.[37]

The prevention of PVOD requires the identification of the patients at risk, i.e., all patients with a systemic-to-pulmonary communication and a pulmonary arterial systolic pressure higher than half the systemic arterial systolic pressure. Also included are all patients with transposition, regardless of pressure or flow, with the possible exception of those with severe pulmonary stenosis. Ideally, all patients at risk should undergo correction or pulmonary arterial banding unless there is proof that the pulmonary arterial systolic pressure has fallen to or is less than half the systemic systolic pressure before the end of the first year of life among those with normally related great arteries. Among patients with transposition with a large VSD or patent ductus arteriosis, action must be taken within the first 3 months of life.

Long-Term Problems with Surgically Corrected Defects

With the advances that have occurred in the surgical treatment of congenital heart defects, more of these patients are living to adulthood. This discussion of potential long-term problems is intended for those who follow these children after surgery and through adult life[41] (see Chap. 64).

There are residua, sequelae, and complications that result from most surgical procedures for congenital heart defects. A residual part of the original defect, such as mitral prolapse in repaired ASD, may purposefully not have been approached surgically. Some sequelae are unavoidable consequences of the surgery, such as pulmonary regurgitation after pulmonary valvotomy. There are also complications that occur as unexpected but related events after successful surgery, such as late complete heart block. When viewed with these possibilities in mind, only surgical correction of a PDA is likely to result in no long-term problems.

Most patients have residual murmurs after surgery for congenital heart defects. Determination of the origin of these murmurs and evaluation of the severity of the hemodynamic abnormalities they

represent are important. Noninvasive diagnostic tools, especially Doppler and two-dimensional echocardiography, are often useful.

The risk of infective endocarditis to patients persists after surgery, with the exception of those who have undergone patent ductus ligation or division or repair of an ASD or VSD in whom there is no residual shunt. Patients in whom it has been necessary to place an artificial valve are at increased risk of endocarditis.[42,43]

There are specific problems related to some of the more common defects. For those with repaired ASDs, VSDs, and AV (canal) septal defects, a residual shunt may be present, but ordinarily it is small and not of hemodynamic significance. Those with repaired AV canal defects may have important AV valvular regurgitation. Repaired coarctation of the aorta can gradually become narrowed again, or patients may develop idiopathic hypertension. Surgery for valvular pulmonary stenosis usually results in mild residual stenosis and regurgitation, which are well tolerated and have little tendency to progress with time. The natural history of valvular aortic stenosis after surgery is not as benign.[44] Because significant regurgitation must be avoided, the initial results may not be as good in terms of the severity of residual stenosis. In addition, aortic stenosis tends to worsen with time; thus, proper follow-up is mandatory for these patients.

Few patients enter adulthood with the continued problem of cyanosis. Since those with residual defects amenable to surgical correction should have had surgery well before this time, only patients with complex and uncorrectable defects and those with pulmonary vascular disease should have problems of cyanosis during the adult years. Particularly important among these patients is management of any attendant psychosocial problems (employment, insurability,[45] and learning disabilities) and difficulties related to pregnancy.[46]

Those who have had surgery for cyanotic defects are more likely to have sequelae and complications. Some degree of exercise intolerance is not unusual in this group of patients, and exercise stress testing aids in their management.[47]

Dysrhythmias are particularly common among these patients. *In those who have had intraventricular repairs, most commonly for tetralogy of Fallot, late complete heart block and serious ventricular arrhythmias can occur and may result in sudden death.*[48] This risk appears to be highest in those who had transient complete heart block at the time of surgery and who develop right bundle branch block with left anterior hemiblock after surgery. Extensive interatrial surgical procedures for transposition of the great arteries also frequently lead to dysrhythmias, most commonly sick sinus syndrome with bradytachyarrhythmias and atrial flutter, with a high incidence of sudden death.[49] Ambulatory 24-h electrocardiographic monitoring (see Chap. 25) and stress testing (see Chap. 14) and intracardiac electrophysiologic studies are important in following patients who have had complex repairs. Atrial dilation after the Fontan operation has resulted in atrial flutter and/or fibrillation, which are frequently problematic therapeutically.[50]

Serious ventricular dysfunction[51] and venous obstructions also may occur, usually in those who had severe defects. Interatrial repairs for transposition of the great arteries leave the anatomic right ventricle to do the work of the systemic ventricle.[52] In addition, these repairs may lead to pulmonary and/or systemic venous obstruction. Atriopulmonary connections for the repair of tricuspid atresia and many types of univentricular hearts frequently leave an anatomically abnormal ventricle as the systemic ventricle. In this group of patients, the right atrium has become the "pulmonary ventricle," with an elevated right atrial pressure that may lead to problems of systemic venous hypertension such as protein-losing enteropathy.[53]

Finally, some children have had repairs in which synthetic prostheses were utilized. Artificial valves do not grow as the child does, and they must be much more durable in view of the child's

life expectancy. There are also some surgical procedures that require the placement of conduits, with or without valves, that can degenerate and become obstructive with time. *Bioprosthetic valves undergo accelerated fibrosis and calcification in patients less than about 30 to 35 years of age*.

It should be kept in mind that in spite of these problems, the majority of patients who reach adulthood after surgical repair of congenital defects are relatively asymptomatic; they can and do lead productive lives.

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

INTRACARDIAC COMMUNICATIONS BETWEEN THE SYSTEMIC AND PULMONARY CIRCULATIONS, USUALLY WITHOUT CYANOSIS

Ventricular Septal Defect

PATHOLOGY AND INCIDENCE

A ventricular septal defect is the most common congenital cardiac anomaly (Table 63-4). It may be an isolated defect or part of a complex malformation. Approximately 80 percent of these defects are paramembranous but may extend into the inlet, trabecular, or outlet sections of the muscular septum. Less common are conal septal or subarterial doubly committed defects (5 to 7 percent), inlet defects lying beneath the septal leaflet of the tricuspid valve in the region of the atrioventricular canal (5 to 8 percent), and defects in the muscular septum that may be in the inlet, trabecular, or outlet area[54] (Fig. 63-5). Multiple muscular defects are not infrequently seen.

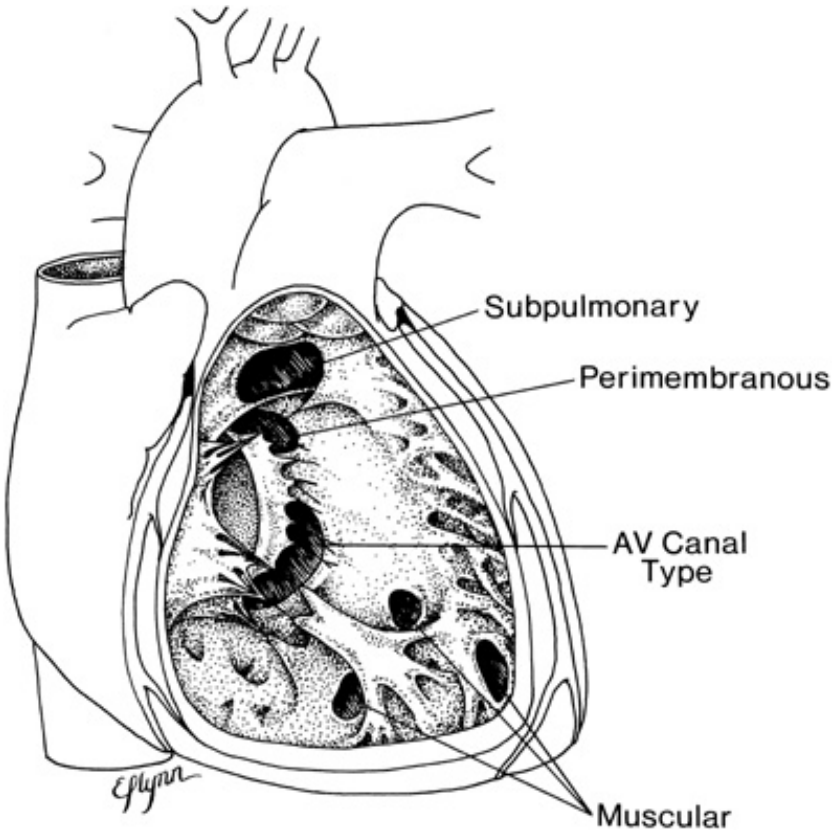

Figure 63-5: Different types of ventricular septal defects when viewed from the right ventricle. (From Fyler DC, ed. *Nadas' Pediatric Cardiology*. Philadelphia: Hanley & Belfus; 1992. Reproduced with permission from the publisher and author.)

Table 63-4: Communications with Predominant Left-to-Right Shunting

Ventricular septal defect	Atrioventricular canal
Atrial septal defect	Patent ductus arteriosus
Partial anomalous pulmonaryvenous connection	Sinus of Valsalva fistula

The incidence of VSDs is about 2 per 1000 live births, and its prevalence among school-age children has been estimated as 1 per 1000, constituting about one-quarter of the congenital cardiac malformations in combined series (Table 63-1). Males and females are affected equally.

VSDs may be isolated or associated with other congenital cardiac abnormalities. Malformations associated with VSD are, in order of decreasing frequency: (1) coarctation of the aorta, (2) additional shunts, most commonly ASD and PDA, (3) intracardiac obstructions such as subpulmonary or subaortic stenosis, mitral stenosis, and anomalous muscle bundle of the right ventricle, and (4) incompetent atrioventricular valves.

ABNORMAL PHYSIOLOGY

The consequences of a VSD depend on the size of the defect and the pulmonary vascular resistance. A small defect offers a large resistance to flow. There is no elevation of right ventricular or pulmonary arterial pressure, and the left-to-right shunt may be so small that it can be detected only by selective left ventricular angiography or two-dimensional imaging with Doppler color flow mapping. This type of defect imposes little physiologic burden on the heart, although there is always the danger of infective endocarditis.

A defect of moderate size still permits a difference between the right and left ventricular systolic pressures but may allow a large left-to-right shunt with resulting left atrial hypertension and dilatation and left ventricular volume overload. The development of pulmonary vascular disease among these patients is unusual but possible.

When the effective area of the defect is large, approximately equal to or greater than the aortic valve orifice, the defect offers virtually no resistance to flow and the systolic pressures in both ventricles, the aorta, and the pulmonary artery are essentially the same. The relative proportion of blood going to the two circulations is directly governed by the relative resistance of the two vascular beds.

At birth, pulmonary vascular resistance is high and there is little, if any, left-to-right shunt despite the presence of a large defect. This resistance to flow gradually falls over the first few weeks of life, permitting a progressively greater amount of blood to flow through the defect, through the lungs, and back to the left atrium and left ventricle. In most infants, the left ventricular volume overload eventually leads to left ventricular "failure" with elevated left ventricular end-diastolic and left atrial pressures and pulmonary congestion.

In term infants born at sea level with a large VSD, clinical deterioration may occur at any time from about 3 to 12 weeks after birth. In premature infants, in whom the less well developed pulmonary vascular hypertrophy regresses more rapidly, failure frequently is noted at 1 to 4 weeks.

History

Infants or children with a small isolated defect are asymptomatic. The murmur of a small defect

may be detected within the first 24 to 36 h of life, since the very restrictive opening permits the normal rapid fall in pulmonary arterial resistance and pressures. Infants with larger defects usually present between 3 and 12 weeks of age with congestive failure, frequently with associated lower respiratory tract infections. Parents describe tachypnea, grunting respirations, and fatigue, particularly with feedings. Weight gain is slow, and excessive sweating is common.

Physical Examination

A child with a small defect is comfortable. With moderate holes, a systolic thrill at the lower left sternal border is common. If the defect is small, the pulmonary artery pressure is normal and so the second heart sound is not accentuated. The systolic murmur along the lower left sternal border is characteristically holosystolic but may be limited to early or midsystole. This latter feature suggests a defect in the muscular septum rather than the membranous septum.

Infants with large defects, large left-to-right shunt, and PAH tend to be restless, irritable, and underweight. Moderate respiratory distress may be present. Both the right and the left ventricular systolic impulses are impressively hyperdynamic to palpation. A thrill at the lower left sternal border is common. The second heart sound is narrowly split, with a loud, frequently palpable pulmonary component. Third heart sound gallops at the apex are common. Characteristically, the systolic murmur is holosystolic at the lower left sternal border and is accompanied by a middiastolic rumble of grade 2 to 3 intensity at the apex, with the latter indicating a pulmonary/systemic blood flow ratio (Q_p/Q_s) of 2:1 or greater. Hepatic enlargement can be identified below the right costal margin. Pulmonary rales may be seen with severe failure.

With the passage of time, one may observe signs of a diminishing left-to-right shunt with an improved rate of weight gain, less dyspnea, a diminution of the precordial hyperactivity, and disappearance of the apical diastolic flow rumble. This clinical improvement may be a result of the defect becoming smaller, the development of subvalvular pulmonary stenosis with little or no appreciable change in the size of the defect, or, most worrisome, the development of PVOD with continued severe PAH. With developing subpulmonary stenosis, the systolic murmur radiates more and more impressively to the upper left sternal border and the second heart sound becomes more widely split, with a progressive diminution in the intensity of the pulmonary component. Decreased flow resulting from pulmonary vascular disease is characterized by a gradual reduction in the intensity and duration of the systolic murmur, more narrow splitting of the second heart sound, and marked accentuation of the pulmonary component.

The clinical picture of advanced pulmonary vascular disease secondary to a congenital left-to-right shunt, or Eisenmenger's syndrome, is that of a relatively comfortable older child, adolescent, or young adult with mild cyanosis and clubbing in whom one finds a prominent a wave in the jugular venous pulse, a mild right ventricular lift, and a second heart sound that is narrowly split or virtually single with a very loud, usually palpable pulmonary component. An early pulmonary systolic ejection sound, reflecting dilatation of the main pulmonary artery, may be heard, and there may be no systolic murmur at all. In older adolescents and adults, an early diastolic murmur of pulmonary regurgitation or a holosystolic murmur of tricuspid regurgitation may appear.

Chest Roentgenogram

In the presence of a small defect, the heart size and shape and the pulmonary blood flow are barely altered. With large defects, there is moderate to marked enlargement of the heart, with prominence of the main pulmonary arterial segment and impressive overcirculation in the peripheral lung fields. The left atrium is dilated unless an associated ASD is present, allowing decompression of the left atrium. With increasing pulmonary vascular disease, there is diminution in heart size toward normal while the central pulmonary arteries remain dilated. The peripheral pulmonary arterial markings become attenuated, and a "pruned" effect is produced in the outer

third of the lung fields.

Electrocardiogram

With a small defect, one can expect the normal progression of the mean QRS axis from right to left and the normal gradual diminution of the prominent right ventricular voltages characteristic of newborns. The left ventricular forces remain within normal limits or become slightly augmented as a reflection of the mild left ventricular volume overload. With large defects, the mean QRS axis tends to remain oriented to the right and there is little or no regression in right ventricular voltage. The left ventricular forces gradually increase, resulting in a pattern of biventricular hypertrophy within the first few weeks of life. Left atrial hypertrophy is usually present, and frequently right atrial hypertrophy as well. With the development of pulmonary vascular disease or significant pulmonary stenosis, the mean QRS axis tends to remain oriented to the right; there is no regression in right ventricular voltage, but the evidence of left ventricular and left atrial hypertrophy lessens or disappears.

Echocardiogram

Two-dimensional imaging can distinguish an uncomplicated VSD from more complex malformations and is capable of imaging most defects directly when multiple transducer positions are used. The addition of pulsed-wave Doppler with color flow mapping permits the identification of small, multiple, muscular, and other less easily visualized defects. The position and size of the opening can be determined as well as its relationships to the aorta, pulmonary artery, and AV valves. Continuous-wave Doppler echocardiography can predict the systolic right ventricular pressure from the difference between the systolic pressure measured by a blood pressure cuff if there is no aortic stenosis and the Doppler gradient (Fig. 63-6). In the absence of associated pulmonic stenosis, the right ventricular systolic pressure provides an estimate of the pulmonary artery pressure. An accurate approximation of right ventricular systolic pressure also can be made by estimating the right ventricular to right atrial systolic pressure gradient across the tricuspid valve if tricuspid regurgitation is present.

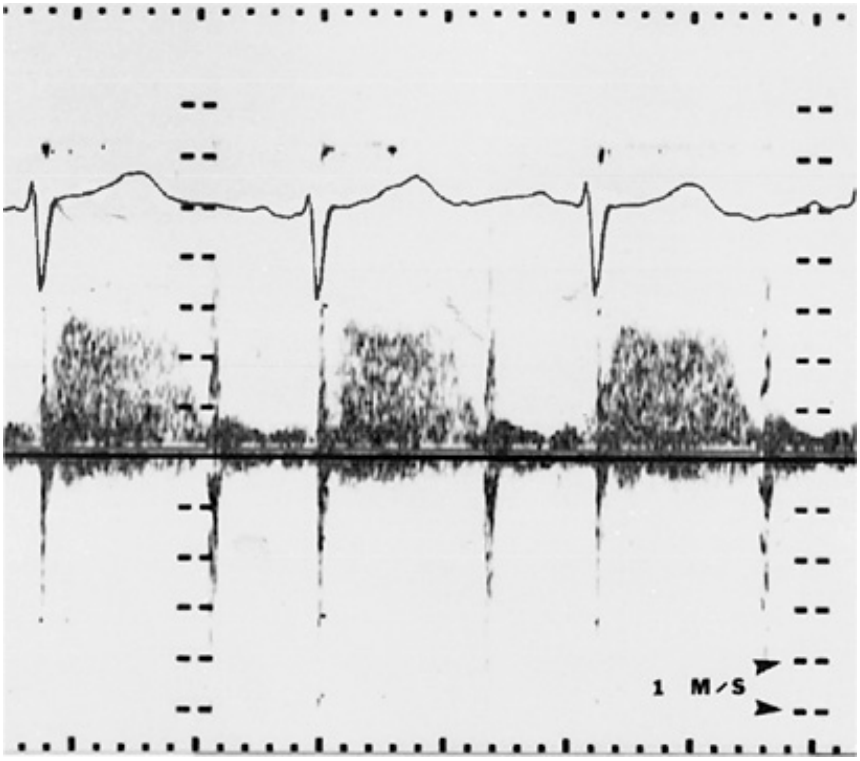

Figure 63-6: Continuous-wave Doppler with spectral display from the left lower sternal border of a child with a ventricular septal defect that demonstrates holosystolic turbulence with peak velocity = 2.8 m/s across the defect, compatible with an instantaneous systolic pressure difference of 31 mmHg between the right and left ventricles.

Cardiac Catheterization

Cardiac catheterization is being done less commonly in VSDs not associated with other cardiac malformations. When it is performed, an increase in oxygen saturation at the right ventricular level reflects the left-to-right shunt via the VSD. With small defects, the right ventricular and pulmonary arterial systolic pressures are normal. With large defects, these pressures are at or near systemic levels, and the mean left atrial pressure may be elevated to the range of 10 to 15 mmHg.

Selective left ventricular angiography in the anteroposterior, lateral, and oblique views with craniocaudal angulation can be done to establish the spatial relations of the great arteries to each other and to the ventricles and also to determine the exact site, size, and number of septal defects (Fig. 63-7). Aortography is helpful in eliminating the possibility of an associated ductus arteriosus or unsuspected coarctation of the aorta if the arch cannot be well imaged by echocardiography.

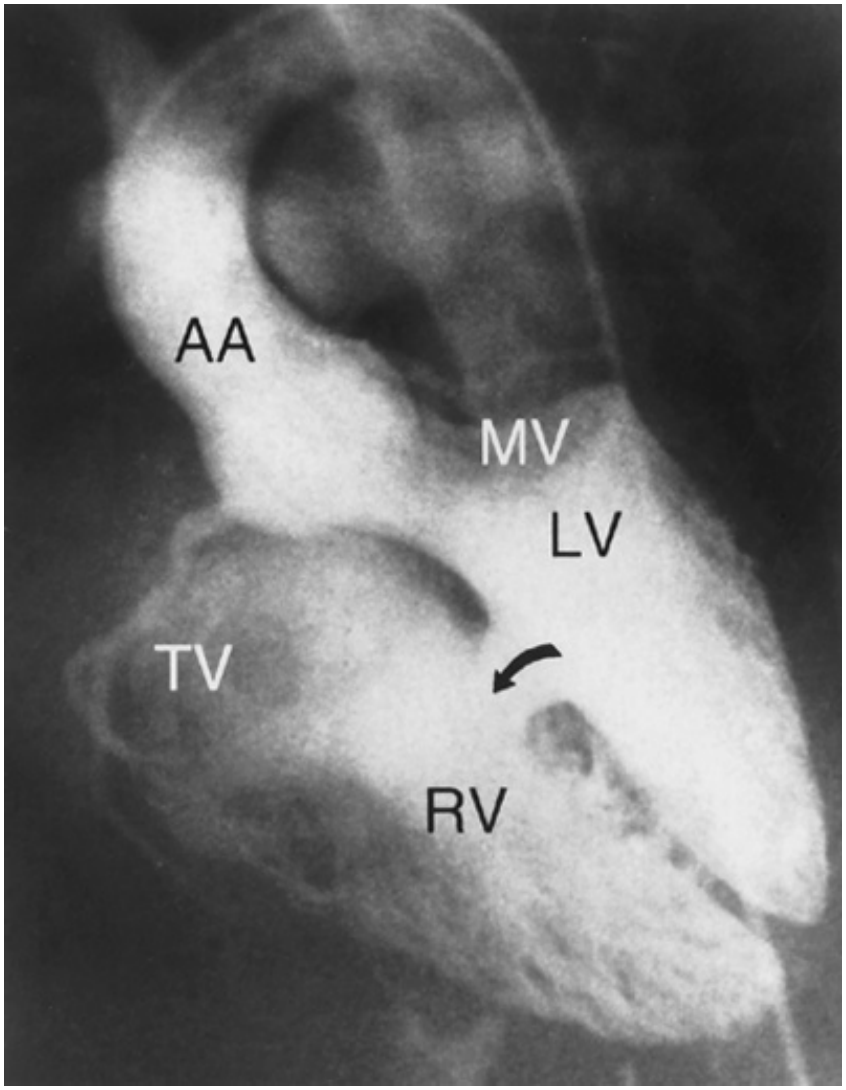

Figure 63-7: Multiple trabecular ventricular septal defects. Retrograde left ventriculogram, four-

chamber projection, profiles the mitral and tricuspid valves and the midtrabecular VSD (*arrow*). Additional VSDs closer to the apex are more anterior in location and are not profiled in this projection. AA = ascending aorta; LV = left ventricle; MV = mitral valve; RV = right ventricle; TV = tricuspid valve. (From Lock JE, Keane JF, Perry SB. *Diagnostic and Interventional Catheterization in Congenital Heart Disease*, 2d. ed. Boston: Kluwer; 2000.)

NATURAL HISTORY AND PROGNOSIS

Fortunately, the majority of VSDs are small and do not present a serious clinical problem. Approximately 24 percent of these small defects close spontaneously by 18 months, 50 percent by 4 years, and 75 percent by 10 years.[55] A spontaneous closure rate approaching 45 percent within the first 12 to 14 months has been observed among infants with an uncomplicated paramembranous or muscular VSD in the neonatal period.[56] Even large defects tend to become smaller, but the likelihood of eventual spontaneous closure is much lower (probably in the range of 60 percent if judged large at 3 months of age and only 50 percent if it is still large at 6 months).[55]

Congestive failure is a threatening and almost inevitable complication of a large VSD. Almost 80 percent of infants with large defects require hospitalization by age 4 months.[3] The risk of death with congestive failure is in the range of 11 percent. Significant subvalvular pulmonary stenosis develops in approximately 3 percent of these individuals and may progress to the point of severe tetralogy of Fallot. PVOD is seldom severe and rarely is irreversible in the first 12 months of life, but thereafter it becomes progressively more common and less likely to regress. At risk of this complication are infants and children with a pulmonary systolic pressure in excess of 50 percent of the systemic arterial systolic pressure beyond the first year of life.[57] A very small number of infants with large VSDs maintain a high level of pulmonary vascular resistance throughout the first year of life and remain almost entirely free of symptoms and congestive heart failure. In these patients, irreversible pulmonary vascular disease may develop without the usual and expected clinical signs and symptoms described above.

A small number of children, 0.6 percent in a large group of carefully followed patients, will develop aortic regurgitation as a result of prolapse of the right, the posterior, or both aortic valve leaflets into the defect.[58] This complication is more prevalent among males, in a ratio of 2:1, and seems particularly likely to occur with defects of the subpulmonary type. Shunt size appears not to be related to the development of this complication. The characteristic aortic diastolic murmur may appear at any time between ages 6 months and 20 years. Regurgitation is usually progressive, sometimes rapidly so, and predisposes these individuals to infective endocarditis.

The risk of infective endocarditis in patients with an uncomplicated VSD that is managed medically lies somewhere between 4 and 10 percent for the first 30 years of life.[59] The development of aortic regurgitation more than doubles this risk. Attempts at surgical closure of the defect with or without aortic regurgitation reduce the risk to less than half that of unoperated patients.[60]

MEDICAL MANAGEMENT

The basis of the medical management of children with ventricular septal defects is an understanding that defects frequently get smaller and may close spontaneously. Approximately 70 percent of small ventricular septal defects probably close.[55] Even large muscular defects may get significantly smaller, and up to 25 percent of them will become hemodynamically insignificant if one can wait long enough. Nevertheless, significant complications can occur, and the decision whether to proceed with medical or surgical management must be reevaluated constantly.

For children with a large ventricular septal defect, the first decision point usually occurs before 8 to 12 weeks of age. Infants with large septal defects usually develop significant left-to-right shunts as the pulmonary resistance drops. Congestive heart failure ensues with tachypnea, tachycardia, and difficulty feeding. Digoxin and diuretics are occasionally useful, but if the left-to-right shunt is very large, feeding may be problematic. For children who cannot gain at least 15 g per day (30 g per day is normal) in whom no other cause is found for failure to thrive, surgical repair is indicated. Occasionally, in marginal cases, increasing the caloric density of the formula from 20 calories per ounce up to 30 to 32 calories per ounce may be useful. In children whom the increased work prevents from taking more than 10 to 12 ounces per day, however, caloric supplementation is unlikely to be sufficient and surgical repair is necessary.

The second decision point in children who do not fail to thrive occurs between 9 and 12 months of age. Children with unrestrictive or mildly restrictive ventricular septal defects have pulmonary artery hypertension that may lead to irreversible pulmonary vascular obstructive disease. If the pulmonary artery pressure is elevated at 9 to 12 months of age, surgery is indicated to prevent this serious life-shortening complication. In some children, the high-pitched nature of the murmur, the normal pulmonary component of the second heart sound, the absence of right ventricular hypertension on ECG, and the large intraventricular pressure gradient on echocardiography make the estimation of normal pulmonary artery pressure firm. Occasionally in children in whom the signs, symptoms, and laboratory findings are ambiguous or conflicting, cardiac catheterization may be necessary to assure that the pulmonary artery pressure is normal and that pulmonary vascular obstructive disease is not a risk.

The third decision point occurs somewhere in midchildhood (5 to 10 years of age). If the defect has not caused failure to thrive and is not associated with pulmonary hypertension, it still may be associated with a significant left-to-right shunt, causing a volume overload to the left ventricle. Eventually, congestive heart failure is possible, and some recommend surgical closure during childhood if there is a significant volume overload. There is no firm number that suggests a dangerous level of left ventricular volume overload. Some centers close the ventricular septal defect when the pulmonary-to-systemic flow ratio (measured by cardiac catheterization, radionuclide angiography, echocardiography or magnetic resonance imaging) is more than 2 to 1. Others use significant left atrial and left ventricular dilation by echo. A minority of centers do not recommend surgical closure as long as the pulmonary artery pressure is normal since there are few adults with a ventricular septal defect who develop problems with late congestive heart failure.

Unfortunately, not all patients with a large defect are encountered during the first or second year of life, when it is possible to prevent injury to the pulmonary vascular bed. If significant PAH is allowed to persist, one can expect progression to irreversible pulmonary obstructive disease. For this reason, *prompt surgical closure of defects is recommended in all individuals beyond the age of 2 years if the pulmonary arterial systolic pressure is greater than half the systemic arterial systolic pressure, the mean pulmonary pressure exceeds 25 mmHg, or the R_p/R_s ratio is higher than 0.3:1*. With severe pulmonary vascular disease, a point eventually is reached where the risk of death at operation or in the months or years immediately after the operation as a result of progressive vascular disease more than offsets the possible benefits from surgical closure. At present, surgery is recommended if the calculated R_p is less than 10 Wood units/m^2 or the R_p/R_s ratio is 0.7:1, provided that the Q_p/Q_s ratio is still 1.5:1. In adults, the upper limit of pulmonary vascular resistance for surgery is approximately 800 dynes, or 10 Wood units.

Patients in whom the defect is judged clinically to be small at 6 months of age may be reexamined at 1- or 2-year intervals to reassure the patient and family, reemphasize the importance of antibiotic protection against infective endocarditis, document further narrowing or closure of the defect, and (in a very small number of patients) detect the first signs of aortic valve prolapse.

In patients with Eisenmenger's complex,[40] stamina is limited by systemic arterial hypoxemia and,

in some, right-sided heart failure. Complications to be anticipated include syncope, hemoptysis, brain abscess, hyperuricemia, and congestive failure. Pregnancy, with a maternal mortality of 30 to 60 percent, and oral contraceptives are contraindicated. Transient symptomatic relief from extreme polycythemia (usually >68 percent) may be achieved with careful erythropheresis. Travel to or living at high altitudes is poorly tolerated, and supplemental oxygen should be provided and used during air travel. The average age of death for individuals with Eisenmenger's complex is 33 years, with sudden death the mode of exit in the majority.

The risk of congenital heart disease for a subsequent sibling of a single affected child is on the order of 1 to 2 percent. The risk to a newborn who has one parent with VSD is approximately 3 percent.[61] Pregnancy in the presence of a small defect and normal pulmonary vascular resistance does not appear to carry an increased risk to the patient or infant, although precautions against infective endocarditis should be taken.

SURGICAL MANAGEMENT

Banding of the pulmonary artery to reduce pulmonary blood flow and pressures played an important role in the management of congestive heart failure and the prevention of PVOD before the era of predictably successful closure of VSDs in infants but now is used rarely. Complications of pulmonary arterial banding include deformity of the pulmonary arteries and/or pulmonary valve, progressive right ventricular hypertrophy with loss of ventricular compliance, and the development of subaortic left ventricular outflow tract obstruction.

VSDs are closed during a total cardiopulmonary bypass with cardioplegic arrest and moderate systemic hypothermia. Total circulatory arrest or minimal perfusion with profound hypothermia (18°C) is sometimes necessary in infants who weigh less than 5 kg.[62]

Paramembranous VSDs may be exposed through the right atrium and the tricuspid valve orifice. A transverse or longitudinal right ventriculotomy may be necessary for closure of high conal septal defects associated with aortic valve leaflet prolapse.

Care is required to prevent injury to the AV node near the ostium of the coronary sinus and to the bundle of His as it courses inferiorly, passing on the left side of the ventricular septum near the posterocaudal margin of the septal defect. Interoperative transesophageal echocardiography with Doppler color flow assessment can be used for the detection of significant residual or previously unsuspected problems that may be corrected in the operating room.

Results from primary surgical closure of VSDs are generally excellent, with surgical mortality less than 1 percent in centers with extensive experience, when surgery is performed during the early months of life before the evolution of PVOD. Operative risk should be even lower in older children if the pulmonary vascular resistance remains low. The pulmonary vascular bed responds favorably when the systemic-to-pulmonary shunt is eliminated before age 2 years. Normal life expectancy and functional capabilities should be anticipated postoperatively. Survival 25 years after the closure of a VSD is approximately 95 percent.[63] The mortality rate is unquestionably higher among patients who are operated on with R_p > 7 Wood units.

The surgical repair of a multiple muscular VSD has been problematic. The highly trabecular right ventricular septal surface can make the localization of all the defects difficult. Recently, techniques have become available to close these defects in the catheterization laboratory.[64] A device that can be anchored on the left ventricular and right ventricular septal surface was approved by the U.S. Food and Drug Administration in 1999 for this indication. Other devices are now in phase 2 testing.

Between February 1989 and July 1998, 148 transcatheter closures were preformed at Children's Hospital in Boston with no deaths or late morbidity resulting from catheter-related events. By echocardiography, 83 percent of the defects were closed or had trivial residual leaks.[64] The relative role of surgery versus interventional catheterization closure remains to be determined in this subset with multiple trabeculated septal defects.

Atrial Septal Defect

DEFINITION

An ASD is a through-and-through communication between the atria at the septal level. It is to be distinguished from a valvular-competent foramen ovale, which may persist into adulthood.

PATHOLOGY

ASDs are usually sufficiently large to allow free communication between the atria. They may be subdivided according to anatomic location[65] (Fig. 63-8).

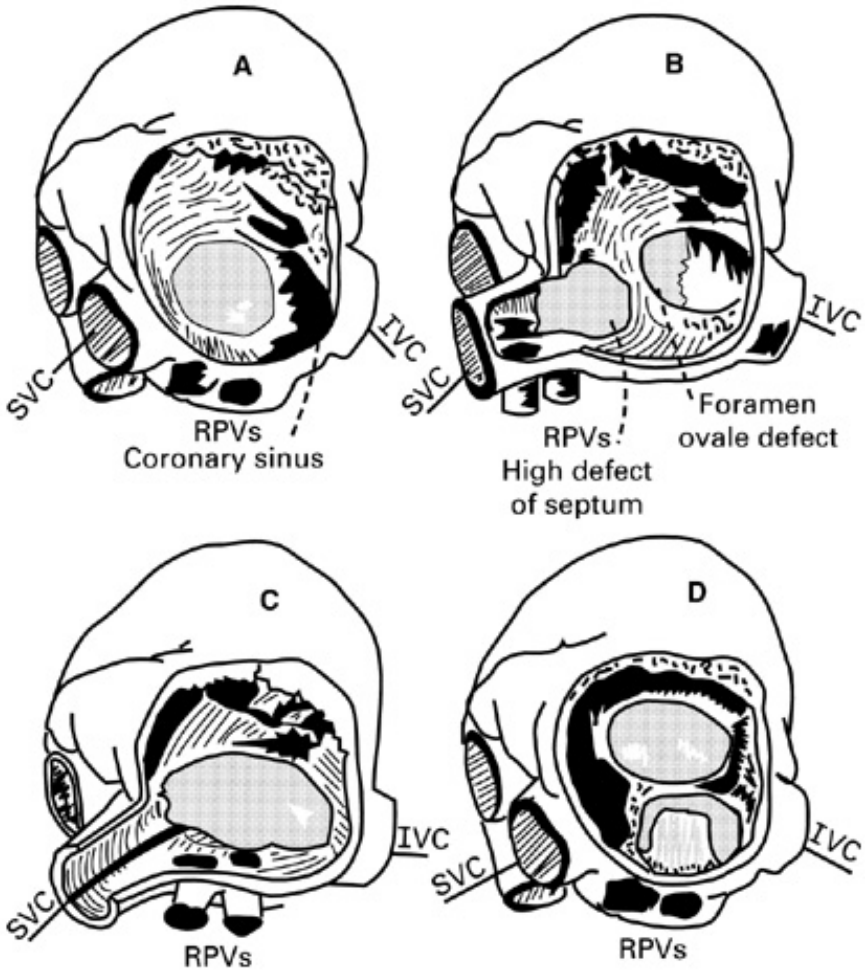

Figure 63-8: Types of interatrial communications. *A*. Large ostium secundum type of atrial septal defect. *B*. So-called sinus venosus type of defect-one high in the atrial septum associated with anomalous connection of the right superior pulmonary vein to the junctional area of the superior vena cava and right atrium. *C*. Very large ostium secundum type of atrial septal defect with absence of the posterior rim. *D*. Partial form of common atrioventricular canal with cleft mitral

valve. SVC = superior vena cava; RPVs = right pulmonary veins; IVC = inferior vena cava. (From Lewis FJ et al.[65] Copyright 1957, American Medical Association. Reproduced with permission from the publisher and authors.)

ANATOMIC TYPES

Defect at the Fossa Ovalis (Ostium Secundum)

This defect classically involves the region of the fossa ovalis and is the most common type (70 percent)[65,66] (Fig. 63-8*A* and *C*). Atrial septal tissue separates the inferior edge of the defect from the AV valves. Associated partial anomalous pulmonary venous connections are not uncommon, with one or more of the right pulmonary veins draining into the right atrium or one of its tributaries. Mitral valve prolapse is present in some cases.

Partial Atrioventricular Canal Defects

Defects of the AV septum, which lies inferior to the fossa ovalis, constitute approximately 20 percent of ASDs and are part of a complex malformation known as *common atrioventricular canal defects*, which are considered below (Fig. 63-8*D*).

Sinus Venosus Defects

These defects, accounting for approximately 6 percent of the total, appear to represent a biatrial connection of the superior vena cava (or, in rare instances, the inferior vena cava), which straddles the otherwise normal intact atrial septum. Also involved is an anomalous termination of one or more of the right-sided pulmonary veins either into the vena cava or into the right atrium near its junction with the vena cava (Fig. 63-8*B*).

Coronary Sinus Defects

A coronary sinus defect is an uncommon type of ASD located in the position normally occupied by the ostium of the coronary sinus. This defect is part of a developmental complex consisting of the absence of the coronary sinus and entry of the left superior vena cava directly into the left atrium.

Conditions Common to All Anatomic Types

The right atrial and ventricular chambers as well as the central pulmonary arteries become enlarged. When pulmonary hypertension intervenes, it usually does not do so before the third decade. The earliest lesion is cellular fibrous intimal thickening in the proximal segments of arterioles. The pulmonary arterial pressure then rises, followed by the development of medial hypertrophy of muscular arteries and the appearance of plexiform lesions. The right ventricular wall hypertrophies, and atherosclerosis may occur in the major pulmonary arteries. Saccular aneurysm and thrombosis with dissecting aneurysm or rupture may occur (see above, "Pulmonary Arterial Hypertension and Pulmonary Vascular Obstructive Disease"). In the final state, the pulmonary vascular bed may be difficult to distinguish from that in VSD with PVOD.

ABNORMAL PHYSIOLOGY

Usually there is no resistance to blood flow across the defect and no significant pressure difference between the two atria. A left-to-right shunt of blood occurs (Fig. 63-9) because (1) the right atrial system is more distensible than the left, (2) the tricuspid valve is normally more capacious than the mitral valve, and (3) the thinner-walled right ventricular chamber more readily

accommodates a larger volume of blood at the same filling pressure than does the left ventricle. A large left-to-right shunt may be found in a neonate or young infant before the right ventricular compliance has had time to change appreciably from that of the left ventricle. Presumably, this occurs because a rapid fall in pulmonary vascular resistance encourages a larger right ventricular stroke volume, a smaller end-systolic volume, and hence an increased ability of the right ventricle to accept a larger volume of blood during the diastolic filling phase of the cardiac cycle.[67]

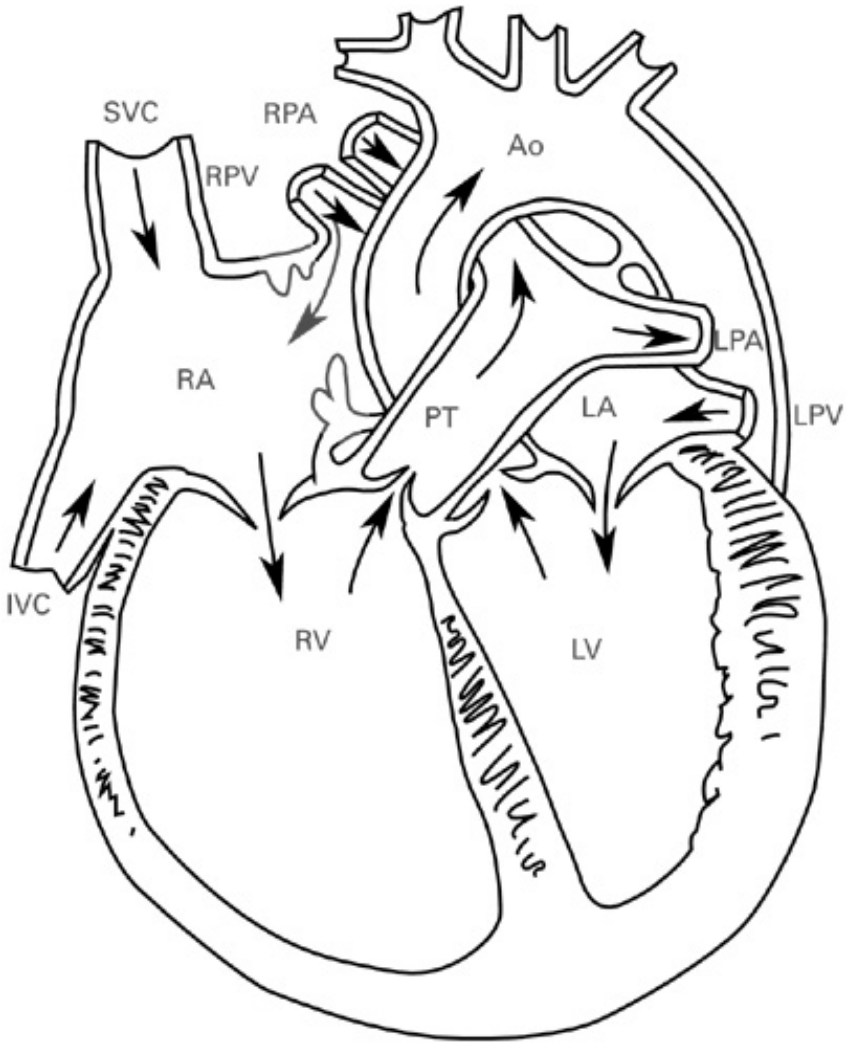

Figure 63-9: Atrial septal defect at fossa ovalis with left-to-right shunt. SVC = superior vena cava; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; PT = main pulmonary arterial trunk; RPA = right pulmonary artery; LPA = left pulmonary artery; RPV = right pulmonary vein; LPV = left pulmonary vein; LA = left atrium; LV = left ventricle; AO = aorta. (From Edwards JE.[66] Reproduced with permission from the publisher and author.)

The pulmonary arterial system undergoes normal maturation after birth, with most patients tolerating the large volume load on the right ventricle and pulmonary circuit quite well for many years. With the development of pulmonary vascular disease and PAH, the left-to-right shunt decreases, largely because of the increased thickness and decreased compliance of the right ventricle. In some patients, this process continues until there is eventually shunt reversal, with arterial desaturation and cyanosis.

CLINICAL MANIFESTATIONS

ASD is found in approximately 6 percent of children who survive beyond the first year of life with congenital heart disease.[5] *If one excludes mitral valve prolapse and a congenitally bicuspid aortic valve, it is the most common form of congenital heart disease among adults.*

ASDs are more common among females, with a female/male ratio of approximately 2:1. The mode of transmission is best explained in most instances on a multifactorial basis, in which the risk would be approximately 2.5 percent for first-degree relatives of a single affected family member. However, examples of autosomal dominant transmission are recognized[68] either as an isolated entity associated with severe AV conduction disturbances or with upper extremity malformations as in the Holt-Oram syndrome. Examples of mendelian autosomal recessive transmission are found in the Ellis-van Creveld syndrome (see Chap. 62).

History

The majority of these children are considered asymptomatic but probably most have some mild diminution of stamina, since it is not unusual for the patient or the parents to comment on the increased endurance that follows surgical correction. Symptoms of mild fatigue and dyspnea tend to be recognized in the late teens and early twenties, and at least three-quarters of these individuals will be definitely symptomatic as adults. Congestive heart failure is rare in childhood, but a few infants, perhaps 5 percent, have heart failure in the first year of life. Failure becomes more common again in the fourth and fifth decades, usually associated with the onset of arrhythmias.[69]

Physical Examination

Many of these children have a slender habitus, but normal growth and development are the rule. Prominence of the left anterior chest is common, and a hyperdynamic right ventricular systolic lift usually can be felt. Looking at the jugular venous pulse demonstrates that the *v* wave is equal to the *a* wave instead of revealing the normal a wave predominance. The first heart sound may be slightly accentuated at the lower left sternal border. The two components of the second heart sound are characteristically widely split, with the interval of splitting fixed despite expiration or the Valsalva maneuver. The pulmonary component of the second heart sound may be accentuated even in the absence of PAH. With increasing pulmonary arterial pressure and resistance, the interval between the aortic and pulmonary components of the second heart sound narrows and the pulmonary component becomes louder, but the lack of respiratory influence on the interval between the two components persists. A midsystolic spindle-shaped murmur of grade 2 to 3 intensity at the left upper sternal border, reflecting increased right ventricular stroke volume and relative pulmonary stenosis, is to be expected. A low- to medium-pitched early diastolic murmur over the lower left sternal border, denoting increased diastolic flow across the tricuspid valve, is present in most individuals with large shunts (see Chap. 10). Cyanosis and clubbing reflect right-to-left shunting. In this setting, the murmurs of tricuspid and pulmonary regurgitation are not uncommon.

Chest Roentgenogram

Mild to moderate cardiac enlargement and prominence of the main and branch pulmonary arteries are characteristic. The absence of left atrial displacement of the barium-filled esophagus in the lateral view helps distinguish ASD from large left-to-right shunts at other levels (Fig. 63-10).

Electrocardiogram

An rsR′ pattern over the right precordium indicating mild right ventricular conduction delay or

mild right ventricular hypertrophy is characteristic in secundum-type ASD. The mean QRS axis in the frontal plane is 90° or greater in 60 percent of patients. Left-axis deviation is common in primum-type ASD. Abnormal leftward p axis is common in sinus venosus-type ASD. Serious arrhythmias are usually, though not invariably, limited to adults; atrial fibrillation and atrial flutter are the most common arrhythmias.

Echocardiogram

M-mode studies reflect volume overload of the right side of the heart with increased right atrial and right ventricular dimensions and paradoxical ventricular septal motion. Two-dimensional and Doppler echocardiography with color flow mapping (see Chap. 13) permit identification and visualization of secundum, AV canal, and sinus venosus defects. Visualization of anomalous draining pulmonary veins is slightly more difficult. The transesophageal approach offers excellent images for those patients in whom the transthoracic approach is inadequate.[70] Recently three-dimensional (3-D) echocardiograms have been used to get excellent images of the atrial defects[71] (Fig. 63-11).

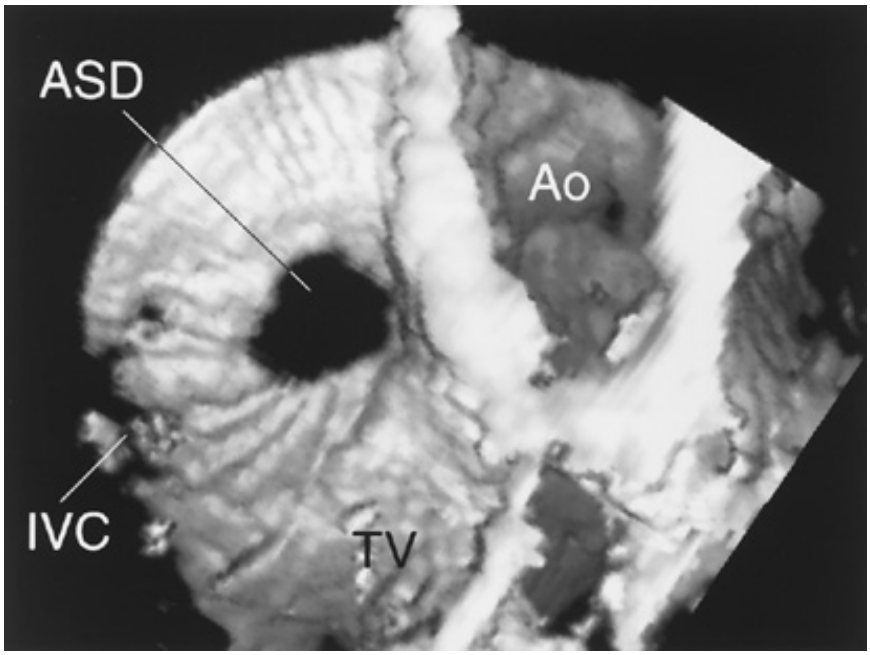

Figure 63-11: Three-dimensional echocardiogram of a secundum atrial septal defect (ASD). This is a right atrial en-face view that shows the size, shape, and position of the defect in relation to the right atrial septal surface. Ao = aortic valve; TV = tricuspid valve; IVC = inferior vena cava. Courtesy of Dr. Gerry Marx.

Cardiac Catheterization

There is a significant increase in oxygen saturation in the blood samples drawn from the right atrium, right ventricle, and pulmonary artery compared with those drawn from the superior or inferior venae cavae. Pulmonary arterial and right ventricular systolic pressures are normal or only slightly elevated. A systolic pressure gradient of up to 20 mmHg across the right ventricular outflow tract is accepted as being secondary to flow rather than to organic obstruction. The right and left atrial mean and phasic pressures are virtually identical, with little, if any, elevation above normal (mean pressure gradient <3 mmHg) unless there are associated abnormalities.

NATURAL HISTORY AND PROGNOSIS

Defects of the secundum type usually go undetected in the first year or two of life because of the lack of symptoms and the unimpressive auscultatory findings. A soft systolic murmur is the usual reason for referral. Symptoms become more common in persons in their late teens and twenties, and by age 40 the majority of these individuals are symptomatic, some severely so.[72] Pulmonary vascular disease with serious pulmonary hypertension begins to make its appearance in the early twenties. *It affects approximately 15 percent of young adults, particularly women, and may be rapidly progressive, especially with pregnancy*. The incidence of atrial fibrillation or flutter also increases with each decade and is closely linked to the onset of congestive failure. Spontaneous closure of secundum defects is rare beyond the first 2 years of life.[69] Congestive heart failure is the most common cause of death among unoperated patients. Other causes of death include pulmonary embolism or thrombosis, paradoxical emboli, brain abscess, and infection.

MEDICAL MANAGEMENT

The few infants who present with symptoms of congestive failure are treated with digoxin and, if necessary, diuretics and are studied by cardiac catheterization. If the defect is uncomplicated and the symptoms persist despite a trial of therapy, surgical closure is advised without further delay. For asymptomatic infants and children, closure is recommended just before entry into school. Restrictions of activity or exercise are unnecessary. If the physical, laboratory, and echocardiographic findings are completely characteristic, preoperative catheterization is not necessary. Closure is recommended if the defect is large and if there is right ventricular volume overload on echocardiography. In those with pulmonary hypertension closure is recommended for patients with Q_p/Q_s ratios >1.5:1 by catheterization provided that the systemic arterial saturation is >92 percent and total R_p < 15 Wood units.[73] Closure would seem prudent before pregnancy or the use of contraceptives in view of the tendency to develop rapidly progressive PVOD in this setting. Transcatheter closure of centrally located secundum in selected older infants, children, and adults using a double-umbrella ("clamshell") or a buttoned device appears to be an acceptable alternative to surgical closure.[74-76] *Infective endocarditis is rare, and antibiotic coverage at times of possible bacteremia is recommended only if associated mitral valve disease is suspected*.

SURGICAL MANAGEMENT

Defects of the interatrial septum are exposed through the lateral wall of the right atrium.

Ostium secundum (fossa ovalis) defects frequently are closed by direct suturing; a very large defect or one with tenuous margins is closed with a patch, usually glutaraldehyde-treated autologous pericardium. Anomalous pulmonary veins are sought along the posterolateral aspect of the superior or inferior vena cava and from within the right atrium before closure of the defect. Sutures are placed with care along the posterior rim of the inferior vena caval orifice to prevent the creation of a tunnel from the inferior vena cava into the left atrium, which would cause postoperative hypoxemia.

High ASDs of the sinus venosus type, which often are associated with anomalous drainage of one or more right pulmonary veins into the superior vena cava, are corrected by means of the placement of a pericardial or tubular Dacron patch from above the abnormally draining vein or veins down to and around the ASD (Fig. 63-12). Pulmonary venous blood thus is diverted through the ASD into the left atrium. Pericardial gusset enlargement of the superior vena cava at the cavoatrial junction may be required. Anomalous right pulmonary veins draining to the right atrium are diverted into the left atrium by placement of a patch baffle well anterior and to the right of the pulmonary vein orifices. The risks of surgery are minimal (less than 0.5 percent), with virtually all these children home by the fourth postoperative day.

In adults, clinical benefit after closure of ASDs can be anticipated even in those with significant physiologic compromise, but mortality is higher than it is in the young and the magnitude of improvement is less certain. Nonetheless, surgical closure of ASDs is advised even when R_p approaches 15 Wood units because of the excessive morbidity and mortality associated with a persistent interatrial communication.[77] *Morbidity in adults and the low risk of surgical closure in young children mandate surgery in the preschool or preadolescent years.*

Although life-threatening complications after closure of ASDs in children are rare, transient postoperative atrial arrhythmias and postpericardiotomy syndrome with pericardial effusions occasionally are seen. The long-term prognosis for a normal life expectancy and functional capability is excellent for patients who have closure of an uncomplicated ASD during the first two decades of life.

Partial Anomalous Pulmonary Venous Connection

PATHOLOGY

In partial anomalous pulmonary venous connection, one or more, but not all, of the pulmonary veins enter the right atrium or its venous tributaries. The atrial septum may rarely be intact, but an ASD is usually present. There are many patterns of anomalous pulmonary venous connection, but the four most common, in order of decreasing frequency, are (1) pulmonary veins from the right upper and/or middle lobe to the superior vena cava, usually with a sinus venosus ASD, (2) all the right pulmonary veins to the right atrium, usually in the polysplenia syndrome, (3) all the right pulmonary veins to the inferior vena cava, entering this systemic vein just above or below the diaphragm, and (4) the left upper or both left pulmonary veins to an anomalous vertical vein draining to the left brachiocephalic vein.

When the right pulmonary veins are connected to the inferior vena cava, the atrial septum may be intact. This venous anomaly may be isolated or may be part of the *scimitar syndrome*. That syndrome includes hypoplasia of the right lung, bronchial abnormalities, anomalous systemic pulmonary arterial supply to the right lung from branches of the descending thoracic and/or abdominal aorta, and dextroposition of the heart.

CLINICAL MANIFESTATIONS

In an old autopsy series, partial anomalous pulmonary venous connection occurred in 0.6 percent of 801 anatomic dissections,[78] a much higher incidence than was suspected clinically, suggesting that many cases may not be recognized during life. There is no sex predilection. Approximately 15 percent of all ASDs have this coexisting anomaly; however, in the case of the sinus venosus type, the association is in the range of 85 percent.

History

When partial anomalous pulmonary venous connection coexists with an ASD, the symptoms, as well as the other clinical manifestations, are indistinguishable from those of an isolated ASD. Isolated, uncomplicated anomalous connection of a single pulmonary vein usually goes undetected clinically, since in this circumstance only about 20 percent of the pulmonary venous flow returns to the right atrium or its tributaries. When the entire venous return from one lung or two pulmonary veins is connected anomalously, approximately 65 percent of the pulmonary venous flow returns to the right side of the heart and the symptoms are similar to those of an ASD with a comparable increase in pulmonary blood flow.

Physical Examination

The findings are the same as those in patients with an ASD with the exception that *the two components of the second heart sound, though usually widely split, move normally with respiration if the atrial septum is intact*.

Chest Roentgenogram

Right ventricular enlargement, pulmonary arterial dilatation, and increased pulmonary blood flow are characteristic when more than one pulmonary vein connects anomalously. With anomalous connection of the right pulmonary veins to the inferior vena cava, the pulmonary venous pattern may assume a crescent-shaped or scimitar curve in the right lower lung field along the right lower heart border (scimitar).

Electrocardiogram

The ECG is normal (in the case of anomalous connection of a single pulmonary vein) or reflects volume overload of the right side of the heart, as was described above in "Atrial Septal Defect."

Echocardiogram

If more than one pulmonary vein drains anomalously, the volume usually is sufficient to produce the characteristic pattern of right ventricular diastolic overload. Failure to visualize an atrial septal opening with two-dimensional imaging and color flow mapping from a subcostal coronal or high right-sided parasternal longitudinal view should arouse suspicion of an intact atrial septum. A variety of views supplemented by color flow mapping may be necessary to identify the anomalous connection.[79]

Cardiac Catheterization

Anomalously connected pulmonary veins may be entered directly with the venous catheter. Selective biplane angiograms in these vessels will document their site of connection. Left-to-right shunting with partial anomalous pulmonary venous connection and an intact atrial septum is usually small or moderate and may go undetected by oximetry techniques. Selective indicator dilution curves in the right and left pulmonary arteries with systemic arterial sampling can detect the lung with the anomalous pulmonary venous connection, and selective biplane angiograms in the pulmonary arterial branches will visualize these connections.

NATURAL HISTORY AND PROGNOSIS

Patients with partial anomalous pulmonary venous connection with ASD appear to follow a course similar, if not identical, to that of patients with an isolated ASD. When the atrial septum is intact, the course depends primarily on the volume of pulmonary venous blood returning to the right side of the heart. Rarely, PVOD may be found even in the presence of a single anomalously connected pulmonary vein and an intact atrial septum.[80] Finally, increasing left atrial pressure caused by mitral valve disease or diminishing left ventricular compliance will, in the course of time, encourage a greater redistribution of pulmonary arterial blood flow to the portion of the lung drained by the more compliant right atrium. Thus, patients who were initially asymptomatic and had a very modest volume of anomalous pulmonary venous return in youth may become symptomatic and even develop congestive failure in adult life.

MEDICAL MANAGEMENT

Asymptomatic patients with small shunts require no treatment. Those with symptoms, larger pulmonary blood flows, congestive failure, or PAH require surgical correction. With an intact

atrial septum, precise preoperative identification of the site of the anomalous venous connection is essential. Long-term follow-up in patients who have not had surgery is indicated to detect increasing flow or the appearance of PAH.

SURGICAL MANAGEMENT

Anomalous connection of a right pulmonary vein or veins to the superior vena cava usually is associated with a sinus venosus ASD (Fig. 63-12). (see "Atrial Septal Defect, Surgical Management," above.) Partial anomalous pulmonary veins draining to the superior vena cava, inferior vena cava, or right atrium are repaired by being diverted through the ASD into the left atrium, using an appropriately placed patch baffle. Isolated left-sided anomalous pulmonary veins draining to the left ascending vertical vein or the left superior vena cava are detached and anastomosed directly to the left atrial appendage. Long-term morbidity and mortality are minimal among patients with uncomplicated partial pulmonary venous connections, equivalent to those observed after closure of an ASD.

Common Atrioventricular Canal Defects

DEFINITION

Atrioventricular canal defects are characterized by an ASD in the lowermost part of the atrial septum (ostium primum), a cleft of the mitral valve (either alone or in combination with a cleft of the tricuspid valve), or deficiency of ventricular septal tissue or some combination. In the most severe form (complete AV canal defect), there is a large deficiency of the lower part of the atrial septum and the upper muscular portion of the ventricular septum and a common AV valve that straddles the ventricular septum. The condition appears to result from incomplete growth of the AV endocardial cushions and the AV septum.

PATHOLOGY

The ostium primum type of ASD is characterized by a crescent-shaped upper border and no septal tissue forming the lower border. The lower aspect of the defect is bounded by the atrial surfaces of the AV valves and, in the complete type (see below), in part by the upper edge of the ventricular septum. A small amount of septal tissue separates the defect from the posterior atrial wall.

ANATOMIC TYPES

Variations occur with respect to the nature of the AV valves. The terms *partial* and *complete* were first introduced to describe these types by Rogers and Edwards.[81]

Partial Type

The ostium primum ASD is associated with a "cleft" in the anterior mitral leaflet or, probably more accurately, a septal commissure between the superior and inferior leaflets of the left AV valve (Figs. 63-8*D* and 63-13).[66] The tricuspid valve is not cleft or shows a minor central deficiency. The ventricular aspects of the anterior mitral valve elements are fused to the upper edge of the deficient ventricular septum, precluding an interventricular communication. If there is no atrial septal tissue or if the atrial septum is so rudimentary that it produces a common chamber involving both atria, the term *common atrium* or *single atrium* is applied.

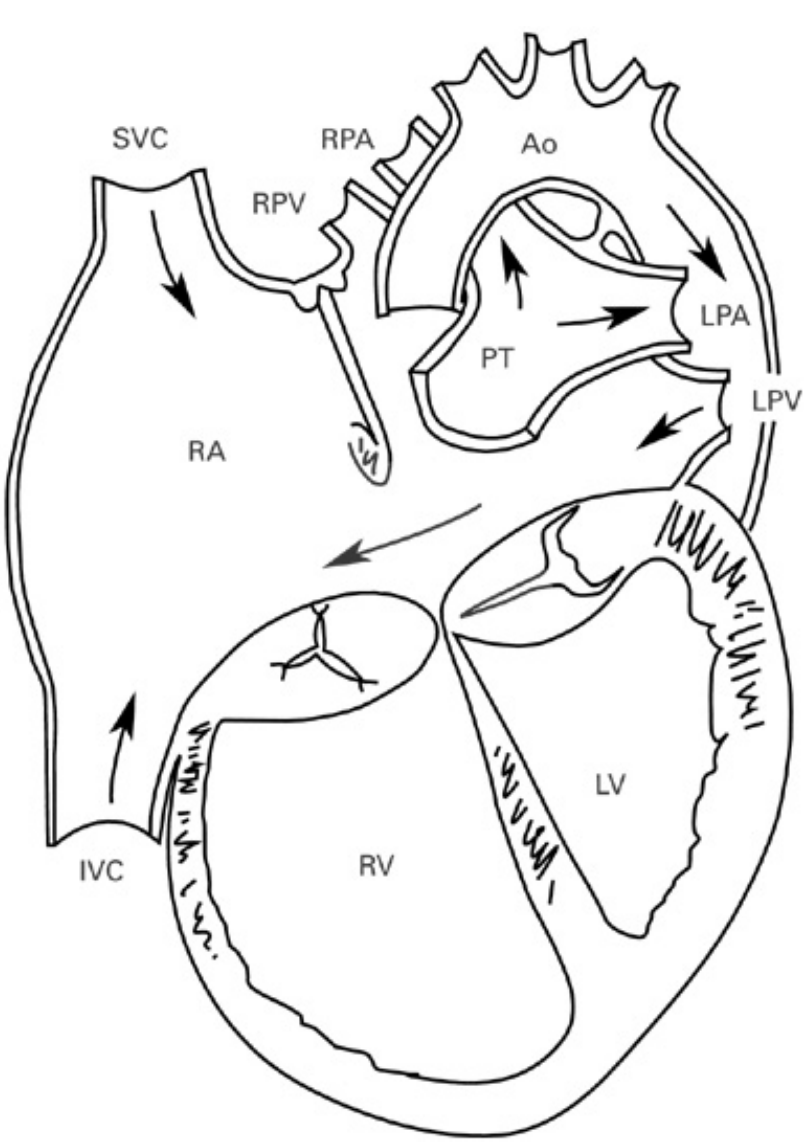

Figure 63-13: Common AV canal of the partial type. The mitral valve shows a cleft in its anterior leaflet, while the tricuspid valve is undisturbed. SVC = superior vena cava; IVC = inferior vena cava; RA = right pulmonary artery; LPA = left pulmonary artery; RPV = right pulmonary vein; LPV = left pulmonary vein; LV = left ventricle; Ao = aorta. (From Edwards JE.[66] Reproduced with permission from the publisher and author.)

Complete Type

The complete type of common AV canal is characterized by failure of partitioning of the primitive canal into separate AV orifices. The orifice between the atria and the ventricles is guarded by a common valve, of which the anterior leaflet is derived from the ventral AV endocardial cushion and represents the anterior halves of the anterior mitral and septal tricuspid leaflets. The posterior leaflet is derived from the dorsal AV endocardial cushion and represents the posterior halves of the anterior mitral and septal tricuspid leaflets.

Usually, considerable space exists between the anterior and posterior leaflets above and the ventricular septum below; thus, in most cases of the complete type, there is free communication between the ventricles.

Rastelli and associates[82] subdivided the complete variety into three subgroups-types A, B, and C-on the basis of the structure of the common anterior leaflet and its chordal attachments to the

ventricular septum and/or papillary muscles (Fig. 63-14). With regard to the posterior common leaflet, there is variation among the three types in regard to the presence or absence of subdivision and whether the posterior leaflet is attached to the ventricular septum by chordae or by an imperforate membrane.

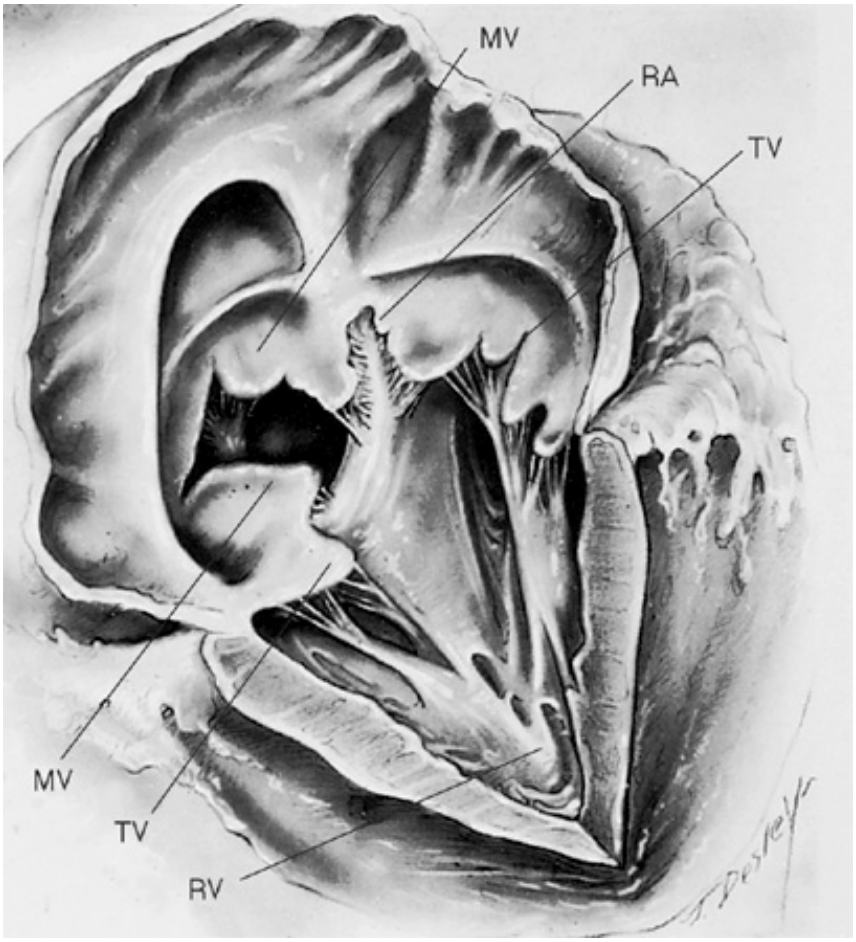

Figure 63-14: Complete form of common AV canal, type A. The common anterior leaflet has a recognizable mitral component (MV) and tricuspid component (TV). In type B, not illustrated, those components are attached by chordae to a papillary muscle in the right ventricle. In type C, not illustrated, the common anterior leaflet is a single unit without any attachment to the underlying ventricular septum. Type A is most amenable to repair. RV = right ventricle; RA = right atrium. (From Rastelli GC et al.[82] Reproduced with permission from the publisher and authors.)

Variations from the classic types of AV canal defects are recognized, the most common being the AV canal type of isolated VSD, isolated ostium primum ASD without malformed AV valves, and isolated cleft of the anterior mitral or septal tricuspid valve leaflets.

ASSOCIATED CONDITIONS

In the asplenia syndrome, the complete variety is almost universal; with polysplenia, it occurs in about one-quarter of cases.[83] An ASD of the secundum type is present in about half the cases. Double orifice of the mitral valve may be associated with the incomplete type, and tetralogy of Fallot may be associated with the complete type.

ABNORMAL PHYSIOLOGY

If the communication at the ventricular level is large, the right ventricular and pulmonary artery pressures will be elevated. These patients are similar to those with large VSDs. Patients with a communication at the atrial level usually have only normal or slightly elevated systolic pressures in the right side of the heart and a large pulmonary blood flow, as in the secundum type of ASD. Defects in the tricuspid valve, mitral valve, or both may result in severe regurgitation or direct shunting of blood from the left ventricle to the right atrium.

CLINICAL MANIFESTATIONS

Approximately 3 percent of infants and children with congenital heart disease have AV canal defects. The majority, some 60 to 70 percent, have the complete form. The female/male ratio is approximately 1.3:1. Well over half the patients with the complete form have associated Down's syndrome. Among children with Down's syndrome, 45 percent have some form of congenital heart disease. Malformations of the AV canal type, usually of the complete variety, account for approximately 50 percent of these abnormalities.[84]

History

Only if the mitral valve is incompetent do the symptoms of patients with partial AV canal differ from those associated with a secundum type of ASD. The complete form of AV canal or the partial form connected with significant mitral regurgitation may be associated with poor weight gain, easy fatigue, dyspnea, repeated respiratory infections, and congestive heart failure. Patients with complete AV canal are almost invariably very sick.

Physical Examination

The findings with a partial defect are those of an ASD. If the cleft anterior mitral leaflet is incompetent, the findings of mitral regurgitation also will be present.

The physical findings with the complete AV canal defect are those of a very large VSD, usually with full-blown congestive failure, but the second heart sound is split and fixed. The murmur of mitral regurgitation may not be heard or recognized as such.

Chest Roentgenogram

Overall cardiac enlargement that is out of proportion to the degree of pulmonary plethora or a cardiac silhouette suggesting combined ventricular dilatation may serve to distinguish an uncomplicated secundum ASD from a primum defect with significant mitral regurgitation. Marked cardiac enlargement and severe pulmonary overcirculation are features of the complete AV canal defect.

Electrocardiogram

One of the most helpful diagnostic features in distinguishing individuals with AV canal defects from those with isolated ASDs or VSDs is the characteristic superior orientation of the mean QRS axis in the frontal plane, with a right bundle branch delay in the precordial leads. Between 92 and 95 percent of both types of canal have a QRS axis lying between 0 and -150°. The patterns of atrial and ventricular hypertrophy reflect the underlying hemodynamic abnormalities.

Echocardiogram

Two-dimensional echo is capable of visualizing the extent of septal defects and, with Doppler study and color flow mapping, left-to-right shunting at the atrial and/or ventricular level and associated mitral and/or tricuspid valvular regurgitation (Fig. 63-15). The anatomic features of the anterior AV leaflet and its connections may be visualized with sufficient clarity to permit subdivision of complete AV canal defects into types A, B, and C (Fig. 63-14). Straddling AV valves, a double-orifice mitral valve, single papillary muscles, and hypoplasia or outflow obstruction of the right or left ventricle also can be determined with this technique.[85]

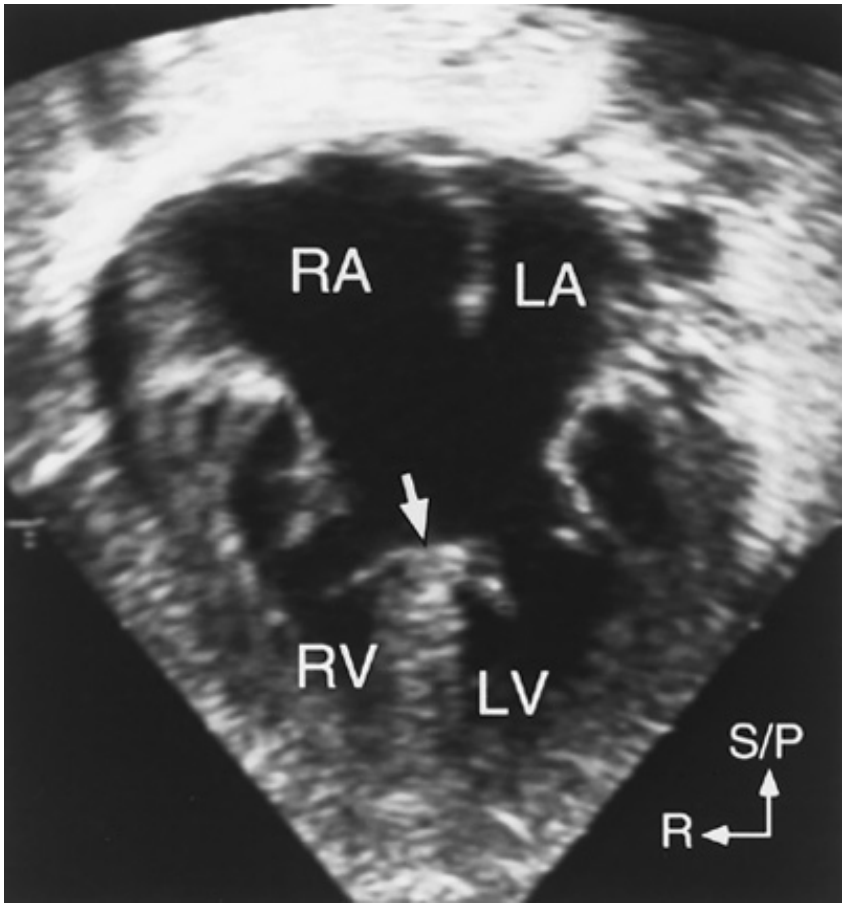

Figure 63-15: Apical four-chamber view of complete common AV canal. Note the large deficiency of both atrial and ventricular septa as well as apical displacement of the AV valves. The arrow points to the attachment of the inferior bridging leaflet to the ventricular septal crest. (From Levine J and Geva T.[85] Reproduced with permission.)

Cardiac Catheterization

Cardiac catheterization rarely is performed if the echocardiogram is characteristic and if the history, clinical examination, and echo suggest a large left-to-right shunt and low pulmonary resistance. When it is performed, a significant increase in oxygen saturation between the superior vena cava and the right atrium is present. A right ventricular or pulmonary arterial systolic pressure in excess of 60 percent of the systemic systolic pressure favors the presence of a complete canal. With a large communication between the two ventricles below the AV valves, the right ventricular, pulmonary arterial, and systemic arterial systolic pressures are virtually identical. Left ventricular angiography in the frontal view demonstrates the "gooseneck deformity" of the left ventricular outflow tract that is characteristic of AV canal malformations and allows a semiquantitative assessment of the degree of mitral regurgitation and shunting from the left

ventricle to the right atrium. The left anterior oblique view with craniocaudal angulation is recommended for visualizing the interventricular defect and judging the extent of ventricular septal deficiency. Aortography is essential to eliminate the possibility of a PDA if the echocardiogram was not diagnostic.

NATURAL HISTORY AND PROGNOSIS

Partial defects without significant mitral regurgitation follow a course similar to that described for the secundum type of septal defects. An exception would be the greater likelihood of infective endocarditis because of the mitral valve deformity. Moderate or severe mitral regurgitation produces heart failure with resulting symptoms and growth retardation. Infants with a complete AV canal without protective pulmonary stenosis quickly develop and continue to have congestive failure until the course is altered by death, the development of PVOD, or surgical intervention.

MEDICAL MANAGEMENT

Children with an uncomplicated partial defect are managed in the same manner as children with an uncomplicated ASD. Those who are symptomatic should undergo early surgical closure of the primum ASD and, if possible, plication of the cleft in the septal commissure of the left AV ("mitral") valve. The few patients with significant residual mitral regurgitation after surgery are managed medically until mitral valve replacement is appropriate. Those without symptoms are repaired before they start school.

The approach to an infant with complete AV canal is the same as that for an infant with a large VSD but is tempered by the knowledge that spontaneous improvement is very unlikely except at the expense of the pulmonary vascular bed. Repair is recommended early if there is significant congestive heart failure or between 4 and 6 months of age if the pulmonary arterial systolic pressure is greater than half the systemic arterial systolic pressure. Elevation of pulmonary vascular resistance in the first year of life warrants surgical intervention without delay.

With regard to genetic counseling, the risk of a subsequent sibling having heart disease in the presence of a single affected family member is in the range of 2 percent; it is probably higher for the offspring of an affected parent, particularly if that parent is the mother.[86] Concordance for AV canal defects among affected siblings or offspring is much higher than it is with other forms of congenital heart disease and approaches 90 percent.

SURGICAL MANAGEMENT

The remarkable clinical improvement that follows anatomic repair of complete common AV septal defects in infancy encourages early correction within the first year of life. Banding of the pulmonary artery in a critically ill infant with a large interventricular defect was used in the past but has been replaced by a more reparative operation in most centers. The specifics of repair are dictated by anatomic detail: Individual variation is considerable (Fig. 63-16), but the creation of a competent, nonstenotic left-sided AV ("mitral") valve is essential for an acceptable early and long-term prognosis.

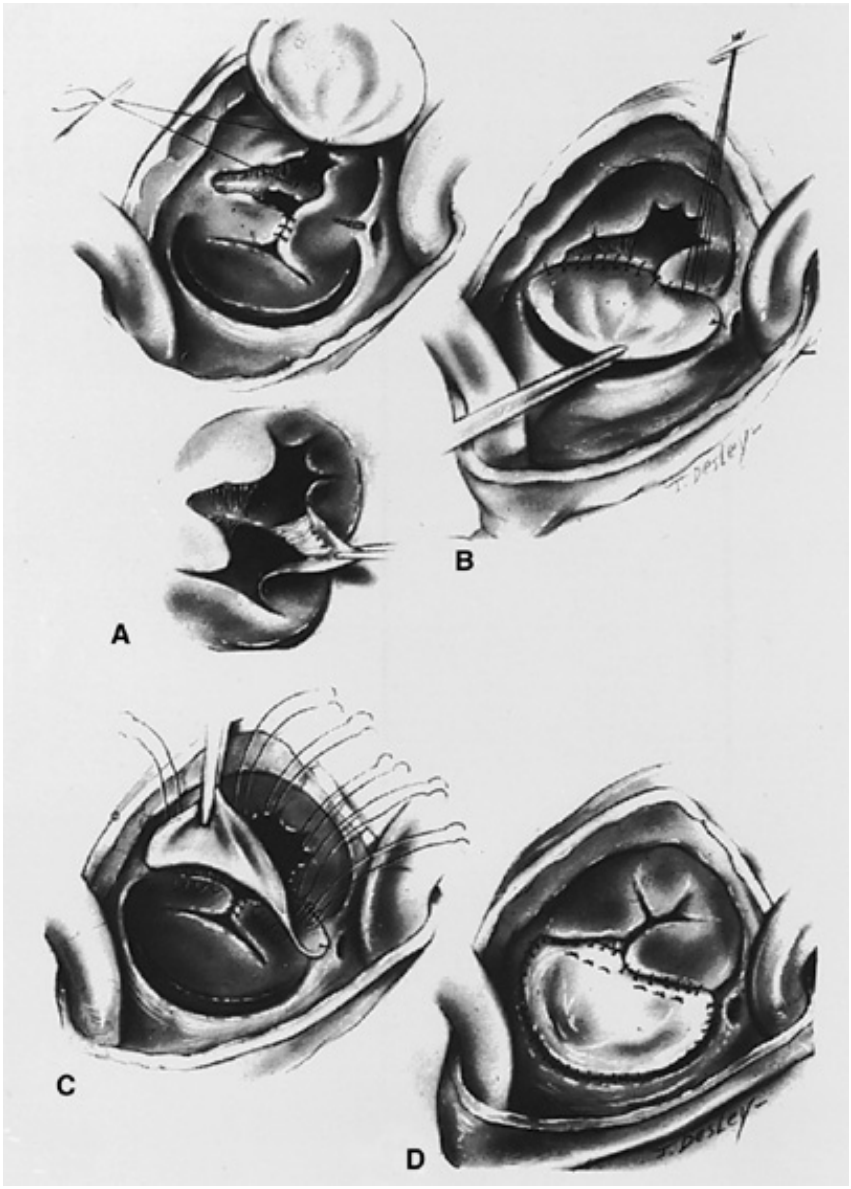

Figure 63-16: Steps in the repair of the complete form of common AV canal, type A. *A* and *B.* A pericardial patch is sutured to the ventricular septum. *C* and *D*. The anterior leaflet of the mitral valve is reconstructed and attached to the patch. A portion of the tricuspid leaflet is attached to the patch. (From Rastelli GC et al.[82] Reproduced with permission from the publisher and authors.)

A patch usually is sutured to the right side of the ventricular septum to obliterate the interventricular communication. The anterior and posterior components of the common valve are divided, and the mitral valve is sutured to the patch at an appropriate level. The "cleft" between the left anterior and left posterior leaflets should be closed by suturing if approximation of these edges appears to increase competence without the creation of stenosis. Prosthetic valve implantation rarely is required during primary anatomic repair.[87] The right-sided AV ("tricuspid") apparatus, although less critical to survival, is repaired using the same principles. The interatrial communication usually is closed with a separate piece of pericardium to minimize hemolysis in the presence of residual mitral regurgitation.[87] Mitral valve competence is assessed by gentle distention of the left ventricle with cold saline.

A partial AV canal is repaired through a right atriotomy. The cleft may be closed with a few simple interrupted sutures to encourage inversion and coaptation of the leaflet margins. The ASD usually is closed with a pericardial patch.

Permanent complete heart block once contributed substantially to early mortality and morbidity but is now rare. Patients undergoing repair of a partial AV canal should be observed for the possible development of subaortic left ventricular outflow tract obstruction caused by redundant or residual endocardial cushion tissue.

In-hospital mortality after correction of a complete AV canal in infancy ranges from 3 to 10 percent;[88,89] the highest mortality is encountered during the first few months of life and in infants with severe AV valve regurgitation, elevated pulmonary vascular resistance, hypoplasia of the left or right ventricle, or other cardiac malformations. At Children's Hospital in Boston, 191 children with a median age of 4.6 months were repaired between January 1990 and December 1998 with an operative mortality of 1.5 percent. Reoperation was necessary in 22 patients (11.7 percent), a mean of 20 months later: 18 for residual mitral regurgitation and 4 for left ventricular outflow tract obstruction.[90] Successful correction of a complete AV canal can be accomplished despite associated tetralogy of Fallot, double-outlet ventricle, and other complex anomalies.[87]

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

EXTRACARDIAC COMMUNICATIONS BETWEEN THE SYSTEMIC AND PULMONARY CIRCULATIONS, USUALLY WITHOUT CYANOSIS

Patent Ductus Arteriosus

DEFINITION

Patent ductus arteriosus, the most common type of extracardiac shunt, represents persistent patency of the vessel that normally connects the pulmonary arterial system and the aorta in a fetus (Fig. 63-17).

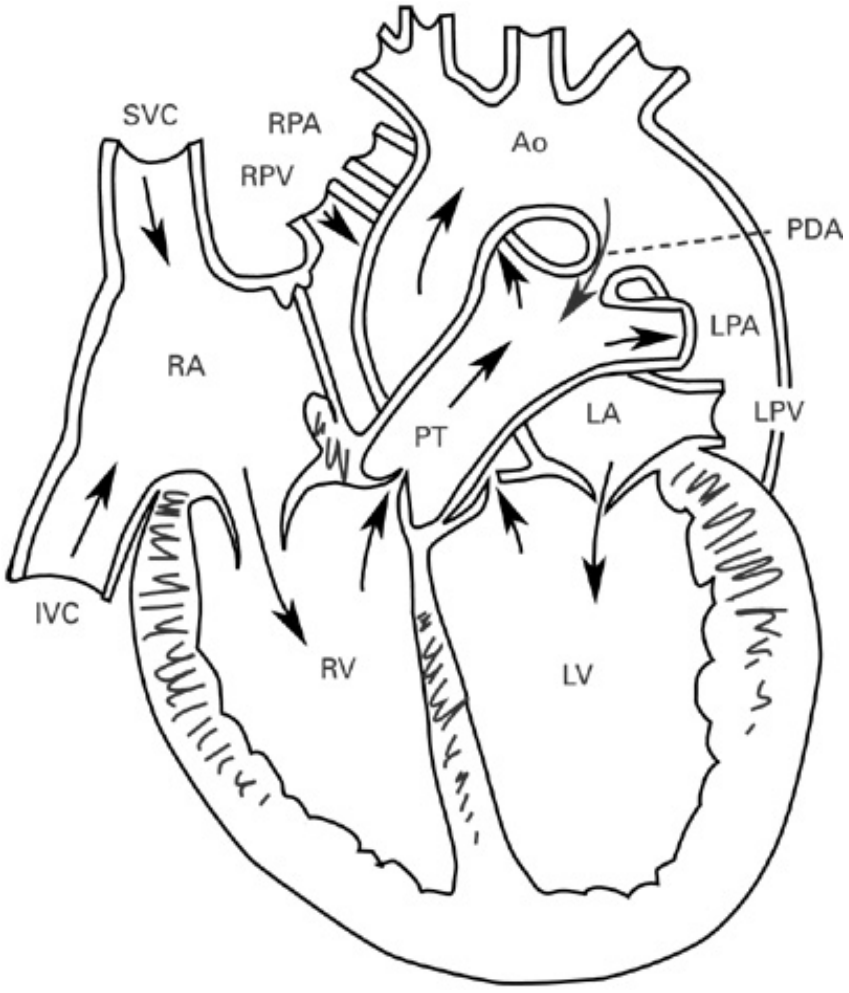

Figure 63-17: Patent ductus arteriosus (PDA). SVC = superior vena cava; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; PT = main pulmonary arterial trunk; RPA = right pulmonary artery; LPA = left pulmonary artery; RPV = right pulmonary vein; LPV = left pulmonary vein; LA = left atrium; LV = left ventricle; Ao = aorta. (From Edwards JE.[66]

Reproduced with permission from the publisher and author.)

PATHOLOGY

The ductus arteriosus usually closes within 2 or 3 days after birth and becomes the *ligamentum arteriosum*, but it may remain patent as long as 8 weeks postnatally. It runs from the origin of the left pulmonary artery below to the lower aspect of the aortic arch just beyond the level of origin of the left subclavian artery above. The recurrent branch of the left vagus nerve hooks around its lateral and inferior aspects. Closure postnatally involves a complex interaction of increased oxygen tension in the blood and circulating prostaglandins. Exogenous PGE_1 has been used extensively to keep the ductus open postnatally,[91] and indomethacin, a prostaglandin inhibitor, can close the ductus in many premature infants in whom persistent patency is disadvantageous.[92]

ABNORMAL PHYSIOLOGY

Patients with PDA may be divided into groups according to whether the vascular resistance through the ductus is low, moderate, or high. The resistance of the ductus is related not only to its cross-sectional area but also to its length. In patients with a very small ductus that offers high resistance, the flow across the ductus is relatively small. The extra volume of work on the left ventricle is small, and the pulmonary pressure and resistance are not elevated. Patients with only moderate resistance in the ductus have some increase in pulmonary artery pressure, with a moderately greater volume of shunting across the ductus.

In patients with a large patent ductus, the aorta and pulmonary artery are essentially in free communication; the systolic pressure in the pulmonary artery is equal to that in the aorta. The volume load of blood recirculating through the lungs is on the left ventricle, with pulmonary congestion resulting from increased pulmonary flow and/or left ventricular failure. With time, the left ventricle compensates with dilation and hypertrophy to carry the volume load, and the pulmonary vasculature may respond to the high pressure (see the section on PAH, above). The right ventricle is burdened mainly by a pressure load.

If the pulmonary resistance equals or exceeds the resistance of the systemic circulation, there is shunting of unsaturated blood from the pulmonary artery to the aorta, resulting in hypoxemia, especially in the lower body and legs.

CLINICAL MANIFESTATIONS

History

The history of the mother's pregnancy and of perinatal events may provide clues that are associated with a high incidence of PDA, such as exposure to rubella in the first trimester in a nonimmunized mother. PDA is also more common in premature infants, especially those with birth asphyxia or respiratory distress.[93]

Symptoms usually are restricted to patients with large shunts that produce heart failure or with other complicating problems, such as respiratory distress in a premature infant. The symptoms related to heart failure were discussed above. Heart failure is most likely to develop in the first few weeks or months of life. If it does not appear during infancy, it is unlikely to occur before the third decade. Growth may be affected in those with large shunts and failure. The clinical presentation in a premature infant is usually very different from that in a full-term infant, particularly in those with a birth weight under 1.5 kg, who are more likely to have moderate to severe respiratory distress. In these infants, the clinical features of respiratory distress often blend over the course of several days into those of heart failure. Increasing ventilatory or oxygen

requirements with carbon dioxide retention or episodic apnea and bradycardia are often the first signs that a PDA may be complicating the picture.

Physical Examination

In a full-term infant or child with PDA, there is frequently a systolic thrill over the pulmonary artery and in the suprasternal notch. The peripheral pulses are generally brisk and bounding, especially with the larger shunts secondary to runoff from the aorta to the pulmonary artery in diastole. A patient with elevated pulmonary vascular resistance and a right-to-left shunt will have "differential cyanosis," with cyanosis and clubbing of the toes but not the fingers, from shunting of hypoxemic blood from the pulmonary artery into the descending aorta. The apex impulse may be increased or displaced in those with large shunts. The right ventricular impulse is increased in a premature infant with respiratory distress and in infants and children with significant pulmonary hypertension. The typical murmur is a continuous, or "machinery," murmur that is best heard at the left upper sternal border and below the left clavicle. It is usually a rough murmur with eddy sounds, which are helpful in making the diagnosis, and it peaks at or near the second heart sound. In patients with at least a moderate shunt, there is a middiastolic rumble at the apex as a result of relative mitral stenosis from increased flow across the mitral valve. The second heart sound may be difficult to hear because of the continuous murmur, but it is usually normal. The pulmonary component is accentuated in those with pulmonary hypertension.

Chest Roentgenogram

Findings on chest roentgenography also are dependent on the magnitude of the shunt. In patients with a small shunt, the chest roentgenogram is normal. With larger shunts, the left atrium and left ventricle are enlarged. Increases in pulmonary arterial flow on x-ray parallel the magnitude of the shunt. In the presence of heart failure, there are signs of pulmonary edema. In older patients who have developed Eisenmenger physiology, the only abnormality may be marked prominence of the central pulmonary arteries, with rapid tapering to the periphery of the lung fields.

Electrocardiogram

With a small shunt, the ECG is normal. Left atrial hypertrophy is probably the most common abnormality found, but left ventricular hypertrophy of the volume overload type, with deep Q waves and increased R-wave voltage in the left precordial leads, is also common as the shunt size increases and left ventricular dilation occurs. Right ventricular hypertrophy is seen with pulmonary hypertension.

Echocardiogram

There is left atrial enlargement, and the left ventricular end-diastolic dimension and mean velocity of circumferential fiber shortening are increased significantly. Small shunts can be detected with color Doppler imaging with a typical spectral flow pattern into the pulmonary artery, while a larger ductus can be visualized with two-dimensional echocardiography. Occasionally, a trivial amount of flow is seen through the ductus as an incidental finding in those with or without associated heart disease.

Cardiac Catheterization

In those with typical, uncomplicated PDA, cardiac catheterization is not necessary. When catheterization is performed, the catheter usually passes preferentially from the left pulmonary artery into the descending aorta, except when the ductus is too small. The saturation is increased in the pulmonary artery compared with the right atrium and ventricle to a degree relative to the size of the shunt. The pulmonary arterial and right ventricular pressures are elevated in those with

a large ductus. The pulmonary vascular resistance is elevated in older patients who have developed changes in the pulmonary vascular bed. These patients also have diminished saturation in the descending aorta once the pulmonary resistance reaches a level that will reverse the shunt. Aortography will opacify the ductus and pulmonary arteries.

NATURAL HISTORY AND PROGNOSIS

The complications related to PDA include infective endarteritis, heart failure, and pulmonary hypertension with vascular damage. Infection of the ductus is a risk regardless of its size. This risk increases with the length of survival. This can lead to the development of a mycotic aneurysm with the potential to compress the recurrent laryngeal nerve, embolize septic material to the lungs, or rupture. Calcification of the ductal wall is common in adults.

In patients with large shunts, heart failure can cause significant morbidity and mortality, particularly in a premature and young infant, and sudden death can occur. Progressive damage to the pulmonary vascular bed can occur in some, but it rarely occurs to an irreversible degree in the first year of life. Once irreversible damage occurs, premature death in late adolescence or early adulthood can be anticipated.

With improved technology, children without associated heart disease are noted to have a trivial amount of flow through a very small (<1 mm) patent ductus. Frequently, the shunt is too small to produce an audible murmur. The natural history of this echo-Doppler-discovered ductus arteriosus without clinical findings is unknown, but most think it is benign since cardiologists have not noted patients with endarteritis in a "silent" ductus.

MEDICAL MANAGEMENT

Interruption of flow through the PDA is the ultimate goal of management. For those in congestive heart failure, usually premature infants, medical management with digoxin and diuretics with fluid restriction may play a minor role, but the ultimate aim is closure to prevent heart failure and promote growth in infants and prevent infective endarteritis and pulmonary vascular disease in older children.

For premature infants, treatment with indomethacin is usually the first-line therapy.[94] Successful closure depends on both the dosage and the timing of treatment, although the major determinants seem to be gestational and postnatal age rather than the concentration of the drug. Because of ductal reopening, serial treatment regimens may be necessary, especially in those weighing less than 1000 g at birth. There is increasing evidence that the administration of "prophylactic" indomethacin in infants weighing less than 1000 g at birth may be associated with a higher closure rate and a better outcome.[92] Indomethacin therapy has been associated with an increased bleeding tendency resulting from platelet dysfunction, decreased urine output secondary to renal dysfunction, and necrotizing enterocolitis.[92] For the very premature with a PDA, however, a trial of indomethacin is preferable to the other options.

For premature infants who failed to close their PDA with a course of indomethacin or for term infants with a persistent PDA, closure has been recommended. If the PDA is large, there is usually a large left-to-right shunt with congestive heart failure. In these infants, the indication for closure is heart failure and usually failure to thrive. Even in the absence of these indications, when a large PDA is associated with PAH, closure is recommended to prevent PVOD. In children with a smaller PDA with an audible murmur but no evidence of significant hemodynamic embarrassment, closure usually is recommended because of the incidence of bacterial endarteritis, which over a lifetime is in the range of 30 percent. For children with a PDA without a heart murmur, which usually is discovered incidentally when an echocardiogram is performed for other

reasons, the author does not currently recommend closure.

SURGICAL AND INTERVENTIONAL CATHETER CLOSURE

Surgery for a persistent PDA was first reported more than 60 years ago and is now done routinely in most centers. The safety and efficacy of this procedure even in very young children are well established, with risks that are very low (well under 1 percent), and success at interrupting flow is almost universal.

The PDA is exposed and mobilized through a small left thoracotomy in the fourth intercostal space.[95] Ductus obliteration is accomplished by division or ligation. A short, broad, or thin-walled ductus is divided between vascular clamps. The ends are closed with a continuous suture. A long, narrow, thick-walled ductus can be divided or ligated with two or three sutures spaced a few millimeters apart. The suture ligatures at each end are anchored superficially in the ductus wall to prevent migration and assure thrombosis and obliteration.

The fragile and thin-walled PDA of a premature infant is obliterated by gentle ligation with a thick suture to minimize disruption or, if small, by occlusion using metallic surgical clips. Extrapleural exposure is preferred by some surgeons. Ligation in the neonatal intensive care unit, avoiding transport to the operating room, is common. Transport from a remote intensive care unit to a cardiac surgical unit for ductus ligation on a "day-stay" basis is also efficacious.[96] Ductus obliteration offers clinical improvement in infants weighing as little as 500 g, with minimal operative risk, a reduced incidence of necrotizing enterocolitis, a reduced duration of intubation, and improvement in late survival.

Closure of a PDA in an adult requires particular caution; calcification and rigidity of the ductus wall complicate clamping. Placement of a Dacron patch over the aortic orifice of the ductus from within the aorta may be advisable.[97]

Recently, advances in less invasive surgery have been applied to the closure of a PDA using video-assisted thoracoscopic surgery. A miniaturized camera is inserted into the thorax, and through a separate tiny incision, a surgical stapler is inserted and a clip is placed across the PDA, interrupting flow. Among 230 patients, there was only 1 with minimal residual flow, 1 with persistent recurrent laryngeal nerve dysfunction, and no deaths, transfusions, or chylothoraces. The mean operating time was 20 min, and the hospital stay lasted only a couple of days.[98] At Children's Hospital in Boston, this procedure has been applied to premature infants as small as 575 g, with discharge from the hospital the day after the procedure in full-term infants and children.[99]

The PDA sometimes can be closed by interventional catheterization techniques. In 1971, Portsmann and Wierny introduced a rather complex methodology to plug a PDA by using a transarterial and transvenous approach employing very large catheters.[100] More recently, Rashkind and Cuaso introduced and others have since popularized the use of a double-umbrella device to plug a PDA,[101] but the large size of the delivery sheath of the Rashkind device makes it inapplicable to young and very small children. Gianturco coils-thin metallic wires glossed with Dacron that assume a coil configuration when released from a catheter-have become an attractive alternative (Fig. 63-18). They can be delivered through relatively small catheters and have been found to be quite effective, although their utility is limited in those <8 months of age with PDAs that are more than 3.5 or 4.0 mm at the narrowest point.[102] In the others using these coils, the results have been very promising, with a 90 percent success rate.

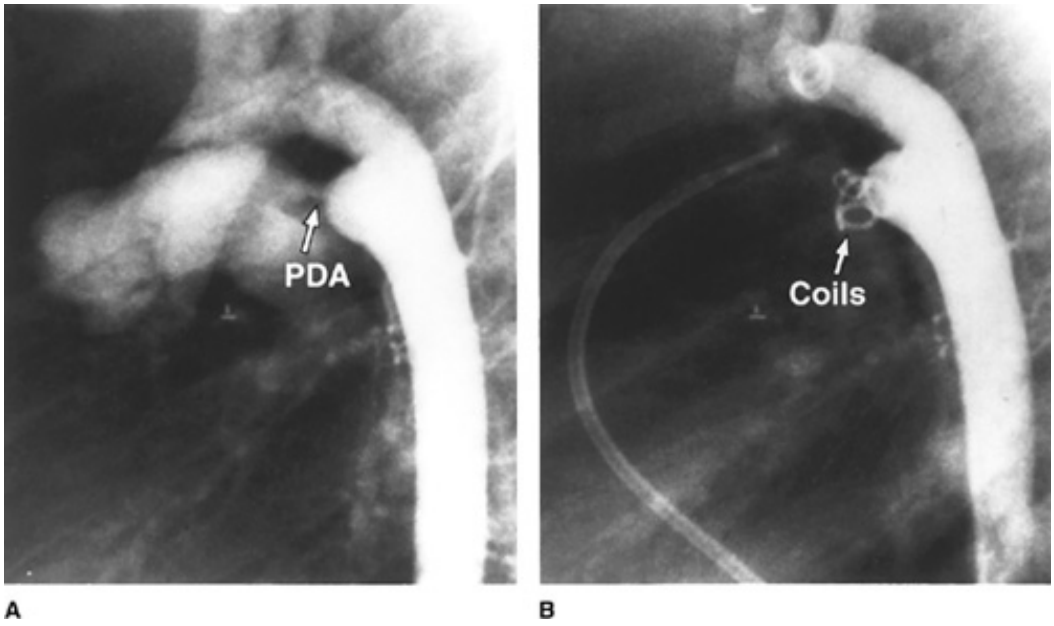

Figure 63-18: Lateral angiogram showing coil occlusion of a patent ductus arteriosus. *A.* Small PDA allows shunting from descending aorta to pulmonary artery. *B.* Shunting is eliminated by a coil placed in the ductus arteriosus. (Courtesy of John F. Keane, MD.)

With several highly successful, low-risk, inexpensive, and minimally traumatic procedures available to close a persistent PDA in a neonate, child, adolescent, or adult without pulmonary vascular disease, local experience is likely to be the best guide to which option is preferable in an individual child.

Sinus of Valsalva Fistula

PATHOLOGY

Sinus of Valsalva fistula is uncommon; it also is referred to as *aortic sinus aneurysm* (see also Chap. 88). Because of an assumed intrinsic weakness at the union of the aorta with the heart, the aortic media may separate from the aortic annulus and retract upward. The structure that lies between becomes aneurysmal and may rupture to form a fistula. The usual sites of the defects are the posterior (noncoronary) sinus aneurysms that rupture through the atrial septal wall into the right atrium (Fig. 63-19*A*) and those of the right sinus that rupture into the right ventricular infundibulum (Fig. 63-19*B*).[103] The aneurysm is represented by a colored pouch with multiple perforations in the wall. The principal associated condition is a supracristal VSD in cases with aneurysms of the right sinus (about 50 percent).

CLINICAL MANIFESTATIONS

Sinus of Valsalva fistulas are most common in adults.[104] When the rupture is secondary to bacterial endocarditis, evidence of a preceding infection is found. If the rupture occurs slowly, a small fistulous tract into the right atrium or ventricle develops and presents recent-onset findings of a small left-to-right shunt. With sudden rupture, there is usually a tearing pain in the midchest associated with the dramatically rapid development of pulmonary congestion caused by the sudden onset of a large shunt. Characteristically, the murmur is loud and continuous but is heard lower on the chest than is the murmur of PDA. A to-and-fro murmur rather than a continuous one may be heard at times. The apex impulse is hyperdynamic, and the pulse pressure is widened. VSD may complicate the clinical picture. Cardiac catheterization will confirm the level of the shunt. A pressure difference across the right ventricular outflow tract may be present if the right

sinus is involved. Aortography or Doppler echocardiography[105] will confirm the diagnosis.

NATURAL HISTORY AND PROGNOSIS

With slow rupture and a small shunt, the major risk is infective endocarditis or extension of the rupture with an increasing shunt. With a large shunt, the heart failure is usually rapidly progressive and may result in death very quickly. A few patients seem to stabilize in this situation.

MEDICAL MANAGEMENT

Appropriate cultures should be drawn and antibiotics should be begun if endocarditis is suspected. Treatment of heart failure should be instituted rapidly. *Because of the natural history, all patients should have this condition corrected surgically*.

SURGICAL MANAGEMENT

Aneurysms or fistulas from the noncoronary or right coronary sinuses are repaired through the aortic root while the patient is supported on total cardiopulmonary bypass with moderate hypothermia, using techniques similar to those employed for aortic valve replacement. The aortic valve leaflets, the margins of the aneurysm, and the coronary arterial orifices must be visualized precisely. Aneurysms of the noncoronary sinus can be repaired through the right atrium; those arising from the right coronary sinus are accessible through the right ventricle. In most cases, the orifice of the aneurysmal fistula is surgically obliterated, using a Dacron patch. In a recent series of 129 patients, reparative methods included plication (47 percent), patch repair (40 percent), and aortic root replacement (12 percent). Sixty percent of those patients needed aortic valve replacement at the same time.[104]

A conal, or supracristal (type I), VSD must be sought and closed through either the aortic valve or the right ventricular outflow tract when an aneurysm of the right coronary sinus extends into the right ventricle.

Surgical results are usually quite good. In the large series cited above, the operative survival was 96 percent with no late deaths in an average of 5.9 years of follow-up.[104]

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

VALVULAR AND VASCULAR MALFORMATIONS OF THE LEFT SIDE OF THE HEART WITH RIGHT-TO-LEFT, BIDIRECTIONAL, OR NO SHUNT

Coarctation of the Aorta

PATHOLOGY

Coarctation of the aorta is a discrete narrowing of the distal segment of the aortic arch. The characteristic lesion is a deformity of the media of the aorta that involves the anterior, superior, and posterior walls and is represented by a curtain-like infolding of the wall that causes the lumen to be narrowed and eccentric[106] (see Chap. 88).

In infants, the lesion lies either opposite the ductus or in a preductal location. In adolescents and adults, it is usually at the ligamentum arteriosum. An aberrant right subclavian artery may be associated. In rare cases, the narrowing lies proximal to the origin of the left common carotid artery or involves a segment of the abdominal aorta.

The principal cardiac abnormality is left ventricular hypertrophy. In some infants, left ventricular endocardial fibroelastosis may be associated. Tubular hypoplasia of the distal aortic arch and isthmus is very common, especially with associated cardiac abnormalities involving left heart obstruction.[107] The proximal aorta may show a moderate degree of cystic medial necrosis. Beyond the coarctation, the lining may show a localized jet lesion.

Prominent collaterals are characteristic in older infants, children, and adolescents. They may be divided into anterior and posterior systems, with the anterior system originating with the internal mammary arteries and making use of the epigastric arteries in the abdominal wall to supply the lower extremities. The posterior system involves parascapular arteries connected with the posterior intercostal arteries and carries blood to the distal aortic compartment principally for supply of the abdominal viscera. The anterior spinal artery, receiving branches from the proximal and distal compartments of the aorta, is also dilated and tortuous.

ASSOCIATED CONDITIONS

The most commonly associated defects are tubular hypoplasia of the aortic arch, PDA, VSD, and aortic stenosis (valvular and/or subvalvular). A bicuspid aortic valve is present in 46 percent of autopsy cases.[106]

ABNORMAL PHYSIOLOGY

In most instances, both the systolic and diastolic arterial pressures above the coarctation are elevated above normal levels. Below the coarctation, the systolic pressure is lower than that in the upper extremities, and the diastolic pressure is usually near or only slightly below the normal range. The mechanism of upper extremity hypertension appears to involve the increased resistance to aortic flow produced by the coarctation itself, the decreased capacity and distensibility of the vessels into which the left ventricle ejects, and humoral factors.[108]

CLINICAL MANIFESTATIONS

Coarctation of the aorta occurs in approximately 4 percent of all infants and children with congenital heart disease and is the predominant lesion in approximately 8 percent of infants presenting with critical heart disease in the first year of life. It ranks behind only VSD, dextrotransposition of the great arteries, and tetralogy of Fallot.[3] Among all individuals born with coarctation, approximately half present within the first month or two of life with heart failure. About 50 percent of infants so admitted have uncomplicated coarctation; the remaining half can be expected to have at least one complicating cardiac abnormality. VSD is the most common (64 percent), followed by left ventricular outflow tract obstruction (31 percent).[109] The timing of ductal tissue constriction in terms of both ductal closure and perhaps aortic constriction appears to play a decisive role in the onset or worsening of symptoms in most of these patients. The male/female ratio is approximately 3:1 for isolated coarctation but is only 1.1:1 for complicated coarctation. Approximately 45 percent of children with Turner's syndrome have coarctation.

History

The clinical picture in a symptomatic infant is one of dyspnea, difficulty in feeding, and poor weight gain. Older children are for the most part asymptomatic, although a few complain of mild fatigue, dyspnea, or symptoms of claudication in the legs when running.

Physical Examination

In a symptomatic infant, signs of congestive heart failure are characteristic. A gallop rhythm is common, and a murmur from associated defects or from the coarctation itself (posteriorly in the interscapular area) may be heard. Frequently, these murmurs are either inaudible or nondescript on admission and become characteristic only when congestive failure is brought under control. Prominent arterial pulsations may be visible in the suprasternal notch and carotid arteries, and the left ventricular impulse is forceful. An early systolic ejection click at the apex suggests the presence of a bicuspid aortic valve. The murmur from the coarctation is medium-pitched, systolic, and blowing in quality. It is best heard posteriorly in the interscapular area, usually with some degree of radiation to the left axilla, apex, and anterior precordium. Low-pitched, continuous murmurs of collateral circulation may be heard over the chest wall, particularly posteriorly, but seldom before adolescence. A short middiastolic rumble at the apex without clinical evidence of mitral disease is relatively common.

The characteristic systolic blood pressure difference between the upper and lower extremities may be difficult to appreciate or measure in infants with severe congestive failure or with a large VSD or PDA. With improved compensation, pulses in the upper extremities become readily palpable. The femoral pulses remain weak, delayed, or absent. In these very young infants, it is important that the pulses in both brachial and carotid arteries be assessed. Weak or absent pulses in all sites are more characteristic of critical aortic stenosis or aortic atresia.

In older children and adults, the radial arterial pulses typically are strong; those in the femoral arteries are diminished, delayed, or absent. A repeatedly measured systolic or mean pressure difference between the upper and lower extremities greater than 10 mmHg is diagnostic. The pulse pressure in the leg is reduced, and in some patients no pressure can be measured by auscultation or Doppler. Approximately one-third of older children have mild to severe hypertension, with severe hypertension defined as a systolic pressure above 150 mmHg, a diastolic pressure above 100 mmHg, or both. Some patients have only a mild pressure difference between the arms and the legs at rest but a much larger difference during treadmill exercise. A systolic pressure difference between the two arms suggests that the origin of one subclavian artery is at or below the obstruction, e.g., aberrent right subclavian from the descending aorta.

In light of the simplicity of measuring blood pressure in the upper and lower extremities of children and the importance of early detection, it is surprising and disappointing that approximately 95 percent of children and adolescents with coarctation are referred by pediatricians and other health care providers to a pediatric cardiologist for evaluation of a heart murmur and/or hypertension without this serious underlying malformation being recognized.[110]

Chest Roentgenogram

For a symptomatic infant, the pattern is one of impressive cardiac enlargement and venous congestion. In an older and asymptomatic child, the heart size is generally at the upper limits of normal with a left ventricular prominence. A figure-three configuration of the left margin of the aorta at the level of the coarctation may be seen in overpenetrated films, with the upper curve formed by the slightly dilated aorta just above the coarctation, the central indentation by the coarctation itself, and the lower curve by the poststenotic dilatation below the coarctation. Notching of the inferior margin of the ribs by tortuous intercostal arteries acting as collaterals is seldom present before 7 or 8 years of age.

Electrocardiogram

The ECG of a symptomatic infant reflects right or biventricular hypertrophy during the first 3 months of life. T-wave inversion in the left precordial leads is common. In older children, the ECG is usually normal or may indicate mild left ventricular and left atrial hypertrophy.

Echocardiogram

Two-dimensional echocardiographic imaging of the aortic arch from the suprasternal notch permits visualization of the coarctation and detection of anatomic variations such as isthmic or transverse arch hypoplasia. The precordial and subxiphoid views are of great value in assessing the presence and severity of associated defects. Doppler flow studies are helpful for diagnostic confirmation. In infants with heart failure, left ventricular dilation and decreased contractility are common. The severity of the coarctation can be evaluated by Doppler gradients and the diminished pulsatile flow in the abdominal aorta.

Cardiac Catheterization

Study of symptomatic infants characteristically reveals left atrial and left ventricular hypertension and a significant systolic pressure difference between the left ventricle and the femoral artery, particularly if the coarctation is isolated. In the presence of a large VSD and PDA, the left ventricular hypertension and the systolic pressure difference between the left ventricle and the femoral artery are less impressive and may not exist at all. Every attempt should be made to define the nature and severity of associated defects. Imaging is recommended in older children to demonstrate the exact site and length of the coarctation as well as to show unusual features of the collateral circulation that may be of importance to the surgeon. Magnetic resonance imaging is an excellent and in most instances preferable alternative to angiography today for demonstrating the site and length of the coarctation (Fig. 63-20).

NATURAL HISTORY AND PROGNOSIS

Approximately one-half of infants admitted with heart failure within the first weeks of life have coarctation without significant associated defects.[109] The majority of these infants respond well to medical management and, if no repair is performed, reach a stage at 2 or 3 years of age where they are indistinguishable from asymptomatic children of the same age whose coarctation is first detected during a routine physical examination. Upper extremity hypertension usually increases during the first several months of life and then tends to diminish again as collateral circulation

improves, while signs of failure diminish at the same time. For infants with severe failure and any serious associated defects, balloon dilation or surgery provides virtually the only chance of survival.

The consequences of persistent hypertension in an individual who has not undergone surgery appear in the second and third decades in the form of severe hypertension, aortic rupture, or intracranial hemorrhage from an aneurysm of the circle of Willis. Congestive heart failure that often is complicated by mitral or aortic valve disease, a dissecting aneurysm of the aorta, or atherosclerosis is seen in the fourth decade. The risk of endocarditis on the aortic or mitral valves or endarteritis at the site of coarctation appears to be spread relatively evenly over the years. The average age of death of patients who survive childhood with coarctation without surgery is 34 years.[111]

MEDICAL MANAGEMENT

Vigorous medical treatment is indicated for infants with severe heart failure. A newborn with severe failure may experience dramatic relief from the intravenous infusion of PGE_1 to reopen the closing ductus.[91] Prompt correction of the coarctation is recommended for all infants in whom there are one or more associated defects and for all infants with isolated coarctation unless the response to medical management has been dramatic and sustained.

The timing and type of correction of isolated discrete coarction of the aorta remain a topic of some dispute. There is general agreement that all children with congestive heart failure should be repaired after a brief period of stabilization and treatment of the failure. Since heart failure usually is limited to infants in the first few months of life and since balloon dilation of native coarctation in children under 6 months of age has had an unacceptable restenosis rate of up to 75 percent,[112] virtually all physicians would consider surgical repair the favored approach. For infants and children without congestive heart failure, the timing has been somewhat more problematic. Historically, the preferred approach was waiting until age 1 to 4 to avoid the problem of recoarctation that was found occasionally among patients corrected before 1 year of age[113] and residual or recurrent hypertension among patients without demonstrable recurrent coarctation, renal disease, or significant aortic regurgitation, which appears to be related to the duration of hypertension before surgery. More recently, the ability to reduce the restenosis rate has led some centers to reduce the age of elective surgical repair of coarctation to 3 to 6 months. For those in whom balloon dilation is contemplated, waiting until age 1 to 4 still seems appropriate.

Although there is general agreement that symptomatic children under 6 months of age with coarctation ought to be repaired surgically and that the first approach to those who develop restenosis at virtually any age should be balloon dilation or stent placement, the proper therapy for the treatment of native coarctation in children older than 1 year of age remains somewhat controversial. For balloon dilation, immediate success (defined as an increase in the coarctation diameter with a residual gradient of less than 20 mmHg) occurs in 80 to 95 percent of patients who are dilated, with the gradient reduction averaging 75 percent. However, long-term gradient relief after angioplasty has been somewhat less than that with surgery. Restenosis rates in the intermediate term seem to be directly related to the age at dilation, with 85 percent of neonates, 35 percent of infants, and 10 percent of children over 2 years of age developing restenosis.[112] Repeat dilation is almost invariably successful, and many advocate this approach even if it requires two dilations rather than a one-step surgical approach. Occasionally in older children a stent can be placed if the balloon dilation fails to persistently increase the luminal diameter (Fig. 63-21). In selected older children and adults, this has been very successful, with an average reduction in the gradient from 25 to 5 mm in 32 patients at Children's Hospital in Boston.[114] Complications usually have been related to associated diseases, although aneurysms, usually small, at the site of dilation have been reported in about 5 percent of cases. Large catheters are necessary, and trauma to the femoral artery is not uncommon.

Patients who have repaired coarctation need to be followed indefinitely. For those with significant recoarctation, expressed as a systolic pressure gradient between the upper and lower extremities of 20 mm or more at rest, balloon angioplasty and/or stent placement are recommended. Repeat surgery for recurrent coarctation is rarely necessary. Occasionally, patients are seen who have insignificant or small resting gradients but manifest abnormal upper extremity hypertension and significant gradients with exercise.[109] These patients probably should undergo balloon angioplasty and stent replacement with pharmacologic control of their hypertension if it is present at rest and beta blockade if the hypertension becomes significant with exercise.

SURGICAL MANAGEMENT

The coarctation is exposed and mobilized through a left posterolateral thoracotomy. It is usually possible to resect the narrow segment and restore continuity with a direct end-to-end anastomosis (Fig. 63-22). When the narrowed segment is longer, repair by subclavian flap aortoplasty or rarely a tubular vascular prosthesis to bridge the gap between the two ends of the aorta may be necessary. In adults with a relatively nonelastic or calcified aorta, a tubular vascular prosthesis can be used to bypass the unresected coarctation or the previous repair. Dacron patch repair of coarctation has an unacceptably high incidence of late aneurysm formation and is no longer advised.[115] Tension-free suture lines are essential. Postoperative bleeding, chylothorax, paraplegia, and injury to the phrenic and recurrent laryngeal nerves remain potential complications.[116]

If a significant VSD is also present, a pulmonary arterial band is placed at the time of coarctation repair during infancy. The VSD then may be repaired electively during the next several months, when the child's congestive heart failure is well controlled. Primary repair of the VSD shortly after or simultaneously with coarctation repair is a viable alternative that has been gaining favor recently.[117]

Adequacy of collateral circulation to the spinal cord is crucial for the safe repair of coarctation. A rise in proximal systemic arterial pressure of more than 20 mmHg when the aorta is clamped above the coarctation suggests a marginal collateral circulation. Mild systemic hypothermia is a simple and useful adjunct, and monitoring of somatosensory cortical evoked potentials may warn of an impending ischemic insult to the spinal cord.[118]

Postoperative paradoxical hypertension is common between the second and fifth postoperative days and may contribute to the *postcoarctation syndrome*, in which ileus, abdominal pain, mesenteric vasculitis, and even visceral infarction can occur. This syndrome rarely is encountered if the postoperative blood pressure is maintained within the normal range for age with sodium nitroprusside, a beta blocker such as propranolol, or captopril.

Operative mortality for infants with isolated coarctation is in the range of 0 to 3 percent [113,116,117] but is 10 percent or higher when other cardiovascular defects are present. Subsequent deaths are uncommon in surviving infants with isolated coarctation but are more likely in those with complicated associated defects.

Valvular Aortic Stenosis

DEFINITION

Aortic stenosis is defined as subtotal obstruction of varying severity in the channel of left ventricular outflow. In order of decreasing frequency, the sites of obstruction by congenital lesions are (1) valvular, (2) subvalvular, and (3) supravalvular (see Chap. 56).

PATHOLOGY

Most commonly, the aortic valve is bicuspid with two commissures, one or both of which are fused to varying degrees. A third rudimentary commissure, or raphe, is frequently present in the larger of the leaflets. The valve opening is eccentric. Less frequently encountered is a unicuspid, unicommissural, or noncommissural valve in which the orifice is often slitlike, at first glance suggesting a bicuspid valve. Uncommonly, a true dome is present, resembling the valve of congenital isolated pulmonary stenosis. Rarely, the valve is tricuspid with fusion of one or more of the three commissures. When survival to adult life occurs, calcification may appear in the valvular tissue, leading to rigidity of the valve. Poststenotic dilation of the ascending aorta occurs in all cases to some degree. Coarctation of the aorta is the most common associated anomaly.

ABNORMAL PHYSIOLOGY

The hemodynamics of congenital valvular aortic stenosis are similar to those of acquired aortic stenosis (see Chap. 56) except that a persistent PDA or stretched foramen ovale in the immediate postnatal period may lessen the severity of pulmonary edema by diverting blood away from the left ventricle.

Severity usually is judged by the peak systolic pressure gradient (PSPG) across the aortic valve, which is determined at cardiac catheterization, and the calculated aortic valve area. In the presence of a normal cardiac output, a PSPG ≥75 mmHg or an aortic valve area <0.5 cm^2/m^2 is considered severe, a PSPG between 50 and 75 mmHg or a valve area between 0.5 and 0.8 cm^2/m^2 is considered moderate, and a PSPG <50 mmHg or a valve area >0.9 cm^2/m^2 is considered mild (see Chaps. 15 and 56).

CLINICAL MANIFESTATIONS

About 7 percent of infants and children with congenital heart disease have aortic stenosis in one of its several forms, and approximately 80 percent of these patients have valvular aortic stenosis. Valvular stenosis is much more common among males than females, with a ratio of 4:1.

History

The detection of a systolic murmur leads to the discovery of this malformation in most patients, the vast majority of whom are asymptomatic. Easy fatigue, dyspnea, syncope, and angina suggest severe obstruction, but severe obstruction may exist in the absence of any symptoms. Sudden death may occur from this malformation, but in most such cases death is preceded by either symptoms or ECG changes. Infants with critical stenosis from birth present with congestive failure within the first week or two of life and represent true emergencies. A similar small number of patients with less critical but still very severe obstruction are detected over the course of the next 4 to 6 months.

Physical Examination

The arterial blood pressure and the quality of the peripheral arterial pulses of older infants and children are usually normal. A measured pulse pressure <20 mmHg suggests severe stenosis. The cardiac apex impulse may be forceful and sustained, and a systolic thrill along the right upper sternal border and over the carotid arteries is present in most of these patients. The absence of such a thrill at the right upper sternal border or suprasternal notch suggests a PSPG less than 30 mmHg. Paradoxical splitting of the second heart sound is rare and is associated with very severe obstruction or coexisting myocardial disease. An early systolic ejection click at the apex is characteristic and serves to distinguish valvular aortic stenosis from other forms of left ventricular

outflow tract obstruction. The classic auscultatory finding is a harsh systolic spindle-shaped murmur that is loudest at the right upper sternal border with radiation into the carotid arteries and down the left sternal border to the apex (see Chap. 56). Among infants with critical obstruction, there may be no palpable peripheral pulses and no distinctive murmur, with a return of weak pulses and a typical murmur only after decongestive therapy.

Chest Roentgenogram

The overall heart size is normal, but infants with failure will have generalized cardiac enlargement and varying degrees of pulmonary edema. Poststenotic dilatation of the ascending aorta is characteristic.

Electrocardiogram

Left ventricular hypertrophy, as indicated by voltage criteria in the left precordial leads, is seldom helpful in distinguishing patients with severe obstruction from those with mild to moderate obstruction. However, diminished anterior forces in the right precordial leads and a deep $SV_1 \geq 30$ mm suggest severe stenosis, as does absence of the Q wave in V_6. Fifty percent of patients with severe obstruction have a flat, biphasic, or inverted T wave in V_6 (Fig. 63-23). Severe and even critical obstruction may be present with none of the ECG abnormalities mentioned above. Monitoring of the ST segment in leads V_5 through V_7 during cautious exercise testing appears to be a reliable method of detecting children in whom a significant PSPG (>50 mmHg) has developed and in whom that gradient may represent a threat of sudden death.[119] Symptomatic infants may show right, left, or biventricular hypertrophy, frequently with T-wave inversion over the left precordium.

Echocardiogram

Continuous-wave Doppler echocardiography guided by two-dimensional echocardiographic imaging predicts very accurately the peak and mean instantaneous systolic pressure gradient across discrete forms of left ventricular outflow tract obstruction (see Chap. 13) (Fig. 63-24). Two-dimensional echocardiography can distinguish valvular from supravalvular or subvalvular obstruction and identify critically ill infants in whom the size of the left ventricle, mitral valve annulus, or aortic root is hypoplastic to a degree that would preclude survival.[120,121]

Cardiac Catheterization

Infants symptomatic with severe aortic obstruction often have a left-to-right shunt through a stretched foramen ovale, PAH, and a right-to-left shunt through a PDA. A marked increase in left ventricular end-diastolic pressure is usually present. The PSPG between the left ventricle and the central aorta should be documented whenever possible. If left ventricular output is markedly diminished, this gradient may be relatively small even in the presence of severe obstruction. Left ventricular angiography will confirm the site of obstruction and outline the size of the left ventricular cavity (Fig. 63-25*A*).

A

B

Figure 63-25: Balloon aortic valvuloplasty. *A.* Left ventricular angiogram showing a domed, thickened aortic valve with fusion of the right and left commissures. *B.* Balloon dilation using a retrograde technique. A waist is demonstrated in the midportion of the balloon before full inflation. (From Lock JE, Keane JF, Perry SB. *Diagnostic and Interventional Catheterization in Congenital Heart Disease.* Boston: Kluwer; 2000: 151.)

In older infants and children, pressures on the right side of the heart are usually normal. Simultaneous recording of central aortic and left ventricular pressures or a pressure tracing upon catheter withdrawal from the left ventricle to the aorta, coupled with an accurate estimate of

cardiac output, is necessary for reliable assessment of severity. Left ventricular angiography will document the site of obstruction. The aortic leaflets typically are thickened and domed, with a central or eccentric jet of contrast material entering the ascending aorta. Poststenotic dilatation is characteristic. Supravalvular aortography is recommended to assess the presence and severity of aortic regurgitation.

NATURAL HISTORY AND PROGNOSIS

About half the infants born with severe valvular aortic stenosis are symptomatic enough to require hospitalization within the first week of life. Not uncommonly, the murmur is mistaken for that of a VSD. Congestive heart failure beyond infancy and before adolescence usually is not seen without the presence of complicating factors. Symptomatic infants require prompt relief of obstruction by balloon or surgical valvotomy, but the mortality rate remains significant. Endocardial fibroelastosis, papillary muscle necrosis, associated intra- and extracardiac deformities, and a small left ventricular cavity contribute to this mortality rate. Survivors may have significant aortic regurgitation, but the majority can be managed medically until valve replacement is feasible.

Most infants beyond the newborn period and children with mild aortic valvular stenosis (PSPG at catheterization <25 mmHg or a Doppler mean pressure gradient <25 mmHg) remain stable, with only a 21 percent likelihood of progression in severity and the need for intervention within the subsequent 25 years. For patients with a PSPG between 25 and 49 mmHg, the likelihood of significant progression rises to 41 percent, and with a PSPG >50 mmHg, it rises to 71 percent.[122] Patients with a PSPG >50 mmHg are judged to be at risk of serious ventricular arrhythmias and sudden death. Infective endocarditis on the aortic valve (see Chap. 73) poses an extremely serious complication in the form of systemic arterial emboli and the production of serious and sometimes catastrophic aortic regurgitation with congestive failure, shock, and death.[60]

MEDICAL AND SURGICAL MANAGEMENT

Infants with the characteristic murmur detected in the first weeks of life should be evaluated very carefully to be certain the obstruction is not severe and does not become severe in the next few weeks or months.[123] Those who develop heart failure should be operated on or undergo balloon valvuloplasty without delay. In a critically ill neonate, intravenous PGE_1 infusion to open the ductus may provide temporary relief of pulmonary edema en route to the operating room or catheterization laboratory. Beyond infancy, a plan of reexamination with careful questioning regarding symptoms and an ECG each year, an echocardiogram with Doppler assessment of the mean and maximum pressure gradient every year or two, exercise testing, and 24-h ECG monitoring about every 3 years should suffice to prevent progression from going unrecognized. Indications for cardiac catheterization for gradient assessment and possible balloon dilation include the appearance of symptoms or syncope, decreased anterior forces with an $SV_1 \geq 30$ mm or flattening or inversion of the T wave in V_6 in the resting ECG, abnormal ST-T segments on exercise testing, or an estimated maximum instantaneous gradient of 65 mmHg or a mean pressure gradient >60 mmHg by echocardiographic Doppler techniques.

Transluminal catheter balloon valvuloplasty has become the acceptable alternative to surgery. In skilled hands, it can provide effective reduction of the transvalvular gradient while producing only a mild increment in aortic regurgitation in most instances.[124,125] Elective balloon dilation is recommended if the PSPG is >50 mmHg at catheterization and aortic regurgitation is mild or nonexistent. For a neonate with critical valvular obstruction, some centers continue to rely on surgical intervention, but catheter balloon valvuloplasty has become a very competitive alternative and in the author's institution is the procedure of choice for these very sick infants.

Balloon dilation has been performed since the mid-1980s, and long-term follow-up studies are not

yet available. Early studies and more recent experience suggest that the balloon diameter should not exceed that of the valve ring, and most centers now use balloons that are 85 to 90 percent of the diameter of the aortic annulus. The balloon usually is inflated to a pressure of 4 to 6 atmospheres until the "waist" produced by the stenotic valve has been abolished (Fig. 63-25*B*). Transient arrythmias are seen occasionally, but other than creating aortic regurgitation, other complications are uncommon.

In older children, the results are usually quite good, with a reduction of the peak gradient of approximately 60 percent, a mortality rate under 2 percent, and a complication rate of about 3 percent.[124,125] In neonates, the results are more problematic, probably because of severity of disease, unstable conditions, and the size of the patient, with 12 percent early and late mortality in one series. In this center, reintervention (usually repeat balloon dilation) was necessary in 40 percent with a mean follow-up of 4.3 years.[126]

When surgical intervention is required for critical aortic stenosis during infancy, the heart is exposed through a median sternotomy and the aortic valve is visualized through the ascending aorta during a brief period of low-flow perfusion with mild hypothermia. Standard cardiopulmonary bypass, mild hypothermia, and cardioplegia are used in older children.[127] The surgeon must discriminate between true commissures and abnormal raphes because incision of the latter produces intolerable aortic valvular regurgitation. Relief of valvular stenosis is accomplished with a carefully placed incision in the middle of each fused but well-supported true commissure.

A conservative attitude is essential during operation for aortic stenosis in an infant or small child. Mild valvular regurgitation almost always occurs consequent to commissurotomy but is usually well tolerated. Moderate residual stenosis is preferred to intolerable aortic valvular regurgitation, especially in infants in whom valve implantation is technically difficult. If valve replacement is necessary in an infant or small child, use of the autograft pulmonary valve in the aortic position offers the attractive possibility of continuing growth of this neoaortic valve that may parallel that of the patient.[128]

The risk of operation is high in critically ill infants, in the range of 10 to 15 percent, particularly in those with a low ejection fraction, high left ventricular end-diastolic pressure, endocardial fibroelastosis, marked congestive failure, or features of left ventricular hypoplasia.[129] Morbidity after aortic valvotomy in an older child is rare, and the likelihood of relief of left ventricular outflow tract obstruction and survival is good. The Natural History Study of Congenital Heart Defects, reporting on 133 children undergoing aortic commissurotomy after age 2 years, found that only 27 percent required a second operation in the subsequent 20 years, with 78 percent of those operations consisting of valve replacement. Aortic regurgitation was the indication for operation in 14 percent of those with valve replacements.[122]

Relief of aortic valve obstruction, whether by balloon valvuloplasty or surgical valvotomy, is palliative rather than curative. Gradual restenosis is the rule, with almost one-third of infants who undergo valvotomy requiring a second operation, usually valve replacement, within the next two decades. Aortic regurgitation, a well-recognized complication of valvuloplasty, valvulotomy, and/or infective endocarditis, may require surgical intervention as well. Endocarditis is a serious and lifelong hazard, with an incidence among patients followed for 20 years of approximately 5 percent, a mortality rate of just over 25 percent, and a predilection for patients in the second, rather than first, decade of life and with PSPGs >50 mmHg.[60,122]

Secondary valvulotomy by balloon or surgery for recurrent or residual stenosis can be attempted, but calcification and restenosis eventually force aortic valve replacement in almost all those requiring surgery on the aortic valve in infancy or childhood. A small aortic annulus severely limits the relief of left ventricular hypertension unless one resorts to Konno's operation, in which

the annulus is divided, the upper ventricular septum resected creating a VSD, patching the VSD with prosthetic material, and replacing the valve (a homograft or pulmonary autograft) into the enlarged annulus. The ascending aorta and anterior right ventricular wall are reconstructed using a prosthetic graft, and in the case of an autograft, the main pulmonary artery and pulmonary valve are replaced with a cryopreserved pulmonary homograft.[130]

Children with more than mild aortic stenosis are restricted from strenuous organized athletics, isometric exercises, and activities that require a good deal of stamina and produce shortness of breath.[131]

Supravalvular Aortic Stenosis

PATHOLOGY

The obstruction in the ascending aorta includes the following three types: (1) hourglass (discrete), (2) hypoplastic (diffuse), and (3) membranous. Associated obstructions in the pulmonary trunk, peripheral pulmonary arteries, and branches of the aortic arch are common.[132] Hypertrophy of the coronary arterial walls and premature coronary atherosclerosis have been described.[133]

CLINICAL MANIFESTATIONS

Supravalvular stenosis may be familial, associated with characteristic facies and mental retardation, sporadic, or (rarely) the result of congenital rubella. All forms may be and usually are associated with varying degrees of peripheral or branch pulmonary arterial stenosis. The familial form is transmitted as an autosomal dominant trait with variable expression (see Chap. 62). Mental retardation is not present, and there are no characteristic facial features.[134] Supravalvular aortic stenosis associated with mental retardation, frequently called *Williams' syndrome*, is associated with a high and prominent forehead, epicanthal folds, underdevelopment of the bridge of the nose and mandible, and a broad, overhanging upper lip. It is due to a deletion of the elastin gene on chromosome 7 and can now be identified by florescent in situ hybridization studies. It has been linked with idiopathic hypercalcemia of infancy, but in the majority of patients recognized beyond infancy, hypercalcemia is not present.[135]

The symptoms of supravalvular aortic stenosis are similar to those of subvalvular aortic stenosis (see below). Patients with the familial form usually have a distinctive family history but one that seldom emerges in its entirety on initial questioning. The physical findings are also similar to those of subvalvular aortic stenosis, although a systolic blood pressure difference may be recorded between the two arms on occasion, with the right arm pressure being greater than the left (Coanda effect).[136] Chest roentgenography and ECG are not distinctive unless associated pulmonary arterial stenosis leads to right ventricular hypertrophy. Echocardiography can identify the narrowed aortic lumen just above the aortic valve and provide an estimate of the severity of the obstruction by the Doppler-derived instantaneous pressure gradient.

At cardiac catheterization, a systolic pressure gradient can be demonstrated just above the aortic valve by careful pullback. Supravalvular aortography or left ventricular angiography will visualize the supravalvular narrowing (Fig. 63-26). Pressure recordings in the branch pulmonary arteries should be obtained, and pulmonary arterial angiography should be performed in the presence of any significant stenoses. Narrowing at the branch points of major arteries (coronary, carotid, mesenteric, renal, etc.) is seen occasionally.

NATURAL HISTORY AND PROGNOSIS

The sequence of progressive obstruction, the appearance of symptoms and ECG changes, and the

possibility of sudden death appear to apply for supravalvular aortic stenosis as well as for valvular aortic stenosis. Infective endocarditis represents a threat to these patients throughout life.

MANAGEMENT

The indications for cardiac catheterization and follow-up are the same as those with valvular aortic stenosis. Noninvasive imaging frequently suffices, but angiography may be necessary to evaluate the gradient and rule out arterial narrowing. Surgery usually is recommended if the gradient across the narrowing exceeds 40 mmHg.

Discrete supravalvular aortic stenosis is relieved by one or more incisions through the narrow segment of the ascending aorta, usually at the level of the sinotubular ridge at the top of the commissures. Incisions are extended well down into the aortic sinuses. Ridges of obstructing fibrous tissue are excised. The aorta is enlarged by the insertion of a gusset of prosthetic vascular graft material or pericardium to increase the circumference.[127] A favorable outcome can be anticipated postoperatively in most patients with supravalvular aortic stenosis if the arterial wall abnormality is localized.[137] Intimal obstruction of the coronary arterial ostia may require debridement, dilation, or even saphenous vein or internal mammary bypass grafting.

Diffuse tubular hypoplasia of the ascending aorta is a technically challenging problem that is associated with a higher mortality rate and usually poor postoperative hemodynamic results.

Subvalvular Aortic Stenosis

PATHOLOGY

Three classic varieties of subvalvular aortic stenosis involve the left ventricular outflow tract: the discrete, tunnel, and muscular types. The discrete type is characterized by a localized fibrous encirclement of the left ventricular outflow tract a short distance below the aortic valve (Fig. 63-27) or fibromuscular tissue that extends onto the mitral leaflet and also may attach to the aortic cusps. The tunnel type involves hypoplasia of the aortic annulus and a channel with a fibrous lining in the subjacent left ventricular outflow tract.[138,139] The muscular type also is known as *hypertrophic cardiomyopathy* (or idiopathic hypertrophic subaortic stenosis) and is discussed in Chap. 67.

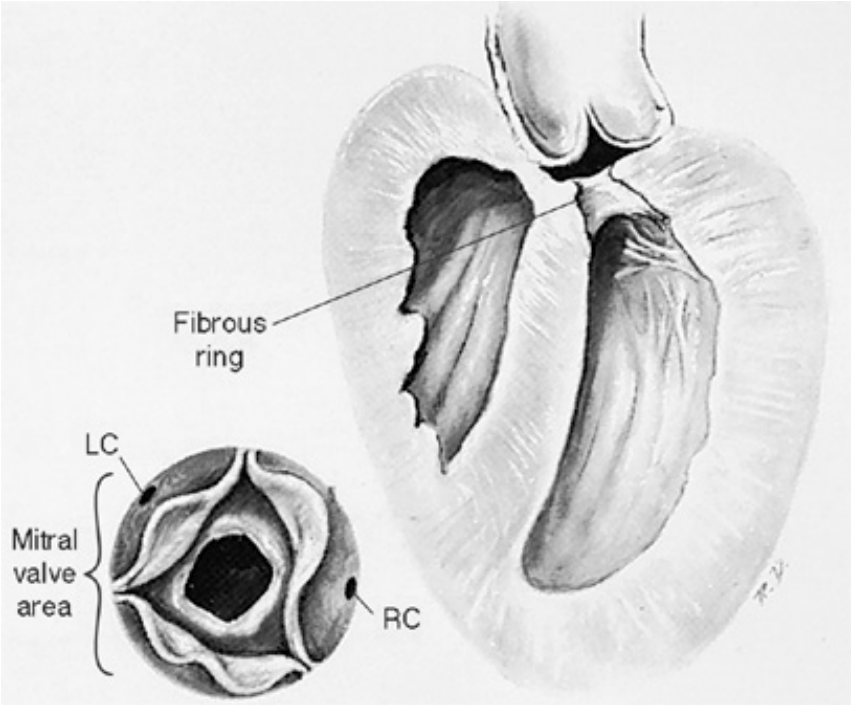

Figure 63-27: Localized subvalvular aortic stenosis. Obstruction is immediately upstream from the aortic valve. LC and RC = left and right coronary arteries. (From Kirklin JW and Ellis FH Jr.[144] Reproduced with permission from the publisher and authors.)

More than half these patients have associated malformations, of which PDA, VSD, or coarctation are the most common.

CLINICAL MANIFESTATIONS

Discrete stenosis is more common among males, with a male/female ratio of approximately 2.5:1. In the isolated forms, the majority of patients are referred because of the detection of a murmur that not uncommonly is mistaken initially for that of a VSD. The symptoms have the same implications as they do for valvular aortic stenosis.

The physical examination is similar to that of valvular aortic stenosis, with two exceptions: An early systolic ejection click is not heard, and an early diastolic murmur of aortic regurgitation is present in approximately one-half of these patients.

The roentgenographic features and ECG are also similar to those of valvular aortic stenosis except for the absence of poststenotic dilatation of the ascending aorta. Two-dimensional echocardiography permits excellent visualization of the anatomy of the obstruction. Estimation of the systolic pressure gradient can be obtained from Doppler echocardiographic studies.

When catheterization is performed, a careful pullback pressure tracing across the left ventricular outflow tract will document the severity of the gradient and establish the site of the obstruction. Left ventricular biplane angiography will outline the nature of the obstruction. Aortography is recommended to evaluate the degree of aortic regurgitation.

NATURAL HISTORY AND PROGNOSIS

Severe congestive failure in infancy is unusual and, if present, is almost invariably associated with complicating defects.[138] The obstruction is progressive in most instances, sometimes rapidly so. In one study, 75 percent of patients showed an increase of 25 mmHg or more in a 5-year

period.[140] The cause of the progression is not known, but an intriguing theory suggests that distorted anatomy increases shear stress, leading to a stimulation of growth factors and cellular proliferation.[141] Associated aortic regurgitation also tends to be progressive and appears to result from damage from the jet of blood through the obstruction, with secondary thickening and deformity of the valve leaflets. The results of surgery depend on the extent of involvement of the left ventricular outflow tract, with the best results being obtained in patients with a thin, discrete subvalvular membrane. The least satisfactory results occur in patients with tunnel obstruction.

MANAGEMENT

Medical management is similar to that of patients with valvular aortic stenosis, but surgery for the discrete type usually is recommended for pressure gradients ≥30 mmHg because of the possibility of progression of obstruction, and the likelihood of progressive aortic valvular deformity and regurgitation.[142]

Continued follow-up for assessment of reobstruction and progression of aortic regurgitation and for reemphasis of the precautions against infective endocarditis is essential in all patients.[143]

Subvalvular fibromuscular (membranous) left ventricular outflow tract obstruction is exposed through the aortic root as was described for aortic valvular stenosis (Fig. 63-27). Small half-circle needles and sutures or hooks are placed into the abnormal fibromuscular tissue, pulling it into view for precise excision from the underlying ventricular septum and the anterior mitral valve leaflet. The area of the bundle of His, which usually is just beneath the anterior commissure between the right and noncoronary leaflets, is avoided. An additional septal myectomy or myotomy beneath and to the left of the commissure between the right and left leaflets may be required if secondary hypertrophy is significant. Immediate and early operative outcome is generally good, but *residual, recurrent, and progressive subaortic obstruction occurs in up to 25 percent of these patients, requiring long-term follow-up*.[144,145]

Diffuse tunnel obstruction in the left ventricular outflow tract poses a difficult technical problem that requires aortoseptoplasty, reconstruction of the left ventricular outflow (Konno's operation or a modification of it).[130,142]

Bicuspid Aortic Valve

PATHOLOGY

Classically, the two cusps are oriented anteriorly and posteriorly, with the anterior or conjoined cusp being the larger. A raphe, or ridge, is present along the aortic aspect of the larger cusp, running from the aortic wall to the free edge of the cusp. The most common associated condition of significance is coarctation of the aorta. The most common complication is calcification of the valve. *In about 85 percent of cases of calcific aortic stenosis in patients below age 70, the valve is congenitally bicuspid*. Aortic regurgitation from prolapse of the larger cusp is a less common complication and is usually not evident until adolescence or adult life.

CLINICAL MANIFESTATIONS

The incidence in the general population approaches 2 percent; therefore, it is the most common congenital abnormality of the heart or great vessels except possibly for mitral valve prolapse (see Chap. 58). Its importance lies in its frequent association with other forms of congenital heart disease: the predisposition of the valve to become stenotic as a result of fibrosis and deposition of calcium over the course of years, the tendency of the valve to become regurgitant, its association with aortic root dilatation and dissection,[146] and finally, the susceptibility of the valve to infective

endocarditis. It is also common among patients with isolated or dominant aortic regurgitation, patients with infective endocarditis with or without a history of predisposing heart disease, and, probably most frequently, otherwise normal individuals who come to the physician's attention because of unrelated illnesses. Patients with uncomplicated bicuspid aortic valve are asymptomatic. The incidence among males is approximately 2.5 times that among females (see Chap. 56).

