This is an uncommon but important complication of GP IIb/IIIa inhibitors: For tirofiban in PRISM-PLUS, the rate of severe thrombocytopenia (<50,000 cells/mm^3) was 0.5 percent compared with 0.3 percent for heparin (p = NS)[78]; in the PURSUIT trial, thrombocytopenia (<20,000 cells/mm^3) occurred in 0.2 percent compared with <0.1 percent for heparin.[76] Thrombocytopenia is associated with increased bleeding and, in a smaller proportion of patients, recurrent thrombotic events.[290,291] This syndrome bears resemblance to heparin-induced thrombocytopenia (HIT) and indicates a need to monitor platelet count daily during the GP IIb/IIIa infusion.

Oral Glycoprotein IIb/IIIa Inhibition

Oral GP IIb/IIIa inhibitors are peptidomimetic agents that are competitive inhibitors of the GP IIb/IIIa receptor. They are usually pro-drugs, which are absorbed and then converted to active compounds in the blood.[237-241] The oral agents all have longer half-lives, such that they can be given once, twice, or three times daily to achieve relatively steady levels of GP IIb/IIIa inhibition. With oral dosing, long-term therapy (i.e., longer than 1 year) is possible. As with the intravenous compounds, two major groups of drugs exist in the oral class: those with competitive inhibition and short "off time" from the receptor (where a high drug level is critical to achieving high levels of platelet inhibition) and those which have "tight" binding to the platelet (similar to abciximab) with the majority of the drug circulating bound to platelets.

INITIAL CLINICAL EXPERIENCE

Pharmacokinetics and Pharmacodynamics

A number of orally active platelet GP IIb/IIIa inhibitors have been studied in clinical trials (Table 44-5). Currently available data suggest that most of these agents inhibit ex vivo platelet aggregation in response to various agonists [ADP, collagen, or Thrombin Receptor Activator Peptide (TRAP)] that correlates closely with plasma level of active metabolite. In addition, the dose/concentration response is maintained without evidence for tolerance or tachyphylaxis over time. Differences in drug half-life may result in drug accumulation and more pronounced platelet inhibition during chronic therapy, depending on the dose interval employed. The pharmacokinetic and pharmacodynamic response to most oral GP IIb/IIIa inhibitors can be illustrated by comparing and contrasting the responses of short-acting (xemilofiban, half-life 4.1 h), moderate-acting (sibrafiban and orbofiban, half-lives approximately 10 to 11 h), and longer-acting agents (roxifiban and cromofiban, half-lives approximately 24 h).

Xemilofiban

The first experience with oral GP IIb/IIIa inhibition was with xemilofiban.[237,292,293] High degrees of platelet inhibition were achieved with this oral GP IIb/IIIa inhibitor. It has a relatively short half-life and thus is given three times daily. The Oral Glycoprotein IIb/IIIa Receptor Blockade to Inhibit Thrombosis (ORBIT) trial was a randomized dose-ranging trial of xemilofiban in patients undergoing percutaneous intervention.[294] Peak inhibition of platelet aggregation was similar following the same dose of xemilofiban administered on days 14 and 28 of the trial. The time to peak blood level following the same dose of xemilofiban was reduced from 4 h following the first dose of drug to 2 h with steady-state dosing during chronic therapy.[294] Most bleeding events were observed during the first 2 weeks of therapy on a three-times daily dosing regimen.[294] Further bleeding events were uncommon during the final 2 weeks of treatment on a twice-daily dosing regimen, and the requirement for blood transfusion was infrequent.

TIMI-12 Trial

This was a phase II, double-blind, dose-ranging trial designed to evaluate the pharmacokinetics, pharmacodynamics, safety, and tolerability of sibrafiban in 329 patients after acute coronary syndromes.[238] In the pharmacokinetics/pharmacodynamics cohort of TIMI-12, a total of 106 patients were randomized to receive one of seven dosing regimens of sibrafiban, ranging from 5 mg daily to 10 mg twice daily for 28 days. In the safety cohort, 223 patients were randomized to one of four dose regimens of sibrafiban (ranging from 5 mg twice daily to 15 mg once daily) or aspirin for 28 days.

High levels of platelet inhibition were achieved: mean peak values ranged from 47 to 97 percent inhibition of 20 μ*M* ADP-induced platelet aggregation on day 28 across the seven doses. Twice-daily dosing provided more sustained platelet inhibition (mean inhibition, 36 to 86 percent on day 28), while platelet inhibition returned to baseline levels by 24 h with once-daily dosing.[238] Major hemorrhage was rare in patients treated with sibrafiban (1.5 percent) or aspirin (1.9 percent). However, protocol-defined "minor" bleeding, usually mucocutaneous, occurred in 0 to 32 percent of patients in the various sibrafiban groups, compared with none of the aspirin-treated patients. In a multivariate model, minor bleeding was related to total daily dose ($p = .002$), once-daily compared with twice-daily dosing ($p < .0001$), renal function ($p < .0001$), and presentation with unstable angina ($p < .01$).[238]

Thus, the oral GP IIb/IIIa antagonist sibrafiban achieved effective, chronic platelet inhibition with a clear dose response but at the expense of a relatively high incidence of minor bleeding. The mucocutaneous bleeds appeared to be related to plasma drug concentrations, the degree of platelet inhibition, and other patient factors (weight and renal function). One lesson learned is that dosing of sibrafiban (or other oral agents) based on such clinical factors might help improve the safety profile of the drug with regard to minor bleeding.

Peak-to-Trough Ratios

In TIMI-12, approximately double the rate of minor bleeding occurred with once-daily dosing, as compared with similar total daily dose of twice-daily dosing (e.g., 15 mg once daily versus 7 mg twice daily). This may indicate that the higher peak drug concentrations and degree of platelet inhibition (sometimes 100 percent) may be related to the bleeding episodes. The bleeding appeared to occur approximately 6 h after study drug ingestion, which correlates with the peak blood level. Thus, these data suggest that using dosing regimens that avoid high peaks may decrease the risk of bleeding.

Variability

In addition, interpatient variability has been observed in drug level and degree of platelet inhibition. In contrast, the 24- to 72-h infusions of intravenous GP IIb/IIIa inhibitors have doses selected to achieve 80 to 95 percent inhibition-and a very steady level of inhibition is achieved. This is one of the major differences in the pharmacokinetics between the intravenous and oral GP IIb/IIIa inhibitors, and it may be an explanation for differences in clinical outcomes observed to date. This variability might lead to too low a level of inhibition at the trough level or too high a level of inhibition in some patients at peak times.

One potential strategy for dosing oral GP IIb/IIIa antagonists is to monitor the degree of platelet inhibition or drug level achieved in individual patients and adjust the dose to a target level, as is currently done with anticoagulant therapy. By avoiding higher levels of platelet inhibition, this strategy may reduce bleeding complications. This could potentially be accomplished with a bedside assay for platelet inhibition.[287] An alternate strategy for adjusting the dose of an oral GP IIb/IIIa inhibitor is to begin using fixed dose initially but lower the dose if the patient experiences minor bleeding. Such strategies may improve the overall safety profile of these potent platelet antagonists.

Thrombocytopenia

This is another key area of tolerability. Data from the Orbofiban in Patients with Unstable Coronary Syndromes (OPUS)-TIMI-16 trial suggest that, with oral therapy, thrombocytopenia generally occurs early, within the first 2 weeks, with very low rates during long-term follow-up.[295] Among patients who developed thrombocytopenia, however, higher rates of both bleeding and cardiac events were seen. Thus, a very small percentage of patients treated with oral GP IIb/IIIa inhibitors developed thrombocytopenia, and a proportion of those developed thrombosis or bleeding. This pattern bears some resemblance to that for heparin and for intravenous GP IIb/IIIa inhibitors, suggesting the pathophysiology may relate to a more general drug-induced thrombocytopenia ± thrombosis (DITT) syndrome.

Degree of Platelet Inhibition and Efficacy

Previous animal and clinical studies have suggested that the maximum benefit of GP IIb/IIIa inhibition occurs when the degree of platelet inhibition is greater than 80 percent.[284,285] Currently, it is not clear whether lower levels of platelet inhibition would also be beneficial. The IMPACT-II study showed a strong trend toward the reduction of recurrent ischemic events after coronary angioplasty at a dose of eptifibatide that achieved only 50 to 60 percent inhibition.[286] In contrast, a greater benefit was observed with a higher dose of eptifibatide (that targeted 85 to 90 percent platelet inhibition) in the ESPRIT trial (Tcheng J, presented at the American College of Cardiology, March 2000). Thus, it appears that greater benefit, at least in the acute setting, is achieved with doses that achieve more than 80 percent inhibition of 20 μ*M* ADP-induced platelet aggregation, but this is not truly a "threshold" below which no benefit is achieved. For long-term therapy, a high level of blockade will need to be balanced with the potential of increased bleeding, and thus a slightly lower level of inhibition may be optimal.

Degree of Platelet Inhibition and Bleeding

As observed in TIMI-12, increasing the degree of platelet inhibition may produce a higher incidence of minor bleeding events.[238] This suggests that a lower degree of platelet inhibition may be better tolerated during chronic, oral therapy. Nevertheless, major hemorrhage appears to be within an acceptable range in the initial trials with oral GP IIb/IIIa inhibitors, even at high levels of platelet inhibition. Therefore, one possible dosing strategy for GP IIb/IIIa inhibitors may be to tailor the dose to the risk of recurrent ischemic events, thus optimizing the degree of platelet inhibition and minimizing the risk of minor bleeding. For example, patients might be given a higher dose during the early phase of their acute coronary syndrome, when they are at highest risk of recurrent ischemic events. The dose could then be lowered during the chronic phase, when the risk of recurrent ischemic events is lower, thereby decreasing the risk of bleeding.

Need for Aspirin

An important aspect of oral GP IIb/IIIa inhibition is concomitant therapy with aspirin. Several factors suggest the benefit of the combination of aspirin and an oral GP IIb/IIIa inhibitor. First, synergism has been demonstrated for inhibition of platelet aggregation in response to collagen, with a greater degree of platelet inhibition with the combination of aspirin plus the GP IIb/IIIa inhibitor.[296] Second, the action of aspirin is to decrease the synthesis of TXA_2 by the platelet, which decreases platelet *activation*, a step proximal to platelet aggregation. Thus, aspirin and GP IIb/IIIa inhibitors inhibit different steps in the formation of a platelet thrombus. In addition, reduction in TXA_2 reduces local coronary vasospasm, which helps reduce ischemia. Additional factors favoring the combination are aspirin's efficacy for primary and secondary

prevention of ischemic events,[184] its relatively good safety profile, and its low cost. Finally, aspirin would provide antiplatelet effects during the troughs in GP IIb/IIIa blockade that may occur between doses. The potential adverse effect of concomitant aspirin is increased risk of bleeding, particularly gastrointestinal bleeding. In addition, it has been argued that the effects of a GP IIb/IIIa inhibitor are an order of magnitude stronger than those of aspirin-and thus adding aspirin is redundant to the antiplatelet effects of the GP IIb/IIIa inhibitor.

Four Large Phase III Trials

The first phase III trial of an oral GP IIb/IIIa inhibitor in patients with acute coronary syndromes was the OPUS-TIMI-16. This trial involved 10,288 patients randomized at 888 hospitals in 28 countries worldwide. The inclusion criteria were onset within the last 72 h of an acute coronary syndrome defined as rest ischemic pain lasting at least 5 min associated with either ECG changes, positive cardiac markers, or a prior history of vascular disease. Major exclusion criteria included renal insufficiency (creatinine >1.6 mg/dL or an estimated creatinine clearance <40 mL/min, increased bleeding risk, or need for warfarin).

Eligible patients were treated with 150 to 162 mg of acetylsalicylic acid (aspirin) and were randomized, in double-blind fashion, to one of two dosing strategies of orbofiban given twice daily or to placebo. In one dose, orbofiban was given 50 mg twice daily throughout the trial (50/50 group); in the other, the 50 mg twice daily dose was given for the first 30 days (the highest risk period), and then the dose was reduced to 30 mg twice daily (50/30 group). Other medical and interventional therapy was at the discretion of the treating physician. Patients were seen at 14 and 30 days and every 3 months. The primary end point was a composite of death, MI, recurrent ischemia leading to rehospitalization or urgent revascularization, or stroke. The planned sample size was to be 12,000 patients, but the trial was stopped prematurely after an unexpected increased mortality rate at 30 days was observed in one of the orbofiban groups.[297]

The composite end-point rates at 30 days were 10.8 percent in the placebo group compared with 9.9 percent in the two orbofiban groups ($p = 0.12$).[297,298] The mortality rate at 30 days was 1.4 percent in the placebo group compared with 2.3 percent in the 50/30 group and 1.6 percent in the 50/50 group. Through follow-up, 10-month event rates were 22.9, 23.1 and 22.8 percent, respectively (p = NS).[297,298] The safety profile was acceptable, with the rate of major hemorrhage and thrombocytopenia (0.6 percent) greater than with aspirin but within the expected range for this class of drugs. Subsequent exploratory analyses found greater benefit for patients who underwent PCI while on study drug and those who were stable on admission (Killip class I).

Substudies from OPUS-TIMI-16 demonstrated that this agent led to increases in measures of platelet activation, such as P-selectin.[299,300] These data are consistent with the observations in vitro of an apparent prothrombotic effect, with increases in platelet activation and aggregation at low levels of platelet inhibition.[301] In contrast, in TIMI-12, no increase in P-selectin was observed with sibrafiban therapy.[18] Further research in this field is ongoing, but it appears that there may be differences among the oral GP IIb/IIIa inhibitors with regard to the potential prothrombotic effects.

Many lessons were learned from OPUS-TIMI-16, the first large trial of oral GP IIb/IIIa inhibition in acute coronary syndromes, which will be helpful in planning future trials of other GP IIb/IIIa inhibitors. First, it appears that it will be beneficial to optimize the dosing strategy used with the oral agents, potentially to mimic the stable antiplatelet effect achieved by the intravenous drugs. This would mean trying to reduce the interpatient and intrapatient variability, potentially adjusting the dose by weight and/or renal function. One might also use the plasma drug level and/or the bedside platelet function test to adjust the dose. Second, our data suggest that one could target stabilized patients. In addition, several new and planned trials will be testing different drugs (e.g., with tight IIb/IIIa receptor binding).

EXCITE Trial

The Evaluation of Oral Xemilofiban in Controlling Thrombotic Events (EXCITE) trial studied the agent xemilofiban in patients undergoing PCI. This trial followed the promising results demonstrated by two pilot studies in PCI.[292,294] In the EXCITE trial, 7232 patients undergoing elective PCI (angioplasty or stent)

without adjunctive intravenous GP IIb/IIIa inhibition were randomized in a double-blind fashion to receive one of two xemilofiban regimens or placebo: 20 mg of oral xemilofiban 30 to 90 min prior to percutaneous coronary revascularization, followed by 10 mg or 20 mg xemilofiban or placebo for both were subsequently administered three times daily for 6 months.[302]

Death, MI, or urgent revascularization at 6 months, the primary end point, occurred in 13.6 percent of patients in the placebo group, 14.1 percent of patients in the 10-mg xemilofiban group, and 12.6 percent of patients in the 20-mg xemilofiban group (p = NS).[302] A trend toward fewer periprocedural MIs in the first 48 h following PCI was not sustained.[302] On the other hand, mortality tended to be higher in 10-mg xemilofiban dose group: The mortality rate at 6 months was 1.0 percent for placebo, 1.6 percent for the 10-mg xemilofiban dose group, and 1.1 percent in the 20-mg dose group.[302] Major hemorrhagic events were significantly more common among the xemilofiban-treated patients.[302] Thus, administration of the oral GP IIb/IIIa receptor inhibitor xemilofiban immediately prior to percutaneous revascularization in patients with acute and stable coronary artery disease, and chronically for up to 6 months thereafter, did not significantly reduce the primary composite end point of death, MI, or need for urgent revascularization. Xemilofiban did reduce the incidence of periprocedural MIs during the first 48 h of dosing.