The characteristic feature is auscultatory and consists of an early systolic ejection click, which is best heard at the apex and does not vary with respiration. A soft, early, or midsystolic murmur is frequently present at the right upper sternal border. Less commonly, a soft murmur of aortic regurgitation may be heard. Two-dimensional echocardiography with adequate images can identify the bicuspid valve with a high degree of sensitivity and diagnostic accuracy.

NATURAL HISTORY AND PROGNOSIS

The majority of congenitally bicuspid aortic valves are nonobstructive at birth, but with the passage of time, a few of these valves become fibrotic, stiffer, and more obstructive and eventually become the site of calcium deposition, primarily among individuals between ages 15 and 65. Important calcium deposition is unusual before age 30, whereas grossly visible deposits of calcium are present in the valves of virtually all patients with severe stenosis beyond that age. A much smaller number of individuals born with a bicuspid aortic valve develop isolated aortic regurgitation. In approximately one-third, this is the result of fibrosis, prolapse, or retraction of one or both of the leaflets; in the remainder, regurgitation results from infective endocarditis on an apparently functionally normal bicuspid valve (see Chaps. 56 and 73).

Congenital Mitral Regurgitation

PATHOLOGY

Mitral regurgitation may be due to a primary valve abnormality or secondary to a more complex defect (see "Common Atrioventricular Canal Defects," above). There are a variety of rare primary malformations, including isolated cleft, fenestration, and double orifice. Mitral regurgitation also occurs frequently with conditions that cause left ventricular dilatation and failure.

CLINICAL MANIFESTATIONS

Poor growth, frequent respiratory infections, and failure occur with significant mitral regurgitation. The physical findings are generally similar to those with mitral regurgitation of other causes (see Chap. 10). There may be a prominent left precordial bulge if cardiomegaly has been present from infancy. The systolic murmur may radiate to the base of the heart. Left atrial and left ventricular enlargement correlate with the degree of volume overload. Echocardiography with Doppler color flow mapping will demonstrate these as well as left ventricular function and the severity of regurgitation. The specific defect may be outlined, such as an isolated cleft or a double-orifice valve. Findings at cardiac catheterization substantiate the hemodynamic alterations (see Chap. 15).

NATURAL HISTORY AND PROGNOSIS

Mild and even moderate mitral regurgitation may be well tolerated, but severe regurgitation leads to progressive deterioration. Endocarditis is a risk.

MANAGEMENT

Vigorous medical treatment of heart failure and infections is warranted. Every attempt should be made to control symptoms to a degree that will allow growth in infants. In infants and young children, only those with very severe and uncontrollable failure are subjected to surgery. In adolescents, continued symptoms justify surgery. Afterload reduction with an angiotensin-converting enzyme blocker may be tried. Surgery is indicated for congestive heart failure or deteriorating left ventricular function.

At surgery, the valve and its apparatus are inspected carefully. In many cases a valvuloplasty is possible, but occasionally replacement may be necessary. Currently, the St. Jude medical prosthesis often is utilized. Lifelong anticoagulation with warfarin (see Chap. 44) is required. With body growth, replacement with a larger prosthesis may be difficult, and no good annular enlarging operation exists.

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

VALVULAR AND VASCULAR MALFORMATIONS OF THE RIGHT SIDE OF THE HEART WITH RIGHT-TO-LEFT, BIDIRECTIONAL, OR NO SHUNT

Pulmonary Stenosis with Intact Ventricular Septum

PATHOLOGY

Valvular pulmonary stenosis with an intact ventricular septum usually is characterized by a dome-shaped stenosis of the pulmonary valve and less commonly by dysplasia of the valve. The valve may be unicuspid, bicuspid, or tricuspid. The annulus also may be narrow. The pulmonary trunk exhibits poststenotic dilatation. In adult patients, calcification of the valve may appear.

In pulmonary valvular dysplasia, the annulus of the valve may be abnormally narrow, but the most dramatic changes are related to the cusps, of which three are identifiable. The cusps are exceedingly thickened by mucoid and dense connective tissue.[147]

Concentric hypertrophy of the right ventricle is present, with its degree reflecting the degree of obstruction at the valve level. *The hypertrophy of the infundibular musculature may cause secondary infundibular stenosis*.

Less commonly, there may be isolated subvalvular pulmonary stenosis caused by infundibular narrowing or an anomalous muscle bundle across the middle of the right ventricle.[148] Both types may be associated with a VSD.

Isolated supravalvular pulmonary stenosis, or pulmonary arterial coarctations, also may occur. From angiographic studies, these are classified into four types: (1) *localized stenosis with poststenotic dilatation*, (2) *segmental stenosis*, (3) *diffuse hypoplasia*, and (4) *multiple peripheral stenoses*. The stenosis may be localized to any segment of the pulmonary arterial system. The process is unilateral in about one-third of cases and bilateral in two-thirds. Pulmonary arterial stenosis is commonly (about 75 percent), though not universally, associated with other cardiovascular abnormalities, such as tetralogy of Fallot. It also may be seen as a sequela of congenital rubella, Williams', Noonan's,[149] or Alagille's syndrome.

ABNORMAL PHYSIOLOGY

There is a pressure difference during systole between the main right ventricular cavity and the pulmonary artery. The area of the pulmonary valve orifice is normally 2 cm^2/m^2; it is about 0.5 cm^2 at birth and increases in size with body growth. In general, the effective valve area must be decreased about 60 percent before there is a hemodynamically significant obstruction to flow. PSPG may reach 150 to 240 mmHg in severe cases. The degree of obstruction is assessed by the peak and mean systolic pressure gradients and the amount of flow across the valve. In neonates, severe stenosis can be associated with a relatively small pressure difference if the flow is very low as a result of right ventricular failure. If pulmonary flow is normal, patients with PSPG at rest <40 mmHg have mild stenosis and patients with PSPG >75 mmHg have severe stenosis.

When the pulmonary stenosis is severe, the right ventricle may fail and the cardiac output may be decreased at rest; this is associated with elevation of both the right ventricular end-diastolic pressure and the right atrial mean pressure. This may cause the foramen ovale to open and allow shunting of blood from the right atrium to the left atrium, resulting in arterial oxygen desaturation and cyanosis. In most adolescent or adult patients with significant pulmonary stenosis, the resting cardiac output is within normal limits but usually does not increase normally during exercise. In contrast, younger children may be able to increase cardiac output during exercise, even with significant obstruction.[119,150]

CLINICAL MANIFESTATIONS

Pulmonary stenosis is one of the most common congenital heart defects and accounts for about 10 percent of patients in most large study populations (Table 63-1). The stenosis is at the level of the pulmonary valve in most instances, but it can occur within the right ventricle, in the pulmonary arteries, or in a combination of the two. Infants with severe stenosis with patency of the foramen ovale may have right-to-left shunting.

History

Most infants and children are asymptomatic, but a small percentage with very severe obstruction manifest symptoms, usually mild fatigue or shortness of breath with exertion. Young infants with critical obstruction present with cyanosis if there is a patent foramen ovale or ASD. Squatting and syncope are rare in childhood.[151]

Physical Examination

Patients with a dysplastic valve and occasional supravalvular stenosis have consistent noncardiac abnormalities in a familial syndrome described by Noonan,[149] with short stature, hypertelorism, ptosis, low-set ears, and mental retardation.

In older patients with valvular pulmonary stenosis, cyanosis is uncommon, except with severe obstruction and an atrial communication. Hepatomegaly and the murmur of tricuspid regurgitation may be present with severe obstruction. With at least moderate obstruction, a prominent a wave is seen on examination of the jugular venous pulse. A systolic thrill in the suprasternal notch and at the left upper sternal border is present with significant obstruction unless there is isolated subvalvular stenosis. The right ventricular parasternal impulse becomes increasingly forceful with more severe obstruction. *An early systolic click with expiration that disappears with inspiration heard at the left upper sternal border is the hallmark of valvular stenosis unless the obstruction is severe or the valve is dysplastic*. A click is not present with isolated stenosis at other levels. As the obstruction increases in severity, the pulmonary component of the second heart sound becomes progressively softer and more delayed, becoming inaudible when the right ventricular pressure reaches systemic levels or greater. The second heart sound is normal or accentuated with supravalvular stenosis. A fourth heart sound is heard if the obstruction is severe. The characteristic systolic murmur is harsh, crescendo-decrescendo in shape, and best heard at the left upper sternal border with radiation toward the left clavicle. The murmur radiates more to the axilla and back with supravalvular stenosis. The duration of the murmur and the timing of peak intensity correlate well with the severity of obstruction. With mild to moderate stenosis, the murmur peaks in midsystole and ends at or before the aortic component of the second heart sound. In patients with severe stenosis, the murmur peaks late in systole and extends beyond the aortic component of the second heart sound (see Chaps. 10 and 59).[151]

Chest Roentgenogram

Most patients have a normal or only slightly increased heart size, primarily of the right ventricle.

Significant enlargement is seen with critical obstruction and is an ominous sign. Characteristically, the main and proximal left pulmonary arteries are prominent as a result of poststenotic dilatation when the stenosis is valvular. This finding may be absent with very severe obstructions, with a dysplastic valve, in very young infants, or with stenosis above or below the valve. The pulmonary vascular pattern is normal in most of these patients, but the vascularity is diminished in those with a right-to-left shunt at the atrial level.

Electrocardiogram

Right ventricular forces in the anterior precordial leads correlate reasonably well with the degree of obstruction.[151] They are normal or demonstrate mild hypertrophy with an rsR′ pattern if there is mild obstruction. With severe stenosis, there is right axis deviation, right atrial hypertrophy, and very tall pure R waves in the anterior precordial leads. The presence of a qR pattern in these leads is almost always a sign of very severe obstruction. Those with a dysplastic valve frequently have a superior QRS axis.

Echocardiogram

Two-dimensional imaging allows identification of the level of obstruction, and Doppler studies provide an excellent measure of severity. Shunting at the atrial level also can be evaluated.[152]

Cardiac Catheterization

Diagnostic catheterizations are rarely necessary, but data obtained before balloon dilation demonstrate an elevated right ventricular systolic pressure with a distinct systolic pressure difference across the narrowed segment, as demonstrated by slow withdrawal of the catheter from the distal pulmonary arterial branches to the proximal right ventricle. Simultaneous measurement of systemic arterial and right ventricular pressures with measurement of flow is necessary to assess severity accurately. The right ventricular end-diastolic pressure and right atrial *a* wave may be elevated. Systemic oxygen saturation is diminished only in those with more severe obstruction and a patent foramen ovale or, less commonly, a true ASD. A left-to-right shunt at the atrial level is detected in some patients with mild to moderate obstruction. With valvular stenosis, right ventricular angiography demonstrates thickened and doming valve leaflets and a jet of contrast material entering the dilated pulmonary artery (Fig. 63-28*A*). Doming is not characteristic of the dysplastic valve. Infundibular subvalvular narrowing caused by muscular hypertrophy may occur secondary to the valvular stenosis or rarely as an isolated anomaly. Isolated anomalous muscle bundles in the right ventricle also may be seen. Pulmonary arterial angiography best demonstrates the sites of obstruction with supravalvular stenoses. Ventricular volume studies have demonstrated depressed ventricular function in patients with rightto-left shunts. Balloon dilation is discussed below under "Management."

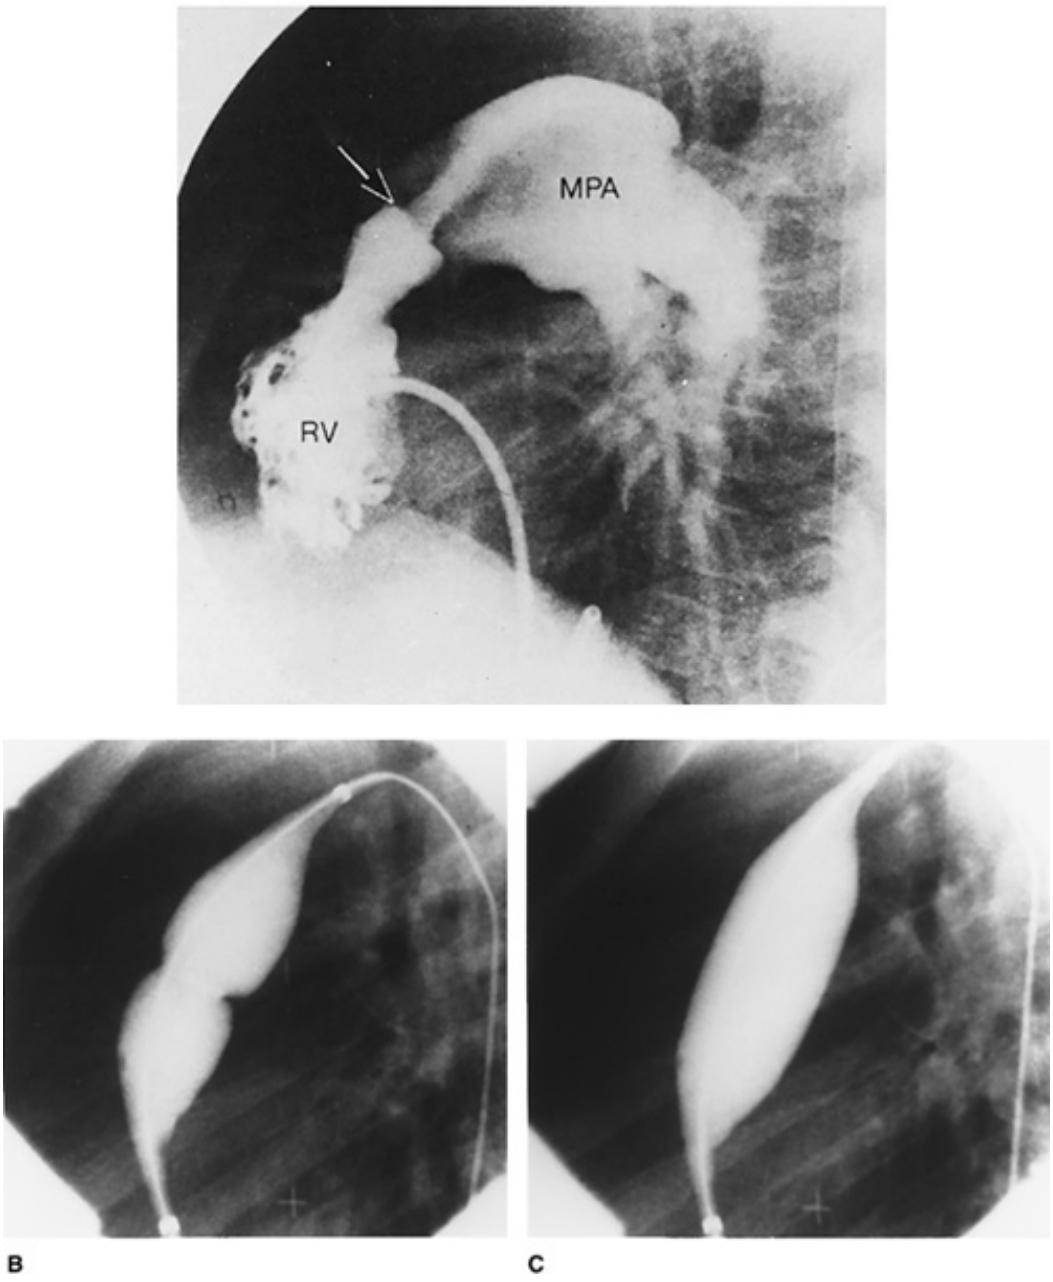

Figure 63-28: *A.* Lateral view of a right ventricular (RV) angiogram demonstrating the typical features of valvular pulmonary stenosis with doming of the pulmonary valve (*arrow*) and a narrow jet of contrast entering the dilated main pulmonary artery (MPA). *B.* An 18-mm balloon is inflated across the 14-mm annulus. A moderate waist is seen at 1 atmosphere of pressure. *C.* The waist is eliminated at 4 atmospheres of pressure. (From Lock JE, Keane JF, Perry SB. *Diagnostic and Interventional Catheterization in Congenital Heart Disease.* 2d ed. Boston: Kluwer; 2000.)

NATURAL HISTORY AND PROGNOSIS

The clinical course of valvular stenosis is favorable in most patients with mild to moderate obstruction. In a national cooperative study,[153] 86 percent of patients had no significant increase in their pressure gradients over a 4- to 8-year interval. Those with a significant increase were less than 4 years of age and had at least moderate stenosis initially. Progression during the period of growth seems to be the likely explanation for most of the increases, but a few patients developed subvalvular muscular hypertrophy, which increased the obstruction. Even mild obstruction may progress significantly in some infants during the first year of life. The prognosis of those with severe obstruction without intervention is poor, especially in infants with critical obstruction. With severe obstruction, right ventricular damage and dysfunction can ensue over the years, and heart

failure or arrhythmias can cause premature death in adults.[154] Tricuspid regurgitation also may result. Obstruction of the subvalvular type frequently increases with time, while supravalvular stenosis usually does not progress. Brain abscess can occur if a right-to-left shunt is present. Infective endocarditis with vegetations on the valve, pulmonary arterial wall, or infundibular region is also a risk. The children originally followed and treated as part of the national cooperative study cited above[151,153] were reevaluated 15 to 25 years later.[155] Among the 580 patients alive at the completion of the previous study, new data were available on 464 (78.4 percent). The probability of 25-year survival was 95.7 percent compared with an expected age- and sex-matched control group survival of 96.6 percent. Ninety-seven percent were asymptomatic. Although cardiac catheterization studies were not repeated, clinical examination and echocardiography at follow-up suggested no pulmonary stenosis in 2 percent, mild stenosis in 93 percent, moderate stenosis in 3 percent, and severe stenosis in only 1 percent. Pulmonary regurgitation was present in 40 percent, usually secondary to surgical valvotomy. Endocarditis was uncommon, as were ventricular arrhythmias.

MANAGEMENT

Management obviously depends on the severity of obstruction. For those with mild to moderate valvular pulmonary stenosis, periodic reexamination is indicated to detect any evidence of progression, with more frequent evaluation for those under 1 year of age. Measures to treat heart failure should be instituted in an infant with critical stenosis, but prompt intervention is mandatory. Cyanosis or a right ventricular systolic pressure well above systemic levels also is an indication for prompt intervention. Intervention is warranted in older children when the gradient exceeds 75 mmHg and is clearly not indicated when the gradient is less than 25 mmHg. *In the intermediate group, there is still some controversy, but general practice suggests valvuloplasty when the gradient exceeds 40 mmHg, although objective data to support therapy at this level are lacking*.

Balloon valvuloplasty has replaced surgical therapy as a first approach. Through the femoral vein, a balloon catheter is advanced across the valve and inflated to about 120 percent of the size of the pulmonary annulus, ripping the domed valve and thus relieving the obstruction (Fig. 63-28*B*).

The Valvuloplasty and Angioplasty of Congenital Anomalies Registry has published the combined results on 822 children.[156] Valvuloplasty resulted in improvement in most children with valvular obstruction, reducing the gradient from 71 ± 33 mmHg to 28 ± 24 mmHg. Valvuloplasty is, not surprisingly, less effective in children with a dysplastic pulmonary valve.[156,157] Complications were uncommon (5 in 822, or 0.6 percent), including two deaths. Valvuloplasty also has been performed in critical neonatal pulmonary stenosis with cyanosis caused by right-to-left shunting at the atrial level with a high success rate.[158,159] Subvalvular obstruction is less amenable to dilatation.

Peripheral pulmonary stenosis also has been occasionally amenable to dilatation, although the results are frequently less dramatic because of the multiple areas of stenosis and the fact that the complications, including pulmonary artery rupture, are more common.[160,161] Recently, stents have been used, with promising results,[161] in those with peripheral pulmonary artery stenosis in an attempt to keep open vessels that recoil back to normal size after the balloon is deflated. For those in whom there is isolated subvalvular stenosis or associated defects or in whom balloon dilatation has failed, surgical intervention is recommended.

The risk of death after pulmonary artery dilation is higher than that after dilation of the valve.[160] In the large collaborative study cited above, the death rate was 3 percent, although a more recent study from the author's institution found a mortality rate less than 1 percent among 400 cases.[162]

SURGICAL MANAGEMENT

Operation rarely is indicated for isolated pulmonary valvular stenosis; balloon valvuloplasty is virtually always successful in eliminating a clinically significant obstruction. A thickened, immobile, dysplastic pulmonary valve, however, is best treated by complete surgical excision (valvectomy). A small annulus is augmented with a pericardial or Dacron gusset.[163]

Subvalvular pulmonary stenosis is relieved through a right ventriculotomy, a main pulmonary arteriotomy, or a right atriotomy. Hypertrophic parietal and septal muscle bands constituting the fibrous orifice of the os infundibulum and obstructing moderator bands or muscle bundles within the body of the right ventricle are excised. Care is exercised to avoid injury to major coronary arterial branches. The right ventriculotomy usually can be closed by direct suturing, but a small oval patch of pericardium or Dacron can be used to prevent constriction of the outflow tract. Right ventricular function is compromised minimally by a small patch that does not extend across the annulus; larger patches to the pulmonary arterial bifurcation probably impair ventricular performance but may be necessary when there is associated annular or main pulmonary arterial hypoplasia. When possible, excision from the pulmonary artery or the right atrium is preferred to avoid ventricular injury. Excellent relief of right ventricular outflow tract obstruction can be expected after resection. Mortality and significant morbidity are rare.

Stenoses of main or extraparenchymal branch pulmonary arteries can be relieved by pericardial, synthetic, or homograft aortic or pulmonary arterial patches if the obstruction is proximal. Proximal coarctations in the larger portion of the arterial tree are more readily corrected than are those in small distal branches beyond the bifurcation of either the right or the left pulmonary artery, where results are poor.[164] In these instances, catheter balloon angioplasty, although certainly not without risk, offers nonsurgical relief of obstruction even in the small pulmonary arterial branches and should be considered the procedure of choice for distal pulmonary arterial stenoses.[160,161]

Prophylaxis against infective endocarditis is recommended for all patients whether or not surgery is performed, although the risks seem to be lower than they are with many other congenital anomalies.

Tetralogy of Fallot

PATHOLOGY

Tetralogy of Fallot is characterized by biventricular origin of the aorta above a large VSD (Fig. 63-29), obstruction to pulmonary blood flow, and right ventricular hypertrophy. Fibrous continuity of the aortic origin and the anterior mitral valve is maintained.[66]

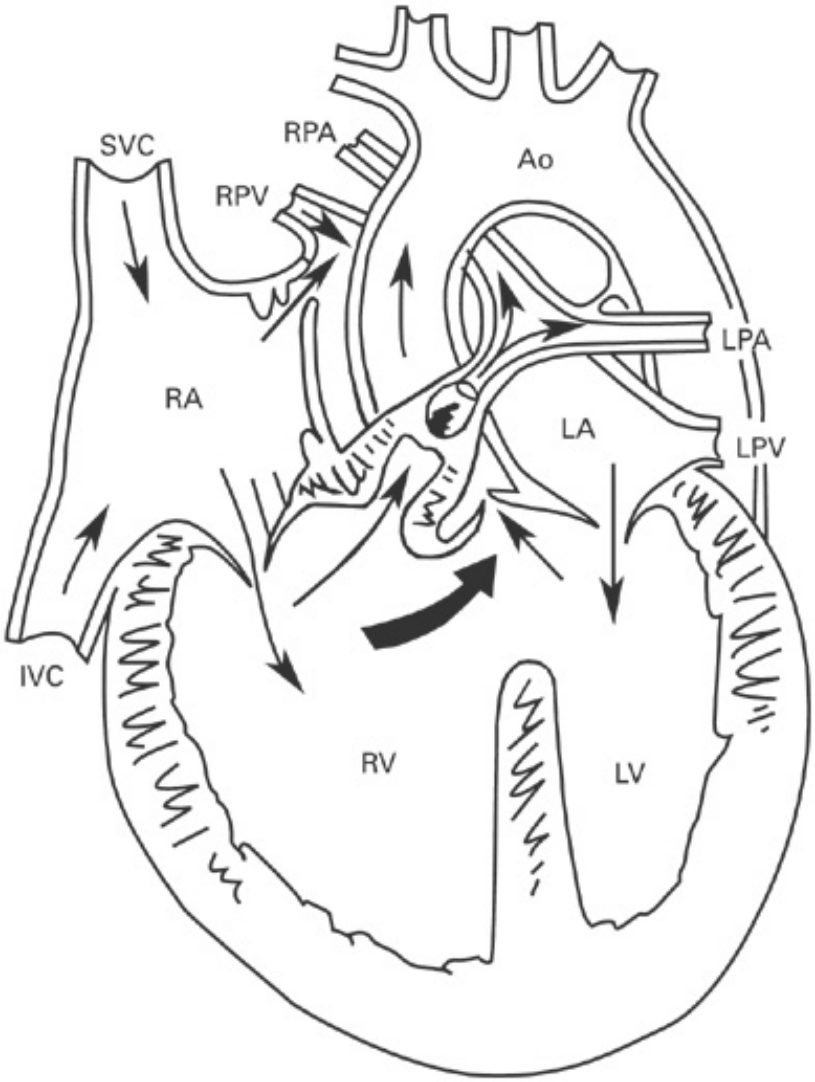

Figure 63-29: Classic tetralogy of Fallot. There are infundibular and pulmonary valvular stenoses. There is also right-to-left shunting at the atrial level. SVC = superior vena cava; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; RPA = right pulmonary artery; LPA = left pulmonary artery; RPV = right pulmonary vein; LPV = left pulmonary vein; LA = left atrium; LV = left ventricle; Ao = aorta. (From Edwards.[66] Reproduced with permission from the publisher and author.)

The right ventricular infundibulum lies anterior to the position of the VSD and is bounded by the anterior and septal walls anteriorly and medially; the posterior wall is said to be a vertical crista supraventricularis or displaced conus septum.[165] The right ventricular infundibulum is a distinctive channel, but the caliber varies widely from only mild obstruction to atresia. Usually, it exhibits a significant degree of stenosis and is the dominant site of the obstruction to pulmonary flow that is characteristic of tetralogy.

The pulmonary valve is often malformed, usually being either bicuspid or unicuspid. That valve may contribute to pulmonary stenosis, but only uncommonly is it the only site of significant obstruction to pulmonary flow. Characteristically, the pulmonary trunk is thin-walled and its lumen is more narrow than normal, but usually it is wider than either the right ventricular infundibulum or the orifice of the pulmonary valve. The aorta is wider than normal, its change in caliber being roughly opposite to that of the pulmonary trunk. The foramen ovale is frequently patent in patients of all ages. In all cases of tetralogy with significant pulmonary obstruction, collateral branches to the lungs arise from the aorta.

There is invariably a large malalignment VSD. Anterior, middle, or apical muscular defects are also present in up to 5 percent of children seen as infants. Many close spontaneously, but if corrective surgery is to be performed successfully, they must be evaluated.

Coronary artery abnormalities are not uncommon. The anterior descending coronary artery in the interventricular septum may arise from the right instead of the left coronary artery. Although physiologically unimportant preoperatively, the course across the right ventricular outflow tract makes the usual site of right ventriculotomy and outflow patch unavailable during reparative surgery, frequently necessitating a conduit to "jump over" the vessel. The anatomy of the coronary circulation used to require angiography to establish, but more recently echocardiography with Doppler color flow has been sufficient to detail the distribution of the proximal coronary circulation in most cases.

ASSOCIATED CONDITIONS

The condition most commonly associated with tetralogy of Fallot is right aortic arch (about 30 percent).[166] A persistent left superior vena cava has been described in 10.6 percent of cases. When an associated ASD exists, this anomaly is referred to as *pentalogy of Fallot.* The ductus arteriosus may be absent, present unilaterally on either the right or the left side, or bilateral.

ABNORMAL PHYSIOLOGY

Since the VSD is usually large, with an area about as great as that of the aortic valve, both ventricles and the aorta have essentially the same systolic pressures. The most important hemodynamic factor is the ratio between the resistance to flow into the aorta and the resistance to flow across the stenotic right ventricular infundibulum. If the stenosis is not severe, the resistance to right ventricular outflow is not large, the pulmonary flow may be twice the systemic flow, and the arterial oxygen saturation may be normal (acyanotic tetralogy of Fallot). However, the resistance to the pulmonary flow may be increased markedly, causing right-to-left shunting, arterial desaturation, and subsequent polycythemia. When the pulmonary stenosis is very severe, the pulmonary blood flow may be by way of collateral vessels from the systemic arteries to the distal pulmonary arteries beyond the stenosis. The infundibular obstruction, which may be in part dynamic, is increased by drugs, heart rate maneuvers, and activities that increase myocardial contractility or decrease right ventricular volume. In addition, the infundibular hypertrophy may increase gradually over time. Since the systolic pressure in the right ventricle cannot exceed that in the left ventricle because of the large VSD, the right ventricle is "protected" from excessive pressure and work, and so congestive heart failure is uncommon.

Hypercyanotic episodes (spells) in patients with tetralogy are of uncertain origin. It is likely that some episodes are caused by unusual hyperactivity of muscular fibers in the right ventricular outflow tract that produce or exaggerate the infundibular stenosis, increasing pulmonary resistance and thus increasing the right-to-left shunting. Some spells may be caused by a decrease in peripheral resistance and systemic arterial pressure, which also may cause the right-to-left shunt to increase and pulmonary blood flow to decrease.

CLINICAL MANIFESTATIONS

Tetralogy of Fallot is the most common congenital cardiac defect that causes cyanosis. Tetralogy with an associated ASD, or pentalogy of Fallot, is not distinguishable clinically. For a discussion on the hypoxemia and the consequences in tetralogy, see the section on cyanosis and its complications earlier in this chapter.

History

Most of these patients now are diagnosed prenatally by ultrasound or present in the first days or weeks of life with a heart murmur. If the right ventricular obstruction is severe, cyanosis is present at birth and is exacerbated when the ductus closes. If the obstruction is milder, the infant may be acyanotic with left-to-right flow through the VSD and occasionally may develop congestive heart failure. In this group, gradually increasing right ventricular obstruction may reduce the left-to-right shunt, and eventually, when infundibular resistance and pulmonary resistance exceed systemic resistance, right-to-left shunting develops, resulting in cyanosis.

Dyspnea with exertion occurs commonly in toddlers and older children with unrepaired defects. Attacks of suddenly increasing cyanosis associated with hyperpnea, or hypoxic spells,[167] are common between ages 2 months and 2 years. There are many precipitating events, including infection, exertion, and summer heat. They occur most often in the morning, with increasing irritability. The frequency and duration vary widely, but prolonged episodes can lead to syncope, seizures, and death. Squatting with exercise is common from 1.5 to 10 years of age in those not previously repaired. These problems are becoming uncommon as more and more children undergo early repair.

Physical Examination

Growth is usually normal unless cyanosis is extreme. Clubbing of the fingers and toes occurs after 3 months of age and is proportional to the level of cyanosis. Signs of congestive heart failure do not appear in tetralogy of Fallot during childhood unless there is a superimposed illness such as anemia or infective endocarditis.

Increased right ventricular activity is observed. A systolic thrill may be palpable at the left midsternal border, with a harsh midsystolic murmur in that location. Softer murmurs signal more severe obstruction and are common when presentation is in the newborn period or during hypoxic spells. The murmur ends before the second heart sound, which is characteristically single. A continuous murmur is heard if a PDA or large collateral vessels are present. An early systolic ejection sound at the left sternal border and apex is uncommon; its presence suggests primarily valvular pulmonary stenosis.

Chest Roentgenogram

The total heart size is usually normal on chest roentgenography, but right ventricular enlargement is present in the lateral view. The aorta arches to the right in many cases. Pulmonary flow is diminished. The pulmonary segment is concave and the apex is elevated, giving the *coeur en sabot* (boot-shaped) contour. A very young infant may have only diminished pulmonary flow.

Electrocardiogram

In tetralogy of Fallot, the mean QRS axis of the ECG is usually to the right, between +90° and +210°. There is right ventricular hypertrophy, with a tall R wave in the right precordial leads and a deep S wave in the left leads. Some of these patients have right atrial hypertrophy.

Echocardiogram

Two-dimensional echocardiography can delineate the anatomic components of tetralogy.[168] Anomalies of the coronary arteries can be demonstrated, and associated defects can be excluded.

Hematologic and Other Laboratory Studies

Before surgical repair, the hemoglobin and hematocrit should be measured and pulse oximetry

should be performed in all patients at initial evaluation and periodically thereafter for determination of the degree of polycythemia and the early detection of anemia relative to the degree of cyanosis. The latter is common, especially in those under 2 years of age, and may predispose a patient to cerebrovascular accidents. Platelet counts and clotting studies may be advisable in older unrepaired patients with marked polycythemia, particularly if a surgical procedure is planned. Serum uric acid levels should be measured if polycythemia is severe and long-standing.

Cardiac Catheterization

In an increasing number of centers, the quality of echocardiography (especially when done in neonates or infants) is sufficiently diagnostic to outline the right ventricular and proximal pulmonary artery anatomy, rule out additional muscular VSDs, and establish the proximal coronary circulation. As a consequence, diagnostic cardiac catheterization and angiography are less commonly performed preoperatively than they were in the past in children with tetralogy of Fallot.

In those in whom the study is performed, the right ventricular systolic pressure is equal to the pressure in the left ventricle and aorta. If the pulmonary artery can be entered, the pressure will be normal or low. The level or levels of obstruction can be evaluated by careful pullback to the right ventricle. Caution should be observed if the pulmonary artery is entered, as the catheter may critically reduce the pulmonary flow and cause a hypoxic episode. Systemic arterial oxygen saturation is reduced because of right-to-left shunting from the right ventricle to the left ventricle. If a patent foramen ovale or ASD is present, there may be an additional right-to-left or bidirectional shunt at the atrial level. Selective biplane right ventricular angiography will demonstrate levels of obstruction, continuity and size of the pulmonary arteries, and size and position of the ventricular defect. If this is not demonstrated by echocardiography or aortography, selective coronary arteriography should be performed on all patients preoperatively to demonstrate the coronary arterial pattern.[169]

MEDICAL MANAGEMENT

Although the definitive treatment of tetralogy of Fallot is surgical, medical management plays a role before surgery and in the postoperative period. For a severely cyanotic newborn, prostaglandin administration is of benefit[91] to keep the ductus open until surgery can be done. Before surgery, the hematocrit and hemoglobin should be monitored and iron-deficiency anemia should be treated promptly to prevent strokes. Fever or other illness that would lead to dehydration and possible thrombotic complications should be treated promptly.

Hypoxic spells in an infant should be treated initially by placing the infant in the knee-chest position and administering a high concentration of oxygen and morphine sulfate. If acidosis is present and does not correct spontaneously and promptly, intravenous sodium bicarbonate and an alpha-adrenergic agonist should be given. Propranalol may be useful in preventing hypoxic spells.[170]

Bacterial endocarditis is a serious complication, especially in those who have had a systemic-to-pulmonary artery shunt. Meticulous care should be taken to maintain good dental hygiene, and prophylactic antibiotics at times of predictable risk are mandatory (see Chap. 73).

SURGICAL MANAGEMENT

Historically, the approach to tetralogy of Fallot has been either palliation or corrective surgery. The introduction of an aorta-to-pulmonary-artery shunt for the treatment of tetralogy of Fallot[171] truly can be called the beginning of effective treatment for pediatric cardiovascular disease. When

open heart surgery was initiated in the 1950s, tetralogy of Fallot was among the first lesions to be corrected.[172] Over the years, the age at which corrective surgery can be performed has dropped so that in many centers primary repair is the procedure of choice at any age. Palliation, when it is now performed, almost inevitably involves a modified Blalock-Taussig shunt that interposes a graft between the subclavian artery and the ipsolateral pulmonary artery, usually on the side opposite the aortic arch.[173] Even in the perinatal period, the placement of a 4-mm tube will result in satisfactory palliation for a year in more than 90 percent of infants.

Surgical correction for those with pulmonary stenosis involves closing the VSD, usually through a right ventriculotomy, resecting infundibular muscle, and, if the infundibulum, pulmonary valve, and main pulmonary artery are hypoplastic, using a pericardial patch to open the narrowed area. Care must be taken to avoid heart block while closing the VSD and avoid cutting a major branch of the coronary artery. If a patent foramen ovale is present, it usually is left open to allow decompression in the perioperative period. If a true ASD is present (pentology of Fallot), it should be closed to avoid left-to-right shunting once the right ventricle has recovered from the perioperative insult.[174]

Children with tetralogy of Fallot and pulmonary atresia with good-sized pulmonary arteries usually are repaired by closing the VSD and interposing a conduit, frequently an aortic homograft, between the right ventricle and the pulmonary artery.[175] If this is done in children under 7 or 8 years of age, replacement of the conduit is to be expected secondary to somatic growth. Children with tetralogy of Fallot and hypoplastic and/or discontinuous pulmonary arteries require an individualized approach that frequently involves balloon dilation of hypoplastic vessels, unifocalization of discontinuous vessels, and, it is hoped, eventual repair with a conduit closing the VSD.[176] Operative and early mortality rates for repair of tetralogy of Fallot are now quite low in most centers. Kirklin and coworkers[173] in the early 1980s reported mortality rates of 1.6 percent with operations at 5 years of age to 4.1 percent at 1 year of age. At Children's Hospital in Boston, there was a 4.2 percent mortality rate among 330 children under 1 year of age operated on between 1973 and 1990, with a mortality rate of only 2.5 percent in the past 6 years of the study (1984-1990).[174] Late complications have included residual peripheral pulmonary stenosis, a small incidence of residual VSDs, and, rarely, aortic regurgitation. The long-term survivors have had atrial or, more commonly, ventricular arrhythmias and continue to be at risk for infective endocarditis.

Physicians at the Mayo Clinic, the first center to use the pump oxygenator to repair tetralogy of Fallot in the 1950s, have reported a minimum 30-year follow-up of the 162 30-day survivors of surgery.[177] The 32-year actuarial survival rate was 86 percent, with subgroup survival rates of those less then 5 years old, 5 to 7 years old, and 8 to 11 years old at the time of surgical repair being 90, 93, and 91 percent, respectively. Late sudden death from cardiac causes occurred in 10 patients during the 32-year period. The performance of some previous palliative operation (Waterston or Pott's shunts) but not a palliative Blalock-Taussig shunt was associated with higher mortality. With earlier surgery and less utilization of palliative procedures, it is hoped that the surgical results will be even better for children born in the 1980s and 1990s and beyond.

Ebstein's Anomaly

PATHOLOGY

In Ebstein's anomaly, the anterior leaflet of the tricuspid valve is attached normally to the annulus, but varying portions of the posterior and septal leaflets are displaced downward, being attached to the ventricular wall below the annulus. The proximal part of the right ventricle is thin-walled and continuous with the right atrium. The functional right ventricle is small and is made up of the apical and infundibular portions of the right ventricle. An additional common finding is that the papillary muscles and chordae are highly malformed, with great variation in the manner of

attachment of the two involved leaflets to the right ventricular wall. Commonly, multiple direct attachments of valvular tissue to the right ventricular mural endocardium occur.[178,179]

An interatrial communication is present in most cases, usually taking the form of a patent foramen ovale. Continuity of right atrial and right ventricular myocardial tissues, in addition to the usual connections by way of the main conduction pathways, has been observed. *The presence of Ebstein's anomaly has been associated with maternal lithium use during pregnancy, although the risk ratio remains unclear*.[180]

ABNORMAL PHYSIOLOGY

Ebstein's anomaly results in obstruction to right ventricular filling because of a decrease in the size of the right ventricle, part of which is incorporated into the huge right atrium. The deformed tricuspid valve also frequently is associated with tricuspid regurgitation with a right-to-left shunt through the foramen ovale. In the perinatal period, when the pulmonary vascular resistance is high, the tricuspid regurgitation may be severe. This results in increased right atrial pressure and, when the patent foramen ovale is open, severe cyanosis. As the pulmonary vascular resistance falls, the right-to-left shunting is decreased and hypoxemia improves. In older children, right-sided congestive heart failure with edema and/or ascites may develop.

CLINICAL MANIFESTATIONS

History

Approximately one-half of reported patients develop symptoms of cyanosis and right-sided heart failure in early infancy. The remainder present with a murmur or abnormal chest roentgenogram, but with no symptoms, in early childhood or because of gradual progression of symptoms through late childhood or adult life.[181] The most common symptom is dyspnea on exertion. The spectrum of exercise intolerance has been described.[182] Palpitations resulting from supraventricular tachyarrhythmias occur in 20 to 30 percent of these children. Occasionally, syncope occurs as a result of arrhythmia or low cardiac output if the atrial septum is intact.

Physical Examination

A newborn with elevated pulmonary vascular resistance has severe cyanosis. In older infants and children, cyanosis and clubbing are mild. Only a small percentage do not have an ASD or patent foramen ovale and thus are not cyanotic. The precordium is generally quiet even in those with striking cardiomegaly. The liver is enlarged, and the jugular venous pulse may be elevated. The holosystolic murmur of tricuspid regurgitation is heard at the lower left sternal border and may be accompanied by a "scratchy" diastolic murmur of tricuspid stenosis. The first heart sound is split and loud, and the second heart sound is widely and persistently split. Loud third and fourth heart sounds are usual, especially in older patients.

Chest Roentgenogram

Heart size, as shown by chest roentgenography, varies, but the heart is ordinarily very large because of the very dilated right atrium. In those with cyanosis, pulmonary blood flow is diminished correspondingly.

Electrocardiogram

Giant, peaked P waves are common, along with a prolonged PQ interval and right ventricular conduction delay or complete right bundle branch block. In approximately 10 percent of these

patients, the pattern of Wolff-Parkinson-White syndrome (with a short PQ interval and slurring of the initial QRS forces or a delta wave) is seen.[181]

Echocardiogram

Two-dimensional echocardiography is very helpful in the diagnosis (Fig. 63-30), identifying the lesion, depicting the degree of displacement of the tricuspid valve into the right ventricle, and assessing the severity of the tricuspid regurgitation. In neonates, evaluation of the pulmonary valve usually allows a distinction between anatomic pulmonary atresia from absence of opening of the valve caused by severe tricuspid regurgitation and high pulmonary vascular resistance.[183]

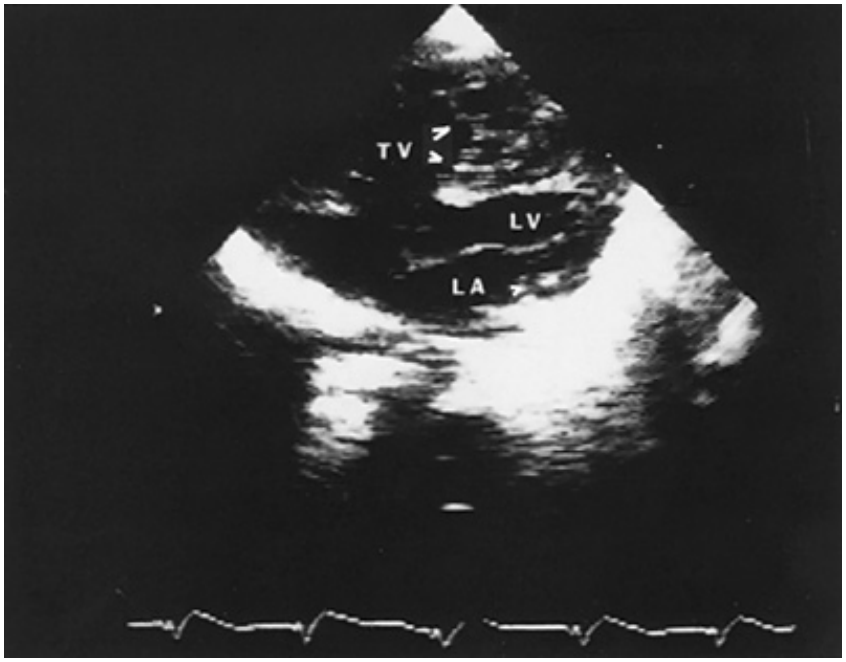

Figure 63-30: Two-dimensional echocardiogram in parasternal view in a patient with Ebstein's anomaly of the tricuspid valve (TV). Numerous attachments of the tricuspid valve (*arrowheads*) to the interventricular septum and right ventricular apex are seen. LV = left ventricle; LA = left atrium.

Cardiac Catheterization

There is a higher than usual risk associated with cardiac catheterization because of the frequency of rhythm disturbances. Proper precautions and prompt use of cardioversion when necessary minimize this risk. In most cases, echocardiography and color Doppler evaluation are sufficient, and catheterization is performed less commonly than it was previously.

There is usually right-to-left shunting at the atrial level. Right atrial hypertension is present. The characteristic right ventricular pressure recording is not obtained until the catheter is advanced to the apex or outflow tract. An intracardiac ECG demonstrates, on pullback from the right ventricle, an area where the ECG is ventricular but the pressure is atrial in contour.[184] This method is not infallible, but it provides good evidence of tricuspid displacement with an "atrialized" portion of the right ventricle.

NATURAL HISTORY AND PROGNOSIS

The natural history varies greatly with the severity of the abnormality. In a study of 50 patients who presented in the neonatal period, 9 (18 percent) died in the perinatal period, with late deaths in another 15 (9 from hemodynamic deterioration, 5 sudden, and 1 noncardiac), for a 10-year actuarial survival of 61 percent.[185] In a study that included more children who presented after the perinatal period, the probability of survival was 50 percent at 47 years of age.[186] Predictors of poor outcome were New York Heart Association class III or IV, cardiothoracic ratio >65 percent, and atrial fibrillation.

For women who survive into adulthood without significant arrhythmias or cyanosis, successful pregnancy with good fetal outcome is possible.[187]

MEDICAL MANAGEMENT

Medical therapy varies depending on the severity of disease and the age at presentation. For those presenting with cyanosis in the perinatal period, procrastination until the pulmonary vascular resistance has decreased may be the best strategy. For those who are severely hypoxemic, maintaining the patency of the ductus with PGE_1 may be lifesaving. Reducing the pulmonary vascular resistance with nitric oxide may reduce right-to-left shunting and improve oxygenation.[188] Persistence of severe cyanosis beyond 1 week of age suggests pulmonary stenosis or pulmonary atresia in addition to Ebstein's deformity of the tricuspid valve.

For children with arrhythmias, an electrophysiologic study may be indicated. For those with disabling or life-threatening arrhythmias, radiofrequency ablation may be performed with initial success rates of about 80 percent but recurrences in 30 percent of patients.[189]

In older children who develop right-sided congestive heart failure, anticongestive measures with digoxin and diuretics may be tried, although this level of deterioration is usually an indication for surgical intervention.

SURGICAL MANAGEMENT

The surgical management of Ebstein's disease remains problematic. In the perinatal period, when the pulmonary vascular resistance is high, watchful waiting is probably the best approach. If the child remains severely hypoxemic (saturations <75 percent) after the pulmonary vascular resistance falls, palliation with a Blalock-Taussig shunt to improve pulmonary blood flow may be sufficient to relieve hypoxemia, and this should allow growth to an age at which other procedures can be considered.[190] For children in whom hypoxemia remains a significant problem, three approaches have been used. The first is a Glenn anastomosis connecting the superior vena cava to the right pulmonary artery, allowing inferior vena cava blood to go through the right atrium and ventricle to the pulmonary artery.[191] A more definitive procedure that eliminates hypoxemia that is used primarily for children with single ventricle but now is applied in this situation as well is the modified Fontan. In this approach, the tricuspid valve is oversewn and the patent foramen ovale is closed, diverting all systemic venous return to the pulmonary arteries by passing the right heart.[192] In a small group of patients, this has been done with success.

The more common approach has been tricuspid valve reconstruction or replacement, usually with a bioprosthesis. Among 189 patients operated on at the Mayo Clinic over a period of almost 20 years, there were 12 hospital deaths (6.3 percent) and an additional 10 late deaths. Among those followed more than 1 year after operation, more than 90 percent were in New York Heart Association class I or II.[193] More recently, other approaches have been suggested, including reconstruction of the normally shaped right ventricle with repositioning of the displaced leaflet of the tricuspid valve at the normal level[194] and reimplantation of the tricuspid valve leaflets with a vertical plication of the atrialized portion of the right ventricle to reduce its size ( Fig. 63-

31).[195] *Although the newer approaches seem promising in small numbers of patients in the short run, many patients with the milder form of the disease can live well into adulthood,*[196] *and so indications for the newer operations in patients who are asymptomatic or only mildly limited remain problematic.*

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

ABNORMALITIES OF THE PULMONARY VENOUS CONNECTIONS

Total Anomalous Pulmonary Venous Connection

PATHOLOGY

When all pulmonary veins terminate in a systemic vein or the right atrium, the term *total anomalous pulmonary venous connection* or *return* is applied (Fig. 63-32). Usually the pulmonary veins leave the lung and then join a chamber-like confluence posterior to the left atrium. From the confluence of veins, one primitive embryologic vessel persists and leads to the anomalous termination. Less commonly, two or more vessels lead to multiple sites of termination.

If the left cardinal vein persists, drainage flows superiorly into the innominate vein and then to the superior vena cava and right atrium or inferiorly into a persistent left superior vena cava and coronary sinus to the right atrium. If the right cardinal vein persists, drainage is to the superior vena cava, the azygous vein, or the right atrium directly. These types are sometimes referred to collectively as supracardiac or supradiaphragmatic drainage and almost never are associated with pulmonary venous obstruction.[197]

If the site of termination is infradiaphragmatic, with connection to the portal venous system or the inferior vena cava, the anomalous vein leaves the confluence of pulmonary veins and descends into the abdomen along the esophagus to join the ductus venosus, the portal vein, or the left gastric vein. *Pulmonary venous obstruction is present in virtually all cases of infradiaphragmatic connection.*[197]

In all cases of total anomalous pulmonary venous connection, there is a patent foramen ovale. The atrium and ventricle of the left side are small in comparison with the right-sided chambers but are within normal limits in regard to absolute size. In the absence of asplenia or polysplenia syndromes, associated anomalies are not common.

ABNORMAL PHYSIOLOGY

In this anomaly, all the blood from both the pulmonary and systemic circulations eventually returns to the right atrium. In neonates with the connection below the diaphragm, the increase in pulmonary flow as the pulmonary resistance decreases after birth cannot be accommodated and the obstruction to flow causes a marked increase in pulmonary venous pressure, resulting in a very high pulmonary vascular resistance. If the ductus arteriosus is still open, the pulmonary vascular resistance exceeds systemic vascular resistance with a right-to-left shunt at the ductal level. When the ductus closes, the increased pulmonary resistance results in increased right ventricular pressure. If the right ventricle fails, the right atrial pressure will increase, and right-to-left shunting at the atrial level may be present, often with profound hypoxemia.

In older children with unobstructed damage above the diaphragm (supracardiac), the pulmonary resistance is usually low. This low resistance facilitates a high pulmonary flow. With mixing of all pulmonary and systemic flow in the right atrium, the oxygen saturation is usually relatively high, resulting in physiology similar to that of an ASD and mild cyanosis.[198]

CLINICAL MANIFESTATIONS

Total Anomalous Pulmonary Venous Connection with Pulmonary Venous Obstruction

Neonates with total anomalous pulmonary venous connection below the diaphragm who have pulmonary venous obstruction present with cyanosis, which may be severe, and dyspnea. Symptoms frequently develop beyond 12 h of age, allowing differentiation from respiratory distress syndrome. In addition to dyspnea, feeding difficulties and cardiac failure are seen.

The physical findings are usually unimpressive. The heart is not hyperactive, and thrills are absent. The second heart sound may be split, with an increased pulmonary component. Significant murmurs are uncommon.

Total Anomalous Pulmonary Venous Connection without Pulmonary Venous Obstruction

These patients are usually asymptomatic at birth, although some may develop transient tachypnea. Presentation typically occurs during the first year of life. Some of these children have tachypnea and feeding difficulties, with frequent respiratory infections. Cyanosis often is mild and may not be clinically apparent. Other children may be asymptomatic and present with a heart murmur.

The cardiac examination is similar to that of an ASD with increased right-sided flow. The right ventricular impulse is usually hyperactive. The jugular venous pulse is elevated, and hepatomegaly appears early. There is a diffuse and hyperdynamic right ventricular impulse. The second heart sound is split and relatively fixed; the loudness of the pulmonary component may be increased. There is usually a grade 2 or 3 midsystolic flow murmur at the left sternal border. At the lower sternal border, there are a middiastolic rumble and prominent third and fourth heart sounds. Rales may be heard over the lung fields, and periorbital edema is common. A continuous murmur rarely may be heard over the common venous channel.

Chest Roentgenogram

With the unobstructed types, the heart is enlarged with increased pulmonary flow. Pulmonary edema is uncommon. In patients with return to the left innominate vein, there may be a characteristic bulging of the superior mediastinum bilaterally, producing a "snowman," or figure-of-eight, contour. With obstructed types, the heart size is nearly normal; there is very marked pulmonary edema, which may give a granular appearance to the lungs, making differentiation from respiratory distress syndrome difficult in a newborn.

Electrocardiogram

There is right axis deviation and right atrial and right ventricular hypertrophy. Commonly, there is a qR pattern in the right precordial leads.

Echocardiogram

Echocardiography with color Doppler is specific in defining the anomaly and the site of drainage.[199] The right side of the heart is enlarged when the venous return is unobstructed with increased flow. Although the right-sided chambers may dwarf the left heart, the left heart is usually of normal size. With obstructed return, there is evidence of severe pulmonary hypertension.

Cardiac Catheterization

If echocardiography is inconclusive in delineating the site or sites of the pulmonary venous connection, catheterization may be necessary. There is an increase in oxygen saturation at the level of the abnormal connection, with similar saturations in the remainder of the chambers on both sides of the heart. Pulmonary arterial pressure is elevated to a variable degree, but it may be above systemic pressure if there is marked pulmonary venous or pulmonary vascular obstruction. Pulmonary capillary wedge pressures are elevated in proportion to the degree of venous obstruction. The atrial communication may rarely be obstructive,[198] and if it is, balloon atrial septostomy may be helpful. Pulmonary arteriography usually will show the anomalous venous connection. Angiography directly in the common venous channel, if it is entered, will outline its course and any sites of obstruction optimally.

NATURAL HISTORY AND PROGNOSIS

The natural history varies depending on the degree of obstruction of egress of blood from the pulmonary veins.[198] Those who present in the perinatal period with severe cyanosis and respiratory distress, usually with pulmonary venous drainage below the diaghram, represent a medical emergency and will die without early surgery.

Those with supracardiac drainage and some degree of obstruction and therefore pulmonary hypertension are frequently sufficiently tachypneic that feeding is problematic, and they fail to gain weight at a normal rate. They tolerate respiratory infections poorly and occasionally need emergency surgery for respiratory failure.

Those with no pulmonary venous obstruction have large left-to-right shunts and mild cyanosis but may have no or minimal symptoms at rest or exercise. If corrective surgery is not performed, they are at risk for pulmonary vascular disease.[200]

MEDICAL MANAGEMENT

For neonates with severe cyanosis and respiratory disease, oxygen, a respirator, and PGE_1 can be used to temporize but survival is dependent on early surgery. For those with mild pulmonary hypertension and failure to thrive, surgery usually is performed semielectively. For those with no pulmonary hypertension, who usually present with murmurs and findings similar to those of an atrial septal defect, surgery is more elective but little is gained by waiting, and more centers are advocating early repair in this group as well.[201]

SURGICAL MANAGEMENT

Correction of total anomalous pulmonary venous connection requires (1) creation of a large communication between the left atrium and the pulmonary venous system, (2) obliteration of the anomalous pulmonary venous connection to the systemic circulation, and (3) closure of the associated interatrial communications.[201]

Supracardiac anomalous connection to the left brachiocephalic (vertical) vein and infracardiac connections to the portal venous system or the inferior vena cava are corrected by the creation of a wide anastomosis between the posterior aspect of the left atrium and the common transverse pulmonary vein. The stretched foramen ovale is closed. The ascending or descending anomalous pulmonary venous connection to the systemic circulation is ligated, as is the PDA.

Anomalous pulmonary venous connection to the coronary sinus is repaired by creating of a large fenestration in the common wall between the coronary sinus and the left atrium. The coronary sinus is diverted into the left atrium by the placement of an intracardiac patch, which also closes the interatrial communication.

Total anomalous pulmonary venous connection to the right atrium is repaired by excision of the atrial septum and the placement of a patch that diverts the opening of the anomalous pulmonary venous connection into the left atrium.

Mixed forms of total anomalous pulmonary venous connection pose particular technical difficulties that require individualized operations. Mortality rates are slightly higher after early repair of symptomatic neonates with mixed types of total anomalous pulmonary venous connections.

Although the results of repair of total anomalous pulmonary venous connection without obstruction in an older child have always been quite good, until recently neonates with obstructed total venous return have been problematic. In the 1960s and early 1970s, the surgical mortality rate exceeded 50 percent.[202] Between 1970 and 1980, surgical techniques improved and the mortality rate was reduced to 10 to 20 percent.[203] More recently, surgical results have continued to improve, with no mortality among 27 infants who underwent reparative surgery at Children's Hospital in Boston in the late 1980s.[204] Late survival has been quite good, with 98 percent surviving a median of 87 months in one study.[205]

After a satisfactory operative course, the prognosis has been excellent in those in whom a large common pulmonary vein can be attached to the back wall of the left atrium with a relatively large anastomosis. For those initially with obstructed total anomalous pulmonary venous return, the left atrium may be small and the anastomosis may be more difficult. Late obstruction of one or more pulmonary veins has been seen. When present, the obstruction can be approached by balloon dilation, stent placement, or repeat surgery.[206]

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

MALPOSITION OF THE CARDIAC STRUCTURES

Definition and Terminology

The *segmental approach* to the diagnosis of complex congenital heart disease[207] provides an orderly, effective method for determining the anatomic and hemodynamic interrelationships of the cardiac chambers, valves, and great vessels. For this approach to be better understood, certain definitions are helpful. Positioning of viscera is described as situs solitus, inversus, or ambiguous. In *situs solitus* (S), the distribution of all the organs is recognized as normal, for example, a left-sided stomach and spleen, a predominantly right-sided liver, a trilobed right lung, and a bilobed left lung. In *situs inversus (totalis)* (I), the organs show a perfect mirror image in regard to left and right to that of situs solitus. Anteroposterior relations are not disturbed. When neither situs solitus nor situs inversus can be identified, *situs ambiguous* (A) is said to be present. This usually applies in cases of asplenia or polysplenia.

With the rarest of exceptions, the *atria follow the body situs* and are so designated (morphologic right atrium to the right of the left atrium in atrial situs solitus and to the left of the left atrium in atrial situs inversus). The AV canal consists of the tricuspid valve, the mitral valve, and the septum of the AV canal and connects the atrial portion with the ventricular portion of the heart. As a rule, *each AV valve is part of the specific ventricle into which it leads*. The valve situs may be solitus, inversus, or ambiguous.

The alignment or type of AV or ventriculoarterial (VA) connection addresses the issue of what flows into what. The connection may be described at the AV or VA level as concordant (e.g., right atrium to right ventricle, left ventricle to aorta) or discordant (e.g., right atrium to left ventricle, left ventricle to pulmonary artery) or may be considered an arrangement that requires a special description. In the case of AV alignment in which the atria are not lateralized, the alignment would be ambiguous. In the univentricular heart, the designation would be double-inlet, absent right, or absent left AV connection. Special descriptions in the case of VA alignment or type of VA connection include double-outlet and single-outlet VA connection. The mode of connections, either AV or VA, addresses the structural makeup of the connecting segments: the AV canal and the infundibulum or conus. The mode of AV connection may be normal, common, stenotic, imperforate, atretic, double-orifice, overriding, straddling, or unguarded. The mode of VA connection may be expressed in terms of the position and development of the conus or infundibulum, which, although normally incorporated into the right ventricle, is not an intrinsic part of the true right ventricle. It may be described as subpulmonary, subaortic, very deficient, or bilaterally present or absent.[208]

The position of the ventricles may be described by the terms *d loop* and *l loop*. When the morphologic right ventricle lies to the right of the morphologic left ventricle, the ventricular portion of the heart is said to exhibit a d loop (D). The ventricles are said to be noninverted or in the solitus position. When the ventricular relations are reversed, l loop (L) is said to be present. The ventricles are inverted or in the inversus position. *These relationships are independent of the visceral or atrial situs as well as the position of the heart or its chambers within the chest.*

The great arteries may deviate from the usual with respect to both their anteroposterior and lateral (left-to-right) relationships. In solitus (S) or *normally related great arteries* (NRGA), the aortic origin lies to the right of and posterior to the position of the pulmonary valve. In the inversus (I) relationship, the anteroposterior relationships are not disturbed but the aortic origin lies to the left of the pulmonary arterial origin. In *transposition of the great arteries* (TGA), the aorta arises from the anatomic right ventricle, the pulmonary artery arises from the anatomic left ventricle, and usually the aortic origin is more anterior than that of the pulmonary artery.

When the aortic origin lies to the right of the pulmonary origin, the transposition is called *dextro* or *d transposition* (D-TGA) (see the discussion of complete transposition of the great arteries, below). When the aortic origin lies to the left of the pulmonary origin, *levo transposition* (L-TGA) is said to be present (see the section on congenitally corrected transposition, below).

When the abnormal relationship of the great arteries is neither complete nor corrected transposition, the term *malposition of the great arteries* (MGA) may be used. Malpositions are designated as D-MGA or L-MGA, depending on the laterality in the relation between the origins of the two great arteries.[208] Within this group are found examples of the abnormal VA alignment, where one great artery arises from the appropriate ventricle and the other great artery also arises from the same (or inappropriate) ventricle. These are examples of *double-outlet right ventricle* (DORV) or *double-outlet left ventricle* (DOLV). Also included is the arterial malposition termed *anatomically corrected malposition* (ACM). This is characterized by the great arteries having a normal VA alignment (concordant), but with the aorta anterior to the pulmonary artery by virtue of an abnormal mode of VA connection: the presence of a well-developed conus lying beneath both the aorta and the pulmonary artery or only beneath the aorta. The route for the flow of blood in ACMs may be normal or abnormal, depending on the AV alignment.[208]

The Segmental Approach to Diagnosis

The segmental, or step-by-step, approach is a valuable tool for arriving at the correct diagnosis in patients with complex congenital heart disease and is independent of cardiac position. In order, one determines (1) the locations of the right and left atria and their venous connections, (2) the location of the right and left ventricles and their alignment with the atria, (3) the mode of connection of the AV valves to the ventricles, (4) the position of the great arteries and their alignment with the ventricles, and (5) the location and status of the infundibulum. In addition, one must search for associated malformations between and within each of these segments.

Determining atrial situs can be accomplished in most instances by taking advantage of the high degree of abdominal visceroatrial concordance. With abdominal situs solitus (S), the liver is on the right and the right atrium almost invariably is on the right as well; with abdominal situs inversus (I), the liver is on the left and the right atrium almost invariably is on the left. With abdominal situs ambiguous (A), the liver may be placed almost symmetrically across the midline and the atria may be located normally or inverted or both atria may have morphologic characteristics of either the right atrium or the left atrium (Fig. 12-4). A symmetric liver is found in approximately 60 percent of patients with situs ambiguous. Lateralization of the liver, which is evident in the remainder, may simulate either situs solitus or situs inversus.

When both atria have characteristics of a right atrium,[209] *dextroisomerism*, or "bilateral right-sidedness," is said to be present. This situation is usually, though not invariably, accompanied by asplenia. When both atria have characteristics of a left atrium, *levoisomerism*, or "bilateral left-sidedness," is said to exist. This usually, but again not invariably, is accompanied by polysplenia.

Bronchial situs, as determined by overpenetrated chest roentgenogram or bronchial tomography, is an excellent predictor of atrial situs, but the most accurate technique appears to be two-dimensional echocardiography with Doppler color flow mapping. The hepatic portion of the

inferior vena cava, which almost always enters the morphologic right atrium, usually can be identified easily, as can the connections and structural details of the superior vena cava, coronary sinus, pulmonary veins, atrial septum, and atrial appendages.

Additional clinical clues to atrial situs may be obtained from the ECG, where a superior and leftward orientation of the P-wave vector suggests levoisomerism and polysplenia. Howell-Heinz and Howell-Jolly bodies in the peripheral blood smear are characteristic of dextroisomerism or asplenia.

For determination of the AV, ventricular, and VA relationships, high-quality selective biplane angiography, supplemented by equally high-quality two-dimensional echocardiography with Doppler color flow mapping, is essential.[209] Symbols used to designate the combination or sequence of segments are arranged in order as follows: (1) the visceroatrial or bronchoatrial situs, (2) the ventricular loop, and (3) the relations of the great arteries. These may be included within parentheses and preceded by abbreviations that indicate the VA alignment, for example, TGA, DORV, or single ventricle (SV). Associated malformations such as VSD, pulmonary stenosis, and straddling tricuspid valve may be listed after the parentheses. Thus, the typical or usual transposition of the great arteries with situs solitus, d-ventricular loop, and aorta arising from the right ventricle and to the right of the pulmonary artery, with an intact ventricular septum (IVS), would be designated TGA (SDD) IVS. The designation for typical corrected transposition (TGA) with situs solitus (S), l-ventricular loop (L), aorta arising from the morphologic right ventricle and lying to the left of the pulmonary artery (L), with VSD and pulmonary stenosis (PS), would be TGA (SLL), VSD, PS. This designation would apply to transposition with situs solitus, whether the heart lay in the right or left chest (dextrocardia or levocardia, respectively). It should be noted that the description of the position of the heart within the chest would offer no additional information referable to the intracardiac anatomy or great vessel alignment.[207]

Levocardia, Dextrocardia, and Mesocardia

The position of the cardiac apex indicates a condition of levocardia, dextrocardia, or mesocardia.

The trend today is to discard the terms *dextroposition, dextroversion, mirror-image dextrocardia*, and *isolated dextrocardia* because they do not provide any significant information beyond what is already known-that the cardiac apex is in the right chest-and to use the broad term *dextrocardia* for all right-sided hearts, followed by a description of the visceroatrial situs. In the case of patients in whom the heart appears to have been pulled or pushed into the right chest by massive atelectasis or hypoplasia of the right lung, diaphragmatic hernia, eventration of the diaphragm, pleural effusion, obstructive emphysema, or pneumothorax, an appropriate descriptive phrase should be added. The term *isolated levocardia* is applied to all left-sided hearts with situs inversus or situs ambiguous, and a description of the visceroatrial situs should follow.

Dextrocardia with complete situs inversus occurs in approximately 2 per 10,000 live births. *The incidence of congenital heart disease is relatively low among these individuals and is estimated to be about 3 percent*. Dextrocardia with situs solitus or situs ambiguous is considerably less common and occurs in perhaps 1 in 20,000 live births. The incidence of congenital heart disease is extremely high in this situation, however, probably in the range of 90 percent or greater. From these figures, one could project that approximately 12 percent of individuals found to have dextrocardia and congenital heart disease would have complete situs inversus. This estimate compares favorably with the figure of 18 percent observed in large autopsy series. About 50 percent of patients with dextrocardia and heart disease have situs solitus, and the remainder, perhaps 30 percent, have situs ambiguous.[207] An l-ventricular loop is found in the majority of patients with dextrocardia regardless of situs but is most common, as one might expect, among patients with situs inversus, in whom it approaches 80 percent. Cardiac malformations usually, although not invariably, are severe and complex. The most common lesions and their approximate

frequency are as follows: transposition of the great arteries, 50 to 75 percent; double-outlet right ventricle, 10 to 18 percent; VSD, 60 to 80 percent; single ventricle, 15 to 40 percent; and pulmonary stenosis or atresia, 70 to 80 percent.[207] Approximately three-quarters of transposed great arteries have the segmental arrangement of corrected transposition. Tetralogy of Fallot is distinctly uncommon. Polysplenia or asplenia is found in about one-third of patients with dextrocardia and almost invariably with situs ambiguous. Kartagener's syndrome, the triad of situs inversus, sinusitis, and bronchiectasis, results from impaired ciliary movement. It is present in approximately 20 percent of patients with dextrocardia and situs inversus totalis.[210] The incidence of isolated levocardia has been estimated at approximately 0.6 per 10,000 live births. It is estimated that over 90 percent of affected individuals have associated heart disease. Situs inversus is present in approximately 15 percent, and the remainder have situs ambiguous, with the ratio of asplenia to polysplenia or accessory spleens being from 2.5:1 to 1.5:1. The associated defects are comparable in complexity and severity to those associated with dextrocardia. *Mesocardia* may exist as a variant position of the normal heart or a variant position of dextrocardia or isolated levocardia.

MEDICAL AND SURGICAL MANAGEMENT

Medical management of patients with cardiac malposition is similar to that of patients with normally located hearts, with the exceptions of continuous daily antibiotic coverage and pneumococcal vaccine for patients with asplenia and the particular attention to detail that is necessary to establish the correct diagnosis in individuals with unusual and complex malformations. Surgical management differs in the technical considerations imposed by the malposition of the heart itself, the frequency of occurrence of the l-ventricular loop, and the variability of the intracardiac conduction system.

Dextro Transposition of the Great Arteries

DEFINITION

In this condition, the aorta and the pulmonary artery are misplaced in relation to the ventricular septum, with the aorta arising from the right ventricle and the pulmonary artery arising from the left ventricle (discordant VA connection).

PATHOLOGY

In the majority of cases, there are situs solitus of the atria and viscera (S) and concordance of the AV connection and the right ventricle lies to the right of the left ventricle (d loop, D) (Fig. 63-33). The aorta lies to the right of the pulmonary arterial origin (d transposition, D) and is anterior. Of the communications between the two sides of the circulation, a narrow patent foramen and PDA are common in very young infants. The ventricular septum is intact in approximately half these patients, and another 10 percent have only a very small VSD. The remainder have a large VSD or multiple VSDs.[211]

Pulmonary stenosis of significance is very uncommon among neonates with an intact ventricular septum but develops with the passage of time in approximately one-third of patients in whom the right ventricle continues to be the systemic ventricle. In most cases it is mild and usually, though not invariably, is the result of a bulging of the ventricular septum into the left ventricular outflow area. Approximately one-third of patients with a large VSD have significant left ventricular outflow tract obstruction (pulmonary stenosis). Causes of this obstruction include leftward malalignment of the infundibular septum, the presence of a membranous collar or ridge encircling the left ventricular outflow tract, anomalous adhesion of the anterior mitral leaflet to the ventricular septum, stenotic deformity of the pulmonary valve, and, rarely, an aneurysm of

endocardial tissue related to the VSD.[212]

The coronary arteries usually arise from the two aortic sinuses adjacent to the pulmonary trunk-the "facing sinuses"-with the most common arrangement being the right coronary artery arising from the rightward sinus and the left coronary artery, with its anterior descending and circumflex branches, arising from the leftward sinus.

Hypertensive pulmonary vascular disease may occur at an inordinately early age and may occur even in patients with an intact ventricular septum and initially low left ventricular pressures. Three-quarters or more of patients with d transposition, situs solitus, and d loop [TGA (SDD)] either have no significant associated cardiac defects or have relatively simple malformations in the form of VSD, ASD, PDA, or pulmonary stenosis. The remainder have more complicated lesions and will not be discussed in this section.

ABNORMAL PHYSIOLOGY

The systemic and pulmonary circulations are arranged so that the systemic venous return is conducted back to the systemic arterial system and the pulmonary venous return is conducted back to the pulmonary arterial system, with no obligatory mixing or interchange. For survival, there must be communication between the two circulations in the form of a patent foramen ovale, a PDA, or a VSD. The hemodynamics are dependent on the combination of defects present and particularly on the amount of mixing between the systemic and pulmonary circulations. The right ventricle is the systemic ventricle, and its systolic pressure is the same as systemic arterial pressure.

CLINICAL MANIFESTATIONS

Approximately 3 to 4 percent of children with recognized congenital heart disease have transposition of the great arteries (Table 63-1). Males are more commonly afflicted than are females in a ratio between 2:1 and 3:1.

History

Among infants with an intact ventricular septum, very early, severe, and progressive cyanosis is the presenting sign, making its clinical appearance within the first hour in over half and by the end of the first 24 h in over 60 percent of neonates so afflicted.[3] In a very few, a persistent PDA in combination with an incompetent foramen ovale or a small VSD permits survival for several weeks, but narrowing or closure of any of the three communications produces critical hypoxemia. Infants with a sizable VSD present with severe congestive failure and only mild or barely detectable cyanosis toward the middle or later part of the first month of life. Infants with a large VSD and significant pulmonary stenosis may present within the first days of life with cyanosis if stenosis is severe; with more moderate stenosis, they may present with cyanosis and little if any congestive failure somewhat later within the first year.

Physical Examination

Among infants with an intact ventricular septum, the most prominent feature is intense cyanosis. Tachypnea and mild dyspnea are present. The right ventricular lift is forceful, and the first sound is usually loud at the lower left sternal border. In most patients, the second heart sound may be heard to be split narrowly, confirming the presence of two semilunar valves. Murmurs are seldom impressive or distinctive. Signs of congestive failure are uncommon unless the infant is beyond the first week of life and a large ductus is present. Among infants with a large VSD, slenderness and mild cyanosis or a grayish pallor are apparent. Breathing is labored, and both the right and left

ventricular impulses are hyperactive. A thrill is uncommon. A systolic murmur at the lower left sternal border is usually present but is seldom loud or completely holosystolic. A gallop rhythm and a diastolic flow rumble at the apex are typical. Infants and children with VSD and significant pulmonary stenosis generally are severely cyanotic.

Chest Roentgenogram

With an intact ventricular septum, the heart size and pulmonary vascularity appear normal or at the upper limits of normal during the first week. Later, a narrow base caused by the displaced pulmonary artery may give rise to the characteristic "egg-on-side" contour. Impressive cardiomegaly, pulmonary plethora, and this characteristic contour are more common during the second week and beyond. With a large VSD, marked cardiac enlargement involving all chambers, impressive pulmonary plethora, and the egg-on-side contour are present. With significant pulmonary stenosis, the heart resembles that of a patient with tetralogy of Fallot, but it is usually slightly larger and the pulmonary vascularity is less diminished than one would expect for a comparable degree of clinical cyanosis. A right aortic arch is present in 4 to 16 percent of those patients.

Electrocardiogram

If the ventricular septum is intact, the ECG may reveal tall or peaked P waves by the second or third day of life; however, clearly abnormal right ventricular forces usually are not apparent until the latter part of the first week. The persistence of an upright T wave in leads V_1 and V_{3R} beyond 4 days of age provides an early clue that the right ventricular systolic pressure is at systemic levels. An older infant will have abnormal right axis deviation and marked right ventricular hypertrophy. A large VSD with a large pulmonary blood flow usually will produce biatrial and biventricular hypertrophy. If pulmonary blood flow is reduced toward normal, whether by significant pulmonary stenosis, pulmonary arterial banding, or severe PVOD, the pattern becomes one of right ventricular and right atrial hypertrophy.

Echocardiogram

Two-dimensional study with Doppler color flow mapping is the diagnostic procedure of choice. The pulmonary artery can be seen arising from the left ventricle, and the aorta from the right ventricle (Fig. 63-34*A*). The presence or absence of VSDs, anomalies of the AV connections, the status of the left ventricular outflow tract, and the coronary arterial pattern can be identified.

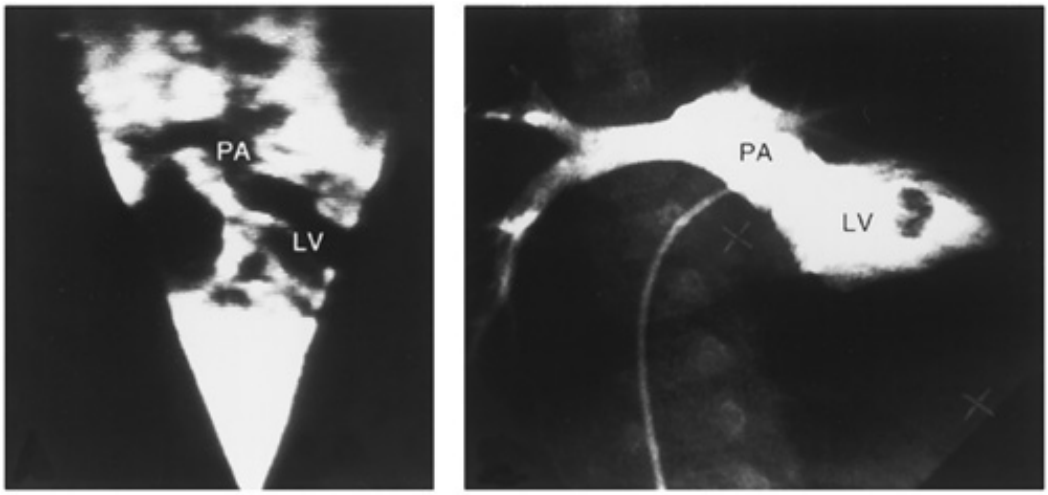

Figure 63-34: *A.* Two-dimensional echocardiogram. The left ventricle leads to a bifurcating great vessel (pulmonary artery, PA), confirming transposition. *B.* Anterolateral projection of an angiogram in the smooth-walled left ventricle (LV). The dye is ejected into the pulmonary artery.

Cardiac Catheterization

Systemic arterial oxygen desaturation is present in all these patients. The pulmonary arterial oxygen saturation is invariably higher than the systemic arterial saturation. The right ventricular systolic pressure will be at systemic levels; the left ventricular pressure also will be at systemic levels if a large VSD, ductus arteriosus, or significant pulmonary stenosis is present. A wide pressure difference between the two ventricles or between the two atria indicates an intact or virtually intact ventricular or atrial septum, but the lack of such a gradient certainly does not guarantee the presence of an adequate opening at either level. Selective ventricular angiography will document the diagnosis and the associated defects (Fig. 63-34*B*). The coronary arterial pattern should be established if it is not visible by echocardiography.[213] *All newborns with transposition can benefit from balloon atrial septostomy at catheterization by virtue of the increased mixing of the pulmonary and systemic venous circulations and the decompression of the left atrium.*

NATURAL HISTORY AND PROGNOSIS

Without balloon septostomy or surgical intervention, 50 percent of infants with transposition die within the first month and 90 percent die within the first year of life.[214] Those with an intact ventricular septum die very early from hypoxemia. Those with a large VSD usually live somewhat longer, but the majority die in the first months of congestive failure; the few survivors have severe PVOD. Those with a large VSD and pulmonary stenosis have the best outlook, but the average life expectancy is barely 5 years even with this combination of defects. With an adequate interatrial opening, whether natural, balloon-induced, or surgically created, infants with an intact ventricular septum do relatively well during the first year. Increasing cyanosis during the first year in these patients may be due to a gradual diminution of the size of the atrial septal opening, narrowing or closure of a persistent PDA or small VSD, the gradual development of subvalvular pulmonary stenosis, or the development of PVOD. Before age 2 years, cerebrovascular accidents are a hazard to these hypoxemic infants and occur almost invariably in a setting of relative anemia rather than extreme polycythemia. The appearance of PVOD is unusual but can occur within the first 12 months of life. It becomes more common, approaching 40 percent, in the second year of life and thereafter. Infants with a large VSD and no significant pulmonary stenosis will develop PVOD and become prohibitive risks for corrective surgery by the end of the first year of life.

Those with a VSD and severe pulmonary stenosis usually become progressively more cyanotic.

Palliative and subsequent corrective operations have enabled a relatively large group of patients to survive beyond infancy and early childhood. Among the survivors of the atrial switch operations, such as the Mustard and Senning procedures, are found residual abnormalities such as pulmonary stenosis and PVOD as well as complications that result from surgery. These complications include residual intraatrial baffle leaks, systemic and/or pulmonary venous obstruction, and arrhythmias. Late sudden death has been described in about 3 percent of survivors and very possibly results from arrhythmias. Finally, right ventricular dysfunction with or without progressive tricuspid regurgitation has been documented in many of the somewhat older survivors of atrial inversion operations and raises the question of whether the right ventricle can function adequately as the systemic arterial ventricle beyond adolescence and early adult life.

While complications have been problematic for some, long-term follow-up of the group as a whole has been good. The Toronto experience is the oldest and largest. Among 534 children who underwent a "Mustard" procedure since 1962, there were 52 early deaths (9.7 percent). Survival at 5 years was 89 percent, and it was 76 percent at 20 years.[215] In a study from New Zealand of 113 hospital survivors of surgery performed between 1964 and 1982, survival at 10, 20, and 28 years was 90 80, and 80 percent, respectively, with 76 percent of survivors being New York Heart Association class I.[216] There has been less long-term follow-up of survivors of the "Senning" type of atrial repair. In a recent study of 100 patients, the actuarial survival at 13 years was 90 percent for those with simple transposition and 78 percent survival for those with complex disease.[217]

MEDICAL MANAGEMENT

The first step in the treatment of infants with an intact ventricular septum is to provide without delay an adequate systemic arterial oxygen saturation. This can be achieved in almost all instances by establishing an adequate interatrial opening with balloon atrial septostomy and providing adequate systemic arterial-to-pulmonary arterial shunting via the ductus with the use of intravenous PGE_1 infusion;[91] the latter procedure frequently is supplemented by endotracheal intubation to compensate for prostaglandin-related apnea. The adequacy of the atrial septostomy opening can be determined by a sustained increase in the systemic arterial oxygen saturation to above 60 percent and verified by direct visualization with two-dimensional echocardiography. If the relief of hypoxemia is unsatisfactory with PGE_1 alone and if the interatrial opening is judged by echocardiography to be small, the alternatives are to perform a balloon atrial septectomy without delay or to proceed directly with corrective surgery in the form of the arterial switch operation.

SURGICAL MANAGEMENT

Arterial switch repair is now the preferred surgical alternative to the atrial inversion procedures for a neonate with an intact ventricular septum and for a slightly older infant with a large VSD and without significant structural pulmonary stenosis (Fig. 63-35). Arterial switching should be performed within the first 2 to 3 weeks of life, before left ventricular systolic pressure falls significantly below that of the right ventricle. For infants beyond 3 weeks of age, if the ratio of left ventricular to right ventricular pressure has fallen below 0.60, a pulmonary arterial band may be applied with or without a systemic-to-pulmonary arterial shunt and the arterial switch operation may be performed approximately 1 week later. Most patterns of coronary arterial origin and course appear to be amenable to the operation, and infants as small as 2.0 kg may be repaired successfully.

In some centers, the surgical risks have been reduced to about 5 to 10 percent,[218] although in other centers, the surgical mortality continues to be higher.[219] Short- and medium-term prognosis is

good,[220] but longer-term studies are awaited. The most common problem has been stenosis at the pulmonary artery anastomotic site.[221] When severe, this usually has been amenable to balloon dilation or stenting.[222]

For infants with transposition, a large VSD, and pulmonary hypertension, the arterial switch technique with VSD closure must be carried out within the first 2 months of life to prevent severe PVOD. Infants with a large VSD and severe pulmonary stenosis usually may be palliated with a systemic-to-pulmonary arterial shunt and repaired in later infancy or as young children,[175] although some centers are doing reparative surgery in infancy.[223] Finally, the severe hypoxemia present in children with a large VSD and severe PVOD may be reduced by an intraatrial repair performed as a palliative procedure, with no attempt at closure of the VSD.[224]

Double-Outlet Right Ventricle

PATHOLOGY

In this malformation, more than 50 percent of the semilunar valve orifices of both great arteries arise from the morphologic right ventricle. In most cases, the ventricles display a d loop, and the pulmonary arterial origin is normally positioned, arising from a conus above the right ventricle. The aorta also arises from the right ventricle above conal tissue. The two semilunar valves are at about the same level, and there is no fibrous continuity between the semilunar and mitral valves (Fig. 63-36).

In most cases, the aortic origin is to the right (d malposition) of the pulmonary arterial origin, with the two vessels usually displaying a side-by-side relationship. Uncommonly, the aortic origin is distinctly anterior to the pulmonary origin or the aorta arises to the left (l malposition) of the pulmonary artery.[225]

With rare exceptions, there is a VSD. The condition may be subdivided further on the basis of the relation of the VSD to the origin of the great arteries. The VSD is subaortic in approximately two-thirds of patients, subpulmonary (*Taussig-Bing heart*) in 18 percent, related to both great arteries (*doubly committed*) in 3 percent, and remote or unrelated to either great artery in about 7 percent.[225]

ASSOCIATED CONDITIONS

Pulmonary stenosis occurs in over half these cases, with the condition usually resulting from a narrow subpulmonary conus. ASD, subaortic stenosis, and coarctation of the aorta are also relatively common, with the latter particularly associated with the subpulmonary defect. Obstruction at the mitral valve may be observed in about one-fifth of cases of double-outlet right ventricle. Mitral valve straddling of the VSD and varying degrees of left ventricular hypoplasia also are encountered.

CLINICAL MANIFESTATIONS

Double-outlet right ventricle, or origin of both great arteries from the right ventricle, is a relatively rare malformation that is found in only 0.8 percent of patients with congenital heart disease. It is of considerable importance, however, because its clinical and laboratory features frequently resemble those of more common and more easily correctable malformations. Double-outlet right ventricle reflects the relationship of the great vessels to the ventricular septum; the presentation and treatment of children with this condition depend on the associated anomalies.

History and Physical Examination

Patients with a subaortic VSD without pulmonary stenosis (Fig. 63-36*A*) have the same findings on examination as do patients with a large isolated VSD. Congestive failure appears within a few weeks of birth, and cyanosis is seldom described. Those with a subaortic VSD and pulmonary stenosis (Fig. 63-36*B*) usually present after the newborn period and follow a course similar to that of patients with tetralogy of Fallot. Patients with a subpulmonary defect without pulmonary stenosis (Fig. 63-36*C*), the Taussig-Bing malformation, resemble patients with transposition of the great arteries and a large VSD without pulmonary stenosis. The findings are those of severe congestive failure and cyanosis.

Chest Roentgenogram

Cardiomegaly with pulmonary overperfusion is characteristic of all types of this anomaly without pulmonary stenosis. Double-outlet right ventricle with subaortic VSD and pulmonary stenosis resembles tetralogy of Fallot. In the case of subpulmonary VSD without pulmonary stenosis, the pulmonary artery usually lies beside rather than posterior to the aorta; this clearly visible, dilated main pulmonary artery may permit distinction of this malformation from transposition, which it mimics so closely.

Electrocardiogram

Right axis deviation and right atrial and right ventricular hypertrophy are characteristic of double-outlet right ventricle.

Echocardiogram

Two-dimensional echocardiography is very useful in demonstrating the anatomic components and associated defects.[225,226]

Cardiac Catheterization

There is an increase in oxygen saturation at the right ventricular level. The pulmonary arterial saturation is lower than that of the aorta in patients with a subaortic VSD and is invariably higher than that of the aorta in those with a subpulmonary septal defect and transposition physiology. Left ventricular systolic pressure may be higher than right pressure if the VSD is small and restrictive. Selective right and left ventricular biplane angiography and an aortogram are recommended.

NATURAL HISTORY AND PROGNOSIS

The clinical course of each variety of double-outlet right ventricle is determined by the associated defects. Without surgical intervention, those with an unguarded pulmonary artery either die in infancy with congestive failure or develop PVOD. Spontaneous narrowing or closure of the VSD may occur and is life-threatening. Increasing dyspnea, increasing intensity of the systolic murmur, and progressive left ventricular hypertrophy suggest this complication. Patients with pulmonary stenosis tend to have progressive obstruction and cyanosis.

MEDICAL MANAGEMENT

Vigorous treatment of heart failure is required for those without pulmonary stenosis. Almost all cases are best treated with surgical palliation or correction in infancy. If there is pulmonary

hypertension, banding or correction should be done by 2 to 3 months of age. Patients with ventricular hypoplasia, mitral stenoses, straddling AV valves, or a remote VSD are usually not candidates for biventricular repair, and initial palliation should prepare the child for a modification of the Fontan operation. Whether or not corrective surgery has been performed, all patients in whom the left ventricular output must pass through the VSD should be observed continuously for the possibility of spontaneous narrowing and obstruction at that site.

SURGICAL MANAGEMENT

Great variability exists in the morphologic spectrum of double-outlet right ventricle. Although primary total repair of most forms of double-outlet right ventricle is now performed and preferred in infancy, palliation (pulmonary arterial banding, repair of aortic coarctation, atrial septal excision, or the creation of a systemic arterial-to-pulmonary arterial or systemic venous-to-pulmonary arterial shunt) to adjust pulmonary blood flow and thus preserve the pulmonary vascular bed, ventricular function, and AV valve competence may be considered in complex variants.

In all forms of double-outlet ventricle, the relation of the VSD to the great arteries and the magnitude of ventricular outflow tract obstruction dictate management. Surgical correction requires (1) obliteration of the interventricular communication, (2) relief of pulmonary stenosis when present, (3) diversion of oxygenated pulmonary venous blood to the aorta, and (4) diversion of hypoxemic systemic venous blood to the pulmonary artery.[227] When the VSD is committed to the aorta, a Dacron semiconduit or tunnel-shaped patch is placed to obliterate the interventricular communication while the left ventricular blood is diverted through the VSD to the aorta. Pulmonary stenosis is corrected by a valvotomy, with excision of obstructive muscle bundles and placement of a transannular patch when necessary. Otherwise, an extracardiac conduit is placed between the right ventricle and the pulmonary artery.[228,229]

When the great arteries are transposed or the VSD is not committed to the aorta, the arterial switch operation, using the concepts of Jatene and Le Compte, permits patch closure of the VSD, directing left ventricular blood into the neoaorta.[230] Further consideration of repair of double-outlet right ventricle associated with more complex defects is beyond the scope of this discussion. For a patient who is not a candidate for biventricular repair because of hypoplasia of a ventricle or a straddling AV valve, initial palliation should prepare the child for a modification of the Fontan operation.

In a 10-year review of repair of double-outlet right ventricle in 73 patients,[228] early mortality was 11 percent, with an overall actuarial survival estimate at 8 years of 81 percent. Twenty-six percent required reoperation, and there was one death; 79 percent of the operative survivors required no restriction of physical activity, and 83 percent required no cardiac medications.

Corrected Transposition of the Great Arteries

DEFINITION

AV discordance and VA discordance form the characteristics of corrected transposition.

PATHOLOGY

Usually situs solitus is present, but the ventricles are inverted (an l loop). The great arteries are transposed and in the l position so that the pulmonary artery arises posteriorly from the right-sided morphologic left ventricle and the l-transposed aorta arises anteriorly from the left-sided right ventricle (SLL) (Fig. 63-37). If situs inversus is present, the segmental pattern is IDD.

Along with the ventricular inversion, there is AV valvular inversion. The two coronary arteries arise from the right and left (posteriorly facing) sinuses, with the right-sided coronary artery giving off the anterior descending and circumflex branches.[231]

ASSOCIATED CONDITIONS

Rarely, no associated conditions are present and the circulation is normal. In the majority of cases (about 75 percent), a VSD is present. It may be in any location, but a perimembranous subpulmonary defect is most common.

The inverted left-sided systemic tricuspid valve frequently shows some degree of abnormality, usually leading to incompetence. The most common abnormality is an Ebstein-like displacement of the septal and posterior leaflets, but dysplasia, clefts, and straddling of the ventricular septum also have been described.

Pulmonary atresia or stenosis is present in about 40 percent of cases, usually associated with a VSD.[231] This obstruction is usually subvalvular, is only rarely valvular, and may characteristically result from attachments of accessory mitral valve tissue.

CLINICAL MANIFESTATIONS

Corrected transposition is an uncommon malformation, occurring in slightly fewer than 1 percent of children with congenital heart disease. The importance of this anomaly lies in its frequent association with serious AV conduction disturbances, the intracardiac malformations, and the medical and surgical implications of the ventricular inversion. The clinical picture is determined primarily by the associated anomalies. At least a third of these patients can be expected to develop complete AV block if followed for a 20-year period.[232]

History

A slow, irregular heart rate often is detected in utero, and 10 percent of patients with congenital complete block prove to have corrected transposition. Patients with a large VSD without pulmonary stenosis usually present within the first month or so of life with symptoms indistinguishable from those of infants with a large VSD alone. Patients with VSD and pulmonary stenosis may present with symptoms of cyanosis and resemble patients with tetralogy of Fallot.

Physical Examination

The murmur of left AV valve regurgitation may be best heard either at the apex or at the lower left sternal border. Most of these patients have a murmur of VSD or pulmonary stenosis. Occasionally, an inordinately accentuated second heart sound at the upper left sternal border suggests the presence of PAH, although in reality it represents a loud aortic valve closure resulting from the anterior and superior displacement of the aorta valve.

Chest Roentgenogram

A straight or gently curved convex upper left heart border representing the contour of the transposed ascending aorta is characteristic and is most easily recognized in patients with a VSD and pulmonary stenosis, in whom there is a mild dilatation of the ascending aorta.

Electrocardiogram

Varying degrees of AV conduction delay are present in almost a third of these patients. The initial forces of ventricular depolarization are characteristically oriented anteriorly and to the left, with Q waves in the right precordial leads and not in leads I, V_5, and V_6 resulting from depolarization of the septum from the left side (right ventricle) to the right side (left ventricle). With normal or nearly normal pressure in the systemic venous or morphologic left ventricle, a QS pattern in the right and an RS pattern in the left precordial leads are usual.

Echocardiogram

Using a segmental approach, two-dimensional echocardiography permits identification of the anatomic components and associated defects.[233]

Cardiac Catheterization

When diagnostic catheterization is performed, the morphologic left ventricle is entered from the right atrium, and in the presence of a VSD, the catheter may cross the defect, traverse the morphologic right ventricle, and enter the ascending aorta in the position normally occupied by the pulmonary artery. Entry into the medially placed pulmonary artery may be much more difficult, but the use of flow-guided catheters permits successful entry for the measurement of pressure. Selective angiography in both ventricles will outline the defects. The ventricular septum usually lies in the anteroposterior plane, and frequently a VSD may be imaged best angiographically in the frontal view (Fig. 63-37). Gentle manipulation of the catheter within the heart is indicated, since the production of varying degrees of transient AV block is not uncommon, and in rare instances, the block may prove permanent.

NATURAL HISTORY AND PROGNOSIS

The clinical course is determined primarily by the severity of the associated defects. It is estimated that only about 1 percent of individuals with corrected transposition have an otherwise normal heart. Even with complicating anomalies, survival to adulthood is possible.[234] Congestive heart failure associated with a large VSD has been the most common cause of death, with most fatalities occurring within the first year of life. AV conduction abnormalities tend to be progressive, and complete AV block may appear at any age. Similarly, left AV valve regurgitation may present at any age and significantly alters the long-term outcome.[235] Finally, the morphologic right ventricle may not be capable of sustaining adequate cardiac output over a normal life span.[236]

MEDICAL MANAGEMENT

Management of corrected transposition includes the treatment of congestive failure, cyanosis, and AV block and the prevention of infective endocarditis. Patients with severe pulmonary hypertension or congestive heart failure should undergo early banding of the pulmonary artery or repair of the defect. Similarly, patients with a VSD, severe pulmonary stenosis, and cyanosis benefit from systemic-to-pulmonary artery shunting procedures or total correction. Those with a congenital block require prompt pacemaker therapy. Patients with significant left AV valve regurgitation require valve replacement. Regularly scheduled follow-up examinations are recommended for all these patients to detect progressive AV conduction disorders and the progression or late appearance of left AV valve incompetence. Antibiotic coverage as protection against infective endocarditis is recommended, as is the introduction of an afterload reducer at the first appearance of AV valve regurgitation.[237]

SURGICAL MANAGEMENT

The conventional approach has been correction of the underlying lesion, closure of the ventricular septal defect in those with an isolated VSD, and closure of the VSD and a conduit from the left (pulmonary) ventricle to the pulmonary artery in those with L-TGA, VSD, and PS.[238] Unfortunately, this approach frequently has led to suboptimal results because of a very high incidence of complete heart block, increasing left AV valve regurgitation, and right systemic ventricular dysfunction and heart failure.[235] Despite recent advances, operative mortality rates for VSD or VSD and pulmonary stenosis or atresia remain in the range of 4 to 15 percent with postoperative heart block in 14 to 33 percent.[239,240] The 10-year actual survival was 83 percent in one study[239] and 55 percent in the other.[240] Replacement of the regurgitant left AV valve at the first sign of progressive ventricular dysfunction has been recommended to preserve ventricular function but has been of limited utility.[241]

In view of the less than optimum results with the standard procedures, more innovative approaches have been suggested.[242] For those with a VSD in association with corrected transposition, an arterial switch can be performed and, since this would create complete transposition, an atrial switch as well. This "double-switch" procedure is clearly a much more complex operation but has the advantage of leaving the left ventricle as the systemic ventricle and leaving the problematic tricuspid valve on the right side of the heart.

For those with corrected transposition, a ventricular septal defect, and pulmonary stenosis, the VSD can be closed in a way that diverts the left ventricle into the aorta and the right ventricle via a conduit into the pulmonary artery. Since this also would create transposition physiology, one needs to do an atrial switch by Mustard's or Senning's technique. Although the early mortality for this approach is about 10 percent,[243,244] it is hoped and expected that the long-term results will be superior to those of the more conventional approach.

Single Ventricle

DEFINITION

The univentricular heart, or single ventricle, is characterized by the entire flow from the two atria being carried directly through the left and/or right AV valves into the single ventricular chamber. The double-inlet type of AV connection may take the form of either one common or two separate AV valves; straddling of one AV valve sometimes is included. The VA connections may be concordant (pulmonary artery from right ventricle and aorta from left ventricle), discordant (pulmonary artery from left ventricle and aorta from right ventricle), double-outlet (both great arteries from either the left or the right ventricle), or single-outlet (atresia of one great artery). Alternatively, one of the AV valves may be atretic. This is associated with normally related great vessels or transposition of the great arteries.

PATHOLOGY

A common type of single ventricle is associated with triscupid atresia in which the ventricle has the morphology of a left ventricle. There may be normally related great vessels (type I), D transposition of the great arteries (type II), or L transposition (type III). Depending on the size of the ventricular communication with the hypoplastic right ventricle, there may be pulmonary atresia (A), pulmonary stenosis (B), or no pulmonary stenosis (C).

In a large series,[245] about two-thirds were type I, and of these about two-thirds had pulmonary stenosis (I B). Among the one-third with transposition, the most common variety is without pulmonary outflow obstruction (II C). L transposition accounts for less than 5 percent in almost all series of children with tricuspid valve atresia.

When the mitral valve is severly stenotic or atretic, the left ventricle and aorta are usually hypoplastic or atretic (hypoplastic left heart syndrome). In this situation, it is the right ventricle that is the predominant ventricle. Depending on the severity of the left-sided hypoplasia, the ascending aorta and aortic arch are usually hypoplastic as well.

When there is one large atrioventricular valve or when both AV valves are present, the valve may straddle the ventricular septum, producing one large ventricle and one small ventricle (Fig. 63-38). The most common situation (65 to 70 percent of cases) is that in which the dominant ventricular chamber has the trabecular pattern of a left ventricle and communicates through an opening, the bulboventricular foramen, with a rudimentary right ventricle.[246] The VA connection is discordant (transposition of the great arteries) in about 90 percent of these patients. In about 20 percent of cases, the dominant ventricle shows the trabecular features of a right ventricle and the rudimentary chamber shows those of a left ventricle. The majority of these patients have a double-outlet VA connection from the main chamber, and a smaller number have a single-outlet connection with pulmonary atresia.[246] In 10 to 14 percent, neither ventricular sinus can be identified; this is the so-called primitive ventricle.

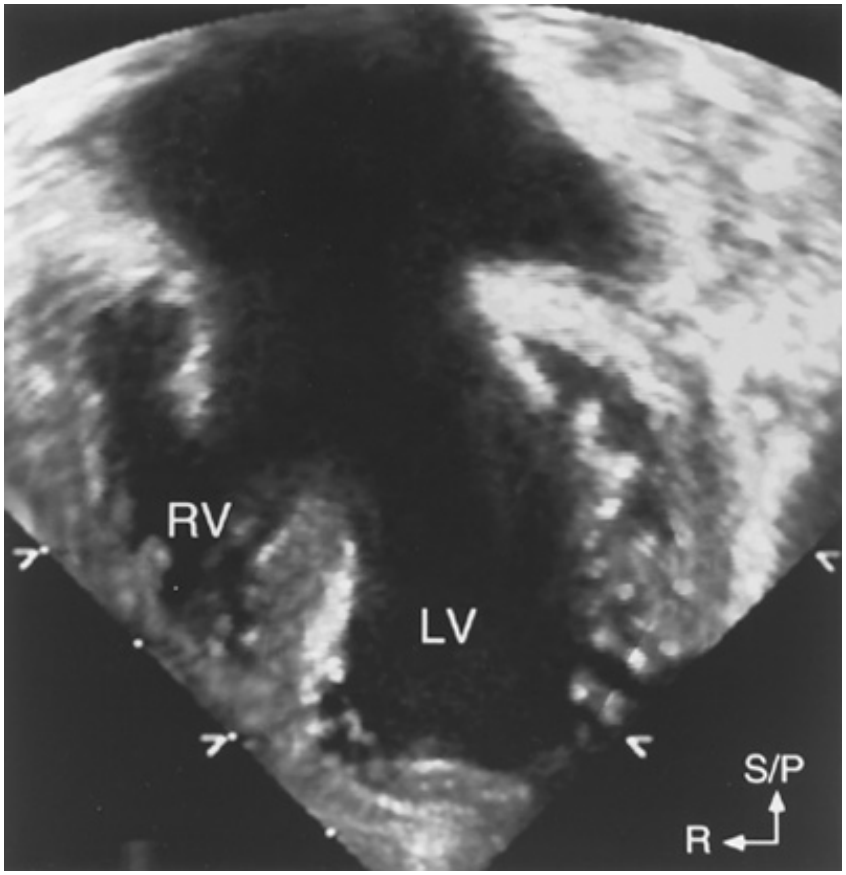

Figure 63-38: A malaligned atrioventricular canal with a large left ventricle (LV) and small right ventricle (RV). This would be repaired by a single ventricle approach (Fontan). (From Levine J and Geva T.[85] Reprinted with permission of the author and publisher.)

The term *Holmes' heart*, which is of historical interest, refers to a double-inlet left ventricle with situs solitus, normally related great arteries (SDS), an absent right ventricular sinus, and a subpulmonary infundibular outlet chamber communicating with the left ventricle via a restrictive bulboventricular foramen.[247]

ASSOCIATED CONDITIONS

Pulmonary stenosis or atresia is common. Subaortic stenosis and coarctation of the aorta occurs in association with L transposition and may result from a narrow bulboventricular foramen. In those with tricuspid or mitral atresia, an atrial communication is present.

CLINICAL MANIFESTATIONS

This complex and challenging malformation is relatively rare. The clinical picture is determined largely by the associated defects, among which pulmonary stenosis or atresia, which is present in a little over half of the patients, and obstruction to aortic flow are the most important.

All these patients have some degree of systemic hypoxemia because of mixing of the two sides of the circulation. If pulmonary stenosis or atresia is present, the presenting symptom is usually cyanosis. Without pulmonary stenosis, the presentation is usually congestive heart failure at 2 to 6 weeks of age as the pulmonary resistance falls. For those with subaortic stenosis and/or coarctation of the aorta, failure can occur within the first days of life as the ductus arteriosus closes. Physical examination depends on the combination of lesions present, but systolic ejection murmurs and a single second heart sound are very common.

Chest Roentgenogram

Almost all these patients have at least some degree of cardiac enlargement. Those with little or no pulmonary stenosis generally have very large hearts with marked pulmonary plethora. Only patients with very severe pulmonary stenosis or atresia show a nearly normal heart size and diminished pulmonary arterial blood flow.

Electrocardiogram

Evidence of right or left ventricular hypertrophy is common depending on which ventricle predominates.

Echocardiography

Two-dimensional echocardiography with Doppler color flow studies can identify the morphologic and functional features of this malformation that are necessary to establish the diagnosis and formulate a plan for clinical management.[248]

Cardiac Catheterization

A degree of systemic arterial oxygen desaturation is present in all these patients, although the severity appears to be related mainly to the volume of pulmonary blood flow. Careful recording of intracardiac and arterial pressures is essential to detect significant or potentially significant obstruction to blood flow across either AV valve, across the atrial septum, or between the ventricle and the aorta or pulmonary artery. The morphologic features of the ventricle, the relation of the aorta and the pulmonary artery, and other features can be established with high-quality selective ventricular angiography, using specially angled views to supplement conventional views.[249]

NATURAL HISTORY AND PROGNOSIS

Since by definition only one ventricle is "usable," treatment must be aimed at preserving the anatomy, physiology, and function to allow this single ventricle to support the circulation and

establishing a method for systemic venous return to go to the lungs without a second pumping chamber.

These patients usually present as newborns with cyanosis, congestive failure, or a combination of both. Those in whom pulmonary arterial pressure and blood flow are increased require surgery to prevent death from congestive heart failure or progressive PVOD. Patients with severe pulmonary stenosis or atresia require systemic-to-pulmonary arterial shunting procedures. Among patients with univentricular heart, there is a propensity for the development of subaortic obstruction[250] and AV valve regurgitation.[251] Both threaten ventricular compliance and diminish the likelihood of successful long-term palliation.[252] Survivors are subject to the threats of infective endocarditis, brain abscess, and progressive PVOD.

MEDICAL MANAGEMENT

Early recognition and identification of patients with these complex defects are important so that successful palliative surgical procedures can be carried out for the relief of congestive failure or cyanosis. PGE_1 is useful in neonates with ductal-dependent defects.[91] An adequate interatrial communication is essential for those with mitral or tricuspid atresia. For those with pulmonary stenosis or atresia, a Blalock-Taussig shunt can be livesaving. Ventricular function and AV valvular competence are preserved by early creation of a bidirectional modified Glenn anastomosis (superior vena cava to undivided pulmonary artery).[253] Subaortic stenosis or obstruction at the bulboventricular foramen can be bypassed by anastomosis of the proximal pulmonary artery to the lateral aspect of the ascending aorta while pulmonary blood flow is delivered to the distal pulmonary arterial tree through a systemic arterial or systemic venous shunt.[254,255] Digitalis and diuretics may be necessary for patients with continuing heart failure. Care should be taken that anemia or severe polycythemia does not develop and that these patients are protected adequately against infective endocarditis. The pulmonary vascular bed must be protected and ventricular function and compliance must be preserved carefully if more definitive procedures are to be considered.

SURGICAL MANAGEMENT

Long-term palliation of children with a single ventricle is usually a three-stage approach: (1) initial palliation in the perinatal period, (2) a bidirectional Glenn at 6 to 18 months of age, and (3) a modified Fontan at 1 to 3 years of age. For complex problems, a heart transplant soon after birth has been suggested.[256]

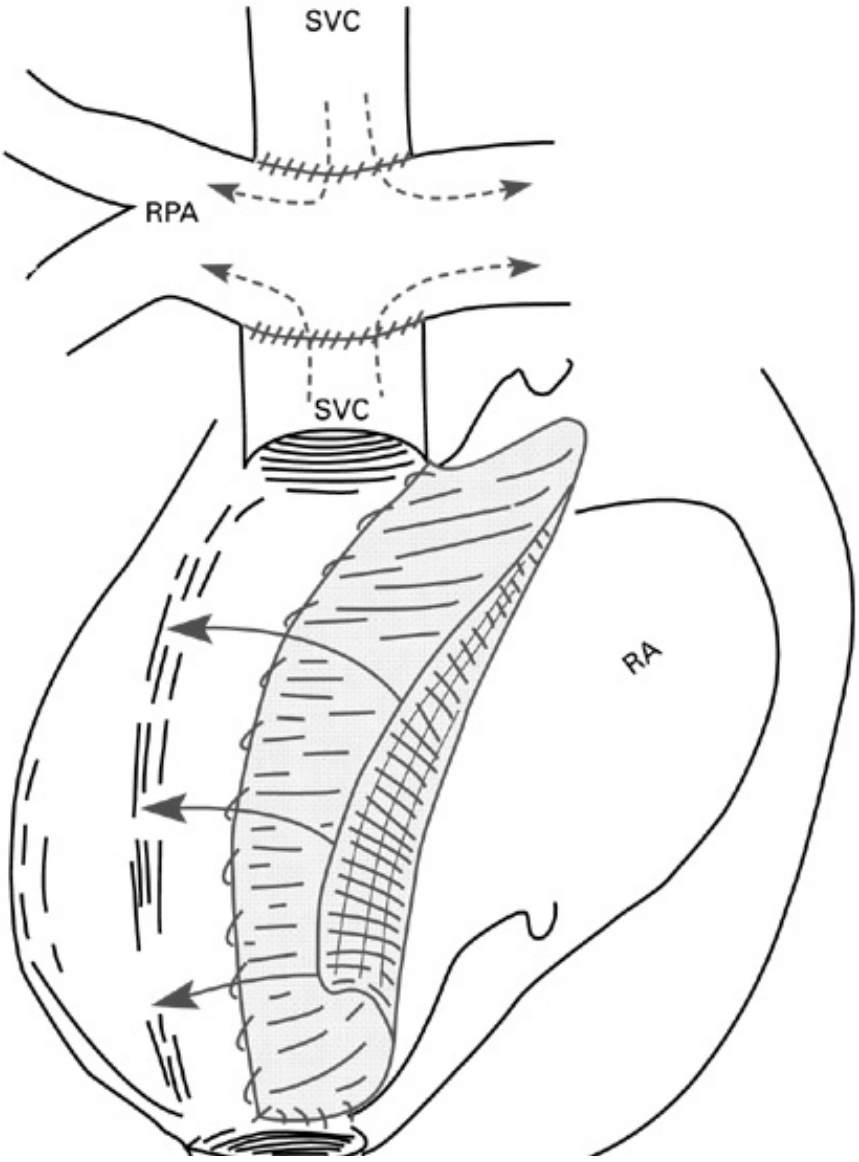
Initial palliation for patients with univentricular AV connections requires adjustment of pulmonary blood flow with a pulmonary arterial band when it is excessive or the creation of a shunt when it is diminished. The modified Blalock-Taussig shunt is preferred in neonates. Relief of aortic stenosis and the creation of an adequate atrial communication frequently are necessary as well. The prognosis is affected adversely by a single ventricle of the right ventricular type[257] and the evolution of AV valvular regurgitation[258] or subaortic obstruction.[259]

Ventricular function and AV valvular competence are preserved by early creation of a bidirectional modified Glenn anastomosis, in which the superior vena cava is divided with the caudad portion patched closed; the cephalad portion is sutured to the top of the right pulmonary artery. If pulmonary atresia is not present, the main pulmonary artery is closed.[260] Subaortic stenosis or obstruction at the bulboventricular foramen can be palliated by anastomosis of the proximal pulmonary artery to the lateral aspect of the ascending aorta, while pulmonary blood flow is delivered to the distal pulmonary arterial tree through a systemic arterial or systemic venous shunt (the Damus-Kaye-Stansel operation). Other surgical options for the relief of subaortic obstruction are direct enlargement of the bulboventricular foramen (VSD), the modified

Norwood operation,[255] and the arterial switch operation.[261]

Although initially some types of single ventricle were repaired by dividing the common chamber into the right and left ventricles, this has largely been abandoned because of unacceptably high initial mortality resulting from problems in connecting the ventricles to the appropriate great vessels without interfering with the atrioventricular valves and the high incidence of complete heart block.

The current approach is a modification of the principal suggested by Fontan and Baudet[262] to bypass the right side of the heart, directing systemic venous blood directly to the pulmonary arteries and allowing the single functioning ventricular chamber to pump blood to the systemic circulation. First, if it has not been done already, a bidirectional Glenn anastomosis is constructed (see above), and then an intraatrial tunnel is constructed to divert the inferior vena caval blood to the caudad portion of the superior vena cava, which then is connected to the underside of the right pulmonary artery (Fig. 63-39). A fenestration in the baffle sometimes is used to decompress the right side in the perioperative period. Recently, instead of tunnelling within the atrium, an external conduit has been used between the inferior vena cava (IVC) and the right pulmonary artery ligating the IVC-right atrial junction. The single ventricle is thus relieved of the burden of the volume overload and ventricular hypertrophy required to maintain the pulmonary circulation and is asked only to deliver systemic cardiac output.[262]



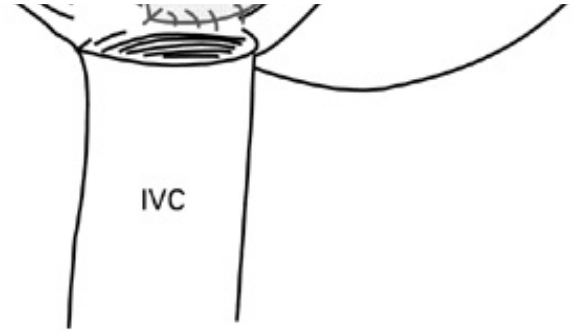


Figure 63-39: The modified Fontan operation. The superior vena cava (SVC) is divided. The cephalad portion is anastomosed to the superior aspect of the right pulmonary artery (RPA), and an intraatrial baffle is constructed from the inferior vena cava (IVC) to the superior vena cava along the lateral wall of the right atrium (RA). The caudad portion of the SVC then is connected to the inferior aspect of the right pulmonary artery.

The surgical risks depend on patient selection. For those with complex forms of single ventricle and those with elevated pulmonary pressure or resistance, ventricular dysfunction, or atrioventricular valve regurgitation, the risks are increased. For those without risk factors and with tricuspid atresia or double-inlet left ventricle, the risks are less than 5 percent.[263] Even for those with some risk factors or with more complex disease, at some centers the mortality is under 10 percent.[263,264]

For children with hypoplastic left heart syndrome, the survival from the three-stage procedure (initial Norwood, bidirectional Glenn, and Fontan) is approximately 50 percent,[265] although some centers are reporting a survival rate as high as 76 percent.[266] There does not seem to be any significant difference in survival in centers that use the three-stage anatomic "repair" from primary heart transplantation in the perinatal period at 36 months of age.[265]

Quality and length of life are clearly improved, but persistent problems (AV valvular regurgitation, systemic embolization, limitation of exercise tolerance, protein-losing enteropathy, atrial arrhythmias, and deterioration of ventricular function) occur with a frequency of about 1 percent per year.[263] For patients with progressive deterioration, cardiac transplantation is recommended.

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

CONGENITAL ABNORMALITIES OF THE CORONARY ARTERIAL CIRCULATION

Coronary Arteriovenous Fistula

PATHOLOGY

A coronary arteriovenous fistula is a fistulous communication between a coronary artery and a cardiac chamber, the coronary sinus, or the pulmonary trunk (Fig. 63-40).

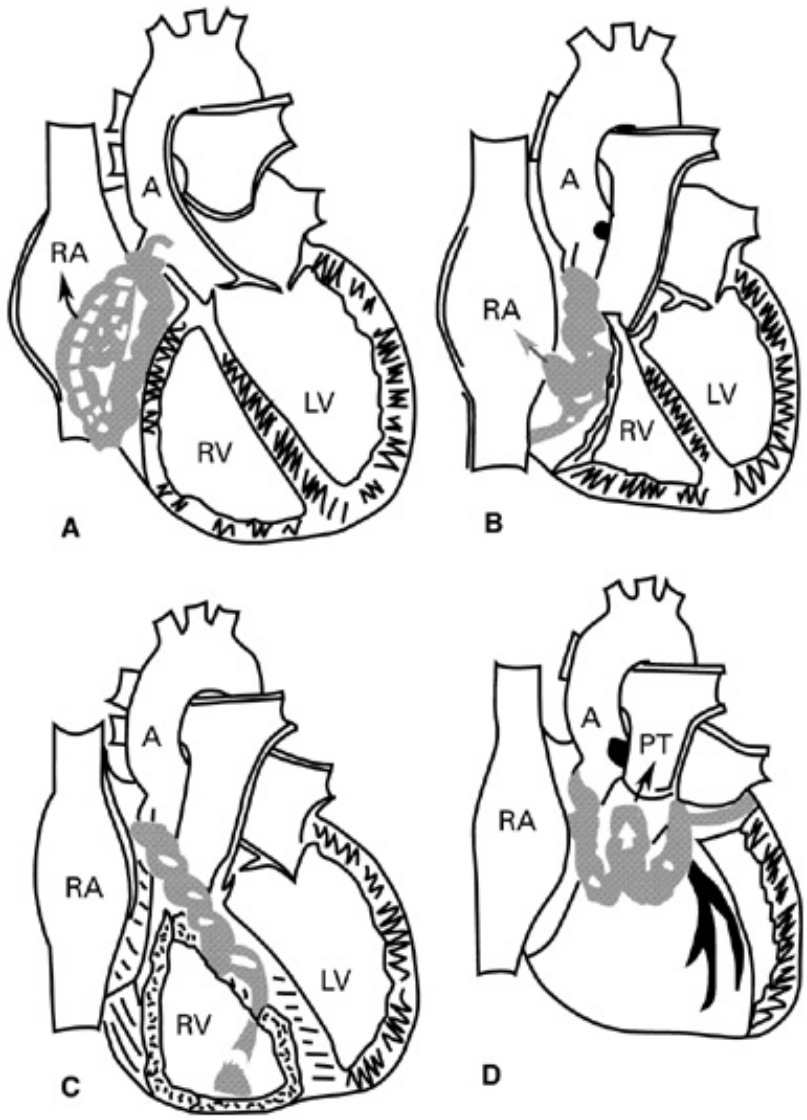

Figure 63-40: Anomalous communications of coronary arteries. *A.* Right coronary artery communicates with coronary sinus. *B.* Right coronary artery communicates with right atrium (RA). *C.* Anomalous communication of right coronary artery with right ventricle (RV). *D.* Two

coronary arteries arise from the aorta (A) and make collateral communication with accessory coronary artery arising from pulmonary trunk (PT). LV = left ventricle.

The site of origin may involve any of the epicardial coronary arteries. *The right coronary artery is the site of origin in somewhat over half the cases, and the two most common sites into which the fistula feeds are a cardiac vein (usually the coronary sinus) and the right ventricle*. Although solitary communication is the rule, there may be multiple sites of termination. A fistula into the pulmonary trunk usually is characterized by one or more vessels opening into the pulmonary trunk and connecting with branches of each of the two main coronary arteries. The artery or arteries feeding the fistula are grossly enlarged and tortuous. Saccular aneurysms may develop in segments of dilated vessels; such aneurysms usually are observed in adults and frequently show calcification of the wall.

CLINICAL MANIFESTATIONS

Many patients with a coronary arteriovenous fistula are asymptomatic.[267,268] In some, the magnitude of the shunt into the right side of the heart is great enough to cause congestive heart failure, with a tendency for this to occur in early infancy or after 40 years of age. The classic finding is that of a continuous murmur with an unusual location, since it is loudest over the fistula. It may have a louder diastolic component, especially if communication is with the right ventricle. In those with large shunts, there may be cardiomegaly and increased pulmonary flow shown by chest roentgenography and right ventricular hypertrophy shown by ECG. Transthoracic echocardiography is usually diagnostic in children;[269] transesophageal studies may be necessary in adults. At cardiac catheterization, an increase in oxygen saturation may be encountered, usually in the right atrium or right ventricle, if the shunt is large enough. Selective coronary arteriography will demonstrate the involved coronary artery and the site of entry of the fistula. The most common complication is infective endocarditis, but thrombosis, myocardial ischemia, and rupture may occur.

SURGICAL MANAGEMENT

Except for very small fistulas, closure is recommended, since the flow tends to increase with age and these patients are at risk for infective endocarditis, congestive heart failure, and myocardial ischemia. Until relatively recently, closure was invariably surgical. Occasionally, closure was done without a coronary bypass by placing obliterating mattress sutures across the fistula beneath the coronary artery as it passes over the surface of the heart.[270] More commonly, cardiopulmonary bypass is preferred for safe exposure of large or multiple fistulas, such as those entering the right atrium near the junction of the superior vena cava and the right atrium, those arising from the artery to the sinoatrial node, and those between the left coronary artery and the left ventricle.[271] The orifice of the fistula is obliterated by direct suture or the placement of a Dacron or pericardial patch. Fistulas have been closed from within the open coronary artery; the artery then is repaired by direct suturing. Surgical mortality should be minimal;[271] the long-term results have been favorable.[272]

Fistulas have been closed by interventional catheterization techniques. Perry and associates[273] attempted to close fistulas in nine patients: four from the left circumflex artery, three from the left anterior descending artery, and two from the right coronary artery. Gianturco coils were used in six patients and a double-umbrella in two, with coils and an umbrella used in one. All were completely occluded. In three patients with multiple fistulas, no attempt was made in the catheterization laboratory and the patients were referred for surgery. This "noninvasive" technique seems to be applicable to some children and adults with coronary AV fistulas, although long-term follow-up is necessary to be certain that the fistulas do not recur.

Origin of the Left Coronary Artery from the Pulmonary Artery

PATHOLOGY AND PATHOPHYSIOLOGY

In this anomaly, the left coronary artery arises from the pulmonary artery rather than from the aorta (Fig. 63-41). In the perinatal period, the pulmonary artery pressure is high and the left coronary is perfused with venous blood. Problems arise when the pulmonary resistance and pulmonary artery pressure fall and the diastolic pressure is insufficient to perfuse the left ventricular myocardium. In the absence of collateral vessels from the right coronary, left ventricular ischemia and eventually infarction of the left ventricular wall and papillary muscles occur. This in turn leads to congestive heart failure, usually by 3 to 8 weeks of age.

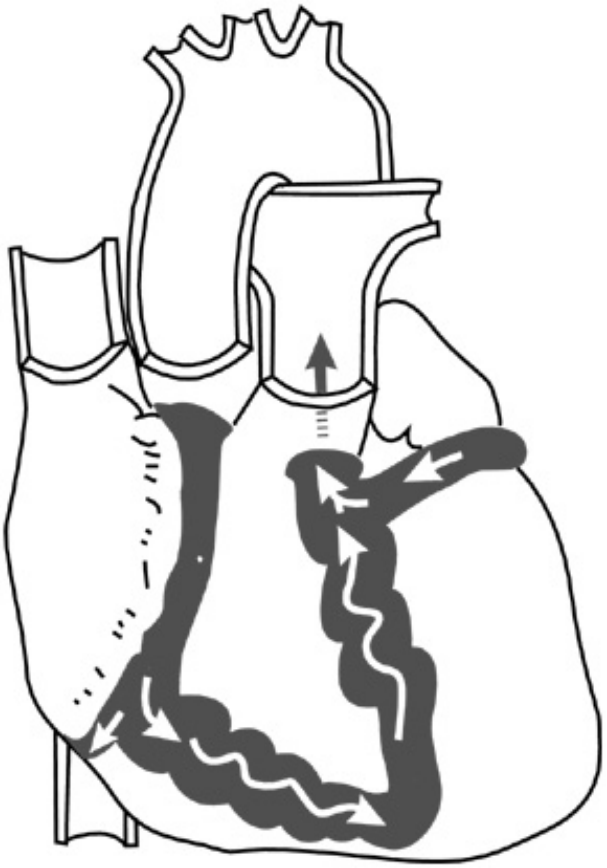

Figure 63-41: Anomalous origin of the left coronary artery from the pulmonary trunk. With time, wide collaterals develop between the two coronary systems so that right coronary arterial blood is shunted into the left coronary system and thence into the pulmonary trunk.

In a small group of children, extensive collaterals between the right coronary (arising normally from the aorta) and the left system develop. Perfusion via the right may be sufficient to oxygenate the left ventricular myocardium so that no ischemia develops. Over time, the higher perfusion pressure in the aorta may allow a left-to-right shunt into the pulmonary artery through the right and then the left coronary system. Eventually this may lead to a "steal" of blood from the myocardium into the lower-resistance pulmonary circuit.

CLINICAL MANIFESTATIONS

The clinical spectrum and mode of presentation in patients with this abnormality vary.[274,275] The majority of these patients present at 6 to 12 weeks of age. Acute episodes of irritability, profuse cold sweating, pallor (? angina), and respiratory distress occur, with evidence of heart failure. Less

often, these patients present at an older age with mitral regurgitation and heart failure. A few reach adolescence or adulthood with no or relatively few symptoms other than occasional exertional angina or palpitations. Sudden death may be the first and only sign of this condition.

On physical examination, the heart is enlarged, with an abnormal left ventricular apex impulse. Other signs of failure are usually present. Pallor and clammy skin are common. In some patients, a soft continuous murmur is heard at the upper left sternal border. This murmur is more prominent in older patients, presumably because of the development of a more extensive collateral circulation. The murmur of mitral regurgitation may be heard at the apex, radiating to the axilla; however, in young infants with heart failure, there can be a surprising degree of regurgitation without a distinctive murmur.

In those with heart failure, the chest roentgenogram typically shows marked enlargement of the heart with posterior displacement of the esophagus by a large left atrium. There is pulmonary edema, and there may be atelectasis of the left lower lobe because of bronchial compression. Those with good collaterals and no left ventricular failure may have a normal x-ray.

In the infant group, the ECG demonstrates the pattern of anterolateral infarction, with deep Q wave in leads I and aV_L and abnormal R-wave progression across the precordium. Arrhythmias are common. The horizontal loop of the vectorcardiogram is clockwise and posteriorly oriented. The echocardiogram shows marked enlargement of the left atrium and ventricle with little or no left ventricular wall motion. The origin of the coronary artery can be imaged, and flow can be seen toward the pulmonary artery instead of toward the heart.[276] Myocardial perfusion imaging with thallium-201 can help distinguish an anomalous coronary artery from congestive cardiomyopathy.[277]

At cardiac catheterization, there may be an increase in saturation in the pulmonary artery if there is enough retrograde flow. There is usually some pulmonary hypertension, with very elevated pulmonary wedge pressure. Aortography or selective right coronary arteriography demonstrates the collateral circulation filling the left coronary artery retrogradely, with at least faint opacification of the main pulmonary artery.

MANAGEMENT

The natural history and prognosis are related by the modes of presentation. Those who present in infancy die without surgical intervention. Medical management is aimed at control of congestive heart failure and arrhythmias before a surgical procedure.

Four approaches have been used for surgical repair. The first, which is of historical interest only, is ligation of the left coronary artery to eliminate the coronary artery-to-pulmonary artery shunt that acts as a coronary artery steal. Many children benefited from this procedure, but there continued to be myocardial ischemia and late sudden death was not eliminated. The second approach was to tunnel the coronary artery inside the pulmonary artery to the wall of the aorta and create an aortopulmonary window.[278] This usually required an external roofing of the pulmonary artery to allow egress of flow from the right ventricle. Although this surgical approach has the advantage of making a two-coronary system, a high proportion of children developed supravalvular pulmonary stenosis at the site of the intrapulmonary artery tunnel. This procedure is now used rarely. More recently, as coronary artery reimplantation has become more common in the arterial switch operation for transposition of the great arteries, surgeons have removed the anomalous coronary artery with a button of pulmonary artery and reimplanted it onto the aorta.[279] Finally, in a few older patients, saphenous vein grafting or internal mammary artery implantation has been used.[280]

The late results after surgery have been quite good.[279,281] The congestive heart failure frequently

improves, the heart becomes smaller, the left ventricular shortening fraction improves, and mitral regurgitation tends to regress. Interestingly, the infarction pattern on ECG with deep anterolateral Q waves frequently disappears, suggesting that the poor function is due to extreme ischemia rather than infarction (hybernating myocardium).[282]

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

List of Figures

Figure 63-8: Types of interatrial communications. *A*. Large ostium secundum type of atrial septal defect. *B*. So-called sinus venosus type of defect-one high in the atrial septum associated with anomalous connection of the right superior pulmonary vein to the junctional area of the superior vena cava and right atrium. *C*. Very large ostium secundum type of atrial septal defect with absence of the posterior rim. *D*. Partial form of common atrioventricular canal with cleft mitral valve. SVC = superior vena cava; RPVs = right pulmonary veins; IVC = inferior vena cava. (From Lewis FJ et al.[65] Copyright 1957, American Medical Association. Reproduced with permission from the publisher and authors.)

Figure 63-9: Atrial septal defect at fossa ovalis with left-to-right shunt. SVC = superior vena cava; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; PT = main pulmonary arterial trunk; RPA = right pulmonary artery; LPA = left pulmonary artery; RPV = right pulmonary vein; LPV = left pulmonary vein; LA = left atrium; LV = left ventricle; AO = aorta. (From Edwards JE.[66] Reproduced with permission from the publisher and author.)

Figure 63-10: Chest roentgenogram of a 4-year-old child with a secundum atrial septal defect, a large left-to-right shunt, and normal pulmonary arterial pressures. *A*. Frontal. *B*. Lateral. Right ventricular enlargement (seen in the lateral view) accompanies prominence of the main pulmonary arterial segment and increased blood flow. No left atrial dilation is present.

Figure 63-11: Three-dimensional echocardiogram of a secundum atrial septal defect (ASD). This is a right atrial en-face view that shows the size, shape, and position of the defect in relation to the right atrial septal surface. Ao = aortic valve; TV = tricuspid valve; IVC = inferior vena cava. Courtesy of Dr. Gerry Marx.

Figure 63-12: *A*. Sinus venosus type of atrial septal defect, with its constantly accompanying anomalous pulmonary venous connection of superior pulmonary vein (SPV) to superior vena cava (SVC). *B*. Repair is effected with a pericardial patch placed to divert pulmonary venous blood across the defect into the left atrium and to divert superior vena caval blood to the right atrium. (This illustration appeared originally in the first edition of *The Heart*, in 1966, and in all subsequent editions. It is reproduced here by courtesy of Dr. John W. Kirklin, Birmingham, Alabama.)

Figure 63-13: Common AV canal of the partial type. The mitral valve shows a cleft in its anterior leaflet, while the tricuspid valve is undisturbed. SVC = superior vena cava; IVC = inferior vena cava; RA = right pulmonary artery; LPA = left pulmonary artery; RPV = right pulmonary vein; LPV = left pulmonary vein; LV = left ventricle; Ao = aorta. (From Edwards JE.[66] Reproduced with permission from the publisher and author.)

Figure 63-14: Complete form of common AV canal, type A. The common anterior leaflet has a recognizable mitral component (MV) and tricuspid component (TV). In type B, not illustrated, those components are attached by chordae to a papillary muscle in the right ventricle. In type C, not illustrated, the common anterior leaflet is a single unit without any attachment to the underlying ventricular septum. Type A is most amenable to repair. RV = right ventricle; RA = right atrium. (From Rastelli GC et al.[82] Reproduced with permission from the publisher and authors.)

Figure 63-15: Apical four-chamber view of complete common AV canal. Note the large deficiency of both atrial and ventricular septa as well as apical displacement of the AV valves. The arrow points to the attachment of the inferior bridging leaflet to the ventricular septal crest. (From Levine J and Geva T.[85] Reproduced with permission.)

Figure 63-16: Steps in the repair of the complete form of common AV canal, type A. *A* and *B*. A pericardial patch is sutured to the ventricular septum. *C* and *D*. The anterior leaflet of the mitral valve is reconstructed and attached to the patch. A portion of the tricuspid leaflet is attached to the patch. (From Rastelli GC et al.[82] Reproduced with permission from the publisher and authors.)

Figure 63-28: *A.* Lateral view of a right ventricular (RV) angiogram demonstrating the typical features of valvular pulmonary stenosis with doming of the pulmonary valve (*arrow*) and a narrow jet of contrast entering the dilated main pulmonary artery (MPA). *B.* An 18-mm balloon is inflated across the 14-mm annulus. A moderate waist is seen at 1 atmosphere of pressure. *C.* The waist is eliminated at 4 atmospheres of pressure. (From Lock JE, Keane JF, Perry SB. *Diagnostic and Interventional Catheterization in Congenital Heart Disease.* 2d ed. Boston: Kluwer; 2000.)

Figure 63-29: Classic tetralogy of Fallot. There are infundibular and pulmonary valvular stenoses. There is also right-to-left shunting at the atrial level. SVC = superior vena cava; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; RPA = right pulmonary artery; LPA = left pulmonary artery; RPV = right pulmonary vein; LPV = left pulmonary vein; LA = left atrium; LV = left ventricle; Ao = aorta. (From Edwards.[66] Reproduced with permission from the publisher and author.)

Figure 63-30: Two-dimensional echocardiogram in parasternal view in a patient with Ebstein's anomaly of the tricuspid valve (TV). Numerous attachments of the tricuspid valve (*arrowheads*) to the interventricular septum and right ventricular apex are seen. LV = left ventricle; LA = left atrium.

Figure 63-31: Danielson repair of Ebstein's malformation. *A.* Anterior cutaway drawing. The atrial septal defect is closed securely with a patch. Pledgeted sutures are placed to position the posterior leaflet at the annulus and imbricate the "atrialized" right ventricular chamber. *B* and *C.* Drawing of the right atrium showing the annuloplasty suture passed through two pledgets. Tying of this suture reduces dilation of the tricuspid valve so that the large anterior leaflet can meet the two smaller cusps and constitute a functional, essentially monocusp valve.

Figure 63-32: Three common types of total anomalous pulmonary venous connection. *A.* Total anomalous pulmonary venous connection to the left brachiocephalic (innominate) vein (LI). *B.* Total anomalous pulmonary venous connection to the coronary sinus (CS). *C.* Total anomalous pulmonary venous connection of the infradiaphragmatic type to the ductus venosus (DV). RA = right atrium; RV = right ventricle; LA = left atrium; LV = left ventricle.

Figure 63-33: Complete D transposition of the great arteries. *A.* With intact ventricular septum. A patent foramen ovale and enlarged bronchial arteries (Br. Art.) are present. *B.* With ventricular septal defect and without pulmonary stenosis. SVC = superior vena cava; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; Ao = aorta; LA = left atrium; LV = left ventricle.

Figure 63-34: *A.* Two-dimensional echocardiogram. The left ventricle leads to a bifurcating great vessel (pulmonary artery, PA), confirming transposition. *B.* Anterolateral projection of an angiogram in the smooth-walled left ventricle (LV). The dye is ejected into the pulmonary artery.

Figure 63-35: Surgical technique of the arterial switch operation. *A.* Aortic cannula is positioned distally in the ascending aorta, the ductus arteriosus is divided between suture ligatures, and the branch pulmonary arteries are dissected out to the hilum to provide adequate mobility for anterior translocation. The broken lines represent the levels of transection of the aorta and the main pulmonary artery. Marking sutures are placed in the anticipated sites of coronary transfer. *B.* Transection of the great arteries. The left ventricular outflow tract, neoaortic valve, and coronary arteries are inspected thoroughly. *C.* The coronary arterial buttons are excised from the free edge of the aorta to the base of the sinus of Valsalva. *D.* The coronary buttons are anastomosed to V-shaped excisions made in the neoaorta. *E.* The pulmonary artery is brought anterior to the aorta (Lecompte maneuver). Anastomosis of the proximal neoaorta is shown. *F* and *G.* The coronary donor sites are filled with autologous pericardial patches. A single U-shaped patch (*F*) or two separate patches (*G*) may be used. *H.* Completed anastomosis of the proximal neopulmonary artery and the distal pulmonary artery. (Modified from Castaneda AR. Anatomic correction of transposition of the great arteries at the arterial level. In: Sabiston

DC Jr, Spencer FC, eds. *Surgery of the Chest.* 5th ed. Philadelphia: Saunders; 1990. Reproduced with permission from the authors and publisher.)

Figure 63-36: Double-outlet right ventricle. *A.* With subaortic ventricular septal defect without pulmonary stenosis. *B.* With subaortic ventricular septal defect and subpulmonary stenosis (Subpul. stenosis). *C.* With subpulmonary, supracristal ventricular septal defect. The so-called Taussig-Bing complex. RA = right atrium; RV = right ventricle; CS = crista supraventricularis; LA = left atrium; PT = main pulmonary arterial trunk.

Figure 63-37: *A.* Posteroanterior view of the left ventricular (LV) angiogram in a child with corrected transposition of the great arteries. The main pulmonary artery (MPA) arises from the smooth-walled left ventricle, which receives the systemic venous blood. *B.* Posteroanterior view of the right ventricular angiogram (RV). The ascending aorta (AO) arises to the left of the pulmonary artery from the more heavily trabeculated right ventricle, which receives the pulmonary venous blood. The ventricular septum, seen here perpendicular to the frontal plane, is intact.

Figure 63-38: A malaligned atrioventricular canal with a large left ventricle (LV) and small right ventricle (RV). This would be repaired by a single ventricle approach (Fontan). (From Levine J and Geva T.[85] Reprinted with permission of the author and publisher.)

Figure 63-39: The modified Fontan operation. The superior vena cava (SVC) is divided. The cephalad portion is anastomosed to the superior aspect of the right pulmonary artery (RPA), and an intraatrial baffle is constructed from the inferior vena cava (IVC) to the superior vena cava along the lateral wall of the right atrium (RA). The caudad portion of the SVC then is connected to the inferior aspect of the right pulmonary artery.

Figure 63-40: Anomalous communications of coronary arteries. *A.* Right coronary artery communicates with coronary sinus. *B.* Right coronary artery communicates with right atrium (RA). *C.* Anomalous communication of right coronary artery with right ventricle (RV). *D.* Two coronary arteries arise from the aorta (A) and make collateral communication with accessory coronary artery arising from pulmonary trunk (PT). LV = left ventricle.

Figure 63-41: Anomalous origin of the left coronary artery from the pulmonary trunk. With time, wide collaterals develop between the two coronary systems so that right coronary arterial blood is shunted into the left coronary system and thence into the pulmonary trunk.

Part 10: CONGENITAL HEART DISEASE
Chapter 64:

CONGENITAL HEART DISEASE IN ADULTS

Authors: Carole A. Warnes, John E. Deanfield

Congenital heart disease occurs in 5 to 10 per 1000 live births.[1] Without early treatment, the majority of patients would die in infancy or childhood, with only 5 to 15 percent surviving until puberty.[2] The advent of surgical procedures, from ligation of a patent arterial duct[3] in 1939 to the innovations of the 1990s, as well as advances in medical treatment, has transformed the outlook for children with even complex defects. The majority now survive into adolescence and adult life (Chap. 63). This success story has radically altered both the size and complexity of the population of young adults with congenital heart disease. In the United States alone, well over a half-million patients with functionally important congenital cardiac malformations have reached adulthood in the past three decades.[4] Despite the fact that most patients now surviving to adult life will have undergone surgery during childhood, "total correction" is not the rule.[5] The term *total correction* is itself a misnomer, perhaps with the exception of the successfully ligated ductus arteriosus without residua. The misperception of "cure" leads adults not to seek understanding of their anomaly, to fail to follow endocarditis prophylaxis, and to fail in pursuing continued cardiac care. The majority, if not all, require long-term surveillance, and many need reoperation. Other adults may require their first operation for congenital heart lesions that were well tolerated during childhood.

Both the "natural" survivors and the postoperative patients require specialized medical care. Arrhythmia is common, as are residual or deteriorating hemodynamic problems and endocarditis. Although cardiologists specializing in the care of adults may be expert in one or more of these areas, the critical relationship between rhythm and hemodynamic status in hearts with complex circulations (as after a Fontan operation or after intraatrial repair for transposition) may lead to treatment errors by those inexperienced in the treatment of congenital heart defects. Patients with cyanosis require special care because of erythrocytosis, bleeding, renal problems, and arthropathy; moreover, they require specific counseling and management regarding pregnancy. In addition to the medical problems, psychosocial problems such as the search for employment, life and health insurance, participation in sports, sexual activity, and contraception are of great importance to adolescents and young adults with congenital heart disease. Many of the "normal" ordeals of growing up are more difficult for this group, in whom chronic illness, embarrassing scars, and/or exercise limitation may inhibit normal social intercourse and maturation.

Over the last few years, the specialist needs of this growing population have begun to be appreciated. In addition to the challenge of continuing the expert care of their complex cardiac problems from the pediatric environment into the much wider adult medical community, knowledge of the long-term fate of patients with congenital heart disease is essential for pediatric cardiologists in order to refine initial management strategy. A rather short-term view of "success" or "failure" has been encouraged by rapid changes in medical and surgical policies over the last three decades. Nevertheless, there are clear examples, such as the management of transposition of the great arteries, where awareness of long-term problems has altered the primary surgical approach. The Mustard or Senning procedures (see below) provide a physiologic repair at acceptably low risk but may result in long-term systemic ventricular dysfunction, arrhythmias, and sudden death. This has enabled the introduction of anatomic repair by the arterial-switch procedure, despite high surgical mortality in the early series, with the expectation of a more satisfactory long-term outcome. Other debates, over such issues as the place of Fontan operations, cavopulmonary anastomosis, and systemic-to-pulmonary shunts, are not yet resolved and will be strongly influenced by the accumulation of rigorously collected outcome data, not merely for survival but also for morbidity and quality of life.

The optimal solutions for delivery of care to the adult with congenital heart disease will depend on the different medical systems in operation around the world. The common requirements include collaboration between pediatric and adult cardiologists; the establishment of a few specialist centers with appropriate medical, surgical, anesthetic, and nonmedical staff together with investigational facilities; the establishment

of treatment guidelines, and centralization of accumulating knowledge.[6] The report of a consensus conference on adult congenital heart disease commissioned by the Canadian Cardiovascular Society represents an important step forward.[7] This includes recommendations for training and a hierarchy of care from the community to the specialist center. Similar training guidelines have been published in the United States.[8]

MEDICAL CONSIDERATIONS

Many young adults with congenital heart disease have mild lesions that have not required and may not ever require surgery. The commonest defects in this category are small ventricular septal defect, mild pulmonary valve stenosis, mild aortic valve stenosis, and mitral valve prolapse (Table 64-1). Such patients need infrequent follow-up (e.g., biannual) to assess any progression in severity of the lesion, to reinforce the need for antibiotic prophylaxis against infective endocarditis (Chap. 73), and to obtain psychosocial advice. Other patients reach adult life with more complex defects that are still unrepaired. Some may still be candidates for palliative or definitive surgery, whereas in others surgery may no longer be possible, often because of the presence of irreversible pulmonary vascular disease. More and more survivors of surgery in childhood are now reaching adult life; they now form the largest group of patients (Table 64-2). The majority need continuing medical surveillance, since late cardiovascular problems may result from hemodynamic disturbances, arrhythmia, and endocarditis. Such patients can also develop noncardiac problems as a consequence of their heart disease (e.g., secondary to cyanosis) and are, of course, susceptible to all the potential acquired "medical problems" of adulthood.