SYMPHONY-I Trial

Following the phase II trial, TIMI-12,[238] the first Sibrafiban Versus Aspirin to Yield Maximum Protection from Ischemic Heart Events Post-acute Coronary Syndromes (SYMPHONY) trial was a randomized, double-blind, aspirin-controlled trial of two regimens of sibrafiban for the treatment of patients following an acute coronary syndrome. A total of 9233 patients with either AMI or high-risk unstable angina (with ST deviation of 0.5 mm or more) who were stabilized for at least 12 h were randomized to receive either aspirin (80 mg every 12 h) or high-dose or low-dose sibrafiban (without aspirin) every 12 h for a total of 3 months. The dose of sibrafiban was either 3, 4.5, or 6 mg, based on body weight and renal function. The primary efficacy end point was a composite of death, MI, and severe recurrent ischemia.

There was no difference in the primary end point between aspirin (9.8 percent), low-dose sibrafiban (10.1 percent), and high-dose sibrafiban (10.1 percent). Similarly there were no differences in mortality alone, MI, or recurrent ischemia. Major bleeding was more common with the two sibrafiban groups, high dose (5.7 percent) and low dose (5.2 percent) compared with aspirin (3.9 percent). In conclusion, sibrafiban without aspirin was not superior to aspirin alone for secondary prevention of cardiac events following acute coronary syndromes.

SYMPHONY-II Trial

The second SYMPHONY trial, which was terminated early at the time the SYMPHONY-I results were available, studied the combination of low-dose sibrafiban plus aspirin, high-dose sibrafiban, and aspirin alone. A total of 6671 patients with stabilized acute coronary syndromes were randomized. Follow-up was on average for 90 days. The primary efficacy end point of death, MI, or severe recurrent ischemia showed no difference in the high-dose sibrafiban group (10.5 percent) compared with 9.3 percent for aspirin alone and 9.2 percent for low-dose sibrafiban plus aspirin. The mortality rate was significantly higher with the high-dose sibrafiban group: 2.4 compared with 1.3 percent for placebo and 1.7 percent for the low-dose sibrafiban plus aspirin group. A similar pattern was seen for recurrent MI: 6.9 percent for high-dose sibrafiban compared with 5.3 percent for aspirin and 5.3 percent for the low-dose plus aspirin group. Major bleeding was more common with the two sibrafiban groups, 4.6 percent with high-dose sibrafiban compared with 4.0 percent for aspirin and 5.7 percent for low-dose sibrafiban plus aspirin.

NEW AGENTS ON THE HORIZON

Another agent, lotrafiban, has been studied in phase II and is currently being studied in a large phase III trial-Blockade for the GP IIb/IIIa Receptor to Avoid Vascular Occlusion (BRAVO)-in which all patients will receive aspirin and be randomized to lotrafiban or placebo. Another agent, cromafiban, has a very long half-life and thus may have more predictable and stable levels of platelet inhibition. Lefradafiban has been tested in a phase II study, with intriguing trends toward benefit among patients with a positive troponin T at

baseline,[303] which is similar to the findings seen with intravenous GP IIb/IIIa inhibitors in the CAPTURE[304] and PRISM trials.[305] These data suggest that identification of the ideal patients with risk-stratification methods may assist in targeting therapy to patients who will benefit most.

Two agents to date have been evaluated as both intravenous *and* oral compounds: Klerval[306,307] and (le)fradafiban.[308] In the TIMI-15B trial, a transition from initial intravenous treatment to prolonged oral treatment with Klerval achieved a smooth transition in the level of platelet inhibition in patients with acute coronary syndromes. Because of low bioavailability, however, the development of this drug was discontinued. Lefradafiban (oral) and fradafiban (intravenous) await further testing.

Roxifiban is an oral agent that binds tightly to platelet receptor and is slow to dissociate.[240,241,309,310] The half-life of dissociation is 7 min, more than 40 times longer than the short-acting molecules like tirofiban (approximately 10 to 20 s) (Table 44-6).[310] Roxifiban's tight binding is similar to that of abciximab, which also has a long half-life of dissociation.[310] This prolonged antiplatelet effect would avoid the possibility of "on-off" proaggregatory effects of the drug binding to the GP IIb/IIIa inhibitor,[301] which may have explained some of the findings from previous trials with oral GP IIb/IIIa inhibitors. Indeed, experimental models have shown that roxifiban has superior antithrombotic effects as compared with other short-acting GP IIb/IIIa inhibitors.[240] With its long half-life, roxifiban is administered once daily. It also has a very high potency and affinity for the GP IIb/IIIa receptor. As such, the oral doses needed are only 0.5 to 1.5 mg once daily. It has a very stable antiplatelet effect over time (i.e., a low peak to trough level of platelet inhibition), and blood levels do not appear to be affected significantly by renal function.

CONCLUSION

Thus, initial disappointment has been seen for the testing to date with oral GP IIb/IIIa inhibitors. Numerous questions remain, such as what level of platelet inhibition is optimal, how efficacy and safety can best be balanced, whether other adjunctive agents are needed, and whether monitoring of platelet function will assist in the use of these agents. In addition, identification of the optimal patients by using tools of risk stratification may assist in targeting therapy to patients who will benefit most. As with other classes of drug, such as beta blockers in congestive heart failure or cholesterol-lowering drugs (beginning with resin drugs 20 years ago), the road toward identifying appropriate patients, doses, and drugs is frequently a long one. With ongoing trials and "second generation" agents (Table 44-6) it is hoped that this class of drugs will be found to be clinically useful.

Chapter 44: THROMBOGENESIS, ANTITHROMBOTIC, AND THROMBOLYTIC THERAPY

ANTICOAGULANT DRUGS

Unfractionated Heparin

Heparin refers not to a single molecule but rather to a family of mucopolysaccharide chains of varying length and composition. Heparin by itself has no anticoagulant property but rather is a cofactor to antithrombin (formerly referred to as antithrombin III). Heparin accelerates the action of two naturally occurring plasma inhibitors, forming a 1:1 stoichiometric complex with antithrombin III (an inhibitor of thrombin and activated factors X, IX, XI, and XII) and, at very high doses, with heparin cofactor II, which acts only on thrombin decay. Heparin contains a unique pentasaccharide that has a high-affinity binding sequence for antithrombin III. This sequence is present in only one-third of heparin molecules and is not required for binding to heparin cofactor II.

Factor Xa bound to platelets and thrombin bound to the endothelium or to fibrin (thrombus) are protected from inactivation by heparin-antithrombin III complex.[311,312] In plasma, approximately 20 times more heparin is needed to inactivate fibrin-bound thrombin than to inactivate free thrombin [311] This explains why more heparin is needed to prevent the extension of venous thrombosis than to prevent formation of the initial thrombus.

When in the bloodstream after parenteral administration, heparin binds to endothelial cells, mononuclear macrophages, and numerous plasma proteins. Some of these neutralize anticoagulant activity (e.g., platelet factor 4 and vitronectin), whereas others such as von Willebrand factor lose their function. Elevated levels of these heparin-binding proteins explain the different individual heparin dose requirements to obtain the same antithrombotic effect and the so-called "heparin resistance" in patients with inflammatory and malignant diseases.[312] Binding of heparin to the endothelium and various plasma proteins reduces bioavailability at low concentrations and causes variability of response to fixed doses of anticoagulant[312] (Table 44-7).

Table 44-7: Advantages and Disadvantages of Unfractionated Heparin, Low-Molecular-Weight Heparin, and Recombinant Hirudin

Unfractionated Heparin	LMW Heparin	Hirudin
Inhibits to the same extent thrombin and factor VII, much less IXa and XIa	Inhibits mainly factor Xa, thrombin to some extent	Specific and potent inhibitor of thrombin
Antithrombin III-dependent	Antithrombin III-dependent	Antithrombin III-independent
Neutralized by heparinase, several plasma proteins, platelet factor 4, and endothelium	Neutralized by heparinase, weak endothelium binding	Not neutralized by heparinase, endothelium, macrophages, fibrin monomer, and plasma proteins
Does not inactivate clot-bound thrombin and factor VII	Does not inactivate clot-bound thrombin and factor VII	Inactivates clot-bound thrombin
Inhibits platelet function	Inhibits platelet function	Prevents thrombin induced aggregation but not other platelet agonists

Induced thrombocytopenia is not rare	Can induce thrombocytopenia	Does not induce thrombocytopenia
Bioavailability after subcutaneous injection, 30%	Bioavailability after subcutaneous injection, >90%	Good bioavailability after subcutaneous injection, circa 85%
Poor dose-effect response	Fair dose-effect response	Fair dose-effect response
Not immunogenic	Not immunogenic	Not or barely immunogenic
Transient increase of liver enzymes is common	Transient increase of liver enzymes possible	No liver toxicity
Increases vascular permeability	No increase of vascular permeability	No increase of vascular permeability

The pharmacokinetics of heparin are complicated. In brief, the anticoagulant response increases disproportionately in intensity and duration as the dose increases. This explains why the anticoagulant effect of heparin has to be closely monitored. At present, no completely satisfactory test measuring the generation of thrombin and the levels of antithrombin is available. The most commonly used test is the activated partial thromboplastin time (APTT), which is sensitive to the inhibitory effect of heparin on thrombin, factor X, and factor IX. Unfortunately, the different commercial APTT reagents vary in their response to heparin, and there are technical variables. The therapeutic level of the APTT should therefore be established in each clinical laboratory to correspond to 0.2 to 0.4 U of heparin per milliliter plasma by protamine titration or to 0.2 to 0.7 IU factor Xa per milliliter of plasma by the chromogenic substrate assay for the determination of anti-factor-Xa activity.

SIDE EFFECTS

The most common and major side effect of heparin is bleeding. The risk is higher when unfractionated heparin is given by intermittent infusion (14.2 percent) rather than continuous infusion (6.8 percent) or subcutaneously (4.1 percent). Also, the dose of heparin, the patient's anticoagulant response, serious concurrent illness, and chronic consumption of alcohol may predispose the patient to bleeding. HIT occurs in 2.4 percent of patients receiving therapeutic heparin and 0.3 percent for prophylactic heparin. In addition, vascular occlusion occurs in 0.4 percent. Rare complications are osteoporosis (usually with prolonged treatment), alopecia, skin necrosis, urticaria, and transient elevation of hepatic transaminases.

CLINICAL USE

Adjunct to Thrombolytic Therapy: Subcutaneous Heparin

Heparin has been studied in numerous trials in conjunction with thrombolytic therapy, and its role and dosing are still being debated. One of the first trials, which pre-dated the use of aspirin, was the Studio sulla Calciparina nell'Angina e nella Trombosi ventricolare nell'Infarcto (SCATI)[224,313] group, which randomized 711 patients to either heparin or no heparin; 433 of these patients also received streptokinase. These patients did not receive aspirin. This study found a 44 percent reduction in mortality rate when 12,500 U subcutaneous heparin was given to patients with acute MI. This reduction in mortality was significant both in the group receiving streptokinase and in those who did not receive the thrombolytic agent.

The use of heparin in those receiving aspirin as adjunctive therapy with thrombolytic agents (Table 44-8) was examined in many studies, including Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico (GISSI) 2, ISIS-3, and GUSTO. In the GISSI-2/International Study, patients who received streptokinase and heparin beginning 12 h after the infusion of the thrombolytic agent had a non-statistically significant trend toward a decrease in mortality rate as compared with those who received streptokinase alone.[314] The mortality rate for those receiving t-PA was the same whether or not heparin was added to the regimen.[315,316]

Table 44-8: Data from Direct Comparison of Antithrombotic Regimens: GISSI-2, ISIS-3, and GUSTO-I

Outcome	GISSI-2 AND ISIS-3, ASPIRIN PLUS ANY THROMBOLYTIC AGENT		GUSTO-I, ASPIRIN PLUS SK	
	No Heparin (*n* = 31,050), %	SC Heparin (*n* = 31,017), %	SC Heparin (*n* = 9971), %	IV Heparin (*n* = 10,377), %
Death	10.2	10.0	7.2	7.4
Reinfarction	3.3	3.0	3.4	4.0
Total stroke	1.2	1.2	1.3	1.4
Hemorrhagic stroke	0.4	0.5	0.5	0.5
Major bleeding	0.7	1.0	0.3	0.5

ABBREVIATIONS: SK = streptokinase; SC = subcutaneous; IV = intravenous.
SOURCE: Hennekens et al.,[314] with permission.

ISIS-3 found that heparin given subcutaneously (12,500 U every 12 h starting 4 h after the start of thrombolytic therapy) and aspirin given with t-PA or streptokinase resulted in a nearly significant decrease in mortality.[317] There was also a trend toward a decrease in hospital reinfarction rate in the heparin group. However, this early benefit was lost when the primary end point of 35 days was reached. Heparin was associated with a very small excess of major bleeding (0.2 percent of patients: 1.0 percent compared with 0.8 percent for no heparin, $p < .01$). Intracerebral hemorrhage also seemed very slightly increased (0.056 versus 0.40 percent, $p < .05$).[317]

Intravenous Heparin

This is an important adjunctive agent in decreasing reocclusion following t-PA for acute ST-elevation MI. Infarct-related artery patency has been studied in four angiographic trials evaluating whether heparin improves patency. No difference in patency was seen at 90 min.[318] Between 18 h and 5 days, however, there was higher patency among patients randomized to receive intravenous heparin.[319-321] Since early patency was similar, the benefit of heparin is felt to be due largely to decreased reocclusion. All trials with novel variants of t-PA [i.e., r-PA (reteplase) and TNK-t-PA, (tenecteplase)] have used adjunctive heparin in the clinical trials.

Following streptokinase or anistreplase (anisoylated plasminogen-streptokinase activator complex [APSAC]), the role of heparin is less clear. One study with APSAC found no difference in coronary artery patency in those receiving heparin plus aspirin compared with aspirin alone.[322] In the GUSTO-I trial, patients treated with streptokinase with intravenous or subcutaneous heparin had similar infarct-related artery patency at 90 min and 24 h, but those receiving intravenous heparin had significantly higher patency at 5 to 7 days (84 versus 72 percent, $p = .04$).[270] Nonetheless, the overall 30-day mortality and the rate of clinical reinfarction were the same between these two groups.[323] It should be noted, however, that patients randomized to the subcutaneous arm did receive intravenous heparin when recurrent ischemia developed. Therefore, intravenous heparin may be considered optional in streptokinase-treated patients. Of note, however, the American College of Cardiology/American Heart Association guidelines do recommend intravenous heparin for patients receiving streptokinase or APSAC if they are at high risk of developing systemic emboli (e.g., large anterior MI or atrial fibrillation).

Very recent preliminary data on the 5-year follow-up of United States' patients only from GUSTO-I showed

that the streptokinase group with intravenous heparin had a survival similar to that of t-PA. Thus, the late (days 5 to 7) patency advantage observed in the GUSTO angiographic substudy for intravenous heparin as compared with subcutaneous heparin might have translated into only a late mortality benefit. Further analysis of these preliminary data is needed, however.

Unstable Angina/Non-ST-Elevation Myocardial Infarction

In unstable angina and non-ST-elevation MI, heparin is an important component of primary therapy. Two initial small studies suggested a reduction in cardiac events by heparin.[324,325] Three studies of heparin in unstable angina and non-ST-elevation MI also suggest benefit: The Montreal Heart Institute trial showed that heparin reduced refractory angina and MI compared with placebo.[67] A follow-up report extending enrollment in that trial found a reduction in the risk of subsequent MI by heparin compared with aspirin alone.[69] The RISC study failed to demonstrate a beneficial effect of heparin compared with aspirin but noted that, during heparin therapy, patients receiving both aspirin and heparin had the lowest rate of death or MI.[68]

The Antithrombotic Therapy for Acute Coronary Syndromes (ATACS) Study Group evaluated the role of combination antithrombotic therapy compared with aspirin alone in patients with acute ischemic syndromes who were not prior aspirin users.[70] They observed a trend toward fewer ischemic events (death, MI, or recurrent ischemia with ECG changes) in patients receiving aspirin and heparin and warfarin at 12 weeks (19 percent) compared with aspirin alone (28 percent) (p = .09).[70] They went on to perform a meta-analysis of the Theroux, RISC, and their own trial, and found that during the 5 days of active treatment with aspirin and heparin the risk of death or MI was lower than for aspirin alone (odds ratio = 0.44; 95% CI = 0.21 to 0.93).[70] A more recent and comprehensive meta-analysis showed a 33 percent reduction in death or MI at 2 to 12 weeks (7.9 versus 10.4 percent; relative risk = 0.67; 95% CI = 0.44 to 1.02) (Fig. 44-17).[71] These data support the use of aspirin plus heparin in unstable angina/non-ST elevation MI.

HEPARIN RESISTANCE

Variability in the anticoagulant effects of heparin, so-called heparin resistance,[326,327] is thought to be due to the heterogeneity of heparin molecules and to the neutralization of heparin by circulating plasma factors and by proteins released by activated platelets.[328-332] Clinically, frequent monitoring of the anticoagulant response by using APTT is recommended, with titrations made according to a standardized nomogram.[190] The use of a standardized nomogram minimizes the variability in the dosing adjustments given by various physicians and has been shown to improve the achievement of a target APTT.[328,333,334]

THERAPEUTIC RANGE

The exact level of anticoagulation that constitutes the therapeutic range is not yet established. Pilot studies in unstable angina[335] and acute MI[336-339] have suggested that lower APTT values are maybe related to recurrent ischemic events or lower infarct-related artery patency,[340,341] suggesting that the lower limit of the target range of APTT is at least 1.5 to 2 times control. On the upper boundary of the target range, higher APTT values are associated with an increased risk of hemorrhage.[342] In the large GUSTO-I trial of thrombolytic therapy, the lowest rate of bleeding (and mortality) was observed in patients who had a 12-h APTT between 50 and 70 s.[339] Furthermore, in unstable angina, in the TIMI-3B trial, there was no apparent benefit of higher levels of anticoagulation.[343]

HEPARIN DOSING

Standard heparin dosing involves a 5000-U bolus followed by a 1000-U/h infusion, which is then titrated according to the APTT.[328,344] The use of weight-adjusted heparin has been suggested as a means of improving APTT control and safety.[345] In one randomized trial, a high percentage of patients "overshot" in the initial APTT at 6 h (median, 150 s).[346] Another trial that examined a 60-U/kg bolus and an infusion of 12 U/kg per hour compared with fixed dosing found a higher percentage of patients within range without a

large number of APTTs above range at 6 h.[347] A third trial that tested standard dosing versus weight-adjusted dosing (70-U/kg bolus and initial infusion of 15 U/kg per hour) found no significant difference in control of APTT with weight-adjusted dosing.[348] Another approach uses on-line feedback of APTT data to a computer algorithm using a pharmacodynamic model of heparin response in the individual patient, with promising results in an initial pilot trial.[349]

An important lesson learned from recent trials is that lower initial doses of heparin in the setting of thrombolytic therapy are associated with a lower rate of intracranial hemorrhage. In the TIMI-10B and Assessment of the Safety of a New Thrombolytic (ASSENT-I) trials,[350] and in TIMI-9 and GUSTO-II trials,[351-354] when the doses of heparin were reduced in the first part of the trial to the second part of the trial, the rates of ICH and major hemorrhage were reduced. A recent overview of all major thrombolytic trials, and of detailed information from the TIMI trials and the Intravenous n-PA for Treatment of Infarcting Myocardium Early II (InTIME-II) trial, confirmed that lower doses of heparin are associated with reduced ICH.[355]

Further very compelling evidence of the benefit of lower doses of heparin comes from the InTIME-II trial, which compared the single-bolus thrombolytic agent, lanoteplase, and accelerated t-PA in 15,078 patients worldwide. The heparin dose was 70-U/kg bolus with a maximum of 4000 U (i.e., 4000 U/kg/h for all patients weighing more than 57 kg) and 15-U/h (max 1000 U/h) infusion. The rate of ICH for t-PA was the lowest ever reported in a large trial for accelerated t-PA: 0.62 percent.[355]

CURRENT RECOMMENDATION

Based on the emerging data, the 1999 update to the American College of Cardiology/American Heart Association guidelines for the management of acute MI will recommend a new lower dose of heparin: a bolus of 60 U/kg (maximum, 4000 U) and an initial infusion of 12 U/kg per hour (maximum, 1000 U/h).[356] No maximum is needed in nonthrombolytic treated patients. The guidelines also call for frequent monitoring of APTT (every 6 h until in the target range and every 12 to 24 h thereafter) and for titration of heparin by using a standardized nomogram, with a target range of APTT between 1.5 to 2 times control or approximately 50 and 70 s.[356]

CORONARY REVASCULARIZATION PROCEDURES

Use of adequate heparinization with aspirin throughout the procedure is strongly recommended.[357] The exact level of anticoagulation with unfractionated heparin has been debated, but current recommendations are to achieve an activated clotting time between 300 and 350 s in patients *not* receiving a GP IIb/IIIa inhibitor.[358] This can generally be achieved using a weight-adjusted dose of a 100-U/kg bolus, with 20-U/kg additional boluses if needed.[359] For patients who do receive a GP IIb/IIIa inhibitor, the target should be approximately 200 to 250 s, based on data from the EPILOG trial.[285]

LMW Heparins

Some of the limitations of unfractionated heparin can be overcome with LMW heparin (mean molecular weight, 4000 to 5000; range, 1000 to 10,000). LMW heparins produce their major anticoagulant effect by binding to antithrombin through the same high-affinity pentasaccharide sequence of unfractionated heparin, which, however, is present in only one-third of the LMW heparins. A minimum additional chain length of 15 saccharides (MW > 5400) is required for the inactivation of thrombin, but the inactivation of factor X requires only the pentasaccharide (Fig. 44-18). Unfractionated heparin has an anti-factor Xa to anti-factor II ratio of 1:1, which is between 4:1 and 2:1 for the various LMW heparins. Drugs with a high anti-factor Xa activity were indeed designed based on the hypothesis that inhibition of earlier steps in the blood coagulation system would be associated with a more potent antithrombotic effect than inhibition of subsequent steps. This is because of the amplification process inherent in the coagulation cascade; that is, a single factor Xa molecule can lead to the generation of hundreds of thrombin molecules.

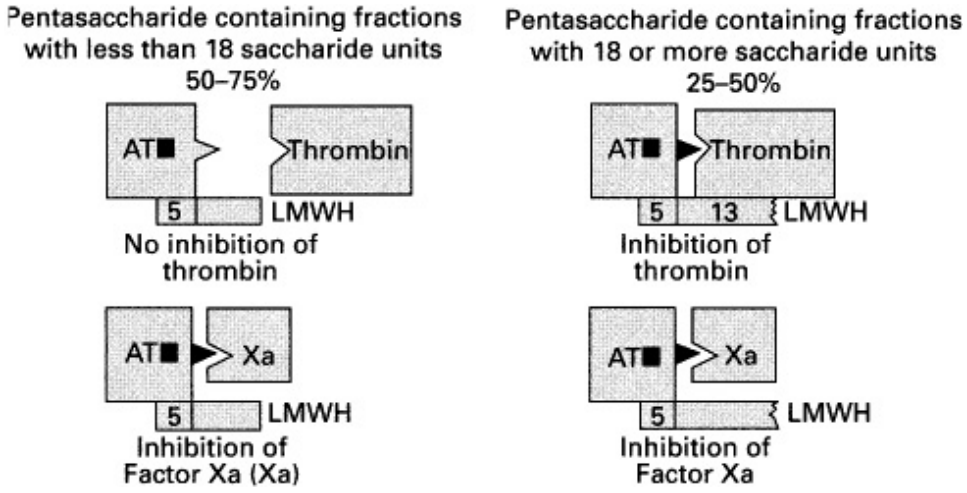

Figure 44-18: Mechanism of action of heparin and low molecular weight heparin (LMWH): Heparin acts as a cofactor to antithrombin to (1) change the conformation of its active site and (2) serve as a "bridge" to bring together an antithrombin (AT) and thrombin. Heparin is a catalyst: after it facilitates the binding of one pair of thrombin and antithrombin molecules, it is released and facilitates another thrombin-antithrombin interaction. LMWH also binds to antithrombin and changes the conformation of its active site, but does not act as a bridge to thrombin. Approximately 25 to 50 percent of the LMWH molecules of different commercial preparations contain at least 18 saccharide units, which allows binding to the heparin-binding site of thrombin, and thus both these molecules inhibit thrombin and factor Xa. The remaining 50 to 75 percent of LMWH molecules contain fewer than 18 saccharide units and inhibit only factor Xa.

The advantages of LMW heparins over unfractionated heparin are numerous (Table 44-7). Factor Xa bound to the platelet membrane in the prothrombinase complex is resistant to inactivation by unfractionated heparin but is not resistant to inactivation by LMW heparins. Also, LMW heparins have lesser binding characteristics to platelet factor 4, other plasma proteins, and endothelial cells, resulting in a higher bioavailability (after subcutaneous injection, greater than 90 versus 30 percent for unfractionated heparin); reduced plasma clearance, which is independent of dose and plasma concentration; a longer half-life (anti-factor Xa activity between 3 and 4 h for LMW heparins compared with 30 to 150 min for unfractionated heparin); and less interindividual variability of the anticoagulant response.[360] LMW heparins have a lower affinity for von Willebrand factor,[361] increase vascular permeability less than unfractionated heparin, and have a weak effect on platelet function. These differences could explain why LMW heparins produce less bleeding than unfractionated heparin with equivalent or higher antithrombotic effect in experimental animals[360] and in some clinical studies.

The long half-life of LMW heparins and their predictable anticoagulant response to weight-adjusted doses allow a twice daily subcutaneous administration without laboratory monitoring.[360]

HEPARINOIDS: MIXTURE OF LMW SULFATE GLYCOSAMINOGLYCANS

Danaparoid sodium (Org 10172) is a LMW heparinoid (6 kDa) and consists of a polydispersed mixture comprising sulfated glycosaminoglycuronides derived from animal mucosa; heparan sulfate (83% wt/wt), of which 4 to 5 percent has high affinity for antithrombin III; dermatan sulfate (12% wt/wt); and a minor amount of chondroitin sulfate (5% wt/wt).[362] There is uncertainty whether the low-affinity fraction of danaparoid sodium has an antithrombotic function[363] or not.[364] Danaparoid sodium was more efficacious than heparin and was associated with less and briefer bleeding than heparin in various animal models of thrombosis.

The complex mechanism of the antithrombotic activity of danaparoid sodium can so far be only partially explained. Its anticoagulant profile is characterized by a high ratio of anti-factor Xa/antithrombin activity (14 over < 0.5), resulting in an effective inhibition of thrombin generation. The anti-factor Xa activity is

mediated by antithrombin and is not inactivated by endogenous heparin-neutralizing factors. The low antithrombin activity is mediated by heparin cofactor II and antithrombin III. The heparan sulfate fraction with low affinity for antithrombin III, despite lacking significant effects on coagulation factors Xa and IIa (thrombin) in vitro, has been shown in animal studies to contribute substantially to the antithrombotic activity. In contrast to heparin, danaparoid sodium shows hardly any or no effect on platelet function in vitro or in vivo. Danaparoid sodium is essentially free of contaminating heparin, has minimal cross-reactivity in in vitro assays for HIT, and has been used successfully in patients with this complication.

Pharmacokinetic studies have been primarily based on the kinetics of relevant anticoagulant activities because no specific chemical assay methods are available. In comparison with heparin, danaparoid sodium has a prolonged elimination half-life of anti-factor Xa activity. After intravenous and subcutaneous administration of danaparoid sodium, the antithrombin activity half-life is shorter (1.8 h) than its anti-factor Xa half-life (17.6 h). Danaparoid sodium has an absolute bioavailability of 100 percent after subcutaneous administration. The kidneys play an important role in the elimination of the anti-factor Xa activity of danaparoid sodium, but a cellular metabolism seems unlikely, since the liver does not affect the anti-factor Xa activity and there is only slight and reversible binding to the endothelium.[71,364]

Danaparoid sodium is effective in the prevention of deep venous thrombosis in patients with thrombotic stroke and after elective hip surgery or hip fracture.[365] The long half-life of danaparoid sodium, which is not effectively neutralized by protamine, has been rather difficult to manage clinically.

Clinical Use of LMW Heparin

LMW heparin has been studied extensively in the prevention and more recently for the treatment of venous thrombosis. In the United States, it is approved for prophylaxis against deep venous thrombosis based on results from several trials.[344,366-368] Other trials for the *treatment* of deep venous thrombosis have also been promising.[344,369-372] Several of these trials have demonstrated a lower rate of major hemorrhage with LMW heparin than with standard heparin.[344]

LMW HEPARIN IN UNSTABLE ANGINA

In recent years, LMW heparin has been studied extensively in unstable angina. Two pilot trials were encouraging.[373,374] A second, open-label pilot trial in unstable angina and non-Q-wave MI has also suggested that LMW heparin may be superior to aspirin and heparin.[375] This study used nadroparin (Fraxaparin), which has a 3:1 ratio of factor Xa-thrombin inhibition.

DALTEPARIN

In the first large trial of LMW heparin in unstable angina, the Fragmin During Instability in Coronary Artery Disease (FRISC) study, dalteparin plus aspirin was found to reduce death or MI dramatically over the first 6 days compared with aspirin alone (1.8 versus 4.8 percent, $p = .001$).[72] (Note that this is a significant reduction compared with aspirin alone, whereas the meta-analysis for unfractionated heparin had a risk reduction of 33 percent and $p = .06$.)[71] Beyond 6 days, dalteparin was continued versus placebo and, at 40 days, the composite of death, MI, or need revascularization was significantly reduced (2.2 versus 5.7 percent, $p < 0.001$).[72] A subsequent trial of patients with unstable angina for less than 72 h, the Fragmin in Unstable Coronary Artery Disease (FRIC) trial, found no difference in clinical outcomes between intravenous heparin and dalteparin, indicating it was a suitable alternative to unfractionated heparin, although it was not shown to be superior in this trial.[376]

ENOXAPARIN

The Evaluation of the Safety and Efficacy of Subcutaneous Enoxaparin in Non-Q Wave Coronary Events (ESSENCE) trial compared enoxaparin (a LMW heparin with 3.8:1 factor Xa-thrombin inhibition ratio) with intravenous heparin in 3000 patients with unstable angina and non-Q-wave MI. A 2 to 3 day course of enoxaparin was superior to unfractionated heparin with regard to the primary end point, the occurrence of

death, MI, or recurrent ischemia at 14 days (16.6 versus 19.8 percent, $p = .019$).[73] The rates of this end point at 30 days were 19.8 versus 23.3 percent ($p = .016$).[73] Death or MI to 30 days also favored enoxaparin (6.2 versus 7.7 percent, $p = .08$).

Interestingly, in this double-blind trial, the rates of catheterization (43 versus 46 percent, $p = .08$ for enoxaparin compared with heparin) and PCI (13 versus 17 percent, respectively, $p = .001$) were lower in patients treated with enoxaparin. A subsequent cost-effectiveness analysis found that there was a minimal increase in the cost for the drug (enoxaparin compared with unfractionated heparin with APTT measurements) ($75)-but with lower rates of catheterization and revascularization, treatment with enoxaparin led to a *savings* of $1172 per patient treated. Thus, both improved outcomes, and lower costs were observed with enoxaparin compared with unfractionated heparin.

TIMI-11 Trials These also studied enoxaparin in unstable angina and non-Q-wave MI. In TIMI-11A, the first goal was to determine the appropriate dose of enoxaparin-whether to use a dose that previously had been shown to be effective in venous thrombosis (1.0 mg/kg subcutaneously twice daily) or whether higher doses would be beneficial in arterial thrombosis. In TIMI-11A, a higher dose (1.25 mg/kg) was found to have an unacceptably high rate of major hemorrhage, 6.5 percent to 14 days, as compared with a rate of 1.9 percent for patients treated with 1.0 mg/kg.[377] There was no difference in the rate of recurrent ischemic events between the two doses. Thus, the dose of 1.0 mg/kg appeared to be appropriate and was used in the TIMI-11B trial.