Table 64-1: Common Congenital Heart Defects Compatible with Survival to Adult Life without Surgery or Interventional Catheterization

Mild pulmonary valve stenosis
Peripheral pulmonary stenosis
Bicuspid aortic valve
Mild subaortic stenosis
Mild supravalvar aortic stenosis
Small atrial septal defect
Small ventricular septal defect
Small patent ductus arteriosus
Mitral valve prolapse
Ostium primum atrial septal defect (atrioventricular septal defect)
Marfan's syndrome
Ebstein's anomaly
Corrected transposition (atrioventricular-ventriculo-arterial discordance)
Balanced complex lesions (e.g, double-inlet ventricle with pulmonary stensosis)
Defects with pulmonary vascular obstructive disease (Eisenmenger's syndrome)

Table 64-2: Common Congenital Heart Defects Surviving to Adult Life after Surgery/Interventional Catheterization

Aortic valve disease, valvotomy or replacement
Pulmonary stenosis, valvotomy
Tetralogy of Fallot
Atrial septal defect
Ventricular septal defect
Atrioventricular septal defect
Transposition of the great arteries, atrial redirection
Complex transposition of the great arteries
Total anomalous pulmonary venous connection
Pulmonary atresia/ventricular septal defect
Fontan operation for complex congenital heart disease
Ebstein's anomaly
Coarctation of the aorta
Mitral valve disease

Hemodynamics

Study of the hemodynamic consequences of repaired and unrepaired congenital heart disease is a crucial aspect of long-term follow-up. Progressive congestive cardiac failure secondary to myocardial deterioration is the most common cause of disability and death in patients whose ventricles may have been subjected to many years of volume and pressure loading, often with chronic hypoxia. A significant number of the adult postoperative patients with congenital heart disease have been repaired at older ages than is the current practice. This may result in greater preoperative damage and pulmonary vascular disease, which may persist postoperatively. In the early era of open-heart surgery, myocardial protection was sometimes less than optimal, resulting in myocardial damage.

It should also be appreciated that postoperative circulations created by the repair of many congenital heart defects result in an adequate physiologic repair (e.g., deoxygenated blood to lungs and oxygenated blood to the body) but often have far from normal anatomy. For example, after the Mustard and Senning operation for transposition of the great arteries, the right ventricle remains on the systemic side of the circulation. Some of these patients have evidence of deteriorating right ventricular function, and there is increasing concern that this will become a major life-threatening problem with longer follow-up.[9] Similar concerns have been expressed for systemic ventricular function after the Fontan operation.[10] The different morphologic characteristics and loading conditions for these ventricles suggest that standard indices of ventricular function, derived from studies of structurally normal hearts, may be inappropriate for such patients (see also Chap. 20).[11] Prospective serial studies are beginning to define "normal ranges" for congenital heart defects and to examine their "natural" and "unnatural" history.[12]

Residual hemodynamic defects are often present in repaired patients and may cause problems even many years after surgery. These may be amenable to further surgery (see below) or require long-term medical treatment. Medical management of cardiac failure in patients with congenital heart disease is adopting therapies shown to be of benefit in large-scale clinical trials of patients with heart failure from predominantly cardiomyopathy or ischemic heart disease.[13-15] Appreciation of ventricular "remodeling" and the effect of neurohumeral responses on symptoms and disease progression has led to increasing and earlier use of angiotensin-converting enzyme inhibitors and, in some cases, beta blockers and long-acting calcium antagonists in addition to standard therapy with digoxin and diuretics (see Chap. 21). These agents

may also slow the rate of progressive deterioration in ventricular function reported in certain congenital heart diseases even when they have been adequately "corrected."

Cyanosis

Adults with congenital heart disease may have central cyanosis from right-to-left shunting secondary to their unrepaired cardiac defect or to pulmonary vascular disease (Eisenmenger's syndrome; see Chap. 63). The latter complication should be seen less frequently in years ahead as a result of the trend toward early recognition and repair of congenital heart disease in infancy. Currently, however, a significant number of patients reach adult life with pulmonary vascular disease as a result of lesions such as large ventricular septal defect, atrioventricular (AV) septal defect, truncus arteriosus, and double-outlet right ventricle. Their pulmonary vascular resistance may already have been too high for surgical repair at the time of diagnosis; in others, pulmonary vascular disease may have progressed despite repair of the congenital heart defect.

Chronic cyanosis may lead to erythrocytosis and hyperviscosity. Many patients with cyanotic congenital heart disease establish a stable high hematocrit but few symptoms of hyperviscosity.[16] They have a low risk of stroke and do not require venesection.[17] In others, the hemoglobin concentration may rise progressively. Once it exceeds 20 g/dL, they are at risk from thromboembolic complications and may suffer from headache, dizziness, and fatigue. Symptoms may be improved with judicious venesection by the removal of 500 mL of blood and volume replacement with normal saline or dextrose solution.[17,18] Overzealous venesection, however, may result in both acute and chronic problems, including cardiovascular collapse in patients with Eisenmenger's syndrome, iron depletion, microcytosis, and hyperviscosity in its own right.[19] The paradoxical anemia of erythrocytotic patients with iron deficiency due to repeated phlebotomy may be missed and indeed has been shown to increase the risk of stroke.[20] It has been demonstrated that phlebotomies and microcytosis were strongly associated with stroke, perhaps due to the fact that iron-deficient red blood cells are less deformable than are normal red blood cells and do not pass through the microcirculation as readily as do iron-replete cells.

Patients with chronic cyanosis also develop defective hemostasis from abnormalities in platelet function and in the coagulation and fibrinolytic systems,[19,20] especially patients with marked erythrocytosis. The risk of hemorrhage, especially at surgery, is well recognized and may be fatal. Hyperuricemia is common because of increased red cell turnover and renal dysfunction. Arthralgia is well recognized, but gouty arthritis is rare and may be misdiagnosed. Renal impairment can deteriorate to renal failure as a result of relatively minor interventions, such as injection of contrast medium at angiography or the injudicious use of nonsteroidal anti-inflammatory agents.[21,22] Patients with right-to-left shunts are at risk of paradoxic embolus, which may cause a cerebrovascular accident or renal infarction. Air filters must be utilized with all intravenous lines. A cerebral abscess is a well-known complication of a septic embolus and must always be considered in the cyanotic patient with any neurologic symptoms, however transient, or low-grade fever. Facial and truncal acne is common, and is not only a cosmetic problem but a potential source of sepsis. A specific concern has been the safety of air travel in adults with cyanotic congenital heart disease, since in-flight atmospheric conditions on commercial jets approach altitude equivalents of 6000 to 8000 ft (1829 to 2438 m). In a recent report, however, only modest (approximately 6 percent) decreases in systemic arterial oxygen saturation were found, with no adverse effects.[23]

Progressive kyphoscoliosis has been recognized for many years as a complication of congenital heart disease.[24] It is common in cyanotic patients and those with previous thoracotomy. The degree of deformity, if left untreated, may become profound and compromise pulmonary function. Treatment with bracing or insertion of a Harrington rod may be indicated, since the kyphoscoliosis may significantly reduce both the quality and quantity of life. Surgical repair is not possible, however, in those with Eisenmenger's syndrome, since the surgical risk is too high.

The prognosis for patients with Eisenmenger's syndrome depends on the site of the lesion and the medical and cardiac care they receive.[25-27] Death may result from right-sided heart failure, pulmonary hemorrhage, or arrhythmia. It can also occur prematurely due to potentially avoidable complication, such as inappropriate drug therapy or injudicious general anesthesia. Special care must be employed during noncardiac surgery, utilizing cardiac anesthesia, maintenance of preload, and cardiac monitoring.[28] Recent data suggest promise for chronic prostacyclin therapy in reducing pulmonary artery pressure, but this is

preliminary.[29]

Infective Endocarditis

Patients with both unoperated and operated congenital heart disease are at risk from infective endocarditis. Lifelong antibiotic prophylaxis is recommended, but the specific indications and optimal regimens are still debated.[30,31] The American Heart Association Special Report on Prevention of Infective Endocarditis has stratified risk groups for the various lesions.[31] Prophylaxis is advocated for all lesions except isolated secundum atrial septal defect and repaired secundum atrial septal defect, ventricular septal defect, or patent ductus arteriosus without residua beyond 6 months (see Chap. 73). The wide variety of portals of entry includes dental work, skin sepsis, obstetric and gynecologic procedures, genitourinary and gastrointestinal interventions, and surgery.[32,33] There is also a risk of bacteremia and infective endocarditis in young adults who have their ears pierced or acquire a tattoo.[34] Patients must be educated and preferably should carry an information card with them. The symptoms of endocarditis may be subtle, and the diagnosis must be considered in any patient who experiences unexplained malaise or fever. Injudicious prescription of antibiotics without previous blood culture may mask the problem and make bacteriologic diagnosis and appropriate treatment difficult. Both general measures, such as oral hygiene as well as skin and nail care, and appropriate antibiotic treatment are important. Among 102 patients with congenital heart disease who filled in a questionnaire, there was a disturbing lack of knowledge about endocarditis prevention measures and indeed about their cardiac lesion in general.[35]

Electrophysiologic Problems

Arrhythmias and conduction defects have a major impact on the prognosis and management of both unoperated and operated patients and have been linked to sudden death in a number of conditions.[36,37] The principles of diagnosis and treatment are similar to those employed in patients with arrhythmia due to other causes (see Chap. 24), with some important exceptions. Rhythm disturbances that may be benign in a structurally normal heart may be life-threatening in congenital heart disease. Restoration of sinus rhythm is usually much more important, and rate control of atrial arrhythmias is usually not a good treatment option. Special consideration must be given before the use of therapies that may have negative inotropic properties. In unoperated patients, chamber dilatation, myocardial hypertrophy, and fibrosis may all contribute to the genesis of arrhythmia. In operated patients, additional sinus or AV node damage and atrial and/or ventricular scarring may cause electrophysiologic problems. The etiology is multifactorial, and the clinical significance of arrhythmia depends very much on the hemodynamic context in which it occurs.

Supraventricular arrhythmia and sinus node injury, not surprisingly, occur most often in conditions with "atrial defects" or those requiring atrial surgery.[38,39] Abnormalities of sinus node function are common in patients with atrial septal defect, particularly the sinus venosus type,[40] and are often seen after Mustard or Senning operation for transposition of the great arteries.[41] Sinus node dysfunction has also been reported after surgery for tetralogy of Fallot, the Fontan procedure, and many other operations for congenital heart lesions.[42] Clinical manifestations include sinus bradycardia, sinoatrial block, sinus arrest, and occasionally the tachybradycardia syndrome with paroxysmal atrial flutter and fibrillation. Although bradycardia has been postulated as the cause of sudden death in some conditions, current evidence indicates that tachyarrhythmia is usually a more likely explanation (see below).[41]

In sinus node disease, insertion of a pacemaker is indicated for patients with symptoms resulting from a slow heart rate, such as tiredness, dizziness, and syncope or for an extremely low heart rate (see Chap. 31). Indications in asymptomatic individuals are still controversial, since the arrhythmia is benign in many cases. It should be noted that pacing may be difficult because of the complex underlying anatomy and lack of a suitable site for endocardial lead fixation.[43] The choice of pacemaker will depend on the precise indication. The simplest VVI pacemaker may be adequate prophylaxis against bradycardia-related sudden death. In general, however, rate-responsive pacemakers are preferable, and dual-chamber pacing may provide the best hemodynamics (see also Chap. 31).[44,45]

Injury to the AV node and proximal conduction tissue may result from surgery for lesions such as ventricular septal defect, AV septal defect, or tetralogy of Fallot. Transient complete AV block in the

postoperative period has been shown to have prognostic significance in some reports, particularly if the site of damage is below the bundle of His. In a 30-year follow-up of ventricular septal defect repair at the Mayo Clinic, the development of transient complete heart block for over 72 h followed by resumption of sinus rhythm was a strong independent predictor of late mortality.[46] Whether transient perioperative AV block warrants permanent pacing and whether an invasive electrophysiologic study can help stratify risk are unresolved.[38] Postoperative right bundle-branch block is frequent after ventriculotomy and may be due to injury related to closure of a ventricular septal defect or to interruption of distal Purkinje fibers by ventriculotomy or muscle resection.[37,38] Occasionally, the electrocardiographic (ECG) pattern of right bundle-branch block with left-axis deviation occurs (bifascicular block), and there may also be PR-interval prolongation (trifascicular block).[47,48] Early reports suggested that these findings were harbingers of sudden cardiac death due to complete heart block.[49] More recent studies, however, have not substantiated this adverse prognosis.[50]

Tachyarrhythmias can be life threatening. Late sudden death has been reported in several lesions, both before and after repair. In general, the worse the disease (i.e., more complex anatomy and/or more extensive surgery), the greater the incidence of sudden death, although aortic stenosis and coarctation are also represented in this group. Studies suggest that the risk increases incrementally 20 years after surgical repair.[51] The identification of patients at risk and their management are important but controversial issues. After the Mustard and Senning operation, atrial flutter with a rapid ventricular response is dangerous, especially when it occurs in association with right ventricular dysfunction or venous pathway obstruction.[52] Medical or electrical cardioversion should be promptly used to restore sinus rhythm, and drug therapy may need to be accompanied by pacemaker insertion. Recently, ablation (surgical or catheter) has been advocated for certain cases of atrial flutter (see Chap. 28). Atrial tachyarrhythmias are also common after the Fontan operation; sinus node injury, atrial suturing, and a dilated hypertensive right atrium probably contribute.[42,51] Modification of the operation to exclude the right atrium from the Fontan circuit, the total cavopulmonary connection, may reduce the incidence of potentially serious early and late rhythm disturbances.[53,54]

Ventricular arrhythmias are known to occur after open-heart surgery, particularly repair of tetralogy of Fallot.[48,55] Studies using ambulatory ECG monitoring in postoperative patients have documented asymptomatic complex ectopy and nonsustained ventricular tachycardia in up to 50 percent of patients,[55-57] and more than 20 percent have inducible ventricular tachycardia at electrophysiologic study.[58,59] Experimental and clinical studies have shown that the electrical substrate for reentry arrhythmia is present in the right ventricle.[60] In several reports, older age at surgery is a predisposing factor,[57,61] an observation that suggests factors present at the time of repair may be involved in the genesis of postoperative arrhythmia, in addition to the myocardial damage occurring at the time of surgery or during postoperative follow-up.[62] This is consistent with morphologic studies that have documented increasing fibrosis of the right ventricle as part of the natural history of defects such as tetralogy of Fallot.[63] The current practice of early surgical repair for tetralogy of Fallot may reduce the incidence of such postoperative ventricular arrhythmia, and encouraging preliminary data support this view.[62,64] Other postulated risk factors include elevated right ventricular systolic pressure, reduced right ventricular ejection fraction, pulmonary regurgitation, and a ventriculotomy scar.[65] The clinical significance of nonsustained ventricular tachycardia and especially the indications for prophylactic antiarrhythmic therapy remain unclear.[52] There is a disparity between the high frequency of ventricular arrhythmia and the much lower incidence of sudden death.[66,67] The predictive value of an abnormal ambulatory ECG or of electrophysiologic study has not been established. Furthermore, prophylactic antiarrhythmic therapy has not been shown to be of value in asymptomatic patients with congenital heart defects. Such therapy may have proarrhythmic potential, be negatively inotropic, or have serious extracardiac side effects. As a result, there is insufficient evidence to advocate prophylactic treatment for asymptomatic individuals with nonsustained arrhythmia. On the other hand, there are a few cases of sudden death, out-of-hospital ventricular fibrillation, and/or sustained ventricular tachycardia in almost all large series of patients after repair of tetralogy of Fallot. Identification of at-risk individuals and appropriate treatment remain a challenge. Recent reports have indicated a link between the electrical and mechanical properties of the right ventricle, which may have clinical relevance.[68] The QRS duration on the surface ECG correlates with cardiothoracic ratio and, in a retrospective review, a QRS greater than 180 ms was a sensitive and specific marker for sudden death or out-of-hospital cardiac arrest.[69] Others have not confirmed this.[70] Further refinements in risk stratification in adults with tetralogy of Fallot or other congenital heart lesions are necessary and probably will involve

hemodynamic and electrophysiologic testing both at rest and after exercise, evaluation of ventricular late potentials (Chap. 26), and heart rate variability.[71] It should be remembered, however, that, despite the attention given to ventricular arrhythmia after repair of tetralogy of Fallot, a major source of morbidity in such patients is from atrial arrhythmia.[72]

Radiofrequency ablation, so successfully used to treat arrhythmia in patients with structurally normal hearts (Chap. 28), is being applied to patients with congenital heart disease. These applications represent some of the most challenging electrophysiologic procedures because of the complex cardiac anatomy, enlarged chamber size, and abnormal localization of the underlying conduction system. Nevertheless, ablation may have a role, not merely in subjects with accessory pathways or AV reentry tachycardia, but also in intraatrial reentry arrhythmias that may be present after operations such as Fontan and Mustard or Senning procedures.[73,74]

Pregnancy

An increasing number of women with complex and postoperative congenital heart defects are reaching childbearing age. Advice is sought on both maternal and fetal risk as well as on the incidence of congenital heart disease in the offspring. In the United States, most maternal cardiac disease is congenital in origin. Data are accumulating regarding outcomes of pregnancy in many complex anomalies.[75-80] Prepregnancy counseling is mandatory for all patients whether operated or unoperated. The evaluation should include a detailed history, physical examination, ECG, and chest x-ray along with a comprehensive echocardiogram to evaluate ventricular function, all valve lesions and defects, and pulmonary artery pressure. If pulmonary artery pressure and resistance is in doubt following noninvasive testing, a cardiac catheterization may be necessary. An exercise test may facilitate a detailed assessment of functional capacity.

There are profound changes in the maternal cardiovascular system during pregnancy, including a large (30 to 40 percent) increase in blood volume, a fall in peripheral vascular resistance, and an increase in cardiac output (approximately 40 percent; see also Chap. 82). In general, women with left-to-right shunts or valvular regurgitation tolerate pregnancy well, whereas those with right-to-left shunts or valvular stenosis do less well.[81,82] Asymptomatic young women with small or moderate left-to-right shunts and normal pulmonary artery pressures can expect an uncomplicated pregnancy and labor. In the presence of a large left-to-right shunt, however, heart failure may be provoked or aggravated by pregnancy. Patients with cyanosis have the most problems in carrying a fetus to term and have a high incidence of early spontaneous abortion. Early studies showed that, with higher degrees of cyanosis (as reflected by the maternal hemoglobin), the incidence of spontaneous abortion increased and the handicap to fetal growth became more pronounced. Infants are unlikely to survive if the maternal hemoglobin level is above 18 g/dL.[83] A study from Presbitero et al. demonstrated a clear relationship between the degree of hypoxia and fetal loss (Table 64-3).[84] When the maternal oxygen saturation was 85 percent, only 2 out of 17 pregnancies (12 percent) resulted in live-born infants. Only 41 of 96 pregnancies (43 percent) produced a live birth in 45 cyanosed mothers. There were 49 spontaneous abortions and 6 stillbirths in this series, again reflecting the high risk that maternal cyanotic congenital heart disease poses for the fetus. Meticulous care during pregnancy and delivery lessened the maternal complication rate, but this was still considerable. Such patients require rest and a short labor as well as avoidance of dehydration and sepsis. In such situations, the decision as to whether to continue with the pregnancy depends on an assessment of the risk to the mother and fetus as compared with the patient's desire to have children.

Table 64-3: Fetal Outcome in Cynotic Congenital Heart Disease and Its Relation with Maternal Cyanosis

Hemoglobin, g/dL[a]	Pregnancy, no.	Live Births, no.	Live Born, %
≤16	28	20	71
17-19	40	18	45
≥20	26	2	8

Arterial Oxygen Saturation, %[b]	Pregnancy, no.	Live Births, no.	Live Born, %
≤85	17	2	12
85-89	22	10	45
≥90	13	12	92

[a]Hemoglobin level unknown in two pregnancies.[b]Arterial oxygen saturation unknown in 44 pregnancies.

An elevated pulmonary vascular resistance, from either Eisenmenger's syndrome or primary pulmonary hypertension, is a clear contraindication to pregnancy. Pregnancy for women with Eisenmenger's syndrome carries approximately a 50 percent mortality rate.[85] Termination of pregnancy is always preferable; ideally, this should be done with cardiac anesthesia. If such patients are seen late in pregnancy and termination is not feasible, management should concentrate on maintenance of adequate preload and avoidance of vasodilation. The ideal management around the time of delivery for these patients is controversial because individual experience is small. Vaginal delivery is usually associated with less blood loss than is cesarean section. The latter, however, can be done quickly with all medical personnel in attendance. One report has suggested an approach of elective delivery by cesarean section under general anesthesia.[86] The use of prophylactic heparin before and after delivery is also controversial, and there is no established consensus.[86,87] Even after successful delivery, however, death frequently occurs within the few days following from deteriorating hemodynamics or pulmonary infarction.[85] Patients with Marfan's syndrome and aortic root dilation (greater than 40 mm) are at greater risk of aortic dissection and rupture, and while those without preexisting cardiovascular disease whose aortic root is smaller often tolerate pregnancy well, the risk is unpredictable.[88,89] Patients with severe aortic stenosis are also at increased risk because of the fall in afterload that accompanies pregnancy and exaggerates the valve gradient.[90,91] While early reports suggested a high risk of aortic rupture and cerebral hemorrhage in patients with aortic coarctation,[92] recent data have been more encouraging.[93] Fetal risk is increased, however, presumably as a result of compromised placental blood supply.

The management of pregnant women with mechanical prosthetic cardiac valves is a special problem because of the risk to the mother of thromboembolism and the risk to the fetus of anticoagulants (warfarin crosses the placenta and is teratogenic).[94,95] Depending on the condition involved and the mother's motivation and compliance, the use of subcutaneous heparin in the first and third trimesters and warfarin in the midtrimester is one treatment option. Heparin, however, is a poor anticoagulant during pregnancy; even with meticulous control of anticoagulation, there is still an increased risk of valve thrombosis.[96] In addition, there is also an increased risk of fetal loss with this approach. Because of the poor results with heparin, some authors have advocated the use of warfarin throughout pregnancy despite the risk of fetal teratogenicity.[97] This risk may be less if the dose of warfarin is less than 5 mg/day.[98] Nonetheless, this approach is still very controversial, despite the fact that fetal teratogenicity with warfarin may have been overemphasized (see Chap. 44).[99] Before prescribing any cardiovascular drug during pregnancy, the effects

on both mother and fetus must be considered.

Management of labor should be specifically directed toward avoidance of rapid changes in circulatory volume, blood pressure, or cardiac output. In most cases, vaginal delivery is recommended, with careful attention to maternal position and analgesic agents. The American Heart Association no longer recommends endocarditis prophylaxis for vaginal delivery.[31] This recommendation, however, is not based on controlled data, and most cardiologists recommend antibiotics under these circumstances for almost all congenital heart defects.

Genetic Counseling

The risk of recurrence is an increasingly important issue as more males and females with congenital heart disease reach reproductive age, and genetic counseling should be provided for all potential parents. Recent genetic advances are clarifying the etiology of a number of congenital heart diseases. It has been estimated that the cause of congenital heart disease is genetic in approximately 8 percent of cases (e.g., velocardiofacial syndrome and Holt-Oram syndrome with autosomal dominant transmission) and environmental in 2 percent (e.g., congenital rubella syndrome).[100] In the remainder, genetic and environmental factors are thought to interact.[101] The greater the number of affected first-degree relatives within the family, the greater the recurrence risk. Recurrence risks in siblings of patients with congenital heart disease are well documented and range between 1 and 8 percent.[102] For the affected potential parents, however, the risk of recurrence in offspring is the key information, and fewer data exist. Early reports suggested that recurrence risks were considerably higher in offspring compared to siblings. Studies, such as the Second Natural History of Congenital Heart Defects, have suggested a low risk (1.2 percent for aortic stenosis, 2.8 percent for pulmonary stenosis, and 2.9 percent for ventricular septal defects).[103] There is considerable variation in recurrence risks in reported series, and factors inherent in study design, ascertainment bias, and follow-up account for many of the differences. In addition, certain forms of congenital heart disease recur more frequently than others (e.g., left ventricular outflow tract obstruction), and the recurrence risk appears to be higher in pregnancies with affected mothers rather than fathers. Accumulation of further information will be invaluable for counseling of patients. Fetal cardiac ultrasound at approximately 18 weeks of pregnancy facilitates early diagnosis.

Investigation and Imaging

Transthoracic echocardiography and cardiac catheterization with angiocardiography are the principal investigations in pediatric cardiology. Transthoracic echocardiography is an invaluable tool in adults also, although image acquisition is more challenging because of body habitus and chest wall abnormalities as a result of previous surgeries.[104] Transesophageal echocardiography is becoming increasingly important for the definition of cardiac structure and function,[104-106] and multiplane probes with color-flow Doppler imaging allow simultaneous assessment of anatomy and physiology. Specific areas and lesions of the heart that are well imaged in this way include systemic and pulmonary venous drainage, atrial lesions (including baffle function), AV valve morphology and function, left ventricular outflow tract lesions (including the ascending aorta in Marfan's syndrome), and intracavity thrombus or vegetations (Fig. 64-1).[106,107]

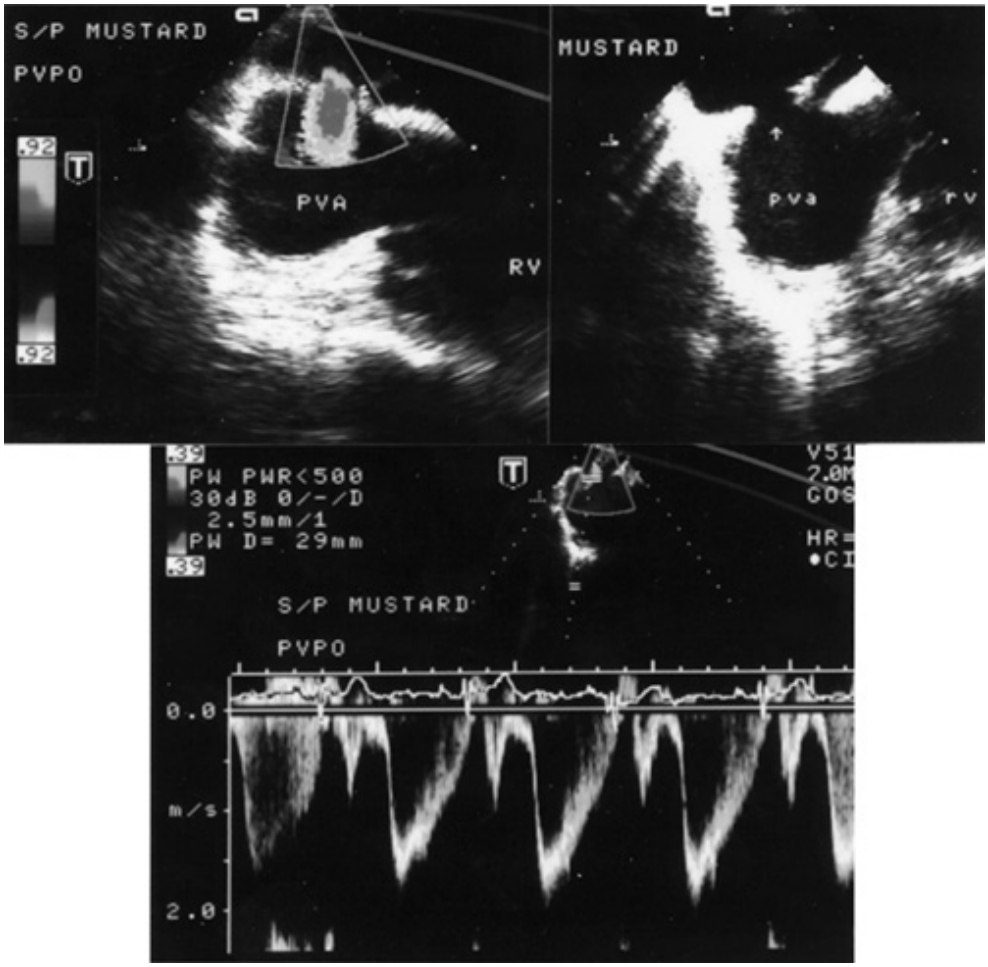

Figure 64-1: Transesophageal echocardiogram and Doppler evaluation after a Mustard operation for transposition of the great arteries. There is moderate pulmonary venous obstruction, indicated by the accelerated flow through the narrowing indicated by the arrow. PVA, pulmonary venous atrium; RV, right ventricle. (Courtesy of Dr. I. D. Sullivan, Great Ormond Street Hospital for Children, London.)

Magnetic resonance imaging (MRI) can also provide valuable anatomic information, which in some cases is superior to that from ultrasound, even via a transesophageal approach. Rapid technologic advances-including three-dimensional image reconstruction; software to study hemodynamics, such as velocity mapping; and cine-MRI-may reduce the need for invasive investigation (Fig. 64-2).[108-110] The expertise required both to acquire and to interpret MRI information is likely to be confined to specialized regional centers, but access to the MRI facility should be available to all units managing adult patients with congenital heart disease.

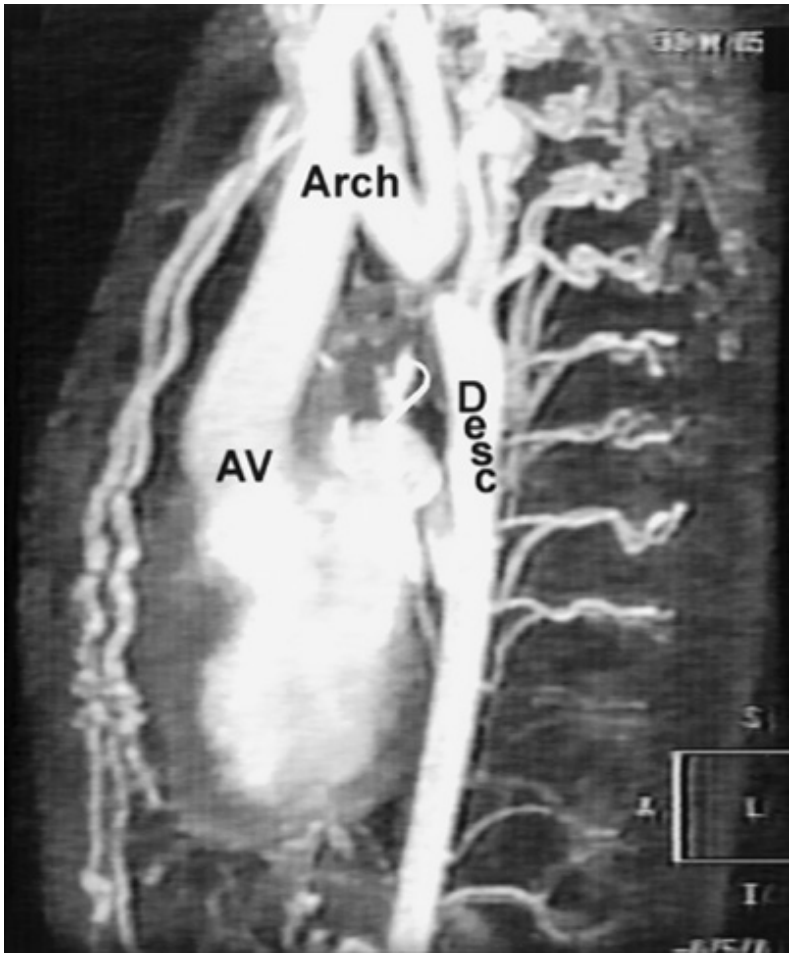

Figure 64-2: MRI angiogram of a 33-year-old man showing a severe coarctation and development of extensive collateralization involving the intercostal and internal mammary arteries. AV, aortic valve; Desc, descending aorta. (From Oh JK, Seward JB, Tajik AJ. Congenital heart disease. In: Oh JK, Seward JB, Tajik AJ, eds: *The Echo Manual*, 2d ed. Philadelphia: Lippincott-Raven, 1999: 233. Reproduced with permission from the publisher and authors.)

In parallel with the decreasing need for diagnostic cardiac catheterization, there has been a dramatic rise in the indications for and scope of interventional procedures in adult patients with congenital heart disease.[111] Residual defects after repair that are amenable to treatment in the catheterization laboratory include coronary fistulas, paravalvular leaks, and pulmonary artery stenoses. Optimum management of patients with complex congenital heart disease can often be achieved by planned collaboration between surgeon and interventional cardiologist. In other patients with a range of relatively simple lesions-including patent ductus arteriosus, pulmonary valve stenosis, atrial septal defect/patent foramen ovale, and certain forms of ventricular septal defect-definitive treatment avoiding surgery may be achieved by interventional catheterization.

Chapter 64: CONGENITAL HEART DISEASE IN ADULTS

PSYCHOSOCIAL ASPECTS

During adolescence, a crucial transition occurs for the patient with congenital heart disease. By the end of the teenage years, the young adult must understand the nature and implications of his or her heart problem. Sensible advice and guidance must be available regarding employment, insurance, socialization, contraception, exercise, and sports.

Employment

Most patients can work and should have access to employment appropriate to their physical and intellectual capabilities. The report of the Natural History Study of Congenital Heart Defects suggested that, among patients with ventricular septal defect, pulmonary stenosis, and aortic stenosis, in comparison with national normal standards, a greater percentage achieved higher levels of education (college and beyond).[112] No similar data are yet available for large groups of patients with more complex defects, although their situation will undoubtedly prove worse.

Despite the excellent potential of many adults with congenital heart disease, job discrimination is frequently encountered, even when a patient has been cleared by a cardiologist. In the United States, the National Rehabilitation Act of 1973 seeks to prevent job discrimination by employers with 10 or more employees by obliging them to consider only the present capacity of applicants to perform a given job and not projections of future deterioration. In other countries, employers frequently take into account future prospects for absenteeism or premature career curtailment. In these circumstances, young adults with congenital heart defects are often at a disadvantage, particularly if they apply for jobs with long training periods.

Restrictions for employment exist for jobs in which the safety of others is the direct responsibility of an individual, such as driving a bus or truck. Most armed services exclude applicants with a cardiac history. The regulations for commercial airline pilots are clearer and subject to regular review. In Europe, a risk of sudden cardiac death or acute disability below 1 percent per annum is the maximum considered acceptable for multicrew flights and below 0.1 percent per annum for solo flights. The number of congenital heart defects in which low risk rates are clearly defined remains small.[113]

Insurance

Possession of adequate life insurance is often a prerequisite for a home mortgage. Insurance companies are of necessity fiscally conservative. As a result, life insurance is difficult to obtain for many young adults in the absence of adequate long-term survival data for their congenital heart lesions. Most of the data used to assess risk are either incorrect or out of date and do not apply to currently performed medical or surgical procedures. In 1986, a survey in the United States recorded that only patients with very simple lesions were insured at regular rates.[114] These included mild pulmonary valve stenosis, uncomplicated repaired atrial septal defect, ventricular septal defect, and patent ductus arteriosus. A similar survey in the United Kingdom in 1993 evaluated both employment status and insurability of young adults with congenital heart disease.[115] In general, policies were as restrictive as those in the earlier survey, with mitral valve prolapse (without regurgitation), postoperative patent ductus arteriosus, and coarctation insurable at standard rates and all other lesions being either insurable at higher rates or not insurable at all.

Marked inconsistencies were found, making "shopping around" mandatory. This situation is likely to improve when health care professionals are able to provide high-quality follow-up data on morbidity and mortality rates relevant to current treatment protocols (see Chap. 104).

Despite surgical repair, long-term cardiac care into adult life is usually required for patients with congenital heart disease. In many countries, health care provision and financing are changing rapidly, with costs spiraling dramatically.[116] There are particular problems in systems that rely on private health insurance. Medical expenses incurred during childhood are usually reimbursed as part of the parents' policy. This coverage often ceases to be available once the patient reaches the age of majority. A new policy sought at this stage at best excludes benefits for medical or surgical treatment of the cardiac condition itself. As a result, the level of medical surveillance of the adult patient with congenital heart disease drops dramatically after age 21 years. This is a major problem, since, with adequate regular follow-up, costs for adults with congenital heart disease are considerably lower than those for other chronic diseases.

Psychosocial Development

Large controlled longitudinal studies of the psychosocial consequences of congenital heart disease are rare and difficult to interpret.[117] Most patients with congenital heart disease appear well adjusted but have subtle feelings of "difference" from their peers. Lack of self-esteem and fear of isolation are common.[118-120] These feelings are often compounded by frequent reminders that they are different through limitation of their activities compared with those of their peers, the presence of scars, cardiac symptoms, hospital visits, and family anxiety. As a result, adolescents and adults with congenital heart disease should be encouraged to lead as normal a life as possible and to discuss their heart disease openly. Anxieties about sexual activity, marriage, and childbirth are common, but patients often find these aspects difficult to discuss, particularly with the doctor in a regular clinic.[120-122] Often, such issues are best handled by the team caring for the patient, which may include a nurse, social worker, and psychologist. As the child with congenital heart disease matures, one of the most potent effects on his or her life is parental overprotection. In adolescents and young adults, this may result in enormous resentment and rebellion against all adult authority figures, including the doctor. Compliance with medical treatment and advice can be affected.

The impact of congenital heart disease on intellectual development is controversial. Interpretation of testing must take into account the very abnormal childhood experienced by many patients, with absences from school for medical reasons as well as decreased social interaction. In addition, patients have often had an overprotected childhood, and their attitude to testing procedures may be different from those of their peers. All studies of intellect exclude patients with genetic syndromes and other dysmorphic, somatic, or neurologic defects, but subtle abnormalities are easily missed.[123] Certain aspects of development appear to be more specifically affected by congenital heart disease. For example, walking is delayed in cyanotic children, but speech is not. This will affect the relevance of early IQ testing to later performance. Currently, data suggest that cyanosis is associated with mild intellectual impairment.[124-126] This association is reduced by early corrective surgery, even involving cardiopulmonary bypass.

Contraception

Sexually active adolescents and young adults should be given appropriate advice about contraception.[127,128] In general, the low-dose estrogen oral contraceptive pill is safe for young women with congenital heart disease.[129] Exceptions include women with hypertension (e.g., associated with coarctation of the aorta) and those with pulmonary vascular disease or cyanosis with associated erythrocytosis. Progesterone preparations are alternatives, although they have a lower contraceptive efficacy.[130] They are, however, inappropriate for patients with cardiac failure because of the tendency for fluid retention; moreover, progesterone-only pills can cause

depression in adolescents. Barrier methods, either using condom or diaphragm, are safe and effective, but intrauterine devices should probably not be used because of the risk of endocarditis and of increased bleeding, particularly in cyanotic women.[131] In women with severe pulmonary vascular disease or with lesions in which pregnancy would result in high maternal risk, laparoscopic sterilization should be considered.

Exercise and Sports

Exercise is of both physical and psychological benefit. It leads to improved cardiovascular fitness and decreased likelihood of obesity, hypertension, and ischemic heart disease.[132,133] Furthermore, participation in exercise and sports is part of normal socialization in adolescent and adult life. In many adults with congenital heart disease, exercise capacity is diminished, even after surgery. Reduced performance may also reflect lack of regular exercise in protected individuals with congenital heart defects. This is often reinforced by doctors who, if in doubt, tend to limit exercise.

The Twenty-sixth Bethesda Conference provided recommendations for competition in athletics by patients with cardiovascular abnormalities.[134] Sports are broadly categorized into those involving dynamic exercise and those involving static exercise, although these two types of exercise are at two extremes of a continuum. Another important consideration is the danger of bodily injury from collision or the consequences of syncope. Significant disease or death precipitated by exercise in patients with congenital heart disease is rare, but the other consideration is whether prolonged long-term exercise might contribute to progressive hemodynamic deterioration (e.g., left ventricular hypertrophy and aortic stenosis). In some cases, exercise capacity is clearly normal and the risk is minimal, as after closure of a small patent ductus arteriosus. In others, exercise capacity is limited and the risk is high, as in severe pulmonary hypertension. Between these extremes is a gray area in which recommendations must take into account the individual, the underlying cardiac defect, hemodynamic status, and the type of sport and form of exercise contemplated (e.g., social or competitive, or contact or noncontact). Formal testing should be performed (preferably including measurement of oxygen uptake), both as a measure of the effects of submaximal and maximal exercise and also as a reassurance to the patient. A 12-min walking test provides a good guide to functional capacity, whereas a treadmill protocol with more strenuous effort is employed to assess risk by revealing occult arrhythmia, ischemia, or fall in blood pressure (Chap. 14). Subjective estimates of exercise capacity are often inaccurate.

In general, volume overload, valve regurgitation, and left-to-right shunts are associated with good exercise tolerance, while pressure overload, valve stenosis, and right-to-left shunt are not. The recommendations provided by the Bethesda Conference should be considered guidelines only. The physician with knowledge of the severity of the patient's lesion and physiologic and psychologic response to training and competition may choose to modify these recommendations.[134] Those patients with a history of symptomatic arrhythmia, syncope, pulmonary hypertension, or myocardial dysfunction deserve special attention, since they are probably at higher risk. Patients with fixed, elevated pulmonary vascular resistance have limited exercise capacity, and for them exercise has considerable risk. Walking should be encouraged but strenuous exercise avoided. The most controversial recommendations are those for aortic stenosis and Marfan's syndrome. It could be argued that exercise may increase the risk of sudden death or progression of left ventricular hypertrophy in the former (see Chap. 56) and of progressive aortic dilatation in the latter (see Chap. 76). Thus, patients with more than mild aortic stenosis should be counseled against moderate to strenuous activities. Patients with Marfan's syndrome, particularly those with aortic root dilatation, should be counseled against isometric exercise and activities with the potential for bodily collision. Supervised training programs for adults with congenital heart disease can improve aerobic fitness and increase the safe level at which they can participate in sports. Such programs also improve psychological adjustment and self-esteem.

Chapter 64: CONGENITAL HEART DISEASE IN ADULTS

SURGICAL CONSIDERATIONS

Reoperations

Reoperations in adults with congenital heart disease provide a particular challenge.[135,136] The risks are often higher than for primary procedures. Careful preoperative planning should include complete understanding of the cardiac anatomy and its relationships to neighboring structures, and study of previous operative reports. Sternal reentry is particularly risky when the ventricle immediately beneath the sternum is a high-pressure chamber or when an extracardiac conduit lies in this position. The use of Gore-Tex membranes under the sternum may reduce the difficulties of future repeat procedures. Postoperative hemodynamic and respiratory problems are particularly common after reoperation because of the increased duration of surgery, previously scarred myocardium and/or lung disease, and greater use of blood products. The need for reoperation may come as a shock to patients and relatives who may have believed that childhood surgery was curative. As a result, resentment is frequent, and tact is required. Indications for reoperation are shown in Table 64-4.

Table 64-4: Indications for Reoperation in Adults with Congenital Heart Disease

1. Inevitable reoperation after definitive repair prosthetic valves, extracardiac conduits placed at an early age that become of inadequate size because of body growth
2. Residual defects after definitive repair: ventricular septal defect after tetralogy of Fallot and left AV valve regurgitation after AV septal defect repair
3. New/recurrent defects after definitive repair: subaortic stenosis, restenosis of aortic valve, pulmonary regurgitation in tetralogy of Fallot
4. Staged repair of complex defects: pulmonary atresia with ventricular septal defect
5. Unexpected complications: infective endocarditis
6. Heart/heart-lung transplantation for uncorrectable congenital heart disease
7. Patient operated on for congenital heart disease with new acquired heart disease: coronary disease

---

Inevitable Reoperation

Early repair of congenital heart defects that have involved insertion of a prosthetic valve or extracardiac conduit commonly results in a need for reoperation to replace prostheses that are either too small or have undergone degeneration. Extracardiac conduits are commonly used for repair of pulmonary atresia with ventricular septal defect, truncus arteriosus, transposition with left ventricular outflow tract obstruction and/or ventricular septal defect, congenitally corrected transposition with left ventricular outflow tract obstruction, and/or ventricular septal defect and were used in early Fontan operations. Development of obstruction is influenced by the type and size of conduit, technique of insertion, and timing of the original operation. In one series of 143 survivors of heterograft conduit insertion, all had to be replaced by 10 years.[137] A homograft aorta or pulmonary artery and valve have also been used for the repair of pulmonary atresia with

ventricular septal defect.[138] Fresh or frozen homografts in childhood have not performed as well as initially hoped.[139] Calcification and obstruction remain significant complications. However, because of their favorable handling characteristics, homografts remain the conduits of choice for many reconstructions.[140,141] Besides the conduit itself, improved operative technique and the use of a large conduit have clear beneficial influence on the need for early replacement. This may be facilitated by utilizing a prosthetic roof of pericardium placed over the fibrous tissue bed of the explanted conduit, thus permitting a large tissue valve to be inserted.[142] Patients with right-sided conduits need careful follow-up, particularly toward the end of the expected life of the conduit. Although conduit obstruction may be suspected from clinical examination, the signs of severe obstruction may be subtle and may be missed. As a result, replacement may be performed too late. The consequent major deleterious effects on right ventricular function increase the risk of surgery and may not be fully reversible. Regular, noninvasive evaluation by transthoracic or transesophageal echocardiography or MRI is indicated in selected patients and may provide the information usually obtained by cardiac catheterization and angiography. Reoperation is usually indicated if the right ventricular pressure is 75 percent of the systemic or if there is evidence of deteriorating ventricular function.[143]

Residual and Recurrent Defects

Residual and recurrent defects may be difficult to distinguish unless careful assessment after the original repair has been performed. They may have a major impact on morbidity and mortality rates, as when major left AV valve regurgitation persists after repair of AV septal defect.[144] Much more long-term follow-up data are needed before guidelines for reoperation for relatively minor residual abnormalities, such as mild left AV valve regurgitation, in this situation can be established.

The reported need for reoperation after the commonly performed reparative operation for tetralogy of Fallot varies between 1.8 and 13 percent over a follow-up of up to 31 years.[145,146] Ventricular septal defect and right ventricular outflow tract obstruction are the commonest residual abnormalities. Pulmonary regurgitation is extremely common and inevitable after transannular patching as part of the original repair. The hemodynamic consequences of pulmonary regurgitation for the right ventricle are greater in the presence of other defects, such as residual obstruction and/or ventricular septal defect. Pulmonary valve replacement has not been frequently required in the first two decades after repair but may become increasingly performed because of the late deleterious effects of pulmonary regurgitation on the right ventricle.[147] Current indications include progressive right ventricular dilatation and a decrease in exercise tolerance.[148] This is often accompanied by progressive tricuspid regurgitation and atrial arrhythmias. When surgery is performed before the development of right ventricular failure, both clinical status and right ventricular function improve.[149] The optimal method for assessing pulmonary regurgitation in serial follow-up has not been determined; therefore, appropriate guidelines for intervention are still not established.

Several studies have emphasized the palliative nature of aortic valvotomy in childhood.[150-152] Isolated aortic stenosis most frequently results from a bicuspid aortic valve, although in neonates and infants the structural abnormality of the aortic valve is more severe and the results of surgery even worse (see Chap. 63). In a series of 59 patients who underwent open aortic valvotomy at over 1 year of age, the actuarial survival rate was 94 percent at 5 years but only 77 percent at 22 years. Reoperation was carried out in 36 percent, and the actuarial probability of reoperation was 44 percent at 22 years. When serious events, comprising death, reoperation, and endocarditis, were grouped together, 92 percent were free of events at 5 years but only 39 percent at 22 years. Others have reported a similar long-term outcome.[150] The causes of restenosis have not been studied in detail but appear to be related to the degree of residual obstruction.

Staged Repair

For complex congenital heart disease, definitive repair may not be possible until the anatomy and physiology of the circulation have been improved by one or more palliative procedures as part of a staged approach to "correction." This course is often necessary for patients with pulmonary atresia and ventricular septal defect, hypoplastic pulmonary arteries, and multifocal pulmonary blood supply. Palliative procedures to increase flow to the central pulmonary arteries and unifocalization of pulmonary flow by anastomosis (direct or indirect) of collateral vessels to the pulmonary arteries may eventually result in the ability to perform a repair (conduit insertion between the right ventricle and pulmonary artery and ventricular septal defect closure) with an acceptable postoperative right ventricular/left ventricular pressure ratio.[153,154] Good surgical results have been reported from such an approach, but the long-term outcome is not yet known.[155]

Other situations in which definitive repair may be indicated in the young adult include complex congenital heart defects with one functioning ventricle palliated by a systemic-pulmonary shunt or pulmonary artery banding in childhood. In selected patients who fulfill the stringent criteria for a Fontan operation, it is likely that long-term results will be better after a Fontan operation than when the ventricle is left with a chronically increased load resulting from a systemic pulmonary shunt.[12] The Fontan operation, however, should be considered palliative rather than curative: long-term problems are frequent.

Unexpected Reoperations

Indications for unexpected reoperation include thrombosis in a low-flow circulation such as the Fontan, prosthetic valve failure or thrombosis, and infective endocarditis. The latter may be particularly difficult to diagnose in complex congenital heart disease where the site of vegetations may not be easy to image (e.g., in a Blalock-Taussig shunt). Reoperation in the patient with uncontrolled endocarditis carries a particularly high risk.

Heart and Heart-Lung Transplantation

Despite the major successes of the last three decades, an increasing number of patients survive to adult life with deteriorating clinical status. Their only remaining prospect may be a heart or heart-and-lung transplant (see Chap. 22). These patients often present specific surgical problems of multiple previous chest incisions, complex venous anatomy, and borderline pulmonary vascular resistance. In addition, the young adult with end-stage heart disease may not have the ideal social milieu to cope with the demands of transplantation and may require considerable psychological support. Nonetheless, the results in this group of patients may be excellent.[156] The shortage of donors and the ability to monitor rejection in a single organ have stimulated great interest in single-lung transplantation for patients with primary pulmonary hypertension and Eisenmenger's syndrome (in conjunction with closure of the shunt).[157]

First Operations for Congenital Heart Disease in Adults

The first surgical repair of a congenital heart defect may be required in a teenager or an adult because the lesion was mild and of little hemodynamic significance in childhood but progressed in severity with time. Examples of such lesions include a bicuspid aortic valve with progressive stenosis (see Chap. 56), Marfan's syndrome with aortic root dilatation (see Chap. 76), and Ebstein's anomaly with worsening symptoms. Alternatively, lesions such as small to moderate atrial septal defects may have been missed or misdiagnosed until adult life. In certain complex congenital heart defects, the combination of lesions produces a balanced hemodynamic state compatible with prolonged survival without intervention. Patients with double-inlet ventricle and pulmonary stenosis, complex pulmonary atresia, and tetralogy of Fallot may remain well until the second and even third decades of life before deteriorating.[158] The contemplation of heart surgery

in an adolescent or young adult is often terrifying, implying the acceptance of the presence of a serious heart problem by the patient and his or her immediate friends and family. The scar on the chest may cause embarrassment, and the patient may be discriminated against both socially and at work. All these issues need to be dealt with sympathetically by the physician.

Noncardiac Surgery

When performed without adequate preparation, noncardiac surgery in adults with congenital heart disease is a major cause of avoidable morbidity and death. All the anesthetic risks encountered for cardiac reoperation apply equally to noncardiac surgery, but in the latter the patient may be managed by medical staff who may be unfamiliar with the significance of the congenital heart disease. Many patients with congenital heart defects are at increased risk for arrhythmia and from agents that depress ventricular function. The surgeon must be aware of the presence of a pacemaker or pacing leads that may affect the safe use of diathermy. Prophylaxis against infective endocarditis is usually indicated, and the choice of antibiotic regimen is dictated by the surgical procedure or intervention being undertaken (see Chap. 73). In patients with pulmonary vascular disease, general anesthesia may have disastrous consequences, with a sudden fall in systemic vascular resistance.[28] Similar hemodynamic changes may induce a severe hypercyanotic spell in a patient with uncorrected tetralogy of Fallot, and meticulous pre-, intra-, and postoperative hemodynamic monitoring is mandatory, together with the avoidance of vasodilating anesthetic agents, hypoxia, hypoventilation, and blood or volume loss. Cyanotic patients also have impaired hemostasis, and some patients may be taking anticoagulants. Intravenous lines, drugs, and infusions must be managed carefully in patients with intracardiac shunts, since air or emboli may reach the systemic circulation. The safety of noncardiac surgery in adults with congenital heart disease is greatly increased when physicians, anesthesiologists, and surgeons familiarize themselves with these issues, seek specialized advice, and, if necessary, refer the patient to a team with more experience.

Chapter 64: CONGENITAL HEART DISEASE IN ADULTS

SPECIFIC LESIONS

General Considerations

Some lesions that are commonly seen in adult congenital heart disease, as a result of both natural and unnatural survival, are listed in Tables 64-1 and 64-2.

Interpretation of the literature on long-term outcome of congenital heart defects is hampered by a number of difficulties. First, follow-up is still short, and numbers of survivors are small for many defects. The era of open-heart surgery for congenital heart defects only began in the 1950s, and "correction" has only been attempted much more recently for many categories of patients now beginning to reach adult life (e.g., the Fontan operation). Second, surgical practice has undergone a process of evolution during this time, with new operations for some lesions (e.g., transposition of the great arteries) or major change in operative technique for others (e.g., the Fontan operation). Third, major advances in cardiopulmonary bypass and myocardial protection have accompanied improved preoperative diagnosis and recognition of intracardiac anatomy, particularly of the disposition of the conduction tissues. Finally, for almost all lesions, the management philosophy has changed, with a trend to early primary repair as opposed to initial palliation. For many defects, therefore, long-term outcome data relevant to current practice are not available.

Correct application of survival analysis is essential for interpretation of follow-up data. In particular, the use of hazard functions providing an estimate of *instantaneous risk* is particularly valuable. The following section deals with some specific defects seen in adults with congenital heart disease.

Atrial Septal Defect

Atrial septal defects are among the commonest congenital anomalies in adolescents and adults, accounting for up to 30 percent of congenital heart disease in this age group.[159,160] Approximately 75 percent of defects are ostium secundum defects, 20 percent ostium primum defects (discussed below), and 5 percent sinus venosus defects; defects at other sites are rare (see Chap. 63).[161,162] Associated lesions include pulmonary stenosis, mitral valve prolapse, and mitral regurgitation. Atrial septal defects may be associated with other syndromes, including the Holt-Oram syndrome (see Fig. 10-2)[163] and may be familial.[164] In the latter, conduction disease manifesting as prolongation of the PR interval and, rarely, heart block have been described.[164] Lutembacher syndrome (atrial septal defect coexisting with mitral stenosis) is now very uncommon.

NATURAL HISTORY

Survival into adulthood is the rule, and patients living into their eighties and nineties have been reported.[159] Life expectancy, however, is not normal. Death during the first 20 years of life is infrequent, but after the age of 40 years, the mortality rate increases to about 6 percent per year.[165,166] Defects may go unrecognized for many years because symptoms are rare until later life and physical signs may be subtle. Later, the natural history is characterized by progressive symptoms and cardiomegaly, the development of atrial arrhythmias, right ventricular hypertrophy, and pulmonary hypertension. The mechanisms for the development of symptoms are

multifactorial[159] and include the following:

1. Change in left ventricular compliance from superimposed hypertension or coronary artery disease may increase the shunt with age. Long-standing right ventricular volume overload, although relatively well tolerated, ultimately leads to right ventricular dysfunction and progression of tricuspid regurgitation.
2. Supraventricular arrhythmias, particularly atrial fibrillation and flutter, increase with time and may cause symptoms and cardiac failure (Fig. 64-3).
3. Progressive pulmonary hypertension may become symptomatic after the third decade of life.
4. Rarer complications may occur, including systemic and pulmonary emboli, recurrent chest infections, and infective endocarditis (in patients with coexisting mitral valve disease).

MANAGEMENT

Surgical closure either by direct suture or use of a patch has been performed for more than 40 years (see Chap. 63). Surgery carries a low risk (less than 1 percent operative mortality rate), provided that the pulmonary vascular resistance is not significantly elevated.[162] In older patients, the indication for closure is a little more controversial. Shah et al. compared the outcome of patients treated medically and surgically when diagnosed after the age of 25 years.[167] This unrandomized study followed patients for more than 20 years and concluded that there was no difference in survival or symptoms between the two groups and no difference in the incidence of new arrhythmia, stroke, or other embolic phenomena in the follow-up period. Notably, however, more than 70 percent of patients in both the medical and surgical groups were asymptomatic at presentation, which may partly explain the favorable outcome of the medically treated group, who had a 91 percent survival. Konstantinides et al. evaluated 179 patients with secundum atrial septal defect 40 years of age or older and compared the outcome of medically and surgically treated groups.[168] They demonstrated a reduced mortality rate after surgical closure, with a 95 percent surgical survival versus an 84 percent medical survival at 10 years. Nonfatal cardiovascular complications, however, were similar, with atrial fibrillation and flutter occurring with a similar incidence in both groups. The functional status of the medically treated group deteriorated in 34 percent of patients and improved in many of the surgical patients, particularly those in class III or IV. It thus seems reasonable to conclude that symptomatic adult patients will improve after surgical repair, and the only real contraindication is severe pulmonary vascular disease. When surgery is delayed, symptoms are likely to be progressive, and surgical repair is less likely to prevent problems with atrial fibrillation and thromboembolic events. For those with preexisting atrial fibrillation, a concomitant right-sided maze procedure may facilitate restoration and maintenance of sinus rhythm.[169] The management of the asymptomatic adult patient is less clear, but certainly closure of the defect halts progression of right ventricular volume overload, tricuspid regurgitation, and progression of pulmonary vascular disease, and it can be accomplished with low surgical risk. The standard surgical approach remains a midline sternotomy, but patients should be made aware of the alternatives of thoracotomy or inframammary incision. Although morbidity rates may be higher, the resulting scar may be less offensive, especially to young women.

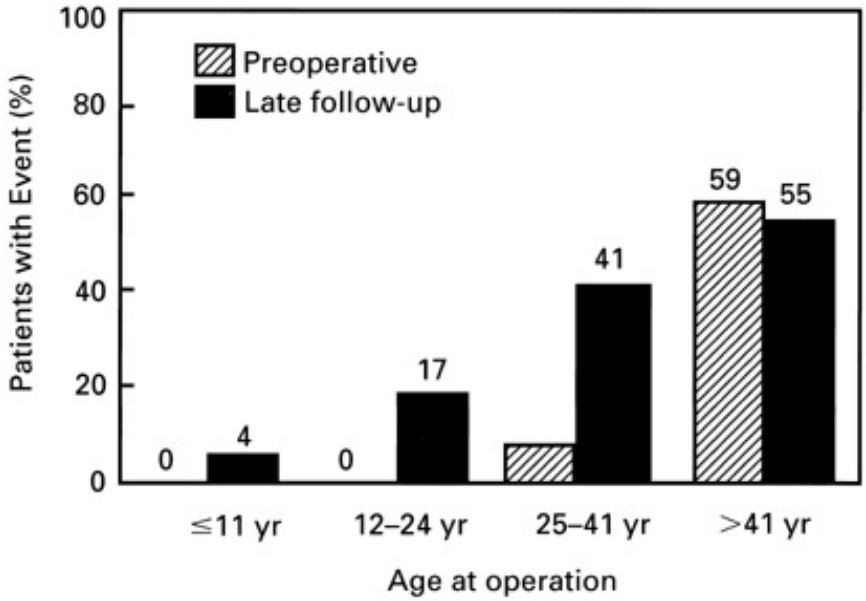

Figure 64-3: Incidence of atrial flutter or atrial fibrillation preoperatively and at late follow-up according to the age at operation after repair of atrial septal defect. (From Murphy JG, Gersh BJ, McGoon MD, et al. Long-term outcome after surgical repair of isolated atrial septal defects: Follow-up at 27-32 years. *N Engl J Med* 1990; 323:1645. Reproduced with permission from the publisher and authors.)

Closure of atrial septal defect has been achieved in selected patients by use of a variety of occlusion devices inserted at cardiac catheterization.[170-174] Several alternatives have been evaluated, but no large series with adequate follow-up are yet available for comparison with surgery. The attractions of closing defects without open-heart surgery are obvious. Eventually, the transcatheter technique may supplant surgery as the method of closure for atrial septal defects of appropriate size, morphologic characteristics, and location. In addition, the presence of a patent foramen ovale has been suggested as a risk factor for cerebral embolus. Determining the risk of clinical events in asymptomatic subjects with patent foramen ovale and indications for treatment are highly controversial areas. Catheter treatment may become the method of choice for patients who have a clear indication for intervention.

LATE RESULTS

In a recent study of patients undergoing surgical repair of an atrial septal defect between 1956 and 1960, late survival of patients undergoing operation at below 24 years of age was not significantly different from that of an age- and sex-matched control population. Late survival in patients aged 25 to 41 years was good but less than that of the control population, while repair after age 41 years was associated with significantly poorer late survival (see Fig. 64-3). The combination of older age at operation and pulmonary hypertension had an additive effect on late mortality rates.[175] In this and other series, the propensity for atrial fibrillation and flutter increased as a function of age both before and after operation (Fig. 64-4).[175,176] Twenty-two percent of late deaths were due to stroke, and all occurred in patients with postoperative atrial fibrillation or flutter. These data support the current policy of repair at a preschool age (Chap. 63). A separate study of 66 patients who underwent closure of atrial septal defect between 60 and 78 years of age implied a benefit in survival in patients discharged from the hospital compared with unoperated historical age- and sex-matched controls.[177] A study of patients over 70 years of age showed improved survival of patients in New York Heart Association (NYHA) class II and III when treated surgically compared to medical treatment. Patients in NYHA class IV did poorly with medical or surgical treatment.

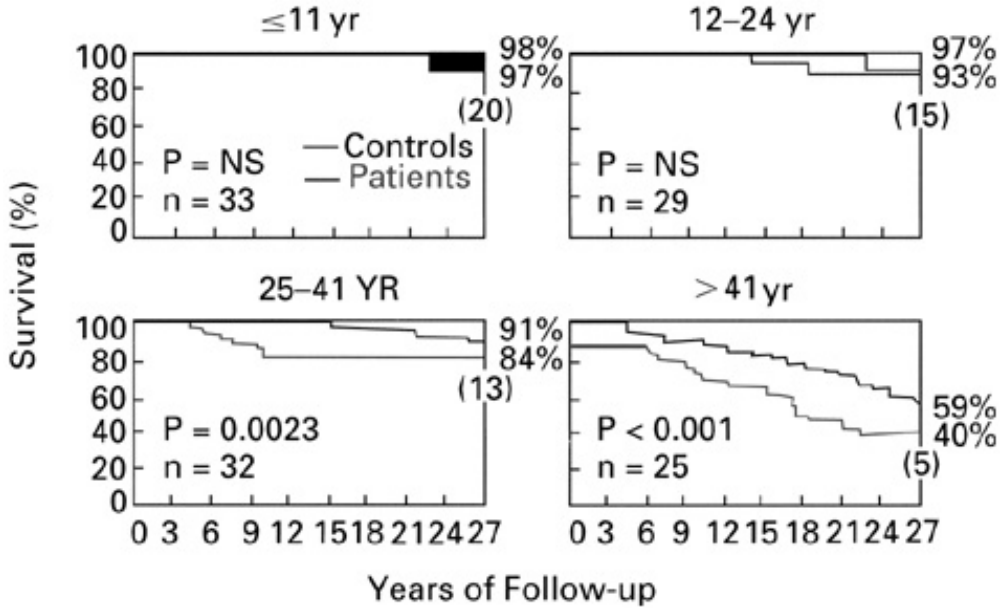

Figure 64-4: Long-term survival of perioperative survivors of atrial septal defect repair by age at time of operation. Controls are survival in an age- and sex-matched population. (From Murphy JG, Gersh BJ, McGoon MD, et al. Long-term outcome after surgical repair of isolated atrial septal defects: Follow-up at 27-32 years. *N Engl J Med* 1990; 323:1645. Reproduced with permission from the publisher and authors.)

The near-normal survival and low morbidity rates in patients undergoing repair within the first two decades of life have important implications for employment and insurance recommendations. Such patients should be encouraged to lead a normal life, and competitive sports should not be restricted in the absence of hemodynamic or electrophysiologic sequelae. Patients who have undergone repair in the third decade of life or later require careful regular surveillance. Although late survival is good, the development of supraventricular arrhythmia and risk of cerebrovascular accident are of concern. Anticoagulation is indicated in patients with atrial fibrillation and should be considered in those with supraventricular tachycardia or atrial flutter in the absence of other contraindications (see also Chaps. 24 and 44). Long-term follow-up is recommended for patients repaired in adult life who have increased pulmonary artery pressure at the end of operation, pre- and postoperative arrhythmia, ventricular dysfunction, or coexisting heart disease.

Ventricular Septal Defect

Isolated ventricular septal defect, although one of the commonest congenital abnormalities in infants and children, is far less frequent in the adolescent and adult for several reasons.[159] First, most patients with a hemodynamically significant defect will have undergone repair in childhood; second, spontaneous decrease in size and closure are common for small or moderate perimembranous or muscular defects (this decreases in frequency with increasing age); finally, patients with large, unoperated defects may die earlier in life.[178] The spectrum of isolated ventricular septal defects in the adult is thus limited to the following four groups of patients: (1) those with small, restrictive defects that were either small to begin with or have partially closed; (2) those with Eisenmenger's syndrome and a predominant right-to-left shunt with cyanosis,[179] who need to be distinguished from those who develop secondary infundibular pulmonary stenosis, which can also decrease the left-to-right shunt and may result in cyanosis with shunt reversal (see Chap. 63);[180] (3) the occasional patient with a moderately restrictive defect in whom the diagnosis has been overlooked or who has not had closure in childhood; and (4) those who have had their defects closed in childhood.

NATURAL HISTORY

The natural history of small, restrictive ventricular septal defects is very favorable. Nevertheless, the risk of infective endocarditis persists (developing in almost 4 percent of patients with ventricular septal defect), and lifelong prophylaxis is required. Spontaneous closure may occasionally still occur in adult life. A subset of patients with perimembranous defects or defects in the outlet septum may develop aortic cusp prolapse and aortic regurgitation. This may be progressive and is often severe by the end of the second decade of life. As incompetence increases, the ventricular septal defect may become "closed" by the prolapsing cusp; if it is left to develop, however, aortic valve replacement may be necessary.[181] Such defects are associated with a high risk of infective endocarditis. Severe and progressive pulmonary vascular disease is a feature of older patients with nonrestrictive large defects. Eisenmenger's syndrome is compatible with survival into young adult life, but the complications of right-sided heart failure, paradoxical emboli, and erythrocytosis usually result in death by the third decade (see Chap. 63). Occasionally, patients with moderate-sized ventricular septal defects and left-to-right shunts who did not develop pulmonary vascular disease present in adolescence and young adult life with symptoms of fatigue, effort intolerance, and respiratory infections.

MANAGEMENT

Patients with small ventricular septal defects are asymptomatic and should be managed conservatively. Continued medical follow-up is, however, helpful to remind patients about the need for prophylaxis against infective endocarditis and to minimize inappropriate discrimination during the search for employment and insurance. Ventricular septal defects associated with aortic cusp prolapse and aortic regurgitation should be repaired even when the shunt is small in an effort to prevent progressive deterioration of the aortic valve. Surgical repair is indicated in the rare adult with a significant left-to-right shunt (pulmonary/systemic flow ratio exceeding 2:1) and a low pulmonary vascular resistance. The management of patients with large defects and infundibular narrowing causing right-to-left shunting and cyanosis is similar to that for tetralogy of Fallot (see below).

Unfortunately, adults are still seen with a large ventricular septal defect and pulmonary vascular disease. In those with borderline pulmonary vascular resistance (7 to 10 U/m^2), surgery may be attempted, but the benefits are unpredictable, since the pulmonary vascular disease may progress despite closure of the defect (see Chap. 63).[182] Medical management and consideration for heart-lung or single-lung transplantation are the only realistic options for patients with established severe pulmonary vascular disease, although prostacyclin may hold some promise.[29]

LATE RESULTS

Late results of surgery are good, but the life expectancy for the whole group is not normal. In a study of 179 operative survivors between 1956 and 1959, 30-year survival was 82 percent, compared with 97 percent in age- and sex-matched controls.[180] Only 25 percent of patients in the series were over 10 years of age at surgery, and their 30-year survival of 70 percent was substantially lower than the 88 percent in patients under 2 years of age at operation. Thirty-year survival was 83 percent for patients aged 3 to 10 years at surgery. Older age at repair and preoperative pulmonary vascular disease are important predictors of late outcome. Postoperative conduction defects, especially right bundle-branch block, are common, but complete heart block, which was seen in the early surgical experience, is now rare. Late ventricular arrhythmia has been reported, as after repair of tetralogy of Fallot.[183] The incidence of late sudden death, however, is extremely low, and prophylactic antiarrhythmic therapy in asymptomatic patients is not indicated.

Certain selected ventricular septal defects may be closed with transcatheter devices. One report

described closure of 21 muscular ventricular septal defects in 12 patients, half of whom had complex heart defects.[184] All the defects were closed successfully, and subsequent cardiac surgery for associated lesions was performed in 11 of 12 patients.

In postoperative patients, the risk of late infective endocarditis is very small, provided that the defect is isolated and is completely closed. Antibiotic prophylaxis, however, is often advised, particularly for 6 months postoperatively. Recommendations regarding physical activity and competitive sports require detailed evaluation, which may include exercise testing, cross-sectional echocardiography, and ambulatory ECG monitoring. The presence of abnormal left ventricular function, a more than trivial residual shunt, arrhythmia, or any degree of pulmonary hypertension mandates some restriction of physical activity.

Atrioventricular Septal Defect

The term *atrioventricular septal defect* describes the spectrum of lesions that involve a defect at the site of the normal AV septum, resulting in an abnormality involving the AV valves, ventricular architecture, and left ventricular outflow tract. A variety of classifications have been used (see Chap. 63), but the defects are usefully divided into "partial" and "complete" forms. In the former, there is a defect in the primum or inferior part of the atrial septum but no direct intraventricular communication (ostium primum defect). In the latter, there is a large ventricular component beneath either or both the superior or inferior bridging leaflets of the AV valve. The deficiency of ventricular septum together with the abnormal AV valve or valves produces an elongated left ventricular outflow tract characteristically described as having a "gooseneck" appearance at angiography. The morphologic and functional features, together with the associated cardiac and noncardiac abnormalities, determine the natural history. Subaortic stenosis is a common association and may occur de novo even after surgical repair.[185]

NATURAL HISTORY

In the New England Regional Cardiac Registry, 5 percent of newborns with cardiac disease had AV septal defects, with two-thirds being the "complete" form.[186] Down's syndrome is very frequently associated, especially with complete defects. The noncardiac features, especially mental retardation, have a major influence on management in adolescence and adult life.

The natural history of partial AV septal defects with little left AV valve regurgitation is similar to that of large secundum atrial septal defects (see above). A small number develop pulmonary vascular disease, and symptomatic deterioration in unoperated adults is often due to the onset of supraventricular arrhythmia. If the left AV valve is more than mildly regurgitant, the natural history is much worse, with a large left-to-right shunt, often with at least moderate pulmonary hypertension, and early symptoms of cardiac failure. Patients with complete defects do even worse. Their course is characterized by the early development of pulmonary vascular disease (especially in patients with Down's syndrome, who may have irreversible damage before their first birthday), with consequent right-to-left shunting and all the problems of patients with Eisenmenger's syndrome. As a result, surgery needs to be undertaken early if it is to be successful, and most uncorrected patients seen by the adolescent or adult cardiologist will have a pulmonary vascular resistance that is too high for repair (greater than 8 to 10 U/m^2; see Chaps. 15 and 63). Their outcome is poor, but survival into their thirties is possible. Uncorrected patients with partial AV septal defects may present to the adult cardiologist for consideration of surgery, which should be recommended for those with a significant left-to-right shunt in the absence of other contraindications.

MANAGEMENT

Surgical repair involves closure of the atrial and ventricular septal defects and restoration of a competent left AV valve as far as is possible (see Chap. 63).[187] The surgical mortality rate in experienced centers is approximately 10 percent for complete defects and less than 5 percent for partial defects.[162]

LATE RESULTS

Patients with repair of both partial and complete forms of AV septal defect have now been followed for more than 20 years. Late results are good in the absence of pulmonary vascular disease and significant residual left AV valve regurgitation. Some patients with complete defects who were corrected later in childhood, before the need for correction in early infancy was appreciated, have developed progressive pulmonary vascular disease. This late complication should be greatly reduced in patients undergoing repair in the first 6 months of life, as is now technically feasible (see Chap. 63). Even patients who are repaired late in adult life (at 40 years of age or more) can have excellent results, with an early mortality rate of only 6 percent and a good chance of left AV valve repair in experienced hands.[188]

During long-term follow-up, careful attention must be paid to the status of the left AV valve. If the regurgitation increases in severity, reoperation and mitral valve replacement may be necessary.[144] Monitoring for arrhythmia at intervals is also currently recommended; in general, little intervention is usually required, apart from lifelong infective endocarditis prophylaxis. Surgically repaired non-Down's patients without pulmonary vascular disease can often enjoy life without cardiovascular disability and should not be discouraged from competitive sports, pregnancy, or employment. Restrictions are clearly required for those with pulmonary vascular disease, left AV valve regurgitation, or mitral valve replacement on anticoagulants. Patients with Down's syndrome, both operated and unoperated, are demanding, and their families require considerable support from the physician as well as from educational and social services. The recurrence risk of congenital heart disease in offspring of mothers with AV septal defect is higher than average, and potential parents should be counseled.

Tetralogy of Fallot

Tetralogy of Fallot is the commonest form of cyanotic congenital heart disease seen in the adult. Nonetheless, in the developed world the unoperated patient with tetralogy of Fallot has, fortunately, become a rarity, since the overwhelming majority of patients will have undergone palliation or, more often, repair in childhood. From an anatomic and pathophysiologic standpoint, the manifestations of tetralogy of Fallot are similar in all age groups, although hypercyanotic spells, which are often seen in infants and young children, are rare in adults. The development of systemic hypertension with age is a problem, since it increases the afterload to both ventricles.[159,189] Although pulmonary blood flow may improve, this occurs at the expense of right ventricular failure. Acquired calcific aortic stenosis has similar effects. Aortic regurgitation may occur as a result of cusp prolapse into the subaortic ventricular septal defect, and the aorta itself may be dilated. The aortic regurgitation may also be exacerbated by infective endocarditis. Since the volume overload is transmitted to both ventricles, patients may present with right ventricular failure as a consequence of aortic regurgitation. The development of chronic obstructive lung disease is another manifestation of an acquired cardiopulmonary disease that may place the adult patient with tetralogy of Fallot at particular risk.

NATURAL HISTORY

Survival into the seventh decade is described,[190] but the natural history in the unoperated patient, which is determined by the severity of obstruction of the right ventricular outflow tract and pulmonary vasculature, is poor. Only 25 percent of patients reach the age of 10 years; 11 percent

are alive at 20 years, 6 percent at age 30 years, and only 3 percent at age 40 years.[159,162,191] Complications of right-to-left shunting and erythrocytosis, which include stroke and cerebral abscess, are common and, in many instances, fatal. Patients are at continuing risk of infective endocarditis; the development of congestive heart failure in adolescence or early adult life is a major cause of death, as is arrhythmia. Myocardial fibrosis resulting from long-standing right ventricular pressure overload and hypoxemia are postulated mechanisms.[192] Prior palliative surgery with a Cooley or Waterston shunt (between the ascending aorta and right pulmonary artery) or a Potts shunt (between the descending aorta and the left pulmonary artery) can lead to the late development of pulmonary vascular disease.[193]

MANAGEMENT

The focus of medical treatment in unoperated patients is on the elevated hematocrit, bleeding disorders, and abnormal uric acid metabolism and the complications of pregnancy. Repair is indicated in all suitable patients, and the principles and techniques are not significantly different in adults than in children (see Chap. 63).[161] Most adults are suitable candidates for repair, but occasionally a patient with an underdeveloped pulmonary vascular bed may require a palliative shunt procedure. Intracardiac repair consists of closure of the ventricular septal defect and relief of right ventricular outflow tract obstruction. In some patients, this may require excision of the pulmonary valve and patch reconstruction of the anulus and outflow tract. In the occasional patient with an anomalous origin of the left coronary artery from the right coronary artery, a conduit between the right ventricle and pulmonary artery may be required.[162]

LATE RESULTS

Late survival is excellent, even in patients who underwent repair during the very early years of open heart surgery.[162] At the Mayo Clinic, the cumulative 30-year survival for patients undergoing successful surgery between 1956 and 1960 was 86 percent compared to 95 percent in age- and sex-matched controls (Fig. 64-4).[194] In a previous series of 396 hospital survivors of repair between 1955 and 1962 at the same institution, 91 percent were alive at 20 years. At 30 years, 77 percent of the initial cohort of 106 patients undergoing surgery between 1954 and 1960 by Lillehei and associates were alive, including 1 patient who was 45 years of age at the time of operation.[195] Surgery cannot be considered "curative," since survival, even in excellent series, is slightly but significantly worse than for a matched control population. The risk factors for an adverse late outcome include older age at surgery, preoperative congestive heart failure, a previous Potts shunt, persistent right ventricular systolic hypertension, and a residual ventricular septal defect.[175,193] Late death may be sudden, due to tachyarrhythmia or, very rarely in the current era, to conduction disease (see above).[50] Left and right ventricular failure due to right ventricular pressure overload or left ventricular volume overload is another important cause of late death in older patients.[159]

The late functional outcome is excellent for the majority of patients. Most lead normal lives, but the results appear to be better in those undergoing surgery at a younger age.[196] Persistent or recurrent symptoms are usually the result of incomplete relief of right ventricular systolic hypertension or recurrent or residual ventricular septal defects. These problems are often manifest within the first few years after surgery and may require reoperation. Progressive aortic dilatation and aortic regurgitation may also occur, requiring aortic valve replacement.[197] Pulmonary regurgitation may be well tolerated for decades but may be associated with late impairment of exercise capacity and, frequently, atrial arrhythmias. Right ventricular volume overload may also be well tolerated for years but ultimately results in right ventricular failure and progressive tricuspid regurgitation. Pulmonary valve replacement can be accomplished with a low risk.[149] In some patients, isolated right ventricular restrictive physiology may paradoxically improve exercise performance and reduce cardiac enlargement, due possibly to shortening of the duration

of pulmonary regurgitation.[68]

Recent information links pulmonary regurgitation, cardiomegaly, QRS duration, and potentially life-threatening ventricular arrhythmia.[68,69] This may be important for identification of risk of late sudden death, which has been a rare event in most long-term follow-up series. Asymptomatic ventricular arrhythmia is very common during long-term follow-up. It is again related to older age at repair, but the link between nonsustained ventricular arrhythmia and adverse clinical outcome is uncertain (see above).[61,62] Objective testing has emphasized the effects of older age at operation on subsequent exercise performance. This is essentially normal for children repaired at below 5 years of age but is usually impaired when surgery is undertaken in adolescence or adulthood.[198]

Before unrestricted physical activity after repair of tetralogy of Fallot can be recommended, careful evaluation-including echocardiography, ECG monitoring, and exercise testing-should be undertaken. Normal activity, including competitive sports, seems reasonable if surgery has been performed at a young age, right and left ventricular function and size are normal, and there are no residual ventricular septal defect, significant right ventricular outflow tract obstruction, or worrisome arrhythmia. In those who do not fulfill these stringent criteria, the degree to which physical activity should be restricted must be individualized. Currently, long-term follow-up of all patients with tetralogy of Fallot is recommended.

Pulmonary Stenosis

Isolated pulmonary valve stenosis is a common form of adult congenital heart disease and is characterized typically by a trileaflet valve with fused commissures. A dysplastic valve without commissural fusion occurs infrequently in otherwise normal children but more commonly in patients with Noonan's syndrome (see Fig. 10-13).[159] Subvalvar stenosis due to infundibular hypertrophy is usually a secondary phenomenon in response to obstruction to right ventricular outflow but may occur as a rare isolated entity. Supravalvar or peripheral pulmonary artery stenosis is also extremely uncommon as an isolated entity but is associated with tetralogy of Fallot and supravalvar aortic stenosis in Williams' syndrome (see Fig. 10-25).

NATURAL HISTORY

Prolonged survival into adult life is common and depends upon the severity of obstruction. In patients with severe pulmonary stenosis, symptoms of right-sided failure increase with time because of progressive obstruction and alterations in right ventricular compliance.[199] In the Joint Study of the Natural History of Congenital Heart Disease, 19 percent of patients with severe stenosis aged 2 to 11 years and 37 percent aged 12 to 21 years were symptomatic. The natural history of moderate pulmonary stenosis in older patients is more favorable, with less tendency to progression.

MANAGEMENT

Patients with mild stenosis are asymptomatic and require no intervention other than antibiotic prophylaxis against infective endocarditis. In patients with more severe stenosis (>140-mm gradient between the right ventricle and pulmonary artery), intervention to reduce severity should be considered even if there are no symptoms.

Surgical valvotomy for isolated pulmonary stenosis has been successfully performed for more than 40 years. Perioperative morbidity and mortality rates are minimal beyond the neonatal period in patients without severe congestive cardiac failure or right ventricular dysplasia.[162] Late results are also excellent. In a study from the Mayo Clinic of patients undergoing surgery between 1956 and 1957, late survival for those undergoing valvotomy who are over 21 years of age was similar

but not identical to that of an age- and sex-matched control population (Fig. 64-5). Among patients undergoing surgery at an older age, late survival, although still good, was less than that of the control population (Fig. 64-6).[200] This effect of age on late outcome, which was independent of the use of ventriculotomy and outflow patches and of pulmonary regurgitation, is likely the result of long-standing pressure overload on the right ventricle. Late functional results are excellent, and pulmonary regurgitation is well tolerated in the short and medium term. More severe pulmonary regurgitation may result when a pulmonary valvectomy or transanular patch is required, as may be the case for a small or dysplastic valve; the long-term consequences on the right ventricle and functional capacity are not yet well documented (see "Tetralogy of Fallot," above).

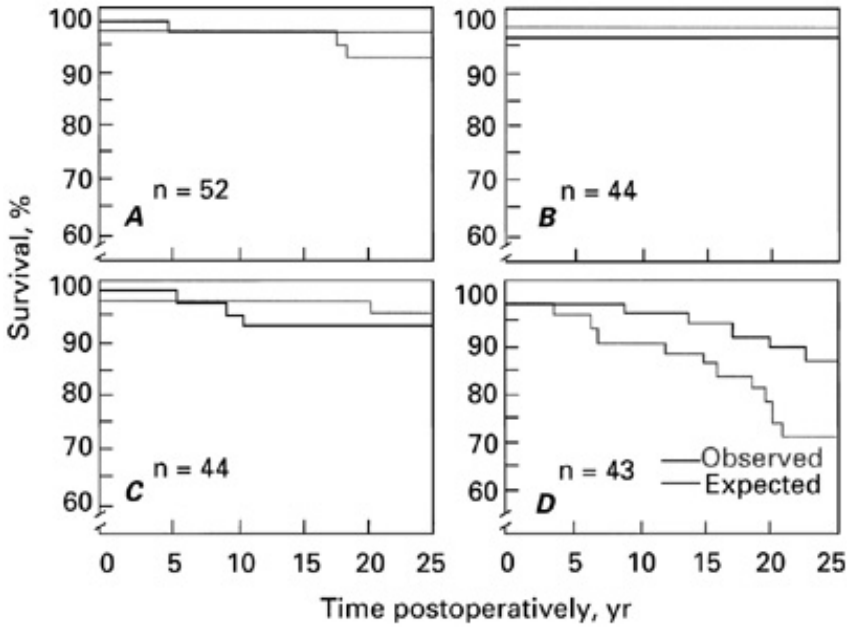

Figure 64-5: Long-term survival of perioperative survivors of surgical repair of pulmonary valve stenosis by age at time of operation. *A*. Ages 0 to 4 years. *B*. Ages 5 to 10 years. *C*. Ages 11 to 20 years. *D*. Ages 21 to 68 years. Expected is survival in an age- and sex-matched population. Values of *p* for comparison between the expected and observed survivals: .07, .34, .16, and <.002 for panels *A*, *B*, *C*, and *D*, respectively. (From Kopecky SL, Gersh BJ, McGoon MD, et al. Long-term outcome of patients undergoing surgical repair of isolated pulmonary valve stenosis: Follow-up at 20-30 years. *Circulation* 1988; 78:1150. Reproduced with permission from the publisher and authors.)

Surgical valvotomy is now rarely required after infancy because of the advent of catheter balloon pulmonary valvotomy. In most institutions, balloon valvotomy is the initial procedure of choice at all ages. In the series of 822 patients in the Valvuloplasty and Angioplasty of Congenital Heart Abnormalities registry, gradient reduction was substantially worse in patients with dysplastic valves.[201] Interventional catheter procedures should be confined to centers with experienced operators.

Long-term follow-up data are not yet available. It appears that the excellent early results are maintained for at least 5 years. The late effects of pulmonary regurgitation resulting from the use of large balloons need to be determined. The risk of infective endocarditis in patients with mild pulmonary stenosis or in those with mild gradients after surgical or balloon valvotomy is low. Long-term follow-up is recommended to evaluate not only the right ventricular outflow tract gradient but also pulmonary regurgitation, right ventricular function, and exercise performance. In patients with good relief of pulmonary stenosis, no restriction of physical activities, including

competitive sports, is required. In those with moderate residual obstruction or right ventricular dysfunction, exercise intensity should be reduced (see also Chap. 77).

Left Ventricular Outflow Tract Obstruction

Congenital left ventricular outflow tract obstruction may occur at valvar, subvalvar, and supravalvar levels (see Chap. 85). Aortic valve stenosis is a common abnormality in adults with congenital heart disease. It may either be an isolated defect or be associated with other lesions, such as coarctation or ventricular septal defect. It is usually due to a bicuspid aortic valve, which may be present in 1 to 2 percent of the total adult population and is three to four times more common in males than in females.[202] Unicuspid and tricuspid stenotic valves are less common.[162] Subvalvar stenosis encompasses a morphologic spectrum of fibrous or fibromuscular obstructions; it can be a discrete "membrane" below the aortic valve, a discrete fibromuscular ridge, or a diffuse narrowing extending well into the left ventricular cavity forming a "tunnel."[203] The condition occurs more commonly in patients with long and narrow left ventricular outflow tracts,[204] and perhaps this morphologic feature promotes turbulence and shear stresses that stimulate cellular proliferation.[205] Abnormal ventricular bands or chords may also contribute to obstruction, along with abnormal chordal attachments of the anterior mitral valve leaflet. A dynamic component of obstruction may also occur as left ventricular hypertrophy progresses. Common associated anomalies include ventricular septal defect and coarctation of the aorta. Supravalvar stenosis is the least common variety of left ventricular outflow tract obstruction in adolescents and adults, except in the context of Williams' syndrome.[206]

NATURAL HISTORY

The natural history of congenital valvar aortic stenosis in adults is variable but is characterized by progressive stenosis with time (Fig. 64-7; see Chap. 56).[159] By the age of 45 years, approximately half of all bicuspid aortic valves have some degree of narrowing. The severity of obstruction at the time of diagnosis correlates with the pattern of progression (Fig. 64-8).[207] Bacterial endocarditis is relatively uncommon (1.8 to 2.7 cases per 100 patient-years),[208] but antibiotic prophylaxis is necessary, even for functionally normal valves. Slowly progressive aortic regurgitation is well recognized in young adulthood, but sudden deterioration is rare, except as a sequel to infection.[209,210] Associated abnormalities of the aorta are not uncommon, and aneurysmal dilatation and dissection of the ascending aorta may be seen even with functionally normal valves. Fragmentation of the elastic fibers in the media has been noted histologically, and, recently, premature smooth muscle cell apoptosis has been implicated. These findings suggest a common genetic abnormality involving both the aortic valve and the ascending aortic wall.[211]

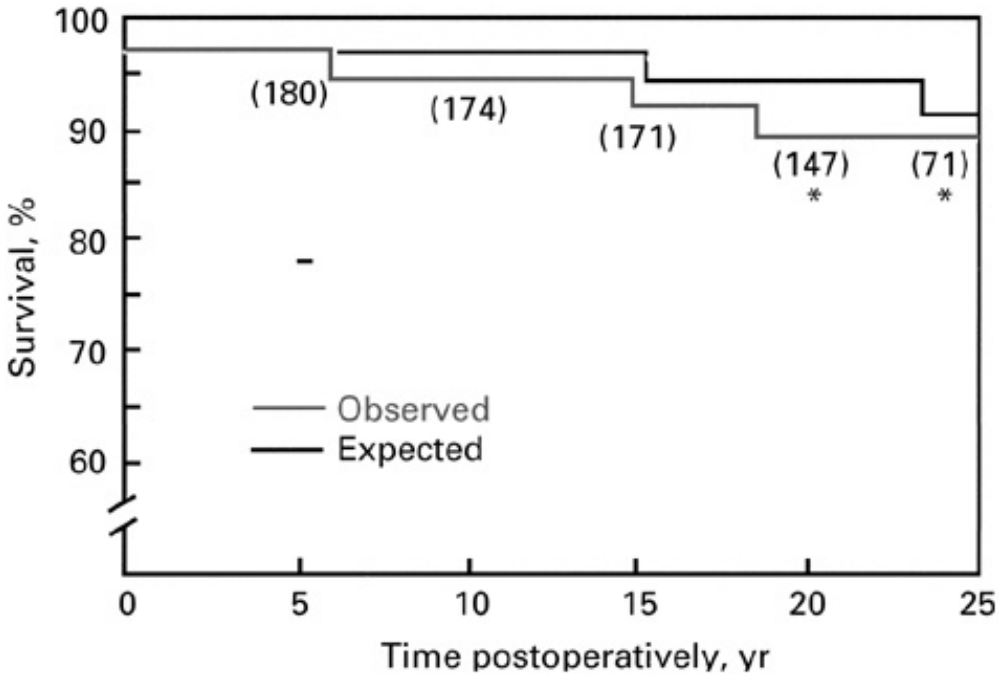

Figure 64-7: Long-term survival of perioperative survivors following surgical repair of isolated pulmonary stenosis and expected survival of age- and sex-matched control populations. Difference between expected and observed $p < .002$. (From Kopecky SL, Gersh BJ, McGoon MD, et al. Long-term outcome of patients undergoing surgical repair of isolated pulmonary valve stenosis: Follow-up at 20-30 years. *Circulation* 1988; 78:1150. Reproduced with permission from the American Heart Association and authors.)

Discrete subaortic stenosis may cause rapidly progressive obstruction in childhood and young adulthood. Progressive aortic regurgitation is common, and infective endocarditis is considered to be a particular hazard (see Chap. 63).[209,210] The natural history of supravalvar aortic stenosis is poor, and survival to adulthood is exceptional.[159] The presence of associated congenital abnormalities and possibly premature coronary artery disease with systolic hypertension is likely a contributory factor to this adverse outcome.

MANAGEMENT

The development of symptoms (e.g., angina, exertional dyspnea, and syncope) mandates prompt intervention in aortic valve stenosis (see Chap. 56). In asymptomatic younger individuals, however, the documentation of severe aortic stenosis may in itself be considered an indication for intervention.[212,213] Mild aortic stenosis in asymptomatic patients with gradients below 50 mmHg warrants careful surveillance. The management of patients in the intermediate group (gradients 50 to 75 mmHg) is more controversial, but evidence argues in favor of elective intervention. Calculation of aortic valve area is important, since left ventricular-aortic gradients may be misleading if there is reduced cardiac output.

Surgery in the young adult with congenital aortic stenosis must be considered palliative.[152,214] In the absence of calcification, young patients may be candidates for aortic valvotomy (see also Chaps. 56 and 63). Perioperative mortality rates in adolescents and adults are extremely low, and late survival is excellent. A large proportion (35 to 45 percent), however, will require reoperation, including aortic valve replacement, over a follow-up period of 20 to 25 years.[150,152] Catheter balloon valvotomy (see Chap. 63) has been utilized in adolescents and young adults with mobile noncalcified valves, but the results are also palliative.[215]

Valve replacement is the only option for valves unsuitable for valvotomy, including those with significant calcification and regurgitation. The pulmonary autograft (Ross) operation represents an attractive surgical alternative to prosthetic or homograft aortic valve replacement. The choice of operation is discussed elsewhere (see Chap. 56), but the age and size of the patient are major considerations, as are individual characteristics that determine the safety of anticoagulation, such as the desire for future pregnancies.

Subaortic stenosis is usually amenable to more definitive surgical repair. This fact, in conjunction with the potential for progressive aortic regurgitation, justifies a more aggressive approach even in asymptomatic patients with lesser gradients.[216,217] Excision of the obstructive membrane, together with a myectomy or myotomy, is usually required. Subaortic stenosis occasionally recurs, and persistent or progressive aortic regurgitation may develop. Operative mortality rates are low, but the risks are greater in patients with "tunnel" forms of obstruction and in patients with obstruction at several levels. Such situations usually require a more aggressive surgical intervention with extensive myectomy, a Konno procedure, or modification thereof.[218]

Hospital mortality rates for repair of supravalvular aortic stenosis are low, and late morbidity and mortality rates are also excellent. Nevertheless, residual abnormality, such as aortic regurgitation or stenosis, may persist after aortoplasty.

Medical follow-up of patients who have undergone surgical or balloon valvotomy should focus on the development of restenosis, the severity and progression of aortic regurgitation, and the constant hazard of infective endocarditis. Echocardiography has facilitated serial evaluation of gradients, valve areas, ventricular dimensions, function, and mass. The acceptable level of physical activity in patients with left ventricular outflow tract obstruction remains very controversial. It is debatable whether any patient who has had significant obstruction should be allowed to participate in competitive sports. We consider a residual gradient greater than 20 mmHg or persistent left ventricular hypertrophy to be contraindications to vigorous physical activity. Before one approves strenuous activity in others, evaluation should include ECG monitoring and maximal exercise testing (see Chap. 14).

Coarctation of the Aorta

Although coarctation of the aorta is a congenital malformation, nearly 20 percent of the cases presenting at the Mayo Clinic over a 20-year period were diagnosed initially in adolescence or adulthood. Most commonly, coarctation diagnosed at ages beyond childhood was discovered in asymptomatic patients in whom a routine physical examination for athletic participation or employment disclosed upper limb hypertension with diminished or absent femoral pulses. Coarctation of the aorta may occur anywhere along the descending aorta, even below the diaphragm, but in more than 95 percent of cases it is located below the origin of the left subclavian artery, and may involve the origin of this vessel. Usually, there is a discrete infolding of the aortic wall, causing eccentric narrowing of the lumen. Frequently, there is secondary aortic dilatation proximal and distal to the coarcted area.

NATURAL HISTORY

Isolated, severe aortic coarctation may cause congestive heart failure as early as the neonatal period. More frequently, however, coarctation producing symptoms during early infancy is associated with other congenital cardiovascular abnormalities, such as ventricular septal defect, left ventricular outflow tract obstruction, or mitral valve abnormality. Many patients with undetected coarctation will remain symptom-free until adolescence or early adulthood, when symptoms such as headaches related to hypertension, leg fatigue, or leg cramps may develop. Occasionally, a major catastrophic event, such as a cerebrovascular accident, infective endocarditis, or even rupture of the aorta, is the first recognized symptom. A bicuspid aortic valve

is found in approximately 25 to 50 percent of patients with coarctation, and these abnormal valves have a tendency to calcify in early or middle adult life, producing aortic stenosis. Aortic stenosis may be the presenting condition, and subsequent investigation may disclose an additional coarctation of the aorta. In the era before surgical intervention, approximately 50 percent of patients with coarctation died within the first three decades, and 75 percent were dead by age 50.[219] Death was most frequently caused by a complication of hypertension, such as stroke or aortic dissection, but other causes included endocarditis, endarteritis, and congestive heart failure.

MANAGEMENT

Infrequently, a mild degree of coarctation may be present that would not justify intervention. In the great majority of cases, however, symptoms or the presence of significant upper-body hypertension mandate surgical repair. On occasion, an asymptomatic adolescent or adult patient with a severe coarctation will be normotensive at rest because of well-developed collaterals around the coarctation site. Such patients have inappropriate hypertension with exercise, however, and should be repaired. There is evidence that residual hypertension and late complications are directly related to age at the time of repair.[220]

Surgery for coarctation has been available since 1945.[221] Various techniques have been used, including end-to-end anastomosis, patch grafting, and the use of the subclavian flap technique.[222] Aneurysmal or atherosclerotic changes in the aorta found in adolescents or adults may occasionally mandate the use of an interposition prosthetic graft. Surgery is performed without cardiopulmonary bypass, and the risk of death from operation is small, although it is higher in adults than in children. Serious morbidity is rare, but occasionally paraplegia secondary to spinal cord ischemia and bowel ischemia or infarction occur.[223] For patients who require concomitant surgical procedures, such as aortic valve replacement, an ascending-to-descending aortic bypass may be utilized through a median sternotomy.[224] Some patients require antihypertensive medication because of transient postoperative hypertension for a short period, whereas in others hypertension may persist, requiring long-term treatment.

Balloon angioplasty of native coarctation has been utilized, but the role of this technique remains controversial.[225] Immediate reduction of the degree of obstruction and gradient is usually possible but is achieved at the price of tearing both the aortic intima and media. Late aneurysm formation, presumably secondary to the disruption of the media, has been observed.[226] Currently, most centers do not perform catheter balloon angioplasty as the primary procedure for coarctation, reserving it for recoarctation, where it appears to have a much greater role.[227] Balloon-expandable stents have also been utilized recently with good results, although long-term follow-up data are not available.[228-231]

LATE RESULTS

The Mayo Clinic has published late results in 646 patients with coarctation operated upon between 1946 and 1981.[220] The median age at operation was 16 years (range 1 week to 72 years) with 72 patients (11 percent) over age 35 years of age. Although survival was good (91 percent at 10 years and 72 percent at 30 years), the mean age of death was 38 years, confirming the previous finding that life expectancy is reduced, even after repair. In this and other series reporting long-term follow-up, the most common cause of death was premature coronary artery disease with secondary myocardial infarction.[232,233] Other causes included congestive heart failure, stroke, and ruptured aortic aneurysm. Age at operation was a powerful prognostic factor. The older the patient at the time of repair, the greater the probability of premature death, making it highly likely that the duration of preoperative obstruction and hypertension is important in the etiology of arterial disease and subsequent cardiovascular events.

The incidence of recoarctation with all surgical techniques is low for repairs performed after

infancy, but surgery in later years for associated abnormalities, such as aortic and mitral valve disease, may be required. The majority of survivors are asymptomatic, but there is a high incidence of late hypertension, despite satisfactory early fall in blood pressure after surgery and good relief of obstruction. In one series, only 32 percent of patients were normotensive 30 years after repair, and 25 percent were significantly hypertensive.[233] Long-term blood pressure surveillance, including blood pressures with exercise, is therefore mandatory, since hypertension is directly related to many of the late vascular complications.[220,232,233] This incidence may decline significantly as more patients are diagnosed and repaired during infancy or early childhood. Long-term regular follow-up should also include surveillance of the repaired aorta (MRI imaging is very suitable), assessment of the aortic valve, and endocarditis prophylaxis.

Transposition of the Great Arteries

In complete transposition of the great arteries, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (discordant ventriculoarterial connection). As a result, the systemic and arterial circulations run "in parallel" rather than "in series," and predominantly desaturated blood enters the aorta. Oxygenation and survival depend on mixing between the systemic and pulmonary circulations at the atrial level in simple transposition (via a patent foramen ovale or atrial septal defect; see Chap. 63). In approximately half the cases, there are associated anomalies: ventricular septal defect (30 percent), left ventricular outflow tract obstruction (5 to 10 percent), ventricular septal defect with left ventricular outflow tract obstruction (10 percent), patent ductus arteriosus, and, more rarely, coarctation of the aorta or AV valve anomalies.[234] These associated conditions affect both the natural history and surgical management.

NATURAL HISTORY

Transposition of the great arteries is relatively common, but the natural history is so poor that very few patients survive past childhood without intervention. Death is usually due to profound hypoxia and its hematologic consequences. In transposition of the great arteries with large ventricular septal defect, severe hypoxia is rare, but patients do badly as a result of heart failure from excessive pulmonary flow and early pulmonary vascular disease.[129] Transposition with ventricular septal defect and left ventricular outflow tract obstruction presents with early hypoxia. Occasionally, prolonged survival into adult life may occur with a large atrial septal defect, ventricular septal defect, and/or patent ductus arteriosus, with the development of pulmonary vascular disease (Eisenmenger's syndrome) or with associated ventricular septal defect and left ventricular outflow tract obstruction.

MANAGEMENT

The outlook has been transformed by the use of catheter balloon atrial septostomy.[235] In the late 1950s and early 1960s, the Senning[236] and Mustard[237] operations, involving atrial redirection of the systemic and pulmonary venous returns, were introduced. These operations are usually performed between 3 and 12 months of age, with a trend over the years to earlier surgery. Both procedures have been undertaken with excellent early mortality rates (approximately 2 percent operative mortality rate and less than 10 percent for the whole early-management protocol). Long-term follow-up for both procedures is now available, with comparable late results, apart from a lower incidence of baffle obstruction after the Senning operation.[238] Follow-up now extends to 30 years in some patients.[239] A recent study reported actuarial survival rates of 90 percent, 80 percent, and 80 percent at 10, 20, and 28 years, respectively, after the Mustard repair.[240,241] Seventy-six percent of the survivors were in NYHA class I. Thus, cardiologists are likely to see patients who have undergone these types of atrial redirection. Late problems, however, are now recognized, with sudden death, arrhythmia, tricuspid regurgitation, and right (systemic)

ventricular dysfunction being the major concerns.[240] These late complications have led to the increasing acceptance of the arterial switch operation as the operation of choice.[242] This procedure involves transection and reanastomosis of the great arteries (aorta to left ventricle and pulmonary artery to right ventricle) with coronary artery transfer. The mortality rate for this procedure has decreased, but the long-term results into adult life are not yet available. For transposition with ventricular septal defect, the mortality rate for atrial repair with ventricular septal defect closure has always been higher than for simple transposition, and arterial switch is the operation of choice. Transposition with ventricular septal defect and left ventricular outflow tract obstruction is usually palliated in infancy with a systemic-to-pulmonary shunt followed by repair by the Rastelli procedure in later childhood.[243] This operation involves closure of the ventricular septal defect to connect the left ventricle to the aorta and insertion of a valved conduit from the right ventricle to the pulmonary artery. Long-term results are good, but further surgery to replace the extracardiac conduit in adolescent and adult life is inevitable (see "Surgical Considerations," above).

LATE RESULTS

Two specific problems after atrial redirection have caused concern during long-term follow-up: arrhythmia and systemic ventricular dysfunction. Loss of sinus rhythm is progressive and has not been prevented by modification of surgical technique for either the Mustard or the Senning operation.[41,244] In most cases, it is asymptomatic, but occasionally profound bradycardia may necessitate pacemaker insertion. There appears, however, to be no relationship between loss of sinus rhythm and risk of sudden death. More worrisome is the development of atrial tachyarrhythmias, including atrial flutter. This arrhythmia has profound hemodynamic consequences after intraatrial repair and is a risk factor for sudden death, especially in the presence of right ventricular dysfunction. Deteriorating performance of the right ventricle supporting the systemic circulation has been reported in some patients, but the precise basis for this problem remains unclear.[9] Although a major concern, it is not yet known whether or not ventricular performance will inevitably deteriorate in the majority of patients and, if so, over what period.[9]

Risk stratification for sudden death remains a clinical challenge. Late death cannot be predicted merely from serial ECGs or ambulatory monitoring.[41] This difficulty underscores the need for a more sophisticated approach involving both electrophysiologic and hemodynamic measurements. Assessment should include evaluation of cardiac performance at rest and exercise, and evaluation of systemic and venous pathways. Transesophageal echocardiography is particularly useful in this situation. Heart transplantation should be considered in the patient who has severe right ventricular failure or disabling arrhythmias. An alternative approach is to perform pulmonary artery banding as preparation for conversion of the atrial repair to an arterial switch. Published results have indicated a significant surgical mortality rate for this approach. As a result, case selection and timing, as well as optimal surgical strategy, remain unclear.[245] The rather limited information after arterial switch operation suggests that electrophysiologic problems are much less prevalent.[246] More recent studies confirm the theoretical advantages of anatomic repair over atrial repair with respect to preservation of sinus node function and lower prevalence of clinically relevant tachyarrhythmias.[247] The systemic left ventricle after the switch is at risk from the surgical procedure itself, potential myocardial ischemia from coronary distortion, and aortic regurgitation. Early results, however, are encouraging, but few patients have yet reached adult life.[248] Because of the high incidence of observed and potential medical problems, all patients who have had both atrial and arterial repair of transposition of the great arteries should have lifelong follow-up by a cardiologist at a center specializing in adult congenital heart disease.

Congenitally Corrected Transposition (Atrioventricular and Ventriculoarterial Discordance)

In congenitally corrected transposition of the great arteries, there is a discordant AV connection

(right atrium to left ventricle and left atrium to right ventricle) and a discordant ventriculoarterial connection (left ventricle to pulmonary artery and right ventricle to aorta). As a result of this "double discordance," the systemic and pulmonary venous returns flow to the appropriate great arteries, giving rise to the potentially confusing term *corrected transposition*.[249]

NATURAL HISTORY

In a small proportion of cases (approximately 10 percent in reported series, but this is probably an underestimate), there are no associated cardiac defects.[250,251] Such individuals are pink and asymptomatic, and survival to the ninth decade has been reported.[76] The only specific difference from normal hearts is the tendency to develop AV conduction problems and complete heart block. Complete heart block may be present from birth (approximately 10 percent of patients)[252] and is said to develop in about 2 percent of patients per year.[253] It is not clear whether the systemic right ventricle in patients with corrected transposition can maintain function over extended periods or whether this has an impact on outcome, since few studies have examined enough patients without associated defects over a long enough period. The majority of patients have a ventricular septal defect (90 percent) and/or pulmonary stenosis (80 percent).[250] The combination of these lesions may cause cyanosis. Abnormalities of the tricuspid valve (systemic AV valve) are common and may be due to an intrinsic tricuspid valve abnormality, such as Ebstein's malformation. These defects influence the natural history and surgical strategy required.

MANAGEMENT

Strategies and indications for surgery differ from those in patients with normal connections because of the potential for the operation to aggravate systemic ventricular dysfunction, systemic AV valve incompetence, or conduction problems. Palliative surgery in childhood is sometimes performed, since definitive repair may involve insertion of an extracardiac conduit. In a large retrospective study of 111 patients managed over a 20-year period, it was concluded that patients with symptomatic heart failure should be repaired before the systemic ventricle dilates and the tricuspid regurgitation becomes severe.[251] Patients with more than mild tricuspid regurgitation whose valves were not replaced did very poorly. In contrast, the patients with cyanosis did much better, and the timing of intracardiac surgery can be delayed and be determined by the patient's symptoms. In one recent series of surgical repair of 127 patients, 56 percent required reoperation within 20 years for AV valve regurgitation, pulmonary stenosis, or both.[254] Left AV valve regurgitation is common in adults with congenitally corrected transposition[255] and tends to be progressive.[256] It may be related to an Ebstein-like malformation of the left AV valve, but these valves, in contrast to Ebstein's anomaly of the right AV valve, cannot be repaired adequately and always need to be replaced. Left AV valve replacement should always be performed before there is compromise of systemic (morphologic right) ventricular function. In one series of 40 patients, left AV valve replacement was accomplished without surgically induced complete heart block, with an early mortality rate of 10 percent (n = 4) and 8 late deaths.[257] The principal cause of death in all 12 patients was systemic ventricular failure. Survival correlated with preoperative systemic ventricular ejection fraction of 44 percent or greater. It thus seems appropriate to refer these patients for valve replacement at the earliest signs of ventricular dysfunction.

Recently, alternative surgical strategies involving a "double switch" have been adopted by some units. These involve an atrial repair by a Mustard or Senning operation together with connection of the left ventricle to the aorta (via a patch through the ventricular septal defect) or an arterial switch.[258,259] The advantage of these approaches is that the morphologic left ventricle (with mitral valve) supports the systemic circulation. While this is an attractive option, it should be stressed that few patients who have received double-switch procedures have reached adolescence, and long-term follow-up data are not yet available for comparison with the conventional surgical approach.

LATE RESULTS

The long-term outcome for well-repaired patients is good, but those with severe symptomatic heart failure preoperatively do badly. Atrial arrhythmias are common in long-term follow-up and in one recent series occurred in 36 percent of survivors.[260] Since repairs may involve insertion of an extracardiac conduit, prosthetic AV valve, and pacemaker, careful long-term follow-up is mandatory.

Complex Lesions

A number of complex congenital heart defects involve structural abnormalities that preclude the creation of a biventricular circulation. The changing nomenclature and classification that have been applied to these defects over the years are a major source of confusion (see Chap. 63). This group of patients includes those with double-inlet ventricle (single ventricle), absent right or left AV connection (tricuspid or mitral atresia), some cases of pulmonary atresia/intact ventricular septum, and cases with straddling of an AV valve and hypoplastic left or right ventricles. The natural history of these defects is highly variable and depends to a large extent on the impact of the associated defects. In a recent report of 191 patients with double-inlet ventricle presenting in the first year of life, the actuarial survival rate before definitive repair for the whole group was 57 percent at 1 year and 42 percent at 10 years.[158] On multivariate analysis, pulmonary stenosis, balanced pulmonary flow, and older age at presentation were factors favoring survival, while right atrial isomerism, common AV orifice, pulmonary atresia, obstruction to systemic output, and anomalous pulmonary venous return were detrimental. Despite the complex morphologic defects, prolonged natural survival is possible, particularly if the physiology is well balanced.[261] The patients with double-inlet left ventricle with discordant ventriculoarterial connection and pulmonary stenosis with balanced pulmonary flow do best, with predicted actuarial survivals of 96 percent at 1 year and 91 percent at 10 years.

MANAGEMENT

For most patients with complex congenital heart disease, prolonged survival into adult life is possible only with one or more palliative operations (e.g., systemic to pulmonary shunt, Glenn shunt, pulmonary artery banding, and relief of systemic outflow obstruction) or after a Fontan-type procedure. With palliative surgery alone, clinical deterioration usually begins in the second decade of life and is often due to progressive ventricular dysfunction and/or AV valve regurgitation.[262-264]

The goals of management during childhood have been to maintain suitable anatomy and physiology for the Fontan circulation. A number of modifications of Fontan's original operation have been introduced (Fig. 64-9).[265-268] The basic principle is to separate the systemic and pulmonary circuits by returning systemic venous blood to the pulmonary artery without incorporating a subpulmonary ventricle. This circulation is less "flexible" than one with two functioning ventricles; the operative risk and postoperative status are largely dependent on the patient's suitability. Most important are a low pulmonary vascular resistance and adequate ventricular function (both systolic and diastolic), allowing the circulation to operate with an acceptably low systemic venous pressure. Careful preoperative hemodynamic assessment is vital to optimize patient selection. The operative risk varies considerably among institutions.

LONG-TERM RESULTS

The early and medium-term results of the successful Fontan operation are excellent when compared to the preoperative status of the patients. Improvements in arterial saturation and

exercise tolerance have been confirmed by objective testing.[268] The patients with the best hemodynamics can perform well at submaximal levels of exercise equivalent to most normal daily activities.[269] With longer follow-up, however, increasing problems develop (Table 64-5).[270,271] Fontan's own analysis of 334 patients revealed a premature decline in survival and functional status and a late rise in hazard for which no risk factors could be identified other than the Fontan state per se.[271] Arrhythmia is a particularly common problem and occurs in approximately 20 percent at 10-year follow-up (Table 64-6).[270] Other problems include thrombus in the atria and declining ventricular function.[270-272] Anticoagulation policy differs widely even among specialist centers. The increasing concerns regarding stasis of blood in the right atrium and thrombus formation have led to wider routine use of long-term anticoagulants, but this is not standard practice. Patients with a history of documented atrial arrhythmias, a fenestration in the Fontan connection, and "smoke" in the right atrium on echocardiography have the strongest indications for anticoagulation. Protein-losing enteropathy (PLE) is another important complication and probably results from elevated systemic venous pressure, which subsequently causes lymphangiectasia. PLE is associated with fluid accumulation, such as pleural effusion, ascites, and peripheral edema. The diagnosis can be confirmed by quantifying gastrointestinal protein loss utilizing $alpha_1$ antitrypsin clearance. The cumulative risk for the development of PLE by 10 years in one reported large series was approximately 13 percent;[273] once this complication had developed, the 5-year survival rate was approximately 50 percent. Therapy includes sodium restriction, dietary modification, and anticongestive measures such as diuretics and afterload-reducing agents. Many patients require periodic albumin infusion, but medical management of PLE is usually only partially successful. Obstruction in the Fontan circuit should always be ruled out as a potential cause, since reoperation may result in resolution of the PLE. Chronic subcutaneous heparin therapy may also resolve the PLE,[274,275] as may percutaneous atrial fenestration.[265,276] Occasional reports suggest improvement with steroid therapy.[277] Cardiac transplantation appears to pose a high risk and does not always resolve the protein loss.[274] Other concerns are the effects of nonpulsatile pulmonary flow, favoring the development of pulmonary arteriovenous malformations, as seen after the Glenn anastomosis.[278] Extrapolation of these data to current practice is difficult, but the Fontan procedure should be considered palliative, not curative.

Despite these complications, more and more modifications of the Fontan operation are being performed, and more long-term data are necessary to see whether important complications can be reduced in this way. Much recent interest has involved conversion of the Fontan to a more "hydrodynamically efficient" circuit to improve atrial arrhythmias and PLE.[279] A high mortality rate, however, is associated with PLE surgery, and in one series only 50 percent of the survivors were cured.[274] Atrial arrhythmias may also persist after Fontan conversion[279,280] even though hydrodynamics are improved. Perhaps concomitant arrhythmia circuit cryoablation may improve the results.[281]

Some surgical modifications that have been introduced may improve early and late hemodynamics and the functional results. Perforation of the patch at surgery (fenestrated Fontan) allows a hypertensive right atrium to decompress via a right-to-left shunt at the atrial level.[282] These holes may be closed later with an occlusion device at catheterization. Recent "Fontan" operations have excluded the right atrium from the circulation, creating a total cavopulmonary connection (superior vena cava to right pulmonary artery via a bidirectional Glenn anastomosis and inferior vena cava blood channeled to the pulmonary artery).[283] Data suggest improved flow and energy characteristics compared to the standard atriopulmonary connection and fewer early supraventricular arrhythmias.[46] Other modifications have created an extracardiac Fontan connection using a tube graft in the hope of preventing atrial distention and atrial arrhythmias.[284,285]

All patients who have complex congenital heart defects palliated by systemic-to-pulmonary shunt, cavopulmonary anastomosis (bidirectional Glenn), or Fontan should have lifelong regular cardiac follow-up at a specialist center. Particular attention should be paid to ventricular function, detection of thrombus in the right atrium, residual shunts, systemic AV valve regurgitation, AV malformations in the lung, obstruction at the Fontan anastomosis (especially in early operations involving a right atrium-to-pulmonary artery conduit), and PLE (see above).

Ebstein's Anomaly of the Tricuspid Valve

Ebstein's anomaly is characterized by displacement of the proximal attachments of the tricuspid valve from the AV ring into the right ventricle (see Chap. 63). This structural abnormality divides the right ventricle into an "atrialized" portion and a distal "ventricularized" portion. The severity is variable and accounts for the broad clinical spectrum, from severe disease causing fetal or neonatal death to mild disease compatible with natural survival as late as the eighth decade of life.[286] Ebstein's anomaly is an uncommon defect occurring in less than 1 percent of patients with congenital heart disease, but it is disproportionately represented in the adult congenital heart disease population because of its favorable natural history.

The diagnosis of Ebstein's anomaly is now much easier with echocardiography, which has altered our understanding of the natural history. In a large collaborative study of Ebstein's anomaly reported in 1974, only 7 percent of patients were under 1 year of age.[286] It is not surprising that neonates presenting with Ebstein's anomaly represent the worst end of the spectrum, with a severe anatomic defect and a high incidence of associated abnormalities, particularly right ventricular outflow tract obstruction. Their poor outcome is predictable from their anatomy.[287] Those who survive this period with or without surgery may live into adult life, although there is continued morbidity and death throughout childhood. Many patients are minimally symptomatic in childhood and do not present until adolescence or adult life. Symptoms and signs, when they develop, include cyanosis due to right-to-left shunting at the atrial level, dyspnea and fatigue secondary to hypoxia and low cardiac output, and palpitation due to supraventricular arrhythmia. Ebstein's anomaly is often associated with ventricular preexcitation, which may involve one or more, usually right-sided, accessory pathways. Approximately 25 to 30 percent of adults will have symptomatic arrhythmias that may be difficult to treat and can result in sudden death.[288] Progressive heart failure may develop with time and may be related not only to right-sided problems but also to left-sided abnormalities. Excessive fibrosis has been reported in the left ventricle, and left ventricular dysfunction may be induced on exercise.[287,289] Early cyanosis is an adverse risk factor for survival, as is congestive cardiac failure.[290]

MANAGEMENT

Surgery may consist of repair or replacement of the tricuspid valve together with closure of the atrial septal defect to prevent cyanosis (Fig. 64-10).[291] In 189 patients aged 11 months to 64 years (mean 19.1 years), a tricuspid valve reconstruction was possible in 58.2 percent, and in 36.5 percent a prosthetic valve, usually a bioprosthesis, was inserted. In the occasional patient, the atrial septal defect may be responsible for a left-to-right shunt and can be closed as the sole procedure. In others, the functioning right ventricle is too small for a biventricular circulation, and a Fontan procedure may be the only option. Cross-sectional echocardiography is very useful in determining whether the tricuspid valve is amenable to repair, delineating the mobility or tethering of the elongated anterior leaflet and the presence or absence of fenestration. The results of surgery are affected by the presence of arrhythmia. Uncontrolled preoperative supraventricular arrhythmia is a risk factor for early postoperative rhythm problems that may have serious hemodynamic consequences.[288] It is usually recommended that division of an accessory pathway be performed at the time of tricuspid valve surgery. The pathways are usually in the posteroseptal or right free-wall position and may be multiple. An alternative approach is to perform catheter radiofrequency ablation of the accessory pathway (see Chap. 28) before surgery. Thus far, few such procedures

have been performed in patients with Ebstein's anomaly. In hearts with marked enlargement of the right atrium, catheter ablation is challenging and, in the setting of an atrial communication, poses the additional risk of a paradoxical embolus and stroke. If there are no accessory pathways, a right-sided maze procedure at the time of tricuspid valve surgery may successfully control supraventricular arrhythmia.[169]

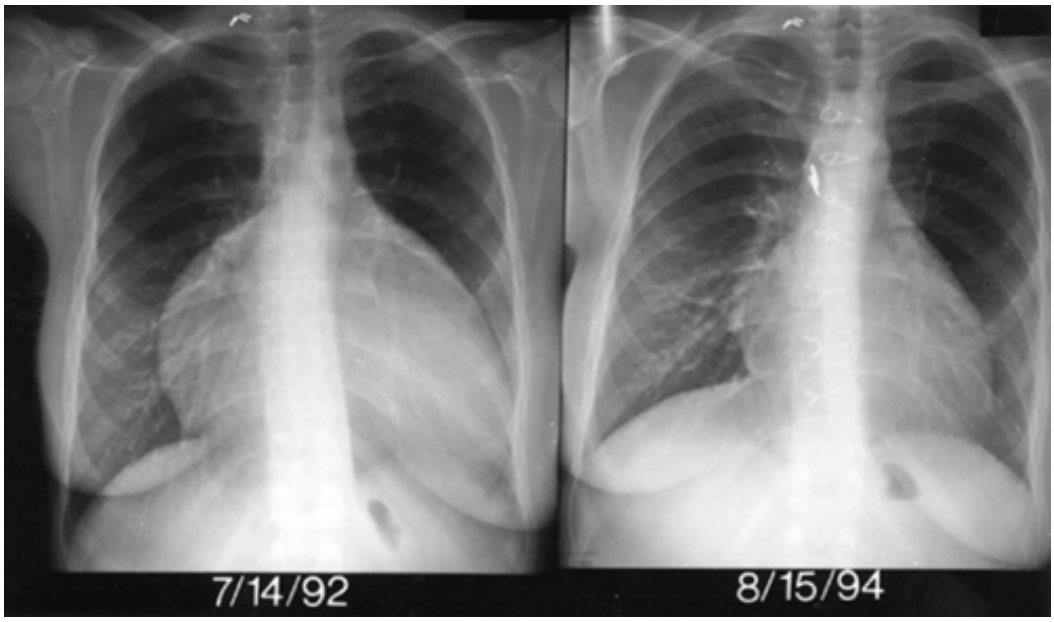

Figure 64-10: (*Left*). The chest radiograph shows severe cardiac enlargement associated with Ebstein's anomaly in a 32-year-old woman. She had had a right Blalock-Taussig shunt at age 12. (*Right*). Following tricuspid valve repair and closure of a secundum atrial septal defect, there has been dramatic reduction in the size of the heart.

LATE RESULTS

The long-term outlook for well-repaired patients is good; reduction in heart size is usual (see Fig. 64-10), and atrial arrhythmias are reduced. Exercise capacity improves postoperatively, particularly in those who are cyanotic before surgery.[292] Of 149 patients receiving a porcine bioprosthesis in the Mayo Clinic series, the 10-year survival was 92.5 percent, and 92 percent of the survivors were NYHA class I or II. Bioprosthesis durability in the tricuspid position performs favorably, with freedom from bioprosthesis replacement being 80.6 percent at 10 and 15 years.[293]

Marfan's Syndrome

Although the autosomally dominant Marfan's syndrome is congenital in the sense that the patient is born with an abnormal gene or genes, the heart defect is usually acquired. Mutations of fibrillin 1, the main constituent of extracellular microfibrils, are the cause of the pleiotropic manifestations of Marfan's syndrome.[294] The typical phenotypic features-tall, thin stature; pectus deformities; arachnodactyly; and high-arched palate-by which the condition is currently diagnosed, may be obvious, subtle, or absent (see Fig. 10-7). Cardiovascular complications occur in 30 to 60 percent of patients and are the cause of a decreased life expectancy.[295] Mitral valve prolapse is the commonest finding in the pediatric population,[296] but aortic root dilation with a potential for aortic dissection or severe aortic valve regurgitation is the most serious later complication.[297] In a review of 257 patients seen between 1939 and 1972, the median age of death was reported to be about 45 years, with aortic root problems accounting for three-fourths of the deaths (see also

Chap. 76).[295] By 1995, a multicenter study reported that the median survival had improved to 72 years.[298]

MANAGEMENT

The risk of dissection is broadly related to the degree of dilation of the aortic root. Dilation can be followed serially by regular cross-sectional echocardiography, which should be performed at least annually. Particularly close monitoring is necessary during puberty and the rapid-growth phase of adolescence. Treatment with beta blockade has been advocated for patients with evidence of aortic root enlargement. Elective aortic root replacement has a low operative mortality rate, but, in contrast, emergency repair, usually for acute aortic dissection, carries a much higher early mortality rate. In a recent multicenter study of 675 patients having aortic root replacement, the 30-day mortality rate was 1.5 percent for those having elective repair, 2.6 percent for those having urgent repair (within 7 days of a surgical consultation), and 11.7 percent for those having emergency repair (within 24 h of a surgical consultation).[297] Forty-six percent of the 158 patients with aortic dissection had an aneurysm with a diameter of 6.5 cm or less. Elective aortic root surgery, therefore, is generally recommended when the aorta exceeds 5.5 cm in diameter.[299] The aortic valve itself may also need to be replaced, although preliminary results from valve-sparing procedures, which eliminate the need for long-term anticoagulants necessary for conventional mechanical valve replacements, suggest cautious optimism.[297,300] It is important to note that more than 10 percent of patients in the multicenter study had problems with the residual aorta, emphasizing the need for continued vigilance of the aorta with MRI or computed tomographic scanning and meticulous control of blood pressure. Since regular, long-term follow-up visits are required, patients with Marfan's syndrome are not uncommon in adult congenital heart clinics. In addition to cardiac care, such patients need expert help with skeletal and ocular problems, genetic counseling, advice on physical activity (see above), and general psychosocial support.

Part 11: CARDIOMYOPATHY AND SPECIFIC HEART MUSCLE DISEASES
Chapter 65:

CLASSIFICATION OF CARDIOMYOPATHIES

Author: Jay W. Mason

Despite controversy in classifying the cardiomyopathies, there is general agreement on the definition. Cardiomyopathy is a primary disorder of the heart muscle that causes abnormal myocardial performance and is not the result of disease or dysfunction of other cardiac structures. Thus, the term *cardiomyopathy* excludes cases of myocardial failure due to myocardial infarction (so-called ischemic cardiomyopathy, a misnomer), systemic arterial hypertension, and valvular stenosis or regurgitation. Although cardiomyopathy is easily defined, classification of its various forms is difficult. This difficulty results because the great majority of cases of cardiomyopathy are associated with generalized cardiac dilatation and ventricular systolic dysfunction, in which the etiology is unknown.

CLASSIFICATION SCIENCE

Physicians and biomedical scientists use classification schemes to draw relations and distinctions between diseases. This process promotes understanding and aids recollection. Even disorders we know little about can be understood if appropriately placed in a class with other disorders we do know about.

The science of classification requires that all items within the classified domain be included and that each item appear in only one class. Inability to make clear distinctions between biologic systems makes this latter requirement the most demanding. Classification must be based on those features of the individual units within the domain that are understood or recognizable and that permit a useful distinction between groups.

Thus, the classification of cardiomyopathies should be based on an extensive, current category of knowledge about heart diseases and should be as useful as possible to physicians and scientists.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

CATEGORIES OF KNOWLEDGE ABOUT CARDIOMYOPATHIES

Knowledge about cardiomyopathies falls into several categories: Etiology, gross anatomy, histology, genetics, biochemistry, immunology, hemodynamic function, prognosis, treatment, and others. No single classification scheme can utilize all of these areas of knowledge because there is so much overlap between them.[1]

The best classifications use a single category of knowledge with which to separate items in the domain. However, the most useful knowledge category differs among users of the classification. A histologic classification will be useful to the pathologist, while a functional categorization is more valuable to the treating physician. If only one classification is to be used by both clinicians and scientists, etiologic categorization seems to be most successful. It must be recognized, however, that no single classification can serve all users and all purposes.

Several commonly employed classifications of cardiomyopathy are discussed below. For clarity, the primary categories of each classification are displayed in Tables 65-1 to 65-6, but only a few representative diseases are mentioned within each category. The exceptions are the etiologic classification (Table 65-3) and the *International Classification of Disease,* **Ninth Revision (ICD-9)** classification (Table 65-5), in which more nearly complete listings are provided.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

THE WORLD HEALTH ORGANIZATION CLASSIFICATION

The only currently used clinical classification of cardiomyopathy that was developed by consensus is that of the *World Health Organization* (WHO) and the International Society and Federation of Cardiology.[2,3] This scheme is outlined in Table 65-1. Because it was developed by a panel of experts and has the implied backing of the WHO, it is widely recognized and frequently used. Although it has been in existence since 1980, it has not gained general acceptance.

The 1980 WHO committee[2] reserved the term *cardiomyopathy* for myocardial disease of unknown cause. This somewhat restricted usage has not been adopted widely and is not fully adhered to in this text. The more common usage includes all forms of heart disease in which the myocardium is primarily involved, as defined at the start of this chapter, but excludes valvular heart disease, systemic arterial hypertension, and coronary atherosclerosis. In its 1995 classification, the WHO committee (entirely new except for one member) moved toward this more common usage, stating, "With increasing understanding of etiology and pathogenesis, the difference between cardiomyopathy and specific heart muscle disease has become indistinct."[3]

Examination of the 1980 and 1995 WHO classifications reveals that they are, in fact, somewhat awkward schemes that employ two separate categorizations in series, one based primarily on left ventricular morphology and function and the other based on etiology. A resultant disadvantage is that diseases are placed in two schema that overlap.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

FUNCTIONAL CLASSIFICATION OF CARDIOMYOPATHIES

The most widely used functional classification of cardiomyopathy recognizes three disturbances of function: dilatation, hypertrophy, and restriction (Table 65-2). *Dilatation* is dominated by left ventricular cavity enlargement and systolic failure. *Hypertrophy* includes both obstructive and nonobstructive forms. *Restriction* is characterized by inadequate compliance causing restriction of diastolic filling. The value of this scheme is that virtually all cardiomyopathies are readily placed in one of the three categories, and the therapeutic approaches to each category are distinctly different. For example, left ventricular afterload reduction is a cornerstone of therapy for dilated cardiomyopathies with systolic failure, but is of little benefit in the restrictive forms. There are some shortcomings of the functional classification however. Many diseases are physiologically heterogeneous. Almost all hypertrophic conditions have an element of diastolic restriction. Most dilated ventricles display myocyte hypertrophy. Some diseases change from one category to another during their course; the best example is cardiac amyloidosis, which initially exhibits diastolic stiffness, with complete preservation of systolic performance, followed years later by dilatation and systolic failure.

The functional scheme also associates diseases that have vastly different causes, some of which require special therapeutic interventions. For example, the primary therapy for cardiac hemochromatosis, often an initially restrictive disease, is removal of excessive iron stores; this would not, of course, be effective treatment for other diseases similarly classified. Despite its shortcomings, the functional classification of cardiomyopathy remains the most popular among clinicians because it is based on easily understood physiology and is relevant to therapy.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

ETIOLOGIC CLASSIFICATION

This scheme utilizes knowledge about cardiomyopathies more extensively than all the others. It has the most primary categories because there are numerous known causes that are not interrelated. Table 65-3 categorizes the diseases covered in Chaps. 69, 73 to 80, 85, 86, and 91 to 94. The general outline established by WHO in 1980 is followed roughly. In many cases the etiologic agent is poorly understood (e.g., uremic "cardiomyopathy"), or the cardiomyopathy is associated with another disease, but the mechanism responsible for heart failure is not known (e.g., cardiomyopathy of systemic neoplasia).

While this classification has the advantage of being inclusive, it has the disadvantage of being awkwardly long. It has 7 primary and 42 secondary categories. In addition, most similarly classified disorders are anatomically, physiologically, and therapeutically unrelated. Thus, this classification is not used routinely by clinicians. It has been used most frequently as an organizational scheme in textbooks and reviews concerning heart muscle disease and cardiomyopathy.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

ENDOMYOCARDIAL BIOPSY CLASSIFICATION

Because the heart can be safely biopsied, antemortem histologic diagnosis can be used to classify cardiomyopathies. Dozens of specific myocardial diseases can be detected by biopsy (Table 65-4). The great strength of histologic diagnosis is that it is definitive and unequivocal when a specific disease is observed. In contrast, numerous deficiencies make this method of classification relatively restricted in use. The foremost problem is that, although the number of specific histologic diagnoses is large, they represent a small proportion of all cases-certainly fewer than 15 percent. The histology in most patients with cardiomyopathy is nonspecific and nondiagnostic. Hypertrophy, or fiber attenuation, and fibrosis may be seen in varying degrees in almost any disorder and are the only findings in most cases of idiopathic dilated cardiomyopathy and hypertrophic cardiomyopathy (as well as in many instances of heart failure due to myocardial infarction and valvular dysfunction). Furthermore, completely normal histology may occasionally be seen on biopsy in cases of severe dilatation and systolic failure.

Myocardial biopsy samples can be subjected to several additional analytic techniques that expand the potential for classification using endomyocardial biopsy. While at present these analyses are only investigational and none can be generally applied, it is likely that one or more of them will become clinically useful in the future and could form the basis of a classification with wide appeal.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

ICD-9 CLASSIFICATION

ICD-9-CM stands for *International Classification of Disease*, Ninth Revision, Clinical Modification. This system was developed by WHO in 1948 for registering disease incidences. In 1977, the United States National Center for Health Statistics modified the ICD-9 code to allow coding of medical records. That modification is the current ICD-9-CM. In 1989 it became mandatory for physicians in the United States to include an ICD-9-CM code on their Medicare claims. It is fascinating to see how utterly different a classification system intended for governmental statistics and claims payment is in comparison to those intended for scientific or clinical purposes. The code is a remarkable hodgepodge, combining multiple categories of knowledge into one classification system. Diseases are variously defined according to one or more features such as etiology, anatomy, physiology, comorbidity, symptoms, and even method and extent of diagnosis. It is no wonder that this code is impossible to remember and notoriously ambiguous and difficult to use. In Table 65-5, the codes describing cardiomyopathies have been extracted from the 1999 version of the ICD-9-CM, where they appear in several groups scattered throughout the listing. Relatively few-25-cardiomyopathy diagnoses are coded, and these represent only 9 specific entities. Some well-recognized myocardial diseases are completely ignored, such as arrhythmogenic right ventricular dysplasia. This classification system and the method of classification it represents are certainly not recommended to physicians and scientists. ICD-9-CM should remain in the bailiwick of bureaucrats and serve as a paragon of classification chaos.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

THERAPEUTIC CLASSIFICATION

A classification based on specific therapies borrows heavily from the functional and the etiologic classifications of cardiomyopathy. This classification adds information regarding treatment that is not available in other schemes and therefore may be useful to clinicians.

Nevertheless, this classification has several shortcomings. First, often more than one class of therapy is appropriate for a disease. Therefore, the classification must categorize diseases on the basis of their *primary* therapy. This introduces some instability to the classification, since therapeutic preferences are subject to variance in opinion and to change with new research. The greatest fault of therapeutic categorization is that when new therapies are introduced, the existing classification becomes obsolete. The therapeutic classification shown in Table 65-6 illustrates the sensitivity of this approach to opinion. Some might argue, for example, that diuretic therapy remains the primary treatment for dilated cardiomyopathy.

Note that some commonly employed therapies, such as inotropic agents and cardiac transplantation, do not appear in Table 65-6 because they are often not the initial or primary therapies.

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

GENE-BASED CLASSIFICATION

Aside from traumatic, iatrogenic, infectious, and certain other secondary cardiac disorders, most heart diseases result from an abnormality of gene function. Many diseases caused by adverse gene behavior are due to inherited or acquired genetic mutations. Several diseases are now defined genetically, including hypertrophic cardiomyopathy, long QT syndrome, forms of dilated cardiomyopathy, muscular dystrophies involving the heart, and arrhythmogenic right ventricular dysplasia. A genetic classification of cardiomyopathies would specify the type of genetic disorder (chromosomal, single genic, polygenic, mitochondrial, or somatic cellular) and the mode of inheritance (autosomal or X-linked, and dominant or recessive), the chromosomes or chromosomal locations involved, and the genes involved. A complete genetic classification might also specify the specific mutation or the regional location of the mutation within the gene, since phenotype does and therapy might vary with each specific mutation or region of mutation. A classification system based upon genetic mutations is diagnostically and therapeutically useless unless the biochemical and resultant physiologic aberrations are understood. Thus, the classification should specify the affected protein products of the mutations, as well as the affected functions provided by the proteins.

In the future, many cardiac diseases will be shown to be due to genes functioning at the extremes of normal behavior, and these behavior abnormalities could be classified in much the same way as inherited mutations. Gene-based classification will become the best classification system for cardiomyopathies, because it will at once precisely and uniquely define the disease, and make evident the necessary diagnostic and therapeutic actions.[4]

Chapter 65: CLASSIFICATION OF CARDIOMYOPATHIES

SUMMARY

No single classification of cardiomyopathy is generally accepted within the biomedical community. An attempt to gain a consensus for one of the many classifications in current use is not likely to succeed because we are unable to subdivide meaningfully cases of idiopathic dilated cardiomyopathy, which constitute the large majority of all cases. At present, it seems best for the individual health practitioner or scientist to use the classification scheme that best serves his or her purpose. For clinicians, this will often be the functional classification.

In the future, a widely acceptable classification may develop that is based on the molecular genetics of myocardial disease. Although this field is only beginning to develop, it is the discipline most likely to contribute to the understanding of causes and the development of new treatments for myocardial disease.

Chapter 66:

DILATED CARDIOMYOPATHIES

Authors: Michael R. Bristow, Luisa Mestroni, Teresa J. Bohlmeyer, Edward M. Gilbert

This chapter describes the phenotypic and clinical characteristics of the primary and secondary dilated cardiomyopathies, the most common cause of the clinical syndrome of chronic heart failure.[1] Heart failure is an enormously important clinical problem that, if not contained or solved, ultimately may overwhelm health care resources.[2] The clinical syndrome of heart failure is a complex process where the primary pathophysiology is quickly obscured by a variety of superimposed secondary adaptive, maladaptive, and counterregulatory processes (see also Chap. 20). Heart failure is best understood and approached from the vantage point of *myocardial failure*, most commonly associated with a dilated cardiomyopathy phenotype.[3] As an indication of the importance of the problems of cardiomyopathy and heart failure, the cardiomyopathies have been reclassified recently by a World Health Organization/International Society and Federation of Cardiology (WHO/ISFC) task force[3] (and elaborated on further below).

IMPORTANCE OF HEART FAILURE

Due to its high prevalence (1-1.5 percent of the adult population) and high morbidity, including frequent hospitalizations, the clinical syndrome of heart failure is among the most costly medical problems in the United States.[2] Despite improvements in the treatment of heart failure introduced in the last 10 years, including the general availability of cardiac transplantation and better medical treatment, clinical outcome following the onset of symptoms has not changed substantially.[1] That is, mortality remains high (median survival of 1.7 years for men and 3.2 years for women),[1] the natural history remains progressive,[1] the cost is excessive,[2] and disability[2] and morbidity[2,4] are among the highest of any disease or disease syndrome.

Chapter 66: DILATED CARDIOMYOPATHIES

RELATIONSHIP OF MYOCARDIAL FAILURE AND DILATED CARDIOMYOPATHIES TO THE CLINICAL SYNDROME OF HEART FAILURE

The vast majority of the cases of heart failure are caused by heart muscle disease (cardiomyopathy). Within the WHO categorization[3] of cardiomyopathy (Table 66-1), the most common cause of the clinical syndrome of heart failure is a secondary (ischemic, valvular, hypertensive, etc.) or a primary (e.g., idiopathic or familial) *dilated cardiomyopathy*, defined as a ventricular chamber exhibiting increased diastolic and systolic volumes and a low (<40 percent) ejection fraction. The natural history of the clinical syndrome of heart failure depends on the course of myocardial failure, since (1) the most powerful single predictor of outcome is the degree of left ventricular (LV) dysfunction, as assessed by the LV ejection fraction,[5] (2) treatment that improves intrinsic ventricular function improves heart failure natural history,[6] and (3) treatment that ultimately worsens intrinsic function, such as many types of positive inotropic agents, is associated with an adverse effect on outcome.[6]

Table 66-1: The World Health Organization/International Society and Federation of Cardiology Classification of the Cardiomyopathies[3]

Category	Definition
I. Dilated (DCM) 1. Primary 2. Secondary	↑ EDV, ↑ ESV; low EF
II. Restrictive (RCM) 1. Primary 2. Secondary	↓ EDV, ↔ ESV; ↑ FP, ↔ EF
III. Hypertrophic (HCM)	↑↑ Septal and ↑ posterior wall thickness, myofibrillar disarray Mutation in sarcomeric protein, autosomal dominant inheritance
IV. Arrhythmogenic RV Dysplasia (ARVC)	Fibrofatty replacement of RV myocardium Autosomal dominant (most) and recessive inheritance
V. Unclassified 1. Primary 2. Secondary	Not meeting criteria for other categories Features of > one category

ABBREVIATIONS: EDV = end-diastolic volume; ESV = end systolic volume; EF = LV ejection fraction; FP = LV filling pressure; CM = cardiomyopathy.

Chapter 66: DILATED CARDIOMYOPATHIES

THE WHO/ISFC CLASSIFICATION OF CARDIOMYOPATHIES

The WHO/ISFC classification of cardiomyopathies was revised recently[3] to accommodate several rapidly emerging realities. The first was that the molecular genetic basis of previously unknown types of heart muscle disease is rapidly being elucidated, and so it really makes no sense to reserve the classification for "unknown etiologies" of cardiomyopathy.[7] The second consideration was that many of the mechanisms responsible for the natural history of myocardial dysfunction are qualitatively similar in primary versus secondary dilated cardiomyopathies,[8] which accurately predicted a qualitatively similar response to treatment targeted at these mechanisms.[9,10] This made the exclusion of secondary or "known cause"[7] cardiomyopathies gratuitous, and their inclusion in the new classification allows all cardiomyopathies to be classified under one scheme.

As shown in Table 66-1, the WHO/ISFC cardiomyopathy classification uses two separate methods to define the individual categories. The first is based on the global anatomic description of chamber dimensions in systole and diastole. Thus the dilated and restrictive categories have definitions based on LV dimensions or volume, which also define function via calculated ejection fraction (see Table 66-1). The justification for this is that these two groups have distinct natural histories and respond distinctly differently to medical treatment. The second method of creating individual categories within the WHO/ISFC classification is for cardiomyopathies that are genetically based, have unique myocardial phenotypic features, and do not exhibit extracardiac phenotypes. Thus hypertrophic cardiomyopathy (HCM), caused by mutations in contractile proteins manifesting as a unique phenotype, merits a separate category. The same is true for arrhythmogenic right ventricular dysplasia (ARVC), which also has a unique phenotype and likely will turn out to be completely genetic in basis, as has HCM. On the other hand, genetic cardiomyopathies without unique phenotypes, such as the dilated cardiomyopathy of Becker-Duchenne, are included as one form of the anatomic/chamber dimension category (category I).