The TIMI-11B trial studied high-risk patients with unstable angina and non-ST-elevation MI. They were required to have ST deviation or positive cardiac serum markers (CK-MB or troponin) to be enrolled. TIMI-11B compared intravenous unfractionated heparin with enoxaparin (1.0 mg/kg subcutaneously twice daily in hospital and a fixed dose b.i.d. as an outpatient) for a total of 43 days. Death, MI, or severe recurrent ischemia requiring urgent revascularization through day 14 occurred in 16.6 percent of patients treated with heparin and in 14.2 percent of patients treated with enoxaparin ($p = .03$), a 15 percent relative risk reduction.[75] The rate of the primary end point to 43 days was 19.6 percent for unfractionated heparin and 17.3 percent for enoxaparin ($p = .049$).[75] Parallel reductions in death and MI were also observed.

A meta-analysis of the TIMI-11B and ESSENCE trials showed that, at 43 days, enoxaparin reduced the rate of death, MI, or urgent revascularization from 18.7 to 15.6 percent ($p = .0006$). Death or MI at 43 days was reduced from 8.6 to 7.1 percent ($p = .02$) (Fig. 44-19).[74] Thus, enoxaparin has been shown in two large randomized trials to be superior to unfractionated heparin for the treatment of unstable angina and non-ST-elevation MI. The FDA has approved enoxaparin for the treatment of patients with unstable angina and non-ST-elevation MI.

LMW HEPARIN IN ANGIOPLASTY, STENTS, AND ACUTE MYOCARDIAL INFARCTION

There is emerging experience with LMW heparin in angioplasty. One study found that LMW heparin did not reduce restenosis.[378] However, LMW heparin may play a role in preventing thrombotic complications after complicated angioplasty. A recent nonrandomized experience of patients with suboptimal angioplasty or stent results treated some patients with LMW heparin for 4 weeks and others with standard care (aspirin). They found a reduced rate (1.5 versus 8.2 percent, $p < 0.05$) of death or recurrent MI during follow-up.[379] Thus, LMW heparin appears to have great promise and further randomized trials are under way.

Similarly, trials of LMW heparin in acute MI treated with thrombolytic therapy are under way.[380,381] In the setting of ST-elevation MI treated with thrombolytic therapy, one recent study found a significant reduction in the rate of death, MI, or readmission for an acute coronary syndrome.[380] A total of 300 patients treated with thrombolysis (predominantly streptokinase, but also anistreplase and t-PA) were randomized to intravenous unfractionated heparin (5000-U bolus and 1250 U/h titrated to an APTT of 2 to 2.5 times control) or enoxaparin (40-mg intravenous bolus, followed by 40 mg subcutaneously every 8 h) for 4 days. The rate of the composite end point at 3 months was 36.4 percent for heparin and 25.5 percent for enoxaparin ($p = .04$).[380] It appeared that rebound was reduced by enoxaparin, with the rate of reinfarction

from days 4 to 6 of 6.6 percent for heparin and 2.2 percent for enoxaparin (p = .05).[380]

In a second recent study, dalteparin was compared with placebo in streptokinase-treated patients. TIMI grade 3 flow 20 to 28 h later tended to be higher in patients treated with dalteparin (68 versus 51 percent, p = .10), and the number of ischemic episodes on continuous ECG monitoring was lower (16 versus 38 percent, p = .04).[381]

Most recently, Heparin Aspirin Reinfarction (HART-II) trial compared enoxaparin with unfractionated heparin as adjuncts to t-PA and aspirin for patients with acute MI.[382] There was a strong trend toward improved early TIMI grade 3 flow with enoxaparin (53 versus 48 percent for unfractionated heparin, p = .06). There was an even greater effect on reocclusion (5.9 versus 9.8 percent).[382] Thus, LWM heparins appear to be beneficial in these pilot trials with thrombolysis, and larger studies are underway to try to confirm these results.

Direct Thrombin Inhibitors

These have also undergone extensive evaluation in conjunction with thrombolytic therapy. The prototypic agent is hirudin, a 65-amino-acid polypeptide that is derived from the leech *Hirudo medicinalis*, which acts as a potent and selective inhibitor of thrombin.[383] Hirudin selectively binds thrombin in a 1:1 fashion at two sites: (1) the carboxy terminus of hirudin binds to the substrate recognition site, the domain of thrombin that recognizes fibrinogen[384] or the platelet;[385] and (2) the amino terminus of hirudin binds to the catalytic site of thrombin.[384] Hirudin does not inhibit other enzymes in the coagulation or fibrinolytic pathways such as factor Xa, IX, kallikrein, activated protein C, plasmin, or tissue plasminogen activator.[383] Hirudin does not bind covalently to thrombin; however, the dissociation rate is extremely slow, making hirudin an essentially irreversible inhibitor of thrombin.[383,386]

In patients with established coronary artery disease with normal renal function (serum creatinine, 1.0 ± 0.2 mg/dL), the plasma half-life of hirudin was found to be 2 to 3 h,[387] in agreement with the half-life of the effect of hirudin on the APTT of about 2 to 3 h. Hirudin is produced in yeast by recombinant DNA technology. Several different hirudin preparations are available, including desirudin[352,354,388] and lepirudin.[389]

Other analogs are also available, including bivaluridin (Hirulog),[390-392] argatroban,[393] efegatran,[394] and inogatran.[395] Hirulog contains three domains: the 12-amino-acid carboxy terminus derived from hirudin; a four-amino-acid sequence, D-Phe-Pro-Arg-Pro, which binds to the catalytic site of thrombin; and a linker region with the optimal length to allow binding of both inhibitory sites.[390] The hirulog-thrombin complex is transient, as thrombin can slowly cleave the Pro-Arg bond in the N-terminal extension. This metabolic cleavage contributes to its half-life on the APTT of about 40 min. Only 20 percent of hirulog is excreted in the urine, indicating an extensive hepatic catabolism or proteolysis at other sites. Argatroban is an arginine derivative that binds to thrombin with intermediate affinity.

Direct thrombin inhibitors have been shown to inhibit all of the major actions of thrombin, including thrombin-induced generation of fibrin and thrombin-induced platelet activation, as well as thrombin's autocatalytic reaction.[383,396] Potential advantages of hirudin over heparin are that hirudin can inhibit clot-bound thrombin,[275] it is not inhibited by activated platelets,[397] and it does not require a cofactor and thus may provide a more stable anticoagulant response.[396]

ADJUNCT TO THROMBOLYTIC THERAPY

The effects of desirudin in the setting of thrombolysis were tested in TIMI-5, 6, and 9 and GUSTO-II.[352,354,388,398] Hirudin provided a more stable APTT, within the target range almost twice as frequently. No episodes of thrombocytopenia were reported for hirudin.

In TIMI-5, a lower rate of recurrent MI was observed (4.3 versus 11.9 percent, for hirudin and heparin, respectively, p = .03), as well as a trend toward lower reocclusion (1.6 versus 6.7 percent, p = .07).[388] In the

phase III TIMI-9B trial, a similar trend in lower reinfarction was observed in hospital (2.3 versus 3.4 percent, $p = .07$), but no difference was observed in the primary end point (death, MI, or severe congestive heart failure/shock) at 30 days (12.9 percent for hirudin and 11.9 percent for heparin, p = NS).[352] Similarly, death or MI was not different between the two anticoagulants (9.7 versus 9.5 percent, p = NS).[352] Hirudin was tested in over 12,000 patients across the full spectrum of acute coronary syndromes in the GUSTO-IIb trial. There was a reduction in reinfarction (5.4 versus 6.3 percent for heparin, $p = .04$) but only a trend toward reduction in death or MI at 30 days (8.9 versus 9.8 percent, $p = .06$).[354] In patients with ST-elevation MI, death or MI was slightly lower (9.9 versus 11.3 percent, $p = .13$). An intriguing trend to benefit was seen in streptokinase-treated patients in GUSTO-II,[399] but this was not observed in TIMI-9B.[352]

In the HIT-III trial, excess ICH was observed with lepirudin (3.4 versus 0 percent). In the subsequent HIT-4 trial, involving 1208 patients and using a lower dose of lepirudin, TIMI flow grade 3 was observed in 40.7 percent in the lepirudin and in 33.5 percent in the heparin group ($p = .16$), No differences were seen between lepirudin and heparin in the rates of hemorrhagic stroke (0.2 versus 0.3 percent), reinfarction (4.6 versus 5.1 percent), or mortality (6.8 versus 6.4 percent) at 30 days. Thus, lepirudin in conjunction with streptokinase did not significantly improve reperfusion or clinical outcomes in this study.

Angiographic trials with other direct thrombin inhibitors in conjunction with thrombolytic therapy have also been conducted. In a pilot study and the Hirulog Early Rerfusion/Occlusion (HERO) trial, a trend toward improved early (90 to 120 min) TIMI grade 3 flow was observed with the higher dose of Hirulog as compared with heparin in patients receiving streptokinase.[391,392] Testing with other agents found modest or no improvements compared with heparin.[393,394,400]

UNSTABLE ANGINA

The hirudin desirudin was tested in the GUSTO-IIb trial involving 12,142 patients with unstable angina/non-ST-elevation MI and ST-elevation MI. In the entire cohort, the 30-day rate of death or MI tended to be lower (8.9 versus 9.8 percent, $p = .06$),[354] with no difference in mortality and a modest reduction in reinfarction (5.4 versus 6.3 percent for heparin, $p = .04$). In the 8011 patients with unstable angina or non-ST-elevation MI, the rate of death or MI was not significantly reduced at 30 days (8.3 versus 9.1 percent, $p = .22$).[354]

Lepirudin was compared with heparin in the Organisation to Assess Strategies for Ischemic Syndromes 2 (OASIS-2) trial,[389] and there was a strong trend toward reduction in cardiovascular death or MI at 7 days (3.6 versus 4.2 percent, respectively, $p = .08$). Major bleeding requiring transfusion was infrequent but more frequent with lepirudin (1.2 versus 0.7 percent for heparin, $p = .01$). The authors performed a meta-analysis of all the hirudin trials and observed a modest 10 percent benefit favoring hirudin, although this was not statistically significant for patients with unstable angina.

Other synthetic direct thrombin inhibitors have also been tested [e.g., argatroban and bivaluridin (Hirulog)], and again only modest or no improvements were observed compared with heparin,[400,401] although lower rates of bleeding have been observed with bivalirudin.[401] The direct thrombin inhibitors have been observed to provide a very stable level of anticoagulation, as measured by APTT,[354,402,403] and no episodes of thrombocytopenia were reported for the hirudin class. Of note, lepirudin is approved by the FDA for use as an anticoagulant in patients with HIT and associated thromboembolic disease.

USE DURING CORONARY ANGIOPLASTY

Following a pilot trial of hirudin in low-risk patients undergoing angioplasty, which showed a reduction in early abrupt closure,[404] a larger randomized, double-blind study compared hirudin (40-mg bolus followed by 0.2 mg/kg per hour) with heparin in the prevention of restenosis after coronary angioplasty.[405] The primary end point was event-free survival (freedom from cardiac death, MI, coronary bypass surgery, bailout procedure, repeat percutaneous transluminal coronary angioplasty, or elective stent placement). At 7 months, event-free survival was 67.3 percent in the group receiving heparin, 63.5 percent in the group

receiving intravenous hirudin, and 68.0 percent in the group receiving both intravenous and subcutaneous hirudin (p = .61). However, the administration of hirudin was associated with a significant reduction in early cardiac events, which occurred in 11.0, 7.9, and 5.6 percent of patients in the respective groups. Although significantly fewer early cardiac events occurred with hirudin than with heparin, hirudin had no apparent benefit with longer-term follow-up. Two retrospective analyses have recently shown that patients with unstable angina, treated with hirudin, and who undergo PCI on the study drug, have a dramatic reduction in death or MI. In the OASIS-2 trial, there was a 60 percent reduction in death or MI in those undergoing PCI compared with 5 percent in those who did not.[406] Thus, these data are consistent with those with GP IIb/IIIa inhibitors, which show a benefit both before and after the procedure.[407]

The direct thrombin inhibitor bivalirudin (Hirulog) was studied in a double-blind, randomized trial of over 4000 patients with unstable angina or recent MI undergoing angioplasty. Patients were assigned to receive either heparin or bivalirudin immediately before angioplasty. Overall, bivalirudin did not significantly reduce the incidence of the primary end point (death, MI, abrupt vessel closure, or rapid clinical deterioration of cardiac origin: 11.4 versus 12.2 percent for heparin). In the prospectively stratified subgroup of 704 patients with postinfarction angina, however, bivalirudin therapy did lead to a significant reduction in the primary end point (9.1 versus 14.2 percent, p = .04). In addition, bivalirudin was associated with a lower incidence of bleeding (3.8 versus 9.8 percent, p 0.001). No differences in recurrent ischemic events were seen at 6 months. Thus, bivalirudin appeared to be as effective as heparin but with a better safety profile during angioplasty. This study pre-dated coronary stenting and GP IIb/IIIa inhibitors, so more information is needed to assess its potential role. The FDA recently approved bivalirudin for use during angioplasty.

Thus, to date, the direct thrombin inhibitors have not produced a dramatic improvement in clinical outcome as adjuncts to thrombolytic therapy. The benefits in unstable angina have been modest and almost reached statistical significance on the primary end point in one trial and in angioplasty one agent is approved for use. There are several large ongoing trials evaluating the direct thrombin inhibitor bivalirudin HERO-2 is comparing bivalirudin with heparin as an adjunctive agent to streptokinase, and another is comparing bivalirudin plus bailout abciximab with heparin plus abciximab.

Warfarin/Oral Anticoagulants

Warfarin sodium and related coumarin congeners are effective antithrombotic compounds that differ in speed in the inhibition of vitamin K-2,3-epoxide within hepatic chromosomes. These compounds depress the synthesis of four vitamin K-dependent procoagulants (factors II, VII, IX, and X) and of two natural inhibitor proteins C and S (Fig. 44-20). The plasma concentration of these proteins will decrease in accord with their half-lives. The coagulation components with the shortest half-lives are the procoagulant factor VII and the endogenous anticoagulant protein C. This may cause a frank imbalance between procoagulants and anticoagulants at the start of treatment and lead to thrombosis of skin capillaries and venules with cutaneous necrosis.[408]

MONITORING OF WARFARIN TREATMENT

The intensity of the effect of warfarin on the synthesis of coagulation factors differs among patients; moreover, in the same individual, it may, over time, vary considerably. This explains the need for close monitoring by having daily blood tests in the first week of treatment with warfarin. The test used is the *prothrombin time*, a term that leads to confusion because the assay depends in fact on the global activity of five coagulation factors (prothrombin and factors V, VII, IX, and X). Among the six factors whose synthesis is inhibited by coumarin derivatives, three (prothrombin and factors VII and X) are effectively measured by this test, but not factor IX and the anticoagulant proteins C and S. On the other hand, the prothrombin time is also sensitive to factor V, a coagulation protein independent of vitamin K.

To perform the prothrombin time, a tissue extract (thromboplastin) and calcium are added to citrated plasma and the time to fibrin formation is measured. Commercial thromboplastin reagents extracted by different methods from various organs and species vary extensively in their sensitivity to reductions in levels of vitamin K-dependent factors. To standardize determinations of prothrombin time and thus allow direct comparison of results obtained with different thromboplastins, the INR is recommended.[409]

At the start of warfarin treatment, the prothrombin time is first prolonged by factor VII depletion because factor VII has a half-life much shorter than that of the other vitamin K-dependent coagulation factors (prothrombin and factors IX and X). Thus, in the beginning of warfarin treatment, the prothrombin time is prolonged, while the intrinsic and common coagulation pathways are still uninfluenced. This explains why, in switching from heparin to warfarin, heparin should be continued unabated for at least 1 day after the prothrombin time (INR) has reached therapeutic values. Also, during long-term warfarin therapy, prothrombin times should be checked regularly, as many drugs and foods can enhance or decrease the warfarin effect. Certain intercurrent diseases (liver insufficiency, heart failure, and hyperthyroidism) may also modify warfarin dose requirements.