The WHO/ISFC classification includes another assignment of nomenclature in "secondary" cardiomyopathies, i.e., those associated with known cardiac or systemic processes.[3] These are referred to as *specific cardiomyopathies,* named for the disease process with which they are associated. Thus an ischemic cardiomyopathy would be a specific cardiomyopathy related to previous myocardial infarction (MI) and the subsequent remodeling process, which usually would fall within the dilated class. On the other hand, a hypertensive cardiomyopathy might be classified as either dilated or restrictive depending on the chamber dimensions. Therefore, the correct term for these cardiomyopathies would be *ischemic dilated cardiomyopathy* and *hypertensive dilated* (or *restrictive*) *cardiomyopathy.*

Chapter 66: DILATED CARDIOMYOPATHIES

MOLECULAR MECHANISMS IN CARDIOMYOPATHIES AND MYOCARDIAL FAILURE: DISEASE PHENOTYPE PRODUCED BY ALTERATIONS IN GENE EXPRESSION

As shown in Table 66-2, there are three general categories of mechanisms whereby altered gene expression can lead to a phenotypic change in cardiac myocytes.[11] These are (1) a single-gene defect, e.g., as present in β-myosin heavy-chain codon 403 in familial HCM[12] and in an analogous region of the α-myosin heavy chain in HCM transgenic mouse models,[13,14] (2) polymorphic variation in modifier genes, such as is present in many components of the renin-angiotensin system,[15-19] and (3) maladaptive regulated expression of completely normal genes, such as for the mechanisms responsible for progressive myocardial dysfunction and remodeling in secondary dilated cardiomyopathies.[6,11]

Table 66-2: Three General Mechanisms by Which Alterations in Gene Expression Can Influence the Development or Progression of a Dilated Cardiomyopathy

Type of Process	Examples
Gene mutation	Cardiac α-actin,[34] desmin,[35] dystrophin,[36,37] lamin[38,39]
Polymorphic variation in modifier genes	Angiotensin converting enzyme (ACE),[16,43,44] β_2-adrenergic receptor[46]
Altered expression of a completely normal, wild type gene	Decreased expression: β_1-adrenergic receptors,[8] α-MHC,[47,48] SERCA-2[49]
	Increased expression: ANP,[50] β-MHC,[47] ACE,[51,52] TNF-α,[53] endothelin,[54] βARK[55]

ABBREVIATIONS: MHC = myosin heavy chain; TNF = tumor necrosis factor; βARK = β-adrenergic receptor kinase; SERCA = sarcoplasmic reticulum calcium ATPase; ANP = atrial natriuretic peptide.

Genetic Causes of Cardiomyopathies in Humans and Animal Models

The ability to genetically manipulate the cardiovascular system has made it possible to investigate the role of a number of genes in the developing and adult mouse heart (for a review, see Robbins[20]). The discovery that mutations in sarcomeric proteins lead to HCM has made it possible to generate animal models for this disease.[13,14] In the case of myosin mutations, a single genetic defect initiates a pathway that ultimately leads to hypertrophy and then in males results in late decompensation and ventricular dilatation.[14] Multiple gene mutations have now been associated causally with familial dilated cardiomyopathies, as discussed later in this chapter.

A serendipitous genetic model of dilated cardiomyopathy and heart failure (*myf*5 mice) has been generated by activation of a skeletal muscle genetic program in the heart.[21] These mice have a dilated cardiomyopathy phenotype characterized by progressive myocardial dysfunction and dilatation. They develop the clinical syndrome of heart failure, and they have an extraordinarily high (>90 percent at 260 days) heart failure-related mortality.[21] Another serendipitous genetic model of dilated cardiomyopathy is the muscle LIM protein (MLP) knockout mouse.[22] MLP is a positive regulator of muscle differentiation that is ordinarily expressed at high levels in the heart and which may be involved in myofibrillar protein

assembly along the actin-based cytoskeleton.[22] MLP knockout mice exhibit typical features of dilated cardiomyopathy, including decreased systolic and diastolic function and β-adrenergic receptor pathway desensitization.[22]

These characteristics make this model very useful in assessing the mechanisms that lead to the development and progression of myocardial failure. Thus, in transgenic mouse models, both altered expression of contractile proteins and perturbation of myocyte cytoarchitecture can lead to the dilated cardiomyopathy phenotype.

There are several additional transgenic mouse models of cardiomyopathy that may be more relevant to the production of a dilated phenotype in humans. Three of them involve overexpression of components of the adrenergic receptor pathway, the heterodimeric G-protein α_s subunit ($G\alpha_s$)[23,24] and the β_1-[25,26] and β_2-adrenergic receptors.[27] These β-adrenergic pathway transgenic mouse models exhibit similar histopathology consisting of myocyte hypertrophy and increased fibrosis, evidence of apoptosis, systolic and diastolic dysfunction, and ultimately, development of LV dilatation.[23-28]

Several transgenic models of concentric or symmetrical LV hypertrophy have now been reported, including overexpression of the protooncogenes *ras*[29] and *myc*,[30] α_1-adrenergic receptors,[31] the heterodimeric G-protein α subunit ($G\alpha_q$),[32] and protein kinase C (PKC).[33] The mechanisms for the induction of increased ventricular wall thickness are diverse, inasmuch as the *ras*, α_1-receptor, $G\alpha_q$, and PKC overexpressors exhibit true cellular hypertrophy with an increase in cell size,[29,31-33] whereas the *myc* animal exhibits cardiac myocyte hyperplasia.[30] The HCM phenotypes discussed earlier illustrate the principle that apparently diverse signals can culminate in the same phenotype, presumably by converging on final common pathways.

Multiple gene defects have been identified that can produce a dilated cardiomyopathy in humans, as discussed in more detail in the section on familial forms of dilated cardiomyopathy. As listed in Table 66-2, these include mutations in the cardiac α-actin,[34] desmin,[35] dystrophin,[36,37] and lamin[38,39] genes.

Polymorphic Variation in Modifier Genes

Genes exhibit polymorphic variation; i.e., normal variants of genes exist in the population that are of slightly different size or sequence.[40] Some gene polymorphisms are associated with differences in function of the expressed protein gene product, and some of these differences in function likely account for "biologic variation" routinely encountered in population studies of disease susceptibility or clinical response to treatment.

Examples of "modifier" genes that may have an impact on the natural history of a dilated cardiomyopathy (see Table 66-2) include the angiotensin-converting enzyme (ACE) *DD* genotype, where individuals are homozygous for the "deletion" variant, which is associated with increased circulating[15] and cardiac tissue[41] ACE activity. The *DD* genotype appears to increase the extent of hypertrophy in HCM[42] and may be a risk factor for early remodeling after MI[43] and for the development of end-stage ischemic or idiopathic dilated cardiomyopathy.[16,44] Other potentially important polymorphic variants that may influence the natural history of a cardiomyopathy involve the angiotensin AT_1 receptor[18,45] and β_2-adrenergic receptors.[46]

Altered, Maladaptive Expression of a Completely Normal Gene

The third way in which altered gene expression can contribute to the development of a cardiomyopathy is altered, maladaptive expression of a completely normal "wild type" gene.[11] This occurs most commonly in the context of progression of heart muscle disease and myocardial failure, which is the natural history of virtually all cardiomyopathies once they are established. Examples in this category (see Table 66-2) include downregulation of β_1-adrenergic receptors,[8] α-myosin heavy chain (α-MHC),[47,48] and sarcoplasmic reticulum Ca^{2+} ATPase[49] genes and upregulation in the atrial natriuretic peptide (ANP),[50] β-myosin heavy chain (β-MHC),[47] ACE,[51,52] tumor necrosis factor (TNF-α),[53] endothelin,[54] β-adrenergic receptor kinase

(βARK)[55] genes. These concepts are discussed further below.

Chapter 66: DILATED CARDIOMYOPATHIES

PATHOPHYSIOLOGIC PROCESSES INVOLVED IN MYOCARDIAL DYSFUNCTION, REMODELING, AND THEIR PROGRESSION

Tissue preparations and myocytes isolated from failing human hearts exhibit evidence of decreased contractile function.[56] Assuming that loading conditions and ischemia are not adversely affecting cardiac myocyte function, in the setting of chronic systolic dysfunction from a dilated cardiomyopathy, progressive myocardial failure is most likely caused by myocardial cell loss or changes in the gene expression of proteins that regulate or produce muscle contraction. Figures 66-1 and 66-2 summarize these general points and emphasize the central roles of the renin-angiotensin system (RAS) and the adrenergic nervous system (ANS) in promoting cell loss, growth and remodeling, and altered gene expression.[6]

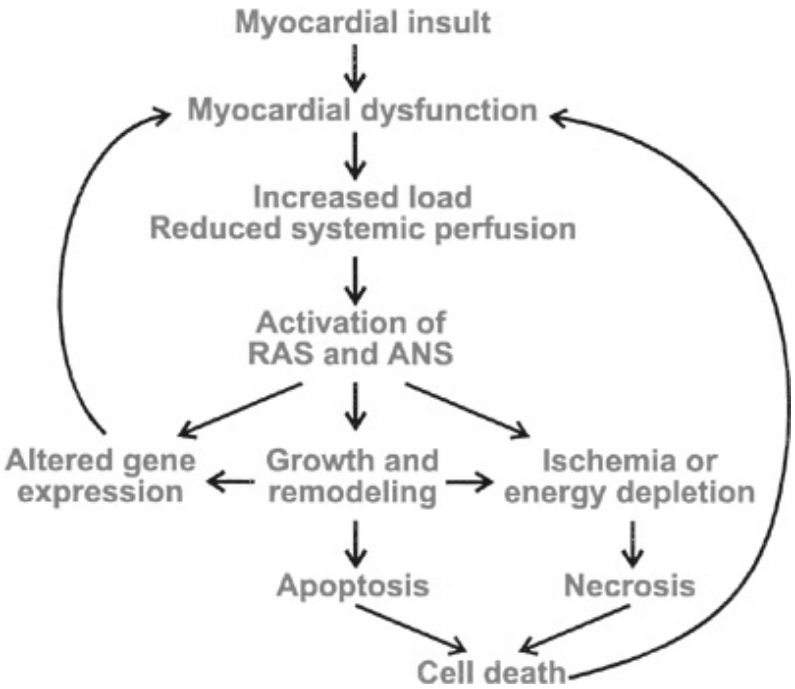

Figure 66-1: Relationship of neurohormonal activation and production of cardiac myocyte loss due to apoptosis and necrosis and altered gene expression. Cell loss and altered gene expression result in more myocardial dysfunction, and a vicious cycle is established. RAS = renin angiotensin system; ANS = adrenergic nervous system.

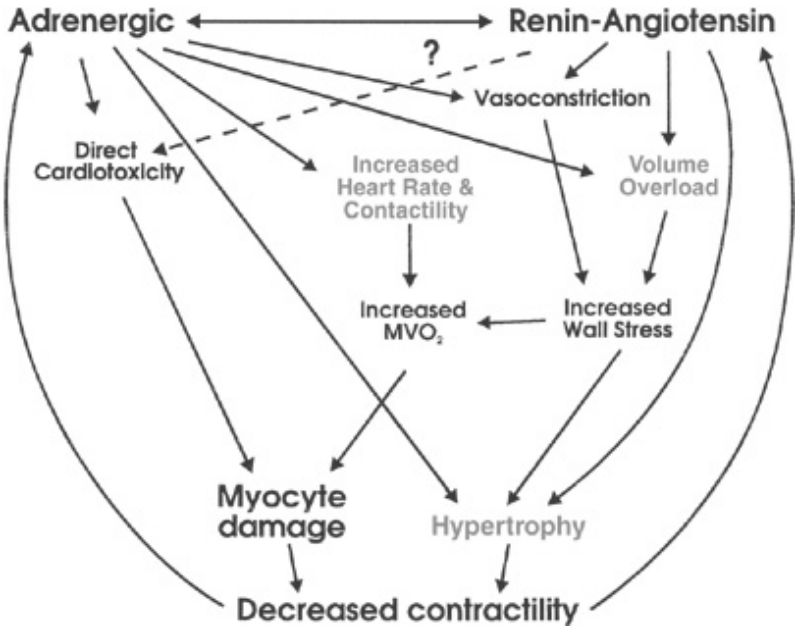

Figure 66-2: Heart failure compensatory mechanisms that are activated to support the failing heart. Light-colored areas indicate physiologic mechanisms that stabilize pump function.

Myocardial Dysfunction and Remodeling due to Altered Expression of Contractility Regulating Genes and Changes in Sarcomeric Assembly

Gene expression can be defined, broadly, as the expression of a fully or normally functioning protein gene product or, more narrowly (and commonly), as the steady-state abundance of a gene's mRNA transcript. Using either definition, numerous abnormalities of gene expression of normal, wild-type genes have been demonstrated in the failing human heart, as discussed earlier, with examples listed in Table 66-2. In order to characterize the abnormalities that may account for progressive myocardial dysfunction and remodeling, it is useful to subdivide them into two general categories,[57] as shown in Table 66-3. The first category encompasses mechanisms that subserve *intrinsic* function, or the mechanisms responsible for contraction and relaxation of the heart in the basal or resting state. *Intrinsic function* is defined as myocardial contraction and relaxation in the absence of extrinsic influences, such as neurotransmitters or hormones. The second general category is *modulated* function, which comprises the mechanisms responsible for the remarkable ability of the heart to increase or decrease its performance dramatically (by 2- to 10-fold) and rapidly in response to various physiologic or physical stimuli. Other critical organs such as the brain, kidney, and liver do not exhibit this quality. *Modulated function* is defined as stimulation or inhibition of myocardial contraction or relaxation by endogenous bioactive compounds, including neurotransmitters, cytokines, autocrine/paracrine substances, and hormones.

Table 66-3: General Categorization of Myocardial Function

Intrinsic (Function in the Absence of Neural or Hormonal Influence)	Modulated (Function that May Be Stimulated or Inhibited by Extrinsic Factors Including Neurotransmitters, Cytokines, or Hormone)
• Contractile proteins • E-C coupling mechanisms • R-G-adenylyl cyclase pathways • Bioenergetics • Cytoskeleton • Sarcomere and cell remodeling	• R-G-adenylyl cyclase pathways • R-G-phospholipase C pathways

ABBREVIATIONS: E-C = excitation-contraction; R-G = receptor-G-protein.

In the failing human heart, changes are present in the expression of genes potentially responsible for both general types of myocardial function depicted in Table 66-2.[6,57] Abnormalities of intrinsic function include the factors responsible for an altered length-tension relation,[58-60] a blunted force-frequency response,[61,62] and/or the signals responsible for abnormal cellular and chamber remodeling.[63,64] In the case of the abnormal force-frequency and length-tension responses, the evidence favors abnormal contractile function of individual cardiac myocytes.[56] As shown in Table 66-3, these abnormalities likely reside in the contractile proteins or their regulatory elements,[47,48,65-67] mechanisms involved in excitation-contraction coupling,[49] or the cytoskeleton.[22,68-70] However, within these possibilities for altered intrinsic function, there is not currently a consensus as to which specific abnormalities are present in idiopathic dilated cardiomyopathy (IDC), the most common form of heart failure studied in humans. For cellular remodeling, in both human ventricles[71,72] and animal models,[64,73] the assembly of sarcomeres in series leads to a myocyte that is markedly increased in length but not in diameter, which contributes to remodeling at the chamber level. Such remodeling places the chamber and the myocyte at an energetic disadvantage because of the attendant increase in wall stress,[74] which is one of the major determinants of myocardial oxygen consumption. Inadequate myocyte energy production, particularly associated with key subcellular ion flux mechanisms or the myosin ATPase cycle,[75] in turn would contribute to myocyte contractile dysfunction. Moreover, the hypertrophy process itself leads to a qualitative change in contractile protein gene expression (induction of a "fetal" gene program) that reduces contractile function.[11,47,48,65] On the other hand, cardiac myocyte contractile dysfunction likely plays a role in the remodeling process, inasmuch as medical treatment that improves intrinsic myocardial function can reverse remodeling.[6] Thus contractile dysfunction and remodeling at the cellular level are intimately related to the progressive contractile dysfunction and chamber enlargement that define the natural history of myocardial failure.[76] These concepts are summarized in Fig. 66-3.

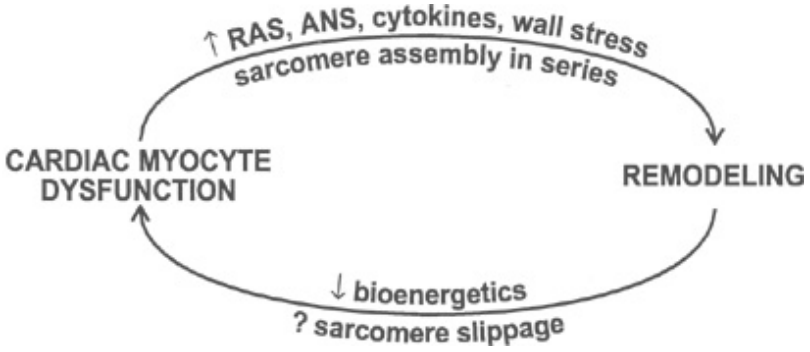

Figure 66-3: Relationship between progressive myocardial dysfunction and remodeling. RAS = renin angiotensin system; ANS = adrenergic nervous system.

In contrast to abnormalities of intrinsic function, a consensus has been reached on several specific abnormalities in the stimulation component of modulated function. Most of these changes concern β-adrenergic signal transduction.[8,11,57] The ability of β-adrenergic stimulation to increase heart rate and contractility is markedly attenuated in the failing heart due to multiple changes at the level of receptors, G-proteins, and adenylyl cyclase. This produces a major abnormality in the stimulation component of modulated function. In addition, the inhibition component of modulated function is also abnormal in the failing heart, due to a reduction in parasympathetic drive.[77]

There is obviously overlap between the two major subdivisions of myocardial function. Recent data indicate that even in the absence of adrenergic stimulation, β-adrenergic receptors have intrinsic activity.[78-81] That is, a small number of receptors are in an activated state without agonist occupancy and as such can support intrinsic myocardial function.[79,80] Thus overexpression of human β_2-adrenergic receptors is able to markedly increase intrinsic myocardial function,[80] as is enhancement of sarcoplasmic reticulum calcium uptake and release by genetic ablation of the phospholamban gene.[82] The recent realization that active state,

agonist-unoccupied β-adrenergic receptors can modulate intrinsic myocardial function is the reason why the "R-G-adenylyl cyclase" mechanism appears in both categories in Table 66-3.

Progressive Myocardial Dysfunction and Remodeling due to Loss of Cardiac Myocytes

The second general mechanism by which myocardial function may be adversely affected is by loss of cardiac myocytes, which also may play a role in the progression of ventricular dysfunction in dilated cardiomyopathies. Cardiac myocyte loss can occur via toxic mechanisms producing necrosis or by "programmed cell death" producing apoptosis. Apoptosis, which is likely due to a combination of growth signaling and cell cycle dysregulation, has been described in end-stage IDC,[83] as well as in the β_1-adrenergic receptor,[25] the $G\alpha_s$ overexpressor transgenic mice,[28] and in models of hypertrophy.[84] However, the human hearts with IDC or ischemic cardiomyopathy were taken from very late stage, literally dying patients maintained on multiple powerful intravenous inotropic medications,[83] and it is not clear if apoptosis plays a significant role in remodeling and/or chamber systolic dysfunction until this point in the natural history of the dilated cardiomyopathies.

Chapter 66: DILATED CARDIOMYOPATHIES

IMPORTANCE OF "COMPENSATORY" MECHANISMS IN THE PROGRESSION OF MYOCARDIAL FAILURE

As depicted in Figs. 66-1 and 66-2, there is now a large body of information supporting the idea that *activation of the ANS and RAS compensatory mechanisms contributes to, or is responsible for, the progressive nature of both myocardial failure and the natural history of the heart failure clinical syndrome*.[6] This evidence includes the observations that activation of both these systems is associated with progression of myocardial dysfunction and the heart failure syndrome and clinical trial data that consistently demonstrate that inhibition of these systems can prevent deterioration in or improve myocardial function as well as reduce mortality.[6,10] Despite the fact that in human heart failure we now know that chronic activation of the ANS and RAS contributes to the progressive nature of myocardial dysfunction, we know virtually nothing about how these systems adversely affect the biology of the cardiac myocyte. What we do know is that mechanisms within both general categories outlined in Table 66-3 must be involved in the adverse myocardial effects mediated by the ANS and RAS. This is so because modulated function may be improved by treatment with ACE inhibitors or β-blocking agents. Progressive myocardial dysfunction and remodeling are attenuated by both β-blocking agents and ACE inhibitors, and in cardiomyopathies, intrinsic myocardial function is improved and remodeling is reversed by chronic treatment with β-blocking agents.[6] Additionally, mortality in chronic heart failure is directly related to activation of the ANS[85,86] and RAS[87] and may be related to activation of other neurohormonal or autocrine/paracrine systems as well.

Regardless of the type or cause of dilated cardiomyopathy, an initial myocardial insult resulting in this phenotype exhibits common pathophysiologic features that are summarized in Fig. 66-1. That is, a myocardial insult that produces systolic dysfunction will be followed by the initiation of processes designed to temporarily stabilize pump function. The possible mechanisms available for such stabilization are in fact limited. As shown in Fig. 66-2, in chronological order of their action, they are an increase in heart rate and contractility mediated by an increase in cardiac β-adrenergic signaling (produced within seconds of the onset of pump dysfunction), volume expansion in order to use the Frank-Starling mechanism to increase stroke volume (evident within hours of the onset of pump dysfunction), and cardiac myocyte hypertrophy to increase the number of contractile elements (evident within days to weeks of the onset of pump dysfunction). As shown in Fig. 66-2, these compensatory adjustments are largely accomplished by activation of the RAS and ANS. However, despite the short-term (days to months) stability achieved via these mechanisms, they ultimately prove harmful.[6] The best evidence that chronic, continued activation of the RAS and ANS contributes to progressive myocardial dysfunction and remodeling comes from clinical trials where both inhibitors of the RAS (ACE inhibitors) and ANS (β-adrenergic receptor-blocking agents) prevent these two phenomena, and β-blocking agents actually may reverse remodeling and progressive systolic dysfunction,[6] as alluded to.

Much current work is focused on the precise pathophysiologic mechanisms by which activation of the RAS and ANS produces remodeling and adverse effects on myocardial function. Some of the possibilities are given in Fig. 66-1, and they include an exacerbation of ischemia and/or energy depletion leading to cell loss via necrosis, cell loss by programmed cell death, direct promotion of hypertrophy and remodeling through stimulation of cell growth, and alterations in cardiac

myocyte gene expression.[6] A key feature of the schema shown in Fig. 66-1 is the process of remodeling, which is discussed in more detail in Chap. 20. Virtually all dilated cardiomyopathies undergo this process, which is characterized by progressive dilatation, progressive myocardial systolic dysfunction in viable segments, and a chamber shape change whereby the ventricle becomes less elliptical and more round.[6,63] As shown in Fig. 66-3, this places the ventricle at an energetic disadvantage,[6,63,74] which likely contributes to further myocardial dysfunction, which then contributes to progressive remodeling. The latter observation is based on data obtained with β-adrenergic blocking agents, which produce an improvement in systolic dysfunction that can be detected prior to a reversal in remodeling.[6] As emphasized by Fig. 66-3, each myocardial degenerative process likely begets the other, leading to an inexorably progressive deterioration in myocardial performance and clinical condition.

Chapter 66: DILATED CARDIOMYOPATHIES

SCOPE OF DILATED CARDIOMYOPATHIES

The number of cardiac or systemic processes that can produce or are associated with a dilated cardiomyopathy are plentiful and remarkably varied, as shown in Table 66-4. The dilated phenotype is by far the most common form of cardiomyopathy, comprising over 90 percent of subjects referred to specialized centers.[88] In the United States, the most common dilated cardiomyopathy is ischemic dilated cardiomyopathy,[1] or the cardiomyopathy that follows MI. Other common secondary dilated cardiomyopathies are hypertensive and valvular dilated cardiomyopathies, both produced in part by chronically increased wall stress. The primary cardiomyopathy, IDC, is another relatively common dilated phenotype,[89,90] as discussed below.

Chapter 66: DILATED CARDIOMYOPATHIES

SELECTED, COMMON TYPES OF DILATED CARDIOMYOPATHIES

Ischemic Cardiomyopathy

DEFINITION/DIAGNOSIS

Ischemic cardiomyopathy is defined as a dilated cardiomyopathy in a subject with a history of MI or evidence of clinically significant (i.e., ≥70 percent narrowing of a major epicardial artery) coronary artery disease, in whom the degree of myocardial dysfunction and ventricular dilatation is not explained solely by the extent of previous infarction or the degree of ongoing ischemia.[3] In other words, *an ischemic dilated cardiomyopathy is present when a post-MI left ventricle experiences remodeling and a drop in ejection fraction.*

DISTINCT PATHOPHYSIOLOGY

Dilatation of the left ventricle and a decrease in ejection fraction occurs in 15 to 40 percent of subjects within 12 to 24 months following an anterior MI[91,92] and in a smaller percentage of subjects following an inferior MI.[92] Based on limited data,[43] it is tempting to speculate that the subjects who undergo the remodeling process and develop an ischemic dilated cardiomyopathy are individuals with particularly heightened compensatory mechanisms (see Figs. 66-1 and 66-2), perhaps as a result in polymorphic variation in these systems.[16] As discussed earlier, the remodeling process is an attempt by the compromised ventricle to increase its performance by increasing stroke volume, but ultimately, it correlates with an adverse outcome[6,63] in the long term.

The gross pathology of ischemic cardiomyopathy includes transmural or subendocardial scarring, representing old MIs, that may comprise up to 50 percent of the LV chamber. The histopathology of the noninfarcted regions is similar to changes that occur in IDC,[71] as discussed below.

PROGNOSIS

Several studies have concluded that ischemic cardiomyopathy patients have a worse prognosis than subjects with a "nonischemic" dilated cardiomyopathy,[93,94] probably because the risk of ischemic events is added to the risk of having a dilated cardiomyopathy.

TREATMENT

The treatment of ischemic dilated cardiomyopathy and chronic heart failure is covered in detail in Chap. 21. In general, treatment consists of the use of ACE inhibitors in asymptomatic or symptomatic patients, the use of diuretics in volume-overloaded subjects, and the use of digoxin in subjects who remain symptomatic on the former medications. An emerging treatment strategy is the use of β-adrenergic blocking agents in mild to moderately symptomatic subjects,[6,10] whereas in both ischemic and nonischemic dilated cardiomyopathies,[9,10,95-97] second- and third-generation compounds improve LV function,[6,9-11] reduce hospitalizations,[9,10,95-97] and lower mortality.[9,10] Additionally, adjunctive therapy includes anticoagulation in subjects with lower LV

ejection fractions to prevent thromboembolic complications, amiodarone to treat symptomatic arrhythmias, maintaining potassium levels in the high normal (4.3-5.0 meq/L) range to prevent sudden death, frequent clinic visits to adjust medications, and an aggressive approach to treating ischemia, including revascularization.

Hypertensive Cardiomyopathy

DEFINITION/DIAGNOSIS

A *hypertensive dilated cardiomyopathy* is diagnosed when myocardial systolic function is depressed out of proportion to the increase in wall stress. In other words, a subject presenting in heart failure with a hypertensive crisis would not carry this diagnosis unless ventricular dilatation and depressed systolic function remained after correction of the hypertension. In addition to producing a "pure" form of hypertensive cardiomyopathy, hypertension is a major risk factor for heart failure from any cause.[98] Within the WHO/ISFC classification, "hypertensive heart disease" may present in the "dilated," "restrictive," or "unclassified" categories.

DISTINCT PATHOPHYSIOLOGY

The most important pathophysiologic element in hypertension in dilated cardiomyopathy is sustained increased systolic wall stress. Interestingly, in both systolic pressure overloaded right and left ventricles, phenotypic expression is qualitatively variable[99,100] and can include dilatation and systolic dysfunction without increased wall thickness, increased wall thickness, concentric hypertrophy with or without systolic dysfunction, and systolic dysfunction without concentric hypertrophy. Other contributors to the pathophysiology of hypertensive cardiomyopathies are local neurohormonal mechanisms.[101]

PROGNOSIS

The prognosis depends on the presence of other comorbid conditions such as diabetes mellitus and coronary artery disease, as well as the extent of control of afterload. Compared with other forms of cardiomyopathy, in the absence of comorbid conditions, the prognosis of hypertensive cardiomyopathy in subjects whose afterload is controlled is probably better than for most other types of dilated cardiomyopathy.[102]

TREATMENT

The treatment is as for ischemic dilated cardiomyopathy, except that afterload must be vigorously controlled.[101] This consists of the addition of pure antihypertensive vasodilators such as amlodipine or α-blocking agents to standard heart failure therapy.

Valvular Cardiomyopathy

DEFINITION/DIAGNOSIS

A *valvular cardiomyopathy* occurs when a valvular abnormality is present and myocardial systolic function is depressed out of proportion to the increase in wall stress. This most commonly occurs with left-sided regurgitant lesions (mitral regurgitation and aortic regurgitation), less commonly occurs with aortic stenosis, and never occurs as a consequence of pure mitral stenosis.

DISTINCT PATHOPYSIOLOGY

The classic explanation for the typical phenotypes observed in valvular cardiomyopathies relates

to exposure to different types of wall stress.[103] Within this construct, the pattern of eccentric hypertrophy derives from increased diastolic wall stress.[103] Thus long-standing mitral regurgitation most commonly results in compensated eccentric hypertrophy that can progress to a dilated failing phenotype. Aortic regurgitation is a particularly poorly tolerated hemodynamic insult because wall stress is increased in both systole and diastole,[103] and when decompensation occurs, ventricular volume will be increased with or without increased wall thickness. Aortic stenosis classically results in compensated concentric hypertrophy, but when decompensation occurs, a variety of phenotypes can be observed that are similar to hypertensive cardiomyopathies. A disturbing and fairly commonly observed phenomenon is the development of a dilated cardiomyopathy after surgical correction of mitral and sometimes aortic valve disease in subjects who preoperatively had only mild LV dysfunction. These cases are likely due to the superimposition of myocardial damage resulting from open heart surgery and/or underlying dysfunction that was likely greater than appreciated preoperatively.

PROGNOSIS

The prognosis is variable and depends on the number of associated conditions, the nature and extent of the valvular abnormality, and most important, the severity of the cardiomyopathy at the time of surgical correction (see below). In general, *severely depressed myocardial function will not improve much with surgical repair of aortic regurgitation or mitral regurgitation, but the prognosis is likely to be improved because of elimination of some of the hemodynamic insult.* Replacement of the mitral valve should not be attempted in the majority of subjects with severe mitral regurgitation and LV ejection fractions less than 25 percent because of prohibitively high operative/perioperative mortality rates. On the other hand, there is no impairment of LV systolic function severe enough to preclude valve replacement of severe aortic stenosis, since function invariably will improve on relief of the hemodynamic insult, and the prognosis is relatively good.

TREATMENT

The treatment of a valvular dilated cardiomyopathy is surgical valve replacement or repair as soon as the cardiomyopathy is detected. Catheter valvuloplasty may be an option for severe aortic stenosis (AS) patients who are not good surgical candidates for reasons other than heart failure.[104] Medical treatment may be the only option in subjects with aortic insufficiency or mitral regurgitation whose LV function is severely impaired. The medical treatment of either disorder should be as mentioned earlier for ischemic cardiomyopathy plus aggressive afterload reduction, usually hydralazine/nitrates on top of ACE inhibitors. The calcium channel blocker amlodipine is another option for afterload reduction,[105] particularly for aortic insufficiency, where calcium channel blocker therapy has been shown to improve survival.[106]

Idiopathic Dilated Cardiomyopathy, Including Familial Forms

DEFINITION/DIAGNOSIS

IDC is diagnosed by excluding significant coronary artery disease, valvular abnormalities, and other causes. IDC is a relatively common cause of heart failure, with an estimated prevalence rate of 0.04 percent[89] and incidence rates varying from 0.005 to 0.006 percent.[89,90] The true incidence of IDC is undoubtedly higher, owing to the fact that subjects may remain asymptomatic until marked ventricular dysfunction has occurred. The incidence of IDC increases with age, and males are afflicted at a higher rate than are females.[89] As discussed below, histologic features are nonspecific and consist of myocardial cell hypertrophy and varying amounts of increased interstitial fibrosis. Although the diagnosis is not difficult, problems arise when an apparent IDC presents in someone with a history of hypertension or excessive alcohol intake. In such cases, it is best to reassign the etiology to alcohol only when the intake has exceeded 80 g/day for males and

40 g/day for females for more than 5 years and to hypertensive heart disease when blood pressure has been uncontrolled and high (>160/100 mmHg), as well as sustained (for years). All subjects with an unexplained dilated cardiomyopathy need a thyroid-stimulating hormone (TSH) determination done to exclude hypo- or hyperthyroidism, and subjects with diastolic dysfunction need to have an infiltrative process excluded. As discussed below, this is best done by performing an endomyocardial biopsy.

DISTINCT PATHOPHYSIOLOGY

IDC may be familial in as many as 35 to 50 percent of the patients when first-degree relatives are carefully screened.[107,108] The analysis of the phenotype identifies a wide range of clinical and pathologic forms indicating genetic heterogeneity. Accordingly, several chromosomal assignments for gene location have been made, and recently, as shown in Table 66-2, several genes have been identified.[34-39,109-118] The majority of familial patients present with autosomal dominant inheritance and a phenotype characterized by low and age-related penetrance (which is the proportion of carriers who manifest the disease). It is estimated that only 20 percent of gene carriers under the age of 20 display the disease phenotype.[119] Autosomal dominant dilated cardiomyopathy can be due to mutations of the cardiac actin[34] or desmin gene,[35] but in the majority of cases the disease gene is still unknown. The detection of an altered creatine kinase level can indicate the existence of a subclinical skeletal muscle disease. In these patients, an X-linked inheritance suggests mutations in the dystrophin gene,[36,37,120-122] whereas an autosomal dominant transmission and the presence of conduction defects and arrhythmia suggests mutations in the lamin A/C gene.[38,39] In *laminopathy*, the phenotype of the affected relatives can be very variable, from a pure IDC to a mild Emery-Dreifuss-like or limb-girdle-like muscle dystrophy[39] (see Chap. 62). Skeletal muscle and endomyocardial biopsy are diagnostic in X-linked dilated cardiomyopathy, showing abnormalities of dystrophin protein expression by immunocytochemistry.[123,124] Finally, autosomal recessive transmission of dilated cardiomyopathy occurs in mutations of sarcoglycan genes, which encode for dystrophin complex-associated proteins.[125]

Dystrophin, sarcoglycans, desmin, and lamin are cytoskeletal proteins. The contractile protein cardiac α-actin also has a force-transmission or cytoskeletal role.[34] Other data support the hypothesis that IDC could represent, in the majority of cases, a disease of the cytoskeleton; absence of the protein metavinculin in the myocardium was reported in one IDC patient,[70] and as discussed earlier, a dilated cardiomyopathy can be created in mice[22] or is present in a hamster line[126] related to mutations in cytoskeletal genes. However, as discussed earlier, it appears that other genetic abnormalities such as mutations in contractile proteins[14,21,34,127,128] and overexpression of β-adrenergic receptors[25-27] or $G\alpha_s$[24] also can produce a dilated phenotype.

In children, X-linked familial IDC suggests mutation in the G4.5 or tafazzin gene, particularly if associated with certain other signs (such as endocardial fibroelastosis, neutropenia, short stature, or skeletal muscle abnormalities).[116] The function of tafazzin is still unknown. In mitochondrial DNA (mtDNA) mutations, myocardial dysfunction usually is associated with multiorgan involvement (encephalopathy, lactic acidosis, skeletal muscle abnormalities, retinitis pigmentosa, etc.).[129] It is still unclear whether a mtDNA mutation can lead to an isolated IDC phenotype in adults.

Although still incomplete, new knowledge on the genetics of IDC has important clinical implications. The frequency of familial forms indicates the need of family screening in IDC, which can allow genetic counseling, an early detection of the disease, and early therapeutic interventions in affected relatives. The complexity of the phenotype requires an accurate skeletal muscle investigation, which can direct the diagnosis toward a specific type of familial myopathy.

Finally, family investigations require more sensitive diagnostic criteria[130] that are able to detect minor cardiac abnormalities as initial signs of the disease. These include initial dilatation without marked systolic dysfunction, arrhythmia, and isolated wall and other abnormalities.[39,108,131]

The major morphologic feature of IDC on postmortem examination is dilatation of the cardiac chambers.[130,131] One ventricle (usually the left) may be more dilated than the other ventricle. The weight of the heart is increased in IDC, with a mean cardiac weight of 551 g for women and 632 g for men.[131] Although there is an increase in muscle mass and myocyte cell volume in IDC, LV wall thickness is usually not increased because of the marked dilatation of the ventricular cavities. Grossly visible scars may be present in either ventricle, and while most scars are small, some may be large and transmural. Scarring occurs in the absence of significant narrowing of the epicardial coronary arteries. In most cases, the degree of fibrosis does not appear to be extensive enough to cause changes in systolic or diastolic function. Intracardiac thrombi and mural endocardial plaques (from the organization of thrombi) are present at necropsy in more than 50 percent of patients with IDC.[132,133] The effect of anticoagulation on the incidence of thrombi has not been studied carefully, but systemic and pulmonary emboli are more frequent in patients with ventricular thrombi or plaques.[134]

The characteristic findings of IDC on microscopy are marked myocyte hypertrophy, very large, bizarrely shaped nuclei[135-137] (Fig. 66-4), increased interstitial fibrosis (see Fig. 66-4), myocyte atrophy, and myofilament loss.[133,138] In isolated cardiac myocytes, the major cellular phenotypic change is marked increase in cell length without a concomitant increase in diameter.[72] As described earlier, this cellular lengthening or remodeling contributes to the chamber remodeling/dilatation that characterizes IDC and other cardiomyopathies. These morphologic changes in IDC are not specific and are generally found in secondary cardiomyopathies such as in the noninfarcted regions of ischemic dilated cardiomyopathy.[71] Also, the morphometric changes in IDC do not correlate with the severity of illness.[137,138] Ultrastructural abnormalities such as mitochondrial changes, T-tubular dilatation, and intracellular lipid droplets may be observed in IDC but also can be observed in other forms of heart disease.[137] There may be interstitial parenchymal and perivascular focal infiltrates of small lymphocytes.[136-140] The lymphocytic infiltrates that are present on histologic examination in IDC are not associated with adjacent myocyte damage, in contrast to myocarditis where adjacent myocyte necrosis is observed. Fibrosis is nearly always present in IDC,[136-140] and its pattern is quite variable from a fine perimyocytic distribution to coarse scars indistinguishable from those present in chronic ischemia. However, small intramural arteries and capillaries are structurally normal in IDC.[137]

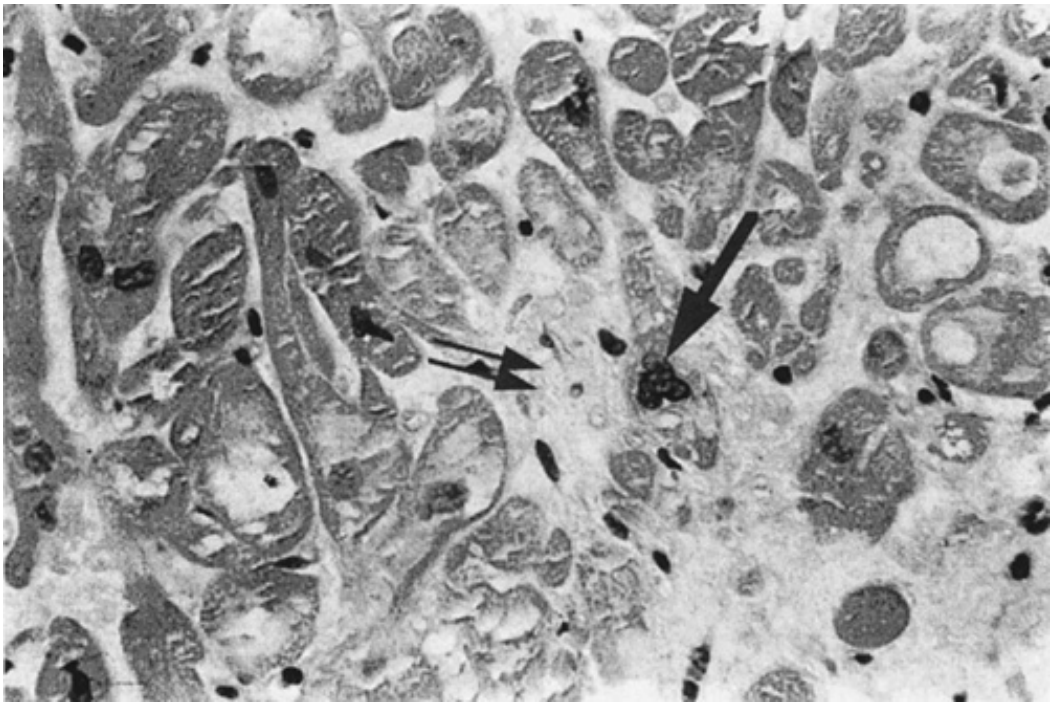

Figure 66-4: Right ventricular endomyocardial biopsy from a subject with IDC. Note the increased nuclear size (*arrow*) and the increased interstitial fibrosis.

A number of immune regulatory abnormalities have been identified in IDC, including humoral and cellular autoimmune reactivity against myocytes,[141] decreased natural killer cell activity,[142] and abnormal suppressor cell activity.[143,144] These abnormalities suggest that immune defects may be important etiologic factors in the development of IDC. These findings, however, are not universally present in patients with IDC, and some abnormalities are also present in other types of heart muscle disease. For example, an increase in the cardioselective M7 antimitochondrial antibodies is found in both IDC and hypertrophic cardiomyopathy but not in heart failure from coronary artery disease.[145] The incidence of some autoreactive antibodies, such as antinuclear and antifibrillary antibodies, increases with the severity of heart failure.[146] It is likely that many of the antibodies detected in IDC and other myocardial diseases do not have pathogenic relevance, but rather are secondary to the primary degenerative process. However, it is possible that certain antibodies present in IDC may have important functional implications. For example, anti-β_1-adrenergic receptor antibodies[147,148] could modify β-adrenergic receptor activity[149] and produce chronic increases in signal transduction that are harmful to the failing heart. Disturbed energy metabolism from antibodies to the ADP/ATP carrier of the inner mitochondrial membrane is another potential pathogenetic autoimmune mechanism[150,151]; these antibodies are present in some individuals with IDC[150] and have been shown to impair metabolism and myocardial function.[151]

There has been great interest in histocompatibility locus antigens (HLAs) in IDC because these antigens are known to be associated with immune regulatory functions, and many autoimmune diseases are found to have positive HLA antigenic associations. HLA associations also have been identified in IDC; the frequency of HLA-B27, HLA-A2, HLA-DR4, and HLA-DQ4 is increased compared with controls, and the frequency of HLA-DRw6 is decreased compared with controls.[152] Genetic abnormalities in the HLA region potentially could alter immune response and thereby increase disease susceptibility to infectious agents such as enteroviruses. Thus the association in IDC with specific HLAs suggest a possible immunologic etiology for this disease. However, these specific HLAs are present in less than 50 percent of patients with IDC, and the heterogeneity of these antigens does not point to a unique site for a putative disease-associated

gene. Thus, while the autoimmune hypothesis is an attractive candidate for the etiology of some cases of IDC, it remains unproved.

A clinical and pathologic syndrome that is similar to IDC may develop after resolution of viral myocarditis in animal models and biopsy-proven myocarditis in human subjects.[153] This has led to speculation that IDC may develop in some individuals as a result of subclinical viral myocarditis. Theoretically, an episode of myocarditis could initiate a number of autoimmune reactions that injure the myocardium and ultimately result in the development of IDC. The abnormalities in immune regulation and the variety of antimyocardial antibodies present in IDC are consistent with this hypothesis. However, it is generally not possible to isolate an infectious virus or to demonstrate the presence of viral antigens in the myocardium of patients with IDC.[153,154] Enteroviral RNA sequences are found in heart biopsy samples in IDC, but only in approximately one-third of patients.[154-156] Furthermore, active myocardial inflammation is usually not detected in IDC.[139,140] However, in controlled trials, corticosteroid therapy of patients with IDC does not result in significant clinical improvements.[157] Importantly, recent experimental data have shown in vitro and in vivo that the enteroviral protease 2A is able to cleave dystrophin and disrupt the cytoskeleton in cardiac myocytes, providing a potential link between viral infection and a genetic model of the disease.[158] Furthermore, analysis of human viruses other than enteroviruses suggests that adenoviruses, herpesvirus, and cytomegalovirus also can cause myocarditis and potentially IDC, particularly in children and young subjects.[159,160] Further investigation will be necessary to understand the significance of these findings, particularly in the adult population.

As also discussed in Chap. 22, endomyocardial biopsy of the right or left ventricle may be a valuable diagnostic adjunct for diagnosing specific myocardial processes that can produce a dilated phenotype, such as myocarditis and infiltrative cardiomyopathies. Since several of these other dilated cardiomyopathies may have specific treatments and/or a different prognosis than IDC, endomyocardial biopsy may be warranted in many individuals presenting with a dilated cardiomyopathy. In the future, biopsy may be used more frequently to identify genetic disorders resulting in abnormal gene or protein expression,[50] such as now can be done to diagnose Becker-Duchenne cardiomyopathy.[123,124] Since special staining, electron microscopy, or molecular analysis of the biopsy material may be necessary, endomyocardial biopsy is best performed in specialized cardiomyopathy/heart failure centers.

PROGNOSIS

Several studies of the natural history of IDC have been conducted.[159,160] The prognosis is generally better than for ischemic cardiomyopathy,[93,94] and prior to the routine use of ACE inhibitors, survival was approximately 50 percent in 5 years.[161] The prognosis has been improved substantially since then,[162] inasmuch as ACE inhibition,[163] cardiac transplantation[164] and β-adrenergic blockade[10] are all effective treatments in this cardiomyopathy.

TREATMENT

The treatment of IDC is similar to that discussed earlier for ischemic cardiomyopathy, except that there is no issue of revascularization. The risk of thromboembolic complications may be higher than in ischemic cardiomyopathy, resulting in a lower threshhold for anticoagulation. β-Adrenergic blockade produces a quantitatively greater degree of improvement in LV function compared with ischemic cardiomyopathy[165,166] either because there is a greater degree of adrenergic activation[8] or there is more viable myocardium to work with in IDC. Approximately 10 percent of IDC subjects treated with β-adrenergic blockade will normalize their myocardial

function, and this form of treatment should be offered to all IDC patients who do not have a contraindication before considering cardiac transplantation.[167]

Chapter 66: DILATED CARDIOMYOPATHIES

SELECTED SPECIFIC DILATED CARDIOMYOPATHIES WITH UNIQUE MANAGEMENT ISSUES

Anthracycline Cardiomyopathy

DEFINITION/DIAGNOSIS

The commonly used and highly efficacious anthracycline antibiotic anticancer agents doxorubicin and daunorubicin produce a dose-related cardiomyopathy[168-173] that may limit their clinical application. Within the WHO/ISFC classification, an anthracycline cardiomyopathy would most likely be in the "dilated" category, but because the extent of dilatation initially may be minimal (see below), it also could be in the "unclassified" category. The cardiomyopathy produced by these agents depends on the total cumulative dose, and for the more widely used compound doxorubicin (Adriamycin), the incidence of heart failure due to cardiomyopathy dramatically increases above total cumulative doses of 450 mg/m^2 in subjects without underlying cardiac problems or other risk factors.[169] *Prior mediastinal radiation involving the heart is a powerful risk factor for anthracycline cardiomyopathy,*[170] *and the risk is also evident if radiation treatment follows chemotherapy.*[172,173] In subjects with risk factors, anthracycline cardiomyopathy can present at lower cumulative doses than 450 mg/m^2.[170-172]

Although the diagnosis of anthracycline cardiomyopathy can be made clinically, the definitive diagnosis depends on the demonstration of a substantial number of cardiac myocytes exhibiting the characteristic anthracycline effect.[168,170-173] Tissue sampling is best done by endomyocardial biopsy, which allows for "thin section" electron microscopic processing of the sample and more definitive resolution of the anthracycline effect with light microscopy.[168,170-173]

DISTINCT PATHOPHYSIOLOGY

In the absence of a tissue diagnosis, anthracycline cardiomyopathy may be diagnosed clinically by exclusion of other causes of cardiomyopathy in a subject who has had at least 350 mg/m^2 of doxorubicin or the equivalent amount of another anthracycline. As shown in Fig. 66-5, the anthracycline cardiac myocytic lesion consists of cell vacuolization progressing to cell dropout, and when 16 to 25 percent of the total number of sampled cells exhibit this morphology, myocardial dysfunction results.[170]

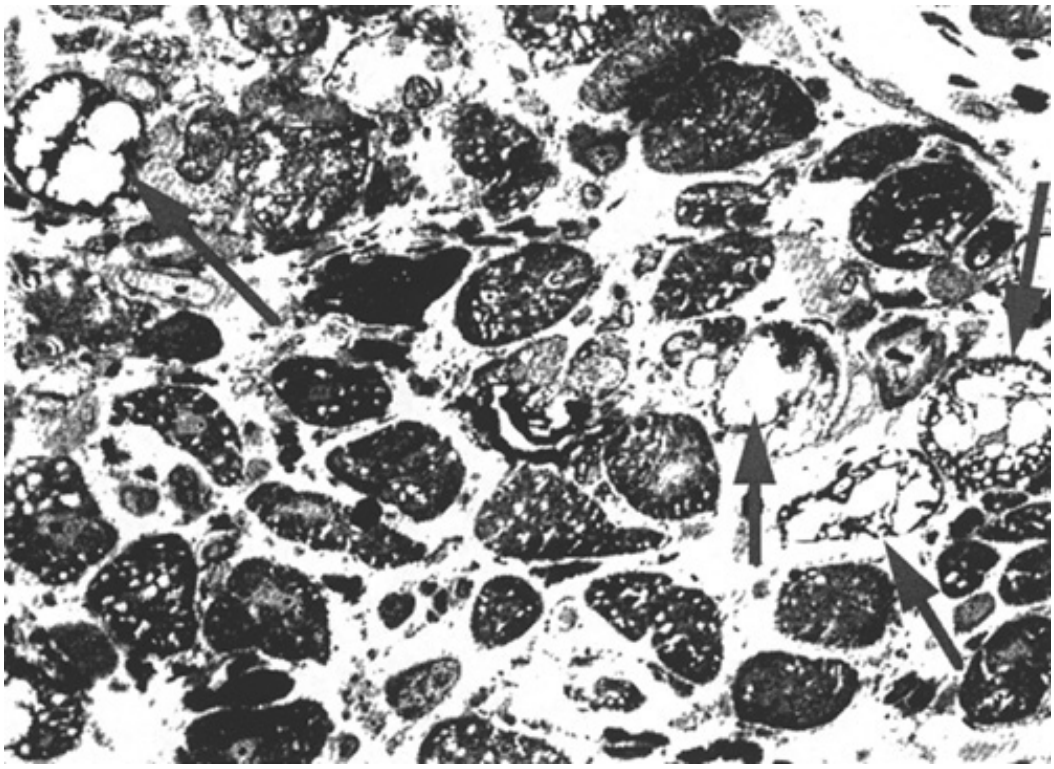

Figure 66-5: Cardiac myocyte vacuolization in cases of Adriamycin cardiomyopathy classified on endomyocardial biopsy as grade 3 by the Billingham classification.[170,171,178]

There are some distinguishing clinical features of anthracycline cardiomyopathy that may relate to its pathophysiology. These include a relative absence of hypertrophy and dilatation and a higher heart rate (110-130 beats per minute) than is usually encountered in ambulatory heart failure. The reasons for these features are that the onset of symptoms may be relatively acute (remodeling takes time to develop), and the anthracycline inhibits contractile protein synthesis,[174] reducing the amount of compensatory dilatation and remodeling. In this situation, the only option available for stabilizing cardiac output is increasing the heart rate, since increasing stroke volume via a larger end-diastolic volume has been precluded. The increased heart rate is produced by a greater than expected hyperadrenergic state, and so these subjects may be exceptionally dependent on adrenergic support.

PROGNOSIS

The prognosis of anthracycline cardiomyopathy is variable and depends on numerous factors, including the age and underlying prechemotherapy cardiac status of the patient and the time of presentation relative to the last dose of drug. Subjects who present late (several months) or very late (years) after the last dose have a better prognosis because the anthracycline myocardial effect takes at least 60 days to become fully manifest.[175] That is, subjects who develop heart failure within a few days of the last dose of drug have an additional cardiomyopathic burden to face, since the last one to two doses produce their full morphologic effect over the next 1 to 2 months.

TREATMENT/PREVENTION

Subjects who develop anthracycline cardiomyopathy should be treated aggressively with conventional heart failure treatment, since some degree of reversibility is likely. Conventional treatment consists of ACE inhibitors, digoxin, and diuretics. β-Adrenergic blockade has been used successfully in some subjects,[176,177] but because of the high adrenergic drive, it may be difficult to administer. On the other hand, the heightened adrenergic mechanism may be producing a

commensurate amount of adverse effect on the myocardium, and so the potential for a favorable response may be even greater than in other kinds of cardiomyopathy. In severe refractory cases, cardiac transplantation may be performed provided that the patient's cancer is in complete remission and is not likely to recur (≈70 percent chance of cure).

Several strategies have been shown to lower the risk of developing anthracycline cardiomyopathy without compromising the chemotherapy response rate. These include using endomyocardial biopsy and right-sided heart catheterization with exercise to assess risk, which virtually eliminates clinical cardiomyopathy and allows more anthracycline to be administered to less susceptible subjects[178]; using serial radionuclide angiography with[179] or without[180] exercise as a monitoring strategy, which may be somewhat helpful but because of a low specificity reduces the total amount of chemotherapy that can be administered safely to some subjects[178,179]; giving the agents as low-dose weekly[181] or as 48- to 72-h infusions[182] rather than as every 3- to 4-week boluses; using a liposomal formulation[183]; or concomitantly administering a second agent that reduces toxicity.[184] Unfortunately, none of these strategies completely eliminates the risk of developing a clinical cardiomyopathy.

Postpartum Cardiomyopathy

DEFINITION/DIAGNOSIS

Postpartum or *peripartum cardiomyopathy* is defined as the presentation of systolic dysfunction and clinical heart failure during the last trimester of pregnancy or within 6 months of delivery.[185] Given the extreme hemodynamic load produced by pregnancy, it is perhaps surprising that postpartum cardiomyopathy is not more common.

DISTINCT PATHOPHYSIOLOGY

Postpartum cardiomyopathy most likely will be classified within the "dilated" WHO/ISFC category but occasionally will be "unclassified" because dilatation and remodeling have not had time to occur. Postpartum cardiomyopathy is likely a heterogeneous group of disorders consisting of the addition of the hemodynamic load of pregnancy to a variety of underlying myocardial processes, including hypertensive heart disease, familial or idiopathic dilated cardiomyopathy, and myocarditis.[185,186]

PROGNOSIS

Approximately half of subjects who develop postpartum cardiomyopathy will recover completely,[187] and the majority of the rest will improve. Subjects who have developed a postpartum cardiomyopathy should never become pregnant again, even if myocardial function has recovered fully.

TREATMENT

Treatment should be aggressive and as for IDC. Cardiac transplantation may be required in severely compromised patients who do not improve.

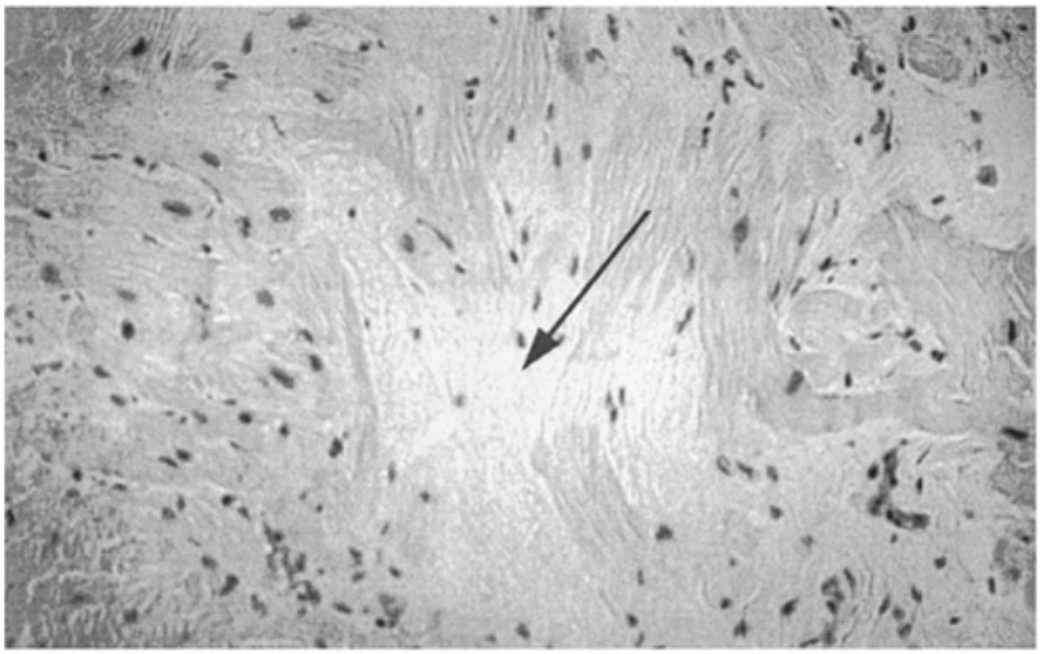
Amyloid Cardiomyopathy

DEFINITION/DIAGNOSIS

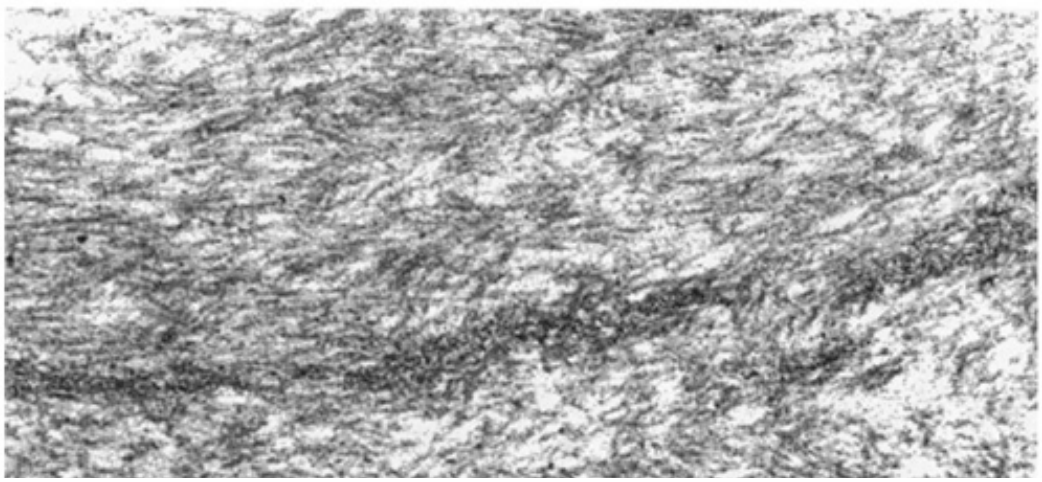
As discussed in Chap. 68, amyloidosis is a group of diseases characterized by extracellular

deposition of proteins characterized by their unique β-pleated sheet conformation and recognized electron microscopically as randomly arranged nonbranching fibers ranging from 8 to 14 nm in length. Amyloidosis is classified according to the type of amyloid protein involved.[188] Amyloidosis involving the heart is not rare and accounts for up to 10 percent of all nonischemic cardiomyopathies in autopsy studies.[189,190]

Amyloid cardiomyopathy may present in the WHO/ISFC "restrictive," "dilated," or "unclassified" categories. Most commonly it presents as a restrictive cardiomyopathy with conduction system abnormalities. In the setting of systemic amyloidosis (secondary or primary forms), the presence of increased wall thickness on echocardiogram plus low electrocardiographic voltage is highly suggestive of cardiac involvement.[191] In primary systemic amyloidosis, a monoclonal immunoglobulin spike is detectable in urine or serum in approximately 80 percent of subjects.[192] The definitive diagnosis of amyloid cardiomyopathy is made by tissue examination, ideally premortem by endomyocardial biopsy.[191] In systemic forms, the tissue diagnosis may be made by rectal, skin, or tongue biopsy of any abnormal tissue in these locations coupled with an unexplained myocardial process. As shown in Fig. 66-6, the characteristic histologic signature of amyloid is extracellular deposition of a fibrillar protein with a characteristic periodicity on electron microscopy.[193] Although a Congo Red stain can identify most cases, electron microscopy is more sensitive and specific and should be used routinely when amyloid is suspected.



A



B

Figure 66-6: *A.* Right ventricular biopsy demonstrating interstitial amyloid deposition (H&E stain, ×100). *B.* Electron micrograph of the same biopsy specimen illustrating the characteristic 8- to 14-nm, nonbranching, randomly oriented amyloid fibrils.

DISTINCT PATHOPHYSIOLOGY

Although the source and chemical nature of amyloid protein differs among the various types of amyloidosis, the tissue/organ pathophysiology is the same, i.e., the slow destruction of the heart by the inexorable deposition of a β-pleated sheet fibril that is insoluble and impervious to proteolytic digestion.[190]

PROGNOSIS

The prognosis is uniformly bad regardless of the type of amyloidosis, and the majority of patients with amyloid cardiomyopathy are dead within 2 years of diagnosis.

TREATMENT

There is no definitive treatment of amyloid cardiomyopathy. Treatment is completely empirical and consists of diuretics when needed, pacemaker treatment of bradyarrhythmias, and the avoidance of digoxin, which may be arrhythmogenic in any infiltrative cardiomyopathy. There is limited evidence that chemotherapy directed at amyloid secretion by abnormal β-lymphocytes can produce favorable effects in some patients.[194] Cardiac transplantation should be avoided even in primary localized amyloid cardiomyopathy because it will invariably recur in the heart or in other organs. The exception may be familial forms of amyloidosis, where the abnormal protein is a transthyretin or prealbumin variant synthesized in the liver. Combined liver and heart transplantation can be curative in this situation.[195]

Alcohol Cardiomyopathy

DEFINITION/DIAGNOSIS

An *alcohol cardiomyopathy* is said to be present when other causes of a dilated cardiomyopathy have been excluded and there is a history of heavy, sustained alcohol intake. The usual requirement in terms of alcohol amount is 100 g alcohol per day, typically over several years. However, in susceptible individuals it is likely that lower amounts of intake can produce a cardiomyopathy. The histologic features of alcohol cardiomyopathy are nonspecific and do not differ from IDC. Other than history, the only potentially distinguishing feature between IDC and alcohol cardiomyopathy is that the latter may present with a relatively high cardiac output.

DISTINCT PATHOPHYSIOLOGY

The pathophysiology of alcohol cardiomyopathy is thought to be related to the toxic effects of alcohol, plus in some subjects nutritional components such as thiamine deficiency.

PROGNOSIS

The prognosis depends on the degree of impairment of myocardial function and the extent of

abstinence from alcohol and, in an extremely compromised patient, the administration of thiamine. There is evidence that the prognosis is somewhat better for alcohol cardiomyopathy than for IDC.[196]

TREATMENT

The treatment of alcohol cardiomyopathy does not differ from IDC, except the inclusion of total abstinence from alcohol. Obviously, these subjects are not good candidates for cardiac transplantation because of the high relapse rate to alcoholism.

Chagas' Cardiomyopathy

DEFINITION/DIAGNOSIS

Chagas' disease is discussed in Chap. 69 as a cause of myocarditis. In addition, Chagas' disease is the most common cause of nonischemic cardiomyopathy in South and Central America, with over 10 million people afflicted.[197] It is caused by a parasite, the leishmanial or tissue form of the protozoan *Trypanosoma cruzi*. Although in the United States the vector (*Triatoma*, or kissing bug) is found only in the Southwest, Chagas' disease may be transmitted by blood transfusions, and as a result, it could become relatively more important in this country. The natural history consists of an initial myocarditis most commonly presenting in childhood, associated with acute myocardial infection followed by recovery and in some individuals the development of a dilated cardiomyopathy 10 to 30 years later.

The diagnosis of Chagas' cardiomyopathy is based on clinical (history, LV functional, and electrocardiographic) criteria and a positive serologic test for *T. cruzi*.[198] Electrocardiographic abnormalities consist of bundle-branch or hemiblocks (indeed, hemiblocks were first described by Rosenbaum et al.[199] in Chagas' afflicted hearts with discrete foci of involvement), LV hypertrophy, and first- or second-degree atrioventricular (AV) block.[200] The histologic lesion of chronic Chagas' consists of mononuclear infiltrates, fibrosis, and as shown in Fig. 66-7, foci of the leishmanial form of *T. cruzi* in myocardial fibers. The LV functional abnormalities initially may be segmental and may include an apical aneurysm but later become more global.[198,200]

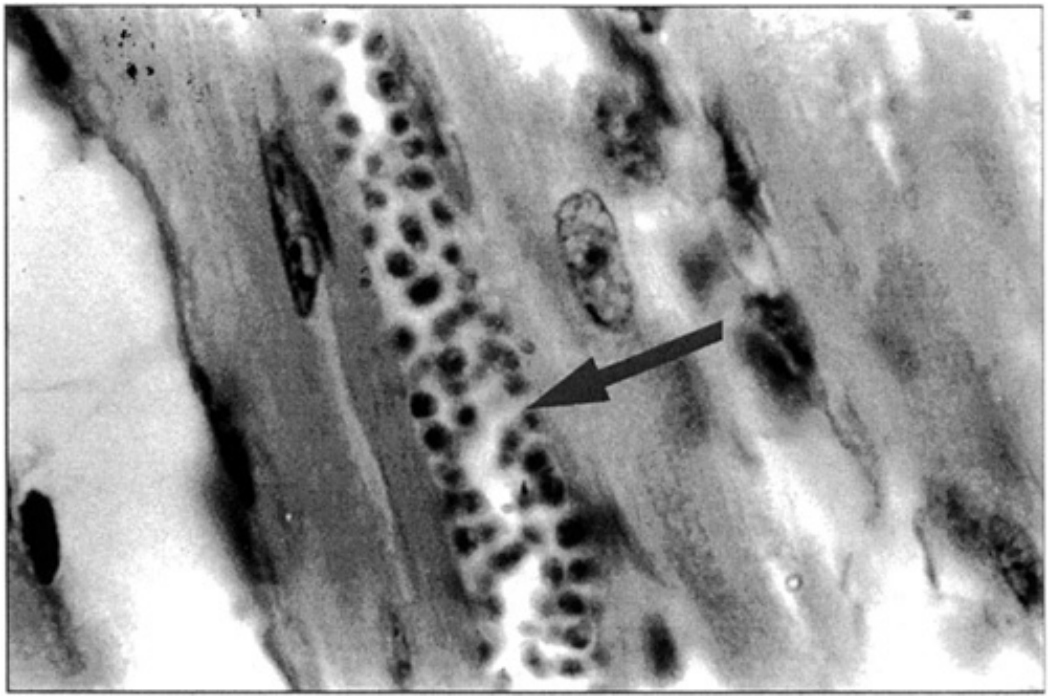


Figure 66-7: Leishmanial forms of *T. cruzi* within the swollen cytoplasm of a cardiac myocyte (Chagas' cardiomyopathy) (H&E stain, ×250). (Courtesy Dr. Elmer Koneman.)

DISTINCT PATHOPHYSIOLOGY

The basis for Chagas' cardiomyopathy is unknown but may be immunologic, whereby antibodies generated against *T. cruzi* crossreact with cardiac myocyte antigens including myosin.[201]

PROGNOSIS

The prognosis is relatively good for a dilated cardiomyopathy and similar to IDC; the 5-year survival in Chagas' cardiomyopathy with heart failure is around 50 percent.[198] Compared with IDC, death likely occurs more commonly due to an arrhythmic mechanism.[198] However, as for IDC and most other dilated cardiomyopathies, mortality risk depends directly on the degrees of ventricular dysfunction and exercise intolerance.[198]

TREATMENT

There is no definitive treatment for Chagas' cardiomyopathy, and nonspecific treatment includes pacemaker implantation for heart block and heart failure treatment as for IDC. The one exception may be the more frequent use of amiodarone, which appears to be particularly effective in treating arrhythmias associated with Chagas' cardiomyopathy and in one study reduced mortality compared with standard treatment.[202] The role of cardiac transplantation is still somewhat uncertain, but it can be done at acceptable risk,[203] especially when coupled with trypanocidal agents.[204]

Chapter 66: DILATED CARDIOMYOPATHIES

SUMMARY

Dilated cardiomyopathies are important because they are the most common cause of heart failure, which is the single most costly medical problem in the adult U.S. population. Cardiomyopathies in general are a heterogeneous group of diseases, but they can be classified under a newly modified WHO/ISFC classification system, which, although imperfect, should be of great value in standardizing the terminology and encouraging systematic investigative and clinical approaches to diagnosis and treatment. Within this classification system, primary and secondary dilated cardiomyopathies comprise the single largest and most important group. Current diagnosis and treatment of dilated cardiomyopathies vary somewhat among the various types, but the cornerstones of medical management are similar in most cases.

Genetic causes and influences on the natural history of dilated cardiomyopathies are the new frontier in this field, and their elucidation is almost certain to lead to new therapeutic and diagnostic approaches. In the near future, molecular genetic testing will be done routinely for many cardiomyopathies that may have a single gene defect as the cause. As we learn more about the influence of polymorphic genetic variation on the natural history and selection of specific medical therapy, genetic testing will be performed in most patients with cardiomyopathies.

Part 11: CARDIOMYOPATHY AND SPECIFIC HEART MUSCLE DISEASES
Chapter 67:

HYPERTROPHIC CARDIOMYOPATHY

Author: Barry J. Maron

Hypertrophic cardiomyopathy (HCM) is a genetically transmitted primary cardiac disease that has been of great interest to clinicians and laboratory scientists because of its particularly diverse clinical, morphologic, pathophysiologic, and molecular genetic manifestations.[1-22] Because of the broad and heterogeneous HCM disease spectrum as well as the relatively low prevalence in cardiologic practice, a measure of confusion and uncertainty has persisted regarding this condition.

HISTORICAL CONSIDERATIONS

There is some uncertainty regarding the first gross anatomic description of HCM. About 1900, French and German authors reported four patients at autopsy in whom striking hypertrophy involving the ventricular septum appeared to be responsible for obstruction to left ventricular ejection.[23,24] The first unequivocal description of HCM was the detailed pathologic report of Teare,[25] which stimulated widespread interest in this disease among cardiologists, pathologists, and surgeons. Teare described a condition in eight patients (seven of whom died suddenly) characterized by an asymmetric pattern of left ventricular wall thickening and nondilated ventricular cavities. The striking ventricular septal hypertrophy and bizarre arrangement of muscle bundles observed in these patients was initially thought to represent a benign tumor of the heart.

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

NOMENCLATURE AND PREVALENCE

Over the past 40 years, numerous studies have led to a dramatic evolution of our concepts concerning the clinical and pathologic spectrum of HCM; in the process, the disease has acquired a myriad of names[7] (Fig. 67-1). This multiplicity of descriptive terms largely reflects the enormous clinical, functional, and morphologic diversity of this disease. However, many of the terms that have been used to describe HCM are somewhat misleading by emphasizing the presence of left ventricular outflow obstruction at rest, a clinical feature that occurs in only a minority of HCM patients (about 20 to 25 percent).[1,3,5] The prevalence of HCM appears to be about 0.2 percent in the general population[26] and 1 percent in primary medical practice[27] based on identification of the disease phenotype with two-dimensional (2D) echocardiography. It is possible, however, that many individuals with HCM go undetected in the community because they manifest no or only mild symptoms and are not referred for echocardiographic studies.[28-31] Reports from a large number of diverse geographic areas suggest that HCM has extensive if not worldwide occurrence; there is also some evidence that the morphologic expression of the disease may differ in certain ethnic or racial groups (such as Japanese).[32-34]

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

DEFINITION AND CRITERIA FOR DIAGNOSIS

The clinical diagnosis of HCM is based on definition of the most characteristic morphologic feature of the disease-i.e., thickening of the left ventricular wall associated with a nondilated cavity in the absence of another cardiac or systemic disease capable of producing the magnitude of hypertrophy evident (e.g., systemic hypertension or aortic stenosis)[7] (Fig. 67-2). Because the nonobstructive form of HCM is predominant, the well-described clinical features of dynamic obstruction to left ventricular outflow-such as systolic anterior motion of the mitral valve, partial premature closure of the aortic valve, and a loud systolic ejection murmur-are not required for diagnosis.[1] Also, not all individuals harboring a genetic abnormality capable of producing the clinical and morphologic abnormalities of HCM show left ventricular hypertrophy at all phases of life.[10,22,31,35-37] For example, some children with HCM will not have left ventricular wall thickening identifiable by 2D echocardiogram prior to about age 16[35] and a few adults with incomplete penetrance may also show little or no hypertrophy.[10,36,38-40]

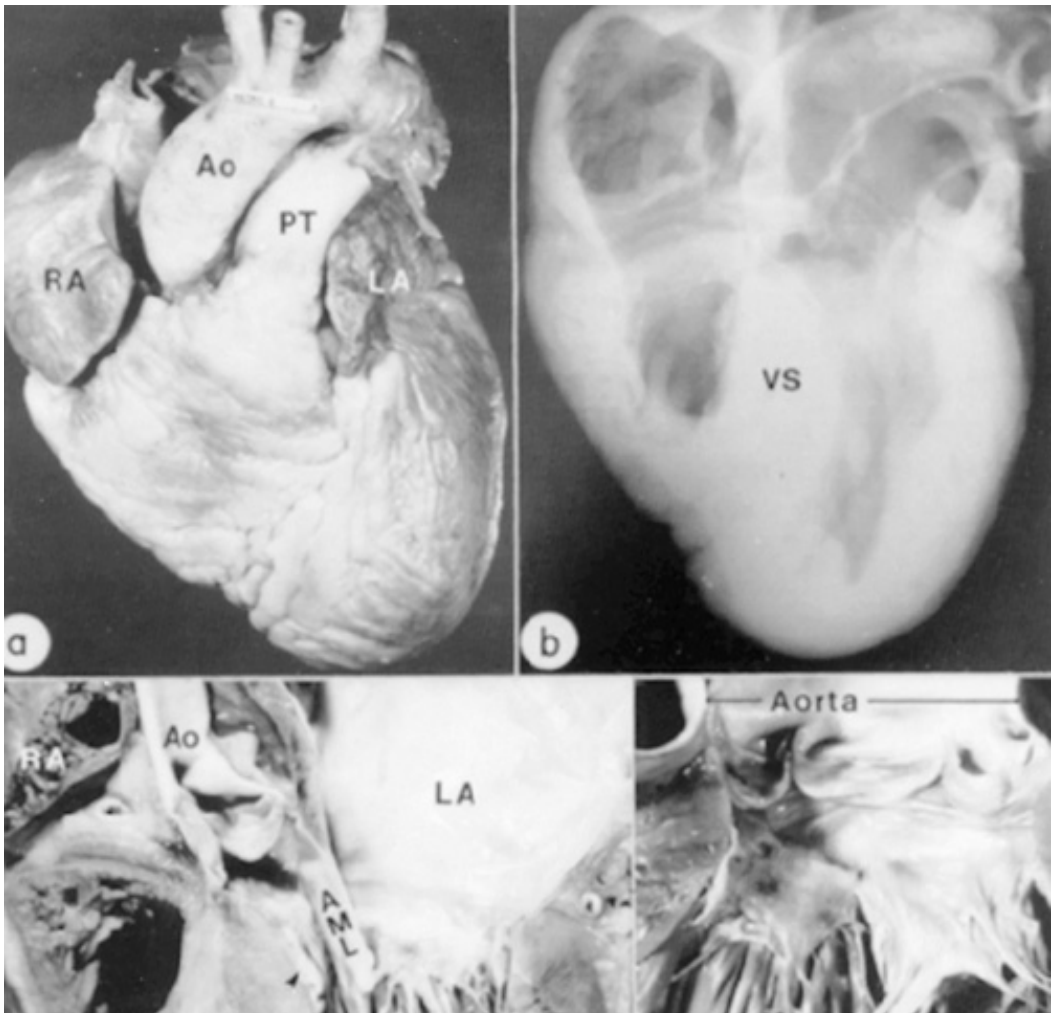
Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

MORPHOLOGIC CHARACTERISTICS

Gross Features

Left ventricular hypertrophy is the gross anatomic marker of HCM and the likely determinant of many of the clinical features identifiable in most patients with this disease[1-7,16-18] (Figs. 67-3 and 67-4). Since the left ventricular cavity is usually small or normal in size, the increased left ventricular mass is due almost entirely to an increase in wall thickness. Although a symmetric (concentric) pattern of left ventricular hypertrophy can be observed,[12,18,41] the distribution of hypertrophy is almost always asymmetric; i.e., with segments of the left ventricular wall thickened to a dissimilar degree, and with the ventricular septum showing disproportionate magnitude of hypertrophy.[12,18] Examination of the heart at necropsy also typically shows dilatation of the atria, enlargement and elongation of the mitral valve leaflets, and areas of replacement fibrosis (scarring) in the left ventricular wall.[16,17,20,42,43] In addition, most hearts show a characteristic fibrous plaque on the mural endocardium of the leftventricular outflow tract in apposition to the thickened anterior mitral leaflet, presumably resulting from systolic (or diastolic) contact between mitral valve and septum[16] (Fig. 67-3).



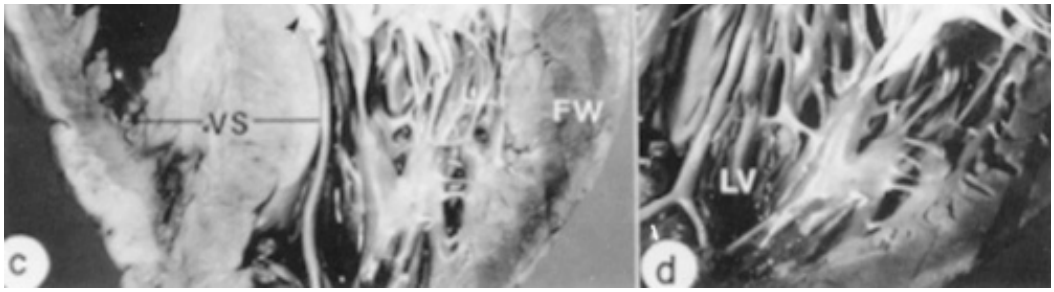


Figure 67-3: Anatomic features of HCM are demonstrated in the heart of a 26-year-old man. *A.* Exterior view; both right atrium (RA) and left atrium (LA) are dilated. Ao = aorta; PT = pulmonary trunk. *B.* Radiography of specimen showing asymmetric thickening of ventricular septum (VS). *C.* Coronal section; the septum is clearly thicker than left ventricular free wall (F); an endocardial mural contact plaque (*arrowhead*) is present in the left ventricular outflow tract in apposition to the anterior mitral leaflet (AML). *D.* Closer view of plaque and thickened anterior leaflet. (From Roberts WC et al.[16] with permission from the authors and publisher.)

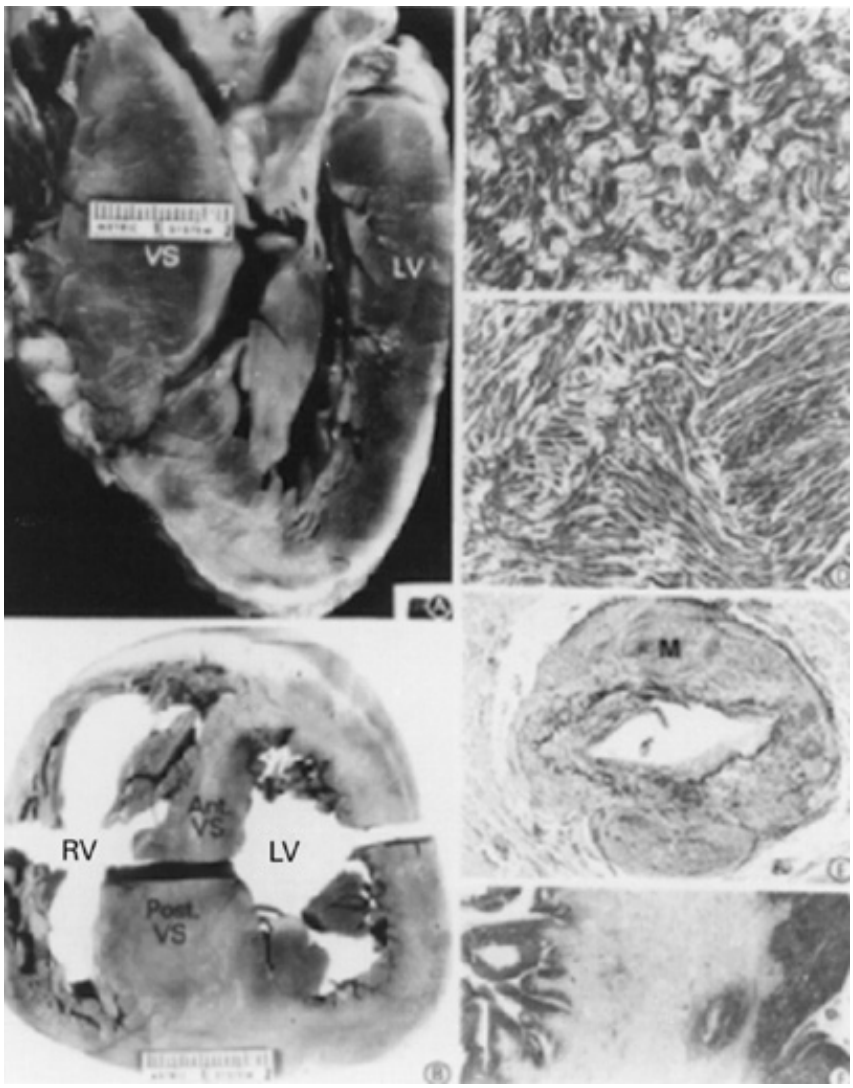

Figure 67-4: Morphologic components of the underlying disease process in HCM. *A.* Gross heart specimen sectioned in a cross-sectional plane similar to that of the echocardiographic (parasternal) long axis. The pattern of left ventricular hypertrophy is asymmetric, with wall thickening confined primarily to the anterior ventricular septum (VS), which bulges into the left ventricular outflow

tract. *B.* Heart specimen illustrating a different pattern of hypertrophy, in which marked left ventricular wall thickening is localized to the posterior portion of the ventricular septum (Post. VS), while the anterior septum (Ant. VS) is only mildly thickened. *C* and *D.* Histopathology characteristic of the left ventricle in HCM. *C.* Septal myocardium shows markedly disordered architecture, with adjacent hypertrophied cardiac muscle cells arranged at perpendicular and oblique angles to each other. *D.* Bundles of hypertrophied cells show a disorganized, "interwoven" arrangement. *E.* Intramural coronary artery with apparently narrowed lumen and thickened wall due primarily to medial (M) hypertrophy. *F.* Extensive scarring of ventricular septum, which is transmural in distribution. LV = left ventricular free wall. (From Maron BJ et al.[3] with permission from the authors and publisher.)

Based on both echocardiographic and necropsy analyses of large numbers of patients, it is apparent that the HCM disease spectrum is characterized by vast structural diversity with regard to the patterns and extent of left ventricular hypertrophy [12,18,41,43] (Figs. 67-5 and 67-6). Indeed, no single phenotypic expression can be considered "classic" or particularly typical of this disease. While maximal thickness of the left ventricular wall varies greatly, the average value in a population is usually 21 to 22 mm. Wall thickness is markedly increased in many patients, with some showing the most severe hypertrophy observed in any cardiac disease (60 mm is the most extreme dimension).[44,45] On the other hand, the HCM phenotype is not always expressed as a particularly thickened left ventricle; some patients may show only a mild increase of 15 to 18 mm, and a few genotyped affected individuals have been observed with normal thicknesses (≤12 mm).[10,36,40,46] Often the pattern of wall thickening is strikingly heterogeneous, involving noncontiguous segments of left ventricle (i.e., with areas of normal thickness evident in between), or with marked differences in wall thickness in adjacent segments of the wall. Transitions between thickened areas and regions of normal thickness are often sharp and abrupt, not infrequently creating right-angled contours of the wall.

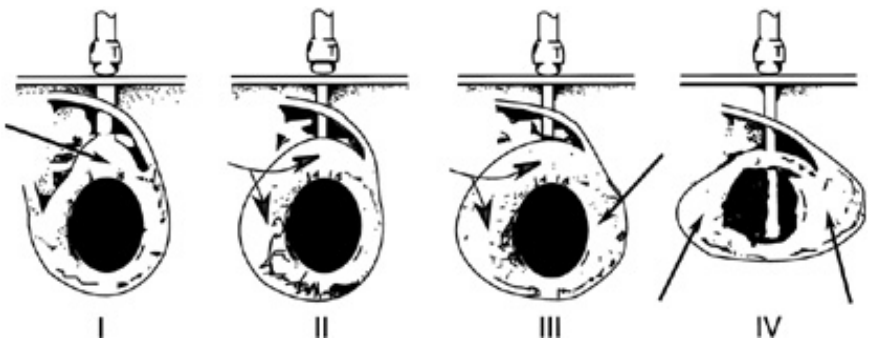

Figure 67-5: Morphologic variability in HCM, based on observations made from two-dimensional echocardiography; areas of hypertrophy are indicated by arrows. All images are drawn in the standard short-axis cross-sectional plane at mitral valve level with anterior chest wall and transducer to the top, posterior free wall to the bottom, posterior septum to the left, and anterolateral free wall to the right. *I.* Relatively mild left ventricular hypertrophy confined to anterior portion of ventricular septum. *II.* Hypertrophy of anterior and posterior septum in the absence of free wall thickening. *III.* Diffuse hypertrophy of substantial portions of both ventricular septum and anterolateral free wall. *IV.* Included are more unusual patterns of hypertrophy in which the thickened portions of left ventricle are present in the posterior septum or anterolateral free wall (as shown here) or at the left ventricular apex. (From Maron BJ[12] with permission from the author and publisher.)

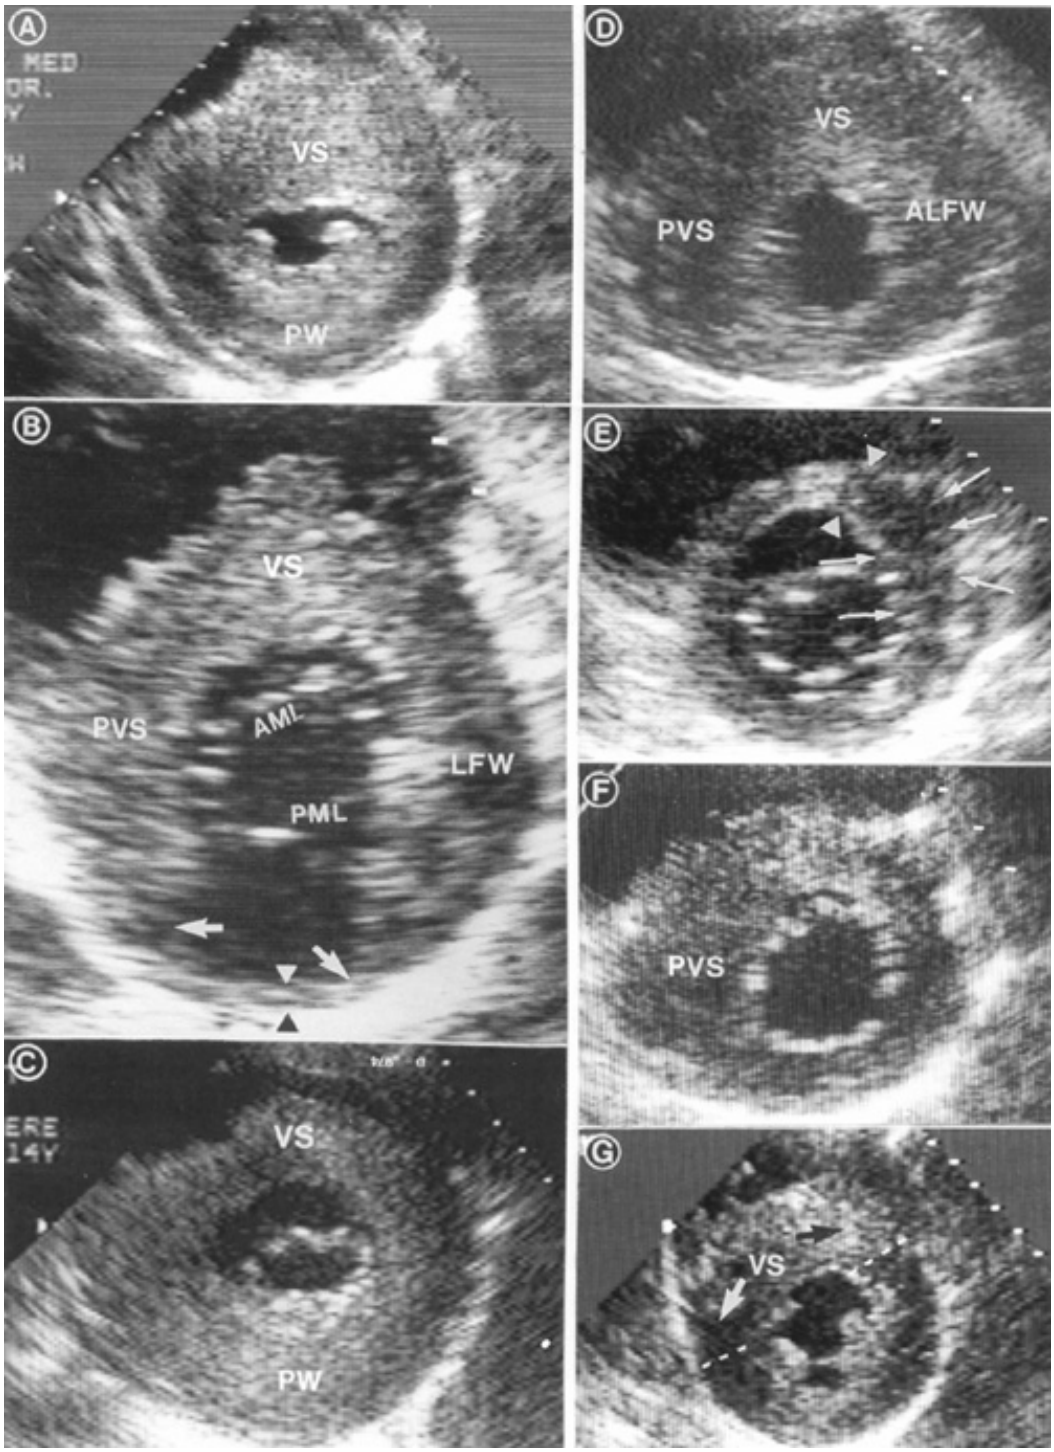

Figure 67-6: Variability of patterns of left ventricular hypertrophy in patients with hypertrophic cardiomyopathy, shown in a composite of diastolic stop-frame images in the parasternal short-axis plane. *A, B,* and *D.* Wall thickening is diffuse, involving substantial portions of ventricular septum and free wall. At the papillary muscle level (*A*), all segments of the left ventricular wall are hypertrophied, including the posterior free wall (PW), but the pattern of thickening is asymmetric, with the anterior portion of ventricular septum (VS) massive (i.e., 50 mm). *B.* Hypertrophy is diffuse, involving three segments of the left ventricle but with the posterior wall spared and thin (<10 mm) (*arrowheads*) and with particularly abrupt changes in wall thickness evident (*arrows*). *C.* Marked hypertrophy in a pattern distinctly different from that in *A, B,* and *D,* in which the thickening of the posterior wall is predominant and the ventricular septum is of nearly normal thickness. *D.* Diffuse distribution of hypertrophy involving three segments of the left ventricle similar to that in *B* but without sharp changes in the contour of the wall. *E.* Hypertrophy predominantly of lateral free wall (*arrows*) and only a small portion of the contiguous anterior

septum (*arrowheads*). *F.* Hypertrophy predominantly of posterior ventricular septum (PVS) and, to a lesser extent, the contiguous portion of the anterior septum. *G.* Thickening of anterior and posterior septum to a similar degree but with sparing of the free wall. Calibration dots are 1 cm apart. AML = anterior mitral leaflet; LVW = lateral free wall; PML = posterior mitral leaflet. (From Klues HG et al.[18] with permission from the authors and publisher.)

In most patients the pattern of hypertrophy is diffuse, involving both septum and substantial portions of the lateral free wall, while the posterior segment of free wall is usually least affected by the hypertrophic process.[12,18] In others, hypertrophy involves only the ventricular septum while sparing the free wall. Of note, in an important proportion of patients (about one-third), wall thickening may be relatively mild and confined to a single segment of left ventricle.[12,13,18] Such segmental hypertrophy is usually localized to the anterior septum but may also be limited to the posterior septum,[12,18] anterolateral free wall,[12,18] posterior free wall,[47] or even the most apical portion of the left ventricle.[14,15,32,48-50] Therefore, the ventricular septum is usually, but not always, prominently involved in the hypertrophic process. Infiltrative and myocardial storage diseases such as cardiac amyloid and Fabry's disease may occasionally mimic HCM morphologically (Chap. 10).

Hypertrophy confined to the left ventricular apex ("apical HCM") has been reported most commonly by Japanese investigators,[32,34,49] who have described this subgroup of HCM patients to be clinically benign and with a "spade" deformity of the left ventricular cavity on angiography and a distinctive electrocardiographic (ECG) pattern of deep ("giant") T-wave inversion. Reports from outside Asia would suggest, however, that apical hypertrophy is uncommonly accompanied by marked T-wave inversion and associated with adverse outcome in some patients.[14,15,48,50] This heterogeneous morphologic expression described for HCM is underlined by the fact that even first-degree relatives with the disease usually show great dissimilarity in the pattern of left ventricular wall thickening.[11]

In some young athletes, segmental hypertrophy of the anterior ventricular septum (wall thicknesses of 13 to 15 mm), consistent with a relatively mild morphologic expression of HCM, may often be difficult to distinguish from the physiologic left ventricular hypertrophy that can represent an adaptation to intense forms of athletic training.[51,52] In asymptomatic individuals within this morphologic "gray zone," the differential diagnosis between athlete's heart and nonobstructive HCM can often be resolved by clinical assessment and noninvasive testing[52] (Fig. 67-7).

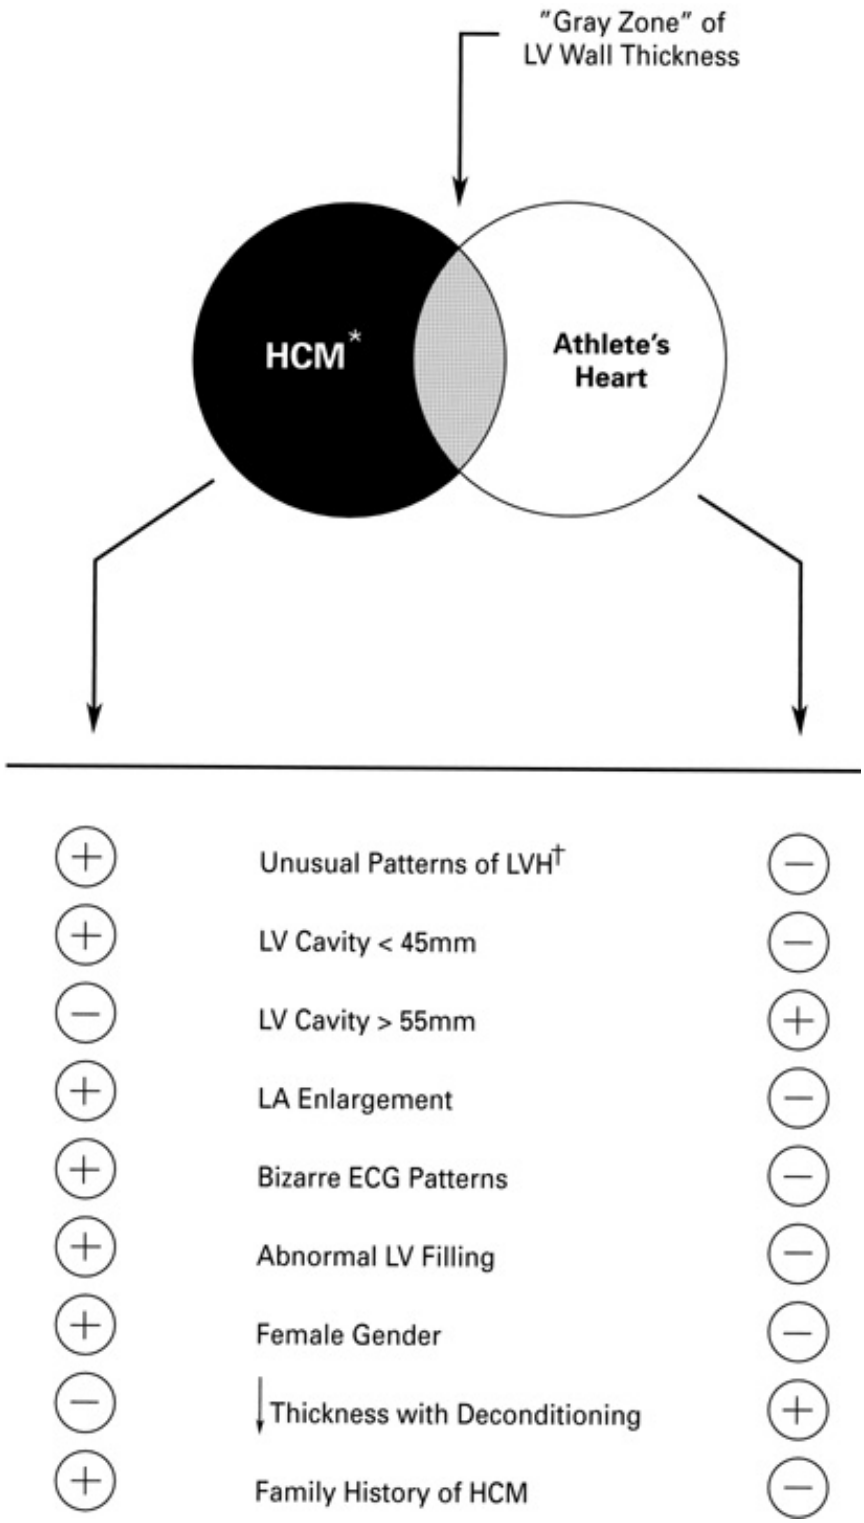

Figure 67-7: Criteria used to distinguish HCM from athlete's heart when left ventricular (LV) wall thickness is within the shaded gray zone of overlap, consistent with both diagnoses. *Assumed to be the nonobstructive form, since substantial mitral valve systolic anterior motion would confirm, per se, the diagnosis of HCM in an athlete. †May involve a variety of abnormalities, including heterogeneous distribution of LV hypertrophy in which adjacent regions may be of greatly different thicknesses, with sharp transitions evident between segments; also, asymmetric patterns in which anterior ventricular septum is spared from the hypertrophic process and the region of predominant thickening may be in the posterior septum or anterolateral or posterior free wall. ↓ = decreased; LA = left atrial. (From Maron BJ et al.[52] with permission from the authors and Williams & Wilkins.)

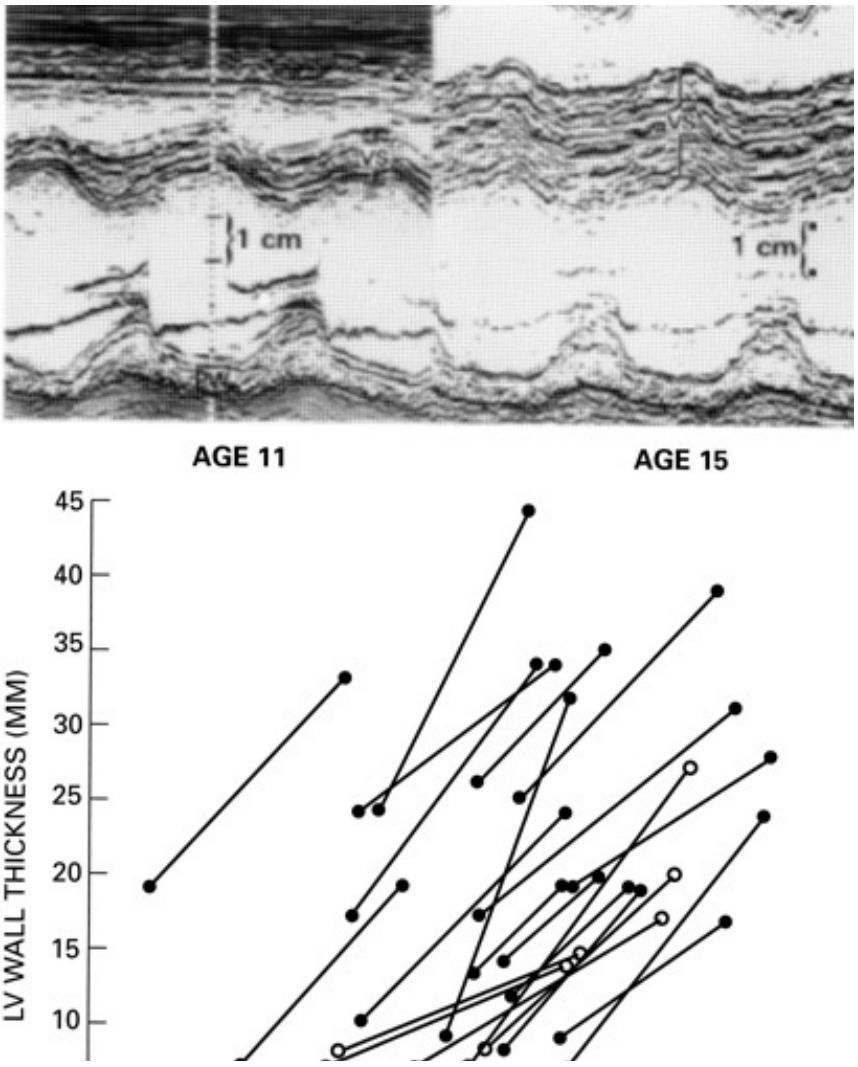
HCM can represent a congenital heart malformation in which phenotypic expression in the form of left ventricular wall thickening begins during fetal development[53] and is evident at or shortly after birth.[54-56] Indeed, HCM has been reported in a small number of very young children, including a few infants under 6 months of age.[54-56] When HCM presents in infancy, the disease is usually associated with marked septal hypertrophy as well as severe progressive congestive heart failure and biventricular outflow obstruction.[54,55,57] However, most cases of idiopathic left ventricular hypertrophy presenting in the first 2 years are not true HCM due to sarcomere protein mutations, but are often associated with other conditions such as Noonan syndrome.[57]

Later in childhood, serial echocardiographic investigations have shown prominent left ventricular remodeling. The morphologic expression of HCM is not usually complete until adulthood,[35,58] and during adolescence children often show striking spontaneous increases in wall thicknesses (i.e., of about 100 percent) and more widespread distribution of hypertrophy, including de novo development of wall thickening, when body growth and maturation are accelerated (Fig. 67-8). Progression of basal septal hypertrophy associated with a developmentally small left ventricular outflow tract appears to be the major determinant for the development of mitral valve systolic anterior motion and outflow obstruction during childhood.[59] In some young children, abnormalities on the 12-lead ECG may be the initial clinical manifestation of HCM, even preceding the appearance of hypertrophy on the echocardiogram.[31,60] Such left ventricular remodeling is usually not associated with development or progression of symptoms or sudden death and appears to be an expression of the genetically predetermined morphologic evolution of the disease.[35,61]



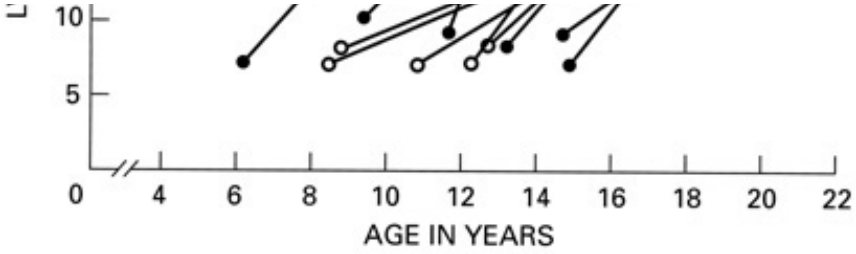


Figure 67-8: Development and progression of left ventricular hypertrophy in children with HCM. *Upper panel:* Development of marked hypertrophy of the anterior basal ventricular septum (VS). M-mode echocardiograms shown here were obtained at the same cross-sectional level in a girl with a family history of HCM. At age 11, ventricular septal thickness was at upper limit of normal (10 mm); at age 15, septal thickness had increased markedly (to 33 mm), and appearance of the echocardiogram is typical of HCM. The patient remained asymptomatic throughout this period of time but died suddenly and unexpectedly at age 17. PW = posterior left ventricular free wall. *Lower panel:* Dynamic, striking changes in left ventricular wall thickness with age in 22 children; each patient is represented by the left ventricular segment that showed the greatest change in wall thickness. Open symbols denote 5 patients who had no evidence of hypertrophy in any segment of the left ventricle at the initial evaluation but subsequently developed de novo hypertrophy typical of HCM. (From Maron BJ et al.[35] with permission of the authors and the Massachusetts Medical Society.)

In symptomatic adult patients with HCM, the magnitude of left ventricular hypertrophy may *decrease* with aging.[62] Very marked degrees of hypertrophy (e.g., maximum wall thickness ≥30 mm) are largely limited to patients under age 40, while older patients over age 60 generally have more modest hypertrophy and rarely show wall thicknesses >25 mm. The explanation for this inverse relation between age and magnitude of hypertrophy could be a higher rate of premature death in younger patients with severe morphologic forms or, alternatively, to a process of wall thinning and remodeling occurring very gradually over long periods of time in many patients.[61]

Histologic Features

Several histologic features of left ventricular myocardium represent components of the primary cardiomyopathic disease process in HCM[1,3,42,63-73]: (1) disarray of cardiac muscle cells (myocytes) (Fig. 67-4*C* and *D*); (2) replacement fibrosis (Fig. 67-4*F*); (3) expansion of the interstitial (matrix) collagen compartment; and (4) abnormally small intramural coronary arteries (Fig. 67-4*E*). Marked distortion of cellular architecture with myocyte disarray, described prominently by Teare in his initial report of HCM,[25] is a characteristic feature of the left ventricle.[64-68,71] Many cardiac muscle cells in both the ventricular septum and left ventricular free wall show increased transverse diameter and bizarre shapes, maintain intercellular connections with several adjacent cells, and are arranged in a disorganized pattern at oblique and perpendicular angles to each other. This myocyte disarray is present in about 95 percent of patients dying of HCM and usually occupies substantial portions of both septum (i.e., about 33 percent) and left ventricular free wall (i.e., 25 percent) (see Fig. 74-4*C* and *D*). However, there is little correlation between absolute wall thickness and amount of disorganized myocardium in segments of the left ventricular wall.[71] Therefore areas of normal or only mildly increased left ventricular wall thickness may also show evidence of the cardiomyopathic process in HCM, in the form of cellular disarray.[71]

Dispersion of disorganized cardiac muscle cells throughout the left ventricular myocardium may impair intercellular transmission of normal electrophysiologic impulses, predispose to electrical instability, and thereby serve as an arrhythmogenic substrate responsible for the genesis of primary ventricular tachycardia/fibrillation.[74]

Patients with HCM (and without atherosclerotic coronary artery disease) often exhibit myocyte necrosis and replacement fibrosis in the left ventricle at necropsy.[42,63,69,72] A spectrum of severity and distribution is observed ranging from isolated small scars to extensive, grossly visible replacement scarring that may even be transmural[42] (Fig. 67-4*F*). These areas of fibrosis, which likely result from repetitive bursts of myocardial ischemia or are related in some other way to the underlying cardiomyopathic disease process, can be identifiable during life as irreversible thallium-201 myocardial perfusion abnormalities[75] and may well contribute to the increased ventricular chamber stiffness and impaired relaxation identifiable in most patients with HCM as well as representing a nidus for the genesis of ventricular arrhythmias.[1,3,5,74] In addition, the interstitial collagen matrix of the left ventricle is substantially increased in size; its components (perimysial coils, pericellular weaves, and struts) are increased in number and morphologically abnormal, often showing a disorganized arrangement.[73]

Abnormal intramural coronary arteries are present in about 80 percent of patients with HCM studied at necropsy and are most commonly evident in the ventricular septum.[69,70] The walls of these arterioles are thickened (because of increased smooth muscle cells, collagen, elastic fibers, and mucoid deposits in the media and intima), and frequently the lumen appears narrowed and compromised (Fig. 67-4*E*). Increased numbers or clusters of abnormal intramural arteries are often observed within or at the margins of sizable areas of fibrosis.[42,69] This association between abnormal intramural coronary arteries and myocardial scarring suggests that a form of "small-vessel disease" present in patients with HCM may be responsible for myocardial ischemia and necrosis.[69]

Mitral Valve Abnormalities

Morphometric analysis of mitral valves removed at operation or necropsy from patients with outflow obstruction supports the concept that primary structural abnormalities of the mitral valve are also characteristic of many patients with HCM[20,43] (Fig. 67-9). About two-thirds of patients show alterations in mitral valve size and shape, with an increased mitral valve tissue area (up to twice normal) due primarily to leaflet elongation (but without evidence of myxomatous degeneration). These enlarged valves demonstrate considerable structural heterogeneity, either with both the anterior and posterior leaflets increased in size or asymmetric and segmental enlargement of one leaflet.[20] Mitral valve systolic anterior motion and outflow obstruction may occur both with normal or enlarged mitral valves but show age-related morphologic and functional features. In younger patients with obstruction, the leaflets are usually elongated and the valve is situated more posterior in the left ventricular outflow tract (at end-diastole), in contrast to elderly patients in whom the mitral valve is often normal-sized and situated much closer to the ventricular septum.[43]

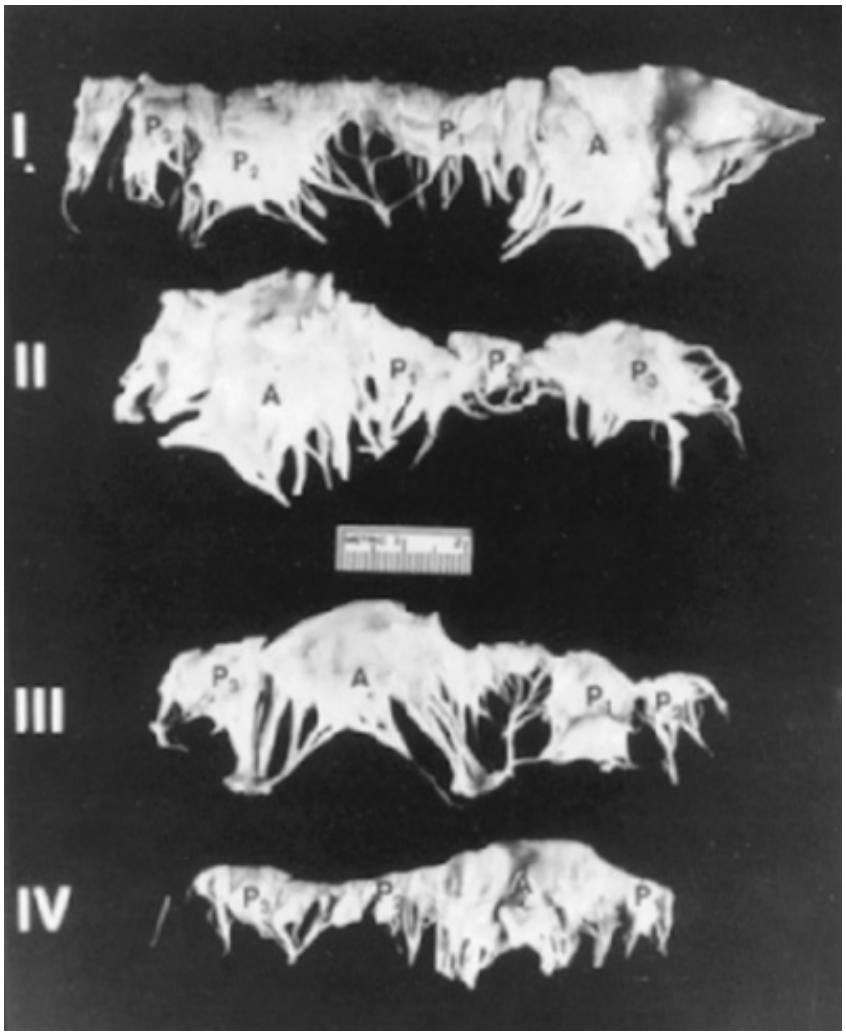

Figure 67-9: Mitral valves from three patients with obstructive HCM, aged 31, 29, and 60 years (I, II, and III), and from a normal control patient without cardiovascular disease (IV), showing variation in valvular size and structure present in HCM. Valves are opened with the circumference displayed in a horizontal orientation, exposing the atrial surface, with annular margin to top and chordal attachments to bottom. *I.* Large valve (area 22 cm2) in which both the anterior (A) and posterior (P) leaflets are greatly elongated and increased in area. *II.* Large valve in which increased valve size (area 18 cm2) is due primarily to elongation and enlargement of the anterior leaflet (A). *III.* Segmental elongation and increased area confined to a scallop of posterior leaflet. (From Klues HG et al.[20] with permission of the authors and Lippincott Williams & Wilkins.)

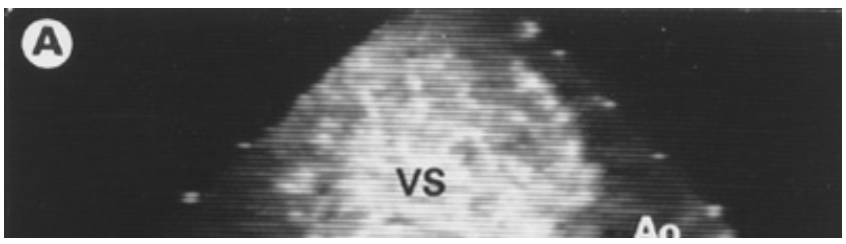
In addition, other HCM patients show a congenital malformation of the mitral apparatus due to an arrest in embryonic development, with anomalous insertion of papillary muscle directly into the anterior mitral leaflet (without the interposition of chordae tendineae)[19] (Fig. 67-10). Greatly enlarged mitral valves and anomalous papillary muscle insertion represent a constellation of structural malformations of the mitral apparatus (in >50 percent of patients studied at necropsy) that expand the morphologic definition of HCM.[19,20,43]



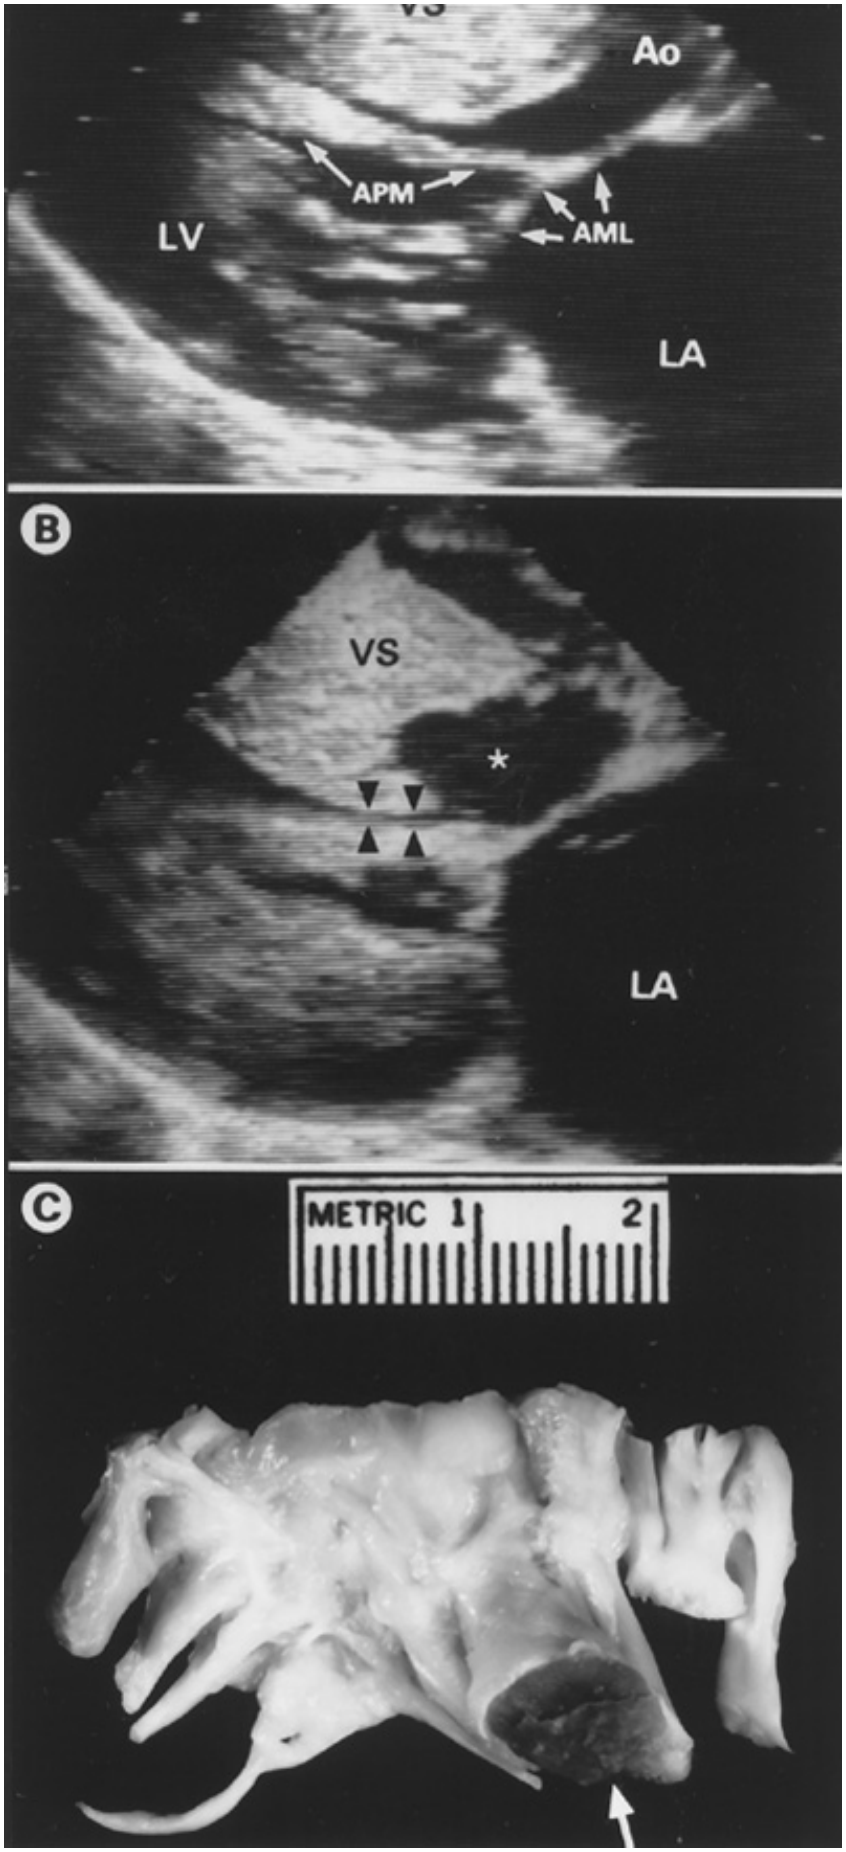


Figure 67-10: Anomalous papillary muscle insertion directly into anterior mitral leaflet (*AML*) in patient with obstructive HCM. *A. Before myotomy-myectomy:* parasternal long-axis

echocardiogram shows AML in direct continuity with the hypertrophied anomalous anterolateral papillary muscle (*APM*), which displaced anteriorly within the left ventricular cavity, producing a long area of midcavity muscular contact with the ventricular septum (VS) and outflow obstruction (*arrows*); tips of the mitral leaflets coapt in the usual position, and typical systolic anterior motion is absent (*small arrows*). *B. After myotomy-myectomy:* Long-axis echocardiogram shows extensive muscular resection (*), extending from base of the septum to beyond the distal margins of the anterior mitral leaflet; nevertheless, a large area of direct muscular contact remains after operation between papillary muscle and ventricular septum (*arrowheads*), which is responsible for persistent and marked obstruction to left ventricular outflow. *C.* Mitral valve specimen excised at operation; a massively hypertrophied anterolateral anomalous papillary muscle (*arrow*) inserted directly into the body of the anterior leaflet. Ao = aorta; LA = left atrial; LV = left ventricle. (From Klues HG et al.[19] with permission of the authors and Lippincott Williams & Wilkins.)

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

ETIOLOGY AND GENETICS

HCM is a mendelian trait with an autosomal dominant pattern of familial inheritance.[1-5,8-11,22,38-40,76-83] Based on 10 years of molecular genetic studies, it is now known that HCM is genetically heterogeneous and caused by mutations in any one of nine genes that encode contractile proteins of the cardiac sarcomere, involving thick filaments (myosin subunits-i.e., beta-myosin heavy chain and essential and regulatory myosin light chains), thin filaments (cardiac troponin T, cardiac troponin I, α-tropomyosin, and α-actin), and-in the case of titin cardiac myosin-binding protein C-the structural network that joins thick and thin filaments.[5,8-11,22,38-40,76-83] Clinical and laboratory data are largely restricted to three disease genes that, together, explain most occurrences of familial HCM: β-myosin heavy chain, myosin-binding protein C, and cardiac troponin T. Overall, more than 100 individual disease-causing HCM mutations have been reported, either of the missense type (with the replacement of one amino acid by another) or mutations leading to truncated proteins. Indeed, most genotyped pedigrees show a mutation apparently unique to that family. Undoubtedly, numerous other genes and mutations await identification. The fact that all mutations known to cause HCM involve genes encoding proteins of the sarcomere represents a unifying principle that permits us to regard this heterogeneous condition as a single disease entity (and as a disease of the sarcomere).[5,8-10,84]

It has been suggested that the prognosis of HCM varies considerably with respect to many of the mutations reported. For example, some β-myosin heavy chain point mutations appear benign (e.g., Val606Met), whereas others are more virulent and associated with reduced survival (e.g., Arg403Gln, Arg453Cys, and Arg719Trp).[8,9,22,76,82] In addition, cardiac troponin-T mutations may have malignant forms associated with reduced survival even though cardiac hypertrophy is often relatively mild.[5,22,38,39] Although, collectively, these observations suggest that genetic data may ultimately predict prognosis and influence clinical management, at present such a risk stratification strategy should be regarded as preliminary considering the relatively small number of genotyped families and the aforementioned genetic heterogeneity.

Occurrence of premature sudden cardiac death in a family should dictate a genetic and/or echocardiographic evaluation in surviving relatives, since the clinical expression of HCM may be particularly virulent in certain families (e.g., "malignant" HCM).[85] Also, because HCM is the most common cause of sudden unexpected death in young competitive athletes,[86] youthful family members should be screened for HCM prior to participation in intense athletic training. Because phenotypic (i.e., morphologic) expression of HCM may not be complete until 17 to 18 years of age,[35] a single screening echocardiogram during early childhood may not definitively exclude HCM. Therefore, children in families with HCM in whom left ventricular hypertrophy is absent on 2D echocardiography should continue to have examinations periodically until they achieve full growth and maturation. There now appears to be one clear exception to the tenet that development or progression of left ventricular hypertrophy does not occur in adulthood-i.e., myosin-binding protein-C mutations[10,46] (Fig. 67-11), which are associated with age-related penetrance; in some young adults, the HCM phenotype may not be evident on echocardiography, and is delayed until much later in life[10,46] (Fig. 67-12).

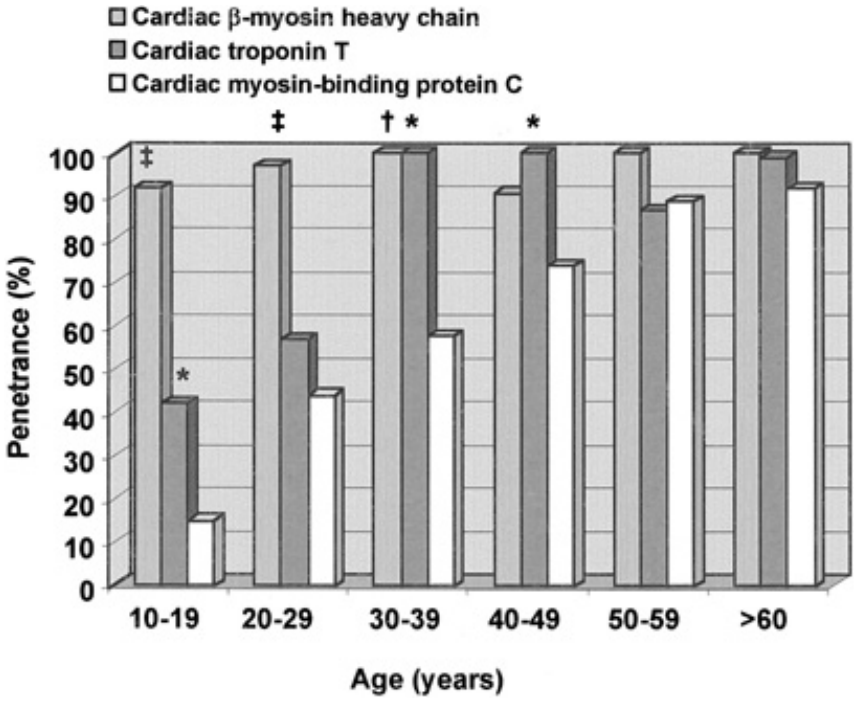

Figure 67-12: Age-related penetrance of familial HCM caused by mutations in the genes for cardiac myosin-binding protein C, cardiac troponin T, and cardiac β-myosin heavy chain. Solid bars denote the percentage of persons with both cardiac myosin-binding protein C mutations and left ventricular hypertrophy. Comparable clinical data for cardiac troponin T and β-myosin heavy chain are shown. Significant differences in the penetrance of familial HCM caused by cardiac myosin-binding protein C mutations and by mutations in cardiac troponin T or cardiac β-myosin heavy chain are indicated as follows: * = $p < 0.05$; = $p < 0.005$; $fy2$æ = $p < 0.001$. (From Niimura H et al. [10] with permission of the authors and the Massachusetts Medical Society.)

Routine echocardiographic screening at ≤12 years of age is usually unproductive, since phenotypic expression of the mutant gene is rarely present at that age.[31,35,59,77] Family screening can usually be deferred in young children until adolescence unless they are involved in intense sports programs (such as swimming and tennis) or are members of families with HCM-related sudden deaths.[85]

With the advent of preclinical genetic diagnosis of HCM, a number of asymptomatic youthful family members havebeen identified as affected on the basis of a DNA diagnosisin the absence of typical phenotypic features of their disease(as assessed with echocardiography and electrocardiography).[5,10,22,31,36,37,40] The increasing availability of gene-based diagnosis will lead to the identification of greater numbers of children and adults with a preclinical diagnosis of HCM (i.e., who have a gene defect but no phenotypic manifestations of HCM).[5,10,22,31,36,37,40] At present, the clinical implications of such gene abnormalities and the appropriate management are largely unresolved issues, although-of note-very few such patients have been reported with adverse outcome.[87,88] Therefore there is not sufficient evidence available at present to preclude such individuals from competitive athletics in the absence of cardiac symptoms or risk factors such as family history of sudden cardiac death.[89] It should be emphasized that, at present, due to the substantial genetic heterogeneity of HCM and the complex, time-consuming, and expensive techniques required for genetic screening, DNA diagnosis is quite demanding, permits only research-oriented genotyping of selected pedigrees, and is not routinely available for clinical practice.[22]

Although the reported sarcomeric protein mutations are regarded as disease-causing for HCM,

many of the abnormal and primary structural features of this disease are not confined to protein abnormalities of the sarcomere but extend to alterations in connective tissue elements-e.g., mitral valve enlargement and elongation as well as other anomalies of the mitral apparatus,[19,20,43] abnormal small intramural coronary arteries,[69,70] and an expanded collagen matrix.[72,73] This fact, together with the observations that the patterns of left ventricular hypertrophy in closely related family members are usually dissimilar[11] and that hypertrophy is frequently confined to only a portion of the wall,[11-13,18] suggests that phenotypic expression is importantly influenced by genetic factors other than the causal mutation (e.g., by modifier genes)[90] or by undefined environmental influences.

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

PATHOPHYSIOLOGY

The symptoms of HCM are varied and include those of pulmonary congestion-such as exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea-as well as fatigue, chest pain (which may be atypical of angina pectoris), palpitations, and impaired consciousness, including dizziness, near syncope, and syncope. The onset of symptoms is often in early adulthood between 20 and 40 years of age, although they can become evident at any age.

A number of pathophysiologic components of the HCM disease process dictate the clinical course and outcome experienced by patients[1,3-5,91-101]: (1) left ventricular outflow tract obstruction; (2) diastolic dysfunction; (3) myocardial ischemia; and (4) supraventricular and ventricular arrhythmias. However, consistent with the heterogeneity of HCM, cardiac symptoms do not always show a direct (one-to-one) correlation with a particular pathophysiologic mechanism in the individual patient, and the relative contributions of each component to symptoms appear to vary considerably among patients. Among patients with outflow gradients, no consistent correlation has been identified between the frequency and severity of symptoms and the magnitude of the gradient. Furthermore, the severity and character of symptoms may be similar in those patients with or without outflow obstruction.

Outflow Obstruction

Obstruction to left ventricular outflow exhibited by patients with HCM (due to systolic anterior motion of the mitral valve and midsystolic contact with the ventricular septum)[4,6,94-97,102,104] is characteristically dynamic, showing spontaneous variability.[2] Interventions or circumstances that decrease myocardial contractility (e.g., beta-blocking drugs) or increase ventricular volume or arterial pressure (squatting or vasoconstrictor agents) have the effect of reducing or abolishing subaortic obstruction. Interventions or circumstances that increase contractility (exercise or infusion of isoproterenol) or decrease arterial pressure or ventricular volume (Valsalva maneuver or a hypotension-producing agent) will increase or provoke obstruction. Not uncommonly, patients with little or no obstruction to left ventricular outflow under basal conditions are capable of generating substantial labile gradients with physiologic or pharmacologic provocations[2-4] or just after the cessation of exercise.[98]

The increase in systolic intraventricular pressure associated with outflow obstruction may increase myocardial wall stress and oxygen demand. It is generally conceded that outflow obstruction in HCM can, in some patients, have long-term detrimental consequences on left ventricular function and be responsible for the genesis of symptoms.[1-6,95] The magnitude of the systolic pressure gradient can be reliably estimated noninvasively by the magnitude and duration of mitral valve systolic anterior motion on M-mode echocardiogram[4,6,94,95] or, more easily and quantitatively, by continuous-wave Doppler interrogation, obviating the necessity of performing serial cardiac catheterizations.[105] The combined use of color-coded, pulsed, and continuous-wave Doppler echocardiography allows assessment of the site and severity of outflow obstruction[104] (Chap. 13).

For the subaortic gradient to occur in HCM, several of the following morphologic and hemodynamic factors will be present: (1) reduced outflow tract dimension at end-diastole; (2) substantial hypertrophy involving the basal anterior ventricular septum; (3) displacement of mitral

valve and papillary muscles anteriorly within the ventricular cavity; (4) increased length of the mitral leaflets; and (5) hyperdynamic left ventricular ejection, creating a high-velocity jet which streams through the narrowed outflow tract, pulling the mitral leaflets forward toward the septum (i.e., Venturi effect), or perhaps more likely due to drag (the hydrodynamic pushing force of flow) on the leaflets as they protrude into the outflow tract.[90] While mitral regurgitation due to outflow obstruction is usually mild-to-moderate in HCM, it may occasionally be much more severe when associated with primary intrinsic abnormalities of the valve (e.g., myxomatous mitral valve with prolapse).[106] Although outflow obstruction is due to mitral systolic anterior motion in most patients with HCM (>95 percent)-with septal contact usually effected by the anterior leaflet and only occasionally by the posterior leaflet preferentially[103]-a small subset of patients demonstrate a peak systolic outflow gradient due primarily to muscular midcavity obstruction; such gradients may result from anomalous papillary muscle insertion directly into the anterior mitral leaflet[19] (Fig. 67-10) or from other forms of muscular apposition, which in some instances are associated with segmental apical or more generalized ventricular hypokinesia.[107]

In infants and young children with HCM, obstruction to right ventricular outflow is common and occurs in association with subaortic obstruction.[54,55,95,108] Right ventricular outflow obstruction in HCM is produced by greatly hypertrophied right ventricular musculature (crista supraventricularis, moderator band, or trabeculae), reflecting an excessive hypertrophic process, and projecting into the relatively small outflow tract.[109]

Diastolic Dysfunction

Echocardiographic, Doppler, contrast, or radionuclide angiographic and hemodynamic studies of left ventricular diastolic function have identified characteristic abnormalities in relaxation and filling that are present in about 80 percent of patients with HCM[1,3,4,6,92,93,99,110-113] and are presumed to have an important role in the genesis of fatigue, exertional dyspnea, and angina pectoris. Therefore, considering the overall HCM disease spectrum, diastolic dysfunction is probably the single most important pathophysiologic mechanism responsible for symptoms. Prior studies have shown that the early filling phase of diastole is significantly prolonged and associated with a decreased rate and volume of rapid filling.[1,4,92,93] Associated with this alteration is a compensatory increase in the contribution of late diastolic filling associated with atrial systole.[1,4,92,93] Diastolic dysfunction may occur in the absence or presence of symptoms or outflow obstruction and appears unrelated to the severity or distribution of left ventricular hypertrophy.[92,113,]

Myocardial Ischemia

There is abundant evidence that myocardial ischemia occurs in HCM as part of the underlying cardiomyopathic process and unrelated to atherosclerotic coronary artery disease.[1,3,69,70,91,114] For example, the presence of regional ischemia can be inferred clinically; patients with HCM may have typical angina chest pain and ECG abnormalities consistent with ischemia and infarction.[115,116] Furthermore, when patients with HCM and a history of anginal chest pain undergo right atrial pacing, the characteristic chest pain usually develops, the induced increase in coronary flow is reduced, and lactate is frequently produced.[91] Also, such patients may have fixed or exercise-induced reversible thallium-201 defects indistinguishable from those of patients with myocardial ischemia secondary to coronary artery disease.[75] Nevertheless, it has proven exceedingly difficult to measure or quantitate precisely the extent and location of such ischemia or to consistently derive clinical correlations or prognostic information for this finding.[110]

Myocardial ischemia and impaired vasodilator reserve in HCM may be due to several potential mechanisms: (1) compromised coronary blood flow to the left ventricular myocardium because of

abnormal intramural coronary arteries (i.e., "small vessel disease"); (2) excessive myocardial oxygen demand that exceeds the capacity of the coronary system to deliver oxygen; or (3) prolonged diastolic relaxation, resulting in elevated myocardial wall tension.

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

ELECTROCARDIOGRAPHIC FEATURES

The 12-lead ECG is abnormal in about 90 percent of patients with HCM and shows a wide variety of patterns, often bizarre in appearance.[2,4,48-50,116] However, no particular ECG alteration is characteristic of most patients with HCM; common abnormalities are increased precordial voltages consistent with left ventricular hypertrophy, ST-segment changes and T-wave inversion, left atrial enlargement, abnormally deep Q waves, and diminished or absent R waves in the right precordial leads. Infants and young children often have the paradoxic finding of right ventricular hypertrophy on ECG, which may reflect obstruction to right ventricular outflow.

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

PREPARTICIPATION SCREENING FOR HCM IN ATHLETIC POPULATIONS

Detection of preexisting cardiovascular abnormalities (such as HCM) with the potential for significant morbidity or sudden death during intense physical activity is an important objective of the widespread practice of preparticipation screening of high school[117,118] and college-aged athletes.[119] In the United States, customary screening practice dictates a personal and family history and physical examination.[117-119] However, under the conditions of standard screening, it is difficult to identify or raise the suspicion of HCM, given that the vast majority of patients have the nonobstructive form of the disease with either no or only a soft systolic heart murmur, and that historical clues such as syncope or family history of sudden death are also uncommon.[1m118] Ideally, the detection of HCM would be enhanced by the incorporation of noninvasive testing during screening, such as 12-lead ECG[120] or echocardiography.[118] However, cost-efficacy and other considerations make the routine application of such tests impractical throughout the United States.[118] Echocardiographic screening for HCM is also limited by the frequency of borderline wall-thickness measurements (and the uncertainty and anxiety created by such findings), as well as the fact that the HCM phenotype may not always be detectable with echocardiography prior to about age 16.[35]

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

NATURAL HISTORY INCLUDING SUDDEN CARDIAC DEATH

HCM may be identified clinically at virtually any age, from infancy to old age (with even a few patients >90 years of age). Understanding the clinical course of HCM, particularly when viewed in the context of predicting outcome for individualpatients, has for 40 years been constrained by three obstacles:(1) uncommon occurrence of the disease (i.e., 0.2 percent inthe general population)[26]; (2) heterogeneity of disease expression[1-22,29,32-34,37-46,58-62,77-83,121]; and (3) tertiary center referral bias.[28,122,123]

Indeed, because much of the considerable published literature on HCM is based on studies performed at tertiary referral centers,[28,124-130] the overall clinical picture of HCM that has emerged is profoundly influenced by the biases created by highly selective patient referral patterns,[28,122,123] which has led to an overestimation of the overall risk for premature death and morbidity. This concept is substantiated by the fact that annual mortality figures from such referral centers are considerably higher (3 to 4 percent and up to 6 percent in children)[108,125,126,128,129] than those more recently reported in relatively unselected regional populations (about 1 percent per year).[122,131-136] Indeed, patient referral patterns are probably the strongest determinants of our prevailing perceptions regarding the clinicalexpression and impact of HCM.[122,123]

In general terms, it is reasonable to characterize HCM as a complex disorder capable of important clinical consequences, including causing premature death in some patients. However, the disease has a more favorable overall clinical course than previously thought, as many patients achieve normal life expectancy with little or no disability and often without the aid of therapeutic interventions. These observations emphasize the need to provide many HCM patients, including many children, with reassurance regarding their clinical outlook, as well as prudence concerning possible adverse consequences.

On the other hand, when HCM is viewed in terms of patient subgroups (rather than the overall disease), some individuals are clearly at much higher risk and may be subject to three modes of death: (1) sudden and unexpected, often in the young; (2) progressive heart failure in midlife; and (3) stroke associated with atrial fibrillation, largely in the elderly.

While frequent in children and young adults, sudden death is not confined to these age groups and may also occur in midlife and beyond, without a statistically significant predilection for any particular age group. Therefore the potential risk period in HCM is particularly long. However, reports of sudden death in infants and very young children are exceedingly rare. Sudden death in HCM usually occurs in previously asymptomatic (or only mildly symptomatic) patients, and such catastrophes are often the first clinical manifestation of the disease.[124] Although most patients die in the morning hours[137] while engaged in sedentary pursuits or during mild exertion, a substantial proportion collapse during or just after vigorous physical activity.[86,124] The latter observation-as well as the fact that HCM is the most common cause of sudden death among young competitive athletes[86] (Fig. 67-13)-supports the view that intense physical activity can act as a trigger for sudden death in the presence of underlying cardiovascular disease.[138] Therefore it is prudent to recommend the disqualification of young athletes with HCM from intense competitive sports, in

accord with the standards of the 26th Bethesda Conference,[89] in an effort to decrease the risk of exercise-related sudden death.

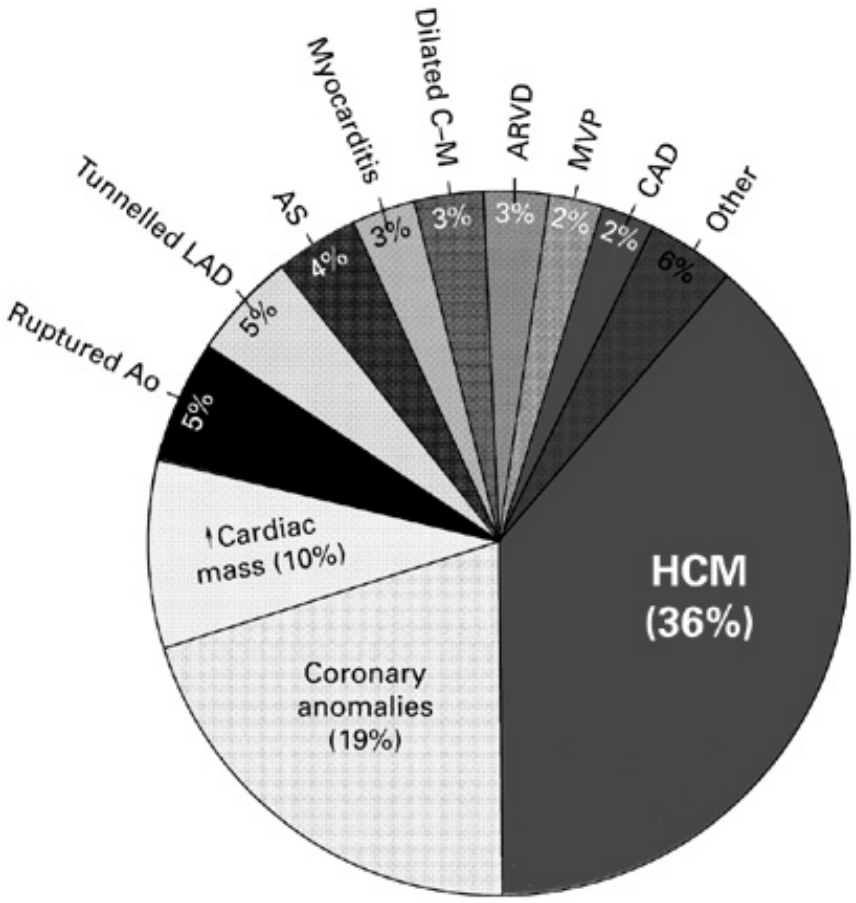

Figure 67-13: Causes of sudden cardiac death in young competitive athletes (median age, 17), based on systematic tracking of 158 athletes in the United States, 1985 to 1995. In an additional 2 percent, no evidence of cardiovascular disease sufficient to explain death was found at necropsy; ↔(increased) cardiac mass = hearts with increased weight and some morphologic features consistent with (but not diagnostic of) HCM. Ao = aorta; LAD = left anterior descending coronary artery; AS = aortic stenosis; C-M = cardiomyopathy; ARVD = arrhythmogenic right ventricular dysplasia; MVP = mitral valve prolapse; CAD = coronary artery disease; HCM = hypertrophic cardiomyopathy. (Adapted from Maron BJ et al.[86] with permission of Lippincott Williams & Wilkins.)

Based on stored electrogram data from HCM patients experiencing appropriate implantable cardioverter-defibrillator discharges, ventricular tachycardia/fibrillation appears to be the primary mechanism most commonly responsible for sudden death in HCM,[74] although a number of other mechanisms may also be involved.[139-146] No particular symptom complex has been shown to be reliably associated with subsequent sudden death in HCM with the exception of recurrent or exertional syncope, particularly in the young.[5] Furthermore, patients with or without subaortic obstruction may die suddenly, and some patients appear to tolerate marked outflow obstruction for virtually their entire lives without adverse consequences.[122] Indeed, the presence or magnitude of the outflow gradient has not been independently associated with increased risk for sudden death, although an association with heart failure-related or total cardiovascular mortality has been cited.[122,136,148]

However, other disease variables have been associated with an increased likelihood of sudden death. The most important of these proposed risk factors include[1,5,8,9,22,38,74,82,85,145,147-149] (Fig. 67-14) the following: prior cardiac arrest or sustained ventricular tachycardia, "malignant" genotype or family history of premature HCM death, multiple-repetitive (or prolonged) bursts of nonsustained ventricular tachycardia on ambulatory ECGs, massive degree of left ventricular hypertrophy (wall thickness, ≥30 mm). A hypotensive blood pressure response to exercise may also be informative regarding risk but is encumbered by a low positive predictive accuracy and is much more powerful as a negative predictor of outcome.[139,140]

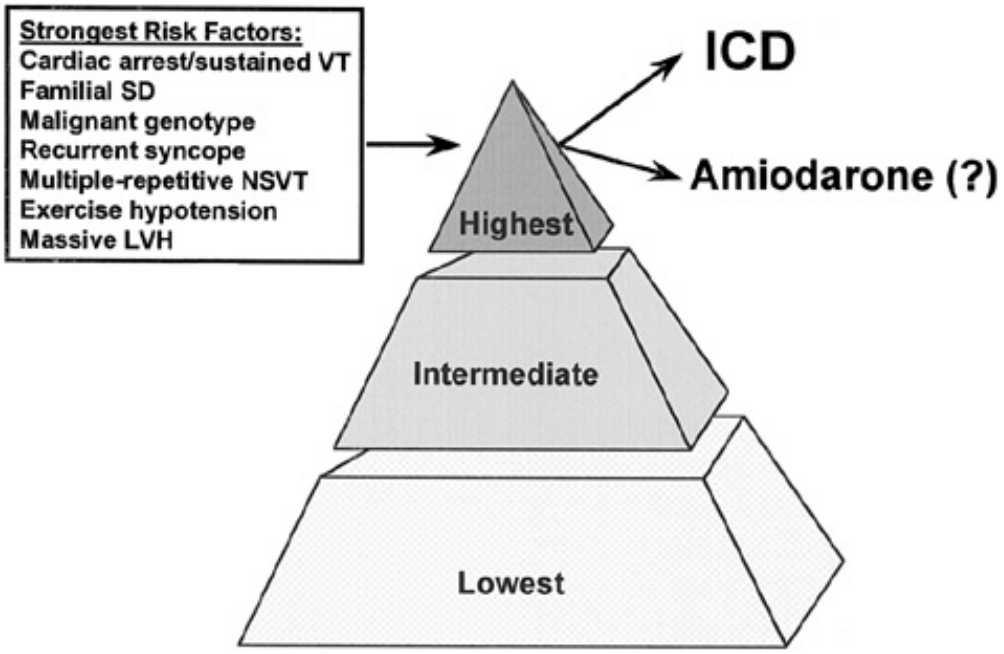

Figure 67-14: Assessment of risk for sudden cardiac death in HCM population. Treatment for the prevention for sudden death is limited to that small subset perceived to be at highest risk compared to all other patients with HCM, based on the presence of ≥1 of the risk factors shown. Patients regarded as low risk are asymptomatic with mild left ventricular hypertrophy and *without* either ventricular tachycardia on ambulatory Holter ECG, hypotensive blood pressure response to exercise, and family history of premature HCM-related death, ICD = implantable cardioverter-defibrillator; LVH = left ventricular hypertrophy; NSVT = nonsustained ventricular tachycardia; SD = sudden death; VT = ventricular tachycardia. (From Maron,1 with permission of the author and *Lancet*.)

A recent retrospective analysis of children with HCM suggested that an intramural course of a segment of the proximal left anterior descending coronary artery (i.e., myocardial bridging) constitutes a risk factor for sudden cardiac arrest.[145] It was proposed that such muscular bridges could produce systolic coronary arterial narrowing, residual diastolic compression, and myocardial ischemia, thereby justifying surgical unroofing when detected.

The data available at this time do not provide convincing evidence that programmed electrical stimulation has a major role in risk stratification in HCM. Particularly aggressive programmed stimulation protocols with triple ventricular premature depolarizations seldom induce monomorphic ventricular tachycardia but frequently trigger polymorphic ventricular tachycardia or ventricular fibrillation in patients with HCM.[5,150] Based on experience in HCM as well as in coronary artery disease and dilated cardiomyopathy, these latter arrhythmias are generally regarded as nonspecific responses.[5]

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

END-STAGE PHASE

A final phase of disease evolution occurring in about 10 percent of symptomatic patients in a referral-based population has been variously referred to as the "end-stage," "burned-out," or "dilated" phase of HCM[61] (Fig. 67-15). This distinctive clinical course is characterized by progressive congestive symptoms with marked exercise limitation and atrial arrhythmias, associated with substantial left ventricular remodeling-i.e., enlarging left ventricular cavity size (occasionally with marked absolute dilatation), thinning of portions of the wall, systolic dysfunction, and-in a few patients-spontaneous reduction of the subaortic gradient. Therefore, the disease in end-stage patients is transformed from the typical morphologic and functional appearance of HCM (hyperdynamic, hypertrophied, and nondilated left ventricle) to a clinical state that is more suggestive of a dilated form of cardiomyopathy (Chap. 66) in which the thickness of the left ventricular wall may be virtually normal. Many such patients exhibit irreversible myocardial perfusion abnormalities, which undoubtedly represent areas of extensive myocardial scarring.[42,63,69,75]

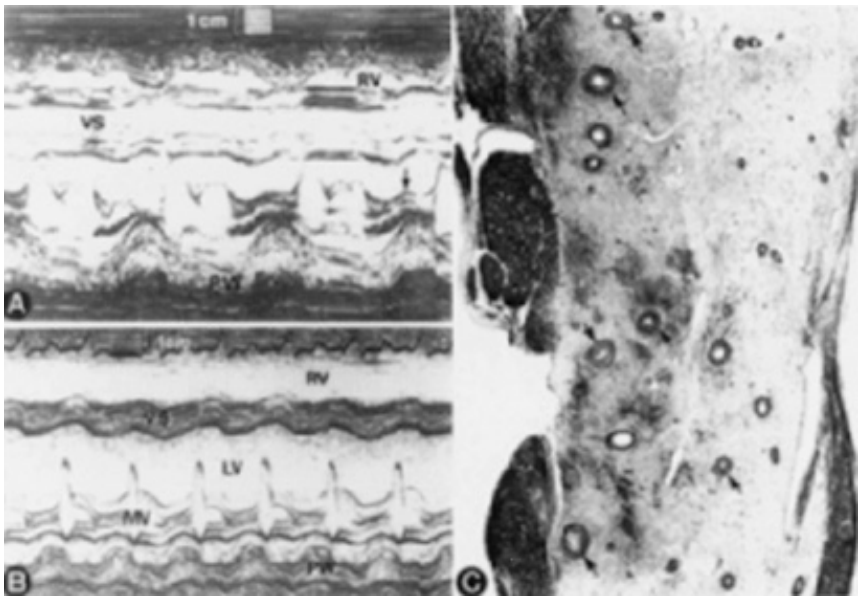

Figure 67-15: Studies in patients with HCM and normal extramural coronary arteries showing changes occurring in association with progressive congestive cardiac failure and transmural myocardial infarction (end-stage phase). *A.* Echocardiographic study from a 26-year-old patient with exertional chest pain and dyspnea. Ventricular septum (VS) is markedly thickened (23 min) and pattern of hypertrophy is asymmetric. Left ventricular end-diastolic dimesion is reduced (38 min), and there is a trivial degree of mitral systolic anterior motion (*arrow*). PW = posterior wall; RV = right ventricular. *B.* From same patient at 30 years of age (9 months before death) after clinical deterioration with progressive cardiac failure, pulmonary edema associated with chronic atrial fibrillation, and cardiopulmonary collapse. Appearance of left ventricular has changed dramatically. Septum has thinned considerably (to 13 mm) and is about as thick as the posterior wall; left ventricular (LV) and right ventricular cavities have enlarged substantially. MV = mitral valve. *C.* Low-power photomicrograph of a specimen from a patient with a clinical course similar

to that of the patient in *A* and *B* showing transmural scarring of the septum and numerous abnormal intramural coronary arteries, some with thickened walls and narrowed lumen (*arrows*) (Magnification ×6). (From Maron BJ et al.3 with permission of the authors and the Massachusetts Medical Society.)

It is possible that the morphologic and functional changes that result in end-stage depression of left ventricular contractile function are due to impaired coronary blood flow and myocardial ischemia resulting from small-vessel coronary artery disease. Patients evolving into the end-stage phase of HCM or experiencing sudden and unexpected cardiac death may coexist in the same family (and share the identical disease-causing mutation).[151] Also, a few patients with aborted episodes of cardiac arrest have themselves died many years later in the end-stage phase.[152]

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

HYPERTROPHIC CARDIOMYOPATHY IN THE ELDERLY

Older patients (over age 60 to 65) with morphologic and clinical features consistent with HCM have been reported.[1,21,153,154] In certain of these patients, HCM may be well tolerated to particularly advanced ages (i.e., 80 to 90 years) and therefore should be regarded as a disease compatible with normal longevity. In an unselected HCM population, about 20 percent of patients had achieved the age of ≥75 years.[122] In other elderly patients, symptoms are not present early in life, but severe functional limitation and heart failure may intervene abruptly for the first time after age 60 to 65.[21,153,155] This prolonged period of symptomatic latency is notable for a disease usually expressed morphologically by age 20 and in which symptoms are usually evident by age 40 to 50.

Older patients with HCM differ in many respects from many younger patients with regard to certain morphologic features.[21,153-155,156] Older patients characteristically have relatively small hearts with only modestly increased left ventricular wall thickness (usually 20 mm)[21,62,122,155] and severely distorted outflow tract morphology, with greatly reduced size, and exaggerated anterior displacement of a normal-sized mitral valve. Substantial deposits of calcium in the mitral annular region are frequently present and may contribute to anterior displacement of the valve in some patients. Outflow obstruction often occurs in the presence of restricted mitral valve systolic anterior motion, with contact between ventricular septum and anterior mitral leaflet produced by a combination of anterior excursion of the mitral valve toward the septum and posterior movement of septum toward the mitral valve.[43] It is uncertain whether the HCM phenotype in such older patients always conveys the same genetic etiology as in younger patients; however, some older patients have been documented to carry the same mutant genes encoding sarcomeric proteins characteristic of other (younger) HCM patients.

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

MEDICAL TREATMENT

Asymptomatic Patients and Prevention of Sudden Cardiac Death

Those patients with clear evidence of high risk should be offered treatment for the prevention of sudden cardiac death.[1,5] The implantable cardioverter-defibrillator (ICD) has proved effective and reliable in relatively young and high-risk HCM patients by virtue of sensing ventricular tachycardia/fibrillation and restoring sinus rhythm by appropriate defibrillation shocks or antitachycardia pacing at an overall rate of 7 percent per year.[74] The ICD may be lifesaving,[74,157] both in the context of secondary prevention after cardiac arrest or in sustained ventricular tachycardia (11 percent per year) or for primary (prophylactic) prevention due to the perception of high risk based on ≥1 sudden death risk factors.[74] Alternatively, long-term prophylactic treatment with amiodarone[158] would seem less realistic in relatively young HCM patients, given the potential side effects and the long risk period in HCM as well as the paucity of data substantiating amiodarone as affording effective protection against sudden cardiac death specifically in this disease. Prophylactic and empiric administration of beta blockers or verapamil to asymptomatic patients for the primary purpose of reducing the risk for sudden death, for which there are no or little data, now seems outdated in view of the availability of more definitive therapeutic measures such as the ICD. Drug treatment to prevent or delay progression of congestive symptoms is empiric, with a complete lack of any controlled data.

Alleviation of Symptoms

Therapeutic strategies for symptomatic patients with HCM are summarized in Fig. 67-16. Responses of HCM patients to medical treatment are highly variable; consequently, therapy must often be tailored to the individual requirements of symptomatic patients.[1,5,159] Historically, beta-adrenergic blocking drugs (propranolol or more cardioselective agents such as atenolol, metoprolol, or nadolol) have been utilized extensively to relieve symptoms in patients with either the obstructive or nonobstructive form of HCM.[1,3-6,159] The beneficial effects of beta blockers on symptoms (principally exertional dyspnea and chest pain) and exercise capacity appear to be due largely to decreased heart rate, with consequent prolongation of diastole, increased passive left ventricular filling, and decreased filling pressures. By reducing inotropic state, beta blockers may also lessen myocardial oxygen demand and decrease the left ventricular outflow gradient during exercise when sympathetic tone is increased.

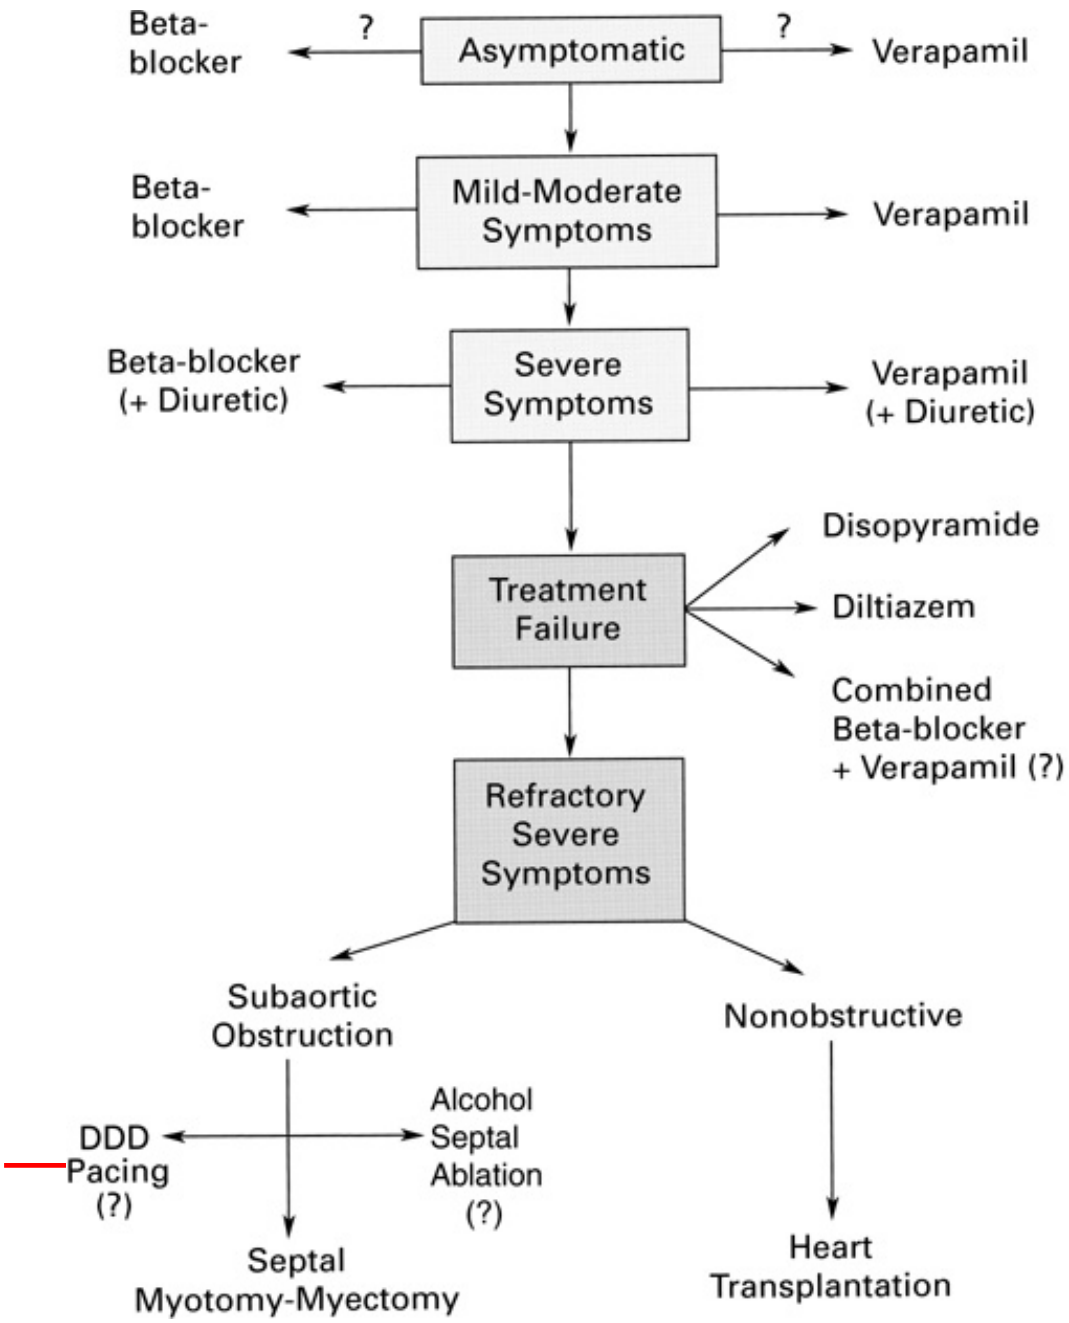

Figure 67-16: Therapeutic strategies for patients with HCM. Question marks indicate treatment recommendations that are largely unresolved.

Calcium channel blockers (principally verapamil) are also important therapeutic agents in the management of symptomatic patients with HCM.[1,160,161] Orally administered verapamil provides improvement in cardiac symptoms and exercise tolerance for many patients with HCM, including those who have failed to benefit from beta blockers. This symptomatic improvement with verapamil appears to be due largely to normalization of left ventricular filling parameters.[1,5]

Beta blockers and verapamil are usually administered empirically at the onset of symptoms by titrating drug dosage to the historical assessment of functional disability, although some investigators utilize exercise testing with or without measurement of oxygen consumption to gauge the effect of medications on symptoms. Furthermore, there is no consensus on the sequence with which beta blockers and verapamil should be administered; usually a trial with one or the other drug is initiated and should a benefit fail to result, the patient is converted to the other drug. Excessive dosages of either a beta blocker or verapamil should be avoided (e.g., >480 mg/day of

verapamil), since such drug levels rarely achieve beneficial results and can incur side effects. There is no evidence that the effect of using beta blockers and verapamil together is superior to that of either drug alone, and this combination should be avoided.

At selected centers, disopyramide has been an alternative medication for patients with obstructive HCM and severe symptoms otherwise unresponsive to standard therapy.[6,162-164] Disopyramide may reduce outflow gradient and improve symptoms by virtue of its negative inotropic properties, although the potential for proarrhythmia has constituted an obstacle to its use in HCM for some investigators. The aforementioned negative inotropic agents have been shown to reduce outflow gradient in HCM by slowing left ventricular ejection acceleration.[164]

Some patients with particularly severe symptoms of heart failure despite treatment with beta blockers or verapamil may show symptomatic improvement with the judicious addition of diuretic agents.[3] The aforementioned therapeutic considerations apply to those patients with HCM in whom symptoms of congestive failure typically occur in the presence of normal or hyperdynamic systolic performance. Conversely, in the subgroup of patients experiencing congestive symptoms secondary to systolic dysfunction (i.e., end-stage HCM)[1,4-6,61,159] therapeutic strategy is similar to that employed for heart failure in other diseases with impaired systolic function, including the use of diuretics, angiotensin-converting enzyme inhibitors, and digitalis; ultimately, heart transplantation should be considered in this subgroup of patients[61,165] (see Chap. 22).

Prevention of Infective Endocarditis

Bacterial endocarditis, a recognized complication of HCM, is virtually confined to patients with the obstructive form of the disease (and mitral valve systolic anterior motion) with a prevalence of about 0.5 percent.[166] Vegetations most commonly involve the anterior mitral leaflet or septal endocardium at the site of mitral valve contact (likely a consequence of the high-velocity outflow jet) and less commonly the aortic valve.[166,167]

Atrial Fibrillation

Atrial fibrillation is a particularly important arrhythmia in HCM,[134,168,169] reportedly occurring in up to about 20 percent of patients followed longitudinally with this disease.[122,134] Atrial fibrillation is associated with an increased risk for systemic thromboembolism, heart failure, and death.[1,3-6] Of note, HCM patients with atrial fibrillation usually show substantial left atrial enlargement but, paradoxically, usually only relatively mild left ventricular hypertrophy.[168] Onset of atrial fibrillation may importantly impair the clinical course in HCM, probably because absence of the atrial systolic contribution to ventricular filling is critical to cardiac function in patients with such poorly compliant ventricles. In many patients, however, chronic atrial fibrillation appears to be reasonably well tolerated as long as ventricular rate is controlled.[169] Beta-adrenergic blocking agents or verapamil are usually efficacious in controlling heart rate in patients with chronic atrial fibrillation. Recurrent atrial fibrillation is managed by restoring sinus rhythm with electrical cardioversion, if necessary, or alternatively by drugs-with amiodarone probably the most effective antiarrhythmic agent for the prevention of recurrent atrial fibrillation. Because of the risk of peripheral embolism and stroke, anticoagulant therapy should be administered (and continued indefinitely) in most patients once atrial fibrillation has been documented.

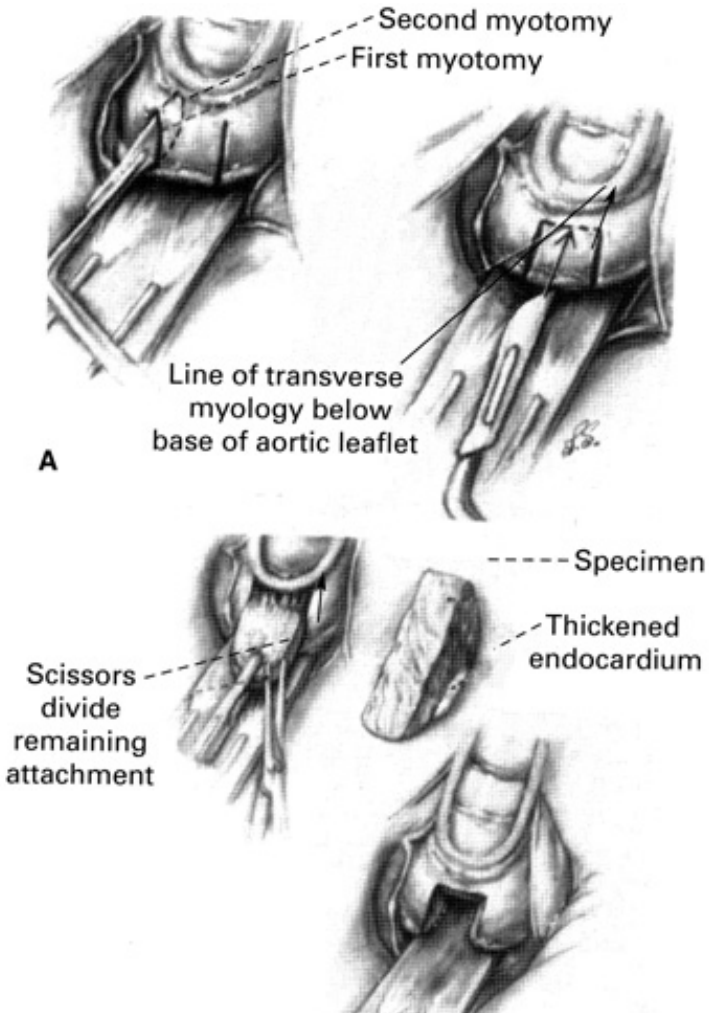
Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

SURGICAL TREATMENT

Operation is regarded as the standard treatment for those HCM patients with obstruction to left ventricular outflow under basal conditions (gradient ≥50 mmHg), and severe drug-refractory symptoms.[1,3-6,159,170-186] Therefore surgery is performed to relieve incapacitating symptoms and subaortic obstruction by normalizing the markedly increased systolic intraventricular pressures.[1,3-6,159,170-186] General agreement is lacking, however, as to whether symptomatic patients with marked outflow gradients-which are present solely or predominantly under provokable conditions such as exercise or with maneuvers in the catheterization laboratory (e.g., isoproterenol infusion, amyl nitrite inhalation, or Valsalva maneuver)-are appropriate operative candidates.[2,4,6,171,179]

Ventricular septal myotomy-myectomy (Morrow operation)[170] (Fig. 67-17) is the surgical procedure of choice; a small amount of muscle is removed from the basal anterior septum (usually about 2 to 6 g) through an aortotomy. However, mitral valve replacement has been employed[177,179,184] in selected patients when the operative site for muscular resection in the basal anterior portion of the septum is relatively thin (i.e., ≤18 mm) or when the distribution of septal hypertrophy is atypical.[179]



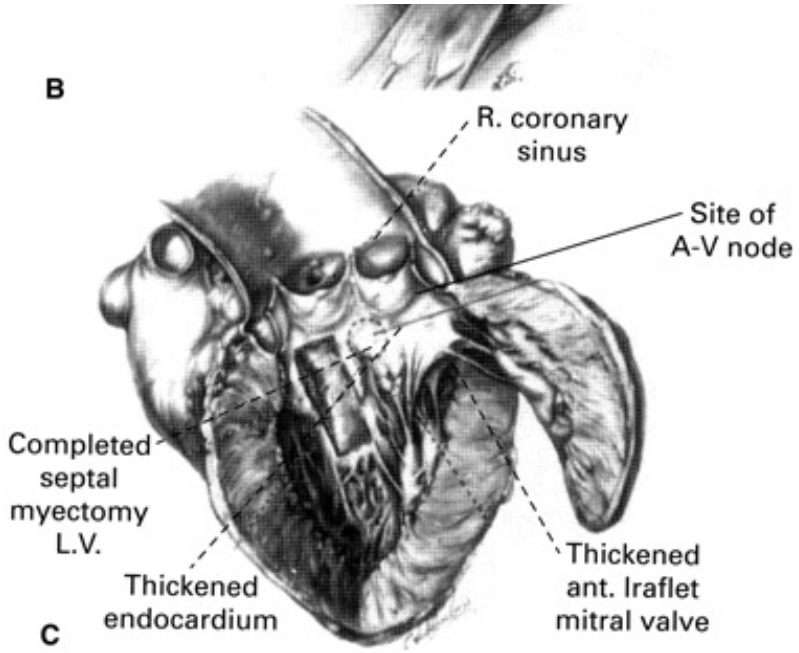


Figure 67-17: Illustration of ventricular septal myotomy-myectomy operation (Morrow procedure). *A.* Two vertical, parallel myotomies are made in the cephalad portion of the septum about 1 cm apart. Transverse incision is then made, connecting the two parallel myotomies. *B.* Attachments of the muscle bar to the septum are divided; this segment of muscle is isolated and then excised. *C.* After completion of the myotomy-myectomy, a rectangular channel about 4 cm long and 2 cm wide is evident extending from the aortic annulus to a point just distal to the caudal margins of the mitral leaflets. (From Maron BJ et al.[176] with permission from the authors and the *European Heart Journal*.)

Occasionally, patients have outflow obstruction from a mechanism other than mitral valve systolic anterior motion. For example, anomalous papillary muscle insertion directly into anterior mitral leaflet without the interposition of the chordae tendineae (Fig. 67-10) producing muscular mid-ventricular obstruction[19] should always be contemplated prior to surgery, since the operative strategy may require a more extensive myectomy[186] or possibly mitral valve replacement.[19] Suture plication of the anterior mitral leaflet (in combination with myotomy-myectomy) has also been introduced in patients judged to have a greatly enlarged mitral valve, so as to reduce the likelihood that mitral valve systolic anterior motion will persist postoperatively.[185]

Intraoperative 2D echocardiography is an important guide to mapping the distribution and magnitude of septal hypertrophy [179,187,188] and determining how the muscle resection should be tailored to the distribution of septal hypertrophy in the individual patient to achieve the desired hemodynamic result and avoid iatrogenic complications such as ventricular septal defect. Transesophageal echocardiography (chap. 13) may also be useful in assessing morphologic and functional abnormalities during surgery, particularly of the mitral valve.[187,188]

Results from a number of North American and European centers employing septal myotomy-myectomy over the past 40 years, in about 2000 patients, have demonstrated salutary hemodynamic as well as symptomatic effects.[1,3-6,159,170-183,189] Operative mortality at the most experienced centers has improved over the past several years and is presently less than 1 to 2 percent.[1,5] Older patients with associated cardiac lesions, such as coronary artery disease requiring bypass grafting, may be at greater operative risk.[190]

Several important effects of operation have been defined in patients with HCM.[1,3-6,159,170-183,189] First, in more than 90 percent of patients, myotomy-myectomy (or mitral valve replacement)

abolishes or substantially reduces the basal subaortic gradient and mitral valve systolic anterior motion without importantly compromising left ventricular function; this consequence of surgery appears to be permanent, with no evidence that the gradient recurs postoperatively or that spontaneous growth of septal musculature recurs in the area of the resection. Second, the reduction in left ventricular systolic pressure is associated with a significant and persistent improvement in symptoms and exercise capacity in 70 percent of patients ≥5 years after operation as well as with a demonstrable increase in myocardial oxygen consumption and improvement in lactate metabolism.[191]

In a minority of patients, even after surgical relief of outflow obstruction, symptoms may nevertheless return (presumably due to persistently impaired left ventricular filling or ischemia, atrial fibrillation, or conduction abnormalities), and premature cardiac death can still ensue many years postoperatively.[189,191] Traditionally, surgery has not been recommended for asymptomatic (or mildly symptomatic) patients with outflow obstruction since, in addition to the operative risk, definitive evidence is lacking that prophylactic relief of outflow obstruction prolongs survival, diminishes risk for sudden death, or mediates the development of symptoms.

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

ALTERNATIVES TO SURGERY

Dual-Chamber Pacing

Although the septal myotomy-myectomy operation is the first therapeutic option for severely limited patients without obstructive HCM, perhaps the major limitation of surgery is the restricted availability of surgeons with the necessary experience to readily afford patients with low operative mortality and a high expectation of hemodynamic and symptomatic success with myotomy-myectomy. In addition, some patients are not ideal surgical candidates, either due to advanced age, insufficient personal motivation, or a limiting medical disability unrelated to HCM. Therefore it is a reasonable aspiration to develop and pursue alternatives to operation for this small but important subgroup of patients. However, proper patient selection for such procedures is a paramount consideration.

Over the past several years there has been some interest in the application of permanent dual-chamber pacing, as an alternative to operative intervention, for severely symptomatic patients with obstructive HCM who are refractory to drug therapy.[192-194] Observational and uncontrolled studies have reported pacing to be associated with reduction in outflow gradient and amelioration of symptoms in many patients over relatively short time periods.[172-174] However, this reported symptomatic benefit has not been consistently accompanied by improved exercise tolerance documented by objective parameters (e.g., treadmill exercise duration and measured oxygen consumption). Randomized, double-blind, crossover pacing studies have shown that the subjectively perceived symptomatic improvement reported by patients is largely due to a placebo effect.[195-197] In addition, the effect of pacing on outflow gradient and symptoms is variable and reduction in obstruction is often much more modest than that achieved with surgery.[196,198] Other laboratory catheterization studies report dual-chamber pacing to have deleterious effects on left ventricular systolic and diastolic function.[199-201] For these reasons and because the underlying HCM disease process and the risk for sudden death do not appear to be altered by permanent dual-chamber pacing, this potential treatment modality cannot be regarded as a primary treatment for the diverse clinical and functional spectrum of HCM.[196] However, there may well be a therapeutic role for certain subsets of patients with this disease.[196,201] In one randomized study, those patients ≥65 years old showed the most convincing benefit from pacing.[196]

Alcohol Septal Ablation

A second, recently introduced potential alternative to surgery is alcohol septal ablation, in which about 2 mL of alcohol is injected directly into the first septal perforator coronary artery for the purpose of producing an MI, septal thinning, and reduced mitral valve systolic anterior motion.[202-205] This procedure is intended to mimic the morphologic and functional consequences of ventricular septal myotomy-myectomy. At present the septal ablation technique is associated with a risk similar to that of surgery but is capable of producing a substantial reduction in the basal gradient. As yet, there is little objective substantiation for the improvement in symptoms reported by many patients over short-term follow-up. This is of particular importance in assessing symptomatic and functional changes for a disease in which pathophysiology is complex and symptoms are variable, often difficult to assess by history, and subject to a placebo effect.[196] As is the case with pacing, alcohol ablation should not be regarded as a primary treatment for the

disease or one capable of reducing the risk of sudden death. Indeed, there is concern[206,207] that this intervention could paradoxically increase the future long-term risk for life-threatening ventricular tachyarrhythmias and sudden death-a risk directly attributable to the intramyocardial scar produced by alcohol ablation (which is not present following myotomy-myectomy) in a patient population that already harbors an arrhythmogenic substrate and often a particularly long period of risk.

Chapter 67: HYPERTROPHIC CARDIOMYOPATHY

List of Figures

Figure 67-6: Variability of patterns of left ventricular hypertrophy in patients with hypertrophic cardiomyopathy, shown in a composite of diastolic stop-frame images in the parasternal short-axis plane. *A, B,* and *D.* Wall thickening is diffuse, involving substantial portions of ventricular septum and free wall. At the papillary muscle level (*A*), all segments of the left ventricular wall are hypertrophied, including the posterior free wall (PW), but the pattern of thickening is asymmetric, with the anterior portion of ventricular septum (VS) massive (i.e., 50 mm). *B.* Hypertrophy is diffuse, involving three segments of the left ventricle but with the posterior wall spared and thin (<10 mm) (*arrowheads*) and with particularly abrupt changes in wall thickness evident (*arrows*). *C.* Marked hypertrophy in a pattern distinctly different from that in *A, B,* and *D,* in which the thickening of the posterior wall is predominant and the ventricular septum is of nearly normal thickness. *D.* Diffuse distribution of hypertrophy involving three segments of the left ventricle similar to that in *B* but without sharp changes in the contour of the wall. *E.* Hypertrophy predominantly of lateral free wall (*arrows*) and only a small portion of the contiguous anterior septum (*arrowheads*). *F.* Hypertrophy predominantly of posterior ventricular septum (PVS) and, to a lesser extent, the contiguous portion of the anterior septum. *G.* Thickening of anterior and posterior septum to a similar degree but with sparing of the free wall. Calibration dots are 1 cm apart. AML = anterior mitral leaflet; LVW = lateral free wall; PML = posterior mitral leaflet. (From Klues HG et al.[18] with permission from the authors and publisher.)

Figure 67-7: Criteria used to distinguish HCM from athlete's heart when left ventricular (LV) wall thickness is within the shaded gray zone of overlap, consistent with both diagnoses. *Assumed to be the nonobstructive form, since substantial mitral valve systolic anterior motion would confirm, per se, the diagnosis of HCM in an athlete. †May involve a variety of abnormalities, including heterogeneous distribution of LV hypertrophy in which adjacent regions may be of greatly different thicknesses, with sharp transitions evident between segments; also, asymmetric patterns in which anterior ventricular septum is spared from the hypertrophic process and the region of predominant thickening may be in the posterior septum or anterolateral or posterior free wall. ↓ = decreased; LA = left atrial. (From Maron BJ et al.[52] with permission from the authors and Williams & Wilkins.)

Figure 67-8: Development and progression of left ventricular hypertrophy in children with HCM. *Upper panel:* Development of marked hypertrophy of the anterior basal ventricular septum (VS). M-mode echocardiograms shown here were obtained at the same cross-sectional level in a girl with a family history of HCM. At age 11, ventricular septal thickness was at upper limit of normal (10 mm); at age 15, septal thickness had increased markedly (to 33 mm), and appearance of the echocardiogram is typical of HCM. The patient remained asymptomatic throughout this period of time but died suddenly and unexpectedly at age 17. PW = posterior left ventricular free wall. *Lower panel:* Dynamic, striking changes in left ventricular wall thickness with age in 22 children; each patient is represented by the left ventricular segment that showed the greatest change in wall thickness. Open symbols denote 5 patients who had no evidence of hypertrophy in any segment of the left ventricle at the initial evaluation but subsequently developed de novo hypertrophy typical of HCM. (From Maron BJ et al.[35] with permission of the authors and the Massachusetts Medical Society.)

Figure 67-9: Mitral valves from three patients with obstructive HCM, aged 31, 29, and 60 years (I, II, and III), and from a normal control patient without cardiovascular disease (IV), showing variation in valvular size and structure present in HCM. Valves are opened with the circumference displayed in a horizontal orientation, exposing the atrial surface, with annular margin to top and chordal attachments to bottom. *I.* Large valve (area 22 cm2) in which both the anterior (A) and posterior (P) leaflets are greatly elongated and increased in area. *II.* Large valve in which increased valve size (area 18 cm2) is due primarily to elongation and enlargement of the anterior leaflet (A). *III.* Segmental elongation and increased area confined to a scallop of posterior leaflet. (From Klues HG et al.[20] with permission of the authors and Lippincott Williams & Wilkins.)

Figure 67-10: Anomalous papillary muscle insertion directly into anterior mitral leaflet (*AML*) in patient with obstructive HCM. *A. Before myotomy-myectomy:* parasternal long-axis echocardiogram shows AML in direct continuity with the hypertrophied anomalous anterolateral papillary muscle (*APM*), which displaced anteriorly within the left ventricular cavity, producing a long area of midcavity muscular contact with the ventricular septum (VS) and outflow obstruction (*arrows*); tips of the mitral leaflets coapt in the usual position, and typical systolic anterior motion is absent (*small arrows*). *B. After myotomy-myectomy:* Long-axis echocardiogram shows extensive muscular resection (*), extending from base of the septum to beyond the distal margins of the anterior mitral leaflet; nevertheless, a large area of direct muscular contact remains after operation between papillary muscle and ventricular septum (*arrowheads*), which is responsible for persistent and marked obstruction to left ventricular outflow. *C.* Mitral valve specimen excised at operation; a massively hypertrophied anterolateral anomalous papillary muscle (*arrow*) inserted directly into the body of the anterior leaflet. Ao = aorta; LA = left atrial; LV = left ventricle. (From Klues HG et al.[19] with permission of the authors and Lippincott Williams & Wilkins.)

Figure 67-11: Pedigree of HCM family with a myosin-binding protein C mutation and variable penetrance. The genetically affected 42-year-old woman (II.2) is both the offspring of an affected parent (I.2), the mother of a 16-year-old affected child (III.4), and the sister of an affected 40-year-old sibling (II.3). In contrast to her father, child, and sister, this woman (II.2) showed no evidence of left ventricular hypertrophy and the HCM phenotype by two-dimensional echocardiography (or 12-lead ECG).

Figure 67-12: Age-related penetrance of familial HCM caused by mutations in the genes for cardiac myosin-binding protein C, cardiac troponin T, and cardiac β-myosin heavy chain. Solid bars denote the percentage of persons with both cardiac myosin-binding protein C mutations and left ventricular hypertrophy. Comparable clinical data for cardiac troponin T and β-myosin heavy chain are shown. Significant differences in the penetrance of familial HCM caused by cardiac myosin-binding protein C mutations and by mutations in cardiac troponin T or cardiac β-myosin heavy chain are indicated as follows: * = $p < 0.05$; = $p < 0.005$; $fy2$æ = $p < 0.001$. (From Niimura H et al. [10] with permission of the authors and the Massachusetts Medical Society.)

Figure 67-13: Causes of sudden cardiac death in young competitive athletes (median age, 17), based on systematic tracking of 158 athletes in the United States, 1985 to 1995. In an additional 2 percent, no evidence of cardiovascular disease sufficient to explain death was found at necropsy; ↔(increased) cardiac mass = hearts with increased weight and some morphologic features consistent with (but not diagnostic of) HCM. Ao = aorta; LAD = left anterior descending coronary artery; AS = aortic stenosis; C-M = cardiomyopathy; ARVD = arrhythmogenic right ventricular dysplasia; MVP = mitral valve prolapse; CAD = coronary artery disease; HCM = hypertrophic cardiomyopathy. (Adapted from Maron BJ et al.[86] with permission of Lippincott Williams & Wilkins.)

Figure 67-14: Assessment of risk for sudden cardiac death in HCM population. Treatment for the prevention for sudden death is limited to that small subset perceived to be at highest risk compared to all other patients with HCM, based on the presence of ≥1 of the risk factors shown. Patients regarded as low risk are asymptomatic with mild left ventricular hypertrophy and *without* either ventricular tachycardia on ambulatory Holter ECG, hypotensive blood pressure response to exercise, and family history of premature HCM-related death, ICD = implantable cardioverter-defibrillator; LVH = left ventricular hypertrophy; NSVT = nonsustained ventricular tachycardia; SD = sudden death; VT = ventricular tachycardia. (From Maron,1 with permission of the author and *Lancet*.)

Figure 67-15: Studies in patients with HCM and normal extramural coronary arteries showing changes occurring in association with progressive congestive cardiac failure and transmural myocardial infarction (end-stage phase). *A.* Echocardiographic study from a 26-year-old patient with exertional chest pain and dyspnea. Ventricular septum (VS) is markedly thickened (23 min) and pattern of hypertrophy is asymmetric. Left ventricular end-diastolic dimesion is reduced (38 min), and there is a trivial degree of mitral systolic anterior motion (*arrow*). PW = posterior wall; RV = right ventricular. *B.* From same patient at 30 years of age (9 months before death) after clinical deterioration with progressive cardiac failure, pulmonary edema associated with chronic atrial fibrillation, and cardiopulmonary collapse. Appearance of left ventricular has changed dramatically. Septum has thinned considerably (to 13 mm) and is about as thick as the posterior wall; left ventricular (LV) and right ventricular cavities have enlarged substantially. MV = mitral valve. *C.* Low-power photomicrograph of a specimen from a patient with a clinical course similar to that of the patient in *A* and *B* showing transmural scarring of the septum and numerous abnormal intramural coronary arteries, some with thickened walls and narrowed lumen (*arrows*) (Magnification ×6). (From Maron BJ et al.3 with permission of the authors and the Massachusetts Medical Society.)

Figure 67-16: Therapeutic strategies for patients with HCM. Question marks indicate treatment recommendations that are largely unresolved.

Figure 67-17: Illustration of ventricular septal myotomy-myectomy operation (Morrow procedure). *A.* Two vertical, parallel myotomies are made in the cephalad portion of the septum about 1 cm apart. Transverse incision is then made, connecting the two parallel myotomies. *B.* Attachments of the muscle bar to the septum are divided; this segment of muscle is isolated and then excised. *C.* After completion of the myotomy-myectomy, a rectangular channel about 4 cm long and 2 cm wide is evident extending from the aortic annulus to a point just distal to the caudal margins of the mitral leaflets. Chapter 68:

RESTRICTIVE, OBLITERATIVE, AND INFILTRATIVE CARDIOMYOPATHIES

Author: Brian D. Hoit

RESTRICTIVE CARDIOMYOPATHY

Definition of Restrictive Cardiomyopathy

The World Health Organization (WHO) and World Heart Foundation define cardiomyopathies as heart muscle diseases of unknown etiology and classify them according to hemodynamic and pathophysiologic criteria.[1] Although this definition differentiates primary cardiomyopathies from other pathologic processes that disturb myocardial function-such as ischemic, hypertensive, valvular, and congenital heart diseases-the WHO classification, despite recent modifications, remains controversial. The clinicopathologic classification scheme initially proposed by Goodwin is similar and includes dilated or congestive, hypertrophic, and restrictive forms.[2] *Restrictive cardiomyopathy* refers to either an idiopathic or systemic myocardial disorder characterized by restrictive filling, normal or reduced left ventricular (LV) and right ventricular (RV) volumes, and normal or nearly normal systolic (LV and RV) function. Thus, the clinical and hemodynamic picture thus simulates constrictive pericarditis and is characterized by elevated venous pressure with prominent X and Y descents, a small or normal sized LV, and pulmonary congestion. Restrictive cardiomyopathy may be noninfiltrative or infiltrative and occurs with or without obliteration; infiltration may be interstitial (e.g., amyloid, sarcoid) or cellular (e.g., hemochromatosis).

Restrictive cardiomyopathy has assumed importance in clinical cardiology for several reasons. First, these myocardial disorders epitomize diastolic heart failure; thus, abnormal ventricular diastolic compliance and impaired ventricular filling constitute their central pathophysiologic components and congestion and elevated diastolic pressure are their major clinical and hemodynamic manifestations. Second, the hemodynamic and clinical manifestations may mimic those produced by constrictive pericarditis, which, in contrast to restrictive cardiomyopathy, is a surgically curable disorder. Accordingly, its lack of recognition may have dire consequences. Third, restrictive cardiomyopathy may present with interventricular conduction delays, heart block, or skeletal muscle disease, often making the diagnosis difficult. Fourth, diagnostic criteria for restriction are not universally accepted, and the morphologic spectrum overlaps with hypertrophic cardiomyopathy challenges our traditional concepts of classification.[3] Finally, a comprehensive echo Doppler assessment has become an important, noninvasive means of detecting the pathophysiology, morphology, and prognosis of the restrictive cardiomyopathies.[4,5]

Clinical Features of Restrictive Cardiomyopathy

Involvement of the myocardium (or endomyocardium), and ventricular obliteration, may occur either in isolation or in the setting of systemic or iatrogenic disease (Table 68-1). Thus, in the strictest sense, restrictive cardiomyopathy is not necessarily a primary disease of heart muscle. Irrespective of the etiology, terminology, or the nature of myocardial process, the ventricles are small (generally <110 mL/m^2), and stiff, restricting ventricular filling. Despite normal (or near normal) systolic function, ventricular diastolic, jugular, and pulmonary venous pressures are

increased. Typically, LV filling pressures exceed RV filling pressures by more than 5 mmHg, but equalization of the diastolic pressures and a "square root" dip and plateau of early diastolic pressures of the RV and LV may be seen if the compliances of these chambers are similarly affected. Importantly, the hemodynamics of constrictive pericarditis may be simulated. Moreover, elevated atrial pressures produce symptoms of systemic and pulmonary venous congestion (dyspnea, orthopnea, edema, abdominal discomfort), and relatively underfilled ventricles are responsible for reduced cardiac output and fatigue. In patients with restrictive cardiomyopathy as part of a systemic disorder, cardiac symptoms may dominate or overshadow symptoms referable to other organ systems. Patients with constrictive cardiomyopathy generally have lower RV systolic pressures (<40 mmHg) and an RV end-diastolic pressure greater than one-third of the pressure RV systolic pressure as opposed to patients with restrictive cardiomyopathy but these differences are far from absolute.

Table 68-1: Classification of the Restrictive Cardiomyopathies

Myocardial

1. Noninfiltrative cardiomyopathies
   - Idiopathic
   - Familial
   - Pseudoxanthoma elasticum
   - Scleroderma
2. Infiltrative cardiomyopathies
   - Amyloidosis
   - Sarcoidosis
   - Gaucher's disease
3. Storage disease
   - Hemochromatosis
   - Fabry's disease
   - Glycogen storage diseases

Endomyocardial

1. Obliterative
   - Endomyocardial fibrosis
   - Hypereosinophilic syndrome
2. Nonobliterative
   - Carcinoid
   - Malignant infiltration
   - Iatrogenic (radiation, drugs)

Physical Findings

Physical examination reflects the elevated systemic and pulmonary venous pressure. Striking elevation of the jugular venous pulse and prominent X and especially Y descents are characteristic (see Chap. 10). A *diastolic* arterial pulse, owing to a reduced stroke volume and tachycardia, may be seen in severe cases. The apical impulse is not displaced and systolic murmurs of atrioventricular regurgitation and filling sounds marking the abrupt cessation of rapid early diastolic filling may be present.

Diagnostic/Imaging Studies

Electrocardiographic (ECG) abnormalities such as abnormal voltage, atrial and ventricular arrhythmias, and conduction disturbances are frequent; when restrictive cardiomyopathy is due to amyloid infiltration, low voltage is usual (Fig. 68-1). The chest radiograph usually reveals normal-sized ventricles, although atrial enlargement and pericardial effusion may produce an enlarged cardiac silhouette. Pleural effusions and signs of pulmonary congestion may also be present. Echocardiographic findings are nonspecific but in many cases are useful to exculpate other, more common causes of heart failure.

DIFFERENTIATION FROM CONSTRICTIVE PERICARDITIS

Although several clinical, imaging, and hemodynamic features are helpful in distinguishing restrictive cardiomyopathy from constrictive pericarditis (Table 68-2), considerable overlap and diagnostic confusion exist. The pathophysiologic basis for this distinction includes (1) transmission of intrathoracic pressure to the ventricles (limited by the stiff pericardium in constrictive pericarditis but not in restrictive cardiomyopathy); (2) the principal determinant of the diastolic ventricular pressure-volume relation (ventricular versus pericardial compliance in restrictive cardiomyopathy as compared to constrictive pericarditis, itself); and (3) involvement of the ventricular septum in restrictive cardiomyopathy versus the capacity for ventricular interdependence in constrictive pericarditis.

Table 68-2: Clinical and Hemodynamic Features That Help Distinguish Restrictive Cardiomyopathy from Constrictive Pericarditis

	Restrictive Cardiomyopathy	Constrictive Pericarditis
History	Systemic disease that involves the myocardium, multiple myeloma, amyloidosis, cardiac transplant	Acute pericarditis, cardiac surgery, radiation therapy, chest trauma, systemic disease involving the pericardium
Chest radiograph	Absence of calcification Massive atrial enlargement	Helpful when calcification persistsModerate atrial enlargement
Electrocardiogram	Bundle branch blocks, AV block	Abnormal repolarization
CT/MRI	Normal pericardium	Helpful if thickened (>4 mm) pericardium
Hemodynamics	Helpful if unequal diastolic pressures	Diastolic equilibration
	Concordant effect of respiration on diastolic pressures	Dip and plateau
Biopsy	Fibrosis, hypertrophy, infiltration	Normal

Recently, Doppler techniques (spectral Doppler, color M-mode, and Doppler tissue imaging) have assumed an important role in characterizing the nature of transvalvular filling and in clinically distinguishing between constrictive pericarditis and restrictive cardiomyopathy (see also Chap. 13).[5-7] These Doppler flow patterns and the associated respiratory changes are illustrated in Fig. 68-2. In the *normal subject,* the early filling wave (E) of mitral flow is greater than the late, atrial systolic wave (A), and neither change significantly with respiration. In contrast, the E and A

velocities of tricuspid valve flow increase slightly with inspiration. The deceleration time of the LV early diastolic wave ranges from 150 to 240 ms, and the LV isovolumic relaxation time ranges from 70 to 110 ms. Pulmonary venous flow is generally biphasic, with a dominant wave during systole (S) and a smaller wave during diastole (D); respiratory changes are minimal and atrial systolic reversals are generally small. Hepatic vein flow consists of a larger S and smaller D wave with small reversals (V_r and A_r) after each wave, respectively. With expiration, S and D waves decrease and V_r and A_r increase. Doppler tissue imaging (DTI) shows a prominent longitudinal axis velocity in early diastole (E_a >8 cm/s) and a smaller velocity after atrial contraction (A_a). The slope of early diastolic LV filling on color M-mode (Vp) is >45 cm/s. In the patient with *restrictive cardiomyopathy*, mitral valve flow shows an increased E/A ratio (≥2) with a short (<150 ms) deceleration time and a short (<70 ms) isovolumic relaxation time (a "restrictive" pattern of filling) without respiratory variation. The tricuspid valve flow shows an increased E/A ratio without respiratory variation, a shortened deceleration time, and a short isovolumic relaxation time that shortens further with inspiration. The S/D ratio of pulmonary venous flow is <1, atrial reversals are increased (not shown in Fig. 68-1), and there is little respiratory variation. The S/D ratio of hepatic venous flow is <1 and prominent reversals are seen during inspiration. Doppler tissue imaging shows a striking decrease in E_a (<8 cm/s) and the propagation velocity on color M-mode is <45 cm/s.

In *constrictive pericarditis*, mitral and tricuspid valve flows are also "restrictive," but unlike those in restrictive cardiomyopathy, they display marked respiratory variation. The isovolumic relaxation time shortens during expiration. The S/D of pulmonary venous flow is <1, with increased velocities (especially diastolic) in expiration, resulting in a further decrease in the S/D ratio. In contrast to restrictive cardiomyopathy, hepatic venous flow reversals occur in expiration, early diastolic tissue velocities (E_a) are normal on DTI, and the transmitral propagation velocity is >45 cm/s.

Despite the considerable interest and potential clinical value in the ability to discriminate restrictive cardiomyopathy from constrictive pericarditis, there is no uniform agreement regarding the characteristic features of the Doppler indices, especially those of venous flows. Moreover, rigorous studies of the sensitivity and specificity of these Doppler findings are lacking and relatively few patients have been examined. Thus, the diagnostic certainty is related to the number of "pathognomonic" findings in concert with clinical information and additional imaging studies.

One report suggested that radionuclide ventriculographic indices of LV diastolic function could differentiate constrictive pericarditis and restrictive cardiomyopathy.[8] However, measurements of LV filling-such as the peak filling rate, time to peak filling, and various filling fractions-require careful attention to technical detail. The need for stable heart rates, the lack of venous flows, and the inability to observe the influence of respiration on cardiac blood flows are important limitations of the radionuclide ventriculographic technique.

Magnetic resonance imaging (MRI) and computed tomography (CT) are useful for accurately assessing pericardial thickness (Fig. 68-3); a pericardium >4.0 mm thick can distinguish the two entities (see also Chap. 18A).[9] Recent preliminary data suggest that constrictive pericarditis is associated with severe autonomic dysfunction that involves all segments of the autonomic nervous system, whereas in restrictive cardiomyopathy the autonomic dysfunction is localized to the parasympathetic efferent pathway.[10] Invasive hemodynamics may be helpful (below), and occasionally a histologic diagnosis is necessary.

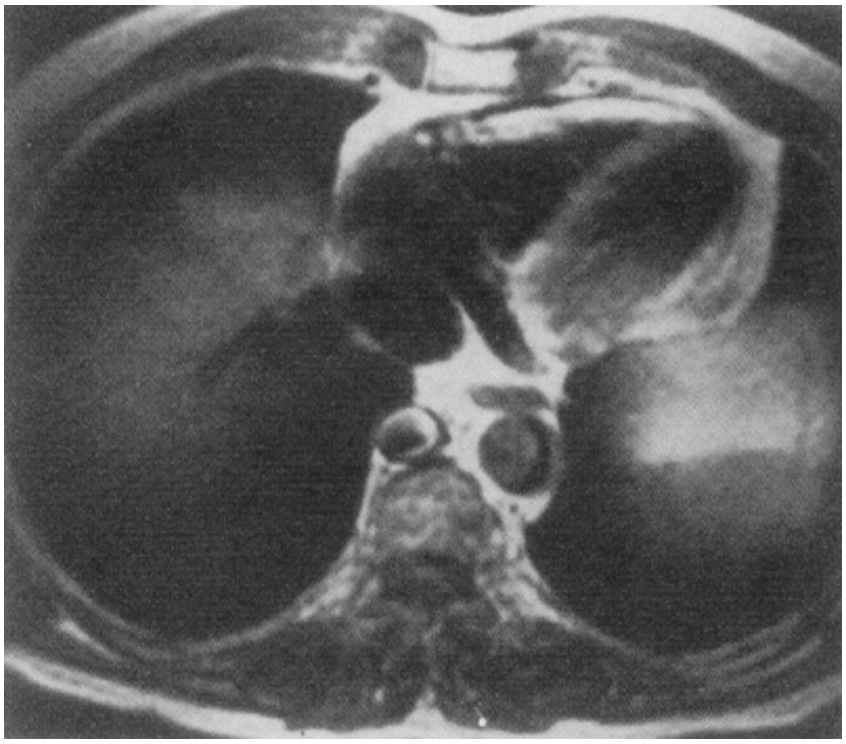

Figure 68-3: Magnetic resonance image showing normal pericardium as a low-intensity (*black*) line anterior to the right ventricle between high-intensity (*white*) epicardial and mediastinal fat. (From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:588. Reproduced with permission.)

It is important to remember that clinical and laboratory testing, including imaging and pathologic studies, may produce results consistent with mixed constrictive pericarditis and restrictive cardiomyopathy; indeed, the two entities may coexist [for example, after mediastinal irradiation or after coronary artery bypass grafting (CABG)]. In these cases, a decision to treat conservatively or surgically explore a patient requires experienced clinical judgment.

Cardiac Catheterization

Most patients in whom restrictive cardiomyopathy is a serious consideration should undergo right- and left-sided heart catheterization to document the diagnosis, assess severity, and, in some patients, establish the etiology by means of endomyocardial biopsy. As in patients with constrictive pericarditis, extra care must be taken to obtain high-quality pressure recordings with appropriate gain and optimal damping conditions, and to attend to details such as the transducer height and system calibration. The venous pressure is elevated and the deep and rapid fall of the right atrial Y descent is striking. During inspiration, the descent of the V wave in the right atrium becomes deeper, steeper, and more pointed, whereas the other waves of the venous pulse and the mean atrial pressure do not vary throughout the respiratory cycle.[11] The RV systolic pressure is often within the range of 35 to 45 mmHg, and the early portion of diastole is characterized by a deep, sharp dip followed by a plateau, during which no further increase in RV pressure occurs (Fig. 68-4). These hemo dynamic features are identical to those of constrictive pericarditis and may cause diagnostic confusion. There is usually only modest pulmonary hypertension and the pulmonary arterial diastolic pressure is a few millimeters higher than the pulmonary wedge pressure, which is often quite elevated. It is not uncommon for the pulmonary wedge and the right atrial pressures to be identical and to simulate further the hemodynamics of constrictive pericarditis; however, a higher LV than RV filling pressure strongly favors the diagnosis of restrictive cardiomyopathy rather than constrictive pericarditis. LV systolic pressure is normal, while the LV diastolic pressure tracing shows the same abnormalities as those of the RV (Fig. 68-

4).

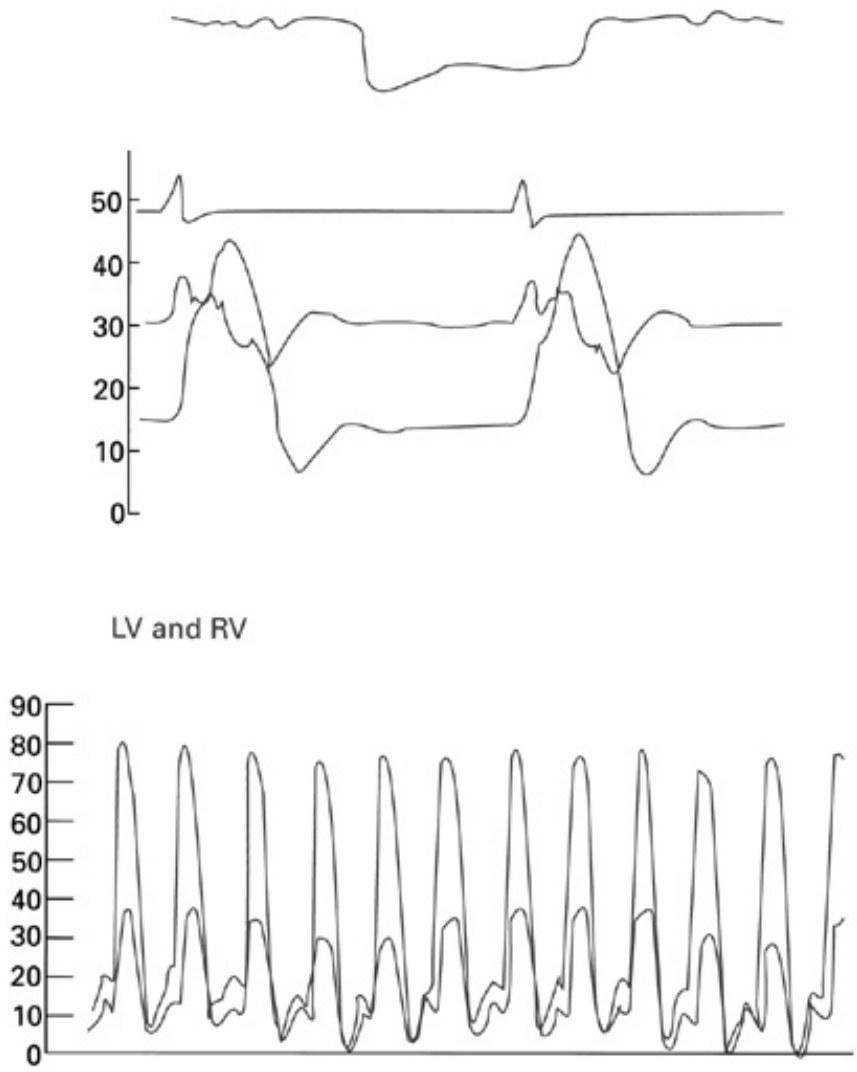

Figure 68-4: *Top:* Right-sided heart hemodynamic data from a patient with amyloidosis recorded with a high-fidelity catheter. From the top tracing down is a respirometer, electrocardiogram, right ventricular (RV) dP/dt, and RV pressure. Note the characteristic dip-and-plateau configuration. *Bottom:* Simultaneous RV and LV pressure tracings from another patient with cardiac amyloidosis. In this patient, the typical dip-and-plateau pattern was not present, but during inspiration LV and RV diastolic pressures equilibrated. (From Shabetai R. Restrictive, obliterative, and infiltrative cardiomyopathies. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart*, 9th ed. New York: McGraw-Hill; 1998:2079. Reproduced with permission.)

Left ventriculography usually shows a normal ejection fraction and the absence of major regional wall motion abnormalities. Endomyocardial biopsy is an integral part of the workup of many patients with restrictive cardiomyopathy. When distinction from constrictive pericarditis is particularly difficult, the biopsy may furnish proof of myocardial disease and establish the cause of restrictive cardiomyopathy (e.g., amyloidosis), or (by virtue of unremarkable histology) suggest the need for surgical exploration, even in the absence of a thickened pericardium.

Treatment of Restrictive Cardiomyopathy (General Considerations)

Except in certain instances described below ("Specific Restrictive Cardiomyopathic Diseases"),

the treatment of restrictive cardiomyopathy is empiric and directed toward the treatment of diastolic heart failure. Reduction in the elevated ventricular diastolic pressures produces substantial improvement in pulmonary and systemic congestion, but judicious use of diuretics is warranted in view of the steep pressure-volume relation of the ventricles and the need to maintain a relatively high filling pressure. Vasodilators may also jeopardize ventricular filling and should be used cautiously. Calcium channel blockers are used by some because of their beneficial effect in hypertrophic cardiomyopathies, but improvement in ventricular compliance with their use has not been demonstrated in restrictive cardiomyopathy.

Chapter 68: RESTRICTIVE, OBLITERATIVE, AND INFILTRATIVE CARDIOMYOPATHIES

SPECIFIC RESTRICTIVE CARDIOMYOPATHIC DISEASES

A useful classification of the restrictive cardiopathies is shown in Table 68-1. This scheme is based upon the cardiac compartment predominantly involved (i.e., myocardial versus endomyocardial) and subdivides the myocardial diseases into the noninfiltrative, infiltrative, and storage and the endomyocardial diseases into obliterative (i.e., endomyocardial fibrosis and the hypereosinophilic syndrome), carcinoid, infiltrative, and iatrogenic.

Myocardial Diseases

NONINFILTRATIVE CARDIOMYOPATHIES

Idiopathic and Familial Restrictive Cardiomyopathy

Recent data suggest that idiopathic restrictive cardiomyopathy may be an autosomal dominant disorder involving myocardium, conduction tissue, and skeletal muscle, with resultant restrictive ventricular filling and heart failure, AV block, and distal skeletal myopathy. Deposition of the intermediate filament desmin has been linked to this syndrome and may represent a distinct pathologic entity; accumulation of desmin immunoreactive material on heart biopsy may be confirmed ultrastructurally.[12,13] Changes in collagen subtypes and matrix metalloproteinase activity may play an important role in the genesis of increased LV stiffness.[14]

Myocyte hypertrophy and fibrosis on endomyocardial biopsy characterize idiopathic restrictive cardiomyopathy, and the absence of myocyte disarray is an important pathologic distinction from hypertrophic cardiomyopathy. However, overlap syndromes characterized by physiologic evidence of restriction and myocyte hypertrophy but without myocyte disarray or LV hypertrophy on echocardiography are reported.[15] Moreover, it was recently postulated that primary restrictive and hypertrophic cardiomyopathies may represent different phenotypic expressions of the same genetic disease.[16] An echocardiographic feature distinguishing primary restrictive cardiomyopathy from cardiac amyloidosis (in addition to the associated clinical features) is the increased LV wall thickness in the latter. In both disorders (and restrictive cardiomyopathies in general), ventricular dimensions are normal or reduced, systolic function is variable, and atrial dimensions are increased.

Two-dimensional and Doppler echocardiography are reliable, noninvasive techniques for diagnosing primary restrictive cardiomyopathy (see Chap. 13).[17] A dominant mitral early diastolic "E" velocity, an increased pulmonary venous atrial systolic "A" reversal velocity and duration, and shortened mitral deceleration time are present in both children and adults with primary restrictive cardiomyopathy (Fig. 68-5). On CT or MRI scans, evidence of restrictive filling (e.g., right atrial and caval enlargement) are common in both restrictive cardiomyopathy and constrictive pericarditis. MRI may differentiate primary restrictive cardiomyopathy from amyloidosis on the basis of tissue characterization.[18]

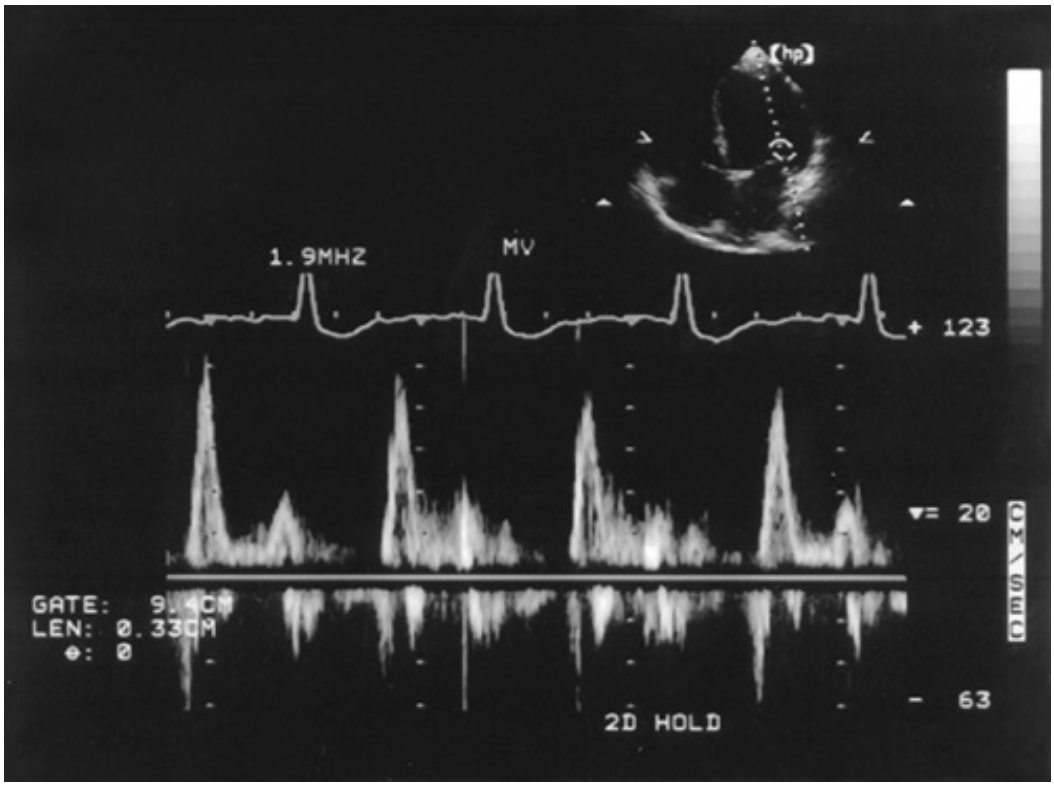

Figure 68-5: Doppler record of mitral inflow velocity from a patient with idiopathic restrictive cardiomyopathy. Note the dominant early diastolic wave. (From Shabetai R. Restrictive, obliterative, and infiltrative cardiomyopathies. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart*, 9th ed. New York: McGraw-Hill; 1998:2077. Reproduced with permission.)

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is a rare, genetically heterogeneous disorder characterized by fragmentation and calcification of elastic fibers involving the skin, eyes, and gastrointestinal and cardiovascular systems. Although endocardial fibroelastosis uncommonly causes restrictive cardiomyopathy (Fig. 68-6), coronary artery disease with premature death is a major problem in these patients.[19]

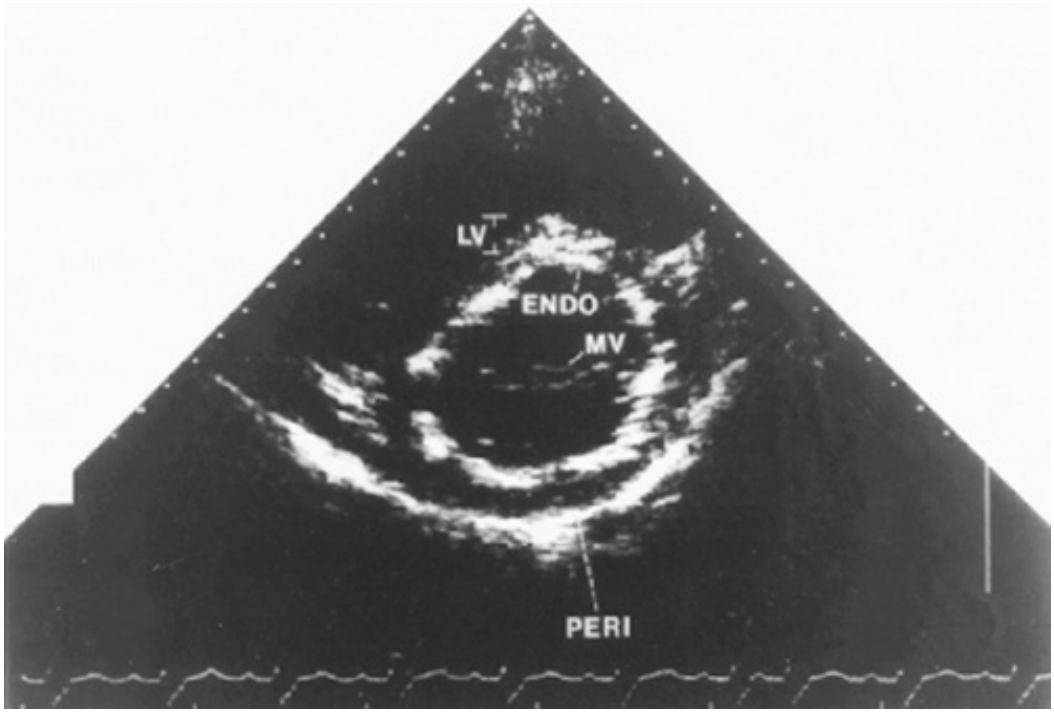

Figure 68-6: Short-axis view of the left ventricle (LV) at the mitral valve (MV) level in a patient with pseudoxanthoma elasticum. Note the calcified endomyocardium (ENDO) and echodense pericardium (PERI). The endocardial calcification was clearly visible by fluoroscopy. (From Shabetai R. Restrictive, obliterative, and infiltrative cardiomyopathies. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart*, 9th ed. New York: McGraw-Hill; 1998:2085. Reproduced with permission.)

Progressive Systmic Sclerosis

Myocardial fibrosis, which may have a patchy distribution and be present in both ventricles, is found in the majority of patients with scleroderma at autopsy. On echocardiography, LV wall thickening in the absence of hypertension and evidence of LV dysfunction may be seen, but heart failure due to either restrictive or dilated cardiomyopathy is rare.[20] Pericardial involvement and electrocardiographic abnormalites (heart block, supraventricular and ventricular tachycardia, and pseudoinfarction patterns) are common. Pulmonary hypertension is a leading cause of morbidity and mortality in patients with scleroderma.

INFILTRATIVE CARDIOMYOPATHIES

Amyloidosis

Amyloidosis is a systemic disorder characterized by interstitial deposition of linear, rigid, nonbranching amyloid protein fibrils in multiple organs (e.g., heart, kidney, liver, nerve). Although there are several types of amyloidosis, cardiac involvement is most common in primary amyloidosis (AL type), which is caused by plasma cell production of immunoglobulin light chains; the latter occurs often in association with multiple myeloma. Multiple myeloma is also reported to cause diastolic heart failure in the absence of amyloidosis.[18,21] Cardiac deposition of amyloid protein (protein A, a nonimmunoglobin) mayalso occur in secondary amyloidosis due to chronic inflammation (such as tuberculosis or rheumatoid arthritis). Amyloidois may also be familial and is commonly present (especially at postmortem examination) in the elderly as senile amyloidosis.

Mutations of the protein transthyretin (formerly prealbumin) are usually inherited as an autosomal

dominant trait and produce peripheral and autonomic neuropathy in addition to cardiac disease; over 50 mutations have been described.[22] Cardiac involvement occurs late in the disease and, although present in less than one-third of cases, it is responsible for over half of the deaths.[23] A transthyretin mutation at isoleucine 122 was recently reported as a cause of late-onset cardiac amyloidosis in African Americans.[24]

CLINICAL FEATURES

Amyloid deposits may be interstitial and widespread, resulting in restrictive cardiomyopathy, or localized to (1) conduction tissue, resulting in heart block and ventricular arrhythmias (especially familial amyloid); (2) the cardiac valves, causing valvular regurgitation; (3) the pericardium, producing constriction; and (4) the coronary arteries, resulting in ischemia. Amyloid may be isolated to the subendocardium in senile amyloid and amyloid secondary to chronic disease. Deposition of amyloid and atrial natriuretic factor (ANF) in the atria is frequent in aged hearts.[25] Despite sinus rhythm, atrial mechanical failure and thrombus formation may result due to electromechanical dissociation.[26] Atrial and brain natriuretic peptide are expressed in ventricular myocytes in patients with cardiac amyloidosis.[27] In some cases, the clinical picture is dominated by autonomic neuropathy (orthostatic hypotension, syncope, diarrhea, lack of sweating, and impotence) and nephropathy and cardiac involvement are unrecognized. Cardiac manifestations define a spectrum, often progressive through stages of severity, from the asymptomatic to biventricular failure.

DIAGNOSTIC/IMAGING STUDIES

The cardiac silhouette on the chest radiograph may be normal or moderately enlarged. The ECG typically shows decreased voltage, a pseudoinfarction pattern, left axis deviation; arrhythmias and conduction disturbances may predominate the clinical course.

The M-mode echocardiogram may reveal symmetrical wall thickness involving the right and left ventricles, a small or normal LV cavity, variable (but often depressed) systolic function, left atrial enlargement, and a small pericardial effusion (Fig. 68-7). Digitized M-mode tracings may reveal decreased rates of systolic wall thickening and diastolic wall thinning and increased isovolumic relaxation time,[28] especially in the early stages.

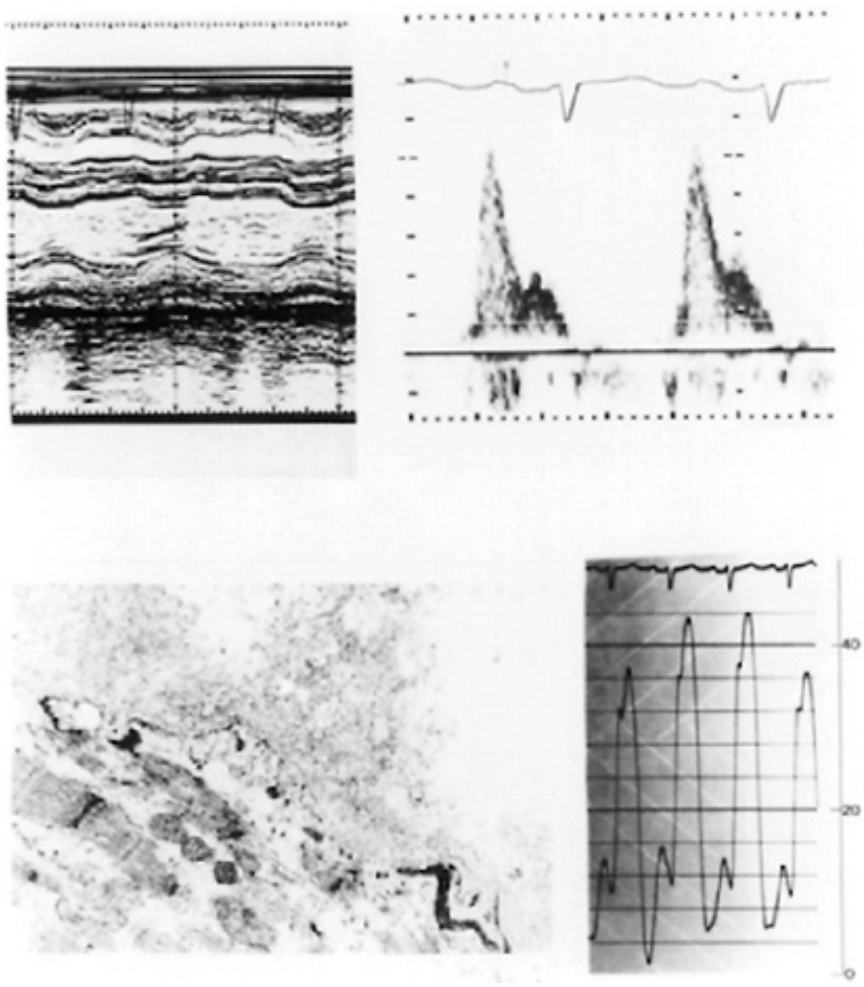

Figure 68-7: Amyloidosis. *Top left:* M-mode echocardiogram showing increased thickness of the left ventricular myocardium (calibration mark = 1 cm). *Top right:* Doppler tracing of mitral inflow velocity. Note that the atrial contribution to mitral blood flow velocity is markedly reduced (calibration mark = 20 cm/s). *Bottom left:* electromicrograph showing extensive replacement of myocardium by amyloid. *Bottom right:* Right ventricular pressure tracing. A diastolic dip-plateau pattern is absent because of tachycardia. (From Shabetai R. Restrictive, obliterative, and infiltrative cardiomyopathies. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart*, 9th ed. New York: McGraw-Hill; 1998:2083. Reproduced with permission.)

Two-dimensional echo findings include thickening of the ventricular myocardium, the interatrial septum and valves (especially the AV valves), enlarged papillary muscles, and dilated atria and inferior vena cava (Fig. 68-8). LV wall thickness is an important prognostic variable; in one study, patients with biopsy-proven amyloidosis having a mean wall thickness ≥15 mm had a median survival of 0.4 years, whereas patients with a mean wall thickness ≤12 mm had a median survival of 2.4 years.[29] Highly reflective echoes producing a granular or sparkling appearance and occurring in a patchy distribution are characteristic echocardiographic findings but are neither sensitive nor specific; concentric hypertrophy, as occurs in hypertension or aortic stenosis, may produce a uniformly speckled or echolucent appearance of the myocardium; and idiopathic hypertrophic cardiomyopathy may display a patchy, granular sparkling. Although they correlate with wall thickness, granular echoes may not be seen. Importantly, their recognition is subjective and is affected by ultrasound instrument settings. Thus, granular sparkling alone is an unreliable finding. The infiltrative pathology associated with amyloidosis may be detected by tissue characterization using MRI.[18] Amyloid cardiomyopathy may exist despite the absence of echocardiographic evidence of infiltration.[30]

Doppler studies may show the restrictive pattern of LV filling-i.e., a transmitral E/A ratio ≥2 without respiratory variation, transmitral diastolic deceleration time <150 ms, and an isovolumic relaxation time ≤70 ms (Fig. 68-7). The RV filling pattern is often abnormal. The systolic-to-diastolic pulmonary venous flow ratio is <1 and atrial reversals increase with inspiration in the pulmonary and hepatic veins. However, the *earliest sign* of amyloid cardiomyopathy is impaired LV relaxation, manifest by an E/A ratio <1, and increased isovolumic relaxation and transmitral diastolic deceleration times. The severity of combined systolic and diastolic abnormalities can be determined with an echo Doppler index using isovolumic contraction and relaxation and ejection times.[31] In addition, Doppler has shown utility in prognosis; a deceleration time <150 ms and an increased E/A transmitral ratio are strong predictors of cardiac death.[32]

Abnormalities of LV filling are also demonstrated with the LV time-activity curve from radionuclide ventriculography.[33] Moreover, radionuclide imaging using technetium-99m pyrophosphate or Indium-111 antimyosin may be useful in diagnosis. The variable clinical, diagnostic, and prognostic features reflect the location, nature, and extent of amyloid deposition and the temporal course of the disease. Serum and urine protein electrophoresis is diagnostic in most cases of primarily amyloidosis, but monoclonal protein is not secreted in 10 percent of cases.[23] Endomyocardial biopsy of the RV (most helpful if an abdominal fat aspirate is negative) provides the diagnosis, establishes the histochemistry, and quantifies myocardial damage and atrophy.[34]

TREATMENT OF AMYLOIDOSIS

The treatment of amyloidosis is unrewarding and symptomatic therapy is fraught with hazard; patients are sensitive to digoxin and calcium channel blockers, and hypotension with vasodilators and diuretics is a threat due to the steep LV pressure-volume relation. Immunosuppressive therapy with melphalan and prednisone is the established treatment regimen for primary (AL) amyloidosis. In a recent study, multiple alkylating agents failed to increase the response rate or survival time over this conventional regimen.[35] Orthotopic cardiac transplantation is generally not recommended because of the systemic nature of amyloidosis and the possibility of recurrence in the transplant, but successful cases have been reported.[36] Liver transplantation may be lifesaving in patients with familial amyloidosis,[37] since the liver is the site of transthyretin production.

Sarcoidosis

Sarcoidosis is a disorder of unknown etiology characterized by the presence of noncaseating granulomas that involve many organs (e.g., lung, skin, lymph nodes, liver, spleen). Granulomas involve the heart in sarcoidosis in as many as 25 percent of patients but are frequently subclinical.[38] Nevertheless, in approximately half of the fatalities, cardiac involvement is responsible.[39] Rarely, sarcoid is confined to the heart. The combination of extracardiac manifestations and cardiac abnormalities favors a presumptive diagnosis of sarcoidosis without biopsy.

Interstitial granulomatous inflammation initially produces diastolic dysfunction, but later, when the disease is more extensive, it may produce systolic (at times focal) abnormalities. Localized thinning and dilatation of the basilar LV resembling ischemic heart disease are characteristic. Restrictive cardiomyopathy is uncommon. However, sarcoid pulmonary involvement is frequent and produces echo and Doppler findings of pulmonary hypertension and right heart failure. High-grade AV block, due to involvement of the conduction system, and ventricular arrhythmias are the principal manifestations and may result in sudden cardiac death; syncope is common. The ECG commonly demonstrates T-wave and conduction abnormalities. Pseudoinfarct patterns may appear with extensive myocardial involvement.

Echocardiographic findings include evidence of systolic and diastolic LV dysfunction, LV aneurysm formation, abnormal ventricular wall thickness, pericardial effusion, regional wall motion abnormalities in the basal septum with apical sparing, and evidence of cor pulmonale. Thallium 201 and gallium 67 have been used to indicate areas of myocardial involvement and serve to predict the response to corticosteroids. MRI may detect mass lesions due to sarcoid granuloma or scar.[40] Endomyocardial biopsy is useful but may be falsely negative. An important entity in the differential diagnosis is giant-cell myocarditis, which is characterized by a more aggressive and fatal course than cardiac sarcoid.[41]

Treatment with prednisone is warranted in highly suspicious or proven cases because the cardiac granuloma may be sensitive. In patients at high risk for sudden cardiac death, an automatic implantable cardioverter defibrillator (AICD) may be appropriate,[42] and cardiac transplantation is an appropriate consideration in some cases.[43]

Gaucher's Disease

Gaucher's disease is due to an inherited deficiency of the enzyme β-glucocerebroside, which results in accumulation of cerebroside in the reticuloendothelial system, brain, and heart. Diffuse interstitial infiltration of the left ventricle occurs, with reduced LV wall compliance and cardiac output, but is often subclinical. LV and left-sided valvular thickening and pericardial effusion are seen on echo.[44]

STORAGE DISEASES

Hemochromatosis

Primary hemochromatosis is an autosomal recessive iron-storage disease that involves the heart, pancreas, skin, liver, and gonads. Myocardial iron deposition in hemochromatosis, either primary or secondary (e.g., resulting from multiple transfusions, ineffective erythropoesis), usually produces dilated cardiomyopathy but may cause restrictive cardiomyopathy. Arrhythmia and conduction disturbances are common; indeed, congestive heart failure, conduction abnormalities, and supraventricular and ventricular arrhythmias occur in one-third of patients.[45] Interstitial fibrosis is variable and unrelated to the extent of iron deposition, which occurs in the myocyte; secondarily, myocardial fibrosis may develop. Bronze diabetes and hepatic dysfunction, reflecting iron deposition in the skin, pancreas and liver are frequent associated manifestations.

One report suggests that cardiac involvement progresses temporally from a small, concentrically hypertrophied LV with diastolic dysfunction to a dilated LV with systolic dysfunction.[46] However, this sequence of events is not universally accepted, and systolic abnormalities may require provocation.[47] Findings consistent with either dilated or restrictive cardiomyopathy may be seen; the presence of systolic dysfunction indicates a poor prognosis (Fig. 68-9). Granular sparkling and atrial enlargement may be observed, but these are nonspecific signs. Quantitative ultrasonic analysis of integrated backscatter has been used experimentally to detect changes in the echo reflectivity of the myocardium due to iron deposition in thalassemia major.[48] Computed tomography and magnetic resonance imaging may demonstrate subclinical cardiac involvement, and tissue characterization may be possible with MRI. Endomyocardial biopsy is confirmatory; in selected instances, it may be useful in excluding the diagnosis.

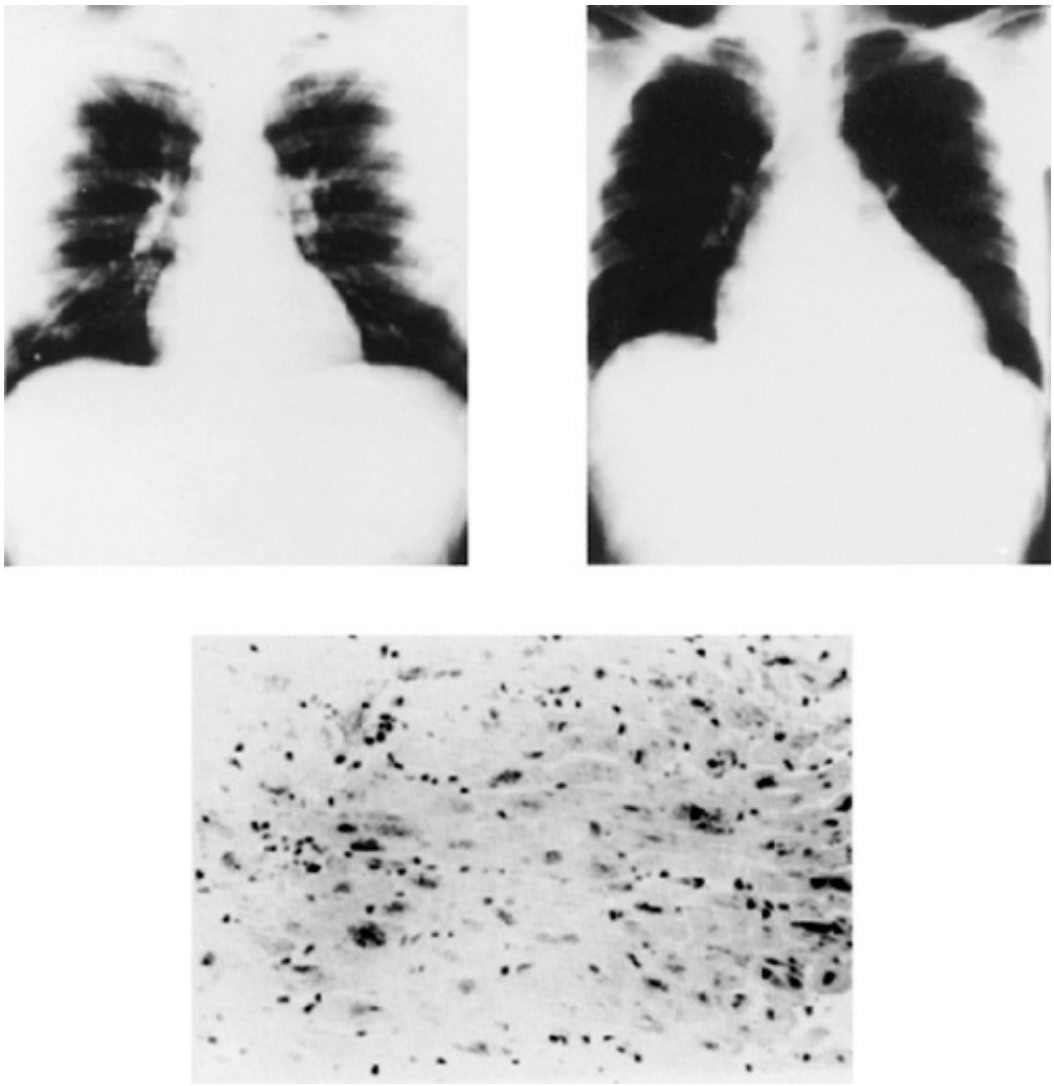

Figure 68-9: Chest radiograph of a patient with cardiac hemochromatosis before (*top right*) and after (*top left*) several months of treatment with phlebotomy. *Bottom:* Endomyocardial biopsy that established the diagnosis. (From Shabetai R. Restrictive, obliterative, and infiltrative cardiomyopathies. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart*, 9th ed. New York: McGraw-Hill; 1998:2084. Reproduced with permission.)

Repeated phlebotomy is recommended for primary hemochromatosis, and the chelating agent desferrioxamine is often beneficial in secondary hemochromatosis. Cardiac transplantation (with or without liver transplantation) may be considered in selected cases.

Fabry's Disease

Fabry's disease is an X-linked, genetically heterogeneous disorder of glycosphingolipid metabolism caused by lysosomal ceramide (α-galactosidase) deficiency that leads to accumulation of glycolipid in the heart, skin, and kidneys. Glycolipid accumulation in the myocardium and vascular and valvular endothelium may present with either a restrictive, hypertrophic, or dilated cardiomyopathy, mitral regurgitation, ischemic heart disease, or aortic degeneration. Echocardiographic findings in restrictive cardiomyopathy mimic those seen in amyloid, and LV mass correlates with the severity of disease.[49] Hypertension, mitral valve prolapse, and heart failure are common clinical presentations. Definitive diagnosis may require endomyocardial biopsy.

Pompe's Disease

Pompe's disease (glycogen storage type II) is due to an inherited (autosomal recessive) metabolic abnormality due to acid maltase deficiency that causes massive amounts of glycogen deposition in the heart and skeletal muscles. A hypertrophied, hypokinetic LV in an infant with muscle hypotonia, hyperreflexia, and failure to thrive are characteristic findings. The echocardiographic manifestations may be indistinguishable from hypertrophic obstructive cardiomyopathy. The diagnosis can be made by absence of α-1,4-glucosidase activity on skeletal muscle biopsy.

Adults with glycogen storage type III disease (debranching enzyme deficiency) may have marked LVH on echocardiography.[50]

Endomyocardial Diseases

OBLITERATIVE ENDOMYOCARDIAL DISEASES

Endomyocardial Fibrosis and Hypereosinophilic Syndrome

Endomyocardial diseases that cause restrictive obliterative cardiomyopathies include endomyocardial fibrosis (EMF) and hypereosinophilic (Loeffler's) syndrome. The former accounts for 10 to 20 percent of deaths due to heart disease in equatorial Africa but is seen throughout the world. In contrast, Loeffler's endocarditis is seen mainly in countries with a temperate climate. Although it shares similar pathological features with EMF, it affects mainly men; is usually related to parasitic infections, leukemia, and immunologic reactions; and is characterized by intense eosinophila and thromboembolic phenomena.[51] The two conditions may represent different forms of the same disease (Loeffler's endocarditis representing an early and EMF an advanced stage), but considerable differences exist. Moreover, the endemic variety EMF may be related to high levels of cerium and low levels of magnesium; it may be pathophysiologically distinct from Loeffler's.[52]

HYPEREOSINOPHILIC SYNDROME

Cardiac involvement occurs in the majority of patients with the hypereosinophilic syndrome (unexplained eosinophilia exceeding 1500 eosinophils/mm^3 for at least 6 months and symptoms of organ involvement) and often has a biventricular distribution. Cardiotoxic eosinophils (abnormal cells containing vacuoles and having fewer than the normal number of granules) are central to the pathogenesis. The cardiac pathology consists of an acute eosinophilic myocarditis, fibrinoid vasculitis of the intramural coronary arteries, mural thrombosis (often with eosinophils), fibrotic endocardial thickening, and ventricular obliteration. In addition to symptoms due to cardiac involvement, patients have skin rash and constitutional symptoms. The disease is aggressive and rapidly progressive. Electrocardiographic abnormalities (especially involving the T wave) are common but nonspecific. Hemodynamic findings are typical of restrictive cardiomyopathy.

ENDOMYOCARDIAL FIBROSIS

In contrast to Loeffler's, EMF has a more insidious onset, has no gender predilection, and most often affects children and young adults. The disease is more indolent than Loeffler's, and biventricular involvement occurs in only about half the cases. LV involvement produces symptoms due to pulmonary congestion, whereas the less common isolated RV involvement (about 10 percent) may simulate constrictive pericarditis. Atrioventricular valve regurgitation and embolic episodes are frequent complications, and atrial fibrillation is common.

ECHOCARDIOGRAPHIC FEATURES

Endomyocardial disease is characterized by endocardial fibrosis of the apex and subvalvular regions of one or both ventricles, resulting in restriction to inflow to the affected ventricle.Although their clinical presentations differ, the pathology, and therefore the cardiac imaging studies, are generally similar in the endomyocardial diseases. M-mode echo findings are nonspecific and digitized M-mode studies reveal a decreased peak filling rate and a decreased duration of the peak filling.[53] On two-dimensional echo, apical obliteration of the right and/or left ventricle, apical thrombus, preservation of ventricular systolic function with thickening of the posterior atrioventricular valve apparatus and posterobasilar LV wall, echo densities in the endocardium, and small ventricular and large atrial cavities are noted (Fig. 68-10).[54] Involvement of the posterior mitral and tricuspid valve leaflets results in mitral and tricuspid regurgitation; less commonly, restricted motion may produce stenosis. Sparing of the outflow tracts is characteristic. Doppler interrogation yields typical patterns of restriction (increased E/A, decreased IVRT, decreased deceleration time), mitral and tricuspid regurgitation, and, less often, stenosis. Not surprisingly, the location, extent, and severity of involvement determine the clinical picture.

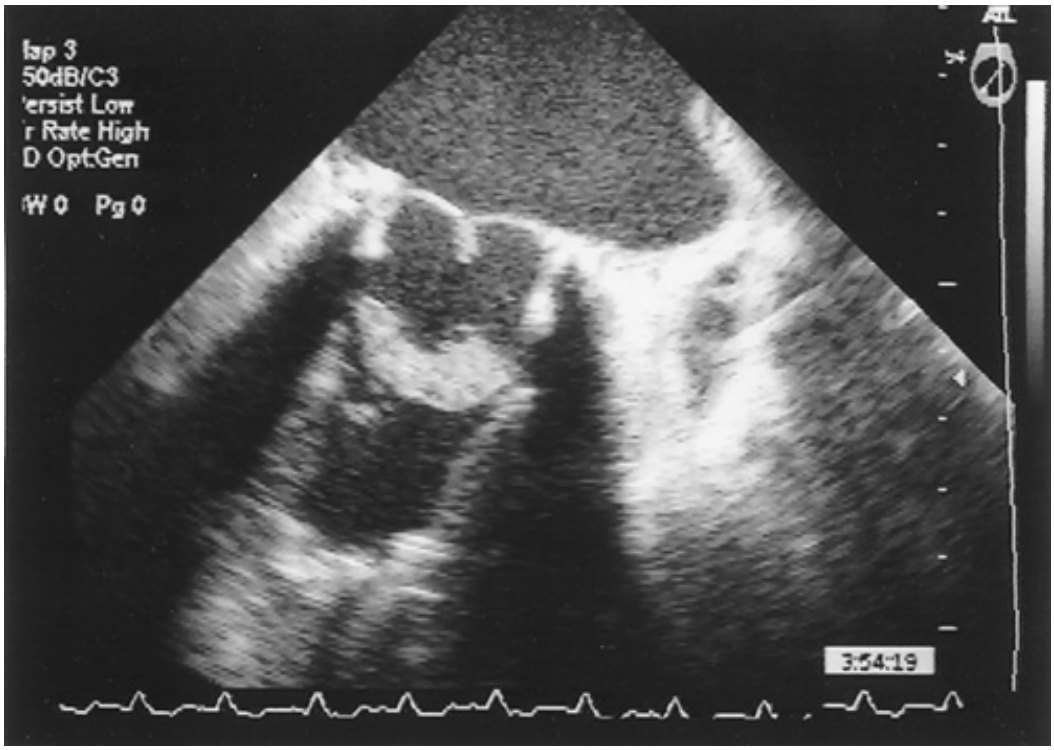

Figure 68-10: Transesophageal echocardiogram from a patient with eosinophilic endocarditis and prosthetic mitral valve replacement. Thrombus is noted below the valve struts, which at the the time of surgery was found to be adherent to the posterior LV wall. Note the apical obliteration and the apical endocardial thickening and calcification.

TREATMENT OF THE OBLITERATIVE RESTRICTIVE CARDIOMYOPATHIES

Medical therapy of Loeffler's is often ineffective and frustrating. Treatment consists of symptomatic relief, anticoagulants, corticosteroids, and hydroxyurea for myocarditis (interferon α has had some success[55]), and palliative surgery in the late, fibrotic stage. Surgical excision of fibrotic endocardium and valve replacement may offer symptomatic improvement, but at the expense of high (15 to 25 percent) operative mortality. The prognosis of advanced disease is grim (50 percent 2-year mortality), but it is considerably better in those with milder disease.

NONOBLITERATIVE ENDOMYOCARDIAL DISEASES

Carcinoid Syndrome

Carcinoid syndrome results from metastatic carcinoid tumors (most commonly arising in the small bowel and appendix, but also the bronchus and other sites) and consists of cutaneous flushing, diarrhea, and bronchoconstriction; involvement of the heart occurs as a late complication of carcinoid syndrome in approximately 50 percent of patients. (see also Chaps. 59 and 77). Hepatic metastases produce serotonin, bradykinin, and other substances that affect right heart structures but are inactivated in the lungs. Thus, LV involvement is distinctly uncommon and its presence suggests a right-to-left intracardiac shunt.[56] Fibrous endocardial plaques comprising smooth muscle cells in a stroma of collagen and acid mucopolysaccharide on the tricuspid and pulmonic valves and right heart endocardium are characteristic. Although tricuspid and pulmonic stenosis and regurgitation dominate the clinical picture, restrictive cardiomyopathy may occur.

The chest radiograph is often normal, but cardiomegaly, pleural effusions, and nodules may be evident; unlike the case with congenital pulmonic stenosis, poststenotic dilatation of the pulmonary artery trunk does not occur.[57] Electrocardiographic abnormalities are common, but nonspecific. Two-dimensional echocardiography reveals thickened, retracted tricuspid and pulmonic valves and right atrial and ventricular enlargement; right atrial wall thickening may be seen on transesophageal echo. Low-velocity tricuspid and pulmonic regurgitation on Doppler indicates normal pulmonary arterial pressures, which is typical of carcinoid heart disease. In one series, echocardiographic findings were detected in two-thirds of patients with carcinoid.[58] In another study, cardiac involvement was associated with a reduced 3-year survival as compared with those without cardiac involvement.[57] Catheterization findings are usually those of tricuspid regurgitation and/or pulmonic stenosis. Therapy is symptomatic, and valvular replacement (mechanical) or repair is warranted in patients with severe valve dysfunction.

Malignant Infiltration

Infiltrating tumors of the heart are generally metastatic (lung, breast, melanoma, lymphoma, leukemia) and rarely produce restriction to ventricular filling unless the pericardium is involved (see Chap. 77). Infiltration on echocardiography is suggested by a localized increase in wall thickness, often associated with abnormal wall motion and pericardial effusion. CT and MRI scans are also useful.

Iatrogenic Disease

Pericardial disease frequently complicates radiation therapy to the chest and may produce constrictive pericarditis; however, endo- and myocardial involvement may produce restrictive cardiomyopathy, at times presenting years after radiation therapy has been completed.[59] Anthracyclines and methysergide can cause endomyocardial fibrosis. Oils containing L-tryptophan were withdrawn from the market when they were implicated in the genesis of the eosinophilia-myalgia syndrome; this syndrome was associated with restrictive cardiomyopathy.[60] Finally, a restrictive pattern of LV filling is common soon after orthotopic cardiac transplantation and may persist for at least 1 year in as many as 15 percent.[61]

Chapter 68: RESTRICTIVE, OBLITERATIVE, AND INFILTRATIVE CARDIOMYOPATHIES

List of Figures

Figure 68-7: Amyloidosis. *Top left:* M-mode echocardiogram showing increased thickness of the left ventricular myocardium (calibration mark = 1 cm). *Top right:* Doppler tracing of mitral inflow velocity. Note that the atrial contribution to mitral blood flow velocity is markedly reduced (calibration mark = 20 cm/s). *Bottom left:* electromicrograph showing extensive replacement of myocardium by amyloid. *Bottom right:* Right ventricular pressure tracing. A diastolic dip-plateau pattern is absent because of tachycardia. (From Shabetai R. Restrictive, obliterative, and infiltrative cardiomyopathies. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart*, 9th ed. New York: McGraw-Hill; 1998:2083. Reproduced with permission.)

Figure 68-8: M-mode and two-dimensional echocardiogram from a patient with biopsy-proven amyloidosis causing hemodynamic restriction. The left ventricular systolic function is mildly impaired, and there is biatrial enlargement and vena cava plethora. Left ventricular hypertrophy is best seen in the M-mode study. PLA, parasternal long axis; 4C, four chamber view; RV, right ventricle; LV, left ventricle; LA, left atrium; RA, right atrium; IVC, inferior vena cava. (From Hoit BD. Restrictive cardiomyopathy. In: Pohost G, O'Rourke R, Shah P, Berman D, eds. *Imaging in Cardiovascular Disease*. New York: Lippincott Williams & Wilkins; in press. Reproduced with permission.)

Figure 68-9: Chest radiograph of a patient with cardiac hemochromatosis before (*top right*) and after (*top left*) several months of treatment with phlebotomy. *Bottom:* Endomyocardial biopsy that established the diagnosis. (From Shabetai R. Restrictive, obliterative, and infiltrative cardiomyopathies. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart*, 9th ed. New York: McGraw-Hill; 1998:2084. Reproduced with permission.)

Figure 68-10: Transesophageal echocardiogram from a patient with eosinophilic endocarditis and prosthetic mitral valve replacement. Thrombus is noted below the valve struts, which at the the time of surgery was found to be adherent to the posterior LV wall. Note the apical obliteration and the apical endocardial thickening and calcification.

Part 11: CARDIOMYOPATHY AND SPECIFIC HEART MUSCLE DISEASES
Chapter 69:

MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

Authors: Donna M. Mancini, Ainat Beniaminovitz

The diagnosis of cardiomyopathy encompasses a wide spectrum of diseases with widely divergent pathogenic mechanisms, that have as their final common pathway the syndrome of congestive heart failure. These heart muscle diseases may be primary or secondary-i.e., resulting from specific cardiac or systemic disorders. A list of etiologies associated with the development of cardiomyopathy is presented in Fig. 69-1.

Coronary artery disease, hypertension, valvular heart disease, and cardiomyopathy are the most common causes of heart failure for both sexes. Comparison of the Framingham[1] and SOLVD[2] (Study of Left Ventricular Dysfunction) registries demonstrates a shift in the predominant etiology of heart failure from hypertension to ischemic heart disease. This probably reflects recent intensified efforts to control high blood pressure.

Inflammatory cardiomyopathies, particularly viral myocarditis, have served as a model to understand the development of heart failure. More than 70 different specific cardiomyopathies associated with general systemic disease, neuromuscular disorders, sensitivity and toxic reactions, and the peripartum state have been described. When considered as a group, these disorders are infrequent; when considered individually, they are rare.

This chapter reviews the inflammatory cardiomyopathies and specific cardiomyopathies with an emphasis on endocrine and infiltrative disorders. Cardiac disorders caused by pulmonary hypertension and congenital cardiac anomalies are not addressed.

ISCHEMIC

Ischemic cardiomyopathy is defined as a dilated cardiomyopathy in a patient with known coronary disease, specifically a patient with a prior history of infarct or a greater than 70 percent narrowing of a major epicardial artery.

Compensatory mechanisms to improve stroke volume result in myocyte hypertrophy, ventricular dilatation, and activation of the sympathetic nervous system. Remodeling of the left ventricle and a decrease in ejection fraction occur in 15 to 40 percent of patients within 12 to 24 months following an anterior wall infarct[3] and in a smaller percentage following an inferior infarction.[4] In the Framingham study, 14 percent of men developed *congestive heart failure* (CHF) within 5 years of a first myocardial infarction[4] and half were dead within 5 years.[5] Prognosis in ischemic heart failure is known to be worse than in other forms of cardiomyopathy,[6,7] presumably due to the superimposed risk of ongoing ischemic events. Aggressive coronary revascularization in instances of significant heart failure may be justified and may achieve a survival benefit without necessarily affecting functional improvement[8] (see also Chaps. 40 and 48).

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

HYPERTENSIVE

Cardiac hypertrophy due to long-standing arterial hypertension is associated with a high incidence of heart failure.[9] Initially, myocyte hypertrophy occurs to reduce wall stress and to accommodate the increased pressure load imposed on the heart.[10] This increase in myocyte wall thickness is accompanied by biochemical and molecular changes, such as a shift to fetal phenotype gene expression[11] and alterations in the intracellular handling of calcium.[12] Alterations in the nonmyocyte compartment-such as excessive myocardial fibrosis-also ensue.[13] In concert these changes lead to an altered contractile performance of the heart.[14]

Although the precise mechanisms that accelerate the progression from compensated hypertrophy to failure are not known, activation of the renin-angiotensin system has been postulated to play a major role.[15] In vivo, angiotensin II has been shown to increase left ventricular mass[16] and contributes to cardiac phenotype modulation independently from its effect on arterial pressure.[17] In vitro, studies have demonstrated that angiotensin II causes myocyte hypertrophy and promotes interstitial fibrosis.[18] A current clinical trial with the angiotensin-converting enzyme (ACE) inhibitor ramapril has demonstrated that blockade of the renin-angiotensin system in patients with normal left ventricular function but at high risk for cardiovascular events leads to a decrease in the combined end point of death from cardiovascular causes, myocardial infarction, and stroke.[19] This clinical prevention trial further confirms the deleterious effects of the renin-angiotensin axis on cardiac function.

The patient with hypertensive cardiomyopathy typically presents with left ventricular hypertrophy in association with features of dilated or restrictive cardiomyopathy. The prognosis is generally better than that of other forms of cardiomyopathy[20]; however, the prognosis is significantly worsened by the presence of comorbid conditions such as diabetes mellitus, coronary artery disease, and persistent hypertension[21] (see also Chap. 58).

Hypertensive cardiomyopathies are common in the elderly and may be related to an increased prevalence of hypertension due to central arterial stiffness and inherent myocardial changes that occur with normal aging. Recent advances in molecular biology and in echocardiographic and Doppler techniques have led to an improved understanding of the various distinct causes of hypertrophic heart disease in the elderly[22] and the realization that the process is not solely due to the changes associated with aging. Hypertrophic obstructive cardiomyopathy, once thought to be a familial disorder affecting primarily younger individ uals, has been diagnosed in older individuals with increasing frequency.[23,24] As shown in Table 69-1, the clinical syndrome, prognosis, and echocardiographic/electrocardiographic findings are somewhat different in the elderly form of the disease.[25]

Table 69-1: Differences between Old and Young Patients with Hypertrophic Cardiomyopathy

Findings	Old	Young
Echocardiographic	Ovoid ventricle	Crescentic ventricle
	Large left atrium	Small left atrium
	LVH diffuse	LVH anterior septum
	Proximal septal bulge	No septal bulge
Mutations	Gene for cardiac myosin-binding protein C	β-myosin heavy chain and cardiac troponin genes
Etiology	Sporadic, 40%	Primarily inherited
Symptoms	More severe	Less severe
Progression	Slower	Rapid
Prognosis	Better	Worse
Sudden death	Uncommon	Common

Similarly, hypertensive hypertrophic cardiomyopathy is another significantly unappreciated cause of hypertensive cardiomyopathy in the elderly.[26] In contrast to the hypertrophic obstructive form, there is a higher female predominance,[26] which is thought to be due to gender-specific differences in the degree of myocyte hypertrophy to intraventricular pressure-overload previously described in women with aortic stenosis.[27] There is no apparent familial component, and patients give a long history of isolated systolic hypertension. In comparison to the prevalence of hypertension in patients over age 65, which varies from 50 to 70 percent, hypertensive hypertrophic cardiomyopathy remains relatively rare, suggesting a unique and currently poorly understood pathophysiology.[28] Many postulate that in hypertensive hypertrophic cardiomyopathy, as in the hypertrophic obstructive form, the development of senescent hypertension may act influentially on an already genetically altered substrate to lead to the respective phenotypes.[29]

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

VALVULAR

Valvular cardiomyopathy is defined as systolic dysfunction out of proportion to the wall stress imposed by the initial valvular lesion.[30] It occurs most commonly with left-sided regurgitant (mitral and aortic insufficiency) rather than stenotic lesions (aortic and mitral stenosis). The prognosis depends on the nature and extent of the valvular abnormality but more importantly on the degree of left ventricular dysfunction at the time of the proposed surgical repair. Generally even severe left ventricular dysfunction due purely to aortic stenosis will have a favorable prognosis after surgical repair. This is in marked contrast to a surgical approach for similar degrees of left ventricular dysfunction due to mitral[31] or aortic regurgitation. Owing to high surgical risks, medical therapy with afterload reduction-and, if indicated, cardiac transplantation-are acceptable modes of therapy in these instances. Cardiac reduction surgery with valve repair has become an increasingly popular modality for treatment of these high-risk patients. No large-center randomized trial is currently available to evaluate the efficacy and safety of this approach.

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

MYOCARDITIS

Infective

VIRAL

As early as 1806, a relationship between infection and chronic heart disease (diphtheria) was postulated, but it was not until the 1970s, with the advent of endomyocardial biopsies, that diagnosis of myocarditis could be established during life. Multiple infectious etiologies (Table 69-2)[32] have been implicated as the cause of myocarditis, with the most common being viral, specifically, Coxsackie B.[33] In the majority of patients, active myocarditis remains unsuspected because the cardiac dysfunction is subclinical, asymptomatic, and self-limited. Histologic evidence of myocarditis following traumatic death is identified in 1 to 3 percent of autopsies,[34,35] suggesting that the frequency of myocarditis is underestimated by analyzing data only from symptomatic patients.

Table 69-2: Causes of Myocarditis

Infectious
Viruses
Coxsackievirus, echovirus, HIV, Epstein-Barr virus, influenza, cytomegalovirus, adenovirus, hepatitis (A and B), mumps, poliovirus, rabies, respiratory synctial virus, rubella, vaccinia, varicella zoster, arbovirus
Bacteria
Cornyebacterium diptheriae, Streptococcus pyogenes, Staphylococcus aureus, Haemophilus pneumoniae, Salmonella spp., *Neisseria gonorrhoeae, Leptospira, Borrelia burgdorferi, Treponema pallidum, Brucella, Mycobacterium tuberculosis,* Actinomyces, *Chlamydia* spp., *Coxiella burnetti, Mycoplasma pneumoniae, Rickettsia* spp.
Fungi
Candida spp., *Aspergillus* spp., *Histoplasma, Blastomyces, Cryptococcus, Coccidioidomyces*
Parasites
Trypanosoma cruzii, Toxoplasma, Schistosoma, Trichina
Noninfectious
Drugs causing hypersensitivity reactions

Antibiotics: sulfonamides, penicillins, chloramphenicol, amphotericin B, tetracycline, streptomycin
Antituberculous: isoniazid, para-aminosalicylic acid
Anticonvulsants: phenindione, phenytoin, carbemazepine
Anti-inflammatories: indomethacin, phenylbutazone
Diuretics: acetazolamide, chlorthalidone, hydrochlorothiazide, spironolactone
Others: amitriptyline, methyldopa, sulfonylureas
Drugs not causing hypersensitivity reactions
Cocaine, cyclophosphamide, lithium, interferon alpha
Nondrug causes
Radiation, giant-cell myocarditis

Pathogenesis

Infection by cardiotropic viruses prompted the initial hypothesis that the viral infection was responsible for myocardial injury. However, several investigators noted that cardiac dysfunction increased after the eradication of the infective agent and speculated that the pathogenesis may be due to the immunologic responses initiated by the virus (Fig. 69-2). Support for this theory comes initially from the work of Woodruff, who noted that the histologic evidence of cardiac injury in Coxsackie B infection occurred only after the virus was no longer detectable in the myocardium.[36] Subsequently, demonstration of T-lymphocyte and macrophage infiltration,[37] perforin granules,[38] and a variety of cytokines known to depress myocardial contractility[39] in endomyocardial biopsies of patients with active carditis strengthened the concept of immune-mediated injury. Furthermore, immunosuppressive therapy in animal models attenuated inflammation-with improved survival, less cellular infiltrate, and less necrosis.

The specific immune responses that lead to the myocardial injury are incompletely defined. A murine model of myocarditis induced by coxsackie B3 has provided some insight into immunologic sequence of events. Following infection with coxsackie B3 virus, macrophages are present in the infiltrate until day 8.[40] After macrophage activity decreases, both effector (CD8) and helper (CD4) T cells are identified within myocardial lesions. At peak infiltration, some murine strains showed a predominance of CD8-positive cells while in others CD4 cells predominate, suggesting participation of both humoral- and cell-mediated immune responses.[41] In human subjects, T-lymphocyte and macrophage infiltration characterizes the immunohistochemical picture, whereas B lymphocytes and natural killer cells are absent.[37] T-lymphocyte subset analysis of human serum does not demonstrate consistency in dominance of CD4 or CD8 cells.

The mechanisms of injury when lymphocytes infiltrate the myocardium are unknown. In the murine model, messenger ribonucleic acid (m-RNA) of perforin, the pore-forming protein mediating cytotoxicity, was identified in cytoplasmic granules of infiltrating cells by in situ hybridization.[42] Similarly, biopsy samples from patients with active myocarditis contain perforin granules in infiltrating cells,[38] implying that direct cytotoxicity can occur. Alternatively, release of cytokines such as interleukin-1, interleukin-6, interleukin-8, and tumor necrosis factor alpha may

cause reversible depression of myocardial contractility without resulting in cell death.[39] Therefore, the effect of T cell-mediated immune injury may be either irreversible as a result of cell death through cytotoxicity (perforin) or reversible as a result of injury mediated by cytokines. A marked reduction in myocardial cell damage is noted in T cell-depleted mice inoculated with encephalomyocarditis virus.

Antiheart antibodies in the serum of patients with myocarditis have been reported but may reflect nonspecific myocardial damage.[43] When serum from patients with myocarditis was screened for autoantibodies, high-titer immunoglobulin G (IgG) with cardiac specificity was detected in 59 percent of patients with myocarditis and in none of the normal samples.[44] Antibodies with specificity for contractile and energy-transport proteins have been identified. In sera from patients with active myocarditis, Western immunoblotting demonstrated reactivity of a fraction that includes antibody to the heavy chain of cardiac myosin.[44] In a murine myocarditis model, cardiac myosin antibodies are observed following coxsackie B virus infection.[45] Moreover, injection of cardiac antimyosin antibodies without infection results in myocarditis that is histologically similar to that seen following coxsackie B3 virus infection.[46,47]

The role of viral infection has been deemphasized following the popularization of the immune injury hypothesis. Viral infection is the trigger for the immune response that is deleterious. Attempts to culture virus from human myocardial tissue generally have been unsuccessful. Only a single case report of Coxsackievirus identified in a myocardial biopsy specimen in an adult has been described.[48] However, identification of viral genomic fragments in myocardial samples by in situ hybridization and polymerase chain reaction from patients with myocarditis and dilated cardiomyopathy have been reported.[49-66] These genomic fragments may not be capable of replicating as intact cardiotropic virus but probably serve as a persistent source of antigen to drive the deleterious immune responses.[67]

In addition to the tropism of the virus, host immune responses play an important role in determining the severity of the clinical disease. When quantitative peripheral T- and B-lymphocyte populations were analyzed in patients with dilated cardiomyopathy and myocarditis, no consistent changes were detected.[68,69] However, immunologic assays demonstrate a reduction in the function of natural killer cells, antibody-dependent cellular cytotoxic cells, and suppressor cells and an increase in circulating levels of interleukin-1 and tumor necrosis factor alpha.[69-72] These immunoregulatory defects may predispose the host with a high antigenic load to develop immune responses that are not modulated by the natural inhibitory immunoregulatory mechanisms.

In addition to chronic inflammatory immune mechanism or persistent viral infection, apoptotic cell death may be another mechanism by which myocarditis can result in cardiomyopathy. Several different viruses have been reported to be triggers for apoptosis.

The association between acute myocarditis and dilated cardiomyopathy has been recognized for the past two centuries. However, the link between these two diseases remains circumstantial. Autoreactive antibodies and interleukin-2 receptors are identified commonly in both patients with myocarditis and those with dilated cardiomyopathy. Serologic titers to cardiotropic viruses are more common in patients with cardiomyopathy than in normal subjects. Viral genomic material can be detected more frequently by polymerase chain reaction (PCR) in patients with dilated cardiomyopathy versus other cardiac diseases. Animal models of myocarditis can progress to dilated cardiomyopathy, as can patients with clinically suspected or biopsy-proven myocarditis. However, the percentage of patients with idiopathic dilated cardiomyopathy that represent the end stage of an active myocarditis is unknown.

Clinical Presentation

The clinical manifestations of myocarditis are variable. Most patients have a self-limited disease, whereas others present in profound cardiogenic shock. The most obvious symptom suggesting myocarditis is an antecedent viral syndrome. Flu-like symptoms occur in approximately 60 percent of patients.[73] Chest pain may occur in up to 35 percent of patients and may be typically ischemic, somewhat atypical, or pericardial in character. Occasionally patients will present with a clinical syndrome identical to an acute myocardial infarction, with left ventricular asynergy, electrocardiographic evidence of injury or Q waves, and ischemic cardiac pain[74] (Fig. 69-3). In this syndrome, at autopsy, the coronary arteries are widely patent, although viral coronary arteritis has been reported.[75,76] Coronary vasospasm has also been associated with acute myocarditis.[77]

Patients may present with syncope or palpitations with atrioventricular (AV) block or ventricular arrhythmia. Complete AV block is common with some patients presenting with Stokes-Adams attacks. The complete heart block is generally transient and rarely requires a permanent pacemaker.[78] Sudden cardiac death can be the initial presentation of myocarditis in some patients, presumably from complete heart block or ventricular tachycardia. In a 20-year review of sudden death among Air Force recruits, 20 percent had myocarditis documented at autopsy.[79] In some patients with refractory ventricular arrhythmias, endomyocardial biopsy or autopsy has revealed myocarditis. Systemic or pulmonary thromboembolic disease is also associated with myocarditis.[80,81]

A familial tendency for the development of myocarditis may be present. In one report, a suppressor cell defect was detected, predisposing to development of active myocarditis.[82] Patients with peripartum cardiomyopathy have a high frequency of myocarditis on endomyocardial biopsy.[83] The immunoregulatory changes during and following pregnancy may heighten susceptibility to viral myocarditis, and exposure to trophoblastic antigens may predispose to immune-mediated myocardial injury.

Patients with new-onset left ventricular dysfunction given the diagnosis of idiopathic dilated cardiomyopathy may actually have active myocarditis despite the absence of clinical signs and symptoms of acute infection.[84]

Diagnosis

Laboratory findings are generally not diagnostic. Sixty percent of patients will have an elevated erythrocyte sedimentation rate and 25 percent an elevated white blood cell count.[73] Elevated titers to cardiotropic viruses may be present. However, a fourfold rise in IgG titer over a 4- to 6-week period is required to document acute infection. Elevated IgM antibody titer may denote an acute infection more specifically than a rise in IgG antibody titer. Unfortunately, a rise in antibody titer documents only the response to a recent viral infection and does not indicate active myocarditis.

Abnormalities in peripheral T- and B-lymphocyte counts have been reported, but these findings have not been consistent and cannot be used as diagnostic adjuncts.

Increase in the MB band of CPK is observed in approximately 12 percent of patients.[73] Troponin levels may also increase. In the Myocarditis Treatment Trial, elevated troponin levels were found in 32 percent of the patients and were predictive of inflammatory involvement.

The electrocardiogram most frequently shows sinus tachycardia. Diffuse ST-T-wave changes, prolongation of the QTc interval, low voltage, and even an acute myocardial infarct pattern has been noted in some patients with myocarditis. Conduction delay is common,[85] with left bundle branch block identified in 20 percent of patients. Cardiac arrhythmias are frequently observed in patients with myocarditis, including complete heart block, supraventricular arrhythmias-especially

in the presence of congestive heart failure or pericardial inflammation, and ventricular arrhythmias.[86]

Echocardiography can reveal left ventricular systolic dysfunction in patients with a normal-sized left ventricular cavity. Segmental wall motion abnormalities may be observed.[87] Wall thickness may be increased, particularly early in the course of the disease, when inflammation is fulminant.[88] Ventricular thrombi are detected in 15 percent of those studies.[89] Echocardiographic findings in active myocarditis can mimic restrictive, hypertrophic, or dilated cardiomyopathy.

Endomyocardial biopsy is the critical test to confirm the diagnosis. Endomyocardial biopsy techniques enable the repetitive sampling of the human myocardium with minimal discomfort and minor morbidity.[84,90,91] Right ventricular myocardial specimens can be obtained by accessing the right internal jugular or femoral vein. Intravascular biopsy of the left ventricle is infrequently performed due to the higher morbidity associated with this approach. The right ventricular bioptome is positioned under fluoroscopy or echocardiography to sample the interventricular septum.[90] As the myocarditis can be focal, a minimum of four to six fragments are obtained. Sampling error is reduced by less than 5 percent. Using the Stanford bioptome, typical samples are 2 to 3 mm in maximal diameter and 5 mg in wet weight. Samples are processed, paraffin-imbedded, sectioned, and stained with hematoxylin-eosin and trichrome. Special stains are employed if other diagnoses are considered. Diagnoses that can be made or confirmed by endomyocardial biopsy are listed in Table 69-3.

Table 69-3: Diagnoses That Can Be Made byEndomyocardial Biopsy

1. Myocarditis
   - Giant cell
   - Cytomegalovirus
   - Toxoplasmosis
   - Chagas
   - Rheumatic
   - Lyme
2. Infiltrative
   - Amyloid
   - Sarcoid
   - Hemochromatosis
   - Carcinoid
   - Hypereosinophilic
   - Glycogen storage
   - Cardiac tumors
3. Toxins
   - Doxorubicin
   - Chloroquine
   - Radiation injury
4. Genetic
   - Fabry
   - Kearns-Sayre syndrome
   - Right ventricular dysplasia

Several investigators have performed endomyocardial biopsies in patients with unexplained

congestive heart failure and/or ventricular arrhythmia.[84,92-122] The percentage of patients with biopsies interpreted as myocarditis varied widely, primarily owing to the different diagnostic criteria for active myocarditis used by the investigators. This variability of endomyocardial biopsy criteria prompted a meeting of cardiac pathologists to reach a consensus on the pathologic definition of myocarditis, now known as "the Dallas criteria." Active myocarditis was defined as "an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease."[123] Examination of a minimum of four to six fragments from each patient is required for interpretation. The term *borderline* myocarditis is applied when the inflammatory infiltrate is too sparse or myocyte injury is not demonstrated. Repeat biopsy is then suggested. A high frequency of active myocarditis is confirmed by repeat biopsy in patients whose initial histologic samples demonstrated borderline myocarditis.[124] When right ventricular endomyocardial biopsy has failed to establish the diagnosis, sampling the left ventricle may improve diagnostic yield (Fig. 69-4).

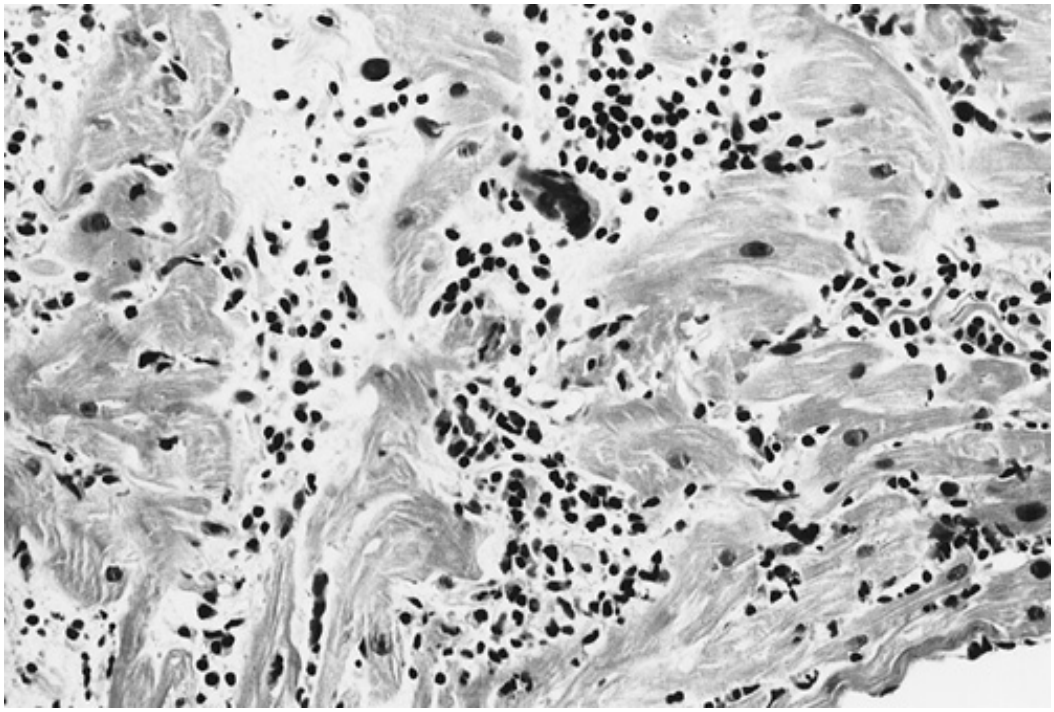

Figure 69-4: Photomicrograph showing extensive interstitial infiltrates of lymphocytes and myocytes with focal myocyte necrosis. (H&E, ×40.)

Endomyocardial biopsy must be applied as quickly as possible to maximize the diagnostic yield. Biopsies in patients with peripartum cardiomyopathy have the highest yield when performed early after onset of symptoms.[83] Resolution of active myocarditis has been documented within 4 days of initial biopsy, with progressive clearing over several weeks on serial biopsy.[125] Progression of active myocarditis to dilated cardiomyopathy has been documented when serial biopsies are performed.[126]

Newer molecular biology techniques are being applied to the analysis of endomyocardial tissue for the detection of viral nucleic acid. The usefulness of PCR amplification of viral genomic material from endomyocardial tissue in children with suspected myocarditis was shown in a study that found PCR amplified viral product in 67 percent of the children studied.

Noninvasive Studies

Although technetium-99m-pyrophosphate scintigraphy has proved useful in the detection of myocarditis in a murine model, it has not been effective in diagnosing myocarditis in humans. Imaging with gallium 67, an inflammation-avid radioisotope, has shown promise as a screening method for active myocarditis, with a specificity and sensitivity of 83 percent and a negative predictive value of 98 percent in biopsy-proven myocarditis.[100] Indium 111-labeled antimyosin antibody scans can be used to detect myocyte necrosis. Application of this technique in patients with myocarditis has demonstrated a sensitivity of 83 percent, a specificity of 53 percent, and a positive predictive value of a normal scan of 92 percent.[124] In those patients who were antimyosin antibody-positive and biopsy-negative, the possibility of inflammation undetected by biopsy has been considered. Antimyosin imaging, however, detects myocyte injury independent of etiology, and noninflammatory causes of heart muscle injury in young patients may cause false-positive scans. The usefulness of scintigraphy in diagnosing myocarditis is limited by low specificiy, radiation exposure, and expense (see also Chap. 16).

Tissue alterations associated with myocarditis may be identifiable using magnetic resonance imaging (MRI).[127] Preliminary results suggest that myocardial inflammation may induce abnormal signal intensity of the myocardial walls. Use of T2-weighted images to visualize tissue edema has been described in several case reports of patients with active myocarditis. More recently, contrast media-enhanced MRI has been used to characterize myocardial changes in myocarditis. The MRI imaging contrast agent gadopentetate dimeglumine accumulates in inflammatory lesions (see Chap. 18A). It is a hydrophilic agent that accumulates in the extracellular space of water-containing tissues. Gadolinium increases the signal of T1-weighted images. A total of 19 patients with clinically suspected myocarditis and 18 normal subjects underwent contrast-enhanced MRI. Global relative enhancement was higher in patients than controls. Contrast MRI also visualized the area of inflammation and the extent of inflammation and may prove to be a valuable technique in both the diagnosis and monitoring of disease activity.

Despite the promise of noninvasive techniques, endomyocardial biopsy remains the diagnostic standard.

Treatment

The immune injury hypothesis generated application of potential therapies, including immunosuppression. Anecdotal success with immunosuppression in active viral myocarditis[101,106] led to the large Multicenter Myocarditis Treatment Trial.[128] In this study, 111 patients with biopsy-proven myocarditis were randomized between conventional medical therapy versus steroid/azathioprine or steroid/cyclosporine immunosuppression. The primary end point of the study was change in ejection fraction over 28 weeks. For all patients, the average increase in ejection fraction over baseline was 9 percent. Treatment assignment was not predictive of improvement in left ventricular ejection fraction, attenuation of clinical disease, or mortality[129] (Fig. 69-5).

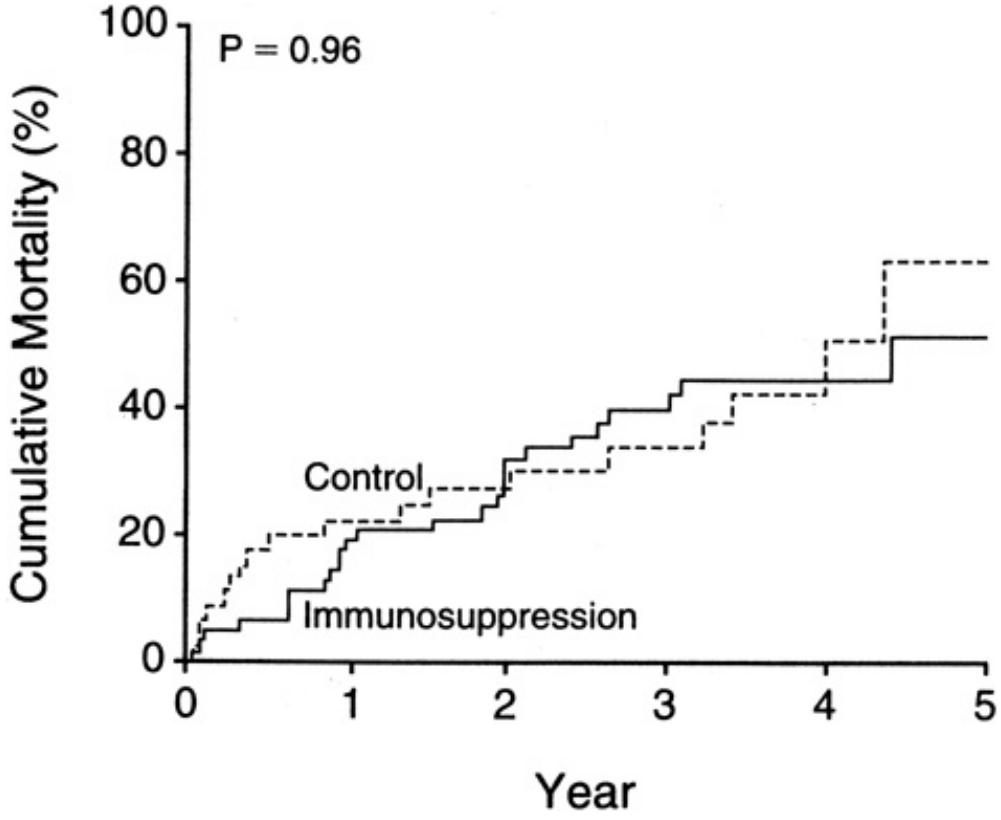

Figure 69-5: Actuarial mortality curves from the Myocarditis Treatment Trial illustrating no difference in survival between the treatment groups. (From Mason et al.,[129] with permission.)

Recently, immune modulatory therapy with immune globulin has been shown to be an effective treatment for Kawasaki's disease and new-onset cardiomyopathy in pediatric patients.[130] Subsequently, a small open-label study was performed in 10 adult patients with new-onset heart failure.[131] Significant improvement in left ventricular function was observed in 9 of 10 patients. These findings formed the basis for a multicenter study investigating the use of this treatment modality. The IMAC trial (Intervention in Myocarditis and Acute Cardiomyopathy with immune globulin) used a single infusion of high-dose immunoglobulin (2 g/kg) to treat presumed inflammatory cardiomyopathies. In this placebo-controlled 6-month trial, the improvement in left ventricular ejection fraction and symptoms was similar in both groups. Thus no benefit of immunomodulation could be demonstrated.

Despite the experimental data supporting the immune injury hypothesis, no randomized study has yet demonstrated the efficacy of immunosuppressive therapy in myocarditis. Immunosuppressive therapy is therefore not routinely recommended for infective myocarditis. Standard heart failure treatment remains the mainstay of therapy.

Prognosis

About one-third of those who present with clinical carditis and recover will be left with some cardiac abnormality ranging from mild changes on electrocardiography (ECG) to significant heart failure. The multicenter myocarditis trial provided insight into the natural history of myocarditis with current treatment. The degree of left ventricular dysfunction at initial presentation was most predictive of recovery. Approximately 40 percent of patients fully recovered.[104] Other predictors of recovery included shorter duration of disease and less intensive conventional drug therapy. One-year survival in this study was 80 percent, with a 4-year survival of only 44 percent.

The prognosis of myocarditis depends to some extent on the causative agent, but if clinical heart

failure develops, 5-year mortality rates are in the 50 to 60 percent range, comparable with figures seen in idiopathic cardiomyopathy.[132] Chronic inflammation, viral persistence, or both may affect disease progression and prognosis. Future therapies will need to identify the predominant factor to target treatment and hopefully improve survival.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) is increasingly recognized as a cause of dilated cardiomyopathy. In some inner-city hospitals, it may represent a very common diagnosis. The relatively recent emergence of this virus in the early 1980s has provided a unique opportunity to prospectively monitor the development of heart failure to chronic viral infection. The etiology of this cardiomyopathy may be from infection of myocardial cells with HIV or coinfection with other cardiotropic viruses, postviral autoimmune response, or cardiotoxicity from illicit drugs or drug therapy. Barbaro et al.[133] recently studied the development of dilated cardiomyopathy in 952 asymptomatic HIV-positive patients. Patients with a history of illicit drug use, prior cardiac disease, previous treatment with antiretroviral or immunomodulating drugs, or with an ejection fraction less than 50 percent were excluded from prospective study. In the 60 months of follow up, 8 percent of the patients developed cardiomyopathy, with annualized incidence rate of 16 cases per 1000 patients. A predisposing factor to cardiomyopathy development was a CD4 cell count below 400/mL. In 83 percent of the patients, a histologic diagnosis of myocarditis was made. In 92 percent of these positive biopsies, HIV nucleic acid sequences were detected by in situ hybridization. Coexistent infection with coxsackie virus group B, cytomegalovirus and Epstein-Barr virus was detected in a small segment of this cohort. Other studies suggest that disease duration and illicit drug use as factors contributing to the development of this disease.[134]

As the symptoms of heart failure and HIV can be very similar (i.e., fatigue, wasting, etc.), careful cardiologic follow-up of these patients is probably indicated to detect early development of left ventricular dysfunction. Conventional heart failure management can then be instituted to alleviate cardiac-related symptoms.

Cytomegalovirus

Cytomegalovirus may lead to myocarditis in the general population, but ordinarily the myocarditis is self-limited and asymptomatic. In the cardiac transplant recipient, however, cytomegalovirus myocarditis may become a more serious disease resulting in cardiac dysfunction.[135] The treatment of cytomegalovirus myocarditis is intravenous ganciclovir, which effectively eradicates the virus. Early cytomegalovirus infection correlates with the development of allograft coronary artery disease, the major cause of death beyond the first year after cardiac transplantation. It is proposed that infection of either subintimal fibroblasts or endothelial cells results in immunologic injury that predisposes to this potentially fatal condition.

NONVIRAL

Chagas' Disease

American trypanosomiasis, or Chagas' disease, is the most common cause of congestive heart failure in the world.[136] This condition results from the bite of the reduviid bug, leading to infection with *Trypanosoma cruzi,* and is endemic to rural South and Central America.

Pathogenesis

The pathogenesis of chronic, chagasic cardiomyopathy is controversial because the parasite is rarely present in the myocardium. As in the viral cardiomyopathy model, the cardiac injury is thus

thought to be immunologically mediated.[137] Both cellular and humoral immune responses have been implemented in the myocardial injury.[137] Myocardial biopsies demonstrate that the inflammatory infiltrate in chronic Chagas' disease consists mainly of CD8+ T cells, with a low number of CD4+ T cells.[138-140] This suggests some degree of immunologic depression in the host, since the activation of T-helper cells is known to be the most effective mechanism of defense against the parasites.[141] Some have postulated that the diminished expression of CD4+ T cells during acute *T. cruzi* infection may be related to a mechanism of tolerance induced by the parasite. Evidence for this comes from studies that have shown that the addition of interleukin-1 (IL-1) in vitro restores helper T-cell function, thus implementing a macrophage defect in this process.[142] Furthermore, IL-2 and the IL-2 receptor are absent or scarce in the inflammatory infiltrate,[143] attesting to the attenuated role of the T-helper subset in this disease.

Clinical Presentation

This parasitic disease has an acute phase, where hematogenous spread of the parasite leads to invasion of various tissues and organ systems. The invasion is accompanied by an intense inflammatory reaction with mononuclear cells and is characterized by fever, sweating, myalgias, myocarditis, hepatosplenomegaly, and a case fatality rate of about 5 percent. Most patients recover from the acute illness and enter an asymptomatic latent phase, but 20 to 30 percent will develop a chronic form of the disease up to 20 years after the initial infection.

The chronic stage is a result of gradual tissue destruction. The gastrointestinal tract and the heart are the most common sites of involvement, with the primary cause of death being cardiac failure. In the gut, the destruction of the myenteric plexus is responsible for the development of megaesophagus and megacolon. In the heart, the myofibrils and the Purkinje fibers are replaced by fibrous tissue, leading to cardiomegaly, congestive heart failure, heart block, and arrhythmia. The microscopic findings are those of extensive fibrosis, but a chronic cellular infiltrate composed of lymphocytes, plasma cells, and macrophages is often present and parasites are found in about a quarter of the patients.

The diagnosis of the acute disease depends on the discovery of trypomastigotes in the blood of the infected individual. In chronic infection, direct diagnosis is less useful due to less circulating trypomastigotes. Xenodiagnosis (where the patient is bitten by reduviid bugs bred in the laboratory and subsequent identification of the parasites in the intestine of the insect) is the most useful test, which will detect infection in about half the patients. The complement-fixation test (MachadoGuerreiro test) also has high sensitivity and specificity for identification of chronic Chagas' disease. In the other lab tests, it is necessary to rely on positive serologic tests (such as the indirect immunofluorescent antibody, the enzyme-linked immunosorbent assay, and the hemagglutination tests) together with symptoms and signs compatible with Chagas' disease.

Endomyocardial biopsy may show active myocarditis using the Dallas criteria.[144] Noninvasive assessment commonly shows segmental wall motion abnormalities, specifically apical aneurysms. Electrocardiographic findings include complete heart block, atrioventricular block, or right bundle branch block with or without fascicular block in 11 percent of infected individuals.[145] Ventricular arrhythmias may require antiarrhythmic drugs, including amiodarone.[146]

The treatment of chronic Chagas' disease is symptomatic and includes a pacemaker for complete heart block, an implantable cardioverter-defibrillator for recurrent ventricular arrhythmia, and standard therapy for congestive heart failure as outlined for other forms of myocarditis. Antiparasitic agents such as Nifurtimox and benzimidazole eradicate parasitemia during the acute phase and are typically curative. They should be administered if the disease has not previously been treated and may be used as prophylaxis if there is a high likelihood of recurrence, such as following immunosuppressive therapy. The role of immunosuppression therapy for chagasic myocarditis is controversial, and heart transplantation is effective for end-stage refractory cardiac

disease.