Bleeding is the most important side effect, and the risk may vary from patient to patient, depending on the presence of comorbid conditions (hypertension, malignancy, older age, recent surgery) and the intensity of anticoagulation. Patients with intensive anticoagulation (INR = 2.5 to 4) have, during the first 3 months, a risk of clinically important bleeding over two times greater (14 versus 6 percent) than those with less intensive anticoagulation (INR = 2.0 to 2.5).[410] On average, the annual overall risk of bleeding is 6 percent, with the incidence of major and fatal bleeding estimated to be 2 and 0.8 percent, respectively.

A rare, nonhemorrhagic side effect of warfarin is coumarin-induced skin necrosis, an unexplained complication that occurs between days 3 and 8 of therapy. The rapid decline in protein C level is postulated to play a role in the obscure pathogenesis of thrombosis of skin venules and capillaries within the subcutaneous fat, usually in the lower part of the body. Coumarin drugs readily cross the placenta and may be teratogenic, particularly during the first trimester of pregnancy. In conclusion, vitamin K antagonists are effective antithrombotic drugs with a narrow risk-benefit ratio that require regular monitoring and a disciplined patient (Table 44-9). Their main virtues are oral administration and low cost.

Table 44-9: Drawbacks of Coumarin Drugs and Profile of an Ideal Antithrombotic Drug

Delayed action
Need for blood monitoring prothrombin time (PT)
PT test does not fully reflect the drug effect
Interaction with many commonly used drugs leading to:
Potentiation of anticoagulation
Decreasing anticoagulation level
Sometimes modifying the activity of the other inter- acting drug
Anticoagulation level influenced by diet
Annual risk of bleeding: Total 6%
Major 2%
Fatal 0.8%
Narrow benefit-to-risk ratio
Embryotoxicity during first trimester of pregnancy

CLINICAL STUDIES

Anticoagulant therapy with warfarin has been shown to be beneficial following MI. In pooled data from seven randomized trials between 1964 and 1980, oral anticoagulant therapy over a 1- to 6-year period

reduced the rate of death or MI by 20 percent.[411] Subsequently, there have been three large studies evaluating warfarin after MI (both ST-elevation MI and non-ST-elevation MI). In Warfarin Reinfarction Study (WARIS), mortality was reduced by 24 percent (p = .027) and reinfarction was reduced by 34 percent. More recently, the Anticoagulants in the Secondary Prevention of Events in Coronary Thrombosis (ASPECT) trial demonstrated a similar reduction in reinfarction (53 percent benefit of warfarin compared with placebo) in patients following acute MI.[412] Thus, warfarin monotherapy appears to be at least as effective as aspirin after MI.

Two clinical trials compared warfarin therapy with antiplatelet therapy in secondary prevention of MI. In the German Austrian Myocardial Infarction Study (GAMIS), 946 patients 38 to 42 days after acute MI were randomized to open-label phenprocoumon (target INR = 2.5 to 5.0), aspirin 1.5 g/day, or placebo.[241,413] No difference was observed between groups in mortality or reinfarction. The French Enquete de Prevention Secondaire de l'Infarctus de Myocarde (EPSIM) study[243,414] revealed no difference in death or reinfarction in patients receiving either oral anticoagulants or aspirin, but there were 54 percent more patients with gastrointestinal events with aspirin and four times more severe hemorrhagic events with warfarin. In the Aspirin Versus Coumadin in the Prevention of Reocclusion and Recurrent Ischemia After Successful Thrombolysis (APRICOT) trial, 300 patients were randomized to either 325 mg of aspirin per day or heparin followed by warfarin (target INR = 2.8 to 4.0) after an initial angiogram less than 48 h after acute MI revealed a patent infarct-related artery.[414] At 3 months, there was no significant difference in reocclusion rates among the warfarin, aspirin, and placebo arms. Aspirin significantly reduced reinfarction compared with placebo but not with warfarin. The mortality rates did not differ between the groups.

The Coumadin Aspirin Reinfarction Study (CARS) evaluated the combination of aspirin (80 mg) and fixed-dose warfarin (1 or 3 mg, not adjusted to a prothrombin time) compared with aspirin alone (160 mg). No benefit was observed with the combinations of fixed-dose warfarin plus aspirin with regard to recurrent MI, cardiac death, or nonfatal ischemic stroke.[415] More recently, a trial involving men at risk for ischemic heart disease, using a slightly higher dose of warfarin (4.1 mg on average titrated to an INR of 1.5), found a significant reduction compared with placebo in coronary death or MI with the combination of warfarin and aspirin 75 mg daily.[416] In this trial, there was an increase in hemorrhagic strokes among patients treated with the combination (0.9 versus 0.1 percent for warfarin alone, 0.2 percent for aspirin alone, and 0 percent for placebo; p = .009).[416] The Combination Hemotherapy and Mortality Prevention (CHAMP) study randomized patients to receive either 160 mg/day of aspirin or 80 mg of aspirin plus coumadin to achieve an INR of 1.5 to 2.5. Results of this study found no difference in mortality or recurrent events with the addition of warfarin to aspirin.[417] Major bleeding was more common in the combination group: 1.25/100 patient years compared with 0.69/100 patient years for aspirin alone. Preliminary results of two studies (APRICOT II and ASPECT II) have shown benefit with the combination of coumadin (higher INR than in previous studies) plus aspirin as compared to aspirin alone (Verhevgt et al., European Congress of Cardiology, Amsterdam, 2000).[418]

There are several other areas for benefit or potential benefit with warfarin therapy. First, warfarin is superior to aspirin in prevention of systemic emboli in patients with atrial fibrillation.[411,419] In addition, beneficial effects in reducing systemic emboli have also been observed in patients after MI with documented left ventricular dysfunction.[420] Thus, in selected patients at risk for systemic emboli, warfarin affords a second beneficial effect. Thus, at present, warfarin is a suitable alternative to aspirin following MI, and is indicated if there is a risk for systemic embolization.

Chapter 44: THROMBOGENESIS, ANTITHROMBOTIC, AND THROMBOLYTIC THERAPY

THROMBOLYTIC DRUGS

All thrombolytic drugs are plasminogen activators, and, as indicated in Fig. 44-21, some are natural activators endogenous to the human fibrinolytic system and others are not.

Streptokinase

Thus is a nonenzyme protein produced by several strains of hemolytic streptococci: it consists of a single polypeptide chain of 414 amino acids with a molecular weight of about 50,000.[421] Streptokinase cannot directly cleave peptide bonds, but it activates plasminogen to plasmin indirectly, following a three-step mechanism.[421] In the first step, streptokinase forms an equimolar complex with plasminogen. This complex undergoes a conformational change, resulting in the exposure of an active site in the plasminogen moiety. In the second step, this active site catalyzes the activation of plasminogen to plasmin. In a third step, plasminogen-streptokinase molecules are converted to plasmin-streptokinase complexes.[422] The active-site residues in the plasmin-streptokinase complex are the same as those in the plasmin molecule, but plasmin is unable to activate plasminogen, whereas the plasmin(ogen)-streptokinase complex is not inhibited by α_2-antiplasmin.

Most individuals have measurable circulating streptokinase-neutralizing antibodies, which may result from previous infections with B-hemolytic streptococci. Therefore, during thrombolytic therapy, sufficient streptokinase must be infused to neutralize these antibodies. A few days after streptokinase administration, the antistreptokinase titer rises rapidly to 50 to 100 times the preinfusion value and remains high for 4 to 6 months, during which renewed treatment with streptokinase is impracticable.[423]

Clinical trials have shown intravenous streptokinase, administered as an infusion of 1.5 million units over 1 h, leads to a significant reduction in mortality rate. In the GISSI-I trial, for patients with acute MI within 12 h, there was a 19 percent reduction in mortality rate.[268] In ISIS-2, there was a 25 percent reduction in mortality rate.[180] In the ISIS-3 trial, streptokinase was found to have an identical mortality rate as the 3-h regimen of t-PA with either subcutaneous or no heparin.[317] In the GUSTO-I trial, however, streptokinase was inferior to t-PA when the latter was administered as an accelerated 90-min bolus and infusion with concomitant intravenous heparin[323] (see also Chap. 42).

Anistreplase (Anisoylated Plasminogen-Streptokinase Complex)

APSAC (anistreplase) was constructed with the aim of controlling the enzymatic activity of the plasmin(ogen)-streptokinase complex by a specific reversible chemical protection of its catalytic center (i.e., by titration with a *p*-anisoyl group).[148,424] Anistreplase, which is an equimolar noncovalent complex between human Lys-plasminogen and streptokinase, has a catalytic center located in the carboxy-terminal region of the molecule, whereas the lysine-binding sites are found within the amino-terminal region of plasminogen. Reversible acylation of the catalytic center would thus not affect the weak fibrin-binding capacity of Lys-plasminogen in the complex. The plasmin(ogen)-streptokinase complex is an efficient activator of plasminogen. Deacylation of anistreplase uncovers the catalytic center, which converts plasminogen to plasmin. Deacylation of anistreplase does, however, occur both in the circulation and at the fibrin surface, and the fibrin specificity of thrombolysis with anistreplase is only marginal at best. A plasma half-life of 70 min was found for anistreplase, compared with 25 min for the plasminogen-streptokinase complex formed in vivo after administration of streptokinase.[425] Patients with high streptokinase antibodies do not respond to anistreplase, and anistreplase causes a marked increase in the streptokinase antibody titer within 2 to 3 weeks, which persists for months.

Clinical studies have shown anistreplase to reduce mortality compared with placebo[426] and to have equivalent mortality to streptokinase and the 3-h regimen of t-PA.[317] In the TIMI-4 trial, TIMI grade 3 flow at 60 and 90 min was inferior to accelerated t-PA, as were clinical outcomes.[427] Because it is a bolus drug, administered as 30 U over 2 to 5 min), anistreplase was used in several trials of prehospital thrombolysis, which showed benefit compared with hospital-based treatment.[428,429] Due to its high cost (approaching that of t-PA) yet inferior patency profile, its use has waned greatly.

UROKINASE

Two-chain urokinase-type plasminogen activator (tcu-PA), a trypsin-like serine proteinase composed of two polypeptide chains (20,000 and 34,000 Da), has been isolated from human urine[430] and from cultured human embryonic kidney cells.[431] The tcu-PA activates plasminogen directly following Michaelis-Menten kinetics but has no specific affinity for fibrin and activates fibrin-bound and circulating plasminogen relatively indiscriminantly. Extensive plasminogen activation and depletion of α_2-antiplasmin may occur following treatment of thromboembolic diseases with tcu-PA, leading to degradation of several plasma proteins, including fibrinogen, factor V, and factor VIII.

PRO-UROKINASE

Single-chain urokinase-type plasminogen activator (scu-PA, pro-urokinase) is a naturally occurring human protein first isolated from natural sources and then produced through recombinant DNA technology.[432] The human gene responsible for its synthesis is located on chromosome 10 and is about 6.4 kb long, organized in 11 exons; it gives rise to a 2.5-kb-long messenger RNA, which transcribes a single-chain glycosylated polypeptide. Evidence for the signal transduction pathways involved in regulation of the urokinase gene has to date demonstrated three mechanisms, which are dependent respectively on activation of c-AMP protein kinase, protein kinase C, and an as yet uncharacterized protein kinase.[433]

The single-chain protein is synthesized principally by renal and vascular endothelial cells but also by a variety of cultured normal, transformed, and malignant cell types. The protein scu-PA has also been expressed by gene-cloning techniques in *E. coli* bacteria[154,434] and mouse hybridoma cells.

The glycosylated natural scu-PA is a single-chain glycoprotein with a molecular weight of 54,000 Da and containing 411 amino acid residues. The N-terminal domain has a homology with the growth factor domain of other proteins, followed by a kringle domain, homologous to plasminogen, t-PA, and other proteins involved in coagulation.[435] However, the single-disulfide-bonded kringle domain of scu-PA does not contain a lysine-binding site, and it does not confer fibrin-binding properties to the enzyme. The single glycosylation site of the glycoprotein is located at asparagine 302. The molecule expressed by *E. coli* lacks the glycosyl group, which reduces the molecular weight to 47,000 Da.[434] The scu-PA is the native zymogenic precursor of urokinase. Limited hydrolysis by plasmin or kallikrein of the Lys^{158}-Ile^{159} peptide bond converts the molecule to tcu-PA (urokinase), which is held together by one disulfide bond essential for the thrombolytic activity[436] (Fig. 44-22). A fully active tcu-PA derivative is obtained after additional proteolysis at position Lys^{135}-Lys^{136}. In purified systems, scu-PA has some intrinsic plasminogen-activating potential, but it is 1 percent of that of tcu-PA. Conversion of scu-PA to tcu-PA in the vicinity of a fibrin clot apparently constitutes a significant positive feedback mechanism for clot lysis in human plasma in vitro. Specific hydrolysis of the Glu^{143}-Leu^{144} peptide bond in scu-PA yields a LMW scu-PA of 32,000 (scu-PA-32k). Thrombin, on the other hand, cleaves the Arg^{156}-Phe^{157} peptide bond in scu-PA, resulting in an inactive double-chain molecule.

Tissue-Type Plasminogen Activator

Native t-PA is a serine proteinase with a molecular weight of about 70,000, composed of one polypeptide chain containing 527 amino acids with serine as the amino-terminal amino acid.[142,157] t-PA is converted by plasmin to a two-chain form by hydrolysis of the Arg^{275}-Ile^{276} peptide bond. The two-chain form is held together by one interchain disulfide bond. t-PA for clinical use is presently produced by recombinant DNA

technology [Activase (Genentech) or Actilyse (Boehringer Ingelheim)] and consists mainly of the single-chain form.

The NH_2-terminal region of t-PA is composed of four domains with homologies to other proteins: residues 4 to 50 (F domain) are homologous to the *finger domains* in fibronectin, residues 50 to 87 (E domain) are homologous to human epidermal growth factor, and two regions comprising residues 87 to 176 and 176 to 262 (K1 and K2 domains) are both homologous to the five "kringle" loop structures of plasminogen (Fig. 44-22). The region comprising residues 276 to 527 is homologous to that of other serine proteinases and contains the catalytic site, which is composed of His^{322}, Asp^{371}, and Ser^{478}. t-PA has a specific affinity for fibrin. The structures involved in the fibrin binding of t-PA are fully contained within the A (heavy) chain. Evidence obtained with deletion mutants suggests that binding of t-PA to fibrin is mediated both via the finger domain and via the second kringle region. A lysine-binding site is involved in the interaction of K2 domain with fibrin but not in the interaction of the finger domain with fibrin. The structures required for the enzymatic activity of t-PA are fully contained within the B chain.

The activation of plasminogen by t-PA, both in the presence and in the absence of fibrin, follows Michaelis-Menten kinetics.[166] There is a consensus that the presence of fibrin enhances the efficiency of plasminogen activation by t-PA by 2 to 3 orders of magnitude.[166] Fibrin provides a surface to which t-PA and plasminogen adsorb in a sequential and ordered way, yielding a cyclic ternary complex. Fibrin essentially increases the local plasminogen concentration by creating an additional interaction between t-PA and its substrate. The high affinity of t-PA for plasminogen in the presence of fibrin thus allows efficient activation on the fibrin clot, while no efficient plasminogen activation by t-PA occurs in plasma. Plasmin formed on the fibrin surface has both its lysine-binding sites and active site occupied and is thus only slowly inactivated by α_2-antiplasmin (a half-life of about 10 to 100 s); in contrast, free plasmin, when formed, is rapidly inhibited by α_2-antiplasmin (a half-life of about 0.1 s). The fibrinolytic process thus seems to be triggered by and confined to fibrin.

Several mutants of recombinant tissue-type plasminogen activator (rt-PA) have been constructed with interesting properties, including slower clearance from the circulation, more selective binding to fibrin, stronger stimulation by fibrin, and resistance to plasma protease inhibitors (see below).