Lyme Carditis

Lyme disease may result from infection with the spirochete *Borrelia burgdorferi*, introduced by a tick bite. The initial presenting symptom in patients with the disease who progress to cardiac involvement is frequently complete heart block. Left ventricular dysfunction may be seen but is unusual.[147] Endomyocardial biopsy may show active myocarditis. Rarely are spirochetes seen on biopsy. Corticosteroid administration is helpful in treating Lyme carditis following therapy with tetracycline.[148]

Among other infectious etiologies is *Toxoplasma gondii*, which is curable by pyrimethamine and sulfadiazine[149] and occurs most commonly in the immune-deficient host. Leptospirosis is yet another common cause in fatal cases of myocarditis. Fifty percent of cases have ST- and T-wave changes on electrocardiography.

Rheumatic Carditis

One form of myocarditis that has declined dramatically in the latter half of the twentieth century is rheumatic carditis.[150] The availability of antibiotics and changes in the virulence and serotypes of group A streptococcus may explain the decreasing frequency of this disease.[151]

Acute rheumatic fever can occur in children and young adults. It generally follows a group A streptococcal pharyngitis, but only indirect evidence linking the two has been found. Rheumatic carditis may result from a direct toxic effect of some streptococcal product versus an immunologic mechanism.[152-154] Group A streptococci have a number of structural components similar to those of human tissue. Antibodies to streptococci cross-react with the glycoproteins of heart valves. The serum of patients with rheumatic fever contains autoantibodies to myosin and sarcolemma. The Aschoff body, pathognomic for this disorder, represents persistent focal inflammatory lesions in the myocardium. These nodules can persist for years after an acute attack. Macrophages containing myosin have been identified in these nodules.

Clinical diagnosis is made using the Jones criteria[155] (see also Chap. 55). The major manifestations are carditis, polyarthritis, chorea, erythema marginatum, subcutaneous nodules, and evidence of preceding streptococcal infection (i.e., positive throat culture, history of scarlet fever, elevated antistreptolysin titers). Minor criteria are nonspecific findings such as fever, arthralgia, previous rheumatic fever or rheumatic heart disease, elevated ESR or reactive protein, and prolonged PR interval. Diagnosis is made by the presence of two major criteria or one major and two minor criteria. Debate into whether the Jones criteria should be modified to incorporate Doppler-Echo indices are ongoing.[156,157]

Two-thirds of patients present with an antecedent pharyngitis, followed by the symptoms of rheumatic fever in 1 to 5 weeks, with a mean presentation of 18.6 days. Severe carditis resulting in death can occur but is unusual. CHF is observed in only 5 to 10 percent of cases. Usually the carditis is mild, with the predominant effect being scarring of the heart valves. Physical exam is notable for fever and heart murmurs reflecting the acute valvulitis. The mitral valve is involved three times as frequently as the aortic valve; therefore mitral murmurs are more common. Mitral regurgitation is the most common finding. A mid diastolic murmur over the apical area can frequently be heard. This is called the Carey Coombs murmur, and its presence almost certainly confirms mitral valvulitis. Aortic insufficiency can be auscultated with aortic valvulitis.

There are no characteristic ECG findings through PR prolongation, and nonspecific ST-T-wave changes are frequently described. Endomyocardial biopsy demonstrates the Aschoff nodules as

well as a diffuse cellular interstitial infiltrate including lymphocytes, polymorphonuclear cells, histiocytes, and eosinophils.

Laboratory tests suggestive of rheumatic fever include antibodies to antistreptolysin O and anti-DNAase B, an elevated sedimentation rate, and elevated C-reactive protein. Extracardiac manifestations generally predominant with an acute migratory polyarthritis of the large joints. Aspirin and penicillin are the mainstays of therapy. Corticosteroids can also provide symptomatic relief. Once rheumatic fever is diagnosed, antibiotic prophylaxis is required to prevent recurrent episodes. The most effective method is a single monthly intramuscular injection of 1.2 million units of benzathine Penicillin G until age 21.

Noninfective

HYPERSENSITIVITY

Hypersensitivity myocarditis is an example of the early phase of eosinophilic myocarditis and is thought to be due to an allergic reaction to a variety drugs (Table 69-4). Methyldopa, the penicillins, sulfonamides, tetracycline, and the antituberculous drugs are the pharmaceuticals most commonly associated with this entity. It is characterized by peripheral eosinophilia and infiltration into the myocardium by eosinophils, multinucleated giant cells, and leukocytes (Fig. 69-6).[158] The major basic protein of the eosinophil granule may be detected in the presence of acute necrotizing myocarditis, suggesting toxicity of the granule contents.[159] Good success has been reported with stopping the offending agent and treatment with corticosteroids.[160] Unfortunately, the presence of this condition often goes unnoticed and the first manifestation of cardiac involvement is sudden death due to arrhythmia.

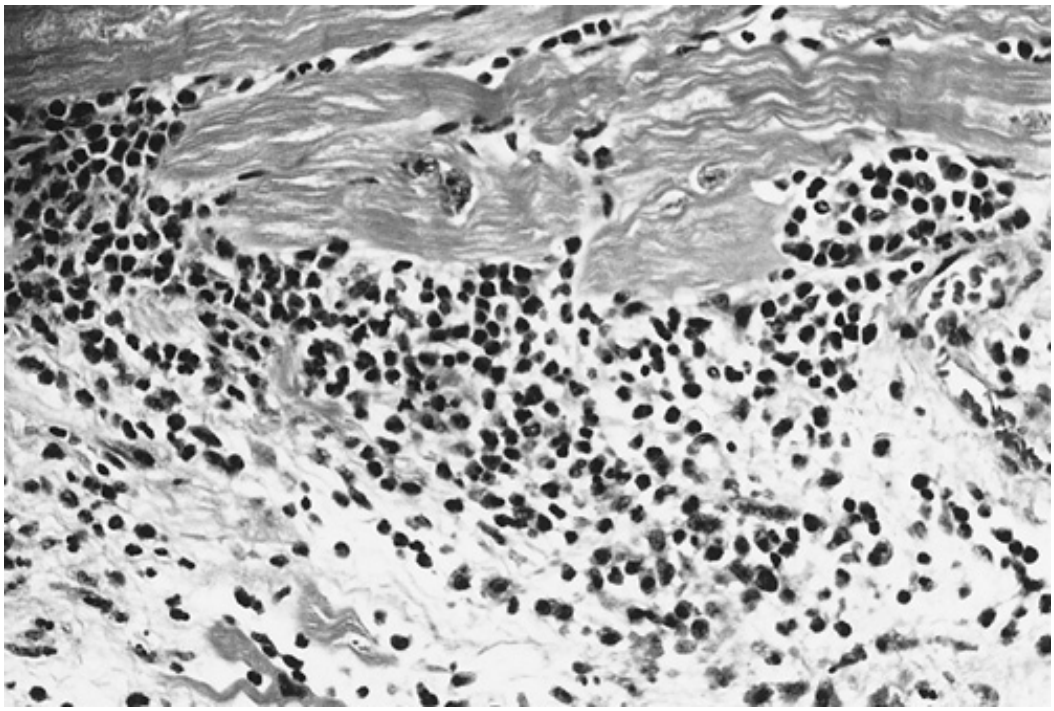

Figure 69-6: Photomicrograph showing interstitial infiltrates rich in eosinophils. (H&E, ×40.)

Table 69-4: Drug Causes of Eosinophilic Myocarditis

Drug	
Acetazolamide	Oxyphenylbutazone
Amitriptyline	Para-aminosalicylic acid
Amphotericin B	Penicillin
Ampicillin	Phenindione
Carbamazepine	Phenobarbital
Cefaclor	Phenylbutazone
Chloramphenicol	Phenytoin
Chlorthalidone	Spironolactone
Desipramine	Streptomycin
Hydrochlorothiazide	Sulfadiazine
Indomethacin	Sulfisoxazole
Interleukin-4	Sulfononylureas
Isoniazid	Tetanus toxoid
Methyldopa	Tetracycline

GIANT-CELL MYOCARDITIS

Giant-cell myocarditis is an extremely rare but aggressive form of myocarditis, typically progressive and unresponsive to medical therapy.[161] This disease is most prevalent in young adults, with a mean age at onset of 42 years (and a range of 16 to 69 years). Association with other autoimmune disorders is reported in approximately 20 percent of cases. Diagnosis is made by endomyocardial biopsy. Widespread or multifocal necrosis with a mixed inflammatory infiltrate including lymphocytes and histiocytes is required for histologic diagnosis. Eosinophils are frequently noted, as are multinucleated giant cells in the absence of granuloma (Fig. 69-7). Immunophenotyping of the cellular infiltrate has shown lymphocyte populations composed of T-helper or in some cases T-suppressor cells.

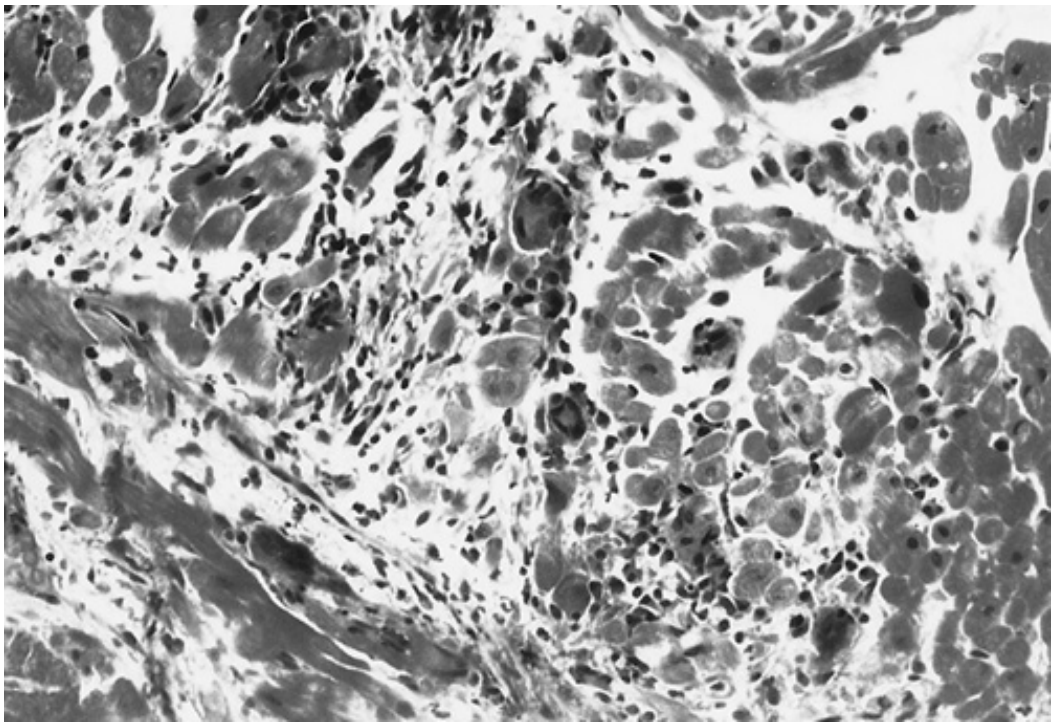

Figure 69-7: Photomicrograph showing extensive myocyte damage and infiltrates of mononuclear cells and numerous multinucleated giant cells. (H&E, ×60.)

The clinical course is usually characterized by progressive CHF and is frequently associated with refractory ventricular arrhythmia.[162] It is almost uniformly and rapidly fatal. Comparison of survival of patients with giant-cell myocarditis with that of patients with lymphocytic myocarditis demonstrates significantly worse survival in those patients with giant-cell disease (Fig. 69-8). There have been rare reports of response to aggressive immunosuppressive regimens that include cyclosporine and azathioprine in addition to corticosteroids.[162,163] Use of immunosuppressive therapy in these patients appears to prolong survival. Cardiac transplantation represents the best treatment option, though most patients expire prior to identification of a suitable donor. Giant-cell myocarditis may recur following cardiac transplantation, but the frequency of recurrence is unknown. Giant cells can be detected on routine surveillance biopsies up to 9 years posttransplant. This cellular infiltrate may respond to an increase in immunosuppressive therapy.

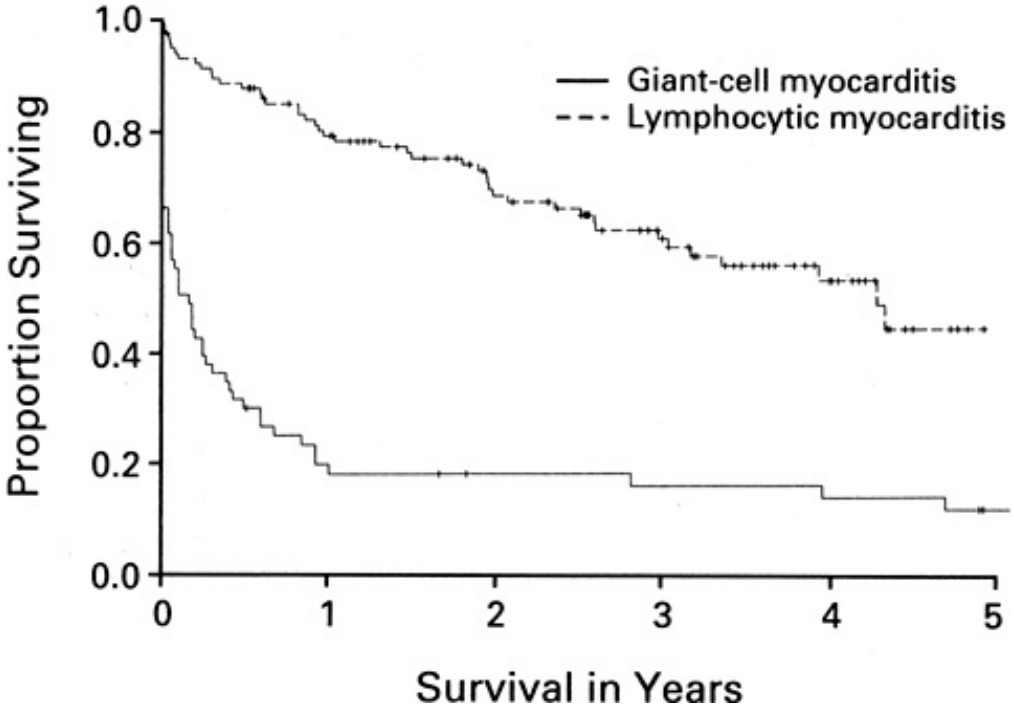

Figure 69-8: Kaplan Meier survival curves for patients with giant-cell myocarditis versus lymphocytic myocarditis. (From Cooper et al.,[161] with permission.)

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

PERIPARTUM

Peripartum cardiomyopathy is an uncommon form of CHF first described by Virchow in 1870.[164] Estimates of its incidence vary from 1 to 1300 to 1 in 15,000 pregnancies.[165] The disease occurs more commonly in obese multiparous black females over age 30.[166] Cesarean delivery, multiple gestations, preeclampsia, and chronic hypertension are other predisposing factors. Patients present with heart failure in the last trimester of pregnancy or in the first 5 months postpartum. Absence of a demonstrable cause of heart failure and structural heart disease is required to make the diagnosis. Indeed, the hemodynamic stress of pregnancy can frequently unmask previously unknown cardiac disease (see also Chap. 82).

PATHOGENESIS

The etiology of this disorder is unclear. Proposed mechanisms include nutritional deficiencies, genetic disorders, viral or autoimmune etiologies, hormonal problems, volume overload, alcohol, physiologic stress of pregnancy, or unmasking of latent idiopathic dilated cardiomyopathy. Several lines of evidence suggest that peripartum cardiomyopathy may be the result of myocarditis due to a viral illness or an autoimmune etiology.[167-172] Given the relatively immunosuppressed state of pregnancy, susceptibility to cardiotropic viruses is higher,[167] as is the viral load during infection.[168] Furthermore, studies have demonstrated that when cardiac output rises, as is the case in pregnancy, myocardial viral lesions worsen.[169] Additionally, several studies have demonstrated histologic evidence of myocarditis on endomyocardial biopsy samples obtained from patients with peripartum cardiomyopathy.[170-172] Other investigators have postulated an autoimmune etiology to peripartum cardiomyopathy, specifically immunologic responses to fetal and endometrial antigens that cross-react with the patient's myocytes. In one case report, a patient with peripartum cardiomyopathy had antibodies to smooth muscle and actin produced in response to actin and myosin released during uterine degeneration after delivery. These antibodies later cross-reacted with the myocardium and induced cardiomyopathy.[173]

CLINICAL PRESENTATION

The presentation is that of heart failure. Presenting symptoms include shortness of breath, dyspnea on exertion, edema, palpitations, syncope, sudden death, and thromboembolic phenomena. The incidence of thromboembolism is high due to the hypercoagulability of pregnancy. Physical findings are notable for S3, S4, tricuspid or mitral insufficiency murmurs, edema, rales, ascites, hepatomegaly, jugular venous distension. The ECG frequently shows left ventricular hypertrophy. Echocardiographic findings can range from single-chamber left ventricular enlargement to four-chamber dilatation. In a small percentage of patients, endomyocardial biopsy may reveal myocarditis, but generally the findings are nonspecific.

PROGNOSIS AND TREATMENT

Too few patients with peripartum cardiomyopathy have been studied to fully analyze the natural history of the disease. In a small series of 27 patients, left ventricular size was analyzed at 6 months; 14 patients (50 percent) had normal dimensions. None of these patients died of CHF-

compared with 85 percent of those patients with persistent cardiomegaly, who died from CHF within 5 years.[174] The authors concluded, therefore, that if the congestive cardiomyopathy persists for more than 6 months, it is likely to be irreversible and to be associated with a worse prognosis. Similar findings were published in another series by O'Connell et al.[83] These authors also noted that those patients with higher ejection fractions and smaller ventricular diastolic dimensions at the time of diagnosis have a better long-term prognosis. Other prognostic studies suggest that those patients with persistent symptoms more than 2 weeks postpartum have a worse prognosis, raising the question as to whether this disorder has different etiologies.[175] The role of corticosteroids in the treatment of this disorder is controversial.[170,171] The incidence of thromboembolism is high due to the hypercoagulabilty of pregnancy; therefore anticoagulation is recommended.[175]

Patients with refractory heart failure referred for transplant have a survival posttransplant comparable with that of patients with idiopathic dilated cardiomyopathy, though higher early rejection rates are noted.

In patients with stable heart failure or recovery of left ventricular function, the possibility of subsequent pregnancy must be addressed. There are several case reports of patients with this diagnosis who went on to subsequent pregnancies. The outcomes of these patients are variable, with a few having uneventful pregnancies and others developing an exacerbation or recurrence of fulminant heart failure. Subsequent pregnancy should be viewed as high risk and all patients with this disorder should be counseled on birth control and even sterilization.

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

HYPERTROPHIC AND FAMILIAL

Hypertrophic cardiomyopathy is characterized by disproportionate hypertrophy primarily of the left ventricle (Fig. 69-9) and occasionally the right ventricle. It most typically involves the septum but can also be concentric[176] and occurs in the absence of a recognizable stimulus to hypertrophy. This has led many to postulate and subsequently demonstrate a genetic basis to this disease.[177] Inheritance is of an autosomal dominant pattern; however, the phenotypic expression of this disease as measured by echocardiography is highly variable and reflects the different genetic mutations and incomplete penetrance.[178-180] The identification of certain well-characterized genetic abnormalities offers some measure of prognostication. Several familial hypertrophic cardiomyopathy-causing mutations have been characterized in the genes encoding sarcomeric contractile proteins-namely, the beta-myosin heavy chain,[181] cardiac troponin T,[178] alpha tropomyosin,[178] and cardiac myosin-binding protein C.[182,183] Previous theories suggested that variations resulting in a change in charge of the substituted amino acid were associated with a poor survival index.[184,185] However, the genotypic-phenotypic correlation is not always preserved. For example, a cytosine-for-guanine mutation hot spot responsible for familial hypertrophic cardiomyopathy has also been described in the beta-myosin heavy chain. In both mutations, a basic residue is replaced by an uncharged one. However, in one mutation, where glutamine replaces arginine, the mutation has a malignant phenotype; in the other, where tryptophan replaces arginine, the phenotype is that of mild hypertrophy with no sudden death.[186,187]

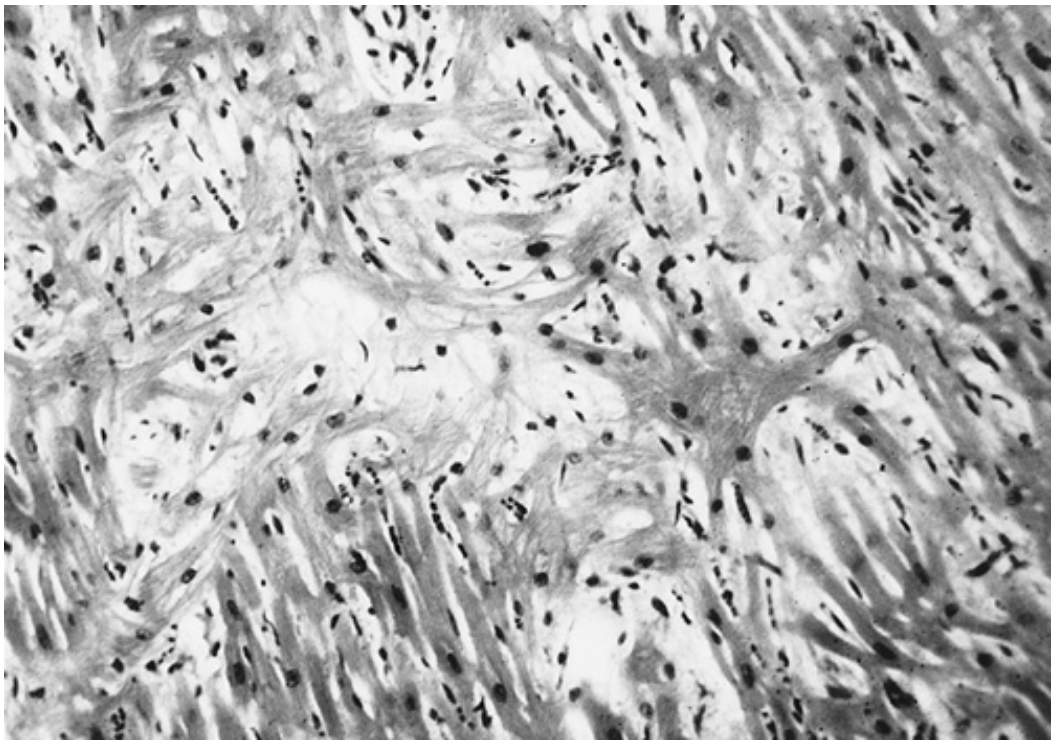

Figure 69-9: Photomicrograph showing significant myocyte disarray in hypertrophic cardiomyopathy. (H&E, ×40.)

Predicting the clinical course and outcome for individual patients with HCM has thus proved difficult.[188,189] In unselected populations, premature mortality is estimated at about 1 percent.[186] Sudden death is most common in the 12- to 35-year age group[190] and typically occurs in those who have previously been asymptomatic.[189] Most patients die while sedentary or during mild exertion; a substantial proportion collapse during or just after vigorous physical activity,[190] which forms the rationale for prohibiting sports participation for those afflicted with hypertrophic cardiomyopathy.

The mechanism of sudden death in hypertrophic cardiomyopathy is complex and probably multifactorial.[191] Recurrent syncope is the only symptom that has been shown to be reliably associated with subsequent sudden death.[192] Other proposed risk factors include prior cardiac arrest, sustained ventricular tachycardia, massive left ventricular hypertrophy, a malignant genotype or a previous family history of sudden premature death, repetitive salvos of nonsustained ventricular tachycardia on Holter monitoring, and early onset of symptoms in childhood.[193-196] The main forms of therapy have been primarily beta blockade, calcium channel blockers, amiodarone, and implantable cardioverter-defibrillators, with conflicting data on their impact on mortality.[197] Cardiac transplantation is pursued when significant symptomatic systolic dysfunction develops.[198]

As in the case of the myosin mutations noted in the hypertrophic cardiomyopathies, single genetic defects are presumed to underlie the dilated cardiomyopathies that have been described in several large families. There has been recent evidence that dilated cardiomyopathy is more frequently familial than generally realized.[199] In a single-center study of 96 patients with a diagnosis of idiopathic cardiomyopathy, approximately 20 percent had a familial basis.[200] Other studies have estimated a familial role in up to 50 percent of cases when firstdegree relatives are carefully screened.[201] The influence of a preceding viral infection,[202] alcohol use,[203] or pregnancy[204] on the clinical manifestation of cardiomyopathy in familial situations remain unclear.

Neuromuscular Diseases

Several heritable neuromuscular dystrophies may be associated with cardiomyopathy. Included in this category are diseases such as Beckel's, Duchenne's, and X-linked cardioskeletal myopathy, myotonic dystrophy (Stingert's disease), congenital myotonic dystrophy, limb-girdle muscular dystrophy (Erb's disease), familial centronuclear myopathy, Dugelberg-Welander syndrome, Friedreich's ataxia and Barth's syndrome. The myocardial involvement, natural history, and prognosis of each of these disorders are variable.

Duchenne's dystrophy is an X-linked disease with proximal muscle weakness and cardiomyopathy. A dystrophin gene mutation is responsible. Death usually results from respiratory and/or cardiorespiratory failure. Patients with myotonic dystrophy present between age 20 and 50 years, usually with arrhythmias.

Several mitochondrial myopathies have also been described.[177,205] Mitochondria are essential cellular organelles that convert oxygen to biochemically useful energy. Additionally, mitochondria function as calcium storage sites and modulators of cellular pH. As such, mitochondrial function affects muscle and ventricular function. Mitochondria are unique organelles with their own maternally inherited DNA, which encodes several respiratory chain proteins. Genetic defects in the mitochondrial respiratory chain enzymes-specifically complexes I, III, and IV-have been recognized as the cause in some cardiomyopathies. The presentation in mitochondrial myopathies is extremely heterogeneous, as each cell will contain a mixture of

normal and mutant DNAs. Deletion mutations in DNA can occur and are frequently observed in these myopathies.

Mitochondrial myopathies include such disorders as Kearns-Sayre syndrome, chronic ophthalmoplegia, myoclonic epilepsy, ragged-red-fiber disease, and mitochondrial encephalomyopathy. The MELAS syndrome-mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes-is associated with cardiomyopathy and generalized microangiopathy. Kearns-Sayre syndrome results from a deletion mutation in mitochondrial DNA. This ocular myopathic disease is associated with dilated or hypertrophic cardiomyopathy with cardiac conduction defects.

Defects in transport of molecules from the cytoplasm into the mitochondria have also been associated with cardiac and skeletal myopathy. One example is that of carnitine deficiency, discussed later in this chapter.

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

INFILTRATIVE

The infiltrative cardiomyopathies comprise several acquired and heritable conditions; these include amyloidosis, hemochromatosis, carcinoid, sarcoidosis, glycogen storage disease, endocardial fibroelastosis, and endomyocardial fibrosis due to hypereosinophilic syndromes or other collagen vascular disorders such as scleroderma or Churg-Strauss syndrome.

Amyloid

CLASSIFICATION AND PATHOGENESIS

The most commonly encountered of the infiltrative cardiomyopathies is amyloidosis, leading to an overproduction of a monoclonal immunoglobulin protein that is deposited throughout the body. Secondary amyloidosis results from the deposition of a protein other than immunoglobulin. Whereas primary amyloid has no associated systemic diseases, other chronic diseases are present in the secondary form. Secondary amyloidosis may result from familial, senile, or chronic inflammatory processes (rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, Crohn's disease, tuberculous paraplegia associated with decubitus ulcers, cystic fibrosis, and heroin use with chronically infected cutaneous injection sites). Familial Mediterranean fever is an autosomal recessive inherited disease of Sephardic Jews, Armenians, and other Mediterranean peoples associated with amyloid deposition. In the familial diseases, more than 40 different genetic mutations of the plasma protein transthyretin (prealbumin) have been associated with amyloid deposition. Inheritance is autosomal dominant, with the genetic defect being confined to a single amino acid substitution in the mature protein.[206,207]

The frequency of cardiac involvement varies with the different etiologies. Of patients with primary amyloid, one-third to one-half have cardiac involvement and more than one-fourth have symptomatic heart failure. Cardiac involvement in patients with secondary amyloidosis is much less frequent. Indeed, in amyloid due to chronic inflammatory processes, amyloid protein deposition is usually limited to the intima and media of arterioles and not the heart. Familial amyloidosis is the rarest form of systemic amyloidosis, affecting only about 4 percent of cases; however, cardiomyopathy is present in 68 percent of those affected. Familial amyloidosis can manifest initially with progressive neuropathy, cardiomyopathy, or renal involvement. In some of the families, cardiac amyloidosis is not even symptomatic, while in others cardiac symptoms predominate. Senile cardiac amyloidosis is common in the elderly but often does not lead to a clinical cardiac syndrome and is only detected postmortem.[208]

CLINICAL PRESENTATION

Amyloid fibrils are rigid and as such lead primarily to relaxation abnormalities and diastolic dysfunction; however, when myocardial replacement occurs, systolic dysfunction becomes a prominent feature.[209] The cardiomyopathy may be restrictive or congestive in nature. Systolic left ventricular function deteriorates late in the disease process only after marked amyloid deposition.[210-217] The clinical presentation is that of congestive heart failure, with a more frequent occurrence of right-sided symptoms. Sudden death and myocardial infarction may result from vascular involvement. Atrial arrhythmias, from infiltration of atrial tissue with amyloid, are not

uncommon.

DIAGNOSIS

Diagnosis is made by characteristic echocardiographic features and endomyocardial biopsy.[218] Echocardiography can demonstrate symmetric thickening of the left ventricular wall with a diffuse hyper-refractile, granular sparkling appearance of the myocardium (Fig. 69-10*A*) (see also Chap. 13). Abnormal left ventricular diastolic filling manifested by reduction in the rate, in the volume of rapid diastolic filling with enhanced atrial contraction can be seen very early in cardiac amyloidosis.[219] The ECG typically demonstrates low voltage despite marked hypertrophy on echo (Fig. 69-10*B*). A pseudoinfarct or postinfarct anterior wall pattern is often present.[220] Cardiac involvement is generally present when mean left ventricular wall thickness on echocardiogram is greater than 11 mm in the absence of a history of hypertension or valvular heart disease, with unexplained low voltage (<0.5 mV) on the ECG. The majority of patients presenting with cardiac involvement have a monoclonal protein spike in the serum or urine reflecting the primary nature of the disease.[210]

Amyloid is detected easily in endomyocardial biopsy specimens using Congo red staining and is seen in the interstitium in a pericellular or nodular pattern, in the endocardium, or in myocardial blood vessels. Sulfated alcian blue, methyl violet, and thioflavine T are other histochemical stains used to detect cardiac amyloid (Fig. 69-10*C*). Immunoperoxidase stains for kappa and lambda light chains and for prealbumin may categorize the type of cardiac amyloid. Electron microscopic examination of biopsy specimens is likely the most sensitive method of recognizing amyloidosis (Fig. 69-10*D*).

Radionuclide imaging using technetium-99m pyrophosphate and indium-111 antimyosin showing increased diffuse uptake can also be used to diagnose cardiac amyloidosis.

TREATMENT

Prognosis is typically poor and treatment ineffective.[221] Increased myocardial concentrations of digoxin may occur from binding of the drug to amyloid fibrils, thus increasing the propensity for digoxin toxicity. Digoxin should therefore be used with caution in these patients. Prognosis depends on the extent of myocardial involvement, but once heart failure is present, the prognosis is poor, with a 5-year survival less than 5 percent. Indeed, patients with primary amyloidosis who fall into New York Heart Association (NYHA) class 3 or have recurrent cardiac syncope rarely survive for more than 6 months. Echocardiography with Doppler assessment can provide prognostic information. A shortened deceleration time and an increased ratio of early diastolic filling velocity to the atrial filling velocity were more powerful predictors of mortality from cardiac causes than left ventricular wall thickness or fractional shortening.[222-224]

A recent clinical trial comparing colchicine to the combination of melphalan, prednisone, and colchicine failed to demonstrate any survival benefit in cases of cardiac amyloid. Stem-cell transplant as treatment for primary amyloidosis is now being investigated.

Because of recurrence in the transplanted heart, results following heart transplantation have proved disappointing.[225] The immediate and early postoperative outcomes are similar to those in patients undergoing transplantation for other cardiac diseases; however, late survival is reduced (39 percent at 48 months) owing to recurrence of the disease in the transplanted organ and progressive disease in other organ systems. With the continuing donor shortage, the outcome associated with primary amyloidosis is unacceptable to the majority of cardiac transplant centers. In the future, combined cardiac and bone marrow transplant may provide successful treatment.

Sarcoidosis

PATHOGENESIS

Sarcoidosis is a systemic granulomatous disease of unknown etiology characterized by enhanced cellular immune responses. The pathologic hallmark of this disease is the noncaseating granuloma (Fig. 69-11). The initial lesion is an inflammatory infiltrate consisting of activated helper-inducer T lymphocytes and abundant macrophages that secrete cytokines. The macrophages aggregate and differentiate into epithelioid and multinucleated giant cells. Fibroblasts, mast cells, collagen fibers, and proteoglycans encase the inflammatory cells into a ball-like cluster. The fibrotic response results in end-organ damage.

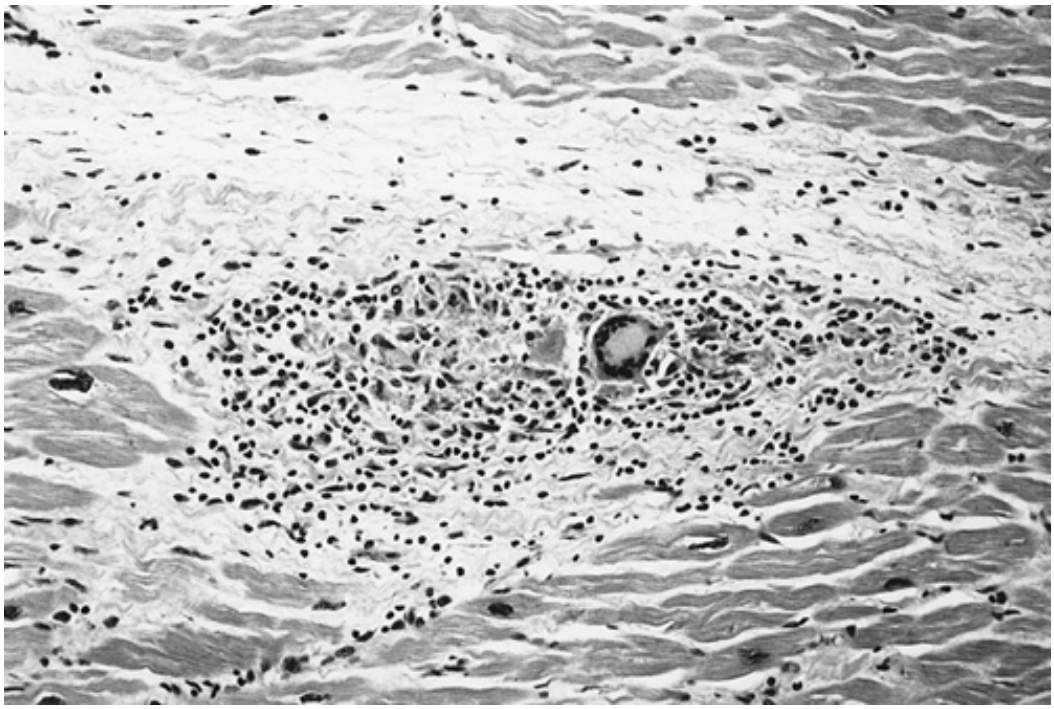

Figure 69-11: Photomicrograph showing interstitial noncaseating granulomas with a multinucleated giant cell. (H&E, ×40.)

Clusters of cases have been observed, suggesting spread by person-to-person exposure or environmental agents/pathogens. Genetic factors may also play a role in the development of the disease, as an exaggerated cellular immune response and the formation of granulomas may develop in genetically predisposed hosts after exposure to the offending antigen.

CLINICAL PRESENTATION

The clinical manifestations of sarcoidosis are protean. The disease may be widespread or limited to a single organ. Virtually any organ except the adrenal gland may be involved. The lymphoid, pulmonary, cardiovascular, hepatobiliary, and hematologic systems are the most commonly involved, with the lungs being affected in over 90 percent of patients.[226-228]

Cardiac sarcoid is more common than previously recognized. In a recent autopsy study of 38 patients with sarcoidosis, 76 percent had cardiac involvement, accounting for 50 percent of the deaths. In other series, sarcoidosis affected the heart in 25 to 50 percent of autopsy cases with fatality in 50 percent of the cases with cardiac involvement.[229] Cardiac sarcoid is more likely fatal

and less likely to be diagnosed antemortem than pulmonary sarcoid. Frequently the initial presentation is that of sudden death. Myocardial involvement peaks between the third and sixth decades of life. Less than 10 percent of patients with sarcoid have symptoms referable to the cardiovascular system.

In myocardial sarcoid, portions of the myocardial wall are replaced by sarcoid granulomas, which preferentially involve the cephalad portion of the ventricular septum or the left ventricular papillary muscles.[230] Myocardial involvement is much more common than pericardial involvement.[226231-234] Cor pulmonale due to extensive pulmonary sarcoidosis with interstitial fibrosis may occur.

Because of the varied extent and location of the myocardial granulomas, presenting signs and symptoms range from first-degree heart block to fulminant heart failure.[235] First-degree AV block, bundle-branch block, complete heart block, ventricular arrhythmias, sudden death, and heart failure occur with a frequency of 10 to 20 percent.[235] Heart failure can present as a cardiomyopathy with restrictive hemodynamics or systolic dysfunction. Some 25 percent of the deaths due to cardiac sarcoid are from heart failure, while sudden death accounts for one-third to one-half of the deaths.

DIAGNOSIS

In diagnosing cardiac sarcoid, evidence of other organ system involvement including lymphadenopathy, hepatomegaly, splenomegaly, or pulmonary findings should be sought. In cases where the heart is involved to a much greater degree than are other organs, little or no evidence of extracardiac sarcoidosis may be found. Chest x-ray, ECG, and echocardiography findings will depend on the extent and location of involvement. Due to the scattered nature of the granulomas, endomyocardial biopsy lacks sensitivity and seldom makes the diagnosis despite high specificity. Magnetic resonance imaging has been useful in diagnosing scars or lesions in the myocardium due to sarcoid.[236]

TREATMENT

Although no controlled trials have been performed, high-dose corticosteroids are usually given in the hope that the course of disease may be altered. Administration of corticosteroids can improve cardiac symptoms and reverse ECG changes in over half of the treated patients.[237] Antiarrhythmic drugs should be used as necessary, although drug therapy of ventricular tachycardia in patients with sarcoidosis, even when guided with programmed ventricular stimulation, is associated with a high rate of arrhythmia recurrence or sudden death.[238] Automatic internal cardioverter-defibrillators have been advocated. Prognosis after the diagnosis of cardiac sarcoid is variable but can be poor.[227] In one series of 247 patients, survival was 41 percent at 5 years and 15 percent at 10 years.[226,239] Transplantation is also a successful treatment, as the recurrence of sarcoid in the allograft is low, possibly due to posttransplant steroid therapy.[240]

Hemachromatosis

Primary hemachromatosis is an inborn error of metabolism leading to iron deposition in a variety of organs, including the heart, and resultant secondary myocardial fibrosis. Both restrictive and dilated presentations can occur.[241,242] In contrast to amyloidosis, treatment with phlebotomy[243] is highly effective. In the secondary forms of hemachromatosis due to multiple blood transfusions for blood dyscrasias, chelation therapy is highly effective. Diagnosis is made by symptom constellation in the presence of an elevated serum iron and ferritin. Endomyocardial biopsy is diagnostic (Fig. 69-12).

Carcinoid

Carcinoid heart disease typically leads to a restrictive pattern and often has asymmetrical involvement due to the predilection of the carcinoid for the tricuspid valve apparatus.[244,245] Diagnosis is generally made with right-sided heart findings in the setting of systemic features of carcinoid syndrome. Cardiac involvement responds favorably to control of the primary tumor with chemotherapy or catheter embolization.[244] Tricuspid valve replacement and/or pulmonary valvulotomy and outflow tract enlargement have been recommended when hemodynamically indicated.[244] Alternatively, balloon valvuloplasty for tricuspid or pulmonary stenoses has been used successfully[246] (see also Chaps. 59 and 77).

There are other heritable lesions leading to infiltrative cardiomyopathy. Pseudoxanthoma elasticum (also known as endocardial fibroelastosis) is an inherited disorder of elastic tissue metabolism that leads to a thickening and calcification of the endocardium.[247] Similarly, a number of metabolic inherited disorders cause massive infiltration of the myocardium in infancy and childhood. The best known is Pompe's disease, which is an autosomal recessive disorder caused by a deficiency of the enzyme α-glucosidase, leading to massive glycogen deposition in the cardiac and skeletal musculature. Interestingly, the pathophysiology resembles that of hypertrophic rather than restrictive cardiomyopathy.[248] Prognosis is poor, with no known therapy. Death typically ensues within the first year of life.

Eosinophilic Heart Disease

Eosinophilic heart disease was originally described several decades ago by Löffler,[249] who reported the observation of endocardial lesions, termed "endocarditis parietalis fibroplastica," in association with blood eosinophilia. Although initially thought to represent an isolated disease, Löffler's syndrome is now recognized to be only one manifestation of a spectrum of hypereosinophilic syndromes. Recently cases of isolated eosinophilic myocarditis without signs of endocardial involvement, with or without vasculitis, have been described.[250] Hypereosinophilic syndromes are characterized by peripheral eosinophilia and endocardial disease consisting of eosinophilic infiltration, fibrosis, and eventual occlusion of the ventricular cavity by scar and thrombus.[251] This leads to a very severe form of restrictive myocardial disease referred to as *obliterative myocardial disease*.[252]

PATHOGENESIS

Löffler's endomyocardial disease is considered to be an immunologic disorder caused by clones of abnormal eosinophils infiltrating both sides of the heart. This group of diseases may begin with myocarditis due to the direct toxic effects of the eosinophils and their granules.[253] Indeed, hypersensitivity myocarditis, discussed earlier in this chapter, may be an early variant of this disease. Chronic disease culminates in endomyocardial fibrosis after the disappearance of the initial eosinophilia.[254] The eosinophilic endocardial disease has since been well described[255,256] and is characterized by intense endocardial fibrotic thickening of the apex and subvalvular regions of one or both ventricles. These changes lead to inflow obstruction and restrictive physiology.

CLINICAL PRESENTATION

Löffler's syndrome was initially described primarily in men from temperate climates in their fourth decade of life with a hypereosinophilic syndrome. Diffuse organ involvement may be observed (lungs, bone marrow, brain), with cardiac involvement in more than 75 percent of patients. The typical clinical presentation includes weight loss, fever, cough, skin rash, and congestive heart failure. Overt cardiac dysfunction occurs in about half the patients and is the leading cause of death. Chest x-ray reveals cardiomegaly. ECG findings most commonly include

nonspecific ST- and T-wave changes, atrial fibrillation, and right bundle-branch block. Echocardiography commonly demonstrates localized thickening of the left ventricle with valvular leaflet abnormalities[257] and atrial enlargement due to atrioventricular valvular regurgitation and restrictive physiology. In cases of advanced endomyocardial fibrosis, there may be apical obliteration by thrombus[253] but normal systolic function.

Diagnosis is easily established in the acute phase by endomyocardial biopsy and typical ECG images.[252] Variable degrees of acute inflammatory eosinophilic myocarditis are observed. Marked changes can be seen histologically in the coronary vessels, including inflammatory, fibrotic, and thrombotic changes typically containing eosinophils. Fibrotic thickening of up to several millimeters[253] can be observed. Mural thrombosis is common.

Medical therapy with corticosteroids and cytotoxic drugs[159,257,258] in the early stages of disease may substantially improve survival. Routine therapy for heart failure with digitalis, diuretics, afterload reduction, and anticoagulation are adjuncts in the management of these patients. Surgical therapy offers palliation once the later fibrotic stages have been reached.[259]

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

CARDIOMYOPATHY DUE TO PERSISTENT TACHYCARDIA

Incessant supraventricular or ventricular tachycardia can lead to severe dilated cardiomyopathy in both animals and humans.[260] Successful medical or surgical treatment of the tachyarrhythmia can lead to resolution of the myopathy. The mechanism between the sustained tachycardia and the development of cardiomyopathy is unknown but may be related to depletion of high-energy substrates.

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

CARDIOMYOPATHY DUE TO RIGHT VENTRICULAR DYSPLASIA

Right ventricular dysplasia is a cardiomyopathy predominantly of the right ventricle. Left ventricle involvement is usually of a lesser and variable degree. Several anomalies may be included under this general heading: Uhl's anomaly,[261] arrhythmogenic right ventricular dysplasia,[262] and right ventricular cardiomyopathy.[263] It is currently recognized as an important inherited cardiomyopathy and a cause of sudden death, especially in youth.[264] Its cause is unknown, although an autosomal dominant pattern with variable expression and penetrance has been suggested, since many cases show a strong familial tendency.[265]

Clinically patients typically present with recurrent ventricular tachycardia of left-bundle-branch-block morphology and, less commonly, CHF. Standard electrocardiography discloses incomplete or complete right-bundle-branch block in most patients or T-wave inversions in leads V_1-V_3 (Fig. 69-13*A*). These conduction or repolarization abnormalities are thought to be due to adipose infiltration of the myocardium. Clinical diagnosis is based on detection of predominantly right ventricular morphologic changes on imaging studies. Echocardiography is an effective tool to demonstrate the characteristic abnormal structure[266] of the right ventricle, including hypokinesis, massive dilatation, and a "parchment-thin" wall[267] (Fig. 69-13*B*). In addition, tricuspid regurgitation and paradoxic ventricular septal wall motion are common. Pathologically, there is variable infiltration or replacement of the right ventricular myocardium by adipose and fibrous tissue.[268]

The importance of right ventricular dysplasia is its association with sudden death, with an incidence of up to 20 percent in some series.[264] Therapy therefore is focused on the prevention of sudden death with implantation of automatic internal cardioverter-defibrillators.

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

CARDIOMYOPATHY DUE TO ENDOCRINE DISORDERS

Thyroid

Thyroid hormone has long been recognized to affect the heart and the peripheral vasculature.[269] Changes in cardiac function are mediated by T3 regulation of cardiac-specific genes.[270] Thyroid hormone metabolism is frequently abnormal in patients with CHF. In a study of 84 patients with advanced heart failure, T3 levels were found to be low.[271] Furthermore, a low T3/reverse T3 ratio was the only independent predictor of prognosis when a multivariate regression analysis was performed with known predictors of poor outcome such as ejection fraction, serum sodium, or hemodynamic variables. The low conversion to T3 was postulated to be an adaptive mechanism to decreased catabolism. In a subsequent study, Hamilton et al. studied the effects of intravenous T3 infusion to patients with class III or IV heart failure.[272] Cardiac output increased without a change in left ventricular ejection fraction or filling pressures. This was thought to be secondary to the effects of T3, causing vascular smooth muscle dilatation and therefore peripheral vasodilation. In another study of thyroid hormone replacement in heart failure, 20 patients with class II and III idiopathic dilated cardiomyopathy were given L-thyroxine orally.[273] Cardiac output improved, peripheral vascular resistance decreased, and exercise performance increased. The improved exercise performance was explained by a higher oxygen consumption at peak exercise due to improved oxygen uptake by skeletal muscle, increased perfusion of the musculature, or improved muscle metabolism by local action of L-thyroxine occurring during training. Similar results were obtained in a study by Moruzzi and colleagues.[274] In this series of 20 patients, ejection fraction, cardiac output, and left ventricular diastolic dimensions all increased. Functional capacity and peak exercise cardiac output also improved. The beneficial effects were sustained with the longer therapy regimen.

Like thyroid deficiency, thyroid toxicity can lead to the development of both high-output and low-output cardiac failure. A prolonged tachycardia and high-output state caused by thyrotoxicosis is thought eventually to produce left ventricular dilatation. A consequent progressive decline in systolic function leads to low-output heart failure. This process can often be reversed by reduction of excess hormone levels. In a study of 7 patients with a dilated cardiomyopathy and hyperthyroidism, Umpierrez et al. demonstrated echocardiographic normalization of left ventricular function after treatment with propylthiouracil or methimazole.[275]

Pheochromocytoma

Hypertension and its sequelae are the major cardiovascular manifestations of pheochromocytoma. However, there have been reports of a specific catecholamine-induced myocarditis[276] and/or cardiomyopathy.[277-279] Degenerative and fibrotic myocardial changes have been described in autopsy specimens of patients dying of suprarenal tumors.[276] Although progression to cardiac involvement is unusual, when the presentation of the tumor is aggressive, pheochromocytoma patients typically die of cardiovascular causes, most commonly congestive heart failure or malignant ventricular arrhythmias.[276,277] In the largest series, 15 of the 26 patients with proven pheochromocytomas had a pathologic diagnosis of myocarditis at autopsy.[276] Hemodynamic stabilization is generally obtained with alpha and beta blockers, and prompt adrenalectomy is required to eliminate catecholamine-induced cardiotoxicity. The cardiac abnormalities can be

reversed with tumor resection[280,281] (see also Chap. 51).

Acromegaly

It is not clear whether acromegalic cardiomyopathy is a specific entity or is secondary to the hypertension or atherosclerosis associated with this condition. However, 10 to 20 percent of patients with acromegaly develop congestive heart failure.[282] The congestive heart failure that develops in these patients is particularly resistant to conventional therapy[283] owing to higher collagen content in the acromegalic heart.[282] Histopathologically, the myocytes display cellular hypertrophy, patchy fibrosis, and myofibrillar degeneration. Inflammatory and degenerative damage to the sinoatrial and AV nodes can lead to sudden death.[283] Surgery and irradiation remain the mainstays of therapy, but often the cardiopathic manifestations persist despite a fall in growth hormone levels.[284]

Diabetes

Analysis of the Framingham data showed that the risk of developing heart failure was substantially increased among diabetic patients. Even after exclusion of patients with prior coronary or rheumatic disease and controlling for age, hypertension, obesity, and hypercholesterolemia, the diabetic patients have a fivefold increased risk of developing congestive heart failure.[285] This increased incidence suggested that the metabolic abnormalities associated with diabetes may contribute to myocyte dysfunction and produce a diabetes-induced cardiomyopathy. Histologically, this cardiomyopathy shows no evidence of epicardial atherosclerotic disease or abnormalities in myocardial capillary basal lamina.[286,287] Typically, interstitial fibrosis and arteriolar hyalinization are present. Clinically both systolic and diastolic dysfunction can occur, and the severity of the dysfunction is related to the degree of metabolic control.[288]

PREVIOUS | NEXT

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

OBESITY

Heart failure in the markedly obese is usually chronic. It often occurs due to reduction in left ventricular compliance due to the increases in left ventricular mass and resultant elevations of filling pressures. The chronic increases in cardiac work due to an increased myocardial output and arterial hypertension ultimately lead to systolic dysfunction. With exercise and weight reduction, left ventricular mass decreases[289] and function improves.[290] The improvement in function, however, seems limited to those patients whose obesity was of relatively short duration.[291]

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

TOXINS

Alcohol

Congestive cardiomyopathy as a result of chronic alcohol abuse accounts for up to 45 percent of all dilated cardiomyopathies.[292] The untoward effects of alcohol on cardiac function were initially described more than 100 years ago. As an estimated 10 percent of the adult population are heavy alcohol users, cardiac toxicity from alcohol is a major problem.

PATHOGENESIS

The cardiodepressant effects of alcohol have been demonstrated following acute and chronic ingestion in animal models and in normal and alcoholic human subjects. Chronic excessive alcohol use can result in congestive heart failure, hypertension, and arrhythmias. Cardiac damage results from direct toxic effects of alcohol or one of its metabolites. Nutritional deficiencies, toxic cofactors, sympathetic stimulation, or coexistent hypertension may also contribute to disease development.[293]

Orally ingested alcohol is converted in the liver to acetaldehyde by the alcohol dehydrogenase enzyme system. Acetaldehyde is then converted into acetic acid by oxidation via acetaldehyde dehydrogenase. The activity of these enzyme systems varies greatly between individuals and in particular between races. Thus, depending on individual enzyme system activity, there are varying levels of alcohol and acetaldehyde concentrations after ingestion of an alcoholic beverage. Alcohol and acetaldehyde are both potent vasodilators. Additionally, acetaldehyde results in marked catecholamine release. Both alcohol and acetaldehyde interfere with a variety of cellular metabolic functions, including calcium transport and binding, lipid metabolism and fatty acid composition of the sarcolemma, protein synthesis, myofibrillar ATPase, and mitochondrial respiration.[292,294] Though ethanol can interfere with a number of myocardial metabolic steps, no predominant factor has been identified. Recently a nonoxidative pathway for the metabolism of alcohol in several organ systems including the heart has been described.[295] Nonesterified fatty acids are esterified with ethanol to produce fatty acid ethyl esters (FAEE). These molecules can accumulate in mitochondria and impair cellular function. Fatty acid ethyl esters are synthesized at high rates in the heart owing to the lack of oxidative ethanol metabolism in this organ. Other studies have demonstrated interference with lipid metabolism leading to triglyceride accumulation and alteration of the fatty acid composition of the sarcolemma.[292] Increased levels of acyl-CoA from enhanced glycerol acyltransferase activity may lead to triglyceride accumulation. The cellular membrane shows reduced changes results in decreased calcium uptake by the sarcolemma. Alcohol also is found to be an inhibitor of the sodium-potassium ATPase.

For many years, alcoholic cardiomyopathy was believed to be due to nutritional deficiencies. The stereotypical malnourished skid-row derelict could have a variety of nutritional deficiencies. Indeed, those subjects with heavy beer consumption could develop thiamine deficiency. As beer contains no thiamine, the consumption of this high-calorie, high-carbohydrate beverage can exhaust existing thiamine stores, particularly in the presence of a deficient diet. Thus, a small percentage of patients with alcohol cardiomyopathy may have coexistent thiamine deficiency. However, the majority of patients develop this disease despite adequate diets.[293]

Contamination of alcoholic beverages with heavy metals has resulted in heart failure. In the nineteenth century, an epidemic of heart failure occurred in Manchester, England, following accidental contamination of the beer with arsenic. More recently, in the 1960s, a new variant of alcoholic cardiomyopathy was described.[296] Patients presented with massive pericardial effusion, low cardiac output, elevated venous pressure, and polycythemia. After considerable medical detective work, the syndrome was linked to cobaltous chloride that was added to the beer as a foaming agent to increase and stabilize the beer head. Removal of the additive resulted in the resolution of this miniepidemic.

CLINICAL PRESENTATION

Although approximately 10 percent of the adult population are heavy drinkers, the prevalence of cardiac disease in this group is low-significantly lower than the prevalence of liver disease in the same population. Although patients with alcoholic cirrhosis may have evidence of asymptomatic myocardial disease, the simultaneous presentation of overt alcoholic liver and cardiac disease is extremely rare.[297]

The disease is observed most frequently in males age 30 to 55 years with a greater than 10-year history of heavy alcohol use. The disease is extremely rare in premenopausal women. The amount and duration of alcohol use is frequently difficult to establish. Criteria used to define heavy chronic alcohol use have included such estimates as the use of 125 mL/day of alcohol and/or 30 to 50 percent of daily calories derived from alcohol for a minimum of 10 years. In a study of 50 asymptomatic alcoholic men, Rubin et al. demonstrated that cardiomyopathy, as well as abnormalities of skeletal muscle, are common among persons with chronic alcoholism, and that alcohol is toxic to striated muscle in a dose-dependent manner.[203]

Presenting symptoms include dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, fatigue, weakness, arrhythmias, or embolic phenomena. Atrial fibrillation is extremely common, followed by atrial flutter and ventricular premature contractions. Sudden death can be the initial presentation. ECG findings include first-degree heart block, left ventricular hypertrophy, nonspecific interventricular conduction defects, bundle-branch blocks and prolongation of the QT interval. The echocardiogram frequently shows left ventricular hypertrophy, single- to four-chamber enlargement, and mural thrombi.

In animal studies, left ventricular biopsies from dogs that developed alcoholic cardiomyopathy showed an accumulation of glucoprotein-like material in the interstitium on light microscopy as well as a dilatation of the intercalated discs on electron microscopic evaluation. These studies also demonstrated abnormalities of the sarcoplasmic reticulum and swelling of subsarcolemma regions.[298,299] The severity of these changes related to the duration and extent of alcohol use. Several histologic changes have been described on endomyocardial biopsies in alcoholic cardiomyopathy, but none of these changes are pathognomonic. Changes include myocyte loss, increased fibrosis, loss of sarcolemmal integrity, myofibrillar degeneration, mitochondrial swelling, intercellular edema and accumulation of fatty acids in particular triglycerides, and diminished levels of arachidonate in the cellular membrane.[300] Electron microscopy shows mitochondrial swelling with dense intramitochondrial inclusions, swollen vesiculated sarcoplasmic reticulum, and myofibrillar disruption.

TREATMENT

The mainstay of treatment is abstinence from alcohol. Alcohol withdrawal may have a remarkable impact on disease manifestation and progression, especially in the milder forms of the disease.[301-303] In animal models, following cessation of alcohol use, the hearts recover. In humans, the duration and extent of abuse is correlated with outcome.[304] Prognosis is extremely poor in those

patients who continue to drink compared with patients who become abstinent. Ninety-one percent of patients who abstain from alcohol after the initial diagnosis are alive at 42 months, versus 43 percent of those who continue to drink.

Although early in the disease process abstinence can result in recovery, there is a point at which cessation of alcohol is no longer effective,[305] and this correlates with the development of structural histologic abnormalities.[301] Survival of patients with alcoholic dilated cardiomyopathy who are abstinent appears to be significantly better than the long-term survival of patients with a comparable class of CHF due to idiopathic cardiomyopathy.[301,306] In a series of 75 patients with CHF, 23 had alcoholic cardiomyopathy compared with 52 with an idiopathic etiology.[306] Mean left ventricular ejection fraction, diastolic volumes, and NYHA class were similar. Overall survival was measured at 1, 5, and 10 years, and was 100, 81, and 81 percent for patients with alcoholic cardiomyopathy, and 89, 48, and 30 percent for patients with idiopathic cardiomyopathy, respectively. In another series however, no mortality difference was found,[307] but this may be due to persistent alcohol use in that cohort despite the onset of CHF.

Cocaine

Myocardial ischemia, infarction, coronary spasm, cardiac arrhythmias, sudden death, myocarditis, and dilated cardiomyopathy are all reported cardiovascular complications of cocaine abuse.[308] Clinical and experimental evidence suggests a variety of theories for the cardiotoxic effects of cocaine (see also Chap. 71).

The pharmacologic effects of cocaine on the heart partly explain its toxic effects.[309] By blocking the reuptake of norepinephrine, cocaine induces tachycardia, vasoconstriction, hypertension, cardiomyopathy, and ventricular arrhythmias. Cardiomyopathy may then result from secondary changes in the heart due to tachycardia or sustained increased ventricular afterload.

Cocaine has also been shown to exert a direct toxic effect on the heart. In vitro studies with isolated rabbit ventricular tissue[310] or isolated blood-perfused dog preparations[311] showed that high-dose cocaine depressed myocardial contractile force. Acute ventricular dilatation and reversible systolic dysfunction after intravenous cocaine administration have been documented in vivo in dogs.[312]

The risks and manifestations of toxic effects of cocaine in any given individual are unpredictable. The duration or amount of cocaine use is not predictable of disease. For example, among Andean Indians, heart failure rarely occurs from the chewing of coca even though plasma levels of cocaine are comparable to those of intranasal cocaine abusers.[313] This raises the possibility of a genetic susceptibility or that a metabolite or contaminant and not cocaine itself may be the inciting factor for development of cardiac damage.

Dilated cardiomyopathy in the absence of coronary abnormalities and myocarditis has been reported.[314,315] In these cases, myocardial depression is global and is generally reversible; it is attributed to a direct myocardial depressant effect of cocaine.[316]

There are no clinical or histologic features specific for cocaine-induced myocardial damage. Endomyocardial biopsy[308] and autopsy studies[317] confirm the presence of myocyte necrosis and a diffuse inflammatory cellular infiltrate in cocaine users. "Contraction-band necrosis" has been seen in a patient presenting with a clinical course similar to that of catecholamine cardiomyopathy,[318] but this is not characteristic. Although eosinophilic infiltrates can be seen, cocaine is not included in the list of typical drugs associated with a hypersensitivity syndrome. Thus the diagnosis is usually presumptive and is one of exclusion. The treatment of cocaine-related myocarditis and cardiomyopathy is nonspecific and focuses on abstinence and heart failure

therapy.

Chemotherapeutic Agents

Several chemotherapeutic agents can cause an acute and/or chronic cardiomyopathy. Among them, the anthracycline group (doxorubicin) and cyclophosphamide are the most common agents associated with heart failure.

Doxorubicin has been used as single or combination therapy for treatment of many different tumors including breast and esophageal tumors as well as sarcomas and lymphomas from the late 1960s. Its use is limited by its cardiotoxicity. The cause of the cardiotoxicity is unknown, but it is suspected to be due to increased oxidative stress from the generation of free radicals by doxorubicin. Moreover, endogenous antioxidants are reduced by treatment with doxorubicin. Increased oxidative stress results in the loss of myofibrils and cellular vacuolization, similar to what is observed with doxorubicin administration.[319]

Doxorubicin can be associated with early or late cardiotoxicity. Risk factors for the development of doxorubicin cardiomyopathy include age greater than 70 years, combination chemotherapy, mediastinal irradiation, prior cardiac disease, hypertension and liver disease. The early or acute cardiotoxicity manifests as a pericarditis-myocarditis syndrome[320] and is not dose-related. Left ventricular dysfunction is rarely seen, but arrhythmias, abnormalities of conduction, decreased QRS voltage, and nonspecific ST-segment and T-wave abnormalities are observed in up to 40 percent of patients.[321] The prognosis is good, with quick resolution of the abnormalities upon discontinuation of therapy.

In contrast, the late or chronic cardiotoxicity is due to the development of a dose-dependent degenerative cardiomyopathy[322] (Fig. 69-14). This syndrome generally occurs at doses above 550 mg/m^2. Serial assessment of nuclear ejection fractions is used clinically to monitor for adverse effects. However, histopathologic grading is most useful in delineating the safety of continued doxorubicin administration.[323] Cardiotoxicity may occur during therapy within a year of the last dose of anthracycline or as late as 6 to 10 years after its cessation. Therefore a course of this chemotherapy commits patients to prolonged cardiac surveillance.

Figure 69-14: Loss of myofibrils and vacuolization of cytoplasm (toluidine blue stain, ×40) in a patient with doxorubicin cardiotoxicity. (From Singal et al.,[319] with permission.)

Prognosis depends to some extent on the severity at time of presentation, but the incidence of death even in milder forms remains high.[324] The best management of anthracycline cardiotoxicity is prevention by limiting dosage. Lowering the peak blood levels of the drug by giving a continuous rather than bolus infusion also appears to significantly decrease drug-related damage.[325] Coadministration of doxorubicin with agents that would block free radical formation and not decrease its antineoplastic effects has been studied. Dexrazoxane, an iron chelating agent, has been used in clinical trials of patients with breast cancer or small-cell lung cancer to limit the cardiotoxicity of doxorubicin. The incidence of heart failure and the decrease in ejection fraction is less in those patients receiving combined therapy. Unfortunately, dexrazoxane is a potent myelosuppressive agent potentiating the effects of doxorubicin. It also may interfere with cancer therapy.

Heart failure due to doxorubicin has been very difficult to treat and is typically refractory to conventional therapy. In children with doxorubicin-induced cardiomyopathy, recent reports have described diminished symptoms and improved left ventricular function after treatment with beta blockers. Further studies on the use of these agents are needed.

In contrast to the anthracyclines, cyclophosphamide leads to an acute cardiotoxicity that is not related to cumulative dose.[326] Pericarditis, systolic dysfunction, arrhythmias, and myocardial edema make up the spectrum of cardiac abnormalities. Prior left ventricular dysfunction is a risk

factor for development of significant cardiomyopathy with cyclophosphamide. Although mortality is not trivial, survivors exhibit no residual cardiac abnormalities.[327]

Chemical Toxins

A variety of compounds can lead to a spectrum of cardiotoxicity, including cardiomyopathy. They include interferon alpha,[328] IL-2,[329] phenothiazines,[330] emetine,[331] methysergide,[332] chloroquine,[333] lithium,[334] hydrocarbons,[335] lead,[336] and carbon monoxide.[337] A summary of the cardiotoxicity seen with each compound is outlined in Table 69-5.

Table 69-5: Major Cardiovascular Complications ofChemical Toxins

Agent	Cardiac Toxicity
Cobalt	Congestive heart failure
Cocaine	Coronary abnormalities, arrhythmias, myocarditis, myocardial depression
Interferon alpha	Arrhythmias, dilated cardiomyopathy, congestive heart failure
Interleukin-2	Myocardial ischemia/infarct, arrhythmias, eosinophilic myocarditis
Phenothiazines	Electrocardiographic, arrhythmias, sudden death
Emetine	Mononuclear and histiocyte infiltration, electrocardiographic abnormalities
Methysergide	Left-sided valvular lesions, fibrotic endocardial and pericardial lesions, restriction and constriction
Chloroquine	Arrhythmias, cardiac dysfunction
Lithium	Arrhythmias, cardiac dilatation with myofibrillar degeneration
Hydrocarbons	Electrocardiographic changes, arrhythmias, and cardiomegaly
Lead	Electrocardiographic changes, arrhythmias, and congestive heart failure
Carbon monoxide	Arrhythmias and transient biventricular dysfunction

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

CARDIOMYOPATHIES ASSOCIATED WITH NUTRITIONAL DEFICIENCIES

Vitamins

Thiamine deficiency, or beriberi, causes a high-output state, which leads to left ventricular dilatation and an elevated pulmonary capillary wedge pressure.[338] Vitamin D deficiency, or rickets, and vitamin D excess are associated with cardiovascular morbidity and mortality as well. There are about 25 reported cases of hypocalcemic cardiomyopathy in the adult population caused mostly by idiopathic hypoparathyroidism.[339] Similarly in children, cardiomyopathy has been documented in cases of hypocalcemia caused by vitamin D deficiency rickets.[340] Excess doses of vitamin D in humans have been associated with calcium deposition in the heart and QT shortening but not frank cardiomyopathy. Similarly, vitamin A, vitamin B_6, vitamin C, and niacin deficiency are not directly associated with overt cardiac dysfunction in humans but can be associated with ECG abnormalities.

Selenium

Interest in the role of selenium deficiency in cardiovascular diseases originated from observations of cardiomyopathy and sudden cardiac death in animals with dietary selenium deficiency.[341] Cardiomyopathy associated with inadequate dietary intake of selenium, termed Keshan's disease, has also been described in humans. This syndrome was discovered in regions of China with a low soil content of selenium.[342] Whether the cardiomyopathy results from the actual selenium deficiency or the selenium deficiency increases suspectibility to cardiotropic viruses is unclear. Coxsackievirus B3 (CVB 3/20), which causes no pathology in hearts of selenium-adequate mice, induces extensive myocarditis in selenium-deficient mice.[343] Furthermore, Coxsackievirus B3 recovered from the hearts of selenium-deficient mice and inoculated into selenium-adequate mice induced significant heart damage, suggesting mutation of the virus to a virulent genotype.[344] These findings may underlie the seasonal variation characteristic of Keshan's disease.

This disease is typically seen in children and pregnant women. Both acute and chronic forms of Keshan's disease exist.[345] In the acute form, cardiogenic shock, severe arrhythmias, and pulmonary edema are the manifestations of the systolic impairment. The chronic type shows a moderate to severe heart enlargement with varying degrees of cardiac insufficiency; often patients are asymptomatic. Its incidence is dramatically reduced with supplementation of sodium selenite.

Other than Keshan's disease, circumstantial evidence supports an association between selenium deficiency and cardiomyopathy. Congestive cardiomyopathy with low selenium levels has been reported in patients receiving total parenteral nutrition.[346] Patients with congestive cardiomyopathy have significantly lower serum selenium concentrations than healthy control subjects. Left ventricular ejection fraction is positively correlated with the selenium concentration in patients with cardiomyopathies.[346]

Carnitine

L-Carnitine is an essential compound in the transport of long chain fatty acids into mitochondria,

where they undergo beta oxidation. Since the normal heart obtains approximately 60 percent of its total energy production from fatty acid oxidation, this function of carnitine is thought to be of major importance.[347] Because of this function of carnitine and numerous case reports that have shown that some patients with carnitine deficiency exhibit cardiomyopathy,[348-350] it is believed that adequate levels of carnitine are required for normal energy metabolism and contractile function of the heart.[351] Interestingly, not all patients with carnitine deficiency exhibit cardiomyopathy. This may be explained perhaps by the degree of carnitine deficiency or by how cardiac performance is assessed.[352]

Deficiencies of carnitine can be either primary or secondary. Primary deficiencies arise from several genetic disorders involving carnitine synthesis or handling. These rare conditions are severe and are associated with muscle and plasma carnitine levels as low as 10 percent of normal (Fig. 69-15). Several case reports have established that primary carnitine deficiency is associated with cardiomyopathy.[353-355] The cardiomyopathy that ensues presents within 3 to 4 years of birth[356] and is profound; clinically, however, it responds to carnitine supplementation.

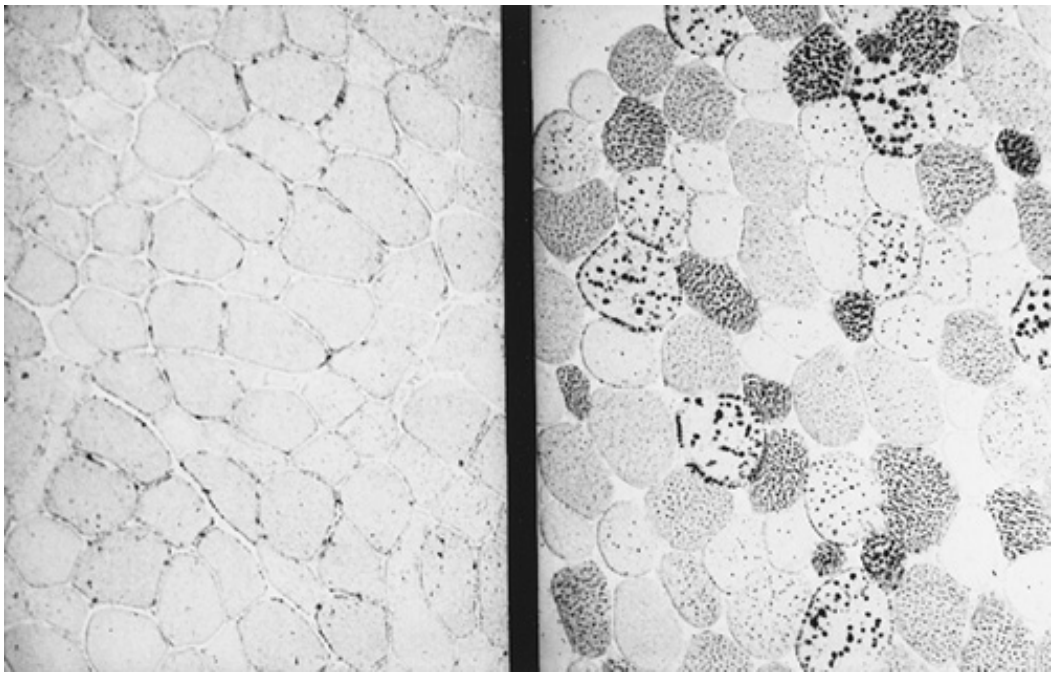

Figure 69-15: Photomicrograph of Oil red O stain demonstrating lipid deposits in type I and IIb fibers in normal (*right*) and carnitine-deficient (*left*) skeletal muscle.

Secondary carnitine deficiencies are much more common and arise from a large number of genetic diseases associated with defects in acyl-CoA metabolism.[357] In patients with long-chain or short-chain acyl-CoA dehydrogenase deficiency, carnitine levels are reduced to 25 to 50 percent of normal and a depression in cardiac contractile performance has been found.[357,358] Secondary carnitine deficiencies can also be acquired as a result of liver disease, renal disease[359,360] (Fanconi's syndrome, renal tubular acidosis), dietary insufficiencies[361] (chronic total parenteral nutrition, malabsorption), diabetes mellitus, and heart failure.[362] Many of these types of secondary carnitine deficiency are often associated with cardiomyopathy.[355,363] In cases of secondary carnitine deficiency, however, it has been difficult to determine whether the symptoms are due to carnitine deficiency or to the underlying genetic metabolic disorder. Based on this observation and the inconsistent reports of cardiomyopathy with these secondary deficiencies, it appears that a clear and strong association can only be made between cardiomyopathy and primary carnitine deficiency.

Coenzyme Q

Coenzyme Q (2,3-dimethoxy-5 methyl-6-decapreyl-1,4-benzoquinone) is another important factor involved in oxidative phosphorylation in mitochondria of the heart.[364] It has been postulated that its depletion, when found in myocardial biopsies of patients with cardiomyopathy,[365] may contribute to heart failure.[366] Several studies have claimed subjective and objective improvement in patients with heart failure after oral therapy with coenzyme Q.[367-369] These studies were small, unblinded, and uncontrolled trials. Recently a placebo-controlled double-blinded randomized crossover trial of coenzyme Q was performed in 30 patients with heart failure stabilized on conventional vasodilator therapy.[370] In this study, treatment with 3 months of oral coenzyme Q failed to improve resting left ventricular systolic function or quality of life despite an increase in plasma levels of coenzyme Q to more than twice basal values. Thus, given the lack of convincing and consistent data, coenzyme Q supplementation is not included in the basic repertoire of heart failure medications.

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

CARDIOMYOPATHIES ASSOCIATED WITH ALTERED METABOLISM

Hyperoxaluria

Both primary and secondary oxalosis are characterized by excessive deposition of calcium oxalate crystals in various body tissues, including the heart.[371] Oxalate crystals are frequently deposited in the conduction system, leading to heart block and occasionally in the myocardium and the coronary arteries. On histology, variable degrees of cellular reaction-including fibrosis, necrosis, and mononuclear cell infiltration-can be seen, as well as foreign-body giant cells and myocardial granulomas. Cases of primary oxalosis can be treated with after combined kidney/liver transplantation.[372,373]

Hyperuricemia

Heart muscle disease associated with hyperuricemia is uncommon[374]; atherosclerosis and coronary artery disease are the most common cardiac manifestations associated with gout. Uric acid crystals can be found in the blood vessel walls, in the myocardial interstitium, along the valve surfaces, and in the pericardium and can lead to a granulomatous response with the formation of multinucleated giant cells.[373]

Chapter 69: MYOCARDITIS AND SPECIFIC CARDIOMYOPATHIES-ENDOCRINE DISEASE AND ALCOHOL

IDIOPATHIC CARDIOMYOPATHY

Idiopathic cardiomyopathy (IDC) is the term used to describe a group of myocardial diseases of unknown cause. Idiopathic dilated cardiomyopathy probably represents the end result of a number of disease processes involving myocyte dysfunction, myocyte loss, myocyte hypertrophy and fibrosis. It is a diagnosis of exclusion. As discussed earlier in this chapter, an idiopathic dilated cardiomyopathy may be the end result of an infectious myocarditis. Endocardial biopsy in patients with dilated cardiomyopathy may reveal an inflammatory infiltrate. Surreptitious alcohol use as well as undiagnosed and untreated hypertension probably represent other etiologies of cardiomyopathy in many of these cases. Familial factors have generally been more predominant in hypertrophic cardiomyopathies than in dilated congestive cardiomyopathy. However more and more data are accumulating to suggest that genetic factors contribute to these cases as well. When one is making the diagnosis of idiopathic dilated cardiomyopathy, it is most important to exclude potentially reversible etiologies (Table 69-6).

Table 69-6: Potentially Reversible Dilated Cardiomyopathies

Ischemic with viable	Endocrine
myocardium	Hyperthyroidism
Valvular without surgi-	Pheochromocytoma
cally correctable lesion	Metabolic
Inflammatory	Hypocalcemia
CMV	Hypophatemia
Toxoplasmosis	Uremia
Mycoplasma	Carnitine
Lyme	Nutritional
Toxic	Selenium
Alcohol	Thiamine
Cocaine	Infiltrative
Cobalt	Hemachromatosis
	Sarcoidosis
	Hypersensitivity

The incidence of IDC has been estimated at 0.005 to 0.006 percent,[375] with the incidence increasing with age and males being more commonly afflicted.[376] A number of immune regulatory abnormalities have been characterized in IDC and include humoral and cellular autoimmune reactivity against myocytes,[377] decreased natural killer cell activity,[378] and abnormal suppressor cell activity.[70] Such findings suggest an immunologic etiology to IDC.

Several studies of the natural history of IDC have concluded that the prognosis is better than for ischemic cardiomyopathy[7]; without treatment, however, mortality approaches 50 percent at 5 years.[379] The risk of thromboembolic complications in IDC may be higher than for the ischemic group, but the clinical response to beta blockade as gauged by improvement in ventricular function is greater.[380] About 10 percent of patients with IDC will normalize their ejection fraction on beta blockade[381]; therefore, if tolerated, this therapy is warranted before consideration of cardiac transplantation.

Part 11: CARDIOMYOPATHY AND SPECIFIC HEART MUSCLE DISEASES
Chapter 70:

AIDS AND THE CARDIOVASCULAR SYSTEM

Author: Melvin D. Cheitlin

INTRODUCTION

The pandemic of acquired immunodeficiency syndrome (AIDS), after nearly 2 decades, has taken a tragic toll in lives in the United States and threatens a catastrophe in Africa and Southeast Asia. An estimated 10 million people worldwide are infected with the human immunodeficiency virus (HIV), and at least another 12 million have full-blown AIDS.[1] In the United States, over a million people are HIV positive, and about 2 million have been diagnosed with AIDS.[2,3]

In New York City, AIDS has become the most important cause of premature death among patients under age 65. In terms of years of potential life lost, AIDS advanced in rank order from the 8th leading cause of death in 1983 to the leading cause in 1994.[4]

AIDS is caused by infection with a virus of the family Retroviridae. This group of retroviruses comprises enveloped ribonucleic acid (RNA) viruses possessing an RNA-dependent deoxyribonucleic acid (DNA) polymerase (reverse transcriptase). There are two classes of AIDS viruses: HIV-1 and HIV-2.

The most specific definition of infection by HIV is by identification of the HIV organism in the host's tissues. Since isolation of the virus is not easily done and therefore lacks sensitivity, a patient with repeated positive screening test results for antibodies to HIV, as with an enzyme-linked immunosorbent assay (ELISA), confirmed by a supplemental test such as the Western blot immunofluorescence assay, should be considered to be infected by HIV.

The following classification system for the different stages of HIV infection as proposed by the United States Centers for Disease Control (CDC) is helpful[5]:

- *Group I:* Acute infection
- *Group II:* Asymptomatic infection
- *Group III:* Persistent generalized lymphadenopathy (PGL)
- *Group IV:* Chronic disease-AIDS with constitutional disease (such as unexplained diarrhea, weight loss, or fever over 1 month), neurologic disease, secondary infectious diseases, secondary cancers (Kaposi's sarcoma, non-Hodgkin's lymphoma, and primary lymphoma of the brain)

In January 1993, the CDC, together with other state and territorial health departments, broadened the surveillance definition for AIDS in adolescents and adults to add a measure of immunosuppression (a CD4+ T-lymphocyte count <200/μL or a CD4+ percentage <14), as well as three additional clinical conditions: pulmonary tuberculosis, recurrent pneumonia (two or more episodes within a year), or invasive cervical cancer.[6]

Patients with HIV infection have also been divided into three clinical categories. Category A includes asymptomatic patients, those with acute HIV infection or progressive lymphadenopathy. Category B includes symptomatic patients without AIDS-defining conditions. Category C includes patients with 25 AIDS-defining conditions, including opportunistic infections, tumors, central nervous system abnormalities, wasting syndrome, pulmonary tuberculosis, invasive cervical carcinoma, and recurrent pneumonia.[6]

The recognition of human infection by HIV in 1981 represented the startling development of a modern epidemic with many of the aspects of epidemics of the past, such as those of poliomyelitis and the black plague. This infection is due to a retrovirus that invades the nucleus of certain cells containing a specific receptor on their cell membranes and incorporates the DNA copy of HIV in the host's genetic material or genome. After an asymptomatic latent period from infection of 2 to 6 weeks, most patients experience a primary HIV-1 infection that is a self-limited viral syndrome not unlike infectious mononucleosis, characterized by fever, fatigue, pharangitis, lymphadenopathy, and maculopapular rash.[7] Over 95 percent of the patients seroconvert to a positive HIV serology within 6 months, most within 6 to 12 weeks.[8] After an apparent incubation (dormant) period of a mean of 8 to 10 years, the virus can eventually express itself by releasing into the cytoplasm double-stranded DNA copies of the virus, thus killing the cell and invading other immune cells, usually T-helper lymphocytes, to the point that the host's immune defense mechanisms are compromised.[9] Studies have demonstrated a high rate of viral replication in the lymph nodes during this quiescent period, indicating active progression of the disease, despite the low levels of infectious HIV in the plasma of some patients.[10]

A long-term prospective study showed the actuarial rate of progression from the time of infection to the appearance of AIDS to be 53 percent at 10 years and 68 percent at 14 years after infection, with an increasing progression after 5 years of infection.[11] About 30 percent of patients with PGL will progress to AIDS in 5 years.[12] A minority of patients have an accelerated course and develop full-blown AIDS in 1 or 2 years.[13] Small groups of patients have also been described who have had HIV infection for over 10 years without any symptoms.[14] At some point, there is a breakdown of the body's defense against certain neoplastic changes, resulting in the development of non-Hodgkin's lymphoma and Kaposi's sarcoma. These complications lead inevitably, at least in a very high percentage of cases, to death.

The average length of life after infection in the absence of treatment is approximately 10 years.[11] With the introduction of highly active antiviral therapy (HAART) including nucleocide reverse-transcriptase inhibitors and especially the protease-inhibitor drugs, elimination of the virus from the peripheral blood and prolongation of life have been demonstrated.[15] The impact of the new treatment with multiple drugs is seen in a fall in the rate of AIDS deaths by 12 percent in the United States in 1996 and by 47 percent in 1997.[16]

At the beginning of the epidemic in the United States, the HIV organism struck mainly at the male homosexual population. Later it was found to be transmitted not only through sexual intercourse but also through bloodborne contamination, soon affecting the population using intravenous drugs and other populations receiving blood products and blood transfusions, such as hemophiliacs. The disease is also transmitted perinatally, so that an increasing number of pediatric patients with AIDS are being seen. Although in the U.S. male-to-male sexual activity and intravenous drug users account for 75 percent of cases, in the developing world heterosexual transmission accounts for the majority of cases.[17]

From work with HIV-1, it has been found that the usual way in which the virus attacks cells is through interaction with a receptor on the surface membrane of the cell, the so-called CD4

receptor. This is present in T-helper lymphocytes. Macrophages, microglia, and Langerhans' cells may have specific receptors for HIV other than CD4. Other cells seem to lack an HIV receptor and therefore are much less often found to be sites of infection; the myocardial cell is one such cell.

From the beginning of the epidemic, it was recognized that the heart could be involved but that significant clinical involvement of the heart was unusual. Originally it was believed, through autopsy studies, that the heart was involved mainly because of pericarditis or metastatic Kaposi's sarcoma.[18,19] A few patients with nonbacterial thrombotic endocarditis (NBTE) were reported, but this could be nonspecific, since many of these patients have a wasting disease in which NBTE is not unusual.[20] On further review of autopsy series and clinical series and especially with the study of patients with AIDS who had echocardiography, it was apparent that abnormalities of the heart were seen frequently, even though clinical manifestations of heart disease still remained unusual.

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

AUTOPSY FINDINGS

The incidence of cardiac involvement at autopsy varies, depending on the definition of cardiac disease. In 15 autopsy series, the incidence of cardiac involvement varies from none to 70 percent of the hearts, depending on whether lymphocytic infiltration with or without myocardial necrosis is included.[18-26] The presence of autopsy-proven cardiac involvement in patients who, during life, had clinically significant cardiac involvement is less impressive, especially if one includes the patients with localized, isolated collections of myocardial lymphocytes.

In evaluating autopsy reports, it is often difficult to discern how many patients had clinically significant abnormalities during life. In the large series of consecutive autopsies of AIDS patients, between 5 and 20 percent appear to have had cardiac lesions of potential clinical importance. These include patients with myocarditis with clinical manifestations, mainly with known pathogens-such as toxoplasmosis, clinically evident pericarditis, or nonbacterial endocarditis-which can cause systemic emboli.[27]

The largest recent autopsy series is by Barbero et al., where 440 AIDS patients had an autopsy. Cardiac involvement was documented in 18.6 percent and dilated cardiomyopathy in 2.7 percent.[28]

More important are the relatively few patients in whom cardiac abnormality was listed as the cause of death. The most common cause of death is respiratory failure and infection.[24,26,29,30] Neoplasm, lymphoma, and encephalopathy are also frequent causes of death.[31] Of 858 autopsied patients with AIDS from 15 series in the literature, only 9 (1 percent) had the cause of death listed as cardiac. If the cases with a recognized etiology for heart disease are removed, only 0.5 percent of deaths were possibly due to HIV "myocarditis."

Right ventricular hypertrophy and/or dilatation was reported in 12 of 71 patients (16.9 percent)[25] and in 18 of 115 patients (15.7 percent).[24] Pericarditis varied in frequency from 3 of 41 (7.3 percent)[20] to 3 of 101 (3 percent).[22]

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

ECHOCARDIOGRAPHIC FINDINGS

Echocardiography in patients with either AIDS or PGL has been reported in a number of studies.[32-39] The prevalence of echocardiographic abnormalities varies from 15 to 60 percent and would be higher if the finding of mitral valve prolapse, an echocardiographic abnormality that may be related to cachexia, is included. The prevalence of left ventricular hypokinesis also varies from 12.5 to 41 percent in three large series.[33,34,36] In one series,[33] four of the eight patients had congestive heart failure; one died and at autopsy had a dilated cardiomyopathy without evidence of inflammatory myocarditis or cardiac opportunistic infections. Only in this study[33] was clinical congestive heart failure mentioned. Dilated cardiomyopathy was seen only in the hospitalized patients. In a large prospective echocardiographic study in 296 HIV-infected adults that was conducted over 4 years, Currie and colleagues found 13 (4 percent) with dilated cardiomyopathy.[37]

Cecchi and colleagues, from 1398 patients admitted for HIV infection, selected 127 (9 percent) with a clinical suspicion of cardiac disease and did echocardiograms on them: 92 (72 percent) had evidence of cardiac involvement, 6.5 percent of total HIV patients; 38 (2.7 percent) had pericardial effusion, and 20 (1.4 percent) had dilated cardiomyopathy.[38]

The finding of pericardial effusion was common, varying from 20 to 40 percent.[34,36,38] The incidence of tamponade varies: In one series[34] of 18 patients with pericardial effusion, 5 (28 percent) had tamponade. In this report of 300 patients with AIDS, 16 (5 percent) had clinically apparent heart disease, due in most cases to opportunistic infection or tumor.[34] Over a period of 3 years at the San Francisco General Hospital, Rapaport found that, of 1171 patients hospitalized with AIDS, an echocardiogram was ordered for 88 (7.5 percent) because of suspicion of cardiac disease (personal communication). Of these echocardiograms, 52 (59 percent) showed at least one abnormality. Of the 88 echocardiograms, 16 (18 percent) showed either left ventricular dilatation and/or left ventricular hypokinesis, and 26 (30 percent) showed pericardial effusion. There were no control subjects.

Steffen and colleagues[39] reported the prospectively collected results of echocardiography in 151 HIV-seropositive patients, 92 percent of whom were men with a median age of 37 years, and 73 percent were homosexual men. Of these, 13 percent were intravenous drug users, of whom 74 percent were in Walter Reed stages IV to VI, a classification using counts of T4 helper cells and clinical data.[40] A total of 107 patients (71 percent) had normal echocardiograms. Echocardiographic abnormalities attributed to HIV infection were present in 31 patients (20 percent). There was an association of abnormal echocardiographic findings with advanced clinical stages of the disease. The mortality during follow-up was the same for those with normal echocardiograms (35 of 102) as for those with abnormal echocardiograms (12 of 29) ($p = .48$). Even in those with the most advanced clinical disease, there was no independent prognostic significance of the echocardiographic cardiac involvement, with 44 percent of both echo-normal and echo-abnormal patients dying. This study shows a remarkably low incidence of HIV-associated echocardiographic abnormalities, most often asymptomatic pericardial effusion.

These studies suggest that the prevalence of echocardiographic abnormalities in HIV-positive patients depends on the stage of their clinical illness, with the sickest patients having the most

abnormalities.

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

PERICARDIAL INVOLVEMENT

In general, pericardial effusion and pericarditis constitute the most commonly recognized cardiac involvement in AIDS. At autopsy, Kaposi's sarcoma involvement and lymphoma may be clinically silent, accompanied by asymptomatic pericardial effusion, or they may be clinically important because of pericardial tamponade.[41] Pericarditis due to specific organisms has frequently been reported. These organisms are most commonly *Mycobacterium tuberculosis*[34,42,43] or *Mycobacterium avium-intracellulare*.[35,42,44] One study[34] reported pericardial tamponade in five patients and large pericardial effusions in six. Of the patients with clinical heart disease in this study, 22 percent had echocardiographic evidence of tamponade, and another 33 percent had large pericardial effusions.

In a review of 15 autopsy and echocardiographic studies involving 1139 patients with HIV disease, the incidence of pericardial disease was 21 percent. Most cases were asymptomatic without an identifiable etiology. In those that were symptomatic, about two-thirds were caused by infection or neoplasm and one-third were of undetermined etiology. In the 66 published cases of pericardial tamponade, 26 percent were caused by *M. tuberculosis*.[42]

At San Francisco General Hospital, experience has been similar. In a consecutive series of 88 in-hospital AIDS patients who had echocardiograms, 36 (41 percent) had normal echocardiograms, whereas the most common abnormality, seen in 26 (30 percent), was pericardial effusion. We have recognized a total of 25 patients with AIDS or PGL who have pericardial disease. Ten of these patients had pericardiocentesis, of whom eight (32 percent) presented with tamponade, two had pericardial windows, and one died and was autopsied. Another two patients, who had neither pericardiocentesis nor pericardial windows, died and were autopsied. No etiology was found on examination of either fluid or tissue in any of the 12 patients.

In a prospective echocardiographic study among 231 patients recruited over a 5-year period, the prevalence of pericardial effusion for AIDS patients entering into the study was 5 percent. Over the follow-up time, the incidence of pericardial effusion increased as the stage of the HIV progressed from 0 percent per year in asymptomatic HIV-infected patients to 11 percent per year in patients with AIDS; 80 percent of these effusions were small and asymptomatic.[45] The survival of the AIDS patients who developed pericardial effusion was significantly shorter than the survival of those who did not, 36 percent versus 93 percent at 6 months. This shortened survival period remained significant even after adjustment for lead-time bias and was independent of CD4+ T-cell count.[45] Since death was not due directly to the pericardial effusion, the development of pericardial effusion in the setting of HIV infection probably suggests end-stage HIV disease.

Flum and colleagues also reported that AIDS-associated pericardial effusion was a grave prognostic sign. They reported 29 patients who had surgical windows for large effusions; only in 2 patients did this result in a change in clinical management. The mortality was 69 percent at 8 weeks after pericardial window.[46] They concluded that pericardial biopsy for diagnosis provided little practical therapeutic information and that surgical windows were justified only to relieve tamponade.

The etiology of pericardial effusion or pericarditis is not obvious; it may be HIV infection or other opportunistic viral infections with Coxsackie virus, cytomegalovirus, or neoplastic.[45] Occasionally, pericarditis has been reported to be caused by common organisms such as *Staphylococcus*,[46] *Cryptococcus neoformans*,[47] or herpes simplex virus.[48]

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

MYOCARDIAL INVOLVEMENT

For a number of years, involvement of the pericardium and myocardium with both common and unusual opportunistic infections and neoplasms, such as Kaposi's sarcoma and lymphoma, has been recognized. At times, this involvement appears to be incidental and associated with the presence of organisms in many tissues, including the heart. Often, this involvement is not accompanied by signs of cell necrosis or even inflammation. At other times, the infection is accompanied by an intense myocarditis. Opportunistic infection has included viruses (herpes simplex, cytomegalovirus, and Coxsackie virus), bacteria, protozoa (*Toxoplasma gondii)*, and fungi (*Candida albicans, C. neoformans*, and *Aspergillus fumigatus*).[49-51] These specific infections have been diagnosed at autopsy but also during life with myocardial biopsy. The importance of identifying a specific organism as the cause of the myocarditis rests in the potential for treatment[42,52]; for instance, amphotericin B and flucytosine may be used to treat cryptococcosis. Grange and colleagues[53] reported a case of *T. gondii* myocarditis in a 58-year-old man with AIDS who was treated successfully with pyrimethamine and clindamycin. A similar case was reported by Albrecht and colleagues.[54]

The most common neoplasms are Kaposi's sarcoma and lymphoma of the non-Hodgkin's type.[18,19,24] With Kaposi's sarcoma, the tumor involvement of the myocardium or pericardium is most frequently an incidental finding. On occasion, myocardial involvement by lymphoma is diagnosed by needle biopsy of the myocardium.

One study reported a collection of 21 cases of lymphoma in AIDS patients-3 Hodgkin's and 18 non-Hodgkin's lymphoma of various histologic types-almost all of which were in the high-grade categories.[55] Unfortunately, these tend to be histologically aggressive tumors involving many organs, and they respond poorly to treatment. At times, the patient presents with pericardial tamponade or even superior vena cava syndrome.[56,58] Echocardiography revealing infiltration into the myocardium and/or myocardial or pericardial masses is most helpful in establishing a diagnosis.

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

CARDIOMYOPATHY

In 1986, Cohen and colleagues reported three patients with AIDS who had clinical, echocardiographic, and morphologic findings of dilated cardiomyopathy.[59] All had a decreased ejection fraction, and two had congestive heart failure. All three died, and two had findings at autopsy compatible with myocarditis resulting in cardiomyopathy. Microscopic examination in both showed focal collections of inflammatory cells together with myofibrillar atrophy and myocardial necrosis. A subsequent report described 58 consecutively autopsied patients.[60] Seven (12 percent) had major clinical cardiovascular abnormalities, including four with congestive heart failure and others with ventricular tachycardia. All were late in the course of their disease. All patients with these major clinical cardiac abnormalities had focal myocarditis at autopsy. The etiology in these cases was not obvious but was believed to be viral myocarditis.

In another study of 71 patients with AIDS, 8 had left ventricular dilatation and decreased contractility and 4 had congestive heart failure.[33] In a similar echocardiographic study, none of 102 AIDS patients had congestive heart failure, although 41 percent had left ventricular hypokinesia.[36]

In autopsy studies reported in the literature, cardiac causes of death have been rare; clinically, the incidence of congestive heart failure has been extremely small, although microscopic focal myocarditis is frequently described. In 14 studies in the literature, 1009 patients with AIDS were reported. A total of eight died of cardiac involvement. One had cryptococcal myocarditis and one had toxoplasmic myocarditis; five came from one institution.[25]

Symptomatic cardiomyopathy in association with HIV-1 infection is uncommon; however, echocardiographic evidence of left ventricular dysfunction is more common, especially in patients who are the furthest along in the course of HIV disease. Individual reports of one to five cases of patients with either dilated left ventricle, hypokinetic left ventricle, or both have been frequent enough to require explanation.[59,61] Furthermore, the occurrence of cardiomyopathy in children, in whom a disease unrelated to HIV infection would be rare, further suggests a relationship between HIV disease and cardiomyopathy.[62]

Lipshultz and colleagues did a prospective study on 196 HIV-infected children, median age 2.1 years. Only two had congestive heart failure at enrollment. An echocardiogram done every 4 months revealed a 2-year accumulative incidence of cardiomyopathy of 4.7 percent (95 percent confidence interval, 1.5-7.9 percent).[63]

Prospective echocardiographic studies have been reported that show a high prevalence of myocardial dysfunction. DeCastro and colleagues did serial echocardiograms prospectively on 136 HIV-positive patients over a mean follow-up time of 415 ± 220 days. Seven AIDS patients developed clinical and echocardiographic findings of global left ventricular dysfunction. Of the six who died, five were autopsied: three had acute lymphocytic myocarditis, one had cryptococcal myocarditis, and one had myocardial fibrosis.[64]

Blanchard and colleagues did serial echocardiograms on 70 HIV-positive outpatients. Of the 50

patients with AIDS, 7 (14 percent) had echocardiographic evidence of left ventricular dysfunction. On repeat echocardiogram, three of the seven had improved left ventricular function, implying a transient problem that caused a transient decrease in left ventricular function.[65]

At San Francisco General Hospital, the cases of 74 AIDS outpatients were prospectively followed using serial quantitative Doppler echocardiography every 4 months. Control populations included HIV-positive patients without disease, HIV-positive patients with AIDS-related complex, and HIV-negative gay men. Over the follow-up period of 16.5 ± 12 months, no differences in left ventricular systolic or diastolic function were detected between the groups and no differences in mean values from the first to the last echocardiogram.[66]

The prospective study by Barbaro and colleagues reported 952 asymptomatic HIV-positive patients whose cases were followed clinically and by echocardiography for 60 ± 5.3 months.[67] By echocardiogram, dilated cardiomyopathy was diagnosed in 76 (8 percent) of patients-an incidence of 1.6 cases per 100 patients per year. A myocardial biopsy was done on all patients with cardiomyopathy, and a histologic diagnosis of myocarditis made in 83 percent. By in situ hybridization HIV nucleic acid sequences were found in 58 patients but only 36 (63 percent) had active myocarditis. Of these 36 patients, 25 percent had other cardiotropic virus infections with Coxsackie B virus in 6 (17 percent), cytomegalovirus in 2 (6 percent), and Epstein-Barr virus in 1 (3 percent). The authors concluded that dilated cardiomyopathy may be related either to direct HIV infection or to an autoimmune process induced by HIV, possibly in association with other cardiotropic viruses.

Possible Reasons for Cardiomyopathy

There are many theories on the etiology of congestive heart failure with a dilated, poorly contracting left ventricle found in the occasional patient. These explanations may well be related also to the more frequently observed echocardiographic reduction in left ventricular function with or without left ventricular dilatation. The most frequently mentioned etiology is that of myocarditis or postmyocarditis cardiomyopathy. There are occasional reports of virus being grown from cardiac muscle. In 1987, Calabrese and colleagues[68] were the first to report the culturing of HIV from a right ventricular myocardial biopsy from a patient with a hypokinetic right ventricle and a normal left ventricle.

There is some evidence that HIV itself invades the myocardial cell. The myocyte has no CD4+ receptors, which are the major way by which the virus enters the cell. Although there are other ways and possibly other receptors by which the virus could invade the cell, no one has convincingly shown the virus or a portion of the viral DNA or RNA within the genome of the myocardial cell.[69] One study reported detecting HIV nucleic acid sequences by in situ hybridization in cardiac tissue sections from 6 of 22 patients examined who had died of AIDS.[61] The hybridization target was thought to be myocytes, but this could not be proved by this technique. Furthermore, the myocardial cells showing the positive hybridization signal were sparse, comprising only one or a few cells per section; the myocardium was normal by light microscopy; and none of the patients had clinical evidence of cardiac disease. Still, the most compelling evidence for the ability of HIV virus to enter the myocardial cell comes from the previously mentioned study by Barbaro and colleagues.[67]

Other Theories for the Development of Cardiomyopathy

OPPORTUNISTIC INFECTIONS

Patients with AIDS are exposed to and susceptible to multiple bacterial, viral, mycotic, and

protozoal infections. Epstein-Barr virus and cytomegalovirus are both known to cause myocarditis in AIDS patients.[67,70] *Cryptococcus neoformans* and *T. Gondii* myocarditis have been well described.[29,52,53,71] Myocarditis due to *M. avium-intracellulare* has been reported.[20] *Aspergillus* endocarditis and myocarditis have been reported.[72]

DILATED CARDIOMYOPATHY AS A POSTVIRAL DISORDER

The study of patients with myocarditis without AIDS has shown that the myocarditis can be precipitated by viral infection and that the inflammatory reaction can progress when the virus is no longer recoverable from either the heart or even the patient. The viral infection precipitates an immune reaction either to viral antigen that cross-reacts with a myocardial protein or to altered myocardial protein, which acts as a foreign antigen, thus precipitating the immune reactions that continue the myocardial necrosis and inflammatory cell infiltration[73] (see also Chap. 69).

The evidence that congestive cardiomyopathy is precipitated by a previous viral myocarditis includes the biopsy finding of inflammatory infiltrate in some patients with dilated cardiomyopathy[74,75] and detection of increased elevated viral antibody titers and viral-specific RNA sequences in myocardial biopsies.[76] Thus, the cardiomyopathy can result from a previous infection with a number of organisms that are no longer recoverable from the myocardium.

Herskowitz and colleagues[77] reported the histologic and immunopathologic results of 37 endomyocardial biopsy samples from patients infected with HIV-1 who developed unexplained global left ventricular dysfunction. Twenty-eight patients had New York Heart Association (NYHA) class III and IV congestive heart failure. Four patients had myocarditis secondary to known etiologies. Of the remaining 33 patients, 17 (51 percent) had histologic evidence of idiopathic active or borderline myocarditis. Specific hybridization within myocytes was abnormal in five patients with HIV-1 antisense riboprobe and in 16 of the 33 with cytomegalovirus immediate early (IE-2) antisense riboprobe. This study is compatible with the possibility that cardiotropic virus infection and myocarditis may be important in the pathogenesis of HIV-associated cardiomyopathy.[77]

IMPAIRMENT OF THE IMMUNE MECHANISM LEADING TO CARDIOMYOPATHY

Humorally mediated autoimmune reactions involving antimyosin antibodies may also be implicated in the development of cardiomyopathy.[78] Circulating cardiac autoantibodies have been identified in four of six AIDS patients with cardiomyopathy and in none of the HIV-positive patients without cardiomyopathy. In situ hybridization with genomic probes failed to show evidence of HIV or any other viruses within the heart muscle. Results of ELISA showed a high titer of immunoglobulin G antibody to myosin and to cardiac mitochondrial adenine nucleotide transporter. In this study, it was concluded that the cardiomyopathy may be related not to HIV infection of the heart but rather to autoimmunity. Apparent improvement of left ventricular function in children with AIDS by using intravenously administered immunoglobulin is also suggestive of an immunologic etiology for the left ventricular dysfunction.[79]

ROLE OF CYTOKINES IN MYOCARDITIS

Ho and colleagues[80] proposed a primary role for neuroglial cell damage from the cytolytic effect of release of substances termed *cytokines* from HIV-infected monocytes, the "innocent bystander" destruction mechanism. Cytokines are biologically active mediators and are soluble proteins released by immune cells. Reversible myocardial depression is well documented in human and canine septic shock.[81,82] This was subsequently demonstrated to be due to a "myocardial depressant factor."[83] The exact nature of this myocardial depressant factor is not agreed upon, but

it could be related to a variety of mediators of sepsis such as endotoxin and the cytokine tumor necrosis factor (TNF) and interleukin 2.[84]

Other studies showed that the administration of endotoxin-released TNF caused depression of left ventricular function independent of left ventricular volume or loading conditions,[85] and elevated circulating levels of TNF have been noted in patients with severe chronic heart failure.[86] Increased circulating levels of TNF have been noted in patients with advanced HIV-1 infection.[87] This finding is consistent with a finding of increased production of the cytokine TNF by peripheral monocytes of patients with AIDS.[88]

Barbaro and colleagues[89] investigated the myocardial expression of TNF-α and inducible nitric oxide synthase (INOS) in endomyocardial biopsies in patients with HIV dilated cardiomyopathy and compared them with myocardium from patients with idiopathic dilated cardiomyopathy. The mean intensity of both TNF-α and INOS immunostaining was greater in the HIV patients compared with the idiopathic cardiomyopathy patients. The staining intensity of both TNF-α and INOS was inversely correlated with the CD4 count.

The increased levels of cytokines-including TNF, interleukins 1 and 2, and α-interferon-may lead to myocardial dysfunction either acting locally in a paracrine fashion on adjacent myocardium or systemically causing a decrease in myocardial function.[90,91]

CACHEXIA

Many patients with AIDS have marked weight loss and cachexia. In patients with anorexia nervosa, wall motion as assessed by two-dimensional echo Doppler was found to be abnormal in 8 of 14 patients but not in control subjects; also, lower stroke volume was found in patients compared with controls, possibly because of decreased heart size.[92] Starvation and refeeding studies in animals have demonstrated myofibrillar atrophy and cardiac interstitial edema that are accompanied by a decrease in left ventricular compliance and decreased peak systolic force.[93] These changes are thought to be due to protein-calorie malnutrition. Congestive heart failure may occur, especially during refeeding and recovery.[94]

VITAMIN- AND SELENIUM-DEFICIENCY STATES

Cachectic people can have vitamin-deficiency states; it is doubtful that many patients with cardiomyopathy have this as a prime etiology. Selenium deficiency has been described, together with reduced cardiac selenium levels in AIDS, similar to the Keshan's disease seen in Chinese with selenium deficiency. In one study, 10 patients with AIDS who had decreased left ventricular fractional shortening on echocardiography received sodium selenite for 23 days.[95] Six of eight showed a return toward normal of left ventricular fractional shortening within 21 days. Selenium deficiency has been reported to be common in malnourished pediatric patients with AIDS.[96]

DRUG-INDUCED CARDIOMYOPATHY

The effect of drugs, both recreational and therapeutic, on myocardial function is not well delineated in patients with AIDS. In most patients with AIDS and cardiomyopathy, however, drugs do not seem to be the cause[61,97]; nevertheless, in patients with AIDS, drugs such as doxorubicin, α_2-interferon, and interleukin 2 have been shown to produce cardiomyopathy that is sometimes reversible. Recombinant α_2-interferon-related cardiomyopathy in patients treated for primary renal cancer has been reported.[98] One report described three cases of reversible cardiac dysfunction associated with α-interferon therapy in AIDS patients with Kaposi's sarcoma.[99]

Cocaine use has been associated with myocarditis and dilated cardiomyopathy, which occasionally has been reported to be reversible.[100,101] Pentamidine has been reported to cause ventricular tachycardia.[102] The most common currently used drug in AIDS, zidovudine (AZT), a nucleoside analog, is a drug that inhibits replication of HIV in vitro, probably by inhibiting the reverse-transcriptase enzyme, which is essential to the replication of the retrovirus. No adverse cardiac effects have been reported in phase 1 clinical trials, and one study failed to show cardiotoxicity[103]; however, a toxic mitochondrial myopathy caused by long-term AZT after 12.8 months of therapy has been reported.[104] This myopathy is characterized by abnormal mitochondria with paracrystalloid inclusions. AZT-induced cardiomyopathy in rats has been shown to be related to oxidative damage and activated ADP-ribosylation reactions damaging mitochondrial energy production.[105] Whether this can occur in cardiac muscle in some patients is not clear. Foscarnet therapy for the treatment of cytomegalovirus infection has also been reported to produce a reversible cardiomyopathy.[106]

Conclusions

Clinical heart muscle disease and heart failure in AIDS are unusual. When this condition occurs, there may be explanations other than direct infection with HIV. The exact incidence of heart muscle disease in AIDS is as yet unknown but must be small, and the mechanisms that can cause failure are probably multiple.

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

METABOLIC CARDIOVASCULAR COMPLICATIONS OF ANTIVIRAL DRUGS

With the introduction of protease inhibitors, a class of drugs that suppresses HIV replication, to the treatment of patients with HIV infection, metabolic abnormalities have been seen that have potential for development of cardiovascular disease. New-onset hyperglycemia similar to type II diabetes mellitus has been described, as well as worsening of preexisting diabetes in 1 to 6 percent of patients. This problem has been described with all of the protease inhibitors.[107] The cause of the hyperglycemia is not known, but it does respond to sulfonylureas, suggesting that the drug causes increased resistance to the peripheral effects of insulin although it is not possible to rule out a reduction in insulin secretion.[108] The treatment of hyperglycemia is similar to that of type II diabetes: diet and oral hypoglycemic drugs.

Lipid metabolic abnormalities have also been seen in patients taking protease inhibitors with extremely high triglyceride levels to over 1000 mg/dL,[109] which can occur within 2 weeks of starting therapy. In a study of ritonavir plus saquinavir, 11 percent of patients developed triglycerides above 1500 mg/dL. There were no instances of pancreatitis. There are also elevations in serum cholesterol.[110]

Although the mechanism by which this drug induces hyperlipidemia is unknown, there is a 60 percent homology of the catalytic region of the HIV-1 protease to which the drugs bind to two proteins regulating lipid metabolism: cytoplasmic retinoic acid-binding protein type I (CRABP-I) and low-density lipoprotein-receptor-related protein (LRP). Binding of the protease inhibitors to LRP would impair hepatic chylomicron uptake and triglyceride clearance.[108] The elevated triglycerides respond to gemfibrozil.

In 45 HIV-infected patients taking protease inhibitors who had abnormally elevated lipids, the National Cholesterol Education Program Guidelines were followed without disrupting the HIV therapy. Mean serum cholesterol prior to initiation of the protease inhibitors was 170 mg/dL. On the protease inhibitor, the mean cholesterol rose to 289 mg/dL, and triglycerides were 879 mg/dL. On diet, gemfibrozil alone, or with atorvastatin, the cholesterol fell to 201 mg/dL ($p = .01$) over a 10-month period.[111]

Finally, an abnormal redistribution of fat from the periphery centrally to the abdomen and thorax has been described. There is a loss of subcutaneous fat from the face and limbs (partial lipodystrophy), and the development of fat deposits in the abdomen ("protease pouch") and dorsocervical fat pad ("buffalo hump").[112-114] The abdominal fat may be either in the subcutaneous tissue or in the intraabdominal visceral fat.[112] The abnormal fat distribution appears to be associated with the use of ritonavir-saquinavir combinations rather than with indinavir and does not respond to dietary restriction or exercise. In patients with a buffalo hump, hypercortosolism has been ruled out as a cause, and half the patients with a buffalo hump had never been on protease inhibitors.[113] The relationship of these abnormalities to protease inhibitors is still not clear.

Since the protease inhibitors are such important drugs in the management of patients with HIV infection, every attempt must be made to control their metabolic side effects without stopping the drug. Diet and oral hypoglycemic drugs can control the hyperglycemia. Gemfibrozil and HMG-

CoA reductase inhibitors decrease the elevated triglycerides, cholesterol, and low-density lipoproteins, as noted. A potential problem is that protease inhibitors are metabolized by the hepatic cytochrome P450 CYP4-A system, and these drugs can both induce and/or inhibit the system. Therefore, other drugs metabolized by the cytochrome P450 system can have their plasma levels either decreased or increased when used together with the protease inhibitors, resulting in an extensive list of drug interactions and possibly drug toxicity. The importance of treating the metabolic abnormalities, however, is seen in the increasing number of reports of premature, extensive coronary artery disease in patients taking protease inhibitors.[115]

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

CLINICAL WORKUP AND THERAPY

The workup of patients with AIDS and suspected cardiac involvement begins with the history and physical examination for symptoms and signs of cardiac disease. Since there is no therapeutic advantage to finding subclinical cardiovascular involvement, there is no justification for screening electrocardiograms or echocardiograms. If there are signs or symptoms suggesting cardiovascular disease-such as a friction rub, an S_3 gallop, or other evidence of congestive heart failure-an echocardiogram is useful in identifying pericardial effusion and in evaluating right and left ventricular function. Invasive diagnostic studies are rarely necessary.

If left ventricular dilatation and hypokinesis are found with or without clinical evidence of heart failure, consideration should be given to stopping all drugs that are not absolutely essential.[116] If, in a 2-week follow-up, echocardiography reveals improvement, the suspected drug should be eliminated.

The question of whether a myocardial biopsy is helpful is controversial. The finding of a treatable cause of biopsy-proved myocarditis is rare. Furthermore, there is no evidence that treating biopsy-proved focal myocarditis with steroids or antimetabolites is effective.[117] Therefore, by available evidence, myocardial biopsy is of little value.

The potential cardiotoxic roles of drugs for opportunistic infection as well as other known etiologies-such as hypertension, hypertrophic cardiomyopathy, and coronary artery disease-should be considered. The treatment of congestive heart failure is similar to that of the treatment of heart failure from other etiologies, e.g., diuretics, digoxin, and angiotensin-converting enzyme inhibitors (see Chap. 21).

Chapter 70: AIDS AND THE CARDIOVASCULAR SYSTEM

CARDIOVASCULAR SURGERY IN AIDS PATIENTS

There has been an increased interest in the danger to AIDS health care workers of becoming infected or of infecting patients and in the possibility of accelerating the disease through surgery. The problem is illustrated by the following questions:

1. Are we performing an expensive procedure that will cause prolonged hospitalization and probably not affect the outcome in AIDS patients?
2. What is the risk of accelerating the disease by surgery?
3. What is the risk of HIV infection to health care workers?
4. What is the risk of getting HIV infection during open-heart surgery?

In general, it is not wise to perform expensive procedures with some degree of morbidity and mortality that result in prolonged hospitalization of patients with a limited life span due to their underlying disease. For this reason, patients with AIDS should not be subjected to surgery that will most probably not significantly affect their survival. Before protease inhibitors were available, probably 70 percent of patients found to have AIDS would die within 3 to 4 years of the diagnosis.[118] Now, with newer drugs, life has been markedly prolonged. Therefore, if patients with AIDS have medically uncontrollable symptoms, invasive procedures that can ameliorate these symptoms are indicated.

With infective endocarditis, the vast majority of HIV-infected patients are intravenous drug users, and the most common valve involved is the tricuspid valve, which almost always can be treated medically. The most frequent problem in which the question of cardiovascular surgery arises in a relatively young subgroup involves the intravenous drug user with infective endocarditis on the aortic and/or mitral valve and congestive heart failure. The presence of HIV disease in these patients, who overall have a high mortality and poor results from surgery, would suggest that they be treated medically for as long as possible.[119] If failure persists, valvular replacement should be done.

HIV-positive patients and patients with PGL who have not had an opportunistic infection or cancer can have a prolonged course over many years and, in general, should be treated like patients without HIV disease. In fact, life span might be prolonged after HIV infection by using combinations of drugs, including reverse-transcriptase inhibitors and the new protease inhibitors. In this subgroup, cardiovascular surgery should be considered for the usual indications.

The question of whether progression of the HIV disease is accelerated by the immunologic challenge that occurs from cardiopulmonary bypass is largely unanswered. Instances of HIV-positive patients who developed AIDS shortly after open-heart surgery have been reported. It is known that cardiopulmonary bypass temporaily depresses phagocytic function and immune globulin production.[120] Cardiopulmonary bypass per se in HIV-negative patients causes prolonged abnormalities in the CD4+/CD8+ T-cell ratio up to 6 days postoperatively.[121] There is, therefore, a basis for concern that cardiopulmonary bypass surgery could accelerate the progression of HIV disease, and this must be taken into consideration.

Whether all patients undergoing cardiovascular surgery or other invasive procedures should have HIV testing is a matter of heated debate. Although the risk to health care personnel is small, HIV infection is usually tantamount to fatal infection; fear is great among both health care workers and the public. On the other hand, AIDS is an emotional subject, and patients who are known to be HIV positive may be subjected to prejudice and discrimination. At present, HIV testing of both health care workers and patients is voluntary; however, there are proposed recommendations requiring disclosure to patients that a health care worker is HIV positive and informed consent from patients before any invasive procedure is done. At present, there is only one instance of transmission of disease by a health care worker, that of an HIV-positive dentist who is believed to have infected five patients, probably from reuse of inadequately sterilized instruments. This matter is still under considerable debate.

Because of this risk, some cardiovascular surgeons and cardiologists are refusing to operate on or catheterize an HIV-positive person or a patient who will not allow an HIV test to be done. In 1989, a survey was done of the attitudes of cardiac surgeons in the United States concerning operating on HIV-positive patients.[122] More than half responded, and two-thirds of these were reportedly willing to perform open-heart surgery on HIV-positive patients no matter how the patients had acquired their HIV infection. One-quarter of the surgeons would not operate no matter how the HIV infection was acquired, and the rest were uncertain. Once the patient has gone from the HIV-carrier state to AIDS, two-thirds of the cardiac surgeons would not operate. Of those responding, 90 percent want to be able to test all their patients for HIV status. Whether these attitudes have changed in the last decade is unknown.

A physician's fear of becoming infected with HIV is understandable, but as in the case of other professions that involved personal dangers, the profession of the physician requires performance. Both the American College of Physicians and the American Medical Association currently have standards stating that physicians may not ethically refuse to treat patients solely because the patients are HIV positive.

As of 1995, the literature has reported 49 health care workers in the United States who had no other risk factors and were known to be HIV negative at exposure who have seroconverted after exposure.[123] The danger to health care personnel is greatest when there is exposure to blood and the chance of accidental needle or knife perforation or blood splash into the eyes or mouth. In one prospective study of 1307 consecutive procedures, accumulated exposure, parenteral or cutaneous, occurred in only 84 procedures (6.4 percent).[124] Parenteral exposure occurred in 1.7 percent. Knowledge of the patient's HIV status or awareness of the patient's high-risk status for such infection did not appear to influence the rate of exposure, suggesting that preoperative testing for HIV infection would not decrease the frequency of accidental exposure to blood.

In combined data from 20 prospective studies of the risk of HIV-1 transmission to health care workers, there were 6498 parenteral exposures among 1948 subjects.[125] The chance of seroconversion was 0.32 percent per exposure (95 percent confidence interval, 0.18 to 0.46 percent); in 2885 mucous membrane exposures, there was one seroconversion (0.03 percent per exposure). The risk of a health care worker developing HIV seroconversion from work-related activities was very low: approximately one infection in 300 documented exposures to HIV-positive blood.

Part 11: CARDIOMYOPATHY AND SPECIFIC HEART MUSCLE DISEASES
Chapter 71:

EFFECT OF NONCARDIAC DRUGS, ELECTRICITY, POISONS, AND RADIATION ON THE HEART

Authors: Andrew L. Smith, Wendy M. Book

This chapter details many deleterious side effects of treatments and environmental agents on the heart. Toxic effects may occur acutely and require emergent intervention or may be chronic and not be manifest until days or years after exposure.

NONCARDIAC DRUGS

Chemotherapeutic Agents

The use of chemotherapeutic agents may result in acute or chronic cardiovascular toxicity. The heart, composed of nonproliferating myocytes, was traditionally thought to be protected from the effects of drugs on rapidly dividing cells. A variety of agents are now recognized to cause cardiovascular complications, including cardiomyopathy, myocarditis, pericarditis, myocardial ischemia, arrhythmias, and peripheral hypotension or vasospasm (see Table 71-1).[1]

Table 71-1: Chemotherapeutic Agents Commonly Associated with Cardiovascular Toxicity

Drug	Associated Toxicity
Anthracyclines	
Doxorubicin	Cardiomyopathy
Daunorubicin	
Epirubicin	
Idarubicin	
Mitoxantrone	
Alkylating agents	
Cyclophosphamide	Reversible systolic dysfunction, hemorrhagic myocarditis
Cisplatin	Raynaud's phenomenon
Antimetabolites	
5-Fluorouracil	Coronary vasospasm
Other	

Amsacrine	Arrhythmias
Paclitaxel	Arrhythmias
Interleukin 2	Hypotension, myocarditis
Interferon alpha	Hypotension, cardiomyopathy

Cardiovascular alterations in the patient receiving chemotherapy may be the result of a specific drug or combination of drugs or be related to tumor-associated factors such as hypercoagulability or release of myocardial depressant factors. Correlating a specific therapy with a particular adverse event may be difficult; however, knowledge of side effects of each agent should be considered when prescribing therapy.

ANTHRACYCLINES

The anthracycline antineoplastics-doxorubicin, daunorubicin, and epirubicine-are the leading cause of chemotherapy-related heart disease. These agents may cause cardiac problems during therapy, weeks after completion of therapy, or, unexpectedly, years later.[2] During acute therapy, electrocardiographic (ECG) changes occur in approximately 30 percent of patients and usually regress within weeks. Findings include ST-T changes, decreased QRS voltage, prolongation of the QT interval, and atrial and ventricular ectopy. Sustained atrial or ventricular arrhythmias are rare. The occurrence of early ECG abnormalities does not predict cardiomyopathy and is not an indication to discontinue therapy.[1] The development of persistent sinus tachycardia (although nonspecific) in an otherwise stable oncology patient, however, may raise the suspicion of ventricular dysfunction and impending congestive heart failure.

Congestive heart failure is related to the cumulative dose of the anthracycline administered. The incidences of heart failure at specific doses of doxorubicin include 0.4 percent at 400 mg/m^2 of body surface area, 7 percent at 550 mg/m^2, and 18 percent at 700 mg/m^2 (see Fig. 71-1). Traditionally, the cardiac limiting dose has been described as 550 mg/m^2 because of the acute rise in heart failure seen above this dose. There is great individual variability, however, with reports of heart failure occurring with doses less than 100 mg/m^2 and, conversely, with some patients tolerating greater than 1000 mg/m^2 without cardiac compromise.[3,4] Risk factors for anthracycline-induced cardiomyopathy are debated but include prior chest radiation, age greater than 70, and preexisting heart disease.[3] [5] Young women may be at particularly increased risk for late cardiac dysfunction.[5] Rapid infusion schedules associated with higher peak drug concentrations appear to result in greater cardiotoxicity. Combination therapy with cyclophosphamide is an additional risk factor.[1]

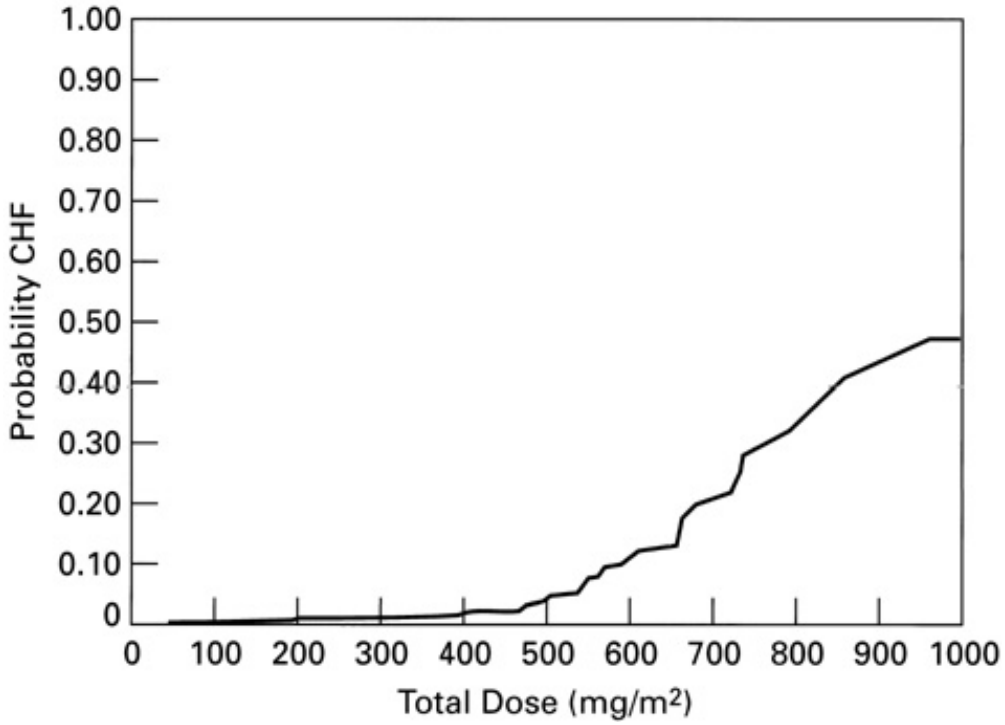

Figure 71-1: The development of doxorubicin-induced heart failure is related to cumulative dose. Toxicity may occur at any dose, but at 550 mg/m2 the probability increases significantly. (From Von Hoff et al.,[3] with permission.)

The pathogenesis of anthracycline-induced cardiotoxicity is not known. Theories generally implicate free-radical damage. One proposal is that enzymatic reduction of the anthracycline-quinone ring results in lipid peroxidation and cell membrane damage. Another theory involves the formation of an anthracycline-iron complex, which undergoes "redoxcycling" that results in oxygen radicals and degradation of microsomal, mitochondrial, and membrane lipids. Disturbances of calcium exchange have also been noted.[6]

The average time to clinical development of heart failure symptoms is 1 month from the end of therapy, but it may occur anytime within 1 year. Patient presentation is similar to that for other dilated cardiomyopathies (see Chap. 66). Biventricular systolic dysfunction occurs, and restrictive hemodynamics have been described.[7] The clinical course varies from fulminant heart failure to gradually progressive deterioration. Some patients have reversibility of systolic dysfunction. Therapy, in addition to withholding further anthracycline dosing or other myocardial toxins, is generally considered the same as recommended for patients with heart failure from dilated cardiomyopathy (Chap. 21).

Noninvasive assessment of left ventricular function has been utilized to guide anthracycline dosing and prevent cardiac toxicity. Serial echocardiography and/or radionuclide angiography (see Chaps. 13 and 16) are most commonly used.[8-10] Improved echocardiographic technologies are likely to increase the use of echocardiography in the adult population. The most commonly used parameter is resting left ventricular ejection fraction. Recognition that resting left ventricular ejection fraction is relatively insensitive for detecting early cardiotoxicity[2] has resulted in investigation of other variables (exercise or dobutamine echocardiography,[9] Doppler velocities, and systolic time intervals) in assessing this problem. These methods have generally been evaluated in small studies and have not gained widespread acceptance in current therapy guidelines. Adult guidelines for serial assessment have been developed. A drop in left ventricular ejection fraction greater than 10 percent (EF units) and to below a normal value of 50 percent is an indication to discontinue therapy. A baseline left ventricular ejection fraction less than 30 percent

has generally been considered a contraindication to initiating anthracycline therapy.[10]

Compared with the noninvasive methods, endomyocardial biopsy is considered more specific and provides earlier sensitivity in detection of anthracycline cardiotoxicity. The Billingham score, which quantifies cytoplasmic changes and the percent of myocytes damaged, has been utilized to assess the risk of congestive heart failure.[11] Clinical utility has been limited because of the invasive nature of this procedure and the special expertise required in obtaining and reading the specimens. Additionally, variability of histologic changes and the potential for sampling error have been noted.[12]

There is growing recognition of the occurrence of cardiac dysfunction years after completion of anthracycline therapy. This is particularly of concern in children. One study reported a 23 percent incidence of late cardiac abnormalities (decreased systolic function by noninvasive testing) in survivors of pediatric malignancies treated with anthracycline therapy.[13] The incidence of abnormalities was higher in the patients with the longer elapsed times since therapy, with a 38 percent incidence in patients with a follow-up period greater than 10 years. This study, as well as others,[14] suggests that subclinical myocardial damage may not become clinically evident until years after therapy. Although fewer than 5 percent of these patients had developed clinical heart failure, the potentially progressive nature of systolic dysfunction raises the issue of need for long-term clinical follow-up. There are presently no accepted guidelines, however, in either the pediatric or adult population for chronic monitoring. Early treatment of systolic dysfunction with angiotensin-converting enzyme inhibitors may be warranted in asymptomatic patients.[2] Additionally, patients presenting late after anthracycline therapy with exertional fatigue and normal resting ejection fractions have been noted to have abnormalities on dobutamine echocardiography. This observation suggests abnormalities in cardiac reserve that may lead to symptoms.

Clinical strategies for preventing anthracycline cardiotoxicity have had to balance the need for antineoplastic efficacy. Lower clinical toxicity has been noted with prolonged infusions of doxorubicin over 48 to 96 h in order to avoid high peak concentrations.[15] Several antioxidants have been evaluated, but with inconclusive results.[6,16] *Dexrazoxane*, [17] an iron-chelating agent, reduces free-radical generation by anthracyclines and is approved for use in women with breast cancer after a cumulative dose of doxorubicin of 300 mg/m^2. Studies demonstrate a decrease in cardiotoxicity and most but not all trials have suggested preserved efficacy of antitumor activity. New anthracyclines, including epirubicine and idarubicin, appear to have diminished cardiotoxic effects, although long-term results cannot presently be assessed.[2]

OTHER CHEMOTHERAPEUTIC AGENTS

Mitoxantrone, an anthracendione lacking the amino sugar of anthracyclines, causes cardiotoxicity with features similar to anthracycline-induced cardiomyopathy.[1] This drug appears to have less cardiotoxicity than doxorubicin at equal myelotoxic doses. Cumulative doses above 160 mg/m^2 are associated with an increasing incidence of congestive heart failure.[18]

High-dose *cyclophosphamide* (120 to 240 mg/kg over several days) used in bone marrow transplantation may cause acute cardiac toxicity.[1,19] Symptomatic systolic dysfunction, usually reversible with drug discontinuation, is associated with decreased QRS voltage on the ECG. Pericardial effusions have been noted, and a hemorrhagic myocarditis may result in death. Necropsy data demonstrate endothelial injury with resultant interstitial fibrin deposition and capillary microthrombosis. The cardiotoxicity of cyclophosphamide is likely due to damage from its biologically active metabolites. Rapid metabolizers of cyclophosphamide appear to be prone to cardiotoxicity. The metabolites cause the toxic endothelial damage leading to muscle damage.[19] Cyclophosphamide may also potentiate the cardiotoxic effects of the anthracyclines.[1]

5-*Fluorouracil* may occasionally cause angina, ECG changes, and rarely myocardial infarction.[1,20] The majority of episodes occur during the first cycle of therapy and resolve spontaneously after discontinuation. Arrhythmias and systolic dysfunction have been observed. The understanding of 5-fluorouracil toxicity is complicated because combination chemotherapy is generally utilized, patients may be systemically ill, and many receiving this medication have preexisting coronary artery disease.[20] The incidence of cardiac toxicity is uncertain but ranges from 1 to 8 percent.[21] Patients with known coronary artery disease are at higher risk for serious cardiotoxicity. The mechanism of toxicity remains unclear, although coronary vasospasm has been suspected. Coronary catheterization has generally failed to demonstrate vasomotor hyperreactivity with 5-fluorouracil on ergonovine challenge.

Amsacrine (AMSA) has been associated with prolongation of the QT interval. Malignant ventricular arrhythmias may occur in 1 percent of patients and are exacerbated by hypokalemia.[22]

Paclitaxel (taxol) is being used with increased frequency for breast and ovarian cancer. The most common cardiovascular effect is the development of transient asymptomatic bradycardia, occurring in up to 30 percent of patients. Bradycardia with adverse consequences occurs in only 0.1 percent of patients. A possible relationship of paclitaxel to heart failure has been questioned, but confirmatory data are lacking.[23]

Herceptin (recombinant humanized anti-HER2 antibody) is a relatively new treatment for breast cancer that appears to have favorable antitumor effects when added to standard chemotherapy in selected patients. Unfortunately, cardiac toxicity may limit the use of this drug. In a breast cancer treatment trial, 27 percent of patients receiving doxorubicin, paclitaxel, and Herceptin had cardiac dysfunction compared with 6 percent receiving doxorubicin and paclitaxel without Herceptin. Close cardiac monitoring is warranted.[24]

Immunomodulating Agents

The biological response modifiers *interleukin-2* (IL-2) and *interferon alpha* have been associated with cardiovascular toxicity predominantly secondary to peripheral vasodilatation. IL-2 causes tachycardia, hypotension, and a capillary leak syndrome. Myocarditis has been reported in patients who died soon after initiation of therapy. IL-2 therapy requires pretreatment assessment of cardiovascular risks and close monitoring during drug administration. Interferon alpha may cause supraventricular tachyarrhythmias. A reversible cardiomyopathy has been described.[1,19,25]

Psychotropic Agents

Psychiatric illness, particularly depression, is common in patients with cardiovascular disease[43] (see Chap. 80). Morbidity and mortality following cardiac events are increased in patients with depression, particularly if untreated.[26,27] A variety of psychotropic agents have conduction or vascular effects (see Table 80-11). A thorough understanding of these therapeutic but potentially toxic agents is necessary in the treatment of patients with preexisting cardiac disease. Intentional overdose with these drugs may result in serious cardiac manifestations.

TRICYCLIC ANTIDEPRESSANTS

The tricyclic antidepressants, including the tertiary (amitryptyline, clomipramine, doxepin, imipramine, trimipramine) and secondary (desipramine, nortriptyline, protriptyline) amines, have potentially serious cardiovascular effects. These effects include increased heart rate, orthostatic hypotension, ECG changes, and possible depression of ventricular function. These drugs have electrophysiologic properties similar to the type IA antiarrhythmics. There is the potential for late

proarrhythmia in patients with structural heart disease who are taking these agents.[28]

The tricyclic antidepressants have several properties that account for the majority of cardiovascular effects. These drugs inhibit uptake of both norepinephrine and serotonin, resulting in greater toxicity compared to the selective serotonin reuptake inhibitors (SSRIs). A hyperadrenergic state may result in tachycardia. Alpha blockade occurs at higher drug levels and may cause marked hypotension in the setting of overdose. The anticholinergic effects result in tachycardia, dry mouth, and constipation; in overdose they may delay gastrointestinal absorption of the drug. Sodium channel blockade, typical of the type IA antiarrhythmic compounds, results in conduction abnormalities[52] and the potential to suppress ventricular function.[29]

The most frequent side effect of tricyclic antidepressant treatment, orthostatic hypotension, is common in older patients and does not generally improve when doses are reduced to lower levels that will still maintain antidepressant effects. Orthostasis, mediated predominantly by alpha-1 adrenergic receptor blockade, may occur with all of these drugs but is less likely with nortriptyline.[29,30]

The most common ECG changes include nonspecific ST-T changes and prolongation of the QT interval, PR interval, and QRS duration. PR prolongation is due to prolonged infranodal conduction. Patients with preexisting conduction disease, particularly bundle branch block, are at increased risk of toxicity.[31] The type IA antiarrhythmic properties may potentially suppress ventricular ectopy. The results of recent antiarrhythmic studies, however, including those with type I agents, suggest the potential for a proarrhythmic effect for these drugs at therapeutic doses in patients with serious structural heart disease.[28,32] Tricyclic antidepressants are generally contraindicated in the recovery phase following myocardial infarction. Although tricyclic antidepressant therapy may be indicated in the treatment of severely depressed patients, the threshold for use should rise as the severity of heart disease increases or when there is QT prolongation.[28] These issues are discussed in detail in Chap. 80.

Tricyclic antidepressants may impair left ventricular function in patients with severe systolic dysfunction; however, decreases in left ventricular ejection fraction have generally not been noted in patients with moderately impaired function. Tricyclic antidepressant overdose carries a mortality of 2 to 3 percent, which is generally related to cardiac complications. Clinical status at initial presentation and serum drug levels are not predictive of prognosis. QRS prolongation is a sign of toxicity but may be absent in the patient with serious cardiac complications. Rightward deviation of the terminal 40 ms of the frontal plane QRS axis is a more sensitive marker. This finding, manifest by a terminal R wave in lead aV_R, has an 83 percent sensitivity and 63 percent specificity for toxicity.[33]

Aggressive support measures in tricyclic antidepressant overdose should be initiated immediately and include airway maintenance, gastric lavage, and repeated dosing of activated charcoal. Alkalinization with intravenous sodium bicarbonate decreases unbound drug and reverses cardiac and central nervous system conduction defects. Alkalinization is indicated in cardiac arrest, hypotension, arrhythmias, acidosis, and QRS prolongation. Hypotension refractory to volume loading and bicarbonate therapy should be treated with vasopressors, including norepinephrine and phenylephrine, and with vasopressor doses of dopamine. Type I antiarrhythmics (quinidine, procainamide, disopyramide) should not be used. Sodium bicarbonate is the initial therapy for ventricular dysrhythmias.[34]

The duration of monitoring after tricyclic overdose is controversial. Signs of major toxicity generally occur within 6 h of presentation in the emergency department. If clinical or ECG evidence of toxicity is absent and two doses of activated charcoal have been given, patients may not require admission for medical monitoring. Fluoxetine increases tricyclic antidepressant serum

levels, and additional monitoring is recommended in patients receiving this medication. Patients with cardiac disease or other serious medical problems may require a longer period of observation.[35]

OTHER ANTIDEPRESSANTS

Selective serotonin reuptake inhibitors (SSRIs) have not been extensively studied in patients with cardiac disease.[36] Case reports of cardiac toxicity are rare, despite the increasing popularity of these agents in the treatment of depression. These agents have rarely been associated with orthostatic hypotension and with bradycardia. Cardiac function does not appear to be depressed by these agents.[37] The SSRIs may affect the cytochrome P450 system and may therefore alter the metabolism of a variety of drugs, including agents used in cardiovascular disease such as antiarrhythmic medications, beta blockers, calcium channel blockers, and warfarin (see Chap. 80).

The monoamine oxidase inhibitors (MAOIs) have little effect on cardiac conduction or myocardial contractility. Orthostatic hypotension is common, particularly in elderly patients. The major concern with these agents is interaction with other drugs or tyramine-containing substances, resulting in hypertensive crisis.[38]

Lithium, used commonly in the treatment of bipolar disorder, is generally well tolerated in patients with cardiac disease. Suppression of sinus node automaticity, resulting in bradycardias, is the most common complication.[39] In patients free of known heart disease, clinically significant sinus node dysfunction occurs in fewer than 1 percent and is reversible with discontinuation of lithium therapy. Preexisting sinus node disease or concomitant therapy with drugs altering sinus node function, however, may result in sinus bradycardia. Lithium-induced hypothyroidism may be a contributing factor.[40] Pacemaker therapy may be required to allow continuation of lithium therapy.

Lithium therapy has been associated with ECG changes simulating hypokalemia. T-wave inversion, prominent U waves, and QT prolongation may occur. PR prolongation, bundle branch block, and complete heart block are rare.[39] Overdose with lithium may result in severe bradycardias requiring temporary pacemaker therapy. A low anion gap may suggest the presence of lithium toxicity.[41]

ANTIPSYCHOTIC AGENTS

The phenothiazine antipsychotic agents have potential cardiac toxicity similar to that of the tricyclic antidepressants. These drugs may cause sinus tachycardia, PR and QT prolongation, and disturbances of intraventricular conduction. Chlorpromazine and thioridazine[42] are the most commonly implicated phenothiazines as causes of torsades de pointes. The butyrophenone haloperidol is also associated with torsades de pointes at high doses given intravenously.[43]

Noncardiac Drugs and Toxic Antidepressants Causing Torsades de Pointes

As discussed above, the tricyclic phenothiazine and other psychotropic agents may prolong the QT interval and induce torsades de pointes. A variety of antiarrhythmic agents, particularly the type I agents, are most strongly associated with this potentially fatal arrhythmia. Other toxic causes of torsades de pointes[44] are listed in Table 71-2.

Table 71-2: Noncardiac Drugs and Toxins Known to Cause Torsades de Pointes

Psychotropic agents	Antihistamines
Tricyclic antidepressants	Terfenadine
Tetracyclic antidepressants	Astemizole
Phenothiazines	Other
Haloperidol	Cisapride
Chloral hydrate	Pentamidine
Antibiotics	Probucol
Erythromycin	Arsenic
Trimethoprim-sulfa-	Organophosphates
methoxazole	Liquid protein diets

The antibiotics erythromycin and trimethoprim-sulfamethoxazole[45,46] have only rarely been associated with torsades de pointes, the exception being the effect of erythromycin on the metabolism of terfenadine, astemizole, and cisapride. Liquid protein diets and starvation[47] may cause marked electrolyte and chemical disturbances, triggering QT prolongation. Probucol[48] may prolong the QT interval, resulting in torsades de pointes.