Clinical Studies

After a series of patients were treated with t-PA,[437] t-PA was compared with intravenous streptokinase in the TIMI-1 trial, in which 290 patients with acute MI underwent initial diagnostic coronary angiography and then were treated with either streptokinase or t-PA in addition to intravenous heparin. The primary end point, reperfusion of initially occluded coronary arteries after 90 min, was achieved in 62 percent of t-PA-treated patients compared with 31 percent of streptokinase-treated patients ($p < 0.001$).[3,438] The patency rate at 90 min independent of findings on baseline arteriogram was 70 percent for t-PA and 43 percent for streptokinase ($p < 0.001$). Nearly identical results were observed in the European study.[439] t-PA was studied in numerous angiographic trials, as reviewed by Granger and coworkers, who observed that the 3-h dosing regimen of t-PA had superior patency and TIMI grade 3 flow,[3] at both 60 and 90 min, compared with streptokinase or anistreplase.[440] Neuhaus and colleagues developed the *accelerated* 90-min dosing regimen,[441] which was found to achieve even higher rates of early reperfusion when compared with the 3-h t-PA dosing regimen,[442] anisteplase,[427,443] or streptokinase.[270]

Given the importance of rapid reperfusion, one would expect that a more aggressive thrombolytic regimen that achieves a higher rate of early infarct-related patency would be associated with a lower mortality rate. This notion was called into question following the results of GISSI-2/International Study[315,316] and ISIS-3[317] (Table 44-10).

Table 44-10: Results from GISSI-2/International Study and ISIS-3

	Streptokinase	t-PA (3-h Regimen)	Anistreplase
GISSI-2/International		10,372	-
No. of patients	10,396		
Mortality (%)	8.4	8.9	-
Total stroke	1.0	1.6	-
ICH	0.4	0.6	-
ISIS-3		13,746	13,773
No. of patients	13,780		
35-Day mortality.(%)	10.6	10.3	10.5
Total stroke	1.04	1.39	1.26
ICH	0.2	0.7	0.6

ABBREVIATIONS: ICH = intracranial hemorrhage; t-PA = tissue-type plasminogen activator.

GUSTO-I Trial

In contrast, in the GUSTO-I trial, the accelerated dosing of t-PA was used in conjunction with intravenousheparin. As shown in Table 44-11, the mortality rate at 30 days was significantly lower in the front-loaded t-PA arm as compared with each of the three other arms.[323] The improvement in mortality was already seen after only 24 h, with t-PA-treated patients having a significantly lower mortality rate. In addition, other major complications were decreased by t-PA. There was less cardiogenic shock, congestive heart failure, and ventricular arrhythmia. Higher patency rate was seen with t-PA (Table 44-12).

Table 44-11: Results from the GUSTO Trial

Outcome	SK and sq Heparin	SK and IV Heparin	Front-Loaded t-PA and IV Heparin	t-PA and SK and IV Heparin	*p* Value t-PA vs. Both SK Regimens
No. of patients	9796	10,377	10,344	10,328	
30-Day mortality (%)	7.2	7.4	6.3	7.0	0.005
Net clinical benefit (death or disabling stroke) (%)	7.7	7.9	6.9	7.6	0.006
24-h Mortality (%)	2.8	2.9	2.3	2.8	0.005
Intracranial hemorrhage	0.5	0.5	0.7	0.9	0.03
Congestive heart failure	17.5	16.8	15.2	16.8	<0.001
Cardiogenic shock	6.9	6.3	5.1	6.1	<0.001

ABBREVIATIONS: IV = intravenous; SK = streptokinase; t-PA = tissue-type plasminogen activator; sq = subcutaneous.
SOURCE: Data from the GUSTO Investigators.[270323]

Table 44-12: GUSTO Angiographic Substudy

No. of patients	293	283	292	299	
Infarct-related artery patency (TIMI grade 2 or 3 flow) at 90 min (%)	54	60	81	73	<0.001
TIMI grade 3 flow at 90 min (%)	29	32	54	38	<0.001

ICH is the dreaded complication of thrombolysis, although it is fortunately a rare complication despite aggressive regimens of thrombolysis, aspirin, and heparin. For each of these streptokinase arms, 0.5 percent of patients suffered an ICH as compared with 0.7 percent of patients treated with front-loaded t-PA and 0.9 percent of patients treated with combination thrombolytic therapy.[323] To put their results in full perspective, the GUSTO investigators developed the concept of *net clinical benefit*, i.e., the occurrence of either death or a disabling stroke. When comparing the net clinical benefit between the four regimens, t-PA had a significantly lower rate compared with the other three regimens.

The explanation of the benefit of t-PA in the GUSTO and TIMI-4 trials and the lack of benefit in GISSI-2 and ISIS-3 is based on two factors: the t-PA regimen and the heparin dosing. The use of the front-loaded t-PA regimen achieves a higher rate of early patency compared with the older 3-h regimen.[440] The use of early intravenous heparin has been shown to improve late infarct-related artery patency (Table 44-12). In contrast, the GISSI-2 and ISIS-3 trials used the slower infusion regimen of t-PA and either no heparin or delayed, subcutaneous heparin, which does not elevate APTT until approximately 24 h after the start of treatment. Because the initial 24 h hold the highest risk of reocclusion of an open infarct-related artery (which is associated with a threefold increase in mortality), the subcutaneous heparin regimen is inadequate at preventing this important complication.

Double-Bolus Tissue-Type Plasminogen Activator

Initial interest in a double-bolus regimen of t-PA came from a series of patients, in which two 50-mg boluses of t-PA were administered 30 min apart, and TIMI grade 3 flow was observed in 88 percent of patients.[444] In a subsequent randomized trial, however, double-bolus t-PA achieved only 58 percent TIMI grade 3 flow, compared with 66 percent for the accelerated 90-min infusion of t-PA.[445] The Continuous Infusion Versus Double-Bolus Administration of Alteplase (COBALT) trial compared double-bolus t-PA with the accelerated infusion of t-PA but was terminated prematurely because of concern about the safety of the double-bolus regimen. The 30-day mortality rate was higher in the double-bolus group than in the accelerated-infusion group: 7.98 percent as compared with 7.53 percent.[446] Rates of hemorrhagic stroke were 1.12 percent after double-bolus alteplase as compared with 0.81 percent after an accelerated infusion of alteplase (p = .23).[446] Statistically, double-bolus t-PA was *not* equivalent to t-PA.[446] Thus, based on this trial, double-bolus t-PA is not recommended for general clinical use,[446] and the accelerated, 90-min infusion of t-PA remains the current standard dosing for acute MI.

Tissue-Type Plasminogen Activator (Reteplase)

This is a single-chain nonglycosylated deletion variant of rt-PA consisting of only the K2 and the protease domains of human t-PA (Fig. 44-23). The active site of the protease domain of reteplase and that of t-PA, and their plasminogenolytic activity in the absence of a stimulator, do not differ, but the plasminogenolytic activity of reteplase in the presence of fragments of fibrinogen as a stimulator was

fourfold lower compared with t-PA, whereas the binding of reteplase to fibrin was five times lower. These differences in plasminogenolytic activity and fibrin binding between the two molecules might be due to the missing finger domain in reteplase. It is known that fibrin binding is mediated through both the finger domain and the lysine-binding site in the K2 domain of t-PA. Reteplase and t-PA are inhibited by PAI-1 to a similar degree, but the affinity of reteplase for binding to endothelial cells and monocytes is reduced, probably as a consequence of deletion of the finger and epidermal growth factor domains in reteplase, which seem to be involved in the interaction with endothelial cell receptors. The thrombolytic properties of reteplase and alteplase (rt-PA) were compared in the rabbit jugular vein thrombosis model.[447] The effective dose for 50 percent thrombolysis (ED_{50}) was 163 kU/kg (0.28 mg/kg) for reteplase and 871 kU/kg (1.09 mg/kg) for alteplase, indicating a 5.3-fold higher potency of reteplase. At equipotent doses (50 percent thrombolysis), the residual concentration of fibrinogen was 74 percent with reteplase and 76 percent with alteplase. Pharmacokinetic analysis of plasma activity at a dose of 400 kU/kg in rabbits revealed a half-life of 18.9 ± 1.5 min for reteplase and 2.1 ± 0.1 min for alteplase. Plasma clearance for reteplase was 4.3-fold slower than for alteplase (4.7 versus 1.2 mL/min per kilogram).[448] One may therefore conclude that the higher potency of reteplase is due to the slower clearance. An initial half-life of 14 to 18 min was also observed with reteplase in healthy human volunteers[449] and in patients with acute MI.[450]

Dose-ranging studies of bolus reteplase were performed in a multicenter trial.[451] With a dose of 10 MU of reteplase, a patent infarct-related coronary artery (TIMI-3 grade) was obtained at 30 min in 46 percent, at 60 min in 48 percent, at 90 min in 52 percent, and at 24 to 48 h in 88 percent of patients with acute MI. With 15 MU, a higher angiographic patency rate at the same time intervals was obtained (38, 58, 69, and 85 percent). Because there was a 20 percent (10 MU) and 12.5 percent (15 MU) reocclusion rate between the 30- and 90-min angiograms, the administration of a second smaller bolus of reteplase (5 MU) 30 min after the initial bolus (10 MU) was investigated in an open uncontrolled study.[452] Patency rates (TIMI-3) reached 50 percent at 60 min, 58 percent at 90 min, and 84 percent at 24 to 48 h. Only one of the 50 patients studied had reocclusion in the first 24 to 48 h.

In the Reteplase versus Alteplase Infusion in Acute Myocardial Infarction (RAPID-I) trial involving 605 patients with acute MI, different bolus doses of reteplase (a single dose of 15 MU, 10 MU, and 5 MU 30 min later; and 10 MU and 10 MU 30 min later) were compared with the conventional dose regimen of alteplase (100 mg over 3 h). TIMI-3 patency rates at 90 min were obtained with the given reteplase regimen in 42.7, 45.4, and 62.9 percent, respectively, and in 47.6 percent of patients treated with alteplase.[453] The difference between the 10 MU + 10 MU reteplase and alteplase arms is significant ($p = .01$).

The RAPID-II trial was a randomized open-label angiographic study of 324 patients with acute MI that was designed to compare the effect of 10 + 10 U reteplase with that of an accelerated, front-loaded dose of alteplase (100 mg over 90 min) on the TIMI grade of the infarct-related coronary artery 90 min after the initiation of thrombolytic therapy.[454] There was no age limit, and patients were recruited up to 12 h after onset of symptoms; all received aspirin. The heparin regimen consisted of a 5000-IU intravenous bolus that was administered before thrombolytic therapy, followed by an infusion of 1000 IU/h for at least 24 h. In this study, reteplase achieved earlier and more complete reperfusion than did accelerated-dose alteplase.[454] TIMI grade 2 or 3 patency and TIMI grade 3 flow rates of the infarct-related artery at 90 min were significantly higher for reteplase relative to the alteplase control (83.4 versus 73.3 percent and 59.9 versus 45.2 percent, respectively).[454] At 60 min, both the TIMI grade 2 or 3 patency and the TIMI grade 3 flow rates were significantly higher for reteplase than for alteplase.[454] Reteplase-treated patients required significantly fewer additional coronary interventions within the first 6 h of treatment (13.3 versus 26.5 percent). As expected in a trial of this size, there were no significant differences between the reteplase and the alteplase groups with respect to 35-day mortality (4.1 versus 8.4 percent) and hemorrhagic stroke (1.2 versus 1.8 percent).[454]

Two mortality trials with reteplase were planned in patients with acute MI. The International Joint Efficacy Comparison of Thrombolytics (INJECT) study was designed to determine whether reteplase was at least as effective in mortality reduction as a standard streptokinase regimen.[455] In this double-blind study, 3004 patients were randomized to a double bolus of 10 + 10 U of reteplase 30 min apart, and 3006 patients were randomized to 1.5 MU of streptokinase over 60 min. Treatment could be started up to 12 h from onset of symptoms. All patients received intravenous heparin for at least 24 h and aspirin. The 35-day mortality rate

was 9.0 percent in the reteplase group and 9.5 percent in the streptokinase group, a nonsignificant difference. That did meet predefined criteria for equivalence.[455] At 6 months, mortality rates were 11.0 percent for reteplase and 12.0 percent for streptokinase.[455] Bleeding events were similar in the two groups (0.7 percent for reteplase and 1.0 percent for streptokinase). The in-hospital stroke rates were 1.23 percent for reteplase and 1.0 percent for streptokinase. The incidence of recurrent MI was similar in the two groups.

In the GUSTO-III mortality trial, reteplase was administered in two bolus injections 30 min apart and compared with front-loaded alteplase (100 mg in 90 min) in 15,059 patients treated within 6 h of symptoms of acute MI. The GUSTO-III trial compared reteplase with front-loaded alteplase (t-PA).[456] Mortality (7.47 versus 7.24 percent, r-PA versus t-PA), ICH (0.91 versus 0.87 percent), and net clinical benefit (death or disabling stroke) were very similar clinically (7.9 percent in each group) between double-bolus reteplase and alteplase infusion, respectively.[456] When applying post hoc criteria for equivalence (evaluating the upper boundary of the 95% CI), reteplase is statistically equivalent for death or disabling stroke when a 1 percent absolute boundary is used [derived from the difference observed between streptokinase (SK) and t-PA]. Thus, clinically, the simpler double-bolus regimen of r-PA appears clinically equivalent to accelerated t-PA.

TNK-Tissue-Type Plasminogen Activator (Tenecteplase)

TNK-t-PA (tenecteplase) is a new thrombolytic agent that is a genetically engineered variant of t-PA (Fig. 44-24). TNK-t-PA is similar to wild-type t-PA, but has amino acid substitutions at three sites, which give it its name: a threonine (T) is replaced by asparagine, which adds a glycosylation site to position 103; an asparagine (N) is replaced by a glutamine, thereby removing a glycosylation site from site 117; and four amino acids-lysine (K), histidine, arginine, and arginine-are replaced by four alanines at the third site. Together, these substitutions lead to, in animal models, a prolonged half-life of the molecule,[457,458] increased fibrin specificity,[457] and increased resistance to inhibition by PAI-1.[459-461]

Pharmacokinetics

Clinical testing of TNK-t-PA began in the TIMI-10A trial, with doses ranging from 5 to 50 mg.[457] TNK-t-PA was demonstrated to have a slowed plasma clearance relative to values for t-PA. The corresponding plasma half-life of elimination of TNK-t-PA ranged from 11 to 20 min, as compared with 3.5 min as previously reported for t-PA.[462] These results were duplicated in the TIMI-10B trial.[458,463]

Fibrin Specificity

TNK-t-PA is much more fibrin specific than t-PA, which is itself more fibrin specific than streptokinase or reteplase. Systemic fibrinogen and plasminogen levels fell by only 5 to 15 percent over the first 6 h at the 30- to 50-mg doses of TNK-t-PA compared with 40 to 50 percent drops following t-PA. Similarly, the consumption of α2-antiplasmin, the fluid-phase inhibitor of plasmin, and a resultant increase in plasmin-α2-antiplasmin complexes was four to five times greater with t-PA as compared with TNK-t-PA. This high level of fibrin specificity of TNK-t-PA compared with t-PA helps explain its efficacy when administered as a 5- to 10-s bolus, and the fact that it does not induce the *plasminogen steal* phenomenon.[464] Furthermore, these benefits in preserving the systemic coagulation factors appear to translate into lower rates of major bleeding in the large phase III trial (see below).