The QT prolongation and torsades de pointes reported with the antihistamines terfenadine and astemizole and with cisapride have been associated with high drug levels from excessive dosing or altered metabolism.[49,50] Prolongation of the QT interval induced by terfenadine, astemizole, and cisapride is due to the electrophysiologic activity of blocking HERG, the ion channel that is responsible for the rapid component of the delayed rectifier current for potassium(I_{kr}).[50] These drugs are metabolized by the cytochrome P450 3A isoenzyme.[51] A variety of agents inhibit this isoenzyme, including antifungals (ketoconazole, fluconazole, itraconazole), erythromycin or clarithromycin (not azithromycin), SSRIs (fluvoxamine, nefazodone, fluoxetine, sertaline), quinine, and grapefruit juice. Serious cardiac arrhythmias have been reported in patients taking terfenadine, astemizole, or cisapride with drugs that inhibit the cytochrome P450 3A isoenzyme. Patients with a history of prolonged QT interval or those with serious underlying cardiac disease are at higher risk for this problem. Some women appear to have slow metabolism of these drugs; thus female gender is a risk factor for drug-induced arrhythmias.[50]

Methylxanthines and Beta-Adrenergic Agonists

The methylxanthines caffeine and theophylline have pharmacologic actions of central nervous system stimulation, bronchial smooth muscle relaxation, and cardiac muscle stimulation and have diuretic effects on the kidneys. At therapeutic doses or those consumed in xanthine-containing beverages, these agents competitively inhibit adenosine receptors. At higher doses, they exhibit phosphodiesterase inhibition.[52] The effect of caffeine consumption on the cardiovascular system is variable and depends on chronicity of use, dose exposure, and individual responsiveness. Although elevations of catecholamines may occur with acute administration, this effect resolves with chronic usage. At higher concentrations, caffeine may cause tachycardia and dysrhythmias. Despite the concern that caffeine may be detrimental in patients predisposed to cardiac rhythm disturbances, it appears that moderate amounts of caffeine consumption may be well tolerated in patients with ventricular arrhythmias. The role of coffee, with or without caffeine, as a risk factor

for coronary artery disease has been debated. While heavy coffee drinking (>4 cups a day) has been suggested as a potential risk factor for cardiovascular mortality, the data are inconclusive.[53,54]

Theophylline has the potential to cause a slight increase in heart rate with minimal effects on blood pressure. Patients with obstructive lung disease commonly have atrial and ventricular arrhythmias, which can be exacerbated by theophylline therapy. Theophylline toxicity is associated with sinus tachycardia, atrial and ventricular arrhythmias, and hypotension.[55] Hypokalemia, hypercalcemia, hyperglycemia, hypophosphatemia, and metabolic acidosis may occur. Esmolol may be useful in the management of refractory arrhythmias. Dialysis may be helpful in patients with refractory arrhythmias or hypotension.[56,57]

The beta-adrenergic agonists terbutaline and albuterol are commonly used to treat asthma and premature labor. Although adverse reactions are uncommon with aerosol therapy, these agents may cause tachycardia and atrial and ventricular arrhythmias and, rarely, may worsen angina pectoris.[58] Use of oral $beta_2$ agonists has been associated with the development of heart failure.[59] Intravenous therapy may cause hypokalemia and acidosis. Controversy exists over the safety of long-term aerosol therapy with beta-adrenergic agonists in asthma. These concerns, however, relate predominantly to airway hyperresponsiveness and not to direct cardiac toxicity.[60]

Antimigraine Drugs

Ergotamine

The ergot alkaloids are commonly used in the treatment of migraine headaches. Ergotamine causes constriction of smooth muscle, and its effect on vascular smooth muscle may result in hypertension and increased peripheral vascular resistance.[61] Ergonovine maleate may be used in the catheterization laboratory to diagnose coronary artery spasm. Chronic use of ergotamine may result in variant angina or myocardial infarction.[61,62] Severe circulatory disturbances of the upper and lower extremities and abdominal arteries have been described.[62] Ergotamine and methysergide have similar chemical structures. Valvular heart disease has been reported with both agents. Either may cause pericardial, pleural, or peritoneal fibrosis or multivalvular heart disease. The occurrence of these side effects is less frequent with ergotamine.[63,64]

Methysergide

Methysergide, used in treating vascular headaches, can cause retroperitoneal, pulmonary, and cardiac fibrosis. Cardiac involvement most commonly affects the valves but may affect the endocardium, myocardium, and rarely the aorta. Regurgitant valvular lesions are most common, affecting the mitral and aortic valves more commonly than the tricuspid and pulmonary valves.[65] Patients receiving methysergide therapy should be monitored for the development of murmurs. Therapy should be discontinued if a new murmur is detected. Regression of valvular lesions may occur, although valve replacement is occasionally required. Patients with known valvular disease should not be given methysergide.

Sumatriptan

Sumatriptan, a selective serotonin type I agonist, may cause coronary artery vasospasm. Sumatriptan should not be taken within 24 h of treatment with ergotamine-like medications because of the risk of prolonged vasoconstriction.[66]

The antimigraine drugs ergotamine, methysergide, and sumatriptan are generally contraindicated in patients with obstructive coronary artery disease.[67]

Weight-Loss Medications

Dexfenfluramine and the combination of fenfluramine and phentermine may cause valvular heart disease (Chaps. 56, 57, and 59).[68-72] These agents had been prescribed for weight loss in obese patients, but dexfenfluramine and fenfluramine were withdrawn from the market in 1997 when up to 30 percent of users were reported to develop asymptomatic valve regurgitation.[69] Later reports suggested a lower incidence of problems, including reports of valvular regurgitation in approximately 7 percent of dexfenfluramine-treated patients versus 2 to 5 percent of controls.[70] The true incidence of valvular problems is uncertain and differences in reported cases may be secondary to differences in length of therapy, time from therapy to cardiac evaluation, and methods used to determine abnormalities. Mild aortic regurgitation is the most common finding. Abnormalities often improve with cessation of therapy.[71,72]

Histamine H_2-Receptor Antagonists

The histamine H_2-receptor antagonists have rarely been associated with cardiac effects. Episodes of severe bradycardia have been reported as well as hypotension, asystole, and ventricular arrhythmias. These complications have generally occurred with large doses given intravenously.[73] Electrophysiologic studies have not demonstrated any direct effect on sinus node function.[74]

Chloroquine

The antimalarial agent chloroquine is commonly used to treat collagen vascular and dermatologic disorders. Irreversible retinal damage is the primary concern with long-term or high-dose therapy. Skeletal myopathy and less commonly cardiomyopathy may occur. With cardiac involvement, features of restrictive cardiomyopathy are most common. Myocardial biopsy with analysis by electron microscopy showing curvilinear and myeloid bodies is diagnostic. These findings may be seen on skeletal muscle biopsy. The ECG may demonstrate T-wave changes and conduction abnormalities. Acute chloroquine poisoning results in hypotension, tachycardia, and prolongation of the QRS and is often fatal.[75,76]

Oral Contraceptive Agents

Epidemiologic studies prior to the 1980s demonstrated that women using oral contraceptives had an increased risk of cardiovascular disease, including venous thromboembolism, myocardial infarction, hypertension, and stroke.[128] Oral contraceptive formulations used in the 1960s and 1970s consisted of relatively high-dose estrogen. Although rare, the risk of myocardial infarction was increased approximately fourfold. Women smokers, particularly those older than age 35, had a dramatically increased risk of infarction. Coronary angiography done postinfarction not uncommonly demonstrated a discrete lesion in a single vessel or no obstructive lesions, suggesting acute thrombosis as a possible mechanism. The risk of venous thromboembolism was 4 to 10 times that of nonusers during this era.[77,80]

Recent formulations of oral contraceptives consist of less than 50 μg of ethinyl estradiol in combination with a low-dose progestin. Recent studies suggest that these second- and third-generation combined oral contraceptives are much safer in terms of cardiovascular complications.[77] The risks of venous thromboembolism and myocardial infarction are significantly reduced compared with the first-generation agents. Hypertension is rare, and the risk of stroke in otherwise healthy women is only minimally increased.[78]

Third-generation oral contraceptives that contain desogestrol or gestodene are reportedly associated with a 1.5 to 2.5 increased risk of venous thromboembolism compared with the second-

generation agents. The significance of this finding has generated controversy, but generally, the cardiovascular risk profile of these agents is considered favorable. However, smokers greater than 35 years of age should use a nonestrogen contraceptive.[77-80]

Anabolic Steroids

Illicit use of androgens has been identified as a problem in competitive athletes and body builders. It is estimated that 300,000 persons in the United States have had recent steroid use and over 1 million have had prior use.[81-83] Anabolic steroids, including testosterone, stanozolol, and nandrolone, are frequently used in combination and at high doses for intermittent periods of several weeks to months. Doses commonly exceed 100 times the doses used for medical purposes.[81] Animal data indicate that these agents can cause abnormal lipids, left ventricular hypertrophy, increased blood volume, and hypertension. Data on human toxicity are limited but suggest similar toxicity.[84] Stanozolol and nandrolone reduce total high-density lipoprotein levels by over 50 percent and increase low-density lipoprotein levels by over 30 percent.[85] Isolated reports of young men (<age 35) developing severe coronary atherosclerosis, myocardial infarctions, or stroke exist in the literature.[81,86] Because of the secrecy surrounding the use of these agents, the full clinical significance of abuse is not known.

Cocaine

Cocaine is a common drug of abuse associated with potentially lethal cardiac toxicity. It is estimated that over 30 million Americans have used cocaine at least once and that 5 million use it regularly.[87] Cocaine may be swallowed, inhaled nasally, smoked, or injected intravenously. Cardiovascular toxicity is broad, ranging from sudden death to chronic cardiomyopathy.[88] A summary of the cardiovascular syndrome associated with illicit cocaine use is shown in Table 71-3. Use of cocaine with other drugs such as ethanol[89] or tobacco[90] may have combined detrimental effects. Cardiovascular susceptibility in an individual is difficult to predict due to the lack of dose-response relationship and the high degree of variability in the individual response to cocaine.[91]

Table 71-3: Cardiovascular Complications of Cocaine

Sudden death
Acute myocardial infarction
Chest pain without myocardial infarction
Accelerated coronary atherosclerosis
Intimal hyperplasia of coronary vessels
Electrocardiographic abnormalities
Sinus tachycardia
Premature ventricular complexes
Ventricular tachycardia
Torsades de pointes
Ventricular fibrillation
Prolongation of QT interval

Early repolarization (ST-segment changes)
Acute reversible myocarditis
Dilated cardiomyopathy
Acute severe hypertension
Acute aortic dissection, rupture
Pneumopericardium
Stroke
Subarachnoid hemorrhage
Endocarditis (intravenous use)

Cocaine has a generalized sympathomimetic effect and has local anesthetic properties.[88] It blocks the reuptake of norepinephrine and dopamine on preganglionic sympathetic nerve terminals. This produces sympathetic stimulation both centrally and peripherally. These catecholamine effects acutely result in tachycardia, hypertension, increased myocardial contractility, and vascular constriction. The local anesthetic effect, occurring through blockade of the fast sodium channel, results in slowed conduction in myocardial tissues. This may result in ECG abnormalities, including prolongation of the PR, QRS, and QT intervals, similar to those seen with toxicity from type I antiarrhythmic agents. These effects increase the vulnerability to reentrant ventricular arrhythmias.[8788-92]

Use of cocaine may result in increased thrombogenicity.[88,90] Platelet aggregation is enhanced and endothelial function is altered,[94] resulting in the potential for development of coronary thrombosis in the absence of coronary atherosclerosis. Chronic use of cocaine is associated with premature coronary atherosclerosis.[88,93] Cocaine indirectly causes constriction of both diseased and nondiseased coronary artery segments, but its effect is more marked in diseased vessels. Ethanol use and tobacco smoking may worsen the potential for vasospasm.[89,90] In up to one-third of reported cases, patients with cocaine-induced myocardial infarctions have normal coronary arteries.[88] The combined cardiac effects-including early coronary atherosclerosis, coronary vasospasm, increased thrombogenicity, increased myocardial oxygen demands, and proarrhythmic effects-make this drug a lethal threat to users of all ages.

Cocaine may produce direct or indirect myocardial toxicity. Animal studies suggest a direct negative inotropic effect on the heart, possibly related to its local anesthetic properties. Chronic dosing has demonstrated myocardial contraction bands, myofibrillar disorganization, interstitial edema, and mitochondrial swelling. Mononuclear infiltrates have been noted. Myocardial changes may mimic those seen with catecholamine excess, as in pheochromocytoma. Clinical case reports have described transient toxic cardiomyopathy, acute myocarditis, and permanently dilated cardiomyopathy.[88]

Chest pain is the most common reason for cocaine users to seek medical attention. Over 64,000 patients are evaluated annually for cocaine-related chest pain, of whom over half are admitted to the hospital.[95] The evaluation of cocaine-related chest pain is difficult. Prospective studies demonstrate that approximately 6 percent of patients presenting to an emergency department with cocaine-related chest pain have myocardial infarction. These patients are often young men without other risk factors for coronary artery disease except for tobacco smoking. The duration and quality of discomfort does not readily distinguish those eventually noted to have enzyme documentation

of infarction. Many young patients have early repolarization patterns with ST elevation in leads V_1 to V_3, a normal variant that may be confused with acute infarction. Infarction has been noted in patients with normal or nonspecific ECGs. Because of the difficulty in excluding myocardial infarctions, patients are often monitored for a period of at least 12 h until enzymes have excluded infarction (Chaps. 40 and 42).[87]

Treatment strategies for cocaine-induced myocardial ischemia have been developed based on the known cardiac and nervous system toxicity of the drug.[87,92] Randomized prospective trials of therapy do not exist. Patients presenting with anxiety, tachycardia, or hypertension may respond well to benzodiazepines. Nitroglycerin may reverse coronary vasoconstriction induced by cocaine. Aspirin may prevent thrombus formation. Patients not responding to these measures may benefit from the alpha-adrenergic antagonist phentolamine or from calcium channel blocker therapy with verapamil.[87] Beta-adrenergic antagonists have been avoided because of the potential of enhanced coronary vasoconstriction and for unopposed alpha-mediated hypertensive crisis. Combined alpha and beta blockade with labetalol has been utilized to treat tachyarrhythmias but is not an accepted therapy for myocardial ischemia.[87] However, the bias against beta blockade is undergoing clinical reevaluation with recognition that beta blockers may block the hyperadrenergic effects that result in thrombosis and vasospasm.[96]

In documented myocardial infarction, thrombolytic therapy is highly effective; however, over 40 percent of patients without infarction will meet accepted ECG criteria for use of lytic therapy.[97] The early repolarization pattern common in young men makes diagnosis difficult, particularly when a prior ECG is not available. Thrombolytic therapy carries increased risk of hemorrhagic stroke in patients with recently uncontrolled hypertension. Therefore emergent coronary angiography may be necessary to document coronary occlusion as well as direct strategies such as primary angioplasty or thrombolysis[147] (see Chap. 42).

Management of supraventricular or ventricular tachyarrhythmias may be facilitated by administration of benzodiazepines. Rhythm disturbances may be exacerbated by acidosis or electrolyte disorders. Intravenous sodium bicarbonate and magnesium may be beneficial. Lidocaine should be used cautiously because of concerns of lowered seizure threshold and potential proarrhythmic effects following recent cocaine use.[92]

Patients with cocaine-associated chest pain not related to myocardial infarction have a favorable 1-year prognosis, particularly if cocaine use is discontinued. Urgent diagnostic cardiac evaluation is not generally recommended. Unfortunately, recurrent cocaine use after cocaine-associated chest pain occurs in over 60 percent of cases.[87]

Methamphetamines

The biologic effects of methamphetamines are similar to those of cocaine, but vasoconstriction is less. Cardiovascular toxicity is common and includes tachycardia, hypertension, and arrhythmias. Chest pain and myocardial infarction are less common than with cocaine.[98] Chronic use may result in a catecholamine-mediated dilated cardiomyopathy.

NEXT

Chapter 71: EFFECT OF NONCARDIAC DRUGS, ELECTRICITY, POISONS, AND RADIATION ON THE HEART

ELECTRICAL INJURY

Environmental Accidents

Accidental contact with electricity may occur in the home, where young children are particularly vulnerable.[100] Job-related electrical injuries are most common in construction and electrical workers but may also occur on any job in which electrical equipment is used, including the health care setting. Approximately 1200 deaths related to domestic electrical injury occur each year in the United States. There are two to three times as many serious injuries, including burns and neurologic complications.[101] Lightning kills at least 100 people per year in the United States, representing a 30 percent mortality rate in reported cases. Lightning injuries generally occur between May and September in the late afternoon hours, and affect predominantly young people involved in outdoor recreational activities.[102] Death following electrical shock is usually secondary to immediate cardiac rhythm disturbances, although later cardiac complications secondary to internal injury may occur.

PATHOPHYSIOLOGY

The degree of total body injury from electricity is determined by the amount of current delivered, tissue resistance, and duration of contact. Specific organs or tissues injured are in part determined by the path of the current. Electrical injuries are classified as high-voltage (>1000 V) or low-voltage (<1000 V). High-voltage electrical wires and household current (120 or 220 V) are alternating currents (AC) that may result in prolonged exposure due to tetatanic muscle contractions and inability of the victim to "let go." The frequencies of domestically generated AC (50 to 60 cycles per second) result in an increased risk for ventricular fibrillation even at household voltages.[101] Sources of domestic direct current (DC) are usually low-voltage (3 to 24 V), including batteries, appliance transformers, and portable emergency generators and are less likely to cause injury. Lightning is extremely high voltage direct current of brief duration.

Heat injury tissue necrosis is more severe with high-voltage AC. These burns are often internal and may mimic crush injuries. Tissue resistance to current flow is least in nervous and vascular tissues; therefore the heart and neurovascular bundles may serve as conduits for electrical current through the thorax. Arm-to-arm pathway of current is associated with greater risk for cardiac injury, followed by arm-to-leg pathways determined by entry and exit sites. A stride potential, leg to leg, is infrequently associated with cardiac effects.

CARDIOVASCULAR EFFECTS

Cardiac damage in electrical injury may occur as a result of contusion injury or myocardial necrosis or may be in part related to massive release of catecholamines. Typical symptoms or signs of myocardial damage may be absent. Lightning injuries result from brief, high-voltage direct current. Immediate death may be secondary to asystole or ventricular fibrillation or may result from apnea secondary to injury of the central respiratory centers. Lightning strikes may occur by a direct hit, side splash, or ground strike. Direct hits cause mechanical trauma to organs secondary to dissipated energy. Strikes to the chest can result in severe, often reversible global myocardial dysfunction or localized myocardial contusion. ECG abnormalities, including QT_c

prolongation and ST-T abnormalities, may be the result of cardiac or neurologic injury. ST elevation has been noted with direct strikes. Conduction abnormalities, including right bundle branch block and complete heart block, have been noted. Pericardial effusions may develop following direct strikes. Elevated levels of CK-MB are generally noted.[102] Splash strikes in which a tree or other object is hit prior to the victim's being hit are associated with CK-MB release in less than two-thirds of patients. Severe myocardial injury is unlikely unless there is a short distance between the directly hit object and the victim. Ground strikes generally do not cause a significant cardiac injury but may be associated with nonspecific ST-T abnormalities.

Domestic alternating current accidents may cause myocardial necrosis and conduction abnormalities. An injury pattern mimicking infarction may be seen on the ECG but is generally related to direct myocardial injury and not from coronary thrombosis.[165] Household voltages (120 to 220 V) may cause sudden death, particularly when they involve arm-to-arm pathways or low skin resistance in a wet victim. Serious myocardial damage is rare.[100]

Treatment for cardiac arrest should be initiated immediately after the patient is disconnected from the current source. Resuscitation efforts should be continued for a prolonged period. In lightning strikes involving multiple victims, attention should be directed first to those who are "apparently dead." This is because there is a higher resuscitation rate for these individuals than for those with medical cardiac arrest. Of note, lightning victims with vital signs generally survive without immediate medical attention.[103]

Patients surviving high-voltage injuries generally require admission, usually for attention to neurologic complications and internal or external burn injuries and less commonly for cardiac monitoring. An initially normal ECG carries a favorable cardiac prognosis, leading some authors to question the need for 24-h ECG monitoring. Patients with arm-to-arm or arm-to-leg passage of current may be at risk for postadmission rhythm disturbances; a higher index of suspicion is required in such patients. Adults and children presenting to the emergency department following low-voltage shocks of less than 240 V have a low incidence of myocardial injury and most do not require further monitoring.[100]

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is accepted for the treatment of a variety of psychiatric illnesses including depression resistant to pharmacologic therapy, severe suicidal ideation with vegetative signs, acute mania, and depression with intolerance to medication side effects secondary to cardiac problems[104] (see also Chap. 80). ECT involves a brief unilateral or bilateral electrical stimulus to the brain while the patient is under short-acting anesthesia with a hypnotic drug and a muscle depolarizing agent.[105] The shock produces brief, intense stimulation of the central nervous system. Cardiovascular complications may result from this stimulation or from the drugs used to modify the response.[106,107]

Initially, the ECT stimulus activates the vagus nerve and may produce bradycardia, hypotension, and rarely asystole. Sympathetic discharge occurs, which is amplified by a 15-fold rise in epinephrine and 3-fold rise in norepinephrine levels, resulting in tachycardia and hypertension. Transient atrial and ventricular tachyarrhythmias may occur in approximately 10 percent of patients with known or suspected cardiovascular disease. Transient ECG alterations-including ST-T-wave changes, QRS changes, QT prolongation, and peaked T waves-may occur.[104-108]

The mortality rate of ECT is less than 3 in 10,000, and the complication rate is approximately 0.3 percent. Patients with severe heart disease may successfully undergo ECT with acceptable risk. Prior to ECT, electrolyte abnormalities should be corrected and systemic hypertension should be controlled. Patients with pulmonary disease require special evaluation, because hypoxia and

respiratory acidosis may precipitate cardiovascular events.[104]

Following ECT, hypertension and tachycardia may be controlled with adrenergic blockade with intravenous labetalol[109] or esmolol.[107] Other antihypertensive agents such as clonidine or calcium channel blockers may be utilized. Sustained ventricular arrhythmias are treated with lidocaine, but pretreatment with lidocaine is not indicated.[104] Patients with cardiac pacemakers can safely undergo ECT.[110] Currently used pacemakers are not likely to be affected by ECT current. Although these newer devices have not been systematically studied, the 50 to 100 W delivered to the scalp during ECT are probably inadequate to reprogram current pacemakers.

Lithotripsy

Extracorporeal shock wave lithotripsy used to treat renal stones and gallstones has the potential to cause cardiac arrhythmias. Rhythm disturbances may be related to electrical stimulus from the shock wave or from enhanced vagal tone associated with the procedure. Electrocardiographic monitoring is recommended for patients with cardiac disease. Gating of the shock waves to the QRS cycle may be necessary in high-risk patients, although ungated lithotripsy with newer devices is reportedly safe in most patients.[111,112]

Chapter 71: EFFECT OF NONCARDIAC DRUGS, ELECTRICITY, POISONS, AND RADIATION ON THE HEART

POISONS

Plants

A variety of plants contain active cardiac glycosides. Ingestion of these plants may result in a clinical presentation similar to that of digoxin toxicity, including gastrointestinal and visual disturbances as well as dysrhythmias. Plants with cardiac glycoside-like effects[113] are listed (Table 71-4).

Table 71-4: Plants with Cardiac Glycoside Effects

Foxglove (*Digitalis purpurea, D. Lanata*)
Oleander (*Nerium oleander*)
Lily-of-the-valley (*Convallaria majolis*)
Christmas rose (*Helleborus niger*)
Wallflower (*Cheirina cheiri*)
Milkweed (*Asclepias* sp.)

Herbal Therapies

The use of herbal treatments and nonprescription remedies is increasing among patients. In one study, 38 percent of congestive heart failure patients questioned were using herbal products.[114] Herbal medicines may contain varying doses and contaminants and are not subject to regulations governing safety and efficacy. Serious adverse effects and drug interactions may therefore occur. The cardiac effects of some herbal remedies are listed in Table 71-5.[115-117]

Snakes and Scorpions

Snake bites cause fewer than 15 deaths per year in the United States but over 40,000 deaths per year worldwide. The majority of lethal snake bites occur in Asia, South America, and Africa. Snake venoms contain a variety of enzymes and toxins that may affect the nervous system, blood vessels, coagulation systems, or heart. The majority of deaths are from the elapids (cobra, mamba, coral snake, taipan), the bites of which cause severe neuromuscular toxicity. Cardiotoxins are present in variable amounts in snake venom. Cobra venoms may cause augmentation of myocardial contraction at low concentration and asystole at high concentration. Rattlesnake venom may affect myocardial sodium channels and depress myocardial contractility. These venoms may cause pulmonary hypertension.[118]

Scorpion stings are a common medical problem in areas including India, Southeast Asia, the southwestern United States, Mexico, and Israel. Venoms from different families have different

toxicities. The *Buthidae* venoms, primarily neurotoxic, result in spontaneous sympathetic and parasympathetic depolarization. Massive catecholamine release may cause cardiac toxicity, including tachycardia, hypertension, arrhythmias, and myocardial impairment.[119,120]

Arthropods

Direct cardiac effects related to bee, hornet, and wasp stings are difficult to establish. Cardiac complications, including arrhythmias, are generally related to anaphylaxis or epinephrine administration. Animal studies of bee venom toxicity suggest direct cardiac effects.[121,122]

Marine Toxins

Exposure to marine toxins may have serious cardiovascular effects. The venom of scorpion fish can cause sympathetic and parasympathetic discharges. Rhythm disturbances and heart failure may result. Stingray venom contains phosphodiesterases and has rarely been associated with cardiac rhythm disturbances. Ingestion of sea cucumber, which contains holothurin, may result in cardiac glycoside toxicity. Ingestion of pufferfish, which contain tetrodotoxin, may result in vascular collapse and severe bradycardia.[118,123]

Halogenated Hydrocarbons

Halogenated hydrocarbons are used in fire extinguishers, solvents, and refrigerants and in the manufacture of pesticides and plastics. Heavy acute exposure to these compounds may result in cardiac arrhythmias and sudden death.[124] Direct cardiac effects include depression of myocardial contractility and sensitization to the arrhythmogenic effects of catecholamines. Indirect cardiotoxicity may result from hypoxia or central nervous system toxicity.[125]

Organophosphates

Organophosphates, used commercially in pesticides, are powerful inhibitors of acetylcholinesterase, and this inhibition can result in parasympathetic overstimulation. Suicide attempts account for the majority of fatalities associated with ingestion of large doses of organophosphates. Signs and symptoms of ingestion include respiratory depression, bronchospasm and secretion, and pulmonary edema. Deaths are generally related to respiratory failure. Cardiac toxicity is generally associated with QT prolongation. Torsades de pointes, atrioventricular conduction disturbances, and ST-T abnormalities have been noted. Cardiac arrhythmias have been noted up to 15 days after exposure. Direct myocardial toxicity has been postulated, in addition to cholinergic hyperactivity.[126] Treatment includes atropine administration at doses sufficient to dry mucous membranes and to increase heart rate to 100 beats per minute. Obidoxime therapy has also been studied in severe overdoses.[127]

Carbon Monoxide

Toxicity from carbon monoxide is related to tissue hypoxia. Carbon monoxide has a much higher affinity for hemoglobin than does oxygen, preventing adequate oxygen exchange. Carbon monoxide exposure worsens angina pectoris and increases the risk of myocardial infarction. Carbon monoxide poisoning results in ECG abnormalities, including sinus tachycardia, atrial fibrillation, atrioventricular block, and ST-T abnormalities. Cardiac enzyme elevation may occur. Severe exposure can result in myocardial necrosis and cardiomyopathy.[128] Transient evidence of cardiac toxicity, however, is not necessarily associated with long-term sequelae.[129]

Chapter 71: EFFECT OF NONCARDIAC DRUGS, ELECTRICITY, POISONS, AND RADIATION ON THE HEART

RADIATION

Mediastinal radiation-commonly used to treat Hodgkin's disease, lung cancer, breast cancer, and seminoma-may result in acute or late cardiac sequelae. Prior to the 1960s, the heart was thought to be resistant to the effects of clinical radiation. It is now recognized that a variety of cardiac problems may result from radiation, including acute or chronic pericardial disease, coronary atherosclerosis, myocardial dysfunction, conduction defects, and, occasionally, valvular dysfunction (Table 71-6).[130,131]

Table 71-6: Radiation-induced Cardiac Disease

Pericardial
Acute pericarditis
Chronic pericarditis
Pericardial constriction
Coronary atherosclerosis
Restrictive cardiomyopathy
Dilated cardiomyopathy (concomitant anthracyclines)
Conduction disease
Valvular abnormalities

The incidence of radiation-induced heart disease is influenced by several factors, including total radiation dose, fraction size, volume of heart irradiated, concomitant anthracycline use, and presence of mediastinal tumor.[130] Improved radiation techniques have diminished the occurrence of acute or chronic cardiac toxicity.[132] Cardiac injury has generally been associated with doses above 40 Gy.[130] Increased toxicity is associated with radiation for Hodgkin's disease, where larger volumes of the heart are irradiated, compared to the small cardiac exposure given as adjuvant treatment for breast carcinoma. Large doses per fraction and anterior-weighted fields result in greater toxicity.[133]

Pericardial disease is the most common manifestation of radiation toxicity to the heart. With the current techniques of subcarinal shielding, equal weighting of anterior and posterior ports, and limiting the dose to less than 30 Gy, the incidence of clinical pericarditis is approximately 2.5 percent.[132] Anatomic changes of the pericardium occur in the majority of patients but are clinically silent. Clinically apparent pericarditis is most frequent 4 to 6 months after therapy. Acute pericarditis, asymptomatic pericardial effusion, or pericardial tamponade may occur. Other etiologies of pericarditis should be considered, particularly malignant involvement of the pericardium. Pericarditis occurring during treatment of a mediastinal mass contiguous to the heart

is generally secondary to tumor effects and does not correlate with late pericardial complications.[134,135]

Radiation may cause an exudative pericarditis. Cellular infiltrate is uncommon. Pericardial fibrosis may follow secondary to fibroblast proliferation and collagen deposition. The majority of patients with pericardial effusion recover spontaneously.[130] Constrictive pericarditis may occur months to years after pericardial effusion or may develop in patients without previously recognized pericardial disease.

The majority of patients with pericardial disease have a relatively benign course. Treatment is based on symptoms, including pericardiocentesis for tamponade and antipyretics for fever. Animal data suggest possible benefit from steroids.[130]

The surgical management of postirradiation constrictive pericarditis is difficult.[134] Extensive mediastinal and pericardial fibrosis make pericardiectomy technically challenging. Surgical morbidity and mortality are significant. Radiation-induced constriction is often associated with coronary atherosclerosis, myocardial dysfunction, or conduction and valvular abnormalities. Comorbid cardiac or general medical conditions should be considered when patients are selected for pericardiectomy.

Clinically important myocardial dysfunction related to radiation generally occurs in combination with pericardial disease. Asymptomatic patients may have varying degrees of myocardial fibrosis. The anterior right ventricle is most susceptible. Areas of fibrosis may be patchy or diffuse. Noninvasive techniques such as echocardiography may show mild impairment of systolic function; however, this is usually not clinically significant.[132] Diastolic abnormalities may occur due to fibrosis.

Restrictive cardiomyopathy has been reported but is rare.[130] Premature coronary artery disease may result from radiation therapy, particularly in patients who were irradiated in an era when cardioprotective techniques were not used. Several series have reported a significantly increased risk of coronary artery disease years following therapeutic radiation involving cardiac exposure.[135] The Stockholm Trial demonstrated increased mortality secondary to coronary artery disease in women receiving high-dose radiation to the heart as adjuvant therapy for carcinoma of the left breast.[135] A review of 635 patients at Stanford treated for Hodgkin's disease before age 21 between the years 1961 and 1991 showed a significantly increased risk for myocardial infarction.[136,137] It is not clear, however, whether present techniques of mediastinal radiation will result in a clinically significant increase in coronary events. Percutaneous angioplasty and coronary bypass surgery have been successful in selected patients. The commonly associated mediastinal and pericardial fibrosis, however, make surgical revascularization more difficult.[130]

Clinically significant valvular heart disease secondary to radiation is rare but, when present, usually involves the aortic or mitral valves.[130,131] Fibrous thickening of the cardiac valves has been noted at autopsy. This thickening often causes asymptomatic aortic or mitral regurgitation.[138] Coexisting pericardial disease is the rule. Symptoms related to valvular dysfunction have been noted to occur 15 to 40 years after radiation treatment. Surgical reports are rare and most commonly are for replacement of the aortic valve due to aortic stenosis.[131]

Radiation may result in fibrosis of the nodal and infranodal pathways. Complete atrioventricular block, right bundle branch block, and, less commonly, left bundle branch block may occur. Progression to complete heart block is rare.

Part 12: PERICARDIAL DISEASES AND ENDOCARDITIS
Chapter 72:

DISEASES OF THE PERICARDIUM

Author: Brian D. Hoit

INTRODUCTION

Anatomy of the Pericardium

The pericardium is composed of visceral and parietal components. The visceral pericardium is a mesothelial monolayer that adheres firmly to the epicardium, reflects over the origin of the great vessels, and, together with a tough, fibrous coat, envelops the heart as the parietal pericardium (Fig. 72-1). The pericardial space is enclosed between these two serosal layers and normally contains up to 50 mL of a plasma ultrafiltrate, the pericardial fluid. Pericardial reflections around the great vessels tether the pericardium superiorly and result in the formation of two potential spaces: the oblique and transverse sinuses. The left atrium is anterior to the oblique sinus and is therefore largely an extrapericardial chamber; this relationship explains why effusions generally are not seen behind the left atrium. Superior and inferior pericardiosternal and diaphragmatic ligaments limit displacement of the pericardium and its contents within the chest and neutralize the effects of respiration and change of body position. The phrenic nerves are embedded in the parietal pericardium and, for this reason, are vulnerable to injury during pericardial resection.

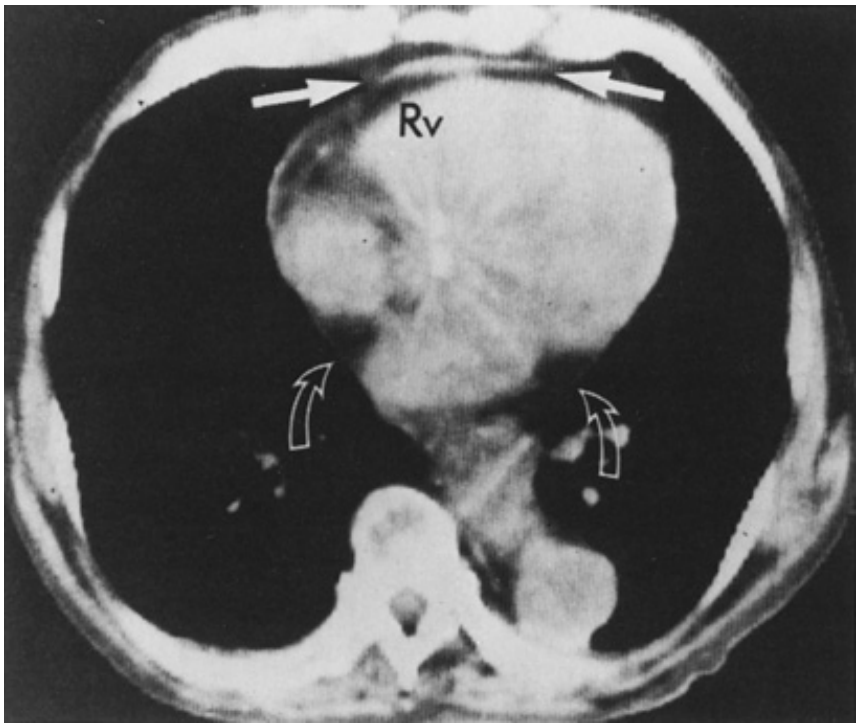

Figure 72-1: Computed tomographic (CT) scan shows the normal pericardium as a thin, curvilinear line (*open arrows*). The increased thickening over the anterior surface of the heart

(*solid arrows*) is probably an artifact from transmitted right ventricular pulsations. (From Moncada R, Baker M. In: Higgins CB, ed. *CT of the Heart and Great Vessels.* Mt. Kisco, NY: Futura; 1983:292. Reproduced with permission.)

Histologically, the pericardium is composed predominantly of compact collagen layers interspersed with elastin fibers. The abundance and orientation of the collagen fibers are responsible for the characteristic viscoelastic mechanical properties of the pericardium. For example, the pressure-volume relation of the pericardium is nonlinear; i.e., the relation is initially flat (producing little to no change in pressure for large changes in volume) and develops a "bend" or "knee" at a critical pressure, which terminates in a steep slope (producing large changes in pressure for small changes in volume) (Fig. 72-2). In addition, the pericardium is anisotropic; i.e., it stretches more in the short axis than in the long axis.

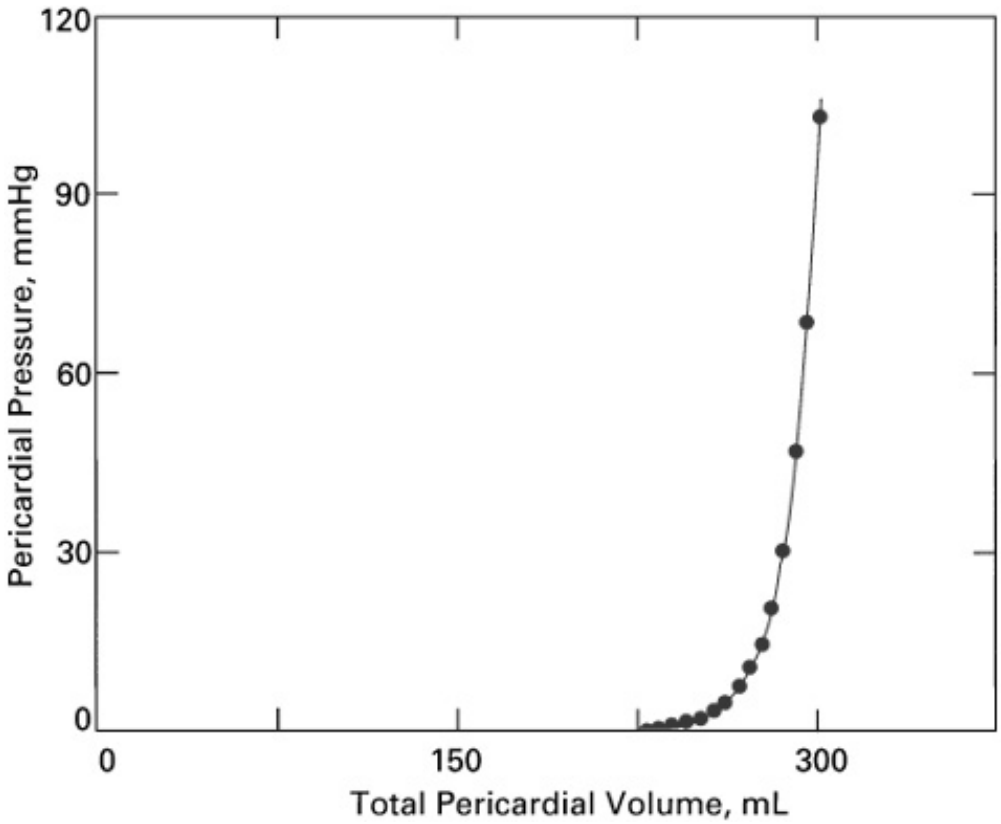

Figure 72-2: Pericardial pressure-volume relation in a dog. (From Holt JP. The normal pericardium. *Am J Cardiol* 1970; 26:455. Reproduced with permission.)

Physiology of the Pericardium

The pericardium is not essential for life; no adverse consequences follow congenital absence or surgical removal of the pericardium. However, the pericardium serves many important (although subtle) functions (Table 72-1). The pericardium limits distention of the cardiac chambers and facilitates interaction and coupling of the ventricles and atria.[1] Thus, changes in pressure and volume on one side of the heart can influence pressure and volume on the other side. Limitation of cardiac filling volumes by the pericardium also may limit cardiac output and oxygen delivery during exercise.[2] The pericardium also influences quantitative and qualitative aspects of ventricular filling[3]; the thin-walled right ventricle (RV) and atrium are more subject to the influence of the pericardium than is the more resistant, thick-walled left ventricle (LV).[4]

Table 72-1: Functions of the Pericardium

Mechanical
Effects on chambers
Limits short-term cardiac distention
Facilitates cardiac chamber coupling and interaction
Maintains pressure-volume relation of and output from cardiac chambers
Maintains geometry of left ventricle
Effects on whole heart
Lubricates, minimizes friction
Equalizes gravitation, inertial, hydrostatic forces
Mechanical barrier to infection
Immunologic
Vasomotor
Fibrinolytic
Modulation of myocyte structure, function, and gene expression
Vehicle for drug delivery and gene therapy

Although the magnitude and importance of pericardial restraint of ventricular filling at physiologic cardiac volumes remain controversial, there is general agreement that pericardial reserve volume (i.e., the difference between unstressed pericardial volume and cardiac volume) is relatively small and that pericardial influences become significant when the reserve volume is exceeded. This may occur with rapid increases in blood volume and in disease states characterized by rapid increases in heart size (e.g., acute mitral and tricuspid regurgitation, pulmonary embolism, RV infarction). In contrast, chronic stretching of the pericardium results in "stress relaxation"; this explains why large but slowly developing effusions do not produce tamponade. In addition, the pericardium adapts to cardiac growth by "creep" (i.e., an increase in volume with constant stretch) and cellular hypertrophy. Pericardial thickening, which is characterized by mesothelial cell and matrix rearrangments, and the absence of diastolic abnormalities on echocardiography are features of vibroacoustic disease.[5]

The pericardium serves a variety of other important functions. It prevents excessive torsion and displacement of the heart, minimizes friction with surrounding structures, and is an anatomic barrier to the spread of infection from contiguous structures. The thin layer of pericardial fluid reduces friction on the epicardium and is thought to equalize gravitational forces over the surface of the heart; transmural cardiac pressures therefore do not change during acceleration or differ regionally within cardiac chambers. In addition, pericardial fluid equalizes inertial and hydrostatic forces. The pericardium also has immunologic, vasomotor, and fibrinolytic activity.[6] Epicardial mesothelial cells may modulate myocyte structure and function and gene expression.[7] Finally, the pericardial space has been used as a vehicle for drug delivery in gene therapy; studies using radiolabeled growth factors indicate that substances more consistently and reproducibly gain

access to the coronary arteries via pericardial fluid than via endoluminal delivery.[8,9]

PERICARDIAL MICROPHYSIOLOGY

The pericardium is richly innervated; neuroreceptors in the epicardium and fibrosa, sympathetic afferents, stretch-sensitive mechanoreceptors, and phrenic afferents monitor dynamic changes in cardiac volume and tension.[10] Chemo- and mechanoreceptors with sympathetic afferents may be responsible for the transmission of pericardial pain.[11]

The mesothelium of the pericardium is metabolically active and produces prostaglandin E_2, eicosanoids, and prostacylin; these substances modulate sympathetic neurotransmission and myocardial contractility and may influence epicardial coronary arterial tone. The concentration of angiogenic growth factors bFGF and VEGF increases in unstable angina,[12] suggesting a role for these factors in response to ischemia and injury. The level of brain natriuretic peptide (BNP) in the pericardial fluid is a more sensitive and accurate indicator of ventricular volume and pressure than is either plasma BNP or atrial natriuretic factor and may play an autocrine/paracrine role in heart failure.[13] In addition, levels of pericardial 8-iso-PGF2α (a marker of oxidant stress) increase directly with increasing ventricular dilatation and severity of heart failure, suggesting a role of oxidant stress in ventricular remodeling and the development of heart failure.[14]

Pericardial Pressure

Pericardial pressure measured by a fluid-filled catheter in the pericardial space is subatmospheric and is essentially equal to pleural pressure throughout the respiratory cycle. Small fluctuations related to the events of the cardiac cycle (pericardial pressure is lowest during ventricular ejection) are superimposed on the larger fluctuations related to the events of the respiratory cycle. Although much of the understanding of pericardial physiology is based on fluid pressure, pericardial restraint is a contact force, defined as fluid pressure plus deformational force (much like the force at the knee joint that, although considerable, is negligible when measured with a needle in the joint space). Pericardial contact pressure measured with flat balloons is considerably higher than liquid pressure and varies regionally.[3]

Balloon pressure is similar to the theoretical pericardial pressure that is calculated as the difference in LV diastolic pressure before and after pericardiectomy. This theoretical pressure has important implications for understanding the role of the pericardium in states of altered ventricular loading, such as pulmonary hypertension, aortic stenosis, and congestive heart failure, but does not explain pericardial influences on transmural pressure, for example, during acceleration and deceleration. When liquid versus contact pressure is more relevant is controversial among physiologists but is far less relevant to clinicians, who measure pericardial pressure only when there is a pericardial effusion.

Pathology of the Pericardium

In view of its simple structure, clinicopathologic processes involving the pericardium are understandably few; indeed, pericardial heart disease includes only pericarditis (an acute, subacute, or chronic fibrinous, "noneffusive," or exudative process) and its complications, tamponade and constriction (an acute, subacute, or chronic adhesive, fibrocalcific response), and congenital lesions. However, despite a limited number of clinical syndromes, the pericardium is affected by virtually every category of disease, including infections, neoplastic, immune/inflammatory, metabolic, iatrogenic, traumatic, and congenital etiologies. Thus, the physician is likely to encounter patients with pericardial disease in a variety of settings, either as an isolated phenomenon or as a complication of a variety of systemic disorders, trauma, or certain drugs.

Pericardial disease often remains clinically silent and may be detected only during the evaluation of unrelated complaints by the electrocardiogram (ECG), chest radiography, or echocardiography. Despite exhaustive etiologic lists (Table 72-2), the cause of pericardial heart disease often is never identified. Recently, an increased prevalence of pericarditis, (owing largely to therapeutic advances such as cardiovascular surgery, hemodialysis, and radiation therapy), pericardial involvement in AIDS, and advances in the recognition, diagnosis, and therapy of pericarditis and its complications have resulted in a resurgence of interest in pericardial heart disease. The remainder of this chapter reviews pericarditis and its sequelae, pericardial effusions, cardiac tamponade and constrictive pericarditis, and congenital diseases of the pericardium.

Table 72-2: Causes of Pericardial Heart Disease

Idiopathic

Chapter 72: DISEASES OF THE PERICARDIUM

ACUTE PERICARDITIS

Acute fibrinous or dry pericarditis is a syndrome characterized by typical chest pain, a pathognomonic pericardial friction rub, and specific ECG changes. A variety of conditions are associated with acute pericarditis (Table 72-2). The following description refers to viral and idiopathic pericarditis without significant effusion. Specific forms of pericardial heart disease are reviewed later in the chapter.

History

Acute pericarditis typically produces sharp retrosternal pain that radiates to the trapezius ridge and is aggravated by lying down and relieved by sitting up; its onset frequently is heralded by a prodrome of fever, malaise, and myalgia (Fig. 72-3). The pain of pericarditis is often worse with inspiration and is difficult to distinguish from pleurisy; in some cases, the pain is indistinguishable from that of myocardial infarction. The quality, severity, and location of pain vary greatly, and chest pain may be absent in acute pericarditis, especially in early pericarditis complicating myocardial infarction or cardiac surgery and in uremic pericarditis.

Physical Findings

The hallmark of acute pericarditis is the pericardial friction rub; because of its superficial, creaky, or scratchy character, it often is likened to the sound of walking on dry snow or the squeak of a leather saddle (Fig. 72-3). Rubs are heard anywhere over the precordium but most often between the lower left sternal edge and the cardiac apex; they usually are heard best with the diaphragm of the stethoscope applied firmly and with respiration suspended. Most pericardial friction rubs are independent of the respiratory cycle, but on occasion they are louder during inspiration. The pericardial rub may be confined to ventricular systole but most often includes a component during atrial systole and occasionally during ventricular diastolic filling, resulting in biphasic and triphasic rubs, respectively. Biphasic rubs must be distinguished from murmurs of mixed aortic valve disease, and monophasic rubs often are mistaken for systolic murmurs. Frequent examinations are necessary to detect a rub because of its evanescent nature; pericardial fluid does not prevent a friction rub.

In uncomplicated pericarditis, the jugular venous pressure usually remains normal. Ventricular third and fourth heart sounds indicate coexisting myocardial disease. The history and physical examination are helpful also in recognizing complications and in identifying underlying diseases associated with pericarditis. Depending on the etiology, there may be fever and other signs of inflammation or systemic illness.

Electrocardiography

The ECG may either confirm the clinical suspicion of pericardial disease or first alert the clinician to the presence of pericarditis (Fig. 72-4). Serial tracings may be needed to distinguish the ST-segment elevations caused by acute pericarditis from those caused by acute myocardial infarction (MI) or normal early repolarization. The ST-T wave changes in acute pericarditis are diffuse and have characteristic evolutionary changes. In the first stage, ST-segment elevations (which differ from ischemic ST elevations by their upward concavity and seldom exceed 5 mm in

height) typically occur within a few hours of the onset of chest pain and persist for hours or days. Depression of the PR segment (except in lead aV_R) may be seen in this stage and may differentiate acute pericarditis from early repolarization variants.[15] In the second stage, the ST segments return to baseline; at this point, the T waves may appear normal or exhibit a loss of amplitude. In the third stage, tracings show inversion of T waves. T-wave inversions may persist indefinitely, particularly with tuberculous, uremic, or neoplastic pericarditis. The ECG normalizes in the variably present fourth stage. In a typical case of acute pericarditis, the approximate time frame for these ECG changes is 2 weeks. However, only about half of patients with acute pericarditis display all four ECG stages, and variations are very common. Atrial arrhythmias complicate 5 to 10 percent of cases of acute pericarditis.[16]

The ST-segment elevation seen in acute pericarditis usually can be distinguished from that of acute MI by the absence of Q waves, the upwardly concave ST segments, and the absence of associated T-wave inversions. The acute ST-segment elevation of Prinzmetal's variant of angina is more transitory and is associated with ischemic pain. Although the ST-segment elevation in the early repolarization variant (common in young individuals, especially blacks, athletes, and psychiatric patients) may simulate the ECG of acute pericarditis, the former is distinguished by the absence of PR-segment depression and evolutionary ST-T wave changes.

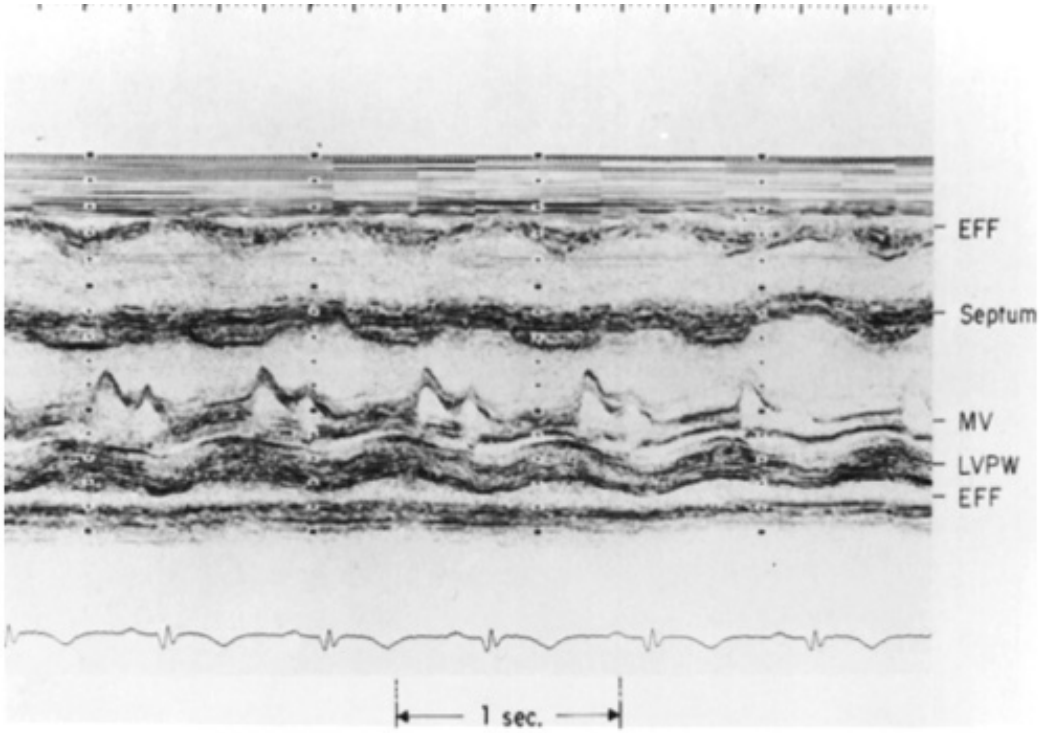
Imaging and Laboratory Studies

In uncomplicated acute pericarditis, the chest radiograph is generally normal. However, an enlarged cardiac silhouette may be evident because of a moderate or large pericardial effusion (Fig. 72-5). The chest radiograph may provide evidence of tuberculosis, fungal disease, pneumonia, or neoplasm.

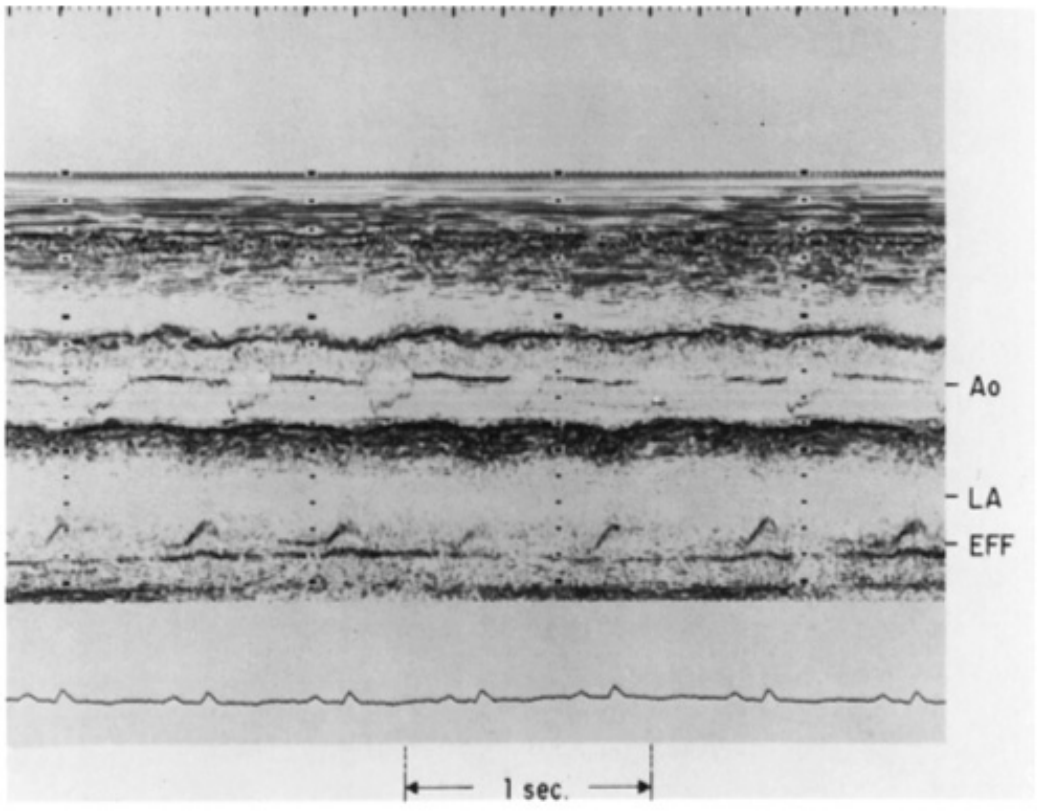
Figure 72-5: Chest radiograph from a patient with a large pericardial effusion. Note the "flask-shape" appearance of the cardiac silhouette. (From Hoit BD. Imaging the pericardium. *Cardiol*

Clin 1990; 8:588. Reproduced with permission.)

Echocardiographic identification of pericardial effusion confirms the clinical diagnosis of acute pericarditis (Fig. 72-6), but a patient with purely fibrinous acute pericarditis often has a normal echocardiogram. Echocardiography estimates the volume of pericardial fluid, identifies cardiac tamponade, suggests the basis of pericarditis, and documents associated acute myocarditis with congestive heart failure.



A



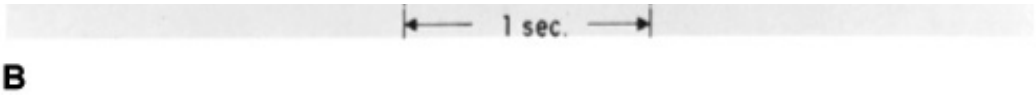


Figure 72-6: M-mode echocardiograms of pericardial effusion (EFF). *A.* The effusion appears as an echo-free space posteror to the left ventricular posterior wall (LVPW). Note that parietal pericardium has relatively flat motion throughout the cardiac cycle. MV = mitral valve. *B.* Pericardial effusion behind the left atrium (LA). Note the exaggerated motion of the posterior left atrial wall. (From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:588. Reproduced with permission.)

Although ^{99}technetium pyrophosphate scans may be positive in patients with pericarditis associated with epicarditis and gallium scans have proved useful in displaying the characteristics of purulent pericarditis, these tests rarely are used to diagnose acute pericarditis.

Nonspecific blood markers of inflammation, such as the erythrocyte sedimentation rate and the white blood cell count, usually increase in cases of acute pericarditis. Patients with extensive epicarditis occasionally have increases in serum cardiac isoenzymes suggestive of acute MI.

Therapy for Acute Pericarditis

Hospitalization is warranted for most patients who present with an initial episode of acute pericarditis to determine the etiology and observe for cardiac tamponade. Establishing the exact cause of acute pericarditis is an important aspect of management, but considerable judgment must be exercised in deciding whether and how to investigate the possibility of concomitant systemic disease.

An extensive evaluation is generally unnecessary in a young, previously healthy adult who presents with a viral syndrome, typical pericardial chest pain, and a pericardial friction rub. Most cases of viral pericarditis are recognized long after the period of viral activity, making a specific etiologic diagnosis and antiviral chemotherapy unnecessary. Thus, differentiating viral from idiopathic pericarditis is difficult, expensive, and generally of little practical importance. Depending on the history and symptoms at presentation, trauma, myocarditis, systemic lupus erythematosus (SLE), and/or purulent pericarditis require consideration in younger patients. In older adults, myocardial infarction, tuberculosis, and neoplastic disease should be considered.

Acute pericarditis usually responds to oral nonsteroidal anti-inflammatory agents (e.g., ASA 650 mg q3-4h or ibuprofen 600 to 800 mg q6h). Indomethacin reduces coronary blood flow and theoretically should be avoided. Some data suggest that the addition of colchicine (1 mg/day) is effective for an acute episode and may prevent recurrences.[17] The intensity of therapy is dictated by the distress of the patient; narcotics may be required for severe pain. Some cases necessitate steroid therapy (prednisone 60 to 80 mg/day) for a week to control pain, with the dose tapered rapidly thereafter. Corticosteroids should be avoided unless there is a specific indication. They may enhance viral multiplication and produce recurrences when the dose is tapered; colchicine may be useful in this situation. Nevertheless, corticosteroids are useful in acute pericarditis associated with uremic pericarditis and connective tissue diseases. Importantly, tuberculous and pyogenic pericarditis should be excluded before steroid therapy is initiated.

Patients in whom pericarditis represents one manifestation of systemic illness (such as sepsis, uremia, connective tissue disease, or neoplasia) should, in addition to palliative and supportive treatment, receive therapy directed toward the primary disorder.

Chapter 72: DISEASES OF THE PERICARDIUM

RECURRENT PERICARDITIS

Recurrent or relapsing acute pericarditis is one of the most distressing disorders of the pericardium for both patient and physician; it may occur with or without pericardial effusion and occasionally is associated with pleural effusion or parenchymal pulmonary lesions. Recurrences occur with highly variable frequency over a course of many years. The reasons for relapse are unclear, but the phenomenon suggests that acute pericarditis itself may represent or generate an autoimmune process. Recurrences may be spontaneous but more commonly are associated with discontinuation or tapering doses of anti-inflammatory drugs. When associated with pericardial effusion, relapsing pericarditis can cause cardiac tamponade; however, this is unusual.

Painful recurrences of pericarditis may respond to nonsteroidal anti-inflammatory agents but commonly require corticosteroids. Once steroids are administered, dependency and the development of steroid-induced abnormalities are potential sequelae. Prednisone is begun at a high dose (60 to 80 mg/day), but rapid tapering should be initiated within a few days of clinical resolution. When necessary, the risks of long-term steroids should be minimized by using the lowest possible dose, alternate-day therapy, combinations with nonsteroidal drugs, or colchicine (1 to 2 mg/day).[18] In the most difficult cases, relapse occurs every time the dose of prednisone is reduced below 5 to 20 mg/day. When this occurs, the patient should be maintained for several weeks on the lowest suppressive dose before the next taper commences. Azathioprine (50 to 100 mg/day) also has been used to prevent recurrent episodes.[19] Although encouraging results have been reported in a series of patients who underwent pericardiectomy for recurrent pericarditis, pericardiectomy may simply abbreviate rather than terminate the painful recurrences. Thus, pericardiectomy should be considered only when repeated attempts at medical treatment have clearly failed.

Chapter 72: DISEASES OF THE PERICARDIUM

PERICARDIAL EFFUSION

Etiology

Accumulation of transudate, exudate, or blood in the pericardial sac is a common complication of pericardial disease and should be sought in all patients with acute pericarditis.

Pericardial effusions are reported to be associated with heart failure, valvular disease, and myocardial infarction in 14, 21, and 15 percent of cases, respectively.[20] Hydropericardium results from elevated right atrial pressure and limited venous and lymphatic drainage from the pericardium. Although this is the usual explanation for effusions associated with heart failure and LV hypertrophy, recurrent bloody effusions that can be attributed only to congestive heart failure may occur.

Pericardial effusions are very common after cardiac surgery. In 122 consecutive patients studied before and serially after cardiac surgery, effusions were present in 103 patients; the majority appeared by postoperative day 2, reached their maximum size by postoperative day 10, and usually resolved without sequelae within the first postoperative month.[21] Symptoms and physical findings of significant postoperative pericardial effusions are frequently nonspecific, and echo-detection and echo-guided pericardiocentesis, when necessary, are safe and effective; prolonged catheter drainage reduces the recurrence rate.[22] Pericardial effusions in cardiac transplant patients are associated with an increased incidence of acute rejection.[23] Chronic effusive pericarditis is an entity of unknown etiology that may be associated with large, asymptomatic effusions. Many conditions that cause pericarditis (e.g., uremia, tuberculosis, neoplasia, connective tissue disease) produce chronic pericardial effusions.

Nature of the Pericardial Fluid

Characteristics of the pericardial fluid other than culture and cytology are usually too nonspecific to be of diagnostic value. However, in one retrospective series, one-fifth of the patients had a specific etiologic diagnosis that had implications for management and prognosis.[24] Moreover, in certain situations it is mandatory to determine the nature of the pericardial fluid. For example, in patients with neoplastic disease, it is important to determine whether pericardial effusion indicates invasion of the pericardium or a complication of radiation therapy. Cytologic examination of the fluid is also important in cases in which the primary tumor has not been identified clearly. In cases of bacterial or other nonviral infections, it becomes necessary to discover whether the pericardial effusion is exudative and to culture pericardial fluid; this is particularly important when tuberculous or fungal pericarditis is suspected. Transudative effusions (hydropericardium) occur in heart failure and other states associated with chronic salt and water retention (including pregnancy), and exudative effusions occur in a large number of the infectious and inflammatory causes of pericarditis. Although frank hemorrhagic effusions suggest recent intrapericardial bleeding, sanguineous and serosanguineous effusions occur in many infectious and inflammatory disorders. In certain disorders, the nature of the pericardial fluid has greater diagnostic value. For example, chylous pericarditis implies injury or obstruction to the thoracic duct, and cholesterol pericarditis is either idiopathic or associated with hypothyroidism, rheumatoid arthritis, or tuberculosis.

Diagnostic Studies

Specific diagnoses are possible using visual, cytologic, and immunologic analysis of the pericardial effusion and pericardioscopic-guided biopsy of the epicardium and pericardium.[20,25] Observations using these techniques have suggested that (1) fibrin strands and neovascularization are common in inflammatory pericardial diseases, (2) the etiology of viral pericarditis can be established by using a variety of methods, such as in situ hybridization, microneutralization, and polymerase chain reaction, (3) combined analysis of the cytology in the effusion and epicardial biopsy are most important, and pericardial biopsy is often inconclusive, and (4) viral and autoreactive effusions are associated with high titers of antimyolemmal and antisarcolemmal antibodies and in vitro cardiocytolysis of isolated rat heart cells. However, the clinical utility of these diagnostic methods and observations remains to be determined.

There are clinical situations in which it is unnecessary to obtain pericardial fluid for analysis. For example, when pericardial effusion is found in a patient with typical viral or idiopathic pericarditis, pericardiocentesis should not be considered unless the effusion fails to respond to anti-inflammatory treatment or cardiac tamponade develops. Similarly, when a patient undergoing chronic hemodialysis develops pericardial effusion, examination of pericardial fluid is needed only when the clinical course suggests a different etiology or when hemodynamic embarrassment is suspected.

IMAGING STUDIES

Echocardiography is the procedure of choice for the diagnosis of pericardial effusion. Although flask-shaped enlargement of the cardiac silhouette on chest radiography occurs with a moderate or large pericardial effusion (Fig. 72-5), differentiation of large effusions from cardiac dilatation often is difficult or impossible. In contrast, the relative contributions of cardiac enlargement and pericardial effusion to overall cardiac enlargement and the relative roles of tamponade and myocardial dysfunction to altered hemodynamics can be evaluated with echocardiography. Attention to technical detail results in excellent sensitivity and specificity. The diagnostic feature on M-mode echocardiography is the persistence of an echo-free space between parietal and visceral pericardium throughout the cardiac cycle (Fig. 72-6). Separations that are observed only in systole represent clinically insignificant accumulations. Two-dimensional (2-D) echocardiography (Fig. 72-7) has superior spatial orientation and allows delineation of the size and distribution of pericardial effusion as well as detection of loculated fluid. As the amount of pericardial fluid increases, fluid distributes from the posterobasilar LV apically and anteriorly and then laterally and posteriorly to the left atrium. Fluid adjacent to the right atrium is an early sign of pericardial effusion. Frondlike, bandlike, or shaggy intrapericardial echoes should alert one to the possibility of a difficult and potentially less therapeutic pericardiocentesis (Fig. 72-8) but have little value in identifying the cause of the effusion.

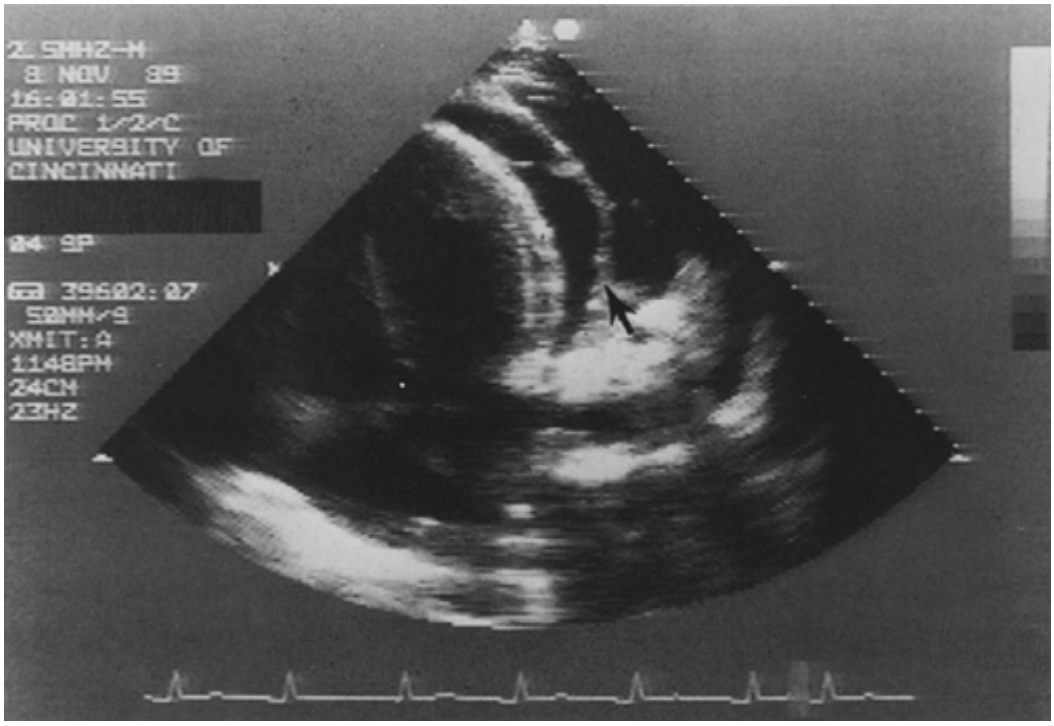

Figure 72-7: Two-dimensional echocardiogram from a patient with pleural and pericardial effusions. The thickness of the pericardium (*arrow*) can be appreciated in this patient. (From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:596. Reproduced with permission.)

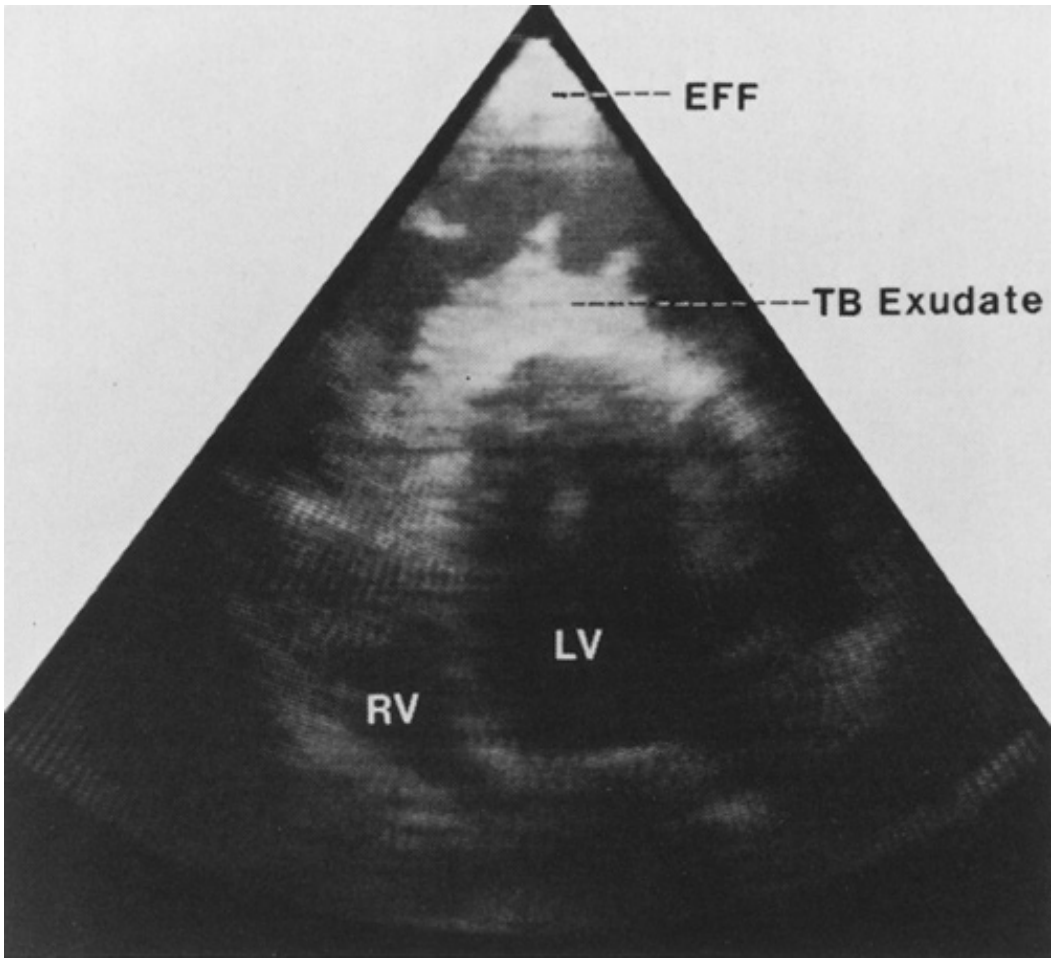

Figure 72-8: Two-dimensional echocardiogram from a patient with tuberculous pericarditis. Note the thickened pericardium with shaggy exudate that bridges a large pericardial effusion (EFF). (From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:590. Reproduced with permission.)

Pericardial effusions are easily detected by computed tomography (Fig. 72-9). The size, geometry, and distribution of pericardial effusions can be obtained with this technique, and the attenuation coefficients for blood, exudate, chyle, and serous fluid are generally sufficiently characteristic to identify the nature of the effusion. Computed tomography may be useful in identifying loculated and atypically loculated pericardial effusions and in guiding pericardiocentesis. Loculated and recurrent pericardial effusions can be treated safely and effectively with video-assisted thoracoscopic pericardial fenestration.[26]

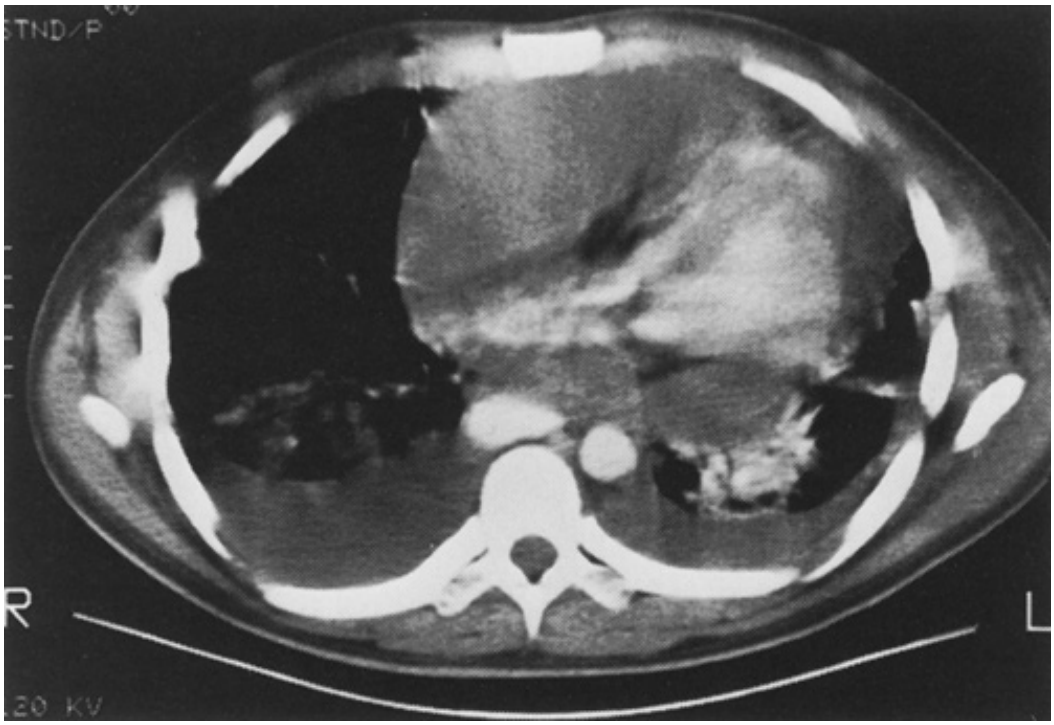

Figure 72-9: Computed tomographic scan from a patient with a large pericardial effusion. Note the compression of contrast-filled cardiac chambers. (From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:590. Reproduced with permission.)

Magnetic resonance imaging (MRI) detects pericardial effusion with high sensitivity and provides an estimate of pericardial fluid volume; in addition, it effectively detects loculated pericardial effusion and pericardial thickening.[27] Inflamed pericardium and adhesions have a high signal intensity relative to pericardial fluid and myocardium, providing a potential means of identifying the nature of the effusion.

Treatment of Pericardial Effusion

Drainage of a pericardial effusion is usually unnecessary unless purulent pericarditis is suspected or cardiac tamponade supervenes, although on occasion, pericardiocentesis is needed to establish the etiology of a hemodynamically insignificant pericardial effusion. Persistent or progressive effusion, particularly when the cause is uncertain, also warrants pericardiocentesis. However, routine drainage of a large pericardial effusion without tamponade or suspected purulent

pericarditis has a low diagnostic yield and no clear therapeutic benefit.[28] Anticoagulants should be discontinued temporarily if possible to reduce the risk of cardiac tamponade. In patients on chronic oral anticoagulation, heparin should be used, since its effect can be reversed rapidly. Large effusions may respond to nonsteroidal anti-inflammatory drugs, corticosteroids, or colchicine.[17] Specific treatment for pericardial effusion is considered below.

Chapter 72: DISEASES OF THE PERICARDIUM

CARDIAC TAMPONADE

Cardiac tamponade is a hemodynamic condition characterized by equal elevation of atrial and pericardial pressures, an exaggerated inspiratory decrease in arterial systolic pressure (pulsus paradoxus), and arterial hypotension. Arterial hypotension is generally a late sign in chronic effusions, and occasionally, a heightened sympathoadrenal state produces systemic hypertension. As intrapericardial pressure rises, venous pressures increase to maintain cardiac filling and prevent collapse of the cardiac chambers. Although the absolute intracardiac pressures are elevated, the transmural pressures-i.e., cavitary diastolic pressure minus pericardial pressure-are practically zero or even negative. The greatly reduced preload is responsible for the fall in cardiac output, and when compensatory mechanisms are exhausted, arterial pressure decreases.

Clinical Features

Cardiac tamponade may be acute or chronic and should be viewed hemodynamically as a continuum ranging from mild (pericardial pressure lower than 10 mmHg) to severe (pericardial pressure higher than 15 to 20 mmHg). Mild cardiac tamponade is frequently asymptomatic, whereas moderate tamponade and especially severe tamponade produce precordial discomfort and dyspnea.

Tamponade may be so sudden that the patient does not complain of symptoms; in less drastic circumstances, patients with acute cardiac tamponade may complain of severe shortness of breath accompanied by chest tightness and dizziness. The venous pressure is greatly elevated, and the systemic arterial pressure is severely depressed. Pulsus paradoxus usually can be appreciated but may be absent when hypotension is extreme. In striking contrast to the elevation of venous pressure, arterial hypotension, and pulsus paradoxus, cardiac pulsations often are impalpable (Beck's triad). In the most severe cases, consciousness may be impaired, and except for the raised venous pressure, such patients appear to be in hypovolemic shock.

When cardiac tamponade complicates a diagnostic procedure, vague discomfort, generalized uneasiness, and precordial pain are common. Fluoroscopy shows an enlarged cardiac silhouette and diminished pulsations.

Cardiac tamponade should be suspected in a victim of recent chest trauma who appears to be in shock, especially when the venous pressure is elevated. When circumstances are deemed life-threatening, an immediate therapeutic trial of rapid infusion of fluid and diagnostic pericardiocentesis should be attempted. Otherwise, pericardiocentesis should be delayed until the presence of significant pericardial fluid can be demonstrated by prompt echocardiography. An exception to this rule is when tamponade occurs in the diagnostic laboratory; in this instance, when pressures are being monitored and fluoroscopy is available, the diagnosis can be established safely without echocardiographic confirmation.

Other causes of acute tamponade are cardiac rupture complicating acute MI and rupture of a dissecting hematoma of the proximal aorta. Although successful pericardiocentesis may relieve aortic tamponade and increase hemorrhage, a limited pericardiocentesis is reasonable if cardiac tamponade is severe enough to be considered a threat to survival. Finally, after cardiac surgery, dyspnea and fatigue should raise the suspicion of tamponade; in these instances, the effusion is

often loculated, and echocardiographic and hemodynamic findings may be unreliable.

A large number of diseases may be associated with more slowly developing cardiac tamponade. In these instances, symptoms may be due to the underlying illness, the culpable pericardial disease, and/or the tamponade itself. Many patients with inflammatory pericarditis give a history of prodromal fever, myalgia, and arthralgia, and patients with neoplastic disease may have symptoms associated with the neoplasm and its treatment. The symptoms of cardiac compression include rapidly progressive dyspnea accompanied by fullness or tightness in the chest, occasionally with dysphagia; pericardial pain is often absent. The course may be less rapid, allowing time for an increase in abdominal girth and the rapid onset and progression of edema.

Pathophysiology

Elevated intrapericardial pressure exerted on the heart throughout the cardiac cycle, with only slight momentary relief when intrapericardial pressure falls (owing to the decrease in cardiac volume during ventricular ejection), is responsible for the pathophysiologic findings of cardiac tamponade. To understand the relation between venous and pericardial pressures in cardiac tamponade, it is useful to review the normal biphasic pattern of venous return. A surge of venous return occurs at the onset of ventricular ejection and is accompanied by a small reduction in intrapericardial pressure. A second surge of venous return occurs in early diastole, when the tricuspid valve opens and atrial pressure decreases. In contrast, the venous return in cardiac tamponade is unimodal and is confined to ventricular systole, and in severe cardiac tamponade, venous return is halted in diastole, at a time when cardiac volume and intrapericardial pressure are maximal. Pericardial pressure and right atrial pressure are elevated above normal and are equal to each other (Fig. 72-10). The inspiratory fall in intrathoracic pressure is transmitted to the pericardial space and preserves the normal inspiratory increase in systemic venous return (Kussmaul's sign is absent).

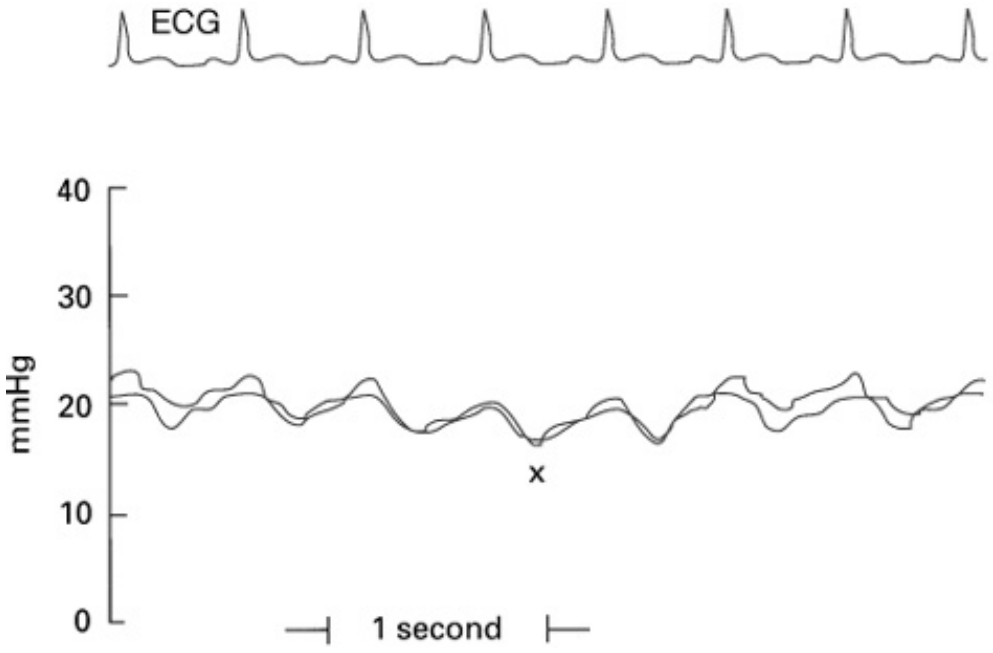

Figure 72-10: Simultaneous right atrial and pericardial pressures from a patient with severe cardiac tamponade. The pressures are elevated and equal to one another, and only the X descent on the right atrial tracing is present; the Y descent is absent. The pressures fall normally during inspiration. (From Shabetai R. Diseases of the pericardium. In: Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart,* 9th ed. New York: McGraw-Hill; 1998:2179. Reproduced with

permission.)

Although systolic ventricular function is often supranormal, unrelieved extreme tamponade becomes fatal when venous pressure cannot increase to equal the pericardial pressure and maintain circulation. In severe cases, diminution of myocardial perfusion is aggravated by direct compression of the epicardial coronary arteries, abnormal transmyocardial distribution of blood flow, and, as a result, impaired ventricular systolic function.

PULSUS PARADOXUS

In healthy individuals, systolic blood pressure may decline by as much as 10 mmHg during quiet inspiration. Pulsus paradoxus is an exaggeration of this normal physiologic response. A number of normal and abnormal mechanisms combine to create pulsus paradoxus in cardiac tamponade. Inspiratory augmentation of systemic venous return in cardiac tamponade increases the volume of the right side of the heart at the expense of the left side. The volume of the left side of the heart is decreased, in part by bulging of the intraventricular septum from right to left (changing the size, shape, and compliance of the LV) and in part by increased transmural pericardial pressure (decreasing pulmonary venous return). However, the inspiratory expansion of the volume of the right side of the heart and the transit time of the resulting augmented right heart stroke volume are important in the genesis of pulsus paradoxus. In addition, the negative thoracic pressure produced by inspiration is transmitted to the aorta, increasing LV afterload and reducing stroke volume. LV stroke volume falls more sharply than normal in response to decreased ventricular filling in cardiac tamponade because the small ventricle is operating on the steep ascending limb of the Starling curve. Finally, inspiratory traction by the diaphragm on the taut pericardium, reflex changes in vascular resistance and cardiac contractility, and increased respiratory effort owing to pulmonary congestion contribute to the genesis of pulsus paradoxus.

Pulsus paradoxus appears when both ventricles fill against a common resistance. Therefore, when LV diastolic pressure is elevated by coexisting LV disease, pulsus paradoxus does not develop in cardiac tamponade.[29] Similarly, atrial septal defects and aortic regurgitation prevent reciprocal inspiratory changes in the filling of the two sides of the heart; therefore, in these conditions, cardiac tamponade can occur without pulsus paradoxus.[30]

Physical Findings

Physical findings are dictated by both the severity of cardiac tamponade and the time course of its development. Careful inspection of the jugular venous pulse waveform is essential for the diagnosis, although the venous pressure may be normal in early tamponade, whereas extreme elevations of venous pressure may go unrecognized in a recumbent or semirecumbent patient. Compression of the heart by pericardial fluid results in a characteristic loss of the atrial Y descent, but because of the decrease in intrapericardial pressure that occurs during ventricular ejection, the systolic atrial filling wave and the X descent are maintained. Kussmaul's sign, a failure of venous pressure to decrease during inspiration, is a sign of constriction and generally is not seen in pure cardiac tamponade.

An inspiratory decline of systolic arterial pressure exceeding 10 mmHg (pulsus paradoxus) may be detected with palpation of an arterial pulse, such as the femoral or brachial artery, and quantified by using sphygmomanometry by subtracting the pressure at which Korotkoff's sounds are heard only during expiration from the pressure at which sounds are heard through the respiratory cycle. The origin of the paradoxical pulse is complex and multifactorial, and pulsus paradoxus is neither sensitive nor specific for cardiac tamponade.[30] Nevertheless, in the appropriate clinical setting, pulsus paradoxus is a key finding that signifies cardiac tamponade, and its presence should be sought diligently.

Diagnostic and Imaging Studies

Low voltage on the ECG and/or electrical alternans should suggest cardiac tamponade. However, electrical alternans is insensitive, occurring in only about 20 percent of instances.[31] When effusion is massive, the heart swings freely within the pericardial sac and acquires a pendular, rotary motion that is associated with electrical alternans. When tamponade is suspected, an echocardiogram should be obtained unless even a brief delay might prove life-threatening. During inspiration, a greater than normal increase in RV dimension and a decrease in LV dimension occur in many cases of tamponade. These respiratory changes also accompany other conditions associated with pulsus paradoxus, such as chronic obstructive lung disease and pulmonary embolism.[32] Diastolic collapse of the RV, which is recognized as an abnormal posterior motion of the anterior RV wall during diastole (Fig. 72-11), signifies that pericardial pressure exceeds early diastolic RV pressure, i.e., that transmural RV diastolic pressure is negative (see also Chap. 13). Although this sign is a relatively sensitive and specific marker for tamponade, RV diastolic collapse is sensitive to alterations in ventricular loading conditions and may not be seen in the presence of RV hypertrophy. In addition, right heart chamber collapse occurs with smaller collections of fluid and higher pericardial pressures when there is coexisting LV dysfunction.[29] Late diastolic right atrial collapse is virtually 100 percent sensitive for tamponade but is less specific (Fig. 72-12). A duration of right atrial collapse exceeding one-third of the cardiac cycle increases specificity without sacrificing sensitivity.[33] Posterior loculated effusions after cardiac surgery have been reported to produce left atrial and LV diastolic collapse.[34,35] The value of transesophageal echocardiography has been recognized in the detection and treatment of unusual cases of cardiac tamponade.[36] In patients with unexplained hypotension who are undergoing transesophageal echo, a diagnosis of a nonventricular limitation to cardiac output was associated with improved survival in the intensive care unit compared with a diagnosis of ventricular disease or hypovolemia/low systemic vascular resistance.[37]

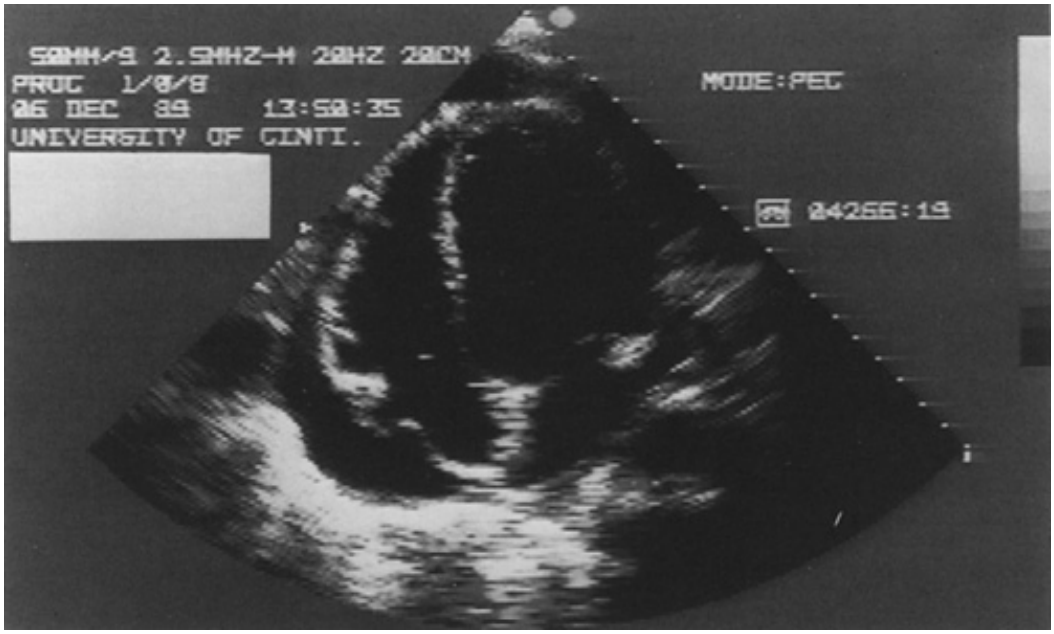

Figure 72-12: Two-dimensional echocardiogram in the apical four-chamber view. During late diastole, there is inversion of the lateral wall of the right atrium. (From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:593. Reproduced with permission.)

During cardiac tamponade, tricuspid and pulmonary flow velocities measured by Doppler

echocardiography (Fig. 72-13) increase markedly with inspiration, and mitral and aortic valve flow velocities decrease significantly compared with normal control patients and patients with asymptomatic effusions.[38] Changes in the pattern of venous flow (reflecting the predominance of systolic flow) and exaggerated respiratory variations of venous flow velocities (Fig. 72-14) also are seen in cardiac tamponade.[39] Indeed, abnormal venous flow had a good correlation with clinical tamponade with greater sensitivity than RV diastolic collapse and greater specificity than right atrial collapse.[40]

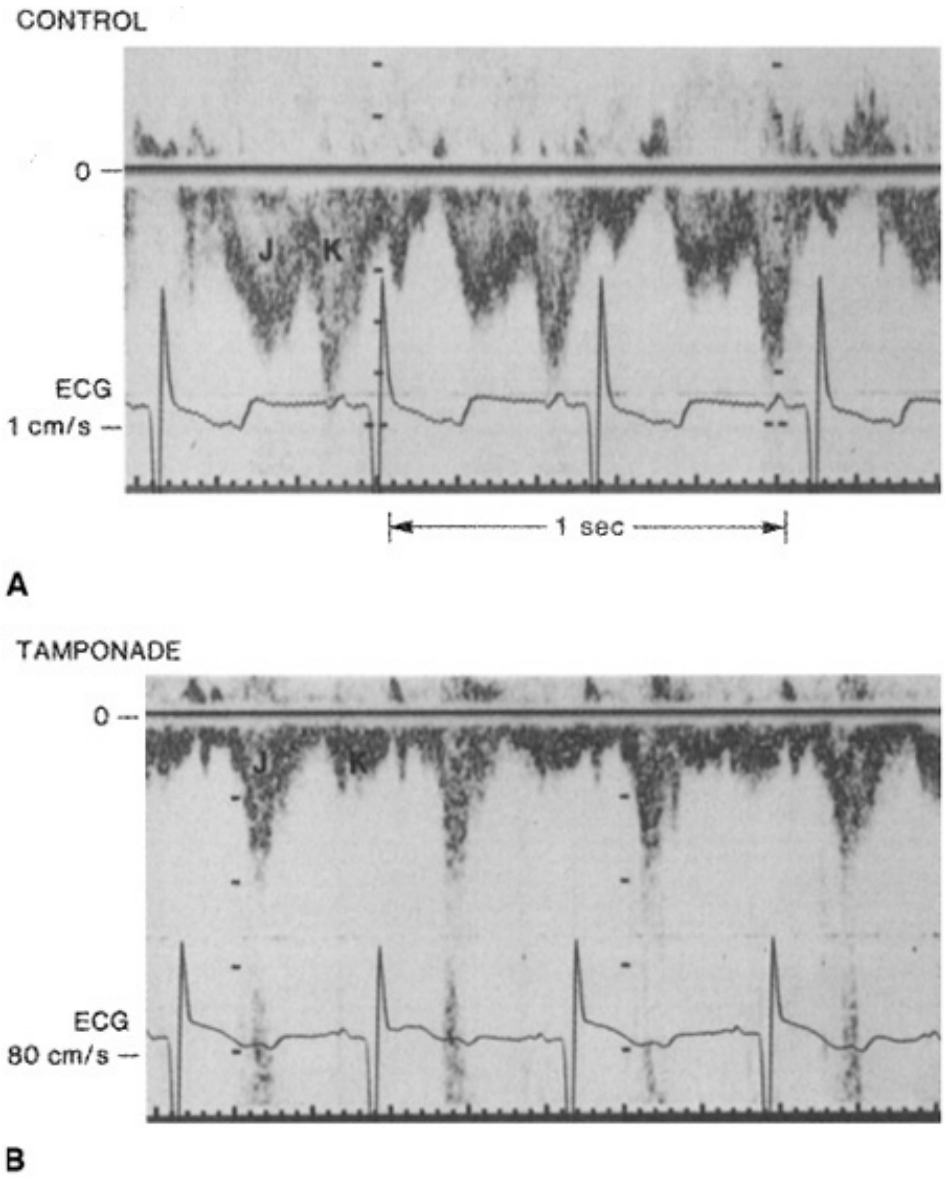

Figure 72-14: Doppler echocardiograms of pulmonary venous flow velocity from a dog before (*A*) and after (*B*) creation of cardiac tamponade. Note the predominance of systolic flow after tamponade. J = systolic flow; K = diastolic flow. (From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:595. Reproduced with permission.)

Cardiac Catheterization

The diagnosis of cardiac tamponade is confirmed by right heart catheterization. The right atrial, pulmonary capillary wedge, and pulmonary artery diastolic pressures are elevated, usually between 10 and 30 mmHg, and are equal within 4 to 5 mmHg (Fig. 72-15). Pericardial pressure is

elevated and is equal to right atrial pressure; the degree of elevation is related to both the severity of tamponade and the patient's intravascular volume status (Fig. 72-16). The right atrial and wedge pressure tracings reveal an attenuated or absent Y descent. Cardiac output is reduced, and systemic vascular resistance is elevated. Equal elevation of diastolic pressures also may be seen with dilated cardiomyopathy and with RV infarction. Neither Kussmaul's sign nor the early ventricular diastolic dip and plateau (i.e., the "square root" sign) characteristic of pericardial constriction is seen in tamponade.

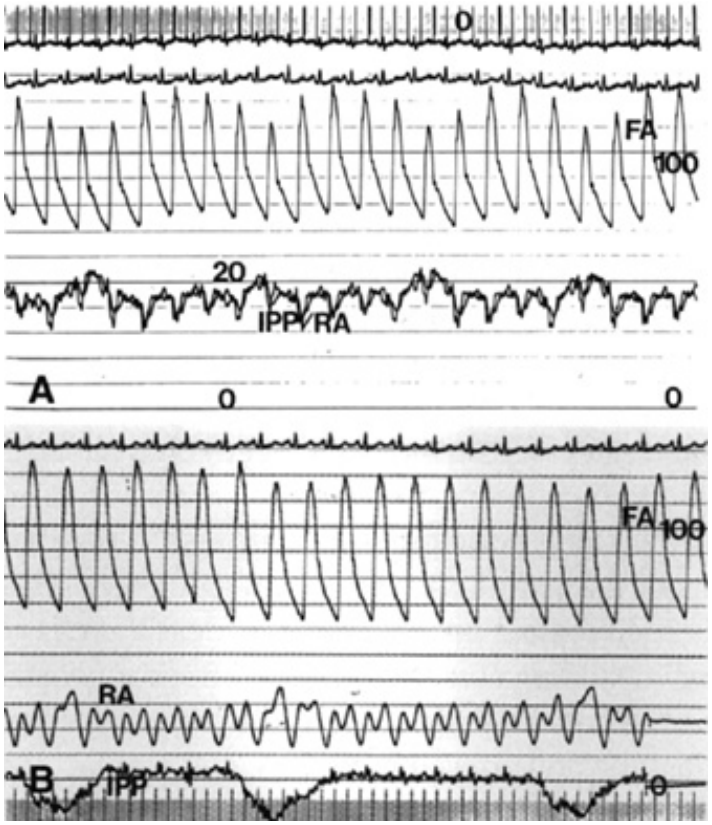

Figure 72-15: Hemodynamic record from a patient with cardiac tamponade before (*A*) and after (*B*) pericardiocentesis. *A*. Pulsus paradoxus is evident from the femoral artery (FA) pressure tracing. Note the absent Y descent on the right atrial (RA) tracing and the equal and elevated RA and pericardial (IPP) pressures. *B.* After removal of pericardial fluid, pericardial and right atrial pressures decrease and the pulsus paradoxus disappears. only slightly elevated but is equal to pericardial pressure. Hypotension and pulsus paradoxus are absent. *B.* After pericardiocentesis, pericardial pressure is consistently lower than ventricular diastolic pressure. (From Shabetai R. Diseases of the pericardium. In Alexander WA, Schlant R, Fuster V, et al., eds. *Hurst's The Heart,* 9th ed. New York: McGraw-Hill; 1998:2185. Reproduced with permission.)

Management of Cardiac Tamponade

Removal of small amounts of pericardial fluid (~50 mL) produces considerable symptomatic and hemodynamic improvement because of the steep pericardial pressure-volume relation. Unless there is concomitant cardiac disease or coexisting constriction (i.e., effusive-constrictive pericarditis), removal of all the pericardial fluid normalizes pericardial, atrial, ventricular diastolic, and arterial pressures and cardiac output.

Unless the situation is immediately life-threatening, pericardiocentesis should be performed by experienced staff in a facility equipped for hemodynamic monitoring. The advantages of needle pericardiocentesis include the ability to perform careful hemodynamic measurements and relatively simple logistic and personnel requirements. The safety of the procedure has been improved by using 2-D echo guidance.[41] A catheter can be advanced over a guidewire into the pericardial space and remain there for several days; sclerosing agents, steroids, urokinase, and specific chemotherapeutic agents may be given through the catheter.[42,43] In a pilot study, intrapericardial instillation of cisplatin for 24 hours prevented recurrence of a hemodynamically significant pericardial effusion after 6 to 12 months in 14 out of 15 patients with a neoplastic effusion; in 12 out of 14 patients with autoreactive pericarditis, recurrence was prevented with intrapericardial triamcinolone.[25] Although pericardiocentesis may provide effective relief, percutaneous balloon pericardiotomy, subxiphoid pericardiotomy, or the surgical creation of a pleuropericardial or peritoneal-pericardial window[44,45] may be required. Nevertheless, in one retrospective review, pericardiocentesis with intrapericardial sclerotherapy was as effective as an open surgical drainage procedure in patients with malignant pericardial effusion.[46] The feasibility and accuracy of three-dimensional computer-assisted pericardiocentesis was recently described in the experimental laboratory.[47]

Open surgical drainage offers several advantages, including complete drainage, access to pericardial tissue for histopathologic and microbiologic diagnoses, the ability to drain loculated effusions, and the absence of traumatic injury resulting from blind placement of a needle into the pericardial sac. The choice between needle pericardiocentesis and surgical drainage depends on institutional resources and physician experience, the etiology of the effusion, the need for diagnostic tissue samples, and the prognosis of the patient. Needle pericardiocentesis is often the best option when the etiology is known and/or the diagnoses of tamponade is in question, and surgical drainage is optimal when the presence of tamponade is certain but the etiology is unclear. It should be recognized that surgical approaches (subxiphoid pericardiotomy and thoracoscopic drainage) can be performed using local anesthesia with little attendant morbidity. Irrespective of the method of retrieval, pericardial fluid should be sent for smear, culture, and cytology.

Fluids should be given to patients with cardiac tamponade who are awaiting pericardial drainage in an effort to expand the intravascular volume. Dobutamine or nitroprusside may be used to increase cardiac output after the blood volume has been expanded, but only as a temporizing measure. Vagal reflexes complicating tamponade and pericardiocentesis are treated with atropine. Positive-pressure breathing should be avoided, and if present, metabolic acidosis should be corrected.

Recurrent effusions may be treated by repeat pericardiocentesis, sclerotherapy with tetracycline, surgical creation of a pericardial window, or pericardiectomy. A pericardial window usually is performed in patients with malignant effusions, and pericardiectomy may be required for recurrent

effusions in dialysis patients. In critically ill patients, a pericardial window may be created percutaneously with a balloon catheter.[48,49]

Chapter 72: DISEASES OF THE PERICARDIUM

CONSTRICTIVE PERICARDITIS

Constrictive pericarditis is a condition in which a thickened, scarred, and often calcified pericardium limits diastolic filling of the ventricles. Although acute pericarditis from most causes may eventuate in constrictive pericarditis, the most common antecedents are idiopathic conditions, cardiac trauma and surgery, tuberculosis and other infectious diseases, neoplasms (particularly lung and breast), radiation therapy, renal failure, and connective tissue diseases. Rare causes include Dressler's syndrome, sarcoidosis, Whipple's disease, amyloidosis, and dermatomyositis. Mulibrey nanism is a hereditary form of constrictive pericarditis that is associated with abnormalities of the *mu*scle, *li*ver, *br*ain, and *ey*es (see Chap. 10).

Clinical Features

Constrictive pericarditis resembles the congestive states caused by myocardial disease and chronic liver disease. Patients generally complain of fatigue, dyspnea, weight gain, abdominal discomfort, nausea, increased abdominal girth, and edema. Although symptoms usually develop over years, they progress over a period of months in patients with subacute constrictive pericarditis after trauma, cardiac surgery, and mediastinal irradiation and may develop acutely and resolve spontaneously during the course of pericarditis.[50]

Physical Findings

Physical findings include ascites, hepatosplenomegaly, edema, and, in long-standing cases, severe wasting. This general appearance often leads to an erroneous diagnosis of hepatic cirrhosis. However, misdiagnosis is avoided through a careful examination of the neck veins. In constrictive pericarditis, the venous pressure is elevated and displays deep Y and often deep X descents. The venous pressure fails to decrease with inspiration (Kussmaul's sign), but frank inspiratory swelling of the neck veins is uncommon. Kussmaul's sign lacks specificity, as it is seen also in cases of restrictive cardiomyopathy, RV failure and infarction, and tricuspid stenosis.[51] The heart is often normal-sized, and when it is not, enlargement is modest. A pericardial knock that is similar in timing to the third heart sound is pathognomonic but occurs infrequently.[51,52] Pulsus paradoxus may occur with associated pericardial effusion (effusive-constrictive pericarditis). Except in severe cases, the arterial blood pressure is normal.

Diagnostic and Imaging Studies

Low QRS voltage, nonspecific T-wave changes, and P mitrale are common, but the ECG findings are nonspecific (Fig. 72-17). Atrial fibrillation is seen in approximately one-third of cases, and atrial flutter is seen less often, although the exact percentage of atrial arrhythmias depends on the duration of constriction.

The cardiac silhouette may be normal or enlarged. Pericardial calcification is present in less than half the cases seen in the United States and Europe. Pericardial calcification may be seen with chronic adhesive pericarditis in the absence of constriction, but then it is usually less dense and has a more patchy distribution (Fig. 72-18).

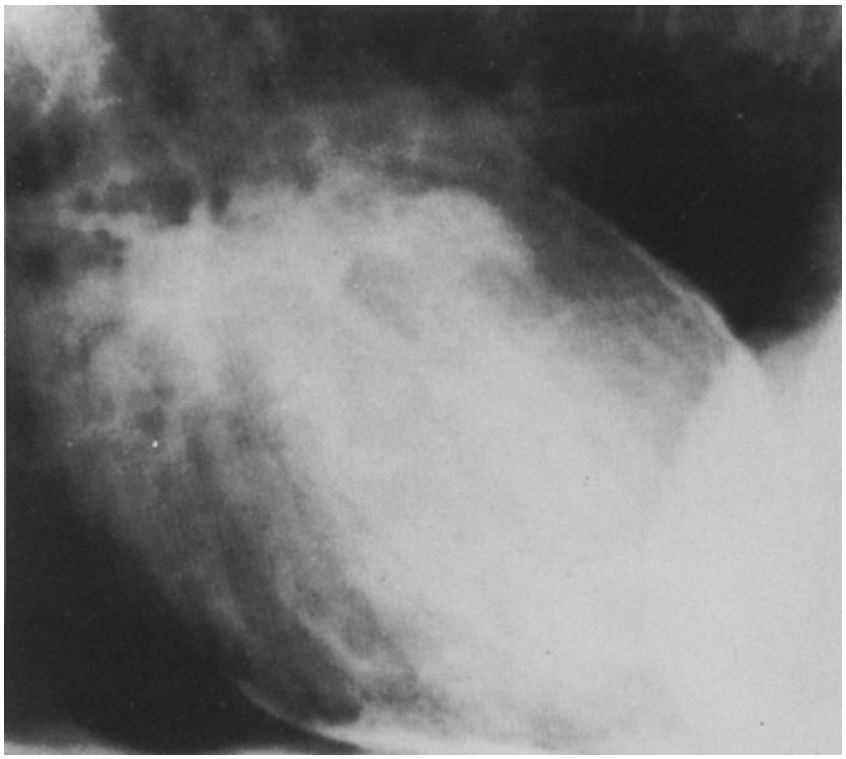

Figure 72-18: Calcification of the pericardium seen on a lateral chest radiograph in a patient with chronic constrictive pericarditis. (Courtesy of Ralph Shabetai, MD. From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:595. Reproduced with permission.)

Pericardial thickening and calcification and abnormal ventricular filling produce characteristic changes on the M-mode echocardiogram.[53] Increased pericardial thickness is suggested by parallel motion of the epicardium and parietal pericardium, which are separated by a relatively echo-free space at least 1 mm thick. Echocardiographic correlates of the hemodynamic abnormalities of constrictive pericarditis include flattening of the LV posterior wall endocardium, abnormal septal motion, and occasionally premature opening of the pulmonary valve (Fig. 72-19). These findings, which reflect abnormal filling of the ventricles, are insensitive and subtle and lack the specificity to be clinically useful. Although no sign or combination of signs on M-mode echocardiography is diagnostic of constrictive pericarditis, a normal study virtually rules out the diagnosis.[53]

Computed tomography (CT) is a highly accurate method of evaluating pericardial thickness and therefore plays an essential role in the diagnosis and management of constrictive disease (Fig. 72-20).[54] The normal pericardium is identified as a 1- to 2-mm curvilinear line of soft tissue density, whereas in constrictive pericarditis, the parietal pericardium is 4 to 20 mm thick. Failure to visualize the posterolateral LV wall on dynamic CT suggests myocardial fibrosis or atrophy and is associated with a poor surgical outcome.[55] Because of the close physiologic similarities of constrictive pericarditis and restrictive cardiomyopathy, increased pericardial thickness detected by tomographic scanning is the most reliable means of distinguishing between the two disorders, as normal pericardial thickness excludes most cases of constrictive pericarditis. CT also is useful in planning pericardiectomy because of its ability to define the distribution of pericardial thickening.[56]

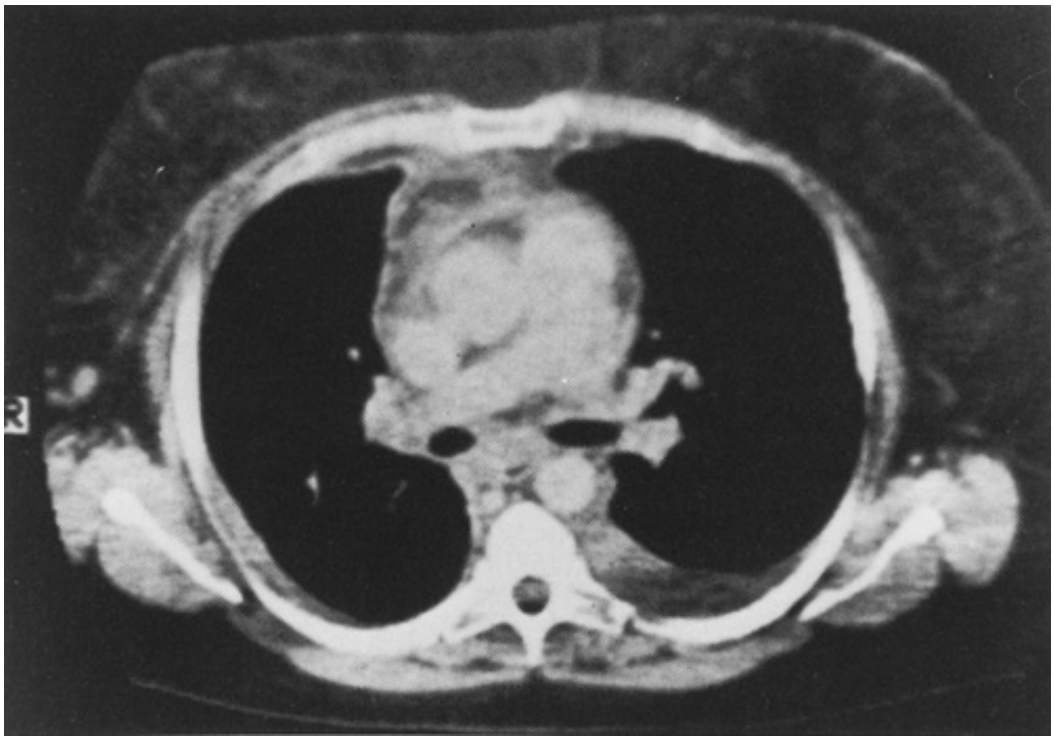

Figure 72-20: Computed tomogram from a patient with constrictive pericarditis. The diffusely thickened pericardium is bordered by low-intensity epicardial and mediastinal fat. (Courtesy of Dr. N. O. Fowler. From Hoit BD. Imaging the pericardium. *Cardiol Clin* 1990; 8:597. Reproduced with permission.)

Accurate definition of pericardial thickness and its distribution also is possible with MRI (Fig. 72-21).[27,57] Unlike CT, ECG gating is necessary for adequate visualization, resolution is not quite as good, and calcification is difficult to distinguish from fibrosis. However, excellent diagnostic accuracy in identifying surgically confirmed constrictive pericarditis has been reported.[58] Preliminary studies suggest that phase velocity mapping techniques may provide additional diagnostic information, analogous to Doppler echo.

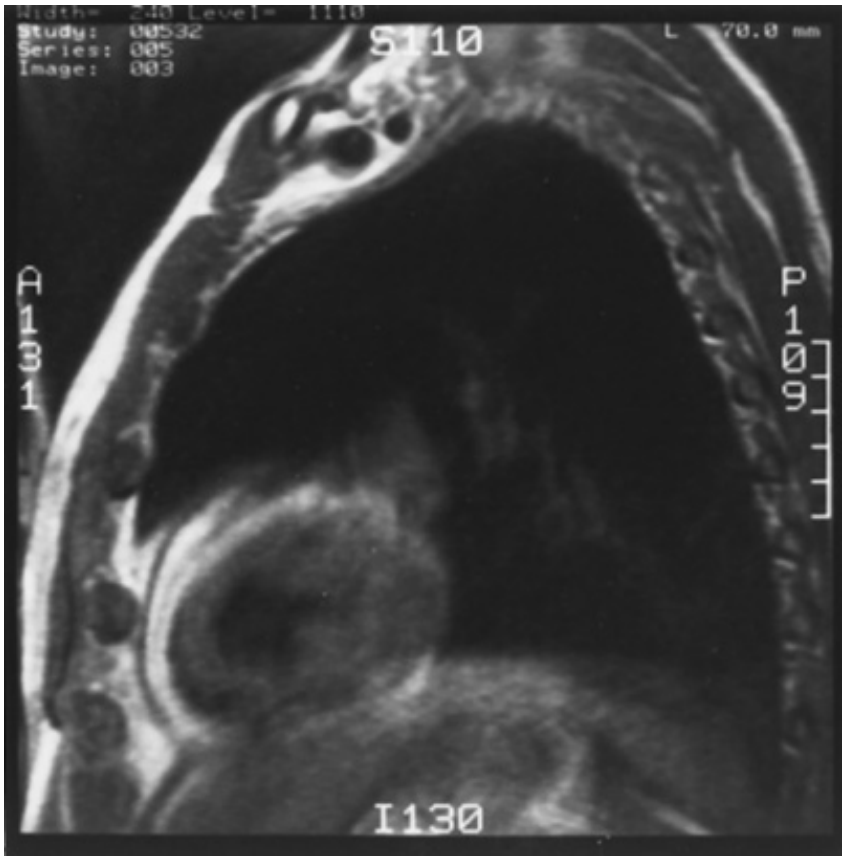

Figure 72-21: MRI scan (spin-echo image) from a patient with constrictive pericarditis. The pericardium is viewed as a line of low signal intensity (black) sandwiched between higher-intensity epicardial and pericardial fat (white). Note the regional variation of pericardial thickness, which is normally 1 to 2 mm. (From Hoit BD. Pericardial disease and pericardial heart disease. In: O'Rourke RA, ed. *Stein's Internal Medicine*, 5th ed. St. Louis, Missouri: Mosby-Year Book;1998:273. Reproduced with permission.)

Cardiac Catheterization

Cardiac catheterization is used to confirm the clinical suspicion of pericardial disease, uncover occult constriction, diagnose effusive-constrictive disease, and identify associated coronary, myocardial, and valvular disease. Endomyocardial biopsy is sometimes necessary to exclude restrictive cardiomyopathy, which shares many hemodynamic abnormalities with constrictive pericarditis.

Differences between Constrictive Pericarditis and Cardiac Tamponade

The waveform of venous pressure in constrictive pericarditis differs from that in cardiac tamponade. In constrictive pericarditis, cardiac volume is determined by the thickened, rigid pericardium, and the heart is unable to exceed this volume, which is attained near the end of the first third of diastole. During ejection, venous return commences unimpeded, and therefore, the normal systolic surge of venous return is preserved. Cardiac compression remains insignificant at end systole (unlike cardiac tamponade), so that when the tricuspid valve opens, blood fills the ventricles at a supranormal rate. Thus, in constrictive pericarditis, the venous return is biphasic, but with a diastolic component greater than or equal to the systolic component.

Unlike cardiac tamponade, the intrapericardial space is obliterated in constrictive pericarditis. As a result, during inspiration, the decreased intrathoracic pressure is not transmitted to the heart, venous pressure does not fall, and systemic venous return fails to increase. Another important

distinction from cardiac tamponade is that early diastolic filling is faster than normal in constrictive pericarditis, and consequently, the ventricular diastolic pressure is characterized by a dip in early diastole (Fig. 72-22). By the end of the rapid filling phase, the ventricles are completely filled and the ventricular diastolic pressure remains unchanged and elevated for the remainder of diastole. The resultant pattern of ventricular diastolic pressure in constrictive pericarditis is referred to as the "dip-and-plateau pattern" or the "square-root sign."

In contrast to cardiac tamponade, early diastolic filling in constrictive pericarditis is unrestrained, and only at the end of the first third of diastole does the stiff pericardium abruptly restrict ventricular filling. As a result, ventricular pressure falls rapidly in early diastole and subsequently rises abruptly to an elevated level, where it remains until the next ventricular systole. End-diastolic ventricular pressures and mean atrial pressures are elevated and nearly equal (within 5 mmHg), and end-diastolic volumes and, consequently, stroke volume and cardiac output are reduced. These pathophysiologic changes are responsible for the hemodynamic and physical findings that characterize constrictive pericarditis.[51]

Pulsus paradoxus is much less common in constrictive pericarditis than it is in cardiac tamponade because in constrictive pericarditis, inspiratory increases in venous return and in the volume of the right side of the heart seldom occur, and the position of the ventricular septum relative to the two ventricles is not as dramatically altered.

Systolic LV function is usually unimpaired in both constrictive pericarditis and cardiac tamponade. Long-standing calcific constrictive pericarditis may invade the myocardium and coronary vessels, leading to conduction disturbances and impaired ventricular function.

Syndromes of Constrictive Pericarditis

Classic *chronic constrictive pericarditis* is encountered less frequently than it was in the past, whereas *subacute constrictive pericarditis* is becoming more common. In the latter syndrome, pericardial calcification is uncommon and the course may span a matter of weeks to a few years. *Postoperative constrictive pericarditis* is an important cause of constriction, with a reported incidence of 0.2 percent[59]; this incidence is surprisingly low considering that in these operations the pericardium is subject to cellular injury and is exposed to proinflammatory substances such as blood and local hypothermia.

Occult constrictive pericarditis requires a fluid challenge for detection.[60] In the first series reported, the patients complained of nondescript chest pain, for which they underwent cardiac catheterization and coronary arteriography. Although hemodynamic studies revealed normal basal atrial and ventricular pressures, the right atrial pressure waveform assumed the characteristics of constrictive pericarditis and the diastolic pressures in the two ventricles became equal after a rapid infusion (10 min) of approximately 1 L of saline solution. Histologic examination confirmed the surgical findings of a thickened and fibrosed pericardium. Rapid, large fluid challenges at cardiac catheterization should be administered with caution; furthermore, the induction of hemodynamic changes suggesting constrictive pericarditis by this technique should seldom, if ever, be taken alone as an indication for pericardiectomy.

Localized constrictive pericarditis is rare, but occasionally a localized band constricts the inflow or outflow region of one or more of the cardiac chambers. The clinical picture then simulates valve disease or venous obstruction. Evidence of *transient* (*acute*)*constriction* may occur in ~15 percent of patients with acute effusive pericarditis.[61] Therefore, before one proceeds with pericardiectomy, the possibility that pericardial constriction may be reversible and amenable to medical therapy should be considered.

Management of Constrictive Pericarditis

Pericardiectomy is the definitive treatment for constrictive pericarditis but is unwarranted either in very early constriction or in severe, advanced disease (functional class IV), when the risk of surgery is excessive (30 to 40 percent mortality) and the benefits are diminished.[62] Involvement of the visceral pericardium also increases the surgical risk. Symptomatic relief and normalization of cardiac pressures may take several months after pericardiectomy; they occur sooner when the operation is carried out before the disease is too chronic and when the pericardiectomy is almost complete. Complete or extensive pericardial resection is desirable, although data suggest that in some instances, subtotal pericardiectomy may be preferred.[63]

Pericardiectomy is commonly carried out via a median sternotomy, although some surgeons prefer a thoracotomy. Despite a decline in the risk of mortality, it remains 5 to 15 percent. The risk is increased by heavy calcification and involvement of the visceral pericardium. LV systolic dysfunction may occur after decortication of a severely constricted heart. Although this condition may require treatment for several months, it usually resolves completely.

Medical therapy of constrictive pericarditis plays a small but important role. In some patients, constrictive pericarditis resolves either spontaneously or in response to various combinations of nonsteroidal anti-inflammatory agents, steroids, and antibiotics.[50] Antibiotic therapy should be initiated before surgery and continued afterward. Diuretics and digoxin (in the presence of atrial fibrillation) are useful in patients who are not candidates for pericardiectomy because of their high surgical risk.

Prevention consists of appropriate therapy for acute pericarditis and adequate pericardial drainage. Although urokinase instillation is promising, corticosteroids are often ineffective.

Chapter 72: DISEASES OF THE PERICARDIUM

EFFUSIVE-CONSTRICTIVE PERICARDITIS

Effusive-constrictive pericarditis occurs when pericardial fluid accumulates between the thickened, fibrotic parietal pericardium and visceral pericardium. Neoplasia, chest irradiation, infection, idiopathic pericarditis, and connective tissue diseases are common antecedents. Transient effusive-constrictive pericarditis may complicate chemotherapy.[64] The hemodynamic features are those of cardiac tamponade before, and constrictive pericarditis after, pericardiocentesis. Thus, removal of pericardial fluid fails to lower atrial and ventricular diastolic pressures, but the previously attenuated or absent atrial Y descent becomes prominent (Fig. 72-23).

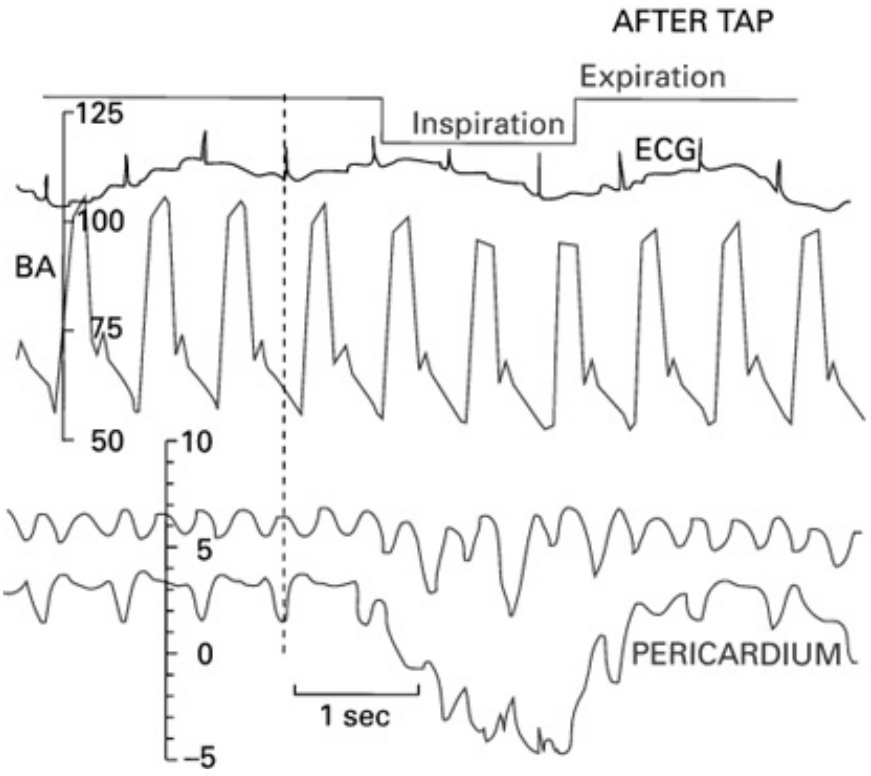

Figure 72-23: Recording from a patient with effusive-constrictive pericarditis caused by lung cancer. The tracings were obtained during the pericardiocentesis; right atrial pressure elevation persists, and there are prominent X and Y descents without respiratory variation. (From Shabetai R. *The Pericardium*. New York: Grune & Stratton; 1981:273. Reproduced with permission.)

Chapter 72: DISEASES OF THE PERICARDIUM

SPECIFIC FORMS OF PERICARDIAL HEART DISEASE

Idiopathic Pericarditis

Acute pericarditis is most often idiopathic and is typically a self-limited disease lasting 2 to 6 weeks.[65] Recurrence occurs in 25 percent of cases and occasionally proves resistant to therapy. Small pericardial effusions occur commonly, but cardiac tamponade is unusual. Heart failure caused by associated myocarditis and constrictive pericarditis are uncommon. These complications usually can be detected by clinical and echocardiographic evaluation. The clinical course and prognosis of individuals with pericarditis are otherwise determined largely by the presence and nature of any underlying disease.

Infectious Pericarditis

VIRAL PERICARDITIS

Viral pericarditis is the most common infectious type, although a definitive diagnosis from acute and convalescent (3 weeks) viral neutralizing antibodies is generally not helpful in a sporadic case of pericarditis. Viral isolation from pericardial fluid and in situ hybridization techniques have been used to identify a specific etiology.[20,66] However, viral infection often is presumed rather than proved, and many cases are classified as idiopathic. Epicardial biopsy via a pericardioscope is a promising investigative technique for establishing the etiology of acute pericarditis. Common viral infections causing acute pericarditis are those resulting from echovirus and coxsackie virus; however, a great many different viruses may cause pericarditis (Table 72-2).

BACTERIAL PERICARDITIS

Bacterial (purulent) pericarditis most often is caused by streptococci, staphylococci, and gram-negative rods; *Haemophilus influenzae* is an important cause in children.[67] The increasing frequency of cardiac surgery and instrumentation, selection-induced changes in the flora responsible for hospital-acquired infections, and the prolonged survival of immunocompromised hosts (HIV, steroids) have changed the incidence and bacterial spectrum of purulent pericarditis. Pericardial involvement often is unrecognized when it complicates systemic infection; unusually high fever and white blood cell counts are clues to the presence of pericarditis. Children and immunosuppressed patients of all ages are most vulnerable, and the characteristic features of acute pericarditis are frequently absent. The course of bacterial pericarditis is fulminant, often presenting with cardiac tamponade; adhesive and constrictive pericarditis are common sequelae in survivors and may develop suddenly and early.[67,68] However, pericarditis complicating systemic infection and sepsis may go unrecognized and misdiagnosed.[69] Many patients lack the typical findings of pericarditis, and the diagnosis of purulent pericarditis often is made either at autopsy or after cardiac tamponade develops; empyema is a common antecedent.[67] Purulent pericarditis rarely is caused by anaerobic bacteria, and the few reported cases resulted from contiguous infection or hematogenous seeding.[70] Bacterial pericarditis is treated with surgical exploration and drainage and appropriate systemic antibiotics. Fibrinolytics may be used to lyse fibrous adhesions and prevent constrictive pericarditis.[71-73]

Legionella infections account for ~10 percent of community-acquired pneumonias and may be

associated with pericarditis more often than previously was appreciated. Studies suggest that patients with pericardial involvement tend to be younger and healthier than are those without it.[74] Recurrent pericarditis, effusion, and chronic constriction occur in about 20 percent of cases.[75] Pericarditis is an early complication of Lyme disease.[76]

MYOCBACTERIAL AND FUNGAL PERICARDITIS

Tuberculosis is a major cause of pericarditis in nonindustrialized countries but is an uncommon cause in the United States. Nevertheless, its incidence is increasing because of HIV infection; therefore, tuberculosis should be considered in the differential diagnosis of pericardial heart disease.[77] Tuberculous pericarditis results from hematogenous spread of primary tuberculosis or from the breakdown of infected mediastinal lymph nodes; therefore, affected individuals generally lack the typical symptoms and signs of pulmonary tuberculosis. Fever, weight loss, and night sweats occur early; pericardial pain and friction rubs are often absent. Patients may present with tamponade or constriction, which may be subacute. A fibrinous pericarditis with caseating necrosis and mononuclear infiltrate gives rise to an effusive phase, which is often voluminous and hemodynamically significant. An adhesive phase follows resolution of the effusion and eventuates in dense, calcific adhesions with clinical constriction in nearly 50 percent of patients.

Mycobacteria are difficult to culture from pericardial fluid, which is diagnostic in only one-third of cases; polymerase chain reaction (rtPCR) recently was used to amplify and identify *Mycobacterium tuberculosis.*[78] A presumptive diagnosis generally requires a history of contact and/or purified protein derivative conversion (although the latter lacks sensitivity and specificity). Gadolinium-enhanced MRI may be useful in early diagnosis.[79] Increased adenosine deaminase activity in pericardial fluid is supportive. However, the diagnosis of tuberculous pericarditis is based on (1) histologic identification, (2) culture of *M. tuberculosis,* (3) pericarditis with proven extracardiac tuberculosis, or (4) pericardial effusion responsive to antituberculosis therapy.

Early pericardiectomy has been recommended by some researchers in all cases of tuberculosis pericarditis, but the long-term (16 years) prognosis of patients without cardiac compression during the acute illness who are treated with medical therapy alone is excellent.[80] Multiple-drug therapy and corticosteroids are effective in tuberculous pericarditis, whereas atypical mycobacterial infections (especially *M. avium-intracellulare*) may be resistant to treatment. Patients with tuberculous pericarditis should receive triple-drug therapy (isoniazid, rifampin, and streptomycin or ethambutol) for a minimum of 9 months. Corticosteroids may be useful if pericardial effusion persists or recurs during therapy; pericardiectomy may be necessary for recurrent cardiac tamponade. Patients should be observed for constriction; up to half these patients will require pericardiectomy.[81] In contrast, pericarditis complicating deep fungal infection (histoplasmosis, coccidioidomyocosis) may be immunologic, resolve spontaneously, and not require specific therapy. Surgical decompression and specific antifungal therapy may be necessary for disseminated infection with *Candida, Aspergillus, Actinomycetes,* and *Nocardia.*

AIDS PERICARDITIS

Acquired immunodeficiency syndrome (AIDS) is an important cause of pericardial heart disease. Typically, pericardial effusions are small and asymptomatic in outpatients, but large effusions and tamponade are common in hospitalized patients with AIDS. Indeed, in one study, a moderate or large effusion was present in more patients with symptomatic than asymptomatic HIV infection (17 percent versus 2 percent), and most of these cases were clinically unsuspected.[82] The incidence and prevalence of pericardial effusion in a prospective, 5-year follow-up study of AIDS patients were high (11 percent/year and 5 percent, respectively).[83] A literature review of echocardiographic and autopsy series found an average incidence of pericardial disease of 21 percent.[84]

Pericardial involvement may be due to associated malignancies (e.g., lymphoma and Kaposi's sarcoma), viruses (including HIV) and opportunistic infections (e.g., mycobacteria, cytomegalovirus, *Nocardia*, and cryptococci) and, irrespective of its cause, predicts a poor prognosis in patients with HIV infection.[85] Large, symptomatic pericardial effusion in patients with HIV infection should be aggressively investigated, as two-thirds of these cases have an identifiable cause.[84] Tamponade in patients with HIV is mycobacterial (*M. tuberculosis* or *avium-intracellulare*) in origin in approximately one-third of patients.[84]

In 68 patients with HIV infection prospectively admitted to the intensive care unit, only 5 had evidence of cardiac disease, but 35 had echocardiographic abnormalities (20 effusions, 2 with tamponade, 15 cases of left ventricular dysfunction, and 4 valvular abnormalities).[86] The presence of an effusion was associated with greater 6-month mortality in patients with AIDS (96 percent versus 36 percent); interestingly, an asymptomatic pericardial effusion may signal end-stage HIV disease, independent of the CD4 count and albumin level.[83]

Neoplastic Pericarditis

Metastatic neoplasia remains the leading cause of pericardial disease in hospitalized patients, most often in patients with lung or breast cancer, melanoma, lymphoma, and acute leukemia. Many cases are asymptomatic and are found only incidentally at autopsy, but others cause symptoms and may progress to cardiac tamponade. Primary cardiac tumors may invade the pericardium directly.

Primary mesothelioma of the pericardium is a rare and highly lethal tumor.[87] Signs and symptoms are nonspecific, and chest radiography and echocardiography are insensitive for its detection; CT and MRI are the most promising diagnostic tests. Other primary tumors of the pericardium are quite rare.

In patients with elevated jugular pressure and an intrathoracic mass, an important inclusion in the differential diagnosis is the superior vena cava syndrome. In this disorder, the characteristic pulsations of the jugular veins are not observed and pulsus paradoxus is not present. However, in a patient with respiratory distress, pulsus alternans, arrhythmia, and/or tachycardia, pulsus paradoxus may be obscured.

The pericardium may be thickened and cause constriction; less commonly, effusive-constrictive pericarditis occurs. Echocardiography rapidly and accurately detects pericardial effusion, identifies metastatic lesions, and provides evidence for cardiac compression. MRI is particularly useful in evaluating pericardial mass lesions. Neoplastic cells can be recovered from the pericardial fluid, which is usually bloody, in many cases. However, it is important to remember that more than half of pericardial effusions in cancer patients are due to causes other than metastatic disease, such as infections, radiation, and drug therapy; thus, the presence of pericarditis in cancer patients does not imply imminent death.[88]

Postmyocardial Infarction Pericarditis

Pericarditis is common in the first few days after an MI, occurring in as many as 28 to 43 percent of fatal infarctions, but is clinically apparent in as few as 7 percent of cases.[89] When friction rub is required for diagnosis, there is an underestimation of the incidence of postinfarction pericarditis. On average, pericarditis was diagnosed by rub alone in 14 percent compared with 25 percent when classic symptoms, a rub, or both were used as diagnostic criteria.[90] The detection of atypical T-wave evolution on ECG (i.e., either persistent positivity or temporally late positivity) may be a more sensitive and objective means of diagnosing postinfarction pericarditis.[91]

Pericardial involvement is related to infarct size and is associated with a poor prognosis.[92] An important clinical problem is the extent to which acute pericarditis in myocardial infarction influences management with anticoagulants. A pericardial friction rub occurring in the first 2 or 3 days without an associated pericardial effusion should not influence clinical decisions, but pericarditis occurring later in the course or accompanied by pericardial effusion or tamponade is a contraindication to anticoagulant therapy.

In a prospective, consecutive series of 174 patients with acute myocardial infarction, pericarditis occurred in 24 percent and was associated with anterior infarct location, heparin therapy, and pericardial effusion.[93] Cardiac tamponade seldom occurs, except in patients who receive systemic anticoagulants or have cardiac rupture.

Thrombolytic therapy almost invariably precedes the development of pericarditis; therefore, clinical decision making usually is not affected. Surprisingly, thrombolytic therapy reduces the incidence of postinfarction pericarditis by approximately one-half.[94] However, when acute pericarditis is mistaken for acute myocardial infarction, thrombolytic therapy can have calamitous consequences. In patients treated mistakenly for myopericarditis with thrombolytics, the outcome was favorable.[95]

Dressler's syndrome (postmyocardial infarction syndrome) consists of pleuropericardial chest pain, friction rub, fever, leukocytosis, and pulmonary infiltrates. It usually occurs weeks or months (>10 days to 2 weeks) after the causative infarction. Dressler's syndrome may be caused by a combination of viral activation and myocardial antibodies and is clinically and pathogenetically similar to the postpericardiotomy syndrome. Cardiac tamponade of and late constriction may occur. For reasons that are not entirely clear, thrombolytic therapy has helped render post-myocardial infarction pericarditis nearly extinct.[96]

Radiation-Induced Pericardial Disease

Radiation injury to the pericardium is said to occur after exposure in excess of 4000 rads; the incidence also is dependent on the use of subcarinal blocks, the nature of the radiation source, and the duration and fractionation of the radiation regimen. For example, approximately 20 percent of Hodgkin's disease patients receiving ^{60}Co radiation with anterior weighting of the beam develop pericarditis, whereas the incidence of pericarditis after high-dose radiation for breast cancer (which includes less of the heart in the radiation field) is less than 5 percent.

Acute pericarditis occurring early during therapy is uncommon and most likely is a result of the radiation-induced effects on the tumor rather than a direct toxic effect of the radiation on the pericardium.[97] In this instance, therapy should not be disrupted, although a reduction in dose may be necessary. A delayed (usually less than 1 year but highly variable) form of pericardial injury may present as acute pericarditis or effusion (often with some degree of cardiac compression). The reaction of the pericardium to radiation is fibrinous inflammation,[98] often with an effusion. Although the acute lesion usually subsides within 2 years without sequelae, constrictive and effusive-constrictive pericarditis may become manifest only after many years.

The pathophysiology of radiation pericarditis is poorly understood but may involve extensive damage to the pericardial microcirculation and pericardial lymphatics with resultant ischemic injury. The incidence increases when anteriorly weighted field techniques are employed and is more common in patients who also have received adjunctive chemotherapy.

In the effusive stage, the differential diagnosis includes recurrence of the neoplasm, and examination of pericardial fluid is then helpful, as the fluid is positive in about 30 percent of cases.[99] Effusion may be due to the hypothyroid state induced by radiation therapy. Cytology is

reliable in breast and lung cancer but less so in lymphoma and leukemia, where pericardial biopsy may be needed. Acute radiation-induced pericarditis can be managed symptomatically as acute idiopathic pericarditis. Hemodynamically insignificant pericardial effusion also can be managed conservatively, as spontaneous resolution is the rule; however, pericardiectomy should be offered to symptomatic patients with large, recurrent pericardial effusions. Constrictive pericarditis requires pericardiectomy unless the biopsy reveals significant endomyocardial fibrosis.

Traumatic Pericardial Disease

Blunt trauma and penetrating trauma are important causes of pericarditis, particularly among young men.[100] Chronic constrictive pericarditis, recurrent pericardial effusion, and recurrent acute pericarditis are well-recognized complications. Traumatic pericarditis may be life-threatening. The application of echocardiography in the trauma unit rapidly and accurately diagnoses hemopericardium in patients with potentially penetrating cardiac wounds.[101] Failure to repair the injury responsible for tamponade is associated with a poor clinical outcome.[102] Constrictive pericarditis occasionally occurs and may be delayed, presenting weeks or years after the injury.[103] Chylous pericardial effusions generally follow traumatic or surgical injury to the thoracic duct but may result from neoplastic obstruction of the thoracic duct or may be idiopathic.

Nephrogenic Pericardial Disease

Pericarditis complicates both uremia and dialytic therapy (hemo- and peritoneal dialysis) and may be clinically silent. The clinical manifestation of nephrogenic pericardial disease may be acute fibrinous pericarditis, pericardial effusion, or cardiac tamponade; classic constrictive pericarditis is rare.

The pathogenesis remains unknown. The etiology of pericarditis in dialyzed patients may be different from that in end-stage renal disease. The theory that uremic pericarditis is a chemical response to retained products of metabolism fails to account for a poor relationship between the blood urea nitrogen (BUN) or other nitrogenous metabolites and the frequency of pericarditis. Since pericarditis is less common in patients undergoing peritoneal dialysis than in those receiving hemodialysis, there is a possible role for "middle molecules." Moreover, the hemorrhagic diathesis seen in the uremic syndrome may predispose to pericarditis; the resultant pericarditis is highly vascular, and consequently, the uremia or dialysis-related pericardial effusion is generally bloody. Renal insufficiency is associated with increased susceptibility to infection, and therefore, the possibility of viral, tuberculous, or even bacterial pericarditis must be considered. Immunologic abnormalities also have been implicated as a cause of pericardial disease in this setting. A presumptive diagnosis of dialysis-related pericarditis should be made only after other causes of pericardial heart disease (such as neoplasia and post-MI) that are common in this patient population have been excluded.

The clinical manifestations of cardiac tamponade may be atypical and difficult to distinguish from cardiovascular deterioration in patients undergoing hemodialysis. Cardiac tamponade remains one of the principal causes of hemodialysis-associated morbidity and terminates fatally in 20 percent of cases.

Although intensification of dialysis is an accepted treatment modality for hemodynamically insignificant disease, considerable controversy exists regarding the optimal management of large, persistent, or recurrent pericardial effusion and tamponade. Severe tamponade is an indication for pericardial drainage, but a conservative approach-intensification of dialysis and nonsteroidal anti-inflammatory agents-may suffice in less severe cases. The instillation of nonabsorbable steroids directly into the pericardial space has been advocated.[42] Dialysis-associated effusive pericarditis usually responds to an intensification of dialysis and regional heparinization or to a change to peritoneal dialysis. Pericardiectomy may be necessary for intractable effusions.

Myxedema Pericardial Disease

Pericarditis with effusion (sometimes containing cholesterol) occurs in about one-third of patients with myxedema. Effusions develop slowly and may reach a prodigious size; slow resolution usually follows the institution of thyroid replacement therapy. A case of hypothyroidism and viral pericarditis in a patient presenting to the emergency room with abdominal pain and shock was reported recently.[104]

Connective Tissue Disease-Related Pericardial Disease

Pericarditis may accompany virtually any connective tissue disease and may present as either acute or chronic pericarditis with or without an effusion.[105] Although tamponade, effusive-constrictive disease, and constrictive pericarditis are recognized complications, most cases are subclinical and in many instances are recognized only at autopsy.[106]

Rheumatoid pericardial disease is more common in middle-aged men in whom the onset of arthritis is acute. Serologic tests for rheumatoid disease are usually positive, and typical rheumatoid nodules are common. Rheumatoid arthritis is one of the causes of cholesterol pericarditis. Constrictive pericarditis is usually subacute and seldom is calcific. Pericardiectomy may be required within months of the first diagnosis of acute pericarditis and is almost always required within 5 years.[107,108]

Effusions are common in patients with SLE, and recurrent pericarditis, adhesion, and constriction may eventuate[109]; indeed, pericardial disease develops in nearly all patients with SLE when life is prolonged by steroid treatment. The pericardial fluid usually has a high protein content and a normal or slightly reduced glucose content; LE cells may be found. As in rheumatoid arthritis, the complement level is low.

Pericardial involvement may be found in systemic sclerosis (scleroderma), often in association with cardiomyopathy and diffuse scleroderma.[110] Dermatomyositis is not infrequently associated with pericardial involvement, including tamponade. Pericarditis is a rare complication in a wide variety of connective tissue disorders and arteritides (Table 72-2).

Iatrogenic Pericardial Disease

Iatrogenic pericardial disease results from both the calculated complications and the unanticipated misadventures of diagnostic and therapeutic procedures. Radiation pericarditis is one type of iatrogenic pericardial disease and was discussed earlier.

Postcardiotomy syndrome, which complicates 5 to 30 percent of cardiac operations, usually appears in the second or third week to 2 months after cardiac surgery; affected patients frequently have high titers of antiheart and antiviral antibodies and may develop cardiac tamponade.

Cardiac perforation complicating diagnostic cardiac catheterization and pacemaker insertion, complications of endoscopic sclerotherapy of esophageal varices, and automatic defibrillator electrode placement are other causes of iatrogenic pericardial disease. Pericardial abnormalities may develop in response to a number of drugs, of which the more important are hydralazine, procainamide, and daunorubicin, although these abnormalities have been reported with a number of agents (Table 72-2). Cardiac tamponade after thrombolysis with rtPA given for stroke has been reported.[111]

Chapter 72: DISEASES OF THE PERICARDIUM

CONGENITAL PERICARDIAL HEART DISEASE

Absence and Partial Absence of the Pericardium

Congenital absence of the pericardium is an uncommon anomaly, usually involving a portion or the whole of the left parietal pericardium. Its presence usually is suspected from the chest radiogram, which shows a leftward shift of the cardiac silhouette, elongation of the left heart border, and radiolucencies between the aortic knob and the pulmonary artery and between the left hemidiaphragm and the base of the heart (Fig. 72-24). This anomaly may be associated with congenital malformations of the heart and lungs.[112]

Although most of these patients are asymptomatic, chest pain may result from torsion of the great vessels, and recurrent pulmonary infections may be a significant feature. Physical findings are not often helpful, but a conspicuous LV heave may be found when the deficiency is substantial. Systolic and diastolic murmurs have been described.