TIMI Grade 3 Flow

In the dose-ranging trial TIMI-10A, the rate of TIMI grade 3 flow at 90 min was achieved in 57 to 64 percent of patients at the 30- to 50-mg TNK-t-PA doses, which was higher than in patients treated with the lower doses ($p = .032$).[457] In TIMI-10B, a total of 886 patients were randomized to receive either front-loaded (90-min infusion) t-PA or a single 5- to 10-s bolus of TNK-t-PA at 30- or 50-mg bolus.[463] The 50-mg dose was discontinued due to increased bleeding and replaced with a 40-mg dose of TNK-t-PA. The 40-mg dose of TNK-t-PA produced a similar rate of TIMI grade 3 flow at 90 min compared with t-PA (63

percent). The 30-mg dose of TNK-t-PA had a significantly lower rate of TIMI grade 3 flow at 90 min than did t-PA (54.6 percent, $p = .04$), whereas the 50-mg dose showed 65.8 percent (p = NS).[463] TIMI grade 2 or 3 flow at 90 min and TIMI frame counts were similar between TNK-t-PA and t-PA. At 60 min, there were no differences in the rates of TIMI grade 3 flow or overall patency.[463]

Weight-Adjusted Dosing

In TIMI-10B and ASSENT-I, a prespecified weight-based analysis was carried out.[463,465,466] The rate of TIMI grade 3 flow was 62 to 63 percent for doses of TNK-t-PA of approximately 0.53 mg/kg and higher but was 51 to 54 percent at doses lower than this ($p = .028$ across quintiles). Further analysis into covariates of the degree of perfusion achieved revealed that, when stratifying dose/weight into tertiles, the median corrected TIMI frame count was significantly lower (i.e., faster flow) in patients who received the higher "weight corrected" dose.[465]

Safety Results in the TIMI-10B Trial

During the initial phase of the trial, i.e., prior to the reduction of heparin dosage previously described, there were three ICHs among the 78 patients (3.8 percent, 95% CI = 0.8 to 10.8) treated with the 50 mg TNK-t-PA dose. In the parallel ASSENT-I trial, however, there were no ICHs at this dose. This dose was dropped from further testing and, at the same time, the doses of heparin were reduced. Further analysis demonstrated that the concomitant heparin may have played a larger role than that of dose of TNK-t-PA in defining the rate of ICH.

Initially in TIMI-10B and ASSENT-I, heparin dosing was at the discretion of the treating physicians, but a protocol amendment mandated that patients receive the following dose of heparin: for patients weighing more than 67 kg, a 5000-U bolus and 1000-U/h infusion, and, for patients weighing 67 kg or less, a 4000-U bolus and 800-U/h infusion. In addition, adjustment of the heparin dose according to the nomogram was mandated to begin with the 6-h APTT.

The rates of both ICH and serious bleeding were lower after the protocol amendment: for TNK-t-PA 30 mg, the ICH rate fell from 2.2 to 0 percent ($p = .047$), and, for t-PA, the rate fell from 2.8 to 1.2 percent ($p = .29$) (overall combined $p = .04$).[463] Similar observations and statistically significant reductions in ICH rate were observed in overall TNK-t-PA experience combining the TIMI-10B and ASSENT-I trials.[350] The rate of severe bleeding also decreased with the reduced heparin dosing: from 3 to 0 percent ($p = .02$) for 30 mg TNK-t-PA, and from 8 to 2 percent ($p = .01$) for t-PA (combined $p = .001$).[463] Thus, for the subsequent phase III trial (ASSENT-II), the lower heparin regimen was used.

Another observation on safety involved the rates of serious (noncerebral) bleeding in TIMI-10B, where lower rates of serious bleeding requiring transfusion were noted. For t-PA, 7.0 percent of patients required transfusion compared with 1.0 percent of TNK-t-PA patients treated with the 30-mg dose ($p < 0.001$) and 1.3 percent treated with the 40-mg dose ($p < 0.01$).[467] Similar low rates of serious bleeding requiring transfusion were observed in the ASSENT-I trial.[467] Thus, there appeared to be early evidence that the very fibrin specific agent TNK-t-PA might have lower rates of bleeding than t-PA.

ASSENT-I Trial

This was a randomized trial of three doses of TNK-t-PA, with the primary goal to determine the rate of ICH of the three doses, to assist in determining the appropriate dose for a large phase III trial. A total of 3235 patients randomized: to receive either 30 mg TNK-t-PA ($n = 1705$), 40 mg ($n = 1457$), or 50 mg ($n = 73$).[468] As noted previously, the 50-mg dose was discontinued and replaced by 40 mg because of increased bleeding observed in the TIMI-10B study. ICH occurred in 0.77 percent of patients overall: 0.94 percent in the 30-mg arm and 0.62 percent in the 40-mg arm. No strokes were found among the 73 patients treated with 50 mg TNK-t-PA. In patients treated within 6 h after symptom onset, the rates of ICH were 0.56 percent (30 mg TNK-t-PA) and 0.58 (40 mg TNK-t-PA). Death, death or nonfatal stroke, or severe bleeding

complications occurred in a low proportion of patients: 6.4, 7.4, and 2.8 percent, respectively, without differences among the 3 doses.

ASSENT-II

TNK-t-PA was compared with accelerated t-PA in a large mortality trial of patients with acute ST-elevation MI presenting within 6 h of the onset of pain. This trial enrolled 16,950 patients worldwide. TNK-t-PA was administered as a weight-adjusted dose of 0.53 mg/kg given in 5-mg increments, ranging from 30 to 50 mg.

Overall mortality was essentially identical between the two agents: 6.17 percent for TNK-t-PA and 6.15 percent for t-PA (p = NS).[469] This trial was an *equivalence* trial[470] and, using its predefined criteria, TNK-t-PA was shown to be equivalent to t-PA (relative risk = 1.00; 90% CI = 0.91 to 1.10; p for equivalence = 0.028). The equivalence of TNK-t-PA to t-PA on reducing mortality was shown in nearly every subgroup tested.

There was an intriguingly *better* outcome for patients treated with TNK-t-PA compared with t-PA more than 4 h after the onset of chest pain. This benefit may relate to the greater fibrin specificity of TNK-t-PA. The first observation of the benefit of greater fibrin specificity in later-treated patients came from the TIMI-1 trial, in which 90-min patency was preserved in patients treated with t-PA with time to treatment of less than or more than 4 h, whereas, for those treated with streptokinase, patency was significantly worse if time to treatment was more than 4 h.[3,438] Similar findings were seen in an analysis of the German angiographic thrombolytic trials.[471,472] The same pattern favoring the more fibrin-specific agent was seen in the GUSTO-III trial, where t-PA had significantly lower mortality than reteplase, a less fibrin-specific agent, in patients treated more than 4 h after the onset of pain.[456] It is hypothesized that the clot may be more resistant the longer it has been able to mature, and the greater fibrin specificity of the thrombolytic agent may enhance the ability to lyse the clot.

Safety Observations

In ASSENT-II, the rate of ICH was also identical for TNK-t-PA and t-PA (0.93 versus 0.94 percent, p = NS). Total stroke was also similar (1.78 percent for TNK-t-PA versus 1.66 percent for t-PA, p = NS). However, there was an intriguingly lower rate (albeit not statistically significant) of ICH in patients older than 75 years of age treated with TNK-t-PA (1.7 percent versus 2.6 percent for those treated with t-PA). Further detailed analysis found that the highest-risk group for ICH was elderly female patients weighing 67 kg or less.[473] This group has been found in two previous multivariate analyses to be at high risk for ICH.[474,475] Most encouragingly, the rates for ICH in this high-risk group were only 1.1 percent following treatment with TNK-t-PA compared with 3.0 percent for those treated with t-PA. The multivariate adjusted odds ratio was 0.30 (95% CI = 0.09 to 0.98, $p < 0.05$).[473] In all other patients, the rates of ICH were similar between the two thrombolytic groups.

Importantly, these benefits on ICH were paralleled by significantly lower rates of major bleeding. In the trial as a whole, the rates of major bleeding were 4.7 percent for TNK-t-PA and 5.9 percent for t-PA (p = .0002).[469] Total bleeding also occurred in fewer patients (p = .0003).[469,476] Similarly, the rate of bleeding requiring transfusion was significantly lower with TNK-t-PA.

Desmodus Salivary Plasminogen Activator The subsistence of vampire bats on a diet of fresh blood is apparently contingent on their ability to interfere with the hemostatic system of the blood donor. The saliva of vampire bats contains a variety of factors that presumably satisfy two essential requirements: to maintain prolonged bleeding from the wound and to preserve blood fluidity following ingestion of a meal.[477] Different molecular forms of the *Desmodus* salivary plasminogen activator (DSPA) have been purified, characterized, cloned, and expressed. Two HMW forms exhibit about 85 percent homology to human t-PA: DSPAα1 (M_r 43) and DSPAα2 (M_r 39), which contain neither a kringle 2 domain nor a plasmin-sensitive processing site. DSPAβ lacks the finger-like structure and DSPAγ lacks the finger and epidermal growth factor structures.[405,478] The two HMW forms exhibit a specific activity in vitro equal to or higher than that

of t-PA, a relative PAI-1 resistance, and a greatly enhanced fibrin specificity with a strict requirement for polymeric fibrin as a cofactor.[479-481] In animal models (rats, rabbits, and dogs) of thrombolysis, DSPAα1 is superior to t-PA in terms of potency (2.5 times higher), terminal half-life (three times longer), and clearance (four- to eightfold slower).[481] Interestingly, the fibrin cofactor requirement of DSPAα1 and DPSAα2, which both bind to fibrin, may not solely depend on fibrin binding, as the two smaller forms, DPSAβ and DSPAγ, are also fibrin dependent but lack fibrin affinity.[481]

ZK152387 is recombinant DSPAα1 produced in mammalian cell culture; its amino acid sequence is identical to that of its natural counterpart.[478] DSPAα1 may be suitable for bolus administration; its long half-life and high specific activity may allow a marked reduction of the absolute dose of drug required for effective thrombolysis as compared with t-PA.

Staphylokinase Mature staphylokinase consists of 136 amino acids in a single polypeptide chain without disulfide bridges. Staphylokinase, like streptokinase, is not an enzyme but forms a 1:1 stoichiometric complex with plasmin(ogen) that activates other plasminogen molecules. Streptokinase and plasminogen produce a complex that exposes the active site in the plasminogen molecule without proteolytic cleavage, whereas generation of plasmin is required for exposure of the active site in the complex with staphylokinase.[482,483]

Staphylokinase does not bind to fibrin, and fibrin stimulates the initial rate of plasminogen activation by staphylokinase only fourfold as compared with twofold by streptokinase. In purified systems α_2-antiplasmin rapidly inhibits the plasmin-staphylokinase complex (second-order inhibition rate constant of approximately $2 \times 10^6\ M^{-1}s^{-1}$), although it does not inhibit the plasmin(ogen)-streptokinase complex. Addition of 6-aminohexanoic acid or of fibrin-like substances (e.g., CNBr-digested fibrinogen) induces a more than 100-fold reduction of the inhibition rates of the plasmin-staphylokinase complex by α_2-antiplasmin. Rapid inhibition by α_2-antiplasmin indeed requires the availability of the lysine-binding sites in the plasminogen moiety of the complex. More detailed studies on the interaction between staphylokinase, plasmin(ogen), and α_2-antiplasmin have shown that neutralization of the plasmin-staphylokinase complex by α_2-antiplasmin results in dissociation of functionally active staphylokinase from the complex, followed by its recycling to other plasminogen molecules.[482]

In plasma, the conversion of plasminogen-staphylokinase to plasmin-staphylokinase complex does not occur at a significant rate because it is prevented by α_2-antiplasmin; without plasmin-staphylokinase complex, no significant plasminogen activation occurs. In the presence of fibrin, generation of the plasmin(ogen)-staphylokinase complex is facilitated, and inhibition of plasmin-staphylokinase by α_2-antiplasmin at the clot surface is delayed. Recycling of staphylokinase to fibrin-bound plasminogen, after neutralization of the complex, will result in more efficient generation of the active complex. This mechanism is mediated via the lysine-binding sites of plasminogen and results in significantly enhanced plasminogen activation at the fibrin surface. These regulatory properties of fibrin and α_2-antiplasmin suggest that the fibrin specificity of staphylokinase is due to rapid inhibition of generated plasmin-staphylokinase complex by α_2-antiplasmin and by a more than 100-fold reduced inhibition rate at the fibrin surface.[482,484]

Recombinant staphylokinase (STAR)[485] was found to have a potency for venous clot lysis in hamsters and rabbits comparable to that of streptokinase. Repeated administration of STAR, in contrast to streptokinase, did not induce resistance to clot lysis in this model. In addition, STAR was found to be significantly more efficient than streptokinase for the dissolution of platelet-rich arterial eversion graft thrombi.[485]

These encouraging results have formed the basis for the evaluation, on a pilot scale, of the pharmacokinetic, thrombolytic, and immunogenic properties of STAR in patients with acute MI.[486] In four of five patients with acute MI, 10 mg of STAR given intravenously over 30 min was found to induce angiographically documented coronary artery recanalization within 40 min. Plasma fibrinogen and α_2-antiplasmin levels were unaffected, and allergic reactions were not observed. In a second series of five patients with acute coronary occlusion, intravenous administration of 10 mg of STAR over 30 min induced recanalization in all patients within 20 min without associated fibrinogen degradation.[190,487] In these patients, however,

neutralizing antibodies were consistently demonstrable in plasma at 14 to 35 days. Thus, with respect to immunogenicity, the initial observations in humans are not as encouraging as the experience in baboons. A subsequent trial was conducted in 100 patients with MI of less than 6-h duration who were allocated to accelerated and weight-adjusted t-PA over 90 min (52 patients) or to recombinant staphylokinase (STAR) (the first 25 patients to 10 mg and the next 23 patients to 20 mg given intravenously over 30 min).[488] All patients received aspirin and intravenous heparin. TIMI-3 flow grade at 90 min was achieved in 62 percent of STAR patients compared with 58 percent of t-PA patients (risk ratio = 1.1; 95% CI = 0.76 to 1.5). With 10 mg STAR, TIMI-3 patency was 50 percent (risk ratio = 0.86; 95% CI = 0.54 to 1.4 versus rt-PA); with 20 mg STAR, it was 74 percent (risk ratio = 1.3; 95% CI = 0.90 to 1.2 versus rt-PA). Residual fibrinogen levels at 0 min were 118 ± 47 percent (mean ± SD) of baseline with STAR and 68 ± 42 percent with rt-PA ($p < .0005$). STAR therapy was not associated with an excess mortality rate or electrical, hemorrhagic, mechanical, or allergic complications, but patients developed antibody-mediated STAR-neutralizing activity from week 2 after STAR treatment.

Chapter 44: THROMBOGENESIS, ANTITHROMBOTIC, AND THROMBOLYTIC THERAPY

CONCLUSION

Thus, with an understanding of the pathogenesis of and risk of thrombus formation,[489] we can formulate a rational approach to the use of antiplatelet, anticoagulant, and thrombolytic agents.[489-491] Many advances have occurred in the treatment of acute coronary syndromes over the past 75 years.[492,493] In ST-elevation MI, new aggressive thrombolytic regimens improve early reperfusion and improve survival. The current focus is on bolus thrombolysis, the combination of reduced-dose thrombolytic therapy with GP IIb/IIIa inhibitors, and the use of LMW heparin in place of unfractionated heparin. In unstable angina and non-ST-elevation MI, two major advances are GP IIb/IIIa inhibition and LMW heparin. The direct thrombin inhibitors have also shown promise. Following acute coronary syndromes, use of the more potent antiplatelet agent than aspirin, clopidogrel, appears to decrease recurrent ischemic events, whereas disappointing results have come thus far from the oral GP IIb/IIIa inhibitors. With a great number of new thrombolytic and antithrombotic therapies for patients with acute coronary syndromes, it is hoped that their use will continue to improve clinical outcomes in the years ahead.

Chapter 44: THROMBOGENESIS, ANTITHROMBOTIC, AND THROMBOLYTIC THERAPY

List of Figures

Figure 44-13: Benefit of aspirin across the spectrum of acute coronary syndromes. The risk of subsequent myocardial infarction (MI) was reduced by aspirin compared with placebo in healthy subjects and thus was effective in primary prevention.[187] Similarly, patients with stable angina had a reduced incidence of MI.[490] In unstable angina, the incidence of death or MI was reduced by over 50 percent in each of three trials shown.[66-68] In acute MI (AMI), aspirin reduced reocclusion of the infarct-related artery,[182] reinfarction, and mortality rates.[180] [Data are from the following trials, respectively: Steering Committee of the Physicians' Health Study Research Group,[187] Ridker et al.,[490] Cairns et al.,[66] Theroux et al.,[67] the RISC Group,[68] Roux et al.,[182] and ISIS-2 (Second International Study of Infarct Survival) Collaborative Group[180].]