The ECG in patients with complete absence of the left side of the pericardium usually shows an incomplete right bundle branch block. Echocardiographic changes consist of RV enlargement and paradoxical septal motion. Contrast-enhanced CT and MRI detect lesions missed by chest radiography and echocardiography and reliably establish the anatomy of the defect.[113]

Total and very small defects are not associated with pathophysiologic changes, whereas medium-size defects may allow herniation of the left atrium. Strangulation requires surgical closure or enlargement of the defect to reduce the herniation; this may be accomplished with a thoracoscope.

Pericardial Cysts

Pericardial cysts are rare remnants of defective embryologic development of the pericardium. Cysts usually present as a prominent round, sharply demarcated opacity seen on chest radiography in an asymptomatic patient. They vary greatly in size and most commonly are found in the right cardiophrenic angle, although hilar and mediastinal locations are observed occasionaly. Cysts are benign and produce no local or general symptoms; their importance lies in differentiation from neoplasm. Although they can be demonstrated on echocardiography, the nature of the lesion usually is confirmed by CT. A case of video-assisted surgical excision of a recurrent pericardial cyst has been reported.[114]

Part 12: PERICARDIAL DISEASES AND ENDOCARDITIS
Chapter 73:

INFECTIVE ENDOCARDITIS

Author: Jeff Anderson

Infective endocarditis is the disease caused by microbial infection of the endothelial lining of the heart. Its characteristic lesion is a *vegetation*, which usually develops on a heart valve but occasionally appears elsewhere on the endocardium. Sometimes a nidus of infection develops on the lining of a large artery, causing *infective endarteritis;* this variant can produce clinical findings that resemble those of infective endocarditis.

DEFINITIONS AND TERMINOLOGY

The following abbreviations for various forms of endocarditis will be used in this chapter:

- IE: Infective endocarditis
- SBE: Subacute bacterial endocarditis
- ABE: Acute bacterial endocarditis
- NVE: Native valve endocarditis
- PVE: Prosthetic valve endocarditis
- NBTE: Nonbacterial thrombotic endocarditis

The terms *subacute* and *acute bacterial endocarditis* (SBE and ABE) have descriptive value when accurately applied. SBE progresses over a period of weeks to months and is usually caused by organisms of low virulence such as viridans streptococci, which possess limited ability to infect other tissues.[1-4]

In contrast, ABE evolves over a period of days to 1 or 2 weeks; the clinical progress is rapidly changing, complications develop earlier, and the diagnosis is usually made in less than 2 weeks.[4-6] ABE is most often caused by primary pathogens such as *Staphylococcus aureus*, which are capable of causing invasive infection at many other sites in the body.

Infection of a heart valve that was either previously normal or damaged by congenital or acquired disease is termed *native valve endocarditis* (NVE). Infection of an artificial heart valve is termed *prosthetic valve endocarditis* (PVE). This infection was first arbitrarily defined as early PVE, when onset is within the first 2 months after surgery, and as late PVE thereafter.[6-11] Some authors have defined infections occurring between 2 months and 1 year of valve replacement as intermediate PVE,[11] while others consider any prosthetic valve infection beginning before 1 year as early PVE.

Sterile vegetations sometimes develop within the heart. The term *noninfective endocarditis* is a misnomer, because the lesions are primarily thrombotic rather than inflammatory.[12] Thus the term *nonbacterial thrombotic endocarditis* (NBTE) is used broadly to describe any sterile vegetation. This category includes a spectrum of lesions ranging from microscopic aggregates of platelets to the large vegetations of marantic endocarditis, which sometimes develop in patients with terminal malignancy or other chronic diseases.[13-15]

Infective endocarditis is designated best by naming the infecting organism, for example, "*Staph. aureus* endocarditis" or "*Candida albicans* PVE." This terminology is specific and informative, allowing useful inferences about the likely natural history, prognosis, and treatment of the case in question.

Chapter 73: INFECTIVE ENDOCARDITIS

EARLY STUDIES

Riviere, Lancisi, and Morgagni each described patients who died with endocarditis in the seventeenth and eighteenth centuries.[16] Jean-Baptiste Bouillaud introduced the terms *endocardium* and *endocarditis* between 1824 and 1835. By 1846, Virchow recognized valvular vegetations at autopsy, but the microbial etiology of infective endocarditis was not fully appreciated until Virchow et al. independently demonstrated bacteria in vegetations between 1869 and 1872.[16]

William Osler studied the disease extensively, choosing infective endocarditis as the subject for his Goulstonian lectures of 1885.[17,18] Further major contributions to the knowledge of the natural history, pathogenesis, and pathology of the disease were made by Lenharz, Harbitz, and Schottmuller[16] in Germany; by Horder[19] in England; and by Blumer,[1] Thayer,[2] Allen,[20] Libman and Friedberg,[21] and Beeson et al.[22] in the United States. The technique of blood culture was introduced in Europe and the United States between 1890 and 1910.[3] In 1955, Kerr published a classic monograph summarizing the state of knowledge on subacute bacterial endocarditis to that date.[3]

Attempts to cure endocarditis before the advent of antimicrobial drugs were unsuccessful. In 1939, one patient with infective endarteritis involving a patent ductus arteriosus was cured by surgical closure of the ductus.[23] The first successes in the treatment of endocarditis are closely linked to the history of penicillin.[24] The first patient to receive parenteral penicillin was a young man with streptococcal endocarditis who was treated in 1940 at Columbia University in New York.[25] Although the patient did not receive enough penicillin to effect a cure, his treatment antedated the first administration of penicillin to a patient by Florey's team (Abraham et al.) in Oxford[26] by several months. After initial failures, by 1944 it had been established that penicillin,[27] unlike sulfonamides,[28] could cure most cases of streptococcal endocarditis. Subsequently, the antibiotic treatment of endocarditis was clearly established.[29-33] After antibiotics, the next great advance was cardiac valve replacement for treatment of endocarditis in 1965,[34] which provided an essential intervention to improve survival rates in selected patients.

Chapter 73: INFECTIVE ENDOCARDITIS

EPIDEMIOLOGY

Incidence

The incidence of infective endocarditis can only be estimated, because it is not a reportable disease. Various studies in developed countries have estimated the incidence to be 1.6 to 6.0 cases per 100,000 person-years.[35-39] In the United States, this would result in 4000 to 15,000 new cases per year. In a study from the Delaware Valley, where the population includes a large number of intravenous drug users (IDU), the estimated rate was much higher: 11.6 cases per 100,000 per year.[40]

Evolution of the Clinical Syndrome

IE today is a different disease from that seen in the preantibiotic era, when its salient clinical features were exhaustively reported.[1-3] Since 1961, many authors have described the "changing face" of "modern endocarditis,"[41-47] identifying the following trends:

- Increased median age of patients
- Increased ratio of males to females
- Increased proportion of acute cases
- Reduced incidence of some of the classic physical signs of advanced SBE, such as Osler's nodes, finger clubbing, splenomegaly, or Roth's spots
- Decreased proportion of cases due to streptococci, with an increased incidence of staphylococci
- Lengthened list of etiologic organisms, with more reports of cases caused by gram-negative bacilli, fungi, and miscellaneous rare or unusual microbes
- Increased number of cases in IDU
- Increased number of prosthetic valve infections
- Increased incidence of concomitant human immunodeficiency virus (HIV) infection and endocarditis

Susceptible Populations

These striking changes in the clinical features and epidemiology of IE are due to changes in susceptible populations, to earlier diagnosis and treatment of patients with subacute disease and to the impact of antibiotic therapy.[45,48] The prevalence of rheumatic valvular disease, formerly the most common substrate for endocarditis, has steadily decreased; meanwhile, the number of children surviving with congenital heart disease has increased. The number of individuals using illicit drugs intravenously has increased markedly in the United States and Europe since the 1960s, and HIV has spread widely throughout this group as well.[49]

Effect of Antibiotics

Although the advent of antibiotics revolutionized treatment of endocarditis, the overall incidence of the disease has not changed strikingly. The availability of rapidly effective treatments for pneumococcal pneumonia and gonorrhea has probably been responsible for the striking decrease in the incidence of endocarditis caused by *Streptococcus pneumoniae* and *Neisseria gonorrhoeaea* since 1944, while the incidence of reported cases caused by miscellaneous unusual antibiotic-resistant organisms has increased during the antibiotic era.[48,50-53] Apart from these special cases, the widespread use of antimicrobial agents seems to have exerted considerably less influence than have alterations in the populations at risk on the changing epidemiology of endocarditis.[45] Prophylactic use of antibiotics before medical procedures that cause bacteremia has not reduced the incidence of endocarditis significantly; this is not surprising considering that only a small proportion of all cases can be attributed to such procedures.[54-56] Also,

startling studies question the effectiveness of prophylactic antibiotics during dental procedures to prevent endocarditis.[56,57]

Preexisting Heart Disease

Some patients develop endocarditis even though they have no known heart disease. This is most common in cases of ABE,[57] in children less than 2 years of age,[58-64] and in IDUs.[65-70] Most patients who develop IE, however, have a preexisting cardiac condition. Approximate figures for the frequency of the main predisposing factors in children, adults, and IDUs are given in Table 73-1.

Table 73-1: Approximate Frequency of Major Preexisting Cardiac Lesions in Patients with Infective Endocarditis in the United States

Lesion	Children under 2 years, %	Children 2-15 Years, %	Adults 15-50 Years, %	Adults >50 Years, %	Adults Who Are IV Drug Abusers, %
○ Prosthetic heart valves ○ Previous infective endocarditis ○ Cyanotic congenital heart disease ○ Aortic valve disease ○ Mitral regurgitation ○ Mitral regurgitation and stenosis ○ Patent ductus arteriosus ○ Ventricular septal defect ○ Coarctation of the aorta					
○ Mitral valve prolapse with regurgitation ○ Pure mitral stenosis ○ Tricuspid valve disease ○ Pulmonary valve disease ○ Asymmetric septal hypertrophy ○ Hyperalimentation or pressure-monitoring lines that reach the right atrium ○ Nonvalvular intracardiac prosthetic implants ○ Degenerative valvular disease in elderly patients					
○ Mitral valve prolapse without regurgitation ○ Trivial valvular regurgitation by echocardiography without structural abnormality ○ Atrial septal defects, secundum type ○ Arteriosclerotic plaques ○ Coronary artery disease ○ Syphilitic aortitis ○ Cardiac pacemakers ○ Surgically corrected cardiac lesions (without prosthetic implants, more than 6 months after operation)					

Includes mitral valve prolapse.
SOURCE: Adapted from Refs. [35-5158-7081,202].

The relative propensity of various cardiac lesions to become infected can be estimated by noting their frequency in published series of cases of IE, even though there is wide variation among individual studies (Table 73-2).

Table 73-2: Estimates of the Relative Risk of Infective Endocarditis Posed by Various Cardiac Lesions

Relatively High Risk	Intermediate Risk	Very Low or Negligible Risk
Prosthetic heart valves	Mitral valve prolapse with regurgitation	Mitral valve prolapse without regurgitation
Previous infective endocarditis	Pure mitral stenosis	
Cyanotic congenital heart disease	Tricuspid valve disease	Trivial valvular regurgitation by echocardiography without structural abnormality
Aortic valve disease	Pulmonary valve disease	
Mitral regurgitation	Asymmetric septal hypertrophy	
Mitral regurgitation and stenosis	Hyperalimentation or pressure-monitoring lines that reach the right atrium	Atrial septal defects, secundum type
Patent ductus arteriosus		Arteriosclerotic plaques
Ventricular septal defect	Nonvalvular intracardiac prosthetic implants	Coronary artery disease
Coarctation of the aorta		Syphilitic aortitis
	Degenerative valvular disease in elderly patients	Cardiac pacemakers
		Surgically corrected cardiac lesions (without prosthetic implants, more than 6 months after operation)

SOURCE: Adapted from Refs. [36,38,39,43,50,51,71-81,86,116,370].

Mitral valve prolapse (MVP) can predispose to endocarditis.[71-78] (see Chap. 58). MVP underlies 15 to 30 percent or more of cases.[35,72,75,76,80] However, MVP is common and represents a broad spectrum of valvular and clinical disease. The annual percentage of patients with MVP that develop complications (including IE) is small, and the need for IE prophylaxis is controversial. Hence, American Heart Association recommendations include an algorithm to more clearly define when prophylaxis is recommended in MVP.[79] The risk of IE is primarily increased (five- to eightfold) when MVP is associated with regurgitation.[72,73,78] The use of prophylactic antibiotics is supported by cost-benefit analysis in those with auscultatory or Doppler evidence for mitral insufficiency.[79] In contrast, endocarditis risk is not

increased in the absence of regurgitation and prophylaxis is not recommended[2,8,9,79] (see Chap. 58).[72,73] However, this remains controversial. Although commonly used to confirm diagnoses, routine use of echocardiography does not appear to be cost effective.[74]

Children

IE occurs at all ages but is relatively uncommon during childhood and rare during infancy,[58-64,81,82] although the incidence is increasing among smaller infants with cyanotic disease.[83] Males predominate-65 percent in one series.[84] Endocardial infection in children with no predisposing heart disease develops most often in association with infection elsewhere, often in infants and very young children.[85] Endocarditis in these settings is likely to be caused by invasive pathogens and follow an acute course. IE can occur as a rare complication of septicemia caused by staphylococci or group B streptococci or of pneumonia, other respiratory tract infections, osteomyelitis, and severe burns.[58,62] Nosocomial cases associated with intravenous catheters are important.[85] Endocarditis complicating congenital or other preexisting heart lesions is more likely to occur in older children and present as a subacute disease without an obvious portal of entry.[85] Children with a systemic pulmonary shunt constructed surgically are most likely to have endocarditis caused by viridans streptococci.[84] *Haemophilus influenzae* type B endocarditis is very rare, even though this organism was a common cause of bacteremia in children prior to the introduction of conjugate vaccines.

The leading underlying cardiac lesions in children are tetralogy of Fallot and other forms of cyanotic congenital heart disease, ventricular septal defects, aortic stenosis, patent ductus arteriosus, pulmonary stenosis, and coarctation of the aorta. A high proportion of cases (77 percent of those with chronic heart disease) occur in children who have undergone palliative or corrective surgery for congenital cardiac defects.[62,84,86] Atrial septal defects of the ostium secundum type very rarely become infected (Chap. 64). Successful repair of ventricular septal defects and closure of patent ductus arteriosus appears to have greatly reduced the risk of endocarditis. In developed countries, preexisting rheumatic heart disease is now much less common than congenital disease. No underlying cardiac disease is found in about 15 percent of children with endocarditis, but the proportion is higher in those less than 2 years of age (Table 73-1).

A firm diagnosis of IE is more difficult to make in infants and small children than it is in adults. Signs and symptoms, however, are similar: fever occurs in 99 percent of pediatric cases, fatigue in 60 percent, arthralgias in 17 percent, petechiae in 21 percent, changing murmur in 21 percent, splenomegaly in 21 percent, and congenative heart failure in 9 percent. Blood cultures are positive in over 90 percent of the cases, which is also similar to adults. Viridans streptococci account for 38 percent of cases, *Staph. aureus* for 32 percent, enterococci for 7 percent, and a mixture of gram-positive cocci and gram-negative organisms for the rest.[84] Once the diagnosis is suspected, improved diagnostic criteria can help determine whether the child has endocarditis.[85] The clinical manifestations of acute rheumatic fever may mimic endocarditis (and vice versa), but fortunately the two conditions rarely coexist.

The choice of antibiotic treatment for children should be governed by the same principles as for adults, with appropriate dose adjustment for age. As in adults, valve replacement or other potentially curative surgical treatment should not be delayed if the child has heart failure that does not respond well to medical therapy.[87] Children with *Staph. aureus* endocarditis are most likely to have persistent fever bactermia, and complications, require surgery, and have a higher mortality rate than those who do not have *Staph. aureus*.[84,88]

The Elderly

With the increase in elderly people, endocarditis in this group has become more common.[89-92] The median age of patients with endocarditis has risen steadily for three decades, from about 30 to about 50 years. At present, approximately one-fourth of all patients are over age 60.[35,93] The annual risk for endocarditis is strongly age-related, being about 5 times higher in patients over age 80.[39] Male patients now outnumber females by approximately 1.5 to 1 overall, but by as much as 8 to 1 among patients over age 60.[33,94] Elderly patients are more likely to have underlying degenerative or calcific valve lesions.[90] Older patients (>70 years) had a higher proportion of bacteria from a gastrointestinal source (group D streptococci and

enterococci accounted for 50 percent of cases in one series).[92] There is a higher mortality rate (28 versus 13 percent) for patients who are <70 years.[92]

Intravenous Drug Users

Illicit intravenous drug use poses a high risk for IE.[65-70,95] IDUs are 300 times more likely to die suddenly with IE than are nonusers.[96] Bacteremias related to parenteral drug abuse are common and arise either from direct intravenous injection of bacteria or from the skin flora and local infections at injection sites, including cellulitis, abscesses, or suppurative thrombophlebitis. Addicts seldom use sterile injection techniques, sometimes even taking water from toilet bowls to dissolve their drugs. Nevertheless, the organisms that cause drug-related endocarditis most frequently originate from the addict's skin and mucosal bacterial flora.[97] Strains of *Staph. aureus* cause more than 60 percent of cases of endocarditis among parenteral drug abusers, more than all other species combined.[50,70] Infections with gram-negative bacilli, especially *Pseudomonas* species[98,99] or yeasts and other fungi,[100] are notably more common than in nonaddicts (Table 73-3). *Candida parapsilosis* and other *Candida* species are the most common fungi causing drug-related endocarditis, but occasional infections with a wide range of other fungal species have been recorded.[100,101] Polymicrobial and culture-negative cases of endocarditis occur occasionally in IDUs, but together account for less than 5 percent of cases.[65,67,70,102]

Table 73-3: Frequency of Various Organisms Causing Infective Endocarditis[a]

Organism	NVE, %	IV Drug Abusers, %	Early PVE, %	Late PVE, %
Streptococci	60	15-25	5	35
Viridans, alpha-hemolytic	35	5-10	<5	25
0x002003 *Streptococcus bovis*	10	<5	<5	<5
0x002003 *Enterococcus faecalis*	10	10	<5	<5
Other streptococci	<5	<5	<5	<5
Staphylococci	25	50	50	30
Coagulase-positive	23	50	20	10
Coagulase-negative	<5	<5	30	20
Gram-negative aerobic bacilli	<5	5	20	10
Fungi	<5	<5	10	5
Miscellaneous bacteria	<5	5	5	5
Diphtheroids, propionibacteria	<1	<5	5	<5
Other anaerobes	<1	<1	<1	<1
Rickettsiae	<1	<1	<1	<1
Chlamydiae	<1	<1	<1	<1
Polymicrobial infection	<1	1-5	5	5
Culture-negative endocarditis	5-10	<5	<5	<5

[a]These are representative figures collated from the literature; wide local variations in frequency are to be expected. NVE = native valve endocarditis; PVE = prosthetic valve endocarditis; IV = intravenous.

SOURCE: Adapted from Refs. [43,51,65-70,100-110,115,159].

Endocarditis in addicts frequently follows an acute course,[5,65,66,101] reflecting the high frequency of *Staph. aureus* infection. This finding partly explains the overall modest increase in the proportion of acute to subacute cases that has been observed over the past 25 years.[45]

The outstanding clinical feature of endocarditis in IDUs is the unusually high incidence of right-sided valvular infection. In various series, the tricuspid valve is involved in 60 to 70 percent of cases.[50,61,103] The aortic and/or mitral valves are involved in 30 to 40 percent.[50,103] More than one valve on either side of the heart may be infected simultaneously. Pulmonary valve infection is unusual even among IDUs, occurring in only some 2 percent of cases.

Tricuspid vegetations commonly embolize to the lungs, causing septic pulmonary infarcts, which result in multiple focal opacities on chest x-ray, sometimes with cavitation. In a drug addict with fever, this radiologic finding is a highly characteristic sign of acute right-sided endocarditis.[5,70] Mortality rates are much lower (4 percent) with endocarditis in IDUs than in other patient populations, even though the most common cause is *Staph. aureus.* This most likely reflects the benign nature of tricuspid valve involvement compared to left-sided disease.

Patients Infected with Human Immunodeficiency Virus

The primary risk factor for IE in HIV-infected people is the continued use of intravenous drugs, although IE is independently associated with HIV infection. Prior endocarditis, female sex, and skin abscesses are independent risk factors.[104] In one study, the adjusted odds ratio for HIV-infected IDUs with CD4 cell levels > 350 who developed endocarditis was 2.31 versus non-HIV-infected IDUs, but increased to an odds ratio of 8.31 when the CD4 cell count fell to < 350.[107] Several cases of *Bartonella* endocarditis have been reported in patients with acquired immunodeficiency syndrome (AIDS);[105] this appears to be a rare instance of true opportunistic infection of the endocardium. Patients in the earlier stages of HIV infection respond well to standard treatment for endocarditis, but mortality due to IE is high after the CD4+ T-cell count falls below 200 cells per cubic millimeter [49,106] (see also Chap. 70).

Post-Cardiac Surgery Patients

Intracardiac operations, especially valve replacements, have created a whole new population at risk for IE. In the 1950s, surgeons first noted that *Staph. epidermidis* endocarditis occurred fairly frequently after mitral valvotomy.[108] Subsequently, *Staph. epidermidis*, which rarely infects native valves, has become a common cause of both early and late PVE (Table 73-3).[8-11,95] Contamination of blood circulating through pump oxygenators with *Staph. epidermidis* or other organisms or from the operating room air can initiate infection at the time of operation, resulting in early PVE. In late PVE, the causative organisms usually originate from the normal flora of the skin or gastrointestinal tract, but their portal of entry largely remains unknown. Gram-negative bacilli and fungi infect prosthetic valves much more frequently than native valves, especially in early postoperative cases.[11,95,109] The spectrum of organisms causing late PVE more nearly resembles that of subacute native valve infection (Table 73-3).

Figure 73-1 shows the curve for incidence of PVE per month after valve replacement. The peak time of onset is 3 to 9 weeks after operation, with the risk falling quickly thereafter.[9] This important time relationship emphasizes that *Staph. epidermidis* and certain other organisms are often inoculated during or immediately after surgery, while streptococci infect the prosthesis during bacteremias that may occur at any time, unrelated to surgery.

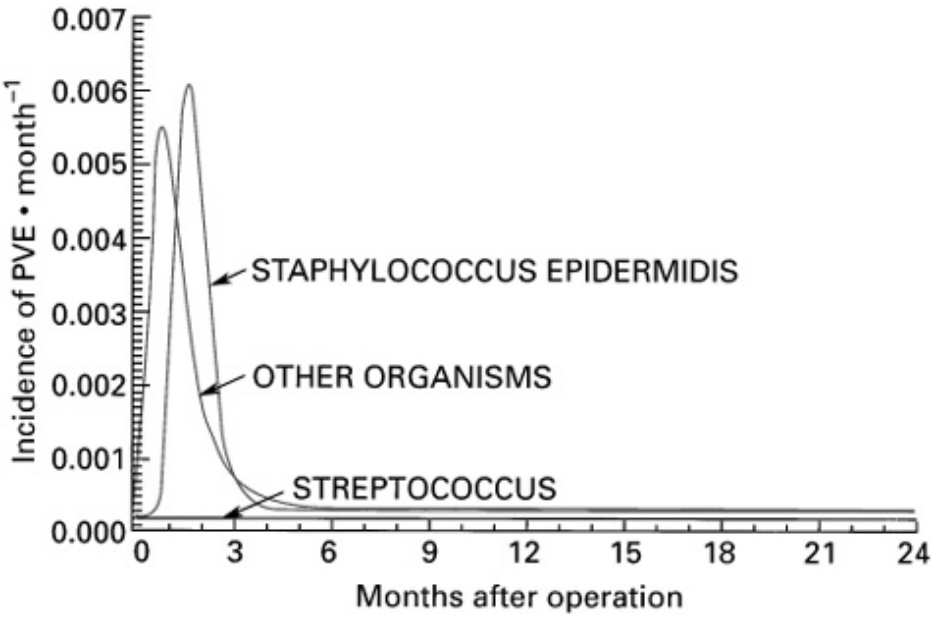

Figure 73-1: Incidence of prosthetic valve endocarditis (PVE) over 24 months after valve replacement. The hazard function has been stratified according to the infecting organisms. (From Ivert TSA, Dismukes WE, Cobbs CG, et al. Prosthetic valve endocarditis. *Circulation* 1984; 69:223. Reproduced with permission.)

The total number of cases of postsurgical endocarditis has increased along with the number of operations, even though the incidence per patient has decreased. This decrease reflects improved operative techniques and possibly the use of prophylactic antibiotics. Currently the rate is about 0.5 percent for early PVE, with a range of 0.3 to 1.2 percent.[8-11]

Patients with prosthetic valves now routinely survive for many years and remain at higher risk for late IE for the rest of their lives.[11,95,109,110] Late PVE occurs at a rate of about 0.3 to 0.5 percent per year.

Obstetric and Gynecologic Patients

Endocarditis occurring as a complication of pregnancy is most likely to develop at the time of delivery or in the puerperium.[111] Normal delivery presents a low risk of endocarditis, even in the presence of preexisting valvular disease,[112] but bacteremias associated with perinatal infective complications such as endometritis, parametritis, septic thrombophlebitis in pelvic veins, or urinary tract infection can seed the mother's endocardium.[111] Septic abortion or pelvic infection related to intrauterine contraceptive devices also can provide the portal of entry for bacteremia resulting in endocarditis.[113] The organisms most often involved are *Enterococcus faecalis*, group B streptococci, *Staph. aureus*, and occasionally gram-negative enteric bacilli or anaerobes.

Nosocomial Endocarditis

Hospital-acquired IE can involve either prosthetic or native valves.[114,115] This serious complication is not rare; one study[116] reported no fewer than 35 examples of probable nosocomial endocarditis among 125 cases (28 percent), and the rate may be rising.[114] Intensive medical care predisposes to endocarditis in several ways. Endocardial damage can be produced by surgery, by intracardiac catheters, and by intravascular devices such as hyperalimentation catheters and cerebrospinal fluid shunts if they reach into the right atrium. Portals of entry for microorganisms are provided by wounds, biopsy sites, pacemakers, intravenous and arterial catheters,[117] urinary catheters, and intratracheal airways. In one study, 75 percent of the suspected sources of infection were vascular access sites.[118] Nosocomial bacteremias arising from local infections are common in seriously ill patients. Up to two-thirds of patients with nosocomial endocarditis had no known predisposing cardiac abnormalities.[118]

Many of the previously mentioned factors coexist in *severely burned* patients. In one study, either NBTE or IE was found at autopsy in all of 6 burned patients who sustained repeated episodes of bacteremia while a pressure-monitoring catheter was maintained in the right side of the heart before death.[119] This observation has been confirmed in another autopsy study of patients with flow-directed pulmonary artery catheters.[120] Of 55 patients, 29 had one or more right-sided endocardial lesions, including 13 with thrombi and 4 with infective endocarditis. *S. aureus* and gram-negative bacilli are the most common organisms isolated. Since persistent bacteremia and fever usually are the only consistent findings, an echocardiogram may be of diagnostic value in this setting.[121] Another group at high risk are patients with *prosthetic valves* who develop nosocomial bacteremias, especially if the organism is a staphylococcus.[115] The portal of entry in these cases is most often an intravascular line or device, and PVE can develop later even if the patient received a course of appropriate antibiotics for the nosocomial infection. In comparison, catheterization of the right side of the heart for brief periods in patients without bacteremia, as in a coronary care unit, presents a very low risk for IE. IE is rare in patients with leukemia but has been observed in other immunocompromised patients-for example, after bone marrow transplantation[122] and heart transplantation.[123] In a report of 46 cases after solid organ transplantation, *Aspergillus fumigatus* and *Staph. aureus* were causative in 50 percent, whereas viridans streptococci were isolated in only 4 percent. Six of 10 cases that occurred within 30 days of transplantation were fungal. No predisposing cardiac abnormality was known to be present in 80 percent. Infected venous access devices and wounds were suspected portals of entry in three-fourths of the cases. The mortality rate was 57 percent, and most infections were not diagnosed prior to death.[124]

Overall, the leading organisms causing nosocomial endocarditis are staphylococci, enterococci, *Candida* species, and gram-negative bacilli. *Staph. aureus* is especially associated with wound infections, cellulitis, and cannula infections; *Staph. epidermidis* with ventriculoatrial shunts; and *C. albicans* with parenteral alimentation.

The prognosis for nosocomial native valve endocarditis is worse than for other forms of native valve infection (up to 50 percent mortality).[114,118] These patients often have serious underlying disease that may delay diagnosis of endocarditis by obscuring the symptoms and signs, while the organisms most commonly involved (staphylococci and enterococci) are more difficult to eradicate than viridans streptococci.

Hemodialysis

Creation of arteriovenous shunts for hemodialysis predisposes patients to develop IE by providing a ready portal of entry for bacteremias. Another possible factor is increased cardiac output. Dogs with high cardiac output due to surgically created arteriovenous fistulas are predisposed to develop not only infective endarteritis at the site of the shunt but endocarditis as well.[125] Therefore, it is not surprising that endocarditis has been reported in 2 to 6 percent of patients on long-term hemodialysis employing either arteriovenous fistulas or cannulas. *Staph. aureus* and *Staph. epidermidis* have been the most common etiologic organisms, followed by viridans streptococci and *E. faecalis*.[126] The diagnosis of endocarditis is difficult in these patients, partly because coexisting intravascular infection at the shunt site often confuses the clinical picture. Mortality is high (53 percent), and a high index of suspicion and use of an echocardiography followed by aggressive treatment of both shunt infections and endocarditis in dialysis patients are necessary to improve outcome.[126] In one study of 20 cases of IE in hemodialysis patients, vegetations were found in 50 percent by transthoracic echocardiogram (TTE) and 81 percent by transesophageal echocardiogram (TEE).[127] In 65 hemodialysis patients with *Staph. aureus* bacteremia, 8 (12 percent) were found to have IE by TEE (6 of whom had normal TTEs).[128]

Pacemaker Infective Endocarditis

The placement of permanent pacemaker leads into the right ventricle may result in endocardial lead infection in 0.2 to 7 percent of patients. These may occur early (6 weeks to 3 months after placement) and are caused by *Staph. epidermidis* in 90 percent, or late, when *Staph. epidermidis* or *Staph. aureus* each account for nearly 50 percent, with gram-negative bacilli causing the remaining few. The definitive diagnosis usually requires TEE, which will detect vegetations in or around the leads in >90 percent of cases. The chest x-ray is predictive in one-third for pulmonary emboli. Cure requires removal of the

pacemaker generator and leads, and treatment with antibiotics.[129-132]

Infective Endarteritis

Focal intravascular infection located outside the heart itself can mimic most of the clinical manifestations of endocarditis, including vascular and immunologic phenomena.[50] In the past, about one-quarter of all patients with an uncorrected patent ductus arteriosus developed bacterial endarteritis.[3] Coarctations of the aorta also presented a significant risk, but endocarditis located on an associated bicuspid aortic valve was 3 times more common than was endarteritis with vegetations located in the coarctation. Endarteritis occasionally complicates traumatic arteriovenous fistulas, but arteriosclerotic aneurysms rarely become infected.[50] When bacterial endarteritis does occur within an aneurysm, the organisms usually grow in a multilayered thrombus in the lumen of the aneurysm rather than in vegetations.

The spectrum of organisms causing infective endarteritis is similar to that found in endocarditis except that there is a higher frequency of infection with salmonellae in arteriosclerotic abdominal aneurysms.[50,133] The pattern of embolization observed differs according to the site of infection. Thus, petechiae may occur on the skin of the lower extremities in a patient with an infected abdominal aneurysm, and infarctions may appear in the lungs of a patient with an infected dialysis fistula in the forearm.

Because many of the congenital and acquired vascular lesions that predispose to infective endarteritis can be corrected by modern surgery, endarteritis-except in arteriovenous shunts constructed for the purpose of hemodialysis-is uncommon today in developed countries.

Chapter 73: INFECTIVE ENDOCARDITIS

ETIOLOGIC ORGANISMS

The range of microbial species that can cause infective endocarditis is extraordinarily wide, yet only a few species account for the great majority of cases. On native valves, streptococci and staphylococci together cause more than 80 percent of infections.[38,43,51,116] By comparison, NVE caused by *Staph. epidermidis*, enteric bacilli, and fungi are uncommon. Among IDUs and patients with prosthetic valves, the incidence of infection due to these organisms is higher. Table 73-3 offers representative data from the literature on the relative frequency of the major etiologic organisms on native valves, in drug addicts, and on prosthetic valves. It should be emphasized that the relative frequency with which various organisms cause endocarditis can vary widely between countries and between medical centers.

Streptococci

Streptococci cause more cases of endocarditis than any other group of organisms.[38,51,134-136] The alpha-hemolytic or viridans streptococci account for the majority of these cases, but have decreased in frequency when compared with others during the last 30 years. Viridans streptococci are ubiquitous (although outnumbered by anaerobes) in the oropharyngeal and gastrointestinal flora. They are usually low-grade pathogens (except for *Strep. milleri*), often recovered from clinical specimens in mixed culture with other organisms but seldom themselves causing disease. Their strong association with SBE is therefore determined by the frequency with which they enter the bloodstream and by their ability to adhere to endocardium rather than by their innate virulence.

The nomenclature of these organisms is complex and has been subject to repeated revisions.[134,137,138] The following species frequently cause SBE: *Strep. sanguis*, *Strep. mitis*, *Strep. oralis*, and *Strep. gordonii*. Many other species occasionally cause SBE; for example, the *Strep. milleri* group: *Strep. anginosus*, *Strep. intermedius*, and *Strep. constellatus*.[134,136,137] A few cases are caused by strains that require media supplemented with L-cysteine or pyridoxine for growth.[139-142] These strains are more difficult to isolate from blood and seem to be more difficult to eradicate with antibiotic treatment than the other viridans streptococci.

Group D streptococci are next in frequency among the streptococci as a cause of endocarditis.[94,143,144] The nonenterococcal group D species, *Strep. bovis*, accounts for about one-fifth of streptococcal cases. IE caused by *Strep. bovis* tends to occur in older patients, affect multiple valves, and require surgery more commonly than IE caused by other organisms.[145] Gastrointestinal lesions, especially colonic polyps and cancers, are present in > 50 percent of patients who develop *Strep. bovis* bacteremia and/or endocarditis.[146,147] Hence, recovery of this species from blood cultures should prompt investigation for colonic disease, whether or not the patient has gastrointestinal symptoms.

Strains of *E. faecalis* (enterococci) cause about 10 percent of streptococcal cases. In the past it was said that this species caused endocarditis "in young women and old men," because it was found in association with infections of the genital and urinary tract in women of childbearing age and of the urinary tract in old men with prostatic disease. Today, enterococcal endocarditis is also likely to be found in drug addicts, in patients with nosocomial endocarditis, and in those with chronic renal failure.[94] Enterococci commonly cause urinary tract, wound, and intravenous line infections,

which often give rise to nosocomial bacteremias.[148,149] Fewer than 2 percent of such patients have endocarditis, but if enterococcal bacteremia is community-acquired without a primary focus of infection, about one-third will have IE.[148] Antibiotic resistance, especially in strains of *E. faecium*, presents major difficulties in treatment of enterococcal endocarditis.[94,150-152]

Many other species and strains of streptococci occasionally cause endocarditis, but they are rare compared with the viridans and group D organisms. *Strep. pneumoniae* endocarditis has become uncommon since the advent of antibiotics. This species causes acute endocarditis,[153] affects primarily the aortic valve in patients without underlying valvular disease (15 of 16 in one series), and often requires immediate valve replacement for aortic insufficiency and cardiac failure (7 of 16).[154,155] In debilitated alcoholics, bacteremic pneumococcal pneumonia is occasionally complicated by the development of pneumococcal endocarditis and meningitis. This triad of simultaneous pneumococcal infections carries an extremely poor prognosis.[153] Beta-hemolytic streptococci rarely cause IE, but in a report of 31 cases, one-third had underlying diabetes mellitis, three-fourths had significant complications, and one-half required cardiac surgery.[156] In children, group A streptococcus may complicate varicella.[157] Group B streptococcal endocarditis is also rare, but may complicate obstetric or other surgical procedures (abortions) or injection drug use, and may involve the tricuspid valve.[158]

Staphylococci

Staph. aureus is the leading cause of acute bacterial endocarditis. Median duration of illness prior to hospitalization was 3 days in one series.[160] It is the predominant etiologic organism in IDUs with endocarditis[70] and frequently causes PVE.[95] *Staph. aureus* endocarditis is also a complication of diabetes mellitis (13 percent in one study), corticosteroid therapy (11 percent), cirrhosis (5 percent), malignancy (4 percent), and chronic renal failure (4 percent).[160] In nosocomial cases, infected intravascular devices were the most common portal of entry. Because it is an invasive primary pathogen, patients with staphylococcal ABE often develop disseminated disease with metastatic infections in skin and soft tissue, bone, joints, eye, or brain.[159-162] More than one-third of patients with *Staph. aureus* endocarditis will have central nervous system involvement.[160]

Only a minority of all patients with *Staph. aureus* bacteremia have endocarditis (6 to 15 percent), and it is often difficult to identify this subgroup clinically. However, use of TEE in this setting is highly effective in establishing the diagnosis of IE. Factors that increase the probability that such a patient has endocarditis are (1) community-acquired bacteremia, (2) absence of a primary focus of infection, and (3) presence of metastatic foci of staphylococcal infection. Up to two-thirds of patients with all 3 of these characteristics have endocarditis.[162] *Staph. epidermidis* is a rare cause of native valve infection (<5 percent), usually associated with an indolent subacute or chronic course.[163] However, serious complications, including systemic embolization, congestive heart failure, myocardial abscess, and valve destruction are common and mortality is high (up to 36 percent).[164] *Staph. lugdunensis*, a recently described species of coagulase negative staphylococcus, appears to be especially virulent and more likely to infect native cardiac valves than *Staph. epidermidis*.[165] In striking contrast, *Staph. epidermidis* is a common cause of PVE (40 to 50 percent), which may follow either an acute or subacute clinical course.[163,166]

Gram-Negative Bacteria

Although most of the species of gram-negative bacteria that colonize and/or infect humans have been reported to cause IE, they account for only a small proportion of cases of native valve infection. A significant subgroup of cases are caused by a group of nutritionally fastidious gram-negative bacilli: *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*. These are often referred to by the acronym

HACEK, which is derived from their initials,[167,168] and cause approximately 3 percent of cases of IE. In one report, most patients had symptoms between 2 weeks and 3 months and presented with fever, a new or changing murmur, splenomegaly, and emboli.[169] Blood cultures usually took 3 to 4 days to turn positive.[169] Prognosis with medical therapy and surgery, when necessary (one-fourth of patients), was good, with 87 percent overall survival.

Cases caused by *Haemophilus* predominate in this group. Endocarditis caused by this genus is usually due to *H. parainfluenza* (62 percent), *H. aphrophilus* (21 percent), *H. paraphrophilus* (10 percent), and only rarely to *H. influenzae*. *Haemophilus* endocarditis is characterized by large vegetations and arterial emboli (35 to 60 percent).[170]

The common aerobic enteric gram-negative bacilli seldom cause endocarditis. For example, cases of endocarditis caused by *Escherichia coli* and *Klebsiella* are notably rare,[99] even though these species frequently cause gram-negative bacteremia. The reasons for this striking disparity are probably multiple, including low adhesiveness of gram-negative enteric bacilli to heart valves[171] and fibrin[172] and susceptibility of many strains to complement-mediated bacteriolysis.[173] Despite these factors, two special populations are at increased risk of gram-negative endocarditis: IDUs and patients with prosthetic valves. Gram-negative bacilli account for about 5 percent of endocarditis in IDUs,[65,68-70] with *Pseudomonas* species, *Serratia,* and *Enterobacter* species predominating. Gram-negative bacilli cause 15 to 20 percent of early PVE and about 10 percent of late PVE.[11,95] Strains of gram-negative bacilli such as *Stenotrophomonas* (*Xanthomonas*) *multophilia,* which are resistant to most antibiotics, are becoming more common. They typically cause nosocomial IE (50 percent), occur on prosthetic heart valves (50 percent), and are associated with IDUs or indwelling vascular catheters (18.8 percent).[174]

Interesting but unusual cases caused by species of *Salmonella, Brucella, Acinetobacter,* and other gram-negative bacilli have been reported.[99] *Brucella* endocarditis is well known in the Mediterranean basin[175-177] but is rare in most other regions. Endocarditis caused by anaerobic bacteria is rare (1 percent or less of cases),[178,179] possibly because the oxygen tension in heart blood is too high to favor growth of these species on the endocardium.

N. gonorrhoeaea causes an acute form of the disease,[2] often involving the right side of the heart. Like the pneumococcus, *N. gonorrhoeaea* has become uncommon as a cause of endocarditis since the introduction of penicillin.[51,52]

Yeasts and Dimorphic Fungi

Although many species of yeasts and other fungi can infect the endocardium, only two genera account for the great majority: *Candida* and *Aspergillus*.[100,101,180,181] *Candida* causes native valve infections in IDUs and in patients receiving parenteral alimentation, while *Aspergillus* species often involve prosthetic valves. Fungal infection of native valves in nonaddicts is rare (Table 73-3).

Miscellaneous Organisms

Many less common organisms occasionally cause endocarditis; for example, *Coxiella burnetii* (Q fever) and *Chlamydia*. Q-fever endocarditis is a chronic, febrile systemic illness with prominent hepatic as well as cardiac valvular involvement.[182-188] Most cases have been reported from Europe, Canada, and Australia and occur in approximately 7 percent of cases of Q fever. Patients typically present with intermittent fever for months to years (91 percent) or with congestive heart failure (77 percent), and almost all have underlying valvular heart disease (97 percent). Diagnosis is difficult and usually based on serology or identification of the organism in cardiac tissue.[183]

One report indicates that *Bartonella* may cause up to 3 percent of cases of IE[189]; in the past, most of these cases were listed as culture-negative, while some were misdiagnosed as chlamydial due to false-positive cross-reacting serologic tests.[189] When suspected on clinical and epidemiological grounds (homeless patient: *Bartonella quintana;* close association with cats: *Bartonella henselae*), PCR (polymerase chain reaction)-based genomic detection or antibody determination are considerably more sensitive than culture in identification of the organism.[190] Chlamydial endocarditis is rare; a few cases have been reported in bird fanciers.[191,192] In such cases, the etiologic diagnosis can be established only by specialized culture techniques, serologic studies, or examination of vegetations using immunofluorescent antibodies. More than 50 cases of *Listeria monocytogenes* endocarditis in both native and prosthetic valves have been reported with a high mortality rate (37 percent).[193] Many other unusual species occasionally infect prosthetic valves, including *Mycoplasma hominis*,[194] *Legionella* species,[53] and mycobacteria.[195] Some examples of rare or unusual organisms that have caused one or more cases of endocarditis are listed in Table 73-4.

Table 73-4: Some Unusual or Rare Causes of Infective Endocarditis

Bacteria	Fungi
❍ *Bacillus cereus* ❍ *Bartonella elizabethae* ❍ *Bartonella henselae* ❍ *Corynebacterium diphtheriae* biotype *gravis* ❍ *Corynebacterium jeikeium* ❍ *Corynebacterium pseudodiphtheriticum* ❍ *Erysipelothrix rhusiopathiae* ❍ *Haemophilus influenzae* type b ❍ *Lactobacillus* species ❍ *Legionella* species ❍ *Mycoplasma hominis* ❍ *Rothia dentocariosa* ❍ *Streptobacillus moniliformis*	❍ *Blastoschizomyces capitatus* ❍ *Conidiobolus* sp. ❍ *Curvularia lunata* ❍ *Engyodontium album* ❍ *Fusarium oxysporum* ❍ *Histoplasma capsulatum* ❍ *Neosartorya fischeri* ❍ *Phialophora richardsiae* ❍ *Pseudallescheria boydii* ❍ *Scedosporium inflatum* ❍ *Scedosporium apio-spermum* ❍ *Thermomyces lanuginosus tsiklinsky* ❍ *Trichosporon beigelii*

Culture-Negative Endocarditis

The term, *culture-negative endocarditis*, refers to the active IE whose repeated blood cultures are

all negative.[196-198] This syndrome was occasionally observed in the preantibiotic era,[199] usually in subacute cases of long duration (*Endocarditis lenta*). Today, most (but not all) culture-negative cases are caused by antibiotic treatment that is sufficient to suppress the bacteremia but not to sterilize the vegetation. In most such cases, organisms will eventually reappear in the blood after antibiotics are discontinued, usually within a few days. The blood cultures from a few patients with active endocarditis remain persistently culture-negative after antibiotics are stopped.[116]

Negative blood culture results should be expected from about one-fifth of patients with NVE or PVE caused by *Candida* or other yeasts,[101] and from four-fifths of patients with endocarditis caused by *Aspergillus* or other molds.[101,180,200,201]

The reported incidence of culture-negative endocarditis varies widely. Among large unselected series of cases collected from several hospitals, as much as 15 to 20 percent may be culture-negative.[51,196-198] Smaller series of patients studied by a single clinical and laboratory team that is experienced in evaluation of endocarditis usually show only about 5 percent culture-negative cases.[202,203] Thus, in a patient with suspected IE, other diagnoses should be meticulously excluded before a diagnosis of culture-negative endocarditis is accepted. When a patient appears to have IE but blood cultures are negative, the following checklist of possibilities should be considered:

- The patient has received some antibiotic therapy, commonly an oral drug such as ampicillin that was taken at home.
- The etiologic organism is slow-growing, requiring longer incubation of the blood culture for isolation, e.g., some nutritionally variant streptococci, some HACEK species, or mycobacteria.
- The etiologic organism is nutritionally fastidious, requiring special procedures or supplemented media for isolation, e.g., nutritionally variant streptococci, *C. burnetii* (Q fever), *Chlamydia*, *Mycoplasma*, *Bartonella*, and *Legionella*.
- The etiologic organism is a strict anaerobe, requiring anaerobic culture conditions.
- The etiologic organism is *Aspergillus* or another mold; these are rarely recovered from blood during the course of endocarditis (although they may be recovered from an arterial embolus removed at surgery).
- The etiologic organism is nonculturable, which is usually diagnosed by PCR on cardiac tissue during surgery for valve insufficiency. Few clinical cases are present as these patients may not have gastrointestinal symptoms, although most will have arthralgias.
- The patient has an alternative diagnosis that simulates IE-e.g., rheumatic fever, tuberculosis, brucellosis, etc.
- The patient has NBTE or marantic endocarditis, associated with a major underlying disease such as malignancy or tuberculosis.
- The patient has Libman-Sacks endocarditis (a variant of NBTE), associated with antiphospholipid antibody syndrome and/or systemic lupus erythematosus.

In some cases, a working diagnosis of endocarditis based on clinical manifestations can be supported by the progress of the disease and good response to empiric antibiotic treatment. If blood culture results always remain negative, a definitive etiologic diagnosis can be made only by detecting organisms in an infected embolus or in vegetations excised during surgery or at autopsy.

Chapter 73: INFECTIVE ENDOCARDITIS

PATHOGENESIS AND PATHOLOGY

A general concept of the pathogenesis of NBTE and SBE is presented in Fig. 73-2.

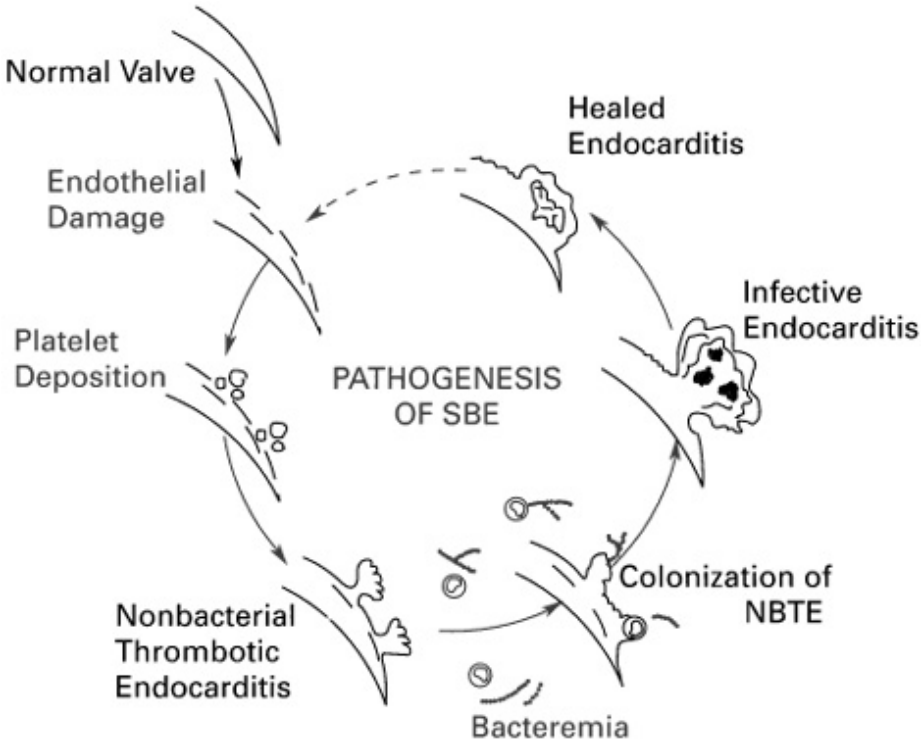

Figure 73-2: The main events in the pathogenesis of nonbacterial thrombotic endocarditis (NBTE) and subacute bacterial endocarditis (SBE).

Noninfective Endocarditis

Sterile thrombotic lesions may develop on heart valves in a variety of clinical conditions.[204] Small aggregates of platelets can occasionally be found on normal valves, but they occur frequently on the surfaces of valves damaged by congenital, rheumatic, or granlomatous disease[205] or by IE. These could be considered as incipient vegetations or microvegetations.

The common factor leading to platelet deposition is endothelial damage. This exposes subendothelial connective tissue containing collagen, which activates platelets to adhere and aggregate at the site. These microscopic platelet thrombi may embolize away harmlessly, or they may be stabilized and grow by deposition of fibrin and more platelets to form vegetations of NBTE. This process can be duplicated experimentally by catheter-induced endothelial damage in animals.[206] In humans, intracardiac pressure-monitoring catheters may produce identical lesions.[119,120] Both experimental[207] and human[119,122,204] NBTE can be colonized by circulating bacteria, resulting in IE.

The vegetations of marantic endocarditis occur most often in patients with advanced malignancy[13-15] but may also complicate other chronic wasting diseases, such as tuberculosis or uremia.

Sterile vegetations (termed *Libman-Sacks endocarditis*-see Chap. 76) sometimes develop in patients with systemic lupus erythematosus and/or antiphospholipid antibodies.[208] Typically, Libman-Sacks vegetations are small, sessile masses located on the ventricular surfaces of the mitral valve leaflets.

The vegetations of NBTE are friable white or tan masses, usually situated along the lines of valve closure (Fig. 73-3, Plate 101). These vary greatly in size; from tiny to large and exuberant, with a corresponding tendency to embolize to arteries supplying the myocardium, spleen, kidney, brain, mesentery, or extremities and causing infection. Since there is little inflammatory reaction at the site of attachment, fresh vegetations can dislodge and embolize frequently.[204] Histologically, the vegetations of NBTE consist of degenerating platelets interwoven with strands of fibrin, forming a bland, eosinophilic mass, featureless except for a few trapped leukocytes.[204,206]

Figure 73-3: (Plate 101) Typical vegetation of nonbacterial thrombotic endocarditis found at necropsy in a cachectic patient who died with disseminated lung cancer.

Pathogenesis of Infective Endocarditis

For IE to develop, two events are essential. First, microbes must attach to an endocardial surface. Second, the microbes must persist and multiply locally, eluding host defense mechanisms. In the case of SBE, which usually develops on previously abnormal valves, bacteria circulating in the bloodstream probably colonize preexisting platelet aggregates or NBTE.[204] It is not known whether ABE, which often affects apparently normal valves, develops in a like manner by colonization of microscopic sterile vegetations, or by direct microbial invasion of normal endothelium.

A critical initial step in the pathogenesis of IE is the attachment or adherence of the circulating microorganism to the disrupted cardiac valve endothelium that has deposits of fibrin and platelets (NBTE). The characteristic that gives the microbe selective adherence advantage to this surface are virulence factors for the development of IE. Early studies identified dextran production in viridans streptococci as an important adherence factor (it had been previously shown to be important in adherence to teeth and production of dental caries).[172] A host of other microbial factors have been described. These include a fibrinectin-binding protein,[377] enterococcal aggregation substance, and enterococcal binding substances (proteins that also mediate formation of mating aggregate between bacteria that cause horizontal transfer of plasmids encoding such things as antibiotic resistance[210] and FimA, a surface-associated protein found on oral streptoccoci and enterococci, that, when used as an antigen (similar to other surface proteins of the Lral family) produce an antibody that reduces adherence to valve surfaces and reduces development of endocarditis in animal model.[209-212] Since FimA is found in 80 percent of streptococci and enterococci strains that produce endocarditis, a protective vaccine strategy is an intriguing probability. Binding to fibronectin appears to be an important property shared by many but not all of the bacterial species that commonly cause endocarditis.[50,209] Clumping factor produced by coagulase-positive staphylococci favors attachment to fibrinogen, adherence to platelet-fibrin clots, and ability to cause endocarditis in rats.[213] Extracellular slime production by coagulase-negative staphylococci may favor localization on prosthetic valves.[214] *Thus, microbial adherence, which can be mediated by a variety of different surface components*

and receptors, is a key virulance factor for colonization of the endocardium.[50,209]

The role of the platelet in this postadherance event has been elucidated. First, adherence of *Staph. aureus* to platelets is an important virulance factor for development of experimental IE.[219-225] In addition, acetylsallicylic acid treatment reduces *Staph. aureus*-induced platelet aggregation and adherence to fibrin (with or without platelets) matrices in vitro and reduced vegetation size and embolic events in vivo.[224,225] When *Staph. aureus* (or enterococci) adhere to damaged valves in vivo, tissue thromboplastin is generated, which locally activates the clotting cascade, generating thrombin.[205,220] A vegetation is formed that provides a protected environment for unrestricted bacterial growth. However, thrombin also elicits the secretion from platelets of a low-molecular-weight cationic protein with potent antimicrobial properties (against *Staph. aureus, Staph. epidermidis,* viridans streptococci and *Candida*) termed *thrombin-induced platelet microbiocidal protein* (tPMP).[221] Strains of *Staph. aureus* that are resistant to tPMP are more likely to cause endocarditis in animals and humans.[222] In addition, strains that hypersecrete alpha toxin (a toxin known to lyse platelets and release tPMP) produced a less virulent form of IE, likely due to the antimicrobial action of tPMP.[223]

Therefore, once lodged on NBTE, bacteria must elude local defenses, including platelet microbicidal proteins[215] and leukocytes, if they are to survive. Microbes that cannot do this may die out quickly after adhering to the endocardium.[216] Those that can survive antimicrobial defense mechanisms multiply rapidly in the vegetation, soon reaching high numbers and then entering a stationary growth phase.[207] The vegetation provides an ideal supporting stroma for the growth of microbial colonies, into which essential nutrients can diffuse from the blood. The presence of bacteria is a powerful stimulus for further thrombosis,[217,218] which may be mediated by thromboplastin generated by leukocytes when they are exposed to fibrin.[218] New layers of fibrin are deposited around growing bacteria, causing the vegetations to enlarge.[206] Inflammatory cytokines are produced by monocytes[226] (and presumably other leukocytes) in response to endocardial infection and likely cause some of the patient's symptoms.

The location of vegetations is relevant to understanding and managing endocarditis. Approximate incidence of vegetations at various locations is given in Table 73-5. The frequency of involvement of each valve is directly proportional to the mean blood pressure upon it;[227] thus, the left side of the heart is involved much more often than the right. This rule does not hold true for acute endocarditis in IDUs, in whom tricuspid infection by *Staph. aureus* predominates (Table 73-5).

Table 73-5: Approximate Frequency of Anatomic Location of Vegetations in SBE, ABE, and Endocarditis Associated with IV Drug Abuse[a]

Location	SBE, %	ABE, %	Endocarditis in IV Drug Abusers, %
Left-sided valves	85	65	40
Aortic	15-26	18-25	15-20
Mitral	38-45	30-35	15-20
Aortic and mitral	23-30	15-20	13-20
Right-sided valves	5	20	50-70
Tricuspid	1-5	15	45-65
Pulmonary	1	Rare	2
Tricuspid and pulmonary	Rare	Rare	3

Left- and right-sided sites	Rare	5-10	5-10
Other sites (patent ductus, ventricular septal defect, coarctation, jet lesions)	10	5	5

[a]SBE = subacute bacterial endocarditis; ABE = acute bacterial endocarditis.
SOURCE: Adapted from Refs. [51,65-70,86,116,159,227,230].

Vegetations are usually located on the downstream side of anatomic abnormalities in the heart or great vessels. Rodbard[228] developed the unifying concept that vegetations usually arise at a site where blood flows from a high-pressure source (e.g., the left ventricle) through a narrow orifice (e.g., a stenotic aortic valve) into a low-pressure sink (e.g., the aorta). Illustrative examples from human disease include aortic stenosis, ventricular septal defect, coarctation, and mitral regurgitation. Experimentally, Rodbard showed that bacteria carried in an aerosol flowing through a constricted tube into an area of low pressure were deposited on the walls of the tube immediately beyond the constriction due to Venturi pressure effects and turbulence.[228] These observations fit well with the actual location of vegetations found at autopsy in cases of endocarditis (Fig. 73-4). Vegetations also may develop on jet lesions, which are areas of endothelial roughening and reactive fibrosis at sites where a swift, turbulent regurgitant stream of blood strikes the endothelium.[229] *MacCallum's patch,* on the wall of the left atrium in some patients with mitral regurgitation, is an example of a jet lesion; an infected vegetation occasionally develops at this site (Fig. 73-4).

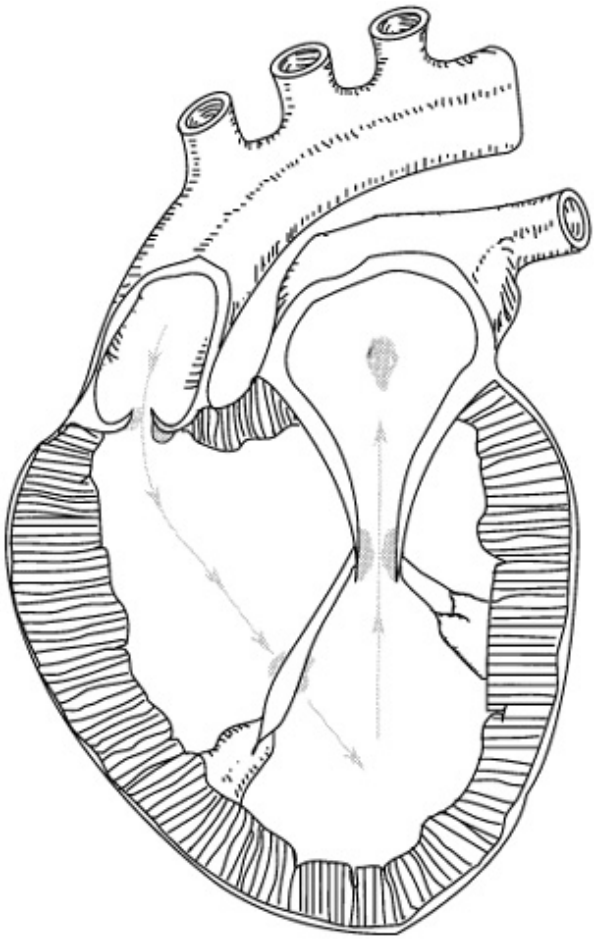

Figure 73-4: The sites where endocarditis occurs in aortic and mitral regurgitation. The arrows on the left

indicate a high-velocity regurgitant stream passing through the orifice of an incompetent aortic valve into a low-pressure sink (left ventricle in diastole). Vegetations appear on the ventricular surface of the aortic valve. The regurgitant stream may cause a jet lesion on the chordae tendineae of the anterior leaflet of the mitral valve. The arrow on the right shows regurgitation from the high-pressure source of the left ventricle during systole into the left atrium, with vegetations developing on the atrial surface of the mitral valve. Vegetations also can occur on the jet lesion where the regurgitant stream through the mitral valve strikes the atrial endocardium, an area known as *MacCallum's patch*. (From Rodbard S. Blood velocity and endocarditis. *Circulation* 1963; 27:8. Reproduced with permission.)

Vegetations of infective endocarditis vary greatly in size and morphology, from small (<1 mm), warty nodules to large (several centimeters), cauliflower-like polypoid masses. That may cause functional stenosis of valve orifices (Fig. 73-5, Plate 102). Fungal vegetations are often larger than bacterial ones, but otherwise the etiologic species does not correlate reliably with vegetation size. Their color also varies widely, from white to tan to greenish-gray.[67,230] Histologically, colonies of microorganisms are found embedded in a fibrin-platelet matrix.[206,207,231,232] The vegetation characteristically contain relatively few leukocytes that are prevented from reaching bacteria by layers of fibrin, which form protective barriers around colonies (Fig. 73-6).

Figure 73-5: (Plate 102) Typical vegetation of bacterial endocarditis, complicated by perforation of the anterior mitral valve leaflet. Note that the valve shows preexisting chronic rheumatic disease, with thickening, deformity, and fusion of chordae tendineae.

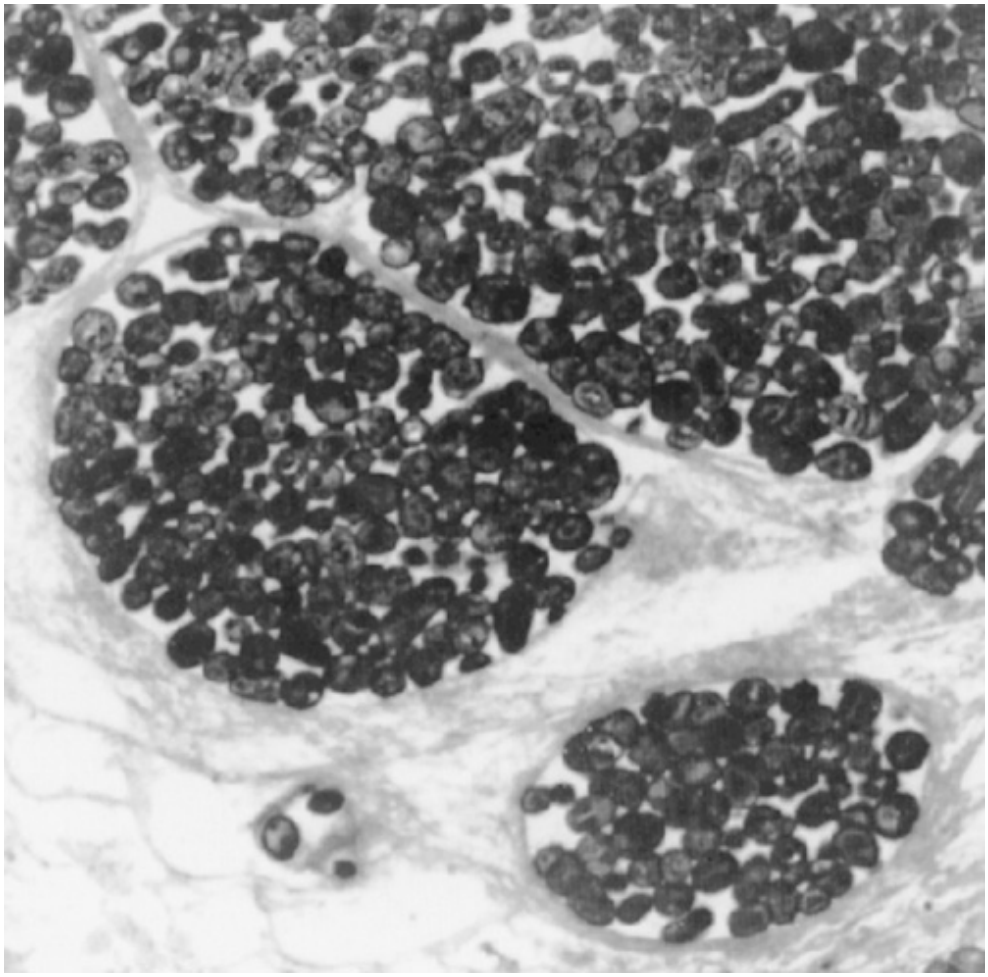

Figure 73-6: Electron micrograph of a vegetation of experimental streptococcal endocarditis (×7800). Note the very large number of cocci in colonies, the protective layers of fibrin, and the absence of leukocytes-all factors that may impede the efficacy of antimicrobial therapy. (From Durack DT. Experimental bacterial endocarditis: 4. Structure and evolution of very early lesions. *J Pathol* 1975; 115:81. Reproduced with permission.)

Development of an abscess is one of the most important complications of valvular infection, and it occurs more frequently with ABE than it does with SBE.[229,231] Abscesses often develop by direct extension of active infection into the fibrous cardiac skeleton-that is, into the rings of supporting connective tissue around the valves. From there, abscesses can extend into the adjacent myocardium and rupture into the pericardium. Hematogenous seeding occasionally leads to development of abscesses elsewhere in the myocardium.

Abscesses are found in the majority of patients who die with active prosthetic valve infection, often spreading around the sewing ring of the prosthesis and causing partial dehiscence of the prosthetic valve.[11,95] Because these valve-ring abscesses are located close to the cardiac conduction system, conduction disturbances commonly result.[233]

Immune Response

Presence of bacteria in endocardial vegetations stimulates the humoral immune system to produce nonspecific antibodies. This can result in a polyclonal increase in gamma globulins, positive rheumatoid factor, and, occasionally, false-positive serologic test results for syphilis.[234] Rheumatoid factor develops in 25 to 50 percent of patients with SBE present for >6 weeks and can provide a useful diagnostic clue; it reverts to negative after eradication of the organisms.[235-237] Antiendocardial and antisarcolemmal antibodies have been detected in 60 to 100 percent of cases;[238] they are more commonly found in SBE than they are in ABE.

Specific antibodies to many of the commensal organisms that cause SBE may be present in low titer before infection. Titers rise during active infection[3] and fall after treatment.

Hemolytic complement levels are low in about 30 percent of patients early in the course of endocarditis, rising later and returning to normal after treatment.[239-245] The lowest levels are found in patients with immune-complex glomerulonephritis.

Circulating immune complexes have been detected in 82 to 97 percent of patients with either ABE or SBE.[244-247] Higher concentrations are correlated with the presence of extracardiac manifestations such as arthritis, splenomegaly, and glomerulonephritis; with longer duration of illness; and with hypocomplementemia. Several studies confirm that glomerulonephritis in patients with endocarditis is mediated by immune complexes.[248,249] It is likely but unproven that arthritis and tenosynovitis-and possibly pericarditis, Osler's nodes, and Roth's spots[244,246,247]-also may represent inflammatory responses involving immune complexes. Antibodies to teichoic acids were found in the serum of 93 percent of patients with *Staph. aureus* endocarditis,[250] but this did not prove to be useful as a routine diagnostic test. Additional relevant information on experimental infective endocarditis is contained in References [251 to 254.]

Chapter 73: INFECTIVE ENDOCARDITIS

CLINICAL MANIFESTATIONS

Clinical and laboratory manifestations of infective endocarditis can be grouped under three headings (Table 73-6):

- Evidence of a systemic infection
- Evidence of an intravascular lesion
- Evidence of an immunologic reaction to infection

History

The symptoms of subacute endocarditis develop insidiously and with great variability.[3,43,51,116] Fevers, chills, rigors, and night sweats provide evidence of systemic infection. General malaise-with anorexia, fatigue, and weakness-is typical. Weight loss is common, along with headaches and musculoskeletal complaints, including myalgias, arthralgias, and back pains.[255] This symptom complex is often described by the patient or the physician as a "flu-like illness." Evidence of an intravascular lesion is provided by symptoms of left- or right-sided heart failure and by manifestations of embolization, such as focal neurologic injury, chest pain, flank pain, left-upper-quadrant pain, hematuria, or ischemia of an extremity. Symptoms usually persist and worsen intermittently over 4 to 8 weeks before the diagnosis is made.[256,257]

In the acute form of IE, the course is accelerated, and the symptoms are often accentuated in severity. Patients experience hectic fevers, rigors, and prostration, usually leading to hospital admission within a few days.[5,51,103,251,258]

Symptoms of cardiac failure may develop gradually or worsen suddenly in either acute or subacute disease due to mechanical complications such as perforation of a valve leaflet, rupture of one of the chordae tendineae, rupture of a sinus of Valsalva, or development of functional stenosis from obstruction of blood flow by large vegetations.[231,259] Alternatively, heart failure may develop insidiously, or preexisting chronic heart failure may worsen due to progressive damage to the valves or associated structures. Myocarditis or myocardial infarction due to coronary artery embolism may contribute to heart failure.

Physical Examination

The physical exam in IE is a diagnosticians delight since the variety of unique physical findings often allows one to make the diagnosis at the bedside.

Patients with endocarditis may appear acutely or chronically ill. Intermittent chills, rigors, and sweating often provide evidence of a systemic infection. Asthenia and recent weight loss are often notable. Anemia is common,[85] especially in SBE, so many patients are pale. The skin of some patients with long-standing SBE shows the sallow hue of uremia.[3]

VASCULAR PHENOMENA

Patients with endocarditis may exhibit a variety of striking physical findings arising from vascular

abnormalities.

Petechiae

In both SBE and ABE, petechiae are common; they are rare in NBTE. In a few cases, the petechiae have a pale central spot. Most are due to microembolization to small vessels in the skin or mucous membranes. They are commonly found in crops in the conjunctual sac, on the hard palate, behind the ears and over the chest. But all areas of the trunk and extremities may be affected.

Splinter Hemorrhages

Linear subungual hemorrhages, resembling tiny splinters of wood under the nails but not reaching the nail margin, are found in about 20 percent of patients with SBE. They are probably caused by microembolization to linear capillaries under the nail. Because splinter hemorrhages are found in some 5 to 8 percent of patients admitted to the hospital who do not have endocarditis, they are of limited diagnostic value when occuring alone.[260]

Osler's Nodes

These are painful, tender, erythematous nodules in the skin of the extremities, usually in the pulp of the fingers[261] (Fig. 10-17, Plate 34; Fig. 10-18). Occasionally, the center of these pea-sized, red lesions is pale, but necrosis does not occur. Osler's nodes occur in 10 to 20 percent of patients with SBE and in fewer than 10 percent of patients with ABE.[261] They are probably caused by inflammation around the site of lodgment of small, infected emboli in distal arterioles, because the etiologic organism can be recovered from some of the lesions.[262] Inflammation due to focal immunologic reactions probably contributes to formation of Osler's nodes, especially in subacute cases.[247]

Janeway Lesions

Janeway lesions are small (less than 5 mm), flat, nontender red spots, irregular in outline, found on the palms and soles of a few patients with SBE and ABE. Unlike petechiae, they are not hemorrhagic, and they blanch on pressure.[3,44]

Ocular Lesions

Conjunctival petechiae show up as small, bright-red hemorrhages that are easily seen if the upper and lower eyelids are everted. These petechiae are not specific for endocarditis, being found sometimes after cardiac surgery and occasionally in septicemia (Fig. 73-7, Plate 103). Nevertheless, the discovery of conjunctival hemorrhages in a patient with unexplained fever and a heart murmur makes the diagnosis of endocarditis highly likely.

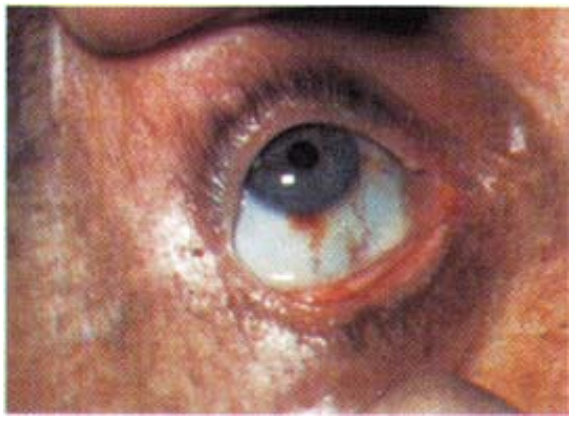

Figure 73-7: (Plate 103) Typical conjunctival petechiae in a patient with subacute bacterial endocarditis due to *Streptococcus sanguis*.

Retinal hemorrhages are found in 10 to 25 percent of cases of both SBE and ABE. They are quite variable in appearance. Some simply represent petechiae in the retina; their round or flame-shaped outline is determined by the layer of the retina in which they develop. Those with a white or yellow center surrounded by a bright-red, irregular halo are known as *Roth's spots*, which probably represent cytoid bodies and associated hemorrhage caused by microinfarction of retinal vessels. Roth's spot are not foci of bacterial infection and are nonspecific to IE.

Loss of vision during the course of endocarditis can occur from embolization to the brain or to the retinal artery, from optic neuritis, or from ophthalmitis. Endophthalmitis may occur in patients with *Candida* endocarditis and/or candidemia. The typical retinal lesions are rounded, white, cotton-like exudates with extension into the vitreous and overlying vitreous haze.[263] Panophthalmitis occurs in some patients with ABE due to hematogenous spread of virulent pathogens.

CLUBBING OF THE FINGERS

Previously common in SBE, finger clubbing is now found in less than 5 percent of cases (Fig. 10-16, Plate 33), presumably because endocarditis is now diagnosed and treated earlier. The pathogenesis of this reaction, which usually resolves after eradication of the infecting organism, is not understood.

SIGNS OF EMBOLIZATION

Decreased or absent arterial pulses in an extremity may signal occlusion of a large artery by a fragment of vegetation. Focal neurologic signs may develop transiently or progress to a completed stroke due to embolization to a cerebral artery (see "Complications," later). Infarctions of the spleen, kidney, or bowel can present with pain and tenderness on palpation of the abdomen, mimicking an acute abdominal event such as bowel obstruction or peritonitis. Myocardial infarction due to obstruction of a coronary artery can cause heart failure or death and is sometimes an unexpected finding at autopsy in patients who die with active disease. These complications are illustrated in Figs. 73-8 to 73-13, Plates 104-109.

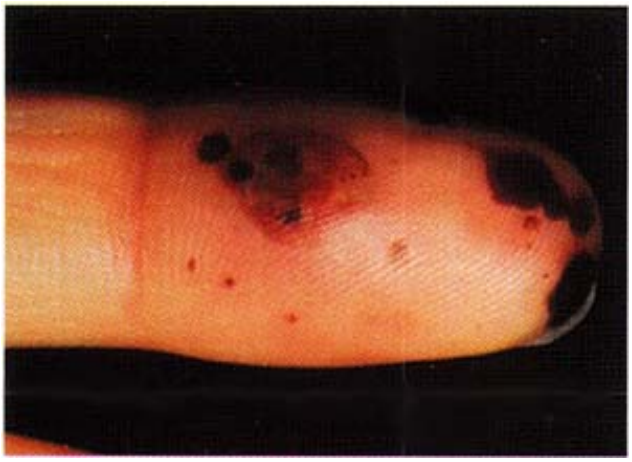

Figure 73-8: (Plate 104) Ischemic, hemorrhagic, and pustular lesions on the extremities in acute *Staphylococcus aureus* endocarditis.

SPLENOMEGALY

Development of splenomegaly is common, occurring in about one-quarter of patients with ABE and one-half of those with SBE. The spleen is usually soft and only slightly tender except in the case of recent embolic infarction, when palpation may be very painful. Radionuclide scanning may reveal infarction or a splenic abscess.

CARDIAC EXAMINATION

The pulse is often rapid as a result of fever or congestive failure. Irregularities of conduction may indicate the presence of an abscess near the conducting system. Underlying or newly developed aortic regurgitation associated with IE may result in a collapsing pulse (Chaps. 10 and 56).

One or more murmurs are present in virtually all patients at some stage of the disease. Even though some of the classic findings of IE are less often seen today than they are formerly, the triad of fever, anemia, and a new murmur should still suggest this disease, provided one remembers that these manifestations are nonspecific. They may be absent initially. *Up to 15 percent of patients do not have a murmur when first seen.*

Only one-third of patients with tricuspid valve endocarditis will demonstrate the typical regurgitant systolic murmur located along the right sternal border that increases with inspiration.[5] Development of a new regurgitation murmur in patients with a prosthetic valve should immediately prompt the suspicion of PVE.

Murmurs present during the course of endocarditis may be due to preexisting cardiac disease, to the infection itself, or to both. Active endocarditis often causes structural damage to the valve, including deformities, tears, perforations, and rupture of chordae tendineae. Since these changes often lead to valvular insufficiency, the murmurs most often heard in association with endocarditis are those of mitral, aortic, or tricuspid regurgitation. IE occurs in association with pure mitral stenosis much less often than it does with mitral regurgitation (with or without associated stenosis) (see Chap. 57). Development of a new aortic regurgitation murmur during a febrile illness strongly suggests the diagnosis of endocarditis, because this finding is seldom associated nonspecifically with increased blood flow due to fever and anemia.

New or changing cardiac murmurs are an important diagnostic finding and are more common in patients with ABE.

Chapter 73: INFECTIVE ENDOCARDITIS

COMPLICATIONS

Heart Failure

Heart failure is the most important complication of infective endocarditis,[51,264-266] because it exerts a critical influence on prognosis. In 1951, Cates and Christie[215] reported a death rate of 37 percent among 314 patients with SBE who had no heart failure and 85 percent death rate among 94 patients who had moderate or severe failure. In the past, congestive heart failure occurred in up to 55 percent of cases, being more common in patients with aortic valve disease (75 percent) than in those with mitral valve (50 percent) or tricuspid valve disease (19 percent).[265] Today, heart failure is less common because of earlier and more effective treatment and valve replacement surgery.

Sudden onset or worsening of left ventricular failure because of perforation or destruction of a valve leaflet or rupture of chordae tendineae is an indication for immediate valve replacement. Intractable left ventricular failure can result from rupture of a sinus of Valsalva due to infection. The right sinus of Valsalva may rupture into the right atrium or right ventricle and the left sinus into the pulmonary artery.[231] This rare condition should be suspected if the severity of heart failure seems out of proportion to the degree of valve dysfunction. Occasionally, bulky vegetations occlude the valve orifice, causing functional stenosis; this phenomenon is most likely to occur during fungal infection of prosthetic valves.[267,268]

Embolization

This important complication is recognized in 12 to 40 percent of patients during the course of SBE and in 40 to 60 percent of those with ABE, but autopsy findings indicate that many other arterial emboli go undetected. Pelletier and Petersdorf[116] reported a 50 percent incidence of major arterial emboli in 125 cases, affecting brain (25 cases), lung (17 cases), coronary artery (8 cases), spleen (8 cases), extremities (8 cases), gut (4 cases), and eye (3 cases). The presence of infection-related antiphospholipid antibodies has been found to be a major risk factor for embolic events.[269]

Conduction Abnormalities

A conduction abnormality is detected during the course of IE in 4 to 16 percent of patients, especially in association with aortic valve infection.[233,259,270] Types of abnormalities observed include first-degree atrioventricular block (45 percent), third-degree atrioventricular block (20 percent), second-degree atrioventricular block (15 percent), and isolated bundle branch blocks (15 percent).[233] *The development of a new, unstable, or changing conduction abnormality is important because it often indicates that a focus of myocardial inflammation has extended near or into the atrioventricular node or the bundle of His and can be associated with a valve-ring abscess. This is associated with a worse prognosis*[266] *and constitutes a strong indication for surgical intervention*. Immediate TEE should be performed in this situation.

Neurologic Manifestations

Involvement of the nervous system during the course of endocarditis is both common and

clinically important.[271-274] Significant neurologic abnormalities occur in 29 to 50 percent of patients with endocarditis.[271,274,275] The initial or presenting complaint involves the nervous system in 10 to 15 percent of patients with endocarditis. A wide range of syndromes occurs, including toxic confusional states, psychiatric symptoms, and minor or major strokes (Fig. 73-13, Plate 00), meningoencephalitis, and cranial or peripheral nerve lesions.[274] (See also Chap. 89.)

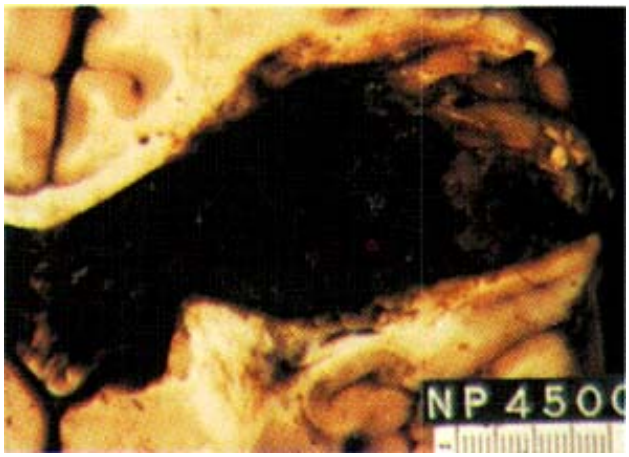

Figure 73-13: (Plate 109) Massive cerebral hemorrhage with intraventricular extension due to rupture of a small, peripheral mycotic aneurysm. The patient had been bacteriologically cured of *Staphylococcus epidermidis* endocarditis several weeks previously. Cultures of the blood, valve, and aneurysm taken at necropsy were negative.

Of 55 patients with cerebrovascular complications of endocarditis, four-fifths suffered infarction and one-fifth hemorrhage.[275] Infarction is usually due to embolism, most often to the middle cerebral arteries. In some series, neurologic complications approach or even surpass heart failure as the leading determinant of mortality.[274] Hemorrhage can be a complication of either emboli or mycotic aneurysms.[116,271-273,276,277]

A meningeal reaction cerebritis occurs in 7 to 15 percent of patients, especially those with staphylococcal ABE.[43,271,273-275] This reaction may be mistakenly diagnosed as acute bacterial meningitis because the cerebrospinal fluid contains polymorphonuclear leukocytes and may have a raised protein concentration. In a minority of such cases (up to 20 percent of those with acute staphylococcal infection) cerebrospinal fluid cultures yield the bacteria causing endocarditis. The glucose level, however, is usually normal; the results of cerebrospinal fluid culture are usually negative; and the abnormalities usually resolve without complications during treatment of the endocarditis. Thus, these cerebrospinal fluid abnormalities more often represent a perivascular cerebritis than true bacterial meningitis.

This cerebritis may develop in brain tissue surrounding small infected emboli lodged in cerebral vessels with associated meningoencephalitis.[274] Computed tomography and magnetic resonance imaging often reveal multiple areas of cerebritis, even in patients with no central nervous system symptoms (Fig. 73-14). In patients with ABE, this inflammatory reaction may progress to form a brain abscess, but more often cerebritis will resolve uneventfully during antibiotic treatment of the underlying disease. Brain abscesses are uncommon in patients with SBE.[274] Bacterial meningitis does occur in some patients with pneumococcal endocarditis.[153]

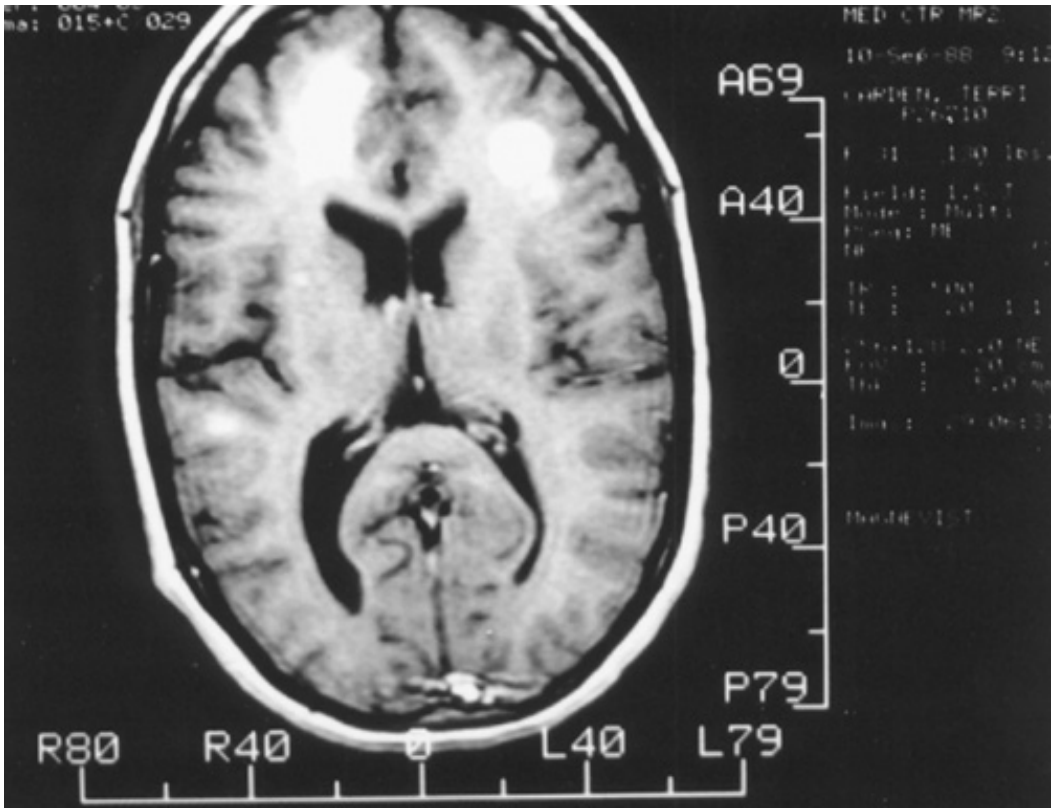

Figure 73-14: Magnetic resonance image of the brain in a patient with acute left-sided *Staphylococcus aureus* endocarditis, showing multiple areas of focal cerebritis. This patient had no focal central nervous system signs and recovered fully with antimicrobial therapy. (MRI by courtesy of the Department of Radiology, Duke University, Durham, NC.)

Mycotic Aneurysm

This complication develops in 3 to 15 percent of patients with IE, and the consequences of expansion and rupture of the aneurysm can be very serious, especially in the brain (Fig. 73-13, Plate 109). In order of frequency, the sites most often involved are the proximal aorta, including the sinuses of Valsalva (25 percent of cases), arteries to the viscera (24 percent), arteries to the extremities (22 percent), and arteries to the brain (15 percent).[276-278] Unfortunately, intracerebral aneurysms are often multiple.[277,278]

Mycotic aneurysms develop when the wall of an artery is damaged by the inflammatory response to microbes.[232,243,279,280] These microbes reach the arterial wall via microemboli to the vasa vasorum or by impaction of a larger infected embolus in the lumen. The arterial wall is apparently an unfavorable culture medium for bacteria because the organisms responsible for weakening the vessel often die out spontaneously, even if untreated. The mycotic aneurysm may continue to enlarge even when living organisms are no longer present, due to the physical effects of arterial blood pressure (Fig. 73-9, Plate 105).[276-278,281]

Chapter 73: INFECTIVE ENDOCARDITIS

DIFFERENTIAL DIAGNOSIS

Because the clinical manifestations of endocarditis are numerous and often nonspecific, the differential diagnosis of this disease is very wide.[3,43,116,282] Of the many conditions that may be considered, only a few leading examples are listed here.

ABE shares many clinical features with nonendocarditic septicemias due to invasive bacterial pathogens such as *Staph. aureus*, *Neisseria*, pneumococci, and gram-negative bacilli. The differential diagnosis for a case of ABE might include sepsis, pneumonia, meningitis, brain abscess, stroke, malaria, acute pericarditis, vasculitis, and disseminated intravascular coagulation.

SBE must be considered during the workup of every patient with fever of unknown origin.[202,282,283] Its manifestations can mimic those of rheumatic fever, osteomyelitis, tuberculosis, meningitis, intraabdominal infections, salmonellosis, brucellosis, glomerulonephritis, myocardial infarction, stroke, endocardial thrombi, atrial myxoma, connective tissue diseases; arthrites of unkown etiology, vasculitis, occult malignancies (especially lymphomas), chronic cardiac failure, pericarditis, and even psychoneurosis.

Diagnostic Criteria

IE can be surprisingly difficult to diagnose with certainty.[202,284] In the course of clinical practice, the diagnosis is suspected much more often than it is confirmed. This is because the presenting symptoms and signs can be highly variable and consistent with many other possible diagnoses. Furthermore, the primary lesion (an endocardial vegetation) is inaccessible to direct inspection except at surgery or autopsy. Major and minor criteria have been defined[202]; they are analogous to the modified Jones criteria[285] (Chap. 55) for diagnosis of acute rheumatic fever[86,202,203] (Tables 73-7 and 73-8). Several diagnostic schemes have been developed to assist the clinician in working through a diagnostic workup, however, it is important to emphasize that while these may be useful guidelines, each patient must be considered on an individual basis. The so-called Duke criteria has received the most attention.[202]

Table 73-7: Criteria for Diagnosis of Infective Endocarditis

Definite Infective Endocarditis
PATHOLOGIC CRITERIA
Microorganisms: demonstrated by culture or histology in a vegetation, or in a vegetation that has embolized, or in an intracardiac abscess, *or*
Pathologic lesions: vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis
CLINICAL CRITERIA, USING SPECIFIC DEFINITIONS LISTED IN TABLE 73-8
Two major criteria, *or*
One major and three minor criteria, *or*
Five minor criteria
Possible Infective Endocarditis

Findings consistent with infective endocarditis that fall short of 'definite,' but not 'rejected'
Rejected
Firm alternate diagnosis for manifestations of endocarditis,
0x002003 *or*
Resolution of manifestations of endocarditis, with antibiotic therapy for 4 days or less, *or*
No pathologic evidence of infective endocarditis at surgery or autopsy after antibiotic therapy for 4 days or less

SOURCE: From Durack et al.,[202] with permission.

Because the Duke criteria emphasize specificity[203,286] above sensitivity, they should not be used to guide urgent management decisions early in the course of a suspected case. To illustrate: a diagnosis of endocarditis made solely on the basis of presence of fever and a heart murmur would be very sensitive but very nonspecific. These findings alone might make a clinician suspect the diagnosis or begin treatment for endocarditis, but the various diagnostic schemes might guide the clinician to make a final diagnosis, to decide on valve replacement, or to accept the diagnosis for the purpose of epidemiologic studies or clinical trials.

Chapter 73: INFECTIVE ENDOCARDITIS

LABORATORY INVESTIGATIONS

Routine Laboratory Tests

Anemia usually develops during the course of SBE.[85,287] It is most often mild or moderate in degree and of the hypoproliferative type, with a normochromic, normocytic smear. Anemia occurs less often in ABE and may be due to hemolysis. Chronic low-grade hemolysis associated with a prosthetic valve may confuse interpretation of the blood picture in a patient with PVE. In addition, blood smear may show schistocytes and other red blood cell fragments. Leukocytosis is not a reliable manifestation of SBE.[85] A low-grade, variable elevation of the polymorphonuclear leukocyte count is characteristic, but in some cases the leukocyte count is normal. A high granulocyte count with an increase in band forms is commonly found in patients with ABE. These neutrophils often show toxic granulations. In a few cases of ABE, staphylococci can be identified inside neutrophils on examination of a gram-stained smear of the buffy coat of the peripheral blood.[288] In addition, abnormal histiocytes may be found in smears of peripheral blood in one-third of patients with SBE,[289] but these tests are not in routine use.

The erythrocyte sedimentation rate (ESR) is elevated in about 90 percent of cases of IE. The median ESR on admission is about 65 mm/h, but the range is wide and 10 percent are in the normal range. The median ESR may rise slightly during treatment and does not fall to normal until 3 to 6 months after diagnosis, so it is not useful as evidence of successful antibiotic therapy. The C-reactive protein is usually elevated (96 percent) and falls to normal more quickly than the ESR during successful treatment.[290] Cryoglobulins have also been reported.[291]

Urinalysis shows microscopic hematuria and/or slight proteinuria in >50 percent of cases, even in the absence of specific renal complications.[3,287] Red blood cell casts and heavy proteinuria are found in those patients who develop immune-complex glomerulonephritis, often in association with decreased total serum complement.[248] Gross hematuria suggests that renal infarction has occurred.

Serologic Tests

Nonspecific serologic abnormalities are common during the course of IE. A positive rheumatoid factor is found in >50 percent of cases of SBE,[235-237] with symptoms for longer than 6 weeks.[202] Rheumatoid factor is rarely positive in patients with ABE. A polyclonal increase in gammaglobulins is characteristic of active endocarditis. Occasional false-positive serologic test results for syphilis occur.[234]

Specific serologic tests are important for the diagnosis of IE caused by *Coxiella* (Q fever) and *Bartonella*, both species that are difficult or slow to grow from culture. In these special cases, positive serology (1:800 antiphase 1 IgG antibody titer for Q fever or positive microimmunofluorescence or PCR test for *Bartonella*) or a single positive blood culture may be added as major criteria for diagnosis of IE.[189,292]

Blood Cultures

Isolation of a typical organism or detection of persistent bacteremia constitutes the most important diagnostic test for endocarditis. Blood cultures should be drawn from all patients with undiagnosed fever and a heart murmur. Cultures should also be taken from patients with other symptoms or signs consistent with endocarditis if no other diagnosis has been made.

Bacteremia in SBE is usually continuous.[22] The number of organisms in venous blood varies widely but is usually between 1 and 200 bacteria per mL in subacute cases. Because most blood cultures in untreated patients will be positive, it is seldom necessary to draw more than 3 separate blood specimens to isolate the organism.[293] In one study, the etiologic organism was recovered from cultures taken on the first day of admission to the hospital in 93 percent of patients with culture-positive endocarditis.[294] In other studies, however, the rate of persistently positive blood cultures was lower, in the range of 62 to 68 percent.[116,202] Additional specimens obtained over a longer period may be needed to isolate the etiologic organism from patients who have received recent antibiotic therapy.

A practical approach for investigation of suspected SBE is to draw 3 separate samples of venous blood, each of 16 to 20 mL, on the first day, with at least 1 h between the first and last venipuncture. Half of each sample should be inoculated into an aerobic broth culture medium, and the other half into another broth (usually anaerobic) medium. These media should be capable of supporting growth of fastidious, nutritionally variant bacteria[139,295] and ideally should contain a resin to remove antibiotics. As soon as a culture turns positive, Gram's stain and subculture should be performed. If all 3 samples (6 bottles) are negative by the second or third day but the diagnosis of endocarditis still seems likely, two more samples of venous blood should be drawn for culture. If the patient had received previous antibiotic therapy, several further venous samples may be taken over the following weeks to identify a possible late recrudescence of bacteremia after partial treatment. For ABE, 3 venous blood samples are drawn for culture and empiric antibiotic therapy is begun at once, because in patients with acute endocarditis, treatment should not be delayed until culture results are available. In cases of *Staph. aureus* endocarditis, greater than 95 percent of blood culture would be positive, usually within 24 hours.[5]

Because *Staph.* epidermidis[251] and diphtheroids[296] can cause endocarditis, special care must be taken during venipuncture to avoid contamination of the specimen with these common skin organisms, which could result in diagnostic confusion. Since endocarditis usually produces continuous bacteremia, all cultures are usually positive; when only 1 of 3 grow a *Staph.* epidermidis or diphtheroid, contamination and not true bacteremia should be suspected! If the diagnosis of endocarditis remains likely, and cultures are negative, cultures should be incubated for 3 weeks and Gram's stains made at 5 days, 2 weeks, and 3 weeks even if no growth is apparent on inspection. The HACEK group of organisms, pyridoxyl requiring viridans streptococci, some fungi, *Bartonella*, and some others may take longer than the standard 3 to 5 days to grow.[297] A number of new seralogic and PCR-based techniques are under development and are desperately needed to clarify diagnosis in these culture-negative cases.[298-300]

Electrocardiography

Electrocardiographic studies should be performed initially and repeated at intervals according to progress during treatment. A disturbance of conduction or onset of myocardial irritability [↑ frequency of ventricular premature complexes (VPCs) or atrial premature complexes (APCs)] that develops during the course of endocarditis suggests extension of infection into the myocardium (see earlier). Such extension may be due to focal myocarditis or to an abscess located close to the conduction system.[110] Thus, development of a prolonged PR interval, if due to an abscess, can have major implications: a probable need for valve replacement and a worse prognosis.[87] Electrocardiograms can reveal evidence of silent myocardial infarction due to embolization of a vegetation to a coronary artery. Continuous electrocardiogram monitoring may be appropriate

when conduction or rhythm changes are observed and disease progression is a concern.

Echocardiography

Echocardiographic studies are important in the diagnosis of IE.[301-305] Positive echocardiographic findings, properly defined, constitute an important criteria for the clinical diagnosis of endocarditis and, in the setting of positive blood cultures, essentially establishes the diagnosis of IE.[202] MVP combined with color-flow Doppler imaging (see Chap. 13) provides a wealth of information for both the diagnosis and the management of endocarditis, including the detection of vegetations, valvular perforations[306] and other abnormalities,[307] abscesses, and pericarditis, as well as the assessment of ventricular function (Fig. 73-15*A*-*D*).[302-304] Sensitivity for detection of vegetations, originally in the range of 33 to 63 percent, today is 50 to 75 percent.[307] Sensitivity can be improved to better than 95 percent by use of TEE (see Chap. 14) in selected cases.[270,302] Transesophageal studies also detect abscesses and valve perforation with much greater sensitivity.[304] TEE is markedly better than MVP for evaluation of prosthetic valve endocarditis, especially involving mitral valves.[308,309]

Echocardiography has some limitations.[301] It is not cost-effective as a means of excluding IE in patients with a low pretest probability of having the disease.[310,311] With higher prior probability, a negative study result has useful negative predictive value, especially if transesophageal studies have been performed, but it cannot totally exclude the diagnosis of endocarditis.[170,202,310,311] It is particularly useful in patients with *Staph. aureus* bacteremia. In one study, MVP identified vegetations in 7 of 26 patients with IE, while TEE revealed evidence of vegetations in all (100 percent).[311] These data suggest that a negative TEE allows the clinician to treat for bacteremia alone (usually antibiotic therapy for 2 weeks versus 4 to 6 weeks for IE). Sensitivity for detection of vegetations is somewhat lower on the right side (about 70 percent) than on the left (better than 95 percent).[270,301] The presence of a prosthetic valve sometimes interferes with detection of vegetations, but even in these patients echocardiographic findings are usually informative. Occasionally, the specificity of echocardiography is compromised by falsepositive readings for "vegetations" that do not exist. Such readings are particularly common in patients with myxomatous degeneration of valve leaflets or other preexisting disease with focal pathology. This must be considered when surgery is contemplated.

Sequential echocardiograms performed during treatment can guide decisions on the need and timing for surgery by providing objective assessments of cardiac function. For example, premature mitral valve closure due to elevated end-diastolic pressure is a useful echocardiographic sign indicating severe aortic regurgitation, usually requiring urgent valve replacement (see Chap. 56).[270] Echocardiograms may detect development of an abscess, perforation of a valve, or rupture of an infected sinus of Valsalva,[231] all strong indications for surgical intervention. During successful antimicrobial treatment, vegetations may disappear, decrease in size, or even persist unchanged; therefore, serial echocardiograms should not be used as a "test of cure."[301] Significant enlargement of a vegetation during treatment, however, indicates possible treatment failure and constitutes a relative indication for surgical intervention. The valve of echocardiography to determine risk of embolization and/or death is controversial. A large meta-analysis concluded that the odds ratio for embolization was 2.8 ($p < 0.01$) when vegetations >10 mm were detected but did not predict death.[312] In another study of *Staph. aureus*, IE visualization of vegetation by MVP carried a higher risk of embolization or death (68 percent) than identified only by TEE (16 percent, $p < 0.01$).[313] Therefore, the value of echocardiography as a mechanism for predicting outcome remains unclear.[314,315]

Other Imaging Studies

The most important contribution of the chest x-ray in assessment of endocarditis is to provide evidence of early congestive heart failure, because this complication carries such important implications for both prognosis and management (see "Complications," earlier).

Various other x-ray findings can be helpful in assessing patients with endocarditis. The presence of multiple small, patchy infiltrates in the lungs of an IDU with fever strongly suggests the diagnosis of septic emboli arising from right-sided IE.[65-67] Valvular calcification may identify a previously abnormal valve, thus aiding the localization of presumed intravascular infection. Widening of the aorta may be caused by a mycotic aneurysm. Fluoroscopy can demonstrate abnormal motion of a prosthetic valve, indicating presence of a vegetation or partial dehiscence of the valve from the aortic root. This information often helps to decide whether or not valve replacement is needed during management of PVE.

Computed tomography (Chap. 17) and magnetic resonance imaging (Chap. 18)[274] can be helpful in defining the cause of focal neurologic lesions in patients with endocarditis, especially infarction, hemorrhage from a mycotic aneurysm, and brain abscess. The computed tomography scan is very effective for diagnosis of intracranial complications[316] and infected aortic aneurysms.[133] Magnetic resonance imaging adds additional useful information in some cases (Fig. 73-14).[317] In one study, Magnetic resonance imaging provided evidence of cerebral embolization in 12 patients with IE. Angiographic studies are usually used to demonstrate mycotic aneurysms in the brain or elsewhere.[277,278]

Cardiac Catheterization with Cineangiography

This investigation is usually not necessary for patients who respond well to antimicrobial therapy without developing cardiac failure. When surgical intervention is considered, cardiac catheterization and cineangiography (Chap. 15) can extend and add to information provided by echocardiography. The condition of the coronary arteries should be assessed before valve replacement in adults over 40 years of age, because simultaneous coronary bypass may be indicated if the patient has coronary artery disease. Other relevant anatomic abnormalities such as valvular lesions, congenital defects, asymmetric septal hypertrophy, coarctation of the aorta, or mycotic aneurysm can be better defined. Occasionally, a previously unsuspected diagnosis, such as the presence of a sinus of Valsalva aneurysm, will be made. Physiologic measurements including cardiac output, pressures in the left and right sides of the heart, and the degree of aortic regurgitation may help to decide whether or not valve replacement is indicated and may influence the timing of the operation. Among 35 patients who underwent cardiac catheterization during active endocarditis, the clinical assessment was materially modified by catheterization in 23 patients, the diagnosis of the site of valve involvement was altered in 14, and in 6 valve-ring abscesses were revealed.[318] Surgery was postponed or canceled in 6 patients in whom catheterization revealed only mild hemodynamic abnormalities. There were no serious complications, indicating that catheterization should not be avoided for fear of dislodging emboli when a proper indication exists. In summary, cardiac catheterization and cineangiography should be performed in most adults with IE who are over 40 years of age and in selected younger patients when surgery is considered.

Radionuclide Imaging

Liver-spleen imaging may reveal defects due to splenic infarction, which confirms embolization. In animals, experimental vegetations have been located by scanning for radiolabeled platelets deposited from the bloodstream onto a growing endocardial lesion.[319] Gallium 67 scans have shown increased uptake in the heart in some patients with endocarditis. Scintigraphic studies following injection of indium 111 labeled leukocytes have detected some intracardiac abscesses,[77,320] but no radionuclide imaging technique has sufficient sensitivity and specificity to

justify routine use for detection of vegetations in IE. In selected cases, leukocyte scintigraphy using indium 111 labeled leukocytes can detect mycotic aneurysms and extracardiac foci of infection.[321] Single photon emission computed tomography immunoscintigraphy with antigranulocyte antibody has been described as a nuclear medicine option for diagnosis of IE.

Chapter 73: INFECTIVE ENDOCARDITIS

TREATMENT

General Principles

Optimal management aims to eradicate the infecting organism as soon as possible, to operate with correct timing if surgical intervention should be required, and to treat complications. Because IE carries a significant risk of death even when well managed, it is important that treatment be continued long enough to ensure that relapse will not occur. In contrast, patients with the more easily cured forms of endocarditis should not be subjected to unnecessarily long, expensive, and potentially toxic treatment in a hospital.[322] This can happen when physicians treat on the basis of outdated rules, such as the one stating that "endocarditis should be treated for 6 weeks." In fact, many patients can be cured in 2[323-325] or 4 weeks,[326] while some require treatment for 6 weeks or longer.

Microbiologic Tests

To choose and regulate antibiotic therapy correctly, certain basic microbiologic information about the infecting organism is required. For group A streptococcal infection, nothing more than positive identification of the organism is necessary, because these organisms, with only rare exceptions, are still sensitive to low concentrations of penicillin. For other species of streptococci, staphylococci, and most other bacteria, the minimal inhibitory concentration (MIC) of relevant antibiotics should be determined. Some of these organisms are resistant to intermediate or high concentrations of penicillin.[327,328] Many strains are tolerant-that is, inhibited but not killed by antibiotic levels achievable in serum.[329,330] Because there is no definitive evidence that tolerance determines treatment outcome in humans, however, it is not necessary to measure minimal bactericidal concentrations (MBC) in most cases.

The serum bactericidal titer (SBT or Schlichter test) has been used frequently to monitor the treatment of endocarditis.[33,331] In this test, the infecting organism is exposed in vitro to the patient's serum, which is drawn while the patient is receiving antibiotic treatment to determine the maximal dilution of serum that will inhibit and kill the organism. On the basis of empirical clinical experience, it was said that the SBT should be 1:8 or higher at intervals during each day of treatment. For streptococcal endocarditis, this can usually be achieved without difficulty; SBTs are often high, in the range of 1:128 to 1:1024. The SBT is technically difficult to perform and to standardize, however, and after years of use, its clinical utility remains unproven.[331,332] Therefore, SBTs are now regarded as obsolete by most experts. Rarely, measurement of the SBT might be informative: in treating unusual organisms, in using unusual antibiotics, in using unusual regimens (such as oral treatment), or when treatment appears to be failing.

Dosage regimens that result in widely fluctuating antibiotic concentrations in serum are traditionally employed for treatment of endocarditis, and they are usually effective. Whether or not the maintenance of continuous serum antibiotic concentrations offers any therapeutic benefit over intermittent dosing regimens is not known; perhaps continuous infusion of antibiotic would be desirable for treatment of some gram-negative organisms, which regrow more rapidly than most gram-positive organisms when antibiotic levels fall below the minimal inhibitory concentration.

Choice of Antibiotics

Bactericidal antibiotics are generally chosen for treatment of endocarditis whenever possible.[33,326] This is not an absolute rule; some patients have been cured with bacteriostatic drugs such as sulfonamides, tetracycline, or chloramphenicol, but the results of treatment with these agents are unreliable.[28,333,334] Bactericidal action is presumably needed because host defense mechanisms are inadequate in the vegetation; relatively few phagocytes are present, and they are hampered by protective layers of fibrin

around the colonies of bacteria (Figs. 73-2 and 73-6). To effect a cure, antibiotic therapy must eradicate organisms completely, without the help of phagocytes to eliminate the subpopulation of microbes that are relatively resistant to antibiotics because they are in the resting phase. In this important respect, IE differs strikingly from bacterial pneumonia in normal hosts, where phagocytes are plentiful and bacteriostatic antibiotics are usually effective. Nevertheless, in treating unusual organisms, it may occasionally be necessary to use a bacteriostatic antibiotic in combination with other drugs to achieve the optimal antibacterial effect. When treatment with unusual combinations of antibiotics is needed, in vitro laboratory tests can be performed to find out whether synergism, indifference, or antagonism exists between them.

For the common forms of bacterial endocarditis caused by gram-positive organisms, specific therapeutic regimens can be recommended with confidence based on extensive published experience.[323,335] Regimens for the more common forms of endocarditis are listed in Table 73-9.

Table 73-9: Treatment Regimens for Infective Endocarditis[a,b]

Organism	Treatment Regimen: Dose and Route	Duration in Weeks	Comments
Fully penicillin-sensitive streptococci: MIC ≤ 0.1 μg/mL viridans (α-hemolytic) streptococci; *Strep. bovis; Strep. pneumoniae; Strep. pyogenes* group A, C, etc.; *Strep. agalactiae* group B	1. Penicillin G 4 million units every 6 h IV alone (4 weeks) *or* 2. Penicillin G 4 million units every 6 h IV with gentamicin (2 weeks) 3. Ceftriaxone 2 g IV or 1 M once daily alone (2 weeks) *or* 4. Ceftriaxone 2 g IV or 1 M once daily or with gentamicin 1 mg/kg twice a day or 3 mg/kg 4 times a day (2 weeks) 5. Vancomycin 15 mg/kg IV every 12 h (4 weeks)[a,b]		
○	4		
○	4		
○	4		
○	Suitable for hospitalized patients but less convenient for outpatient therapy		
○	For patients allergic to penicillins but not cephalosporins or for outpatient therapy in selected patients		
○	For patients allergic to penicillins and cephalosporins		

Relatively penicillin-resistant streptococci: MIC > 0.1 < 1.0 μg/mL, some viridans (α-hemolytic) streptococci; some *Strep. pneumoniae;* etc.	1. Penicillin G 4 million units IV every 4 h *plus* gentamicin 1.0 mg/kg every 12 h IV or IM (for first 2 weeks only)[a] *or* 2. Vancomycin 15 mg/kg IV every 12 h[b]	❍ 4(2) ❍ 4 ❍ For outpatient therapy in selected patients, ceftriaxone 2 g IV once daily may be substituted for penicillin if ceftriaxone MIC ≤ 4 μg/mL, *plus* gentamicin 2.0 mg/kg given once daily ❍ For patients allergic to penicillins
Penicillin-resistant streptococci: MIC ≥ 1.0 μg/mL, *E. faecalis, E. faecium,* other enterococci; some other streptococci	1. Penicillin G 18-30 million units/day IV continuously or in divided doses *plus* gentamicin 1 mg/kg IV or IM every 8 h *or* 2. Ampicillin 12 g/day IV continuously or in divided doses *plus* gentamicin 1.0 mg/kg IV every 8 h, *or* 3. Vancomycin 15 mg/kg IV every 12 h *plus* gentamicin 1.0 mg/kg IV every 8 h[a,b]	❍ 4-6 ❍ 4-6 ❍ 4-6 ❍ Susceptibility testing needed; do not use penicillin- or ampicillin-containing regimen if strain produces β-lactamase. ❍ 4-week regimen recommended for most cases with symptoms for <3 months, otherwise 6 weeks ❍ For patients allergic to

	penicillin; 4 weeks should be adequate for most cases; serum levels should be monitored		
Staphylococci (in the absence of prosthetic material) β-lactam-containing regimens preferred over vancomycin unless patient is definitely hypersensitive to penicillins and cephalosporins; for patients with severe disseminated staphylococcal infection, antimicrobial synergy may be advantageous during early stages of treatment; therefore, gentamicin 1.0 mg/kg IV every 8 h for first 3-5 days only may be added to any of these regimens	Methicillin-susceptible staphylococci: 1. Nafcillin 2 g IV every 4 h IV 4-6 wks *or* 2. Nafcillin 2 g IV every 4 h IV × 4-6 wks plus gentamicin 1.0 mg/kg every 8 h IV × 3-5 days 3. Vancomycin 15 mg/kg IV every 12 h 4-6 wks[b] ○ 4-6 ○ 4-6 ○ 4-6		
In right sided uncomplicated tricus-pid endocarditis	Nafcillin 2 g IV every 4 h and gen-tamicin 1 mg/kg twice a day or 3 mg/kg 4 times a day	2	
	Methicillin-resistant staphylococci: Vancomycin 15 mg/kg IV every 12 h[b]	4-6	
Staphylococci (associated with pros-thetic valve or other prosthetic material)	Methicillin-susceptible staphylo-cocci: Nafcillin 2 g IV every 4 h *plus* gentamicin 1.0 mg/kg IV ev-ery 8 h[a] plus rifampin 600 mg orally 4 times a day	≥6	Cefazolin or vancomycin may be substituted for nafcillin if neces-sary due to drug hypersensitivity
	Methicillin-resistant staphylococci: Vancomycin 15 mg/kg IV every 12 h *plus* gentamicin 1.0 mg/kg IV or IM every 8 h *plus* rifam-pin 300 mg orally every 8 h[a,b]	≥6	

HACEK group organisms: *Haemophilus* species *Actinobacillus actinomycetemcomitans Cardiobacterium hominis Eikenella* species *Kingella kingae*	1. Ceftriaxone 2 g IV or IM once daily *or*	4	Other third-generation cephalospo-rins may be substituted, using ap-propriate dose adjustment
	2. Ampicillin 12 g/day IV continu-ously or in divided doses *plus* gentamicin 1.0 mg/kg every 12 h IV or IM[a]	4	Less convenient for outpatient therapy
Pseudomonas aeruginosa, other gram-negative bacilli	Extended-spectrum penicillin *or* third-generation cephalosporin *or* imipenem *plus* aminoglyco-side	4-6	Combination therapy recom-mended; final choice of antibiotic regimen to be made after sensi-tivity results available
Neisseria species	1. Penicillin G 2 million units IV every 6 h *or* 2. Ceftriaxone 1 g IV or IM once daily	○ 3-4 ○ 3-4	Organisms often highly sensitive to penicillin, but must be tested for β-lactamase production; 3 weeks should be adequate for most patients without complica-tions

[a]All gentamicin- and vancomycin-containing regimens require monitoring for potential toxicity; monitoring of serum concentrations usually will be required.
[b]Vancomycin dose not to exceed 2.0 g per 24 h.

SOURCE: Adapted from Scheld and Sande[50] and from Wilson et al., and The Sanford Guide 2000.[323]

Currently, increasing rates of antibiotic resistance threaten the efficacy of traditional treatment regimens. Penicillin resistance is increasing among viridans streptococci, the majority of which had previously been fully sensitive.[336,337] In 1996, 13 percent of blood culture isolates showed high-level resistance (MIC 4.0 mg/mL or greater) and 42 percent showed intermediate resistance (MIC 0.25 to 2.0 mg/mL).[337] Use of combined antibiotic regimens such as beta-lactam plus aminoglycoside or even vancomycin plus aminoglycoside should be considered for treatment of resistant strains.[336] Synergistic combinations of a beta-lactam and an aminoglycoside have been used successfully to treat enterococci for many years, but increasing resistance among enterococci, especially vancomycin-resistant enterococci, presents new problems for therapy.[338] The most resistant species is *Enterococcus faecium*, which may exhibit high-level resistance to vancomycin as well as intrinsic resistance to beta-lactam antibiotics and imipenem.[94] The optimal treatment for IE caused by these problem strains is not known. Several antibiotic combinations have been tried with some success often with adjunctive surgical valve replacement. These include high-dose ampicillin plus imipenem +/- a fluoroquinolone,[94,339] ampicillin plus imipenem plus vancomycin,[340]

ampicillin plus a fluoroquinolone,[341] and quinupristin/dalfopristin plus doxycycline plus rifampin.[342] Since great variability exists between isolates as to sensitivity and whether drugs are cidal or static, in vitro testing with time-kill experiments and testing various drugs alone and in combination will help with selection. An infectious disease consultation is recommended.[94,339-344]

Staph. epidermidis PVE is difficult to eradicate with antibiotics alone.[166] These staphylococci are frequently resistant to semisynthetic penicillins, cephalosporins, and other antibiotics. A regimen combining vancomycin, rifampin, and an aminoglycoside chosen according to sensitivity tests is most likely to succeed. The organism may develop resistance to rifampin during treatment.

Treatment of endocarditis due to less common organisms must be chosen on the basis of more limited published experience,[50,51,108,326] together with the results of tests performed upon the infecting organism in the microbiology laboratory. Treatment must often be individualized. In general, one of the beta-lactam antibiotics should be included in the regimen whenever possible. Combinations of two or more antibiotics are often employed. The list of potentially useful regimens for these rarer forms of infective endocarditis is too long to detail here.

Empiric Therapy

When the etiologic organism is not known, the choice of empiric therapy should depend on whether the patient has acute or subacute disease. ABE requires broad-spectrum therapy that covers *Staph. aureus* as well as many species of streptococci and gram-negative bacilli. SBE requires a regimen that treats most streptococci, including *E. faecalis.* To meet these requirements, the following suggestions are offered:

- For ABE: nafcillin 2.0 g IV q 4 h plus ampicillin 2.0 g IV q 4 h plus gentamicin 1.5 mg/kg IV q 8 h. If methicillin-resistant *Staph. aureus* is considered likely (for example, in a hospital-acquired case), vancomycin 1.0 g IV q 12 h should be substituted for nafcillin in this regimen until the antibiotic sensitivity is known.
- For SBE: ampicillin 2.0 g IV q 4 h plus gentamicin 1.5 mg/kg IV q 8 h.

Treatment should be adjusted as appropriate when the etiologic organism is identified and again when antibiotic sensitivity is known. In those few cases where empiric therapy is administered as a therapeutic trial to help confirm a diagnosis, treatment should be continued without interruption or unnecessary changes for at least 2 weeks; otherwise, no useful diagnostic information will be gained.

Duration of Therapy

Extensive experience with treatment of the common forms of endocarditis provides the basis for recommendations on duration of therapy (Table 73-9). In the case of *Staph. aureus* endocarditis, the response to appropriate treatment can be variable; some patients recover swiftly without complications, especially young IDUs, who can often be cured within 2 weeks.[70,324] In contrast, some patients remain febrile for 10 to 14 days due to complications such as abscesses or other extracardiac manifestations of disseminated staphylococcal disease. Although 4 weeks of therapy is adequate in most cases, this should not be regarded as a rigid rule, because some patients with *Staph. aureus* endocarditis require treatment for 6 weeks or longer to achieve a cure. For *E. faecalis* endocarditis, 4 weeks of treatment is usually adequate. The relapse rate, however, seems to be higher in patients with mitral valve infection and in those who have had symptoms for more than 3 months,[143] where treatment should continue for 6 weeks.

Parenteral treatment can be completed in the patient's home or in the outpatient clinic in carefully selected cases. Availability of antibiotics with long half-lives, such as vancomycin or ceftriaxone, allows once-daily administration. Supervised parenteral treatment outside the hospital should be fully effective in achieving a microbiologic cure and offers obvious benefits: convenience for the patient and cost containment.[344-346] The risks posed by a possible late complication, such as an embolic stroke or the sudden onset of heart failure, must be balanced against these benefits in selecting candidates for home parenteral therapy. Further trials are needed to refine the criteria and proper applications for outpatient therapy for endocarditis, but current experience indicates that more than one-half of endocarditis patients could receive at least some of their treatment as outpatients.

In general, the less extensive the published experience with a particular organism and treatment regimen, the more one should lean toward prolonging treatment in order to provide a reasonable margin of safety. Guidelines for the duration of treatment of the more common etiologic organisms are listed in Table 73-9. For less common organisms, the optimal duration of treatment required may vary according to individual circumstances.

Role of Surgery

Optimal management of IE requires operative intervention during treatment for about one-third of patients.[87-347] Correct selection of this subgroup of patients and optimal timing of surgery are both critically important.[348]

Major indications for surgery are moderate or severe heart failure not responding to medical treatment, valvular obstruction, periannular or myocardial abscess, prosthetic valve dehiscence, persistent bacteremia despite appropriate antibiotics, and fungal infection. In most such cases, surgery should proceed promptly even if the infection is still active.

Relative indications for surgery include recurrent emboli; staphylococcal and gram-negative bacillary infections, especially involving prosthetic valves; persistent fever despite treatment; and vegetations that enlarge during treatment.[11,110,266,348]

Correct timing is the essence of good surgical management of endocarditis.[347] If surgery is undertaken too soon, the risks of operative mortality and the early and late morbidity associated with valve replacement may be inflicted on the patient unnecessarily, because some patients respond well to medical therapy, allowing surgery to be postponed indefinitely. If surgery can be delayed safely, antibiotic therapy should have eradicated or at least greatly reduced the number of organisms in the vegetation and in any sites of metastatic infection, thus increasing the chance of a successful outcome if surgery becomes necessary. If time is available for the effective treatment of complications such as septicemia, renal failure, pneumonia, myocarditis, and neurologic complications[316] before surgery, the operative risk should be lower. In comparison, if surgery is delayed too long, patients may die suddenly, or their hemodynamic status may deteriorate so seriously that surgery is no longer feasible. This would be a tragic error, because many authors have emphasized that both survival and long-term outcome can be improved by earlier operation for selected patients, even if the endocardial infection is still active.[266,349,350]

Careful, frequent reexamination of the patient, together with repeated echocardiographic studies and sometimes cardiac catheterization to confirm the clinical findings, is indicated in every case where operation might be needed. The decision to operate should also be influenced by knowledge of the natural history of the type of endocarditis being treated. For example, penicillin-sensitive streptococcal endocarditis can almost always be cured bacteriologically (Table 73-10), and the immediate prognosis is good provided that cardiac failure or other major complications do not develop. Therefore, surgery should usually be considered only for those patients with cardiac failure that does not respond well to medical treatment. Similarly, because young IDUs with acute staphylococcal endocarditis have a good prognosis,[5,324] surgery should usually be reserved for those who develop intractable heart failure or definite signs of treatment failure. In contrast, the likelihood that fungal prosthetic valve endocarditis can be eradicated with antifungal drugs alone is negligible (Table 73-10). Such patients should usually undergo valve debridement or replacement early, without waiting to test the remote possibility that antifungal treatment could eradicate the infection.[351] The development of severe aortic regurgitation, especially when accompanied by heart failure, usually requires urgent surgery. Other examples of patients who are highly likely to require operation are those with early-onset PVE, valve-ring abscesses, or gram-negative bacillary infection of prosthetic valves.[11]

Over the past decade, surgical approaches have evolved toward increasingly radical debridement of infected tissue and more extensive use of reconstructive materials.[266,351] For example, an aortic root homograft instead of a standard prosthetic valve is now often inserted after debridement of a valve-ring abscess.[352] The Ross operation, transposing the patient's own pulmonary valve into the aortic position as an autograft after extensive debridement of infected tissue (replacing the pulmonary valve with a homograft) has been

advocated as treatment for patients with complicated aortic root infections.[353,354]

In addition to valve replacement, several other surgical procedures may be available for the treatment of endocarditis.[348] Debridement of vegetations ("vegetectomy"), often combined with valvuloplasty, can cure the infection while sparing the native valve in selected patients.[267,268,355] This can be especially beneficial for young patients, women who wish to bear children, and patients who cannot or will not take anticoagulant therapy reliably.

Early consultation with the surgical service should be sought for most patients with endocarditis, so that an appropriate operation can be performed without delay if necessary. The sudden onset of aortic or mitral regurgitation with consequent acute left ventricular failure can occur without warning, even in the most favorable forms of endocarditis.

Anticoagulant Therapy

Even though the infected vegetation is essentially a thrombotic lesion, there is no evidence that anticoagulation has any useful therapeutic effect on the course of the endocarditis itself. On the contrary, early experience showed that simultaneous treatment with penicillin and heparin carried an increased risk of fatal intracerebral hemorrhage.[356] For this reason, anticoagulation was considered to be strongly contraindicated in patients with endocarditis, until further experience showed that warfarin could usually be given safely during the treatment of patients with prosthetic valve infections.[357-359] However in a series of 21 pH with PVE caused by *Staph. aureus*, 12 had CVS events including 6 intracranial hemorrhages and 5 ischemic strokes that had hemorrhagic transformation. All 11 died, and all had been on oral anticoagulants.[359] Currently available information suggests the following guidelines for patients with IE:

- Avoid use of heparin except for urgent indications, such as treatment of massive pulmonary embolism.
- Discontinue or avoid oral anticoagulants if possible, especially in patients with intracranial complications and if *Staph. aureus* is the cause of IE.
- Anticoagulate with warfarin if there is a clear-cut indication, such as a mechanical prosthetic heart valve, taking care to regulate the prothrombin time between International Normalized Ratio (INR) 2.5 and 3.5.
- Choose an antibiotic treatment regimen that does not require intramuscular injections if anticoagulation is instituted.

Thrombolytic agents theoretically could promote lysis or resolution of vegetations. Adjunctive treatment with recombinant tissue plasminogen activator decreased vegetation size and improved the results of short-term penicillin therapy in rabbits with fresh vegetations.[12] Similarly, aspirin therapy can reduce the size of experimental vegetations and improve rate of sterilization by antibiotics.[360] The potential value of antithrombotic agents, however, has not been demonstrated in human beings; thrombolytic therapy might not work on the older vegetations typical of SBE in human beings and could possibly cause serious hemorrhagic complications.

Management of Complications

HEART FAILURE

The development of moderate or severe cardiac failure due to structural valvular damage indicates the need for **prompt surgical intervention** in most patients with endocarditis, even if the intracardiac infection is still active.[347,349] In patients with mild heart failure, the decision should be individualized, always remembering that lives may be lost unnecessarily if cardiac function suddenly worsens, so that surgery becomes either hazardous or unfeasible.

EMBOLI

The occurrence of one or more significant arterial emboli during the treatment of endocarditis is a relative indication for surgery. The predictable early and long-term mortality and morbidity rates of valve

replacement must be weighed against the highly unpredictable likelihood of further emboli. For this reason, embolization is a weaker indication for valve replacement than is cardiac failure.[348,349] In the author's opinion, operative intervention during antibiotic treatment should seldom be undertaken solely to prevent further emboli unless the patient has suffered more than one or two proved major emboli. Because the frequency of emboli falls rapidly after 1 to 2 weeks of antibiotic therapy,[361] the most logical time to operate for the purpose of preventing emboli would be early, within 1 week of diagnosis.

RENAL FAILURE

In the preantibiotic era, patients with SBE frequently developed chronic renal failure before they died.[3] Subsequently, both the incidence of renal failure and its importance as a cause of death have greatly diminished. In one series, up to one-third of 204 patients with IE developed evidence of acute renal failure, however. Risk factors for renal failure were increased age, hypertension, thrombocytopenia, IE caused by *Staph. aureus*, and PVE. While the earlier diagnosis and antibiotic treatment have forestalled the development of immune-complex glomerulonephritis, in those (about 5 to 10 percent) who still develop this complication of SBE, timely dialysis can maintain the patient until antibiotic treatment results in disappearance of the bacterial antigens that triggered immune-complex nephritis. Renal function usually normalizes smoothly once infection has been controlled, but recovery may take weeks or months. In a few cases, creatinine clearance worsens for a time despite effective antibacterial treatment, perhaps reflecting persistence of bacterial antigen in vegetations after bacteriologic cure. Corticosteroids may have been of value in a small number of cases.[362] Some patients with septicemia, shock, or disseminated intravascular coagulation associated with ABE develop acute renal failure and require dialysis as part of their intensive care.

MYCOTIC ANEURYSM

This complication is diagnosed in less than 5 percent of patients with IE, but the local consequences of aneurysm expansion and rupture can be very serious, especially in the brain (see Chap. 89).[276,278,279] Small aneurysms will often thrombose or resolve spontaneously during or after antibiotic therapy. Once aneurysms exceed 0.5 to 2 cm in diameter, they are likely to enlarge and eventually rupture despite eradication of the etiologic bacteria by antibiotic therapy.[281] Surgery is indicated for accessible aneurysms before this complication occurs.

Intracranial mycotic aneurysms are especially difficult to manage. They may present with headaches, subarachnoid hemorrhage, or stroke, but many are asymptomatic. Even small aneurysms may bleed at any time; they may be multiple and/or located in inaccessible sites. This presents a therapeutic dilemma: whether to treat conservatively with antibiotics and hope for resolution (risking serious or fatal hemorrhage) or to operate (risking neurologic damage and permanent sequelae). Symptoms or signs consistent with an intracranial aneurysm indicate the need for prompt imaging, using computed tomography and/or magnetic resonance imaging. Cerebral angiography may be needed if the findings are inconclusive. In general, large (over 0.5 cm in diameter) or expanding aneurysms or aneurysms that have already leaked or begun to bleed should be clipped if a surgical approach is feasible. An individualized decision must be made on whether or not to operate for smaller aneurysms that have not leaked or ruptured.

Chapter 73: INFECTIVE ENDOCARDITIS

PROGNOSIS

IE is one of the few infectious diseases that are virtually always fatal if untreated. Spontaneous recovery was reported occasionally in the preantibiotic era,[3] but most of these patients probably had illnesses other than IE. The interval between the onset of symptoms and death in patients with untreated subacute disease varied widely, with a median time to death of about 6 months.[3] Almost all patients with acute IE died within less than 4 weeks.

Heart failure is the leading adverse prognostic factor.[264] Other adverse factors include central nervous system complications, renal failure, culture-negative disease, gram-negative bacillary or fungal infection, prosthetic valve infection, and development of abscesses in the valve ring or myocardium.[363] Survival 6 months after PVE in one series was only 54 percent.[364] Six-month survival after early-onset PVE (37 percent) was significantly worse than it was for late-onset PVE (65 percent). Because modern treatment methods, including valve replacement, are effective for treatment of heart failure, central nervous system complications have replaced heart failure as the most important adverse prognostic factor in some case studies.[274]

Favorable prognostic factors include youth, early diagnosis and treatment, infection involving a prolapsing mitral valve, and penicillin-sensitive streptococcal infection. The prognosis is good for young IDUs with *Staph. aureus* infection of the tricuspid valve.[5,335] With earlier diagnosis and appropriate therapy, including surgery, the prognosis for elderly patients can be substantially improved.[90] Eradication of the etiologic organisms (microbiological cure) can be achieved in a high proportion of all patients with bacterial endocarditis.[6,323,344,345] Both early and long-term mortality rates remain significant, however, due to any preexisting disease and added damage caused by endocarditis before the organisms were eradicated. Survival curves after admission with IE show a significant number of late deaths despite microbiologic cure.[9,365]

An analysis of experience over the past 25 years permits a reasonably accurate formulation of the prognosis for microbiologic cure among the various subgroups of patients with IE. Approximate figures are listed in Table 73-10.

Chapter 73: INFECTIVE ENDOCARDITIS

RECURRENT ENDOCARDITIS

Recurrent endocarditis is a general term that includes both relapses and reinfections. The term *relapse* refers to recurrence of infection with the same organism because treatment failed. The frequency of relapse can be predicted from published experience for each of the various forms of IE (Table 73-10). Because relapses occasionally occur even after an optimal treatment regimen has been used, follow-up clinical evaluation should be meticulously performed during the first 2 months after treatment. Any clinical suspicion that relapse might have occurred indicates the need to draw blood cultures. Most relapses occur within a few weeks of ending treatment, but living organisms can persist in seemingly healed vegetations for many months and may occasionally cause late relapse.

The term *reinfection* refers to a new episode of endocarditis occurring after the cure of a previous episode.[366] Usually a different etiologic organism is involved, but if the new isolate appears similar to the initial etiologic organism, molecular typing techniques can be used to determine if the case is a relapse or an infection.

Patients remain permanently at risk of reinfection after cure of IE because of residual valve damage superimposed on the original predisposing lesion (see Tables 73-1 and 73-2). Recurrent episodes are fairly common, being recorded in from 2 to 31 percent of cases.[3,46,48,365,366] This wide variation in reported incidence is partly due to variable duration of follow-up. IDUs and patients with severe periodontitis are at highest risk for reinfection. Occasionally, a patient may suffer three or more separate episodes of IE.[366] Patients who have previously had NVE and have required valve replacement, are at high risk to develop prosthetic valve infection (often with a different organism) for reasons that are not yet understood.[9]

Chapter 73: INFECTIVE ENDOCARDITIS

THE CHALLENGE OF PROPHYLAXIS

Because various invasive procedures induce bacteremias with bacterial species that often cause IE,[367-369] prophylactic antibiotics are frequently given to susceptible patients in an attempt to prevent bacterial endocarditis. Although antibiotics definitely can prevent endocarditis in experimental animals, its effectiveness in human beings has not been proved in prospective randomized clinical trials and likely never will be. Many relevant questions remain unanswered. These include the following:

- Is antibiotic prophylaxis effective?
- Does the prophylactic effect (benefit) outweigh the potential side effect of the drug cost and influence the emergence of drug-resistant bacteria?
- Which operations and diagnostic procedures should be covered?
- Which patients should receive antibiotics?
- What antibiotic regimens will be most effective?

Although the risk of infection has not been quantitated, it is sufficiently low that most of these questions cannot be answered by clinical trials; the number of susceptible patients required to provide significant results would be too large.[55,349]

Less than 15 percent of SBE cases and even fewer of ABE cases follow identifiable medical procedures that cause transient bacteremias[54,367,368,370]; therefore, the proportion of cases that is potentially preventable by antibiotics is vanishingly small.

Because endocarditis causes serious morbidity and mortality, the American Heart Association and the practicing medical community have accepted the practice of using antibiotic prophylaxis without evidence-based studies. It has been accepted that prevention of even a few cases could be worthwhile. For this reason, currently accepted standards of practice require that an antibiotic regimen be administered before certain dental and surgical procedures in patients with known heart lesions that pose a significant risk of endocarditis.

Because several hundred cases of streptococcal endocarditis following dental and genitourinary tract procedures have been recorded, the potential causative role of these procedures is certainly suggested.[367,368] A rather short "incubation period" for endocarditis is typical, in that most of these patients noticed symptoms within 2 weeks of the procedure.[256] It should be emphasized that the link between a case of endocarditis and a recent procedure causing bacteremia cannot be proved, because the infection could have been caused by one of the transient, asymptomatic, low-grade bacteremias that occur very commonly, induced by everyday events such as chewing and cleaning the teeth. In fact, when 273 cases of endocarditis are examined retrospect from 1, 2, and 3 months prior to endocarditis, no correlation to dental procedures were found.[56,367]

In the absence of prospective controlled trials, empirical recommendations[55,370,371] for prophylaxis of bacterial endocarditis have been made on the basis of indirect information. This information includes the reported frequency of bacteremia after various procedures (Table 73-11); the relative risk posed by the patient's cardiac lesion (Table 73-2); case reports of prophylaxis failures[75]; in vitro susceptibility studies on the relevant organisms, especially streptococci; experimental studies in laboratory animals[254,372]; and retrospective studies in human beings.[373-375]

Table 73-11: Representative Rates for Frequency of Bacteremia after Various Dental, Diagnostic, and Therapeutic Procedures

Procedure	% Bacteremia	% Range (if available)
None	0	(0-3)
Oral cavity		
Extraction of teeth	60	(18-85)
Periodontal surgery	88	(60-90)
Brushing teeth or irrigation	40	(7-50)
Tonsillectomy	35	(33-38)
Respiratory tract		
Tracheal intubation	<10	(0-16)
Nasotracheal suctioning	16	
Bronchoscopy (rigid bronchoscope)	15	
Bronchoscopy (flexible bronchoscope)	0	
Genitourinary tract		
Catheter insertion and removal	3	(0-26)
Prostatectomy (sterile urine)	12	(11-13)
Prostatectomy (infected urine)	60	(58-82)
Dilatation of strictures	28	(19-86)
Normal delivery	3	(1-5)
Intrauterine device insertion or removal	0	
Gastrointestinal tract		
Upper gastrointestinal endoscopy	4	(0-8)
Transesophageal echocardiography	1	(0-17)
Endoscopic retrograde cholangiopancreatography	5	(0-6)
Barium enema	10	(5-11)
Colonoscopy	5	(0-5)

Sigmoidoscopy (rigid sigmoidoscope)	5	
Sigmoidoscopy (flexible sigmoidoscope)	0	
Proctoscopy	2	
Hemorrhoidectomy	8	
Esophageal dilatation	45	
Vascular system		
Cardiac catheterization	2	(0-5)
Insufficient data		
Insertion and removal of tympanostomy tubes		
Cesarean section		

SOURCE: From Durack,[370] with permission.

Information from these sources indicates that experimental endocarditis in animals can be prevented by bactericidal antibiotics; that prevention is probably effective in human beings; that only a small proportion of total cases is potentially preventable by use of antibiotics[370,374]; and that the cost per prevented case would be very high.[76,374] Thus, prevention probably would not be cost-effective as a general strategy, but it might be effective for selected individuals (namely patients with previous IE and patients with prosthetic valves), especially for high-risk procedures such as tooth extractions.[370,376]

For the individual patient, the decision to administer prophylaxis should be made by assessing two main factors: the risk posed by the preexisting cardiac lesion and the risk posed by the procedure that might cause bacteremia. For example, if a patient with a prosthetic valve undergoes prostate resection, antibiotic prophylaxis is recommended because both factors present a significant risk of endocarditis. In contrast, if a patient with mitral valve prolapse is scheduled for gastroscopy, prophylaxis is not necessary because the risk for endocarditis in this setting is very low.[369] Such risk assessments may be difficult or inaccurate; in many situations uncertainties will remain. For these, there is no one "correct" answer; the patient's and the physician's attitudes and preferences may influence the decision to use prophylaxis. Updated consensus recommendations by the AHA may be useful in guiding decision making.[79]

These guidelines emphasize the following points:

1. Most cases are not attributable to an invasive procedure.
2. Cardiac conditions should be stratified into light, moderate, and negligible risk categories; these are primarily based on potential outcomes if endocarditis occurs.
3. There are procedures that may cause high grade bacteremia and for which prophylaxis is most likely to be effective.
4. There is an algorithm to use in deciding on prophylaxis in patients with mitral valve prolapse.
5. The initial dose of amoxicillin is reduced to 2 g for oral and dental procedures and a follow-up dose is no longer recommended; clindamycin (not erythromycin) is recommended as an alternative therapy in penicillin-allergic individuals.
6. Prophylactic recommendations in gastrointestinal and genitourinary procedures have been simplified.[79]

Attempted prophylaxis does not always succeed. Of 52 cases of apparent prophylaxis failure in one series, 42 involved patients with heart disease who received oral penicillin or erythromycin, usually to cover dental procedures.[75]

Surprisingly, in one series 12 of 16 patients with known cardiac abnormalities who developed IE with organisms of dental origin and who had a dental procedure within 3 months of onset of IE received prophylactic antibiotics according to AHA guidelines. In fact, only 10 percent of cases of IE in this study would qualify for prophylaxis according to the AHA standards. Even if a prophylaxis was 100 percent effective, it would reduce the incidence of IE by only 2.0 cases per 1,000,000 person-years.

The authors agree with Durack, that on the basis of existing data, it is most reasonable to use prophylaxis prior to dental extractions or gingival surgery including implant placement but not routine dental care, filling of cavities, root canal, cleaning and sealing of teeth, in patients with prosthetic valves or history of prior endocarditis. If any of the four conditions are present, antibiotic prophylaxis seems reasonable.[56]

Common errors in attempted prevention of endocarditis are starting antibiotics too early, continuing for too long, using low doses, covering tooth extractions but not lesser dental procedures, and confusing prevention of rheumatic fever (requiring long-term, low-dose antimicrobial drugs) with prevention of endocarditis (short-term, high-dose).[55]

In the absence of pelvic infection, prophylaxis for endocarditis in patients with heart lesions is not recommended to cover normal delivery, therapeutic abortion, dilation and curettage, and insertion or removal of intrauterine contraceptive devices. Similarly, antibiotics are not recommended before many common procedures, such as cardiac catheterization, insertion of temporary pacemakers, endotracheal intubation, bronchoscopy, endoscopy, or radiographic contrast studies of the upper and lower gastrointestinal tract. In comparison, some physicians choose to cover even these low-risk procedures in patients with prosthetic valves because they are at higher risk for endocarditis than are patients with native valves. Specific regimens suggested for prophylaxis of endocarditis are listed in Table 73-12.

Cardiac surgeons currently administer antibiotics to virtually all patients undergoing cardiac surgery, attempting to prevent both wound infections and endocarditis, although the efficacy of prophylaxis in prevention of endocarditis has not been proved.[55] Current recommendations call for parenteral administration of an antistaphylococcal antibiotic just prior to operation, followed by 1 or 2 further doses (Table 73-12). The regimen may be modified if local experience shows that cases of early PVE caused by *Staph.* epidermidis or gram-negative bacilli have occurred with significant frequency (Table 73-12).

The paradigms that have been proposed by various expert bodies (including the AHA) for the use of antibiotics to prevent IE have developed over time and have been based on indirect evidence derived from studies in animals that demonstrated that prevention was possible, on case reports tying IE to various procedures known to cause bacteremia, and from a concern about the dire consequences of the disease. These recommendations have been accepted as "standard of care" and failure to follow them has taken on medicolegal implications. Various authors have questioned this practice and new information has emerged calling into question the clinical benefit of prophylactic antibiotics in this setting. This is especially important in an era where overuse of antimicrobials is fueling the dangerous epidemic of antibiotic-resistant bacteria. Therefore, it seems prudent for the various expert committees who write such recommendations to carefully weigh the apparent minimal benefits with the downsides of toxicity, cost, and resistance that has come with excessive use of antibiotics.

Chapter 73: INFECTIVE ENDOCARDITIS

List of Figures

Figure 73-14: Magnetic resonance image of the brain in a patient with acute left-sided *Staphylococcus aureus* endocarditis, showing multiple areas of focal cerebritis. This patient had no focal central nervous system signs and recovered fully with antimicrobial therapy. (MRI by courtesy of the Department of Radiology, Duke University, Durham, NC.)

Figure 73-15: *A-D.* Echocardiograms from 4 patients with infective endocarditis showing vegetations located at different sites. *A.* Transesophageal echocardiogram (TEE) showing a large vegetation *(arrow)* on the tricuspid valve (TV). IVC = inferior vena cava; RA = right atrium; AV = aortic valve; RVOT = right ventricular outflow tract. *B.* Large vegetation *(arrowhead)* involving both the atrial and ventricular surfaces of the posterior mitral valve leaflet. LA = left atrium; MV = anterior leaflet of the mitral valve; LVO = left ventricular outflow tract; AV = aortic valve. *C.* TEE showing vegetations on both the mitral *(open arrow)* and aortic valve *(arrow)* in a patient with acute *Staphylococcus aureus* endocarditis. LA = left atrium; LV = left ventricle; VS = ventricular septum. *D.* TEE showing a vegetation on the cusp of a bioprosthetic valve *(arrow)*. LA = left atrium; LV = left ventricle; S = artificial valve struts. (Kindly provided by Dr. B. Khanderia and Dr. J. Steckelberg, Mayo Clinic, Rochester, Minn.)