Figure 44-14: Benefit of clopidogrel compared with aspirin in patients with symptomatic atherosclerosis. Subgroups of patients are shown in the *left panel*, and outcome events in the total group are shown in the *right panel*. IS = ischemic stroke; MI = myocardial infarction; PAD = peripheral arterial disease. (Data are from the CAPRIE Steering Committee[181] and Gent.[217])

Figure 44-15: Meta-analysis of large Glycoprotein IIb/IIIa trials. (From Topol et al.[492] Reproduced with permission from the publisher and authors.)

Figure 44-16: Primary Results from the ESPRIT trial of eptifibatide in coronary stenting. (Presented by Tcheng J at American College of Cardiology, March 2000.)

Figure 44-17: Meta-analysis of six randomized trials comparing unfractionated heparin plus aspirin compared with aspirin alone, showing benefit of the combination therapy. The rate of death or myocardial infarction (MI) during follow-up (2 to 12 weeks in the various studies) tended to be reduced in patients randomized to aspirin plus heparin. (Adapted from Oler et al.[71] Reproduced with permission from the publisher and authors.)

Figure 44-18: Mechanism of action of heparin and low molecular weight heparin (LMWH): Heparin acts as a cofactor to antithrombin to (1) change the conformation of its active site and (2) serve as a "bridge" to bring together an antithrombin (AT) and thrombin. Heparin is a catalyst: after it facilitates the binding of one pair of thrombin and antithrombin molecules, it is released and facilitates another thrombin-antithrombin interaction. LMWH also binds to antithrombin and changes the conformation of its active site, but does not act as a bridge to thrombin. Approximately 25 to 50 percent of the LMWH molecules of different commercial preparations contain at least 18 saccharide units, which allows binding to the heparin-binding site of thrombin, and thus both these molecules inhibit thrombin and factor Xa. The remaining 50 to 75 percent of LMWH molecules contain fewer than 18 saccharide units and inhibit only factor Xa.

Figure 44-19: TIMI-11B/ESSENCE meta-analysis (TESSMA): Data from over 7000 patients randomized in these two trials show a consistent and significant 20 percent reduction in the rate of death or myocardial infarction (MI) at each of the four time points in patients treated with enoxaparin compared with unfractionated heparin. (Adapted from Antman et al.[74] Reproduced with permission from the publisher and authors.)

Figure 44-20: Vitamin K in its reduced form (vitamin K hydroquinone) is essential for the gamma-carboxylation reaction of glutamic acid (Glu)-to gamma-carboxyglutamic acid (Gla-). In this carboxylation, vitamin K hydroquinone is converted to vitamin K_1 epoxide and an epoxide-reductase regenerates active vitamin K hydroquinone. It is this regeneration step that is blocked by all coumarin-type anticoagulant drugs (e.g., warfarin).

Figure 44-21: Components of the fibrinolytic system. In the *left top box*, natural plasminogen activators (endogenous to the human fibrinolytic system) and their mutants in clinical use are grouped separately from other plasminogen activators in clinical use (*right top box*).

Figure 44-22: Primary structure of tissue-type plasminogen (t-PA) activator (*A*) and pro-urokinase (*B*). The amino acids are represented by their single-letter symbols, and the black bars indicate disulfide bonds. st = active site residues His322, Asp371, and Ser478; arrow in A = plasmin cleavage site for conversion of single-chain t-PA to the two-chain molecule; arrows in B = tcu-PA (Lys158-IIe159), and 54-kDa tcu-PA (Lys135-Lys136), the thrombin cleavage site (Arg156-Phe157) yielding inactive 54-kDa tcu-PA, and the conversion site to 32-kDa scu-PA (Glu143-Leu144).

Figure 44-23: Schematic representation of the primary structure of reteplase (Retavase) (amino acids Ser1-Gln3 and Gly176-Pro527 of tissue-type plasminogen activator). The amino acids are represented by their single-letter symbols; black bars indicate disulfide bonds and the asterisks indicate the active-site residues in the protease part. The arrow indicates the plasmin cleavage site.

Figure 44-24: Schematic representation of the primary structure of recombinant tissue-type plasminogen activator-TNK (TNK-t-PA, tenecteplase) (substitution on rt-PA of Thr103 by Asn, Asn111 by Gln, and Lys296-His-Arg-Arg by Ala-Ala-Ala-Ala). The amino acids are represented by their single-letter symbols, black bars indicate disulfide bonds, and the asterisks indicate the active site residues in the protease part. The arrow indicates the plasmin cleavage site.

Part 6: CORONARY HEART DISEASE
Chapter 45:

PERCUTANEOUS CORONARY INTERVENTION

Authors: John S. Douglas, Jr., Spencer B. King III

The treatment of patients with coronary heart disease changed dramatically with the advent and refinement of coronary artery surgical techniques in the 1970s and percutaneous coronary intervention in the next decade. This chapter addresses the development and contemporary use of catheter-based coronary artery intervention, including selection of patients and devices, procedural issues, results, complications, and long-term outcome.

DEVELOPMENT OF BALLOON ANGIOPLASTY

Percutaneous transluminal coronary angioplasty (PTCA) was conceived and shepherded into worldwide acceptance and application by Andreas R. Gruentzig, but the stage was set by the pioneering effort of others. Gruentzig's ideas were a direct extension of the work of Dotter and Judkins,[1] who in 1964 mechanically dilated femoral arteries with a coaxial double-catheter system, and of Zeitler,[2] who applied this technique successfully in West Germany and introduced it to Gruentzig. After Gruentzig's development of a polyvinyl chloride balloon catheter with fixed maximal inflated diameters in 1974, modern balloon angioplasty evolved rapidly. With further balloon catheter miniaturization and building on the coronary arteriography techniques of Sones and Judkins, Gruentzig succeeded in dilating experimental stenoses in canine coronary arteries[3-5] and then in dilating human arteries during bypass surgery. In September 1977, the first PTCA was performed in Zurich in a 37-year-old insurance salesman with severe angina pectoris and high-grade stenosis of the proximal left anterior descending (LAD) coronary artery.[6-8] Balloon angioplasty was successful in relieving the stenosis, and on the tenth anniversary of this landmark procedure, coronary arteriography revealed angiographically normal coronary arteries (Fig. 45-1). Over 20 years later, the patient remained asymptomatic.

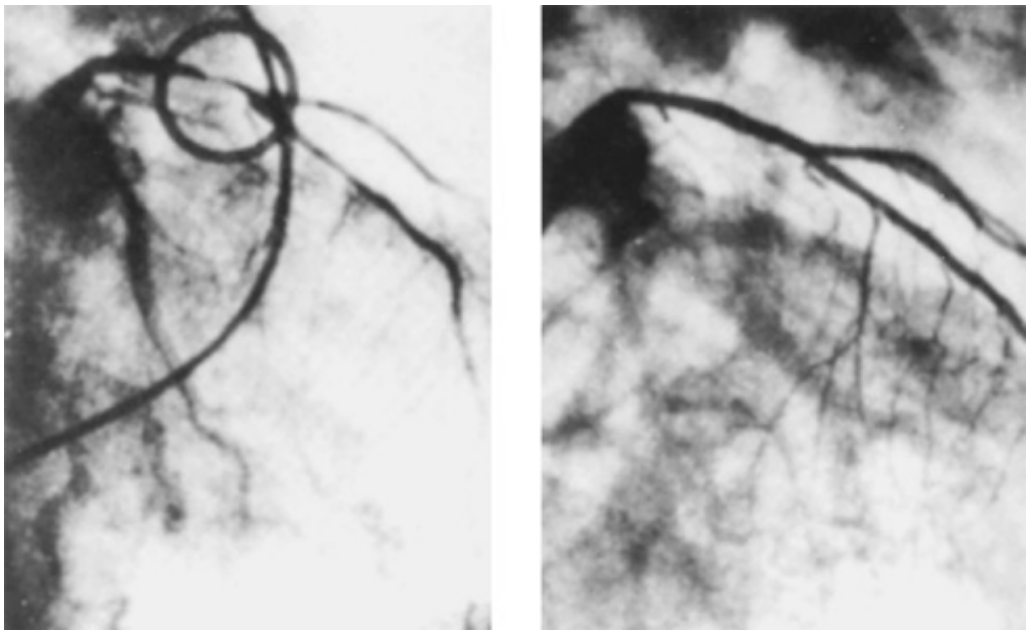

Figure 45-1: Right anterior oblique coronary arteriogram of the first patient who underwent transluminal coronary angioplasty on September 16, 1977 (*left*) and on September 16, 1987 (*right*). During this 10-year period, the patient remained completely asymptomatic, and the arteriogram at 10 years showed no narrowing in the coronary arteries. Over 20 years later, the patient is free of symptoms.

Following the report of Gruentzig's first five patients in 1978[9] and 50 patients in 1979,[10] worldwide interest in the technique was assured. Under the auspices of the National Heart, Lung, and Blood Institute (NHLBI), multicenter registries were formed to report experiences with the evolving technique of balloon coronary angioplasty.[11-13] Development of an over-the-wire balloon catheter by Simpson et al.,[14] combined with advances in guidewire and balloon catheter technology, resulted in a steerable balloon catheter system capable of crossing and dilating heretofore unreachable coronary stenoses (Fig. 45-2). The use of percutaneous revascularization increased dramatically, exceeding 130,000 procedures in the United States in 1986, 400,000 in 1995, and 600,000 in 1999. By 1986 at Emory University Hospital, catheter-based revascularization techniques were performed more frequently than coronary artery bypass grafting (CABG) for relief from symptoms of ischemic heart disease (Fig. 45-3).

Initially, coronary balloon angioplasty was performed for discrete, proximal, noncalcified, subtotal lesions located in one coronary artery. Gruentzig was able to dilate successfully 64 percent of the initial 50 patients and 78 percent of the first 169.[10,15] Most of the patients dilated successfully were improved symptomatically. A 10-year follow-up of Gruentzig's early Zurich series revealed an overall survival rate of 90 and 95 percent for those with single-vessel disease.[15,16] Five-year survival in the NHLBI Registry was 93 percent for single-vessel disease and 87 percent for patients with multivessel disease,[17] and 70 percent of patients were free of target vessel revascularization at 10 years.[18] Large observational studies comparing medical, surgical, and PTCA therapy suggested that revascularization surpassed medical therapy for most anatomic subsets and that surgery provided a survival benefit over PTCA in severe multivessel disease.[19,20] Recently published observational data from the 1993-1995 New York State Cardiac Procedure Registry of 60,000 CABG and PTCA procedures reported better 3-year survival with CABG in patients with three-vessel disease and those patients with two-vessel disease/proximal LAD stenosis treated with CABG, whereas those with one-vessel disease/no LAD stenosis had better survival with PTCA. All other patients had similar survival with PTCA and CABG.[21] Only now are outcomes for similar anatomic subsets being reported from randomized trials,[22] and these

results do not indicate a superiority of CABG over PTCA except in diabetics with three-vessel disease (see "Randomized Trials of Balloon Angioplasty," below).

Chapter 45: PERCUTANEOUS CORONARY INTERVENTION

RANDOMIZED TRIALS OF BALLOON ANGIOPLASTY

PTCA versus Medical Therapy

The favorable results of these observational studies and others reporting single-vessel and multivessel $ir23,9p6sease patients[23,24] led to a series of randomized trials comparing balloon angioplasty with medical therapy[25-31] and with CABG.[32-38] The Angioplasty Compared to Medical Therapy Evaluation (ACME), involving 212 patients with single-vessel disease and abnormal stress tests, revealed greater freedom from angina in the angioplasty group at 6 months (64 versus 46 percent) as well as better treadmill performance (2.1- versus 0.5-min increase). There was no difference in death or myocardial infarction (MI).[25] The Second Randomized Intervention Treatment of Angina (RITA-2) trial randomized 1018 patients with stable angina to PTCA or medical therapy.[28] The majority (60 percent) had single-vessel disease, and 33 percent had two-vessel disease. Angina relief and treadmill performance were significantly better in the PTCA patients, but complications also were more frequent; death or myocardial infarction occurred in 6.3 percent of PTCA patients compared with 3.3 percent of medically treated patients. Symptomatic benefit was greater in the patients with severe angina at baseline. In the Veterans Affairs Non-Q-Wave Infarction Strategies in Hospital (VANQWISH) trial, 920 patients were randomly assigned to either an invasive strategy (routine coronary angiography and myocardial revascularization) or conservative management (medical therapy and noninvasive testing).[26] Although there was no difference in mortality during 12 to 44 months of follow-up, there was a higher incidence of a composite end point (death or nonfatal infarction) in the invasive group at 1 month and at 1 year (111 versus 85 events; $p = 0.05$). Although stents, ticlopidine, and IIb/IIIa inhibitors were not used, there were no deaths at 30 days in the invasive group treated with PTCA but an 11.6 percent 30-day mortality in this group treated with CABG. Whereas the VANQWISH investigators recommended the conservative approach, the recently reported, larger Fast Revascularization During Instability in Coronary Disease (FRISC II) study strongly supported an invasive approach.[30,31] Among men at 6 months, the invasive strategy in FRISC II resulted in a 34 percent reduction in death or MI ($p = 0.002$) and a 52 percent reduction in mortality (1.5 versus 3.2 percent; $p = 0.03$). Although there was no reduction in death or MI in women, there was an approximately 50 percent reduction in symptoms of angina and need for readmissions during 6 months of follow-up.

In 341 mildly symptomatic patients (59 percent asymptomatic or class I, 40 percent class II) in the Atorvastatin versus Revascularization Treatment (AVERT) trial, PTCA was compared with aggressive lipid-lowering therapy (atorvastatin 80 mg).[29] At 18-month follow-up, angina relief was significantly better ($p < 0.009$) in the PTCA group, with 54 percent having improvement, versus 41 percent in the aggressive lipid-lowering group, but quality-of-life scores were similar, and there was a trend toward more events (primarily hospitalization for ischemia) in the PTCA group. In AVERT, stents were used in 30 percent of patients. This study suggests that in low-risk patients with no or mild symptoms, aggressive lipid lowering is as effective as PTCA in reducing subsequent ischemic events and emphasizes the importance of extending aggressive lipid lowering in all patients with obstructive coronary artery disease. The Medicine, Angioplasty or Surgery Study (MASS) randomized 214 patients with stable angina, normal left ventricular function, and severe proximal LAD stenosis to bypass surgery [with left internal mammary artery (LIMA)

graft], PTCA, or medical therapy.[27] At 3 years, there was no difference in death or MI. Both revascularization strategies yielded better symptom relief, but subsequent procedures were more common in the PTCA group.

PTCA versus CABG

Over 5000 patients have been randomized in nine trials comparing angioplasty with CABG surgery. Two of these trials were sponsored by the NHLBI and performed in the United States. The first, the Emory Angioplasty versus Surgery Trial (EAST), was a single-center study,[32] whereas the larger Bypass Angioplasty Revascularization Investigation (BARI)[33,34] involved 18 centers. In-hospital mortality was similar for angioplasty and bypass surgery (approximately 1 percent) in these two studies of patients with multivessel disease, and 5-year survival also was similar (Table 45-1). Repeat revascularization procedures, however, were more common in the angioplasty group. Freedom from angina was better in the CABG group in both EAST and BARI. Meta-analyses of eight randomized published trials comparing PTCA and CABG (BARI not included) reported no difference in mortality or MI at 1 year after angioplasty or CABG, but 18 percent of the angioplasty patients had required bypass surgery and 20 percent had an additional angioplasty, a significantly higher rate of repeat revascularization than in the surgery group.[35,36] This increased need for additional revascularization procedures in angioplasty patients, largely due to restenosis, eroded the initial cost advantage of angioplasty; by 3 years in the EAST study, angioplasty had been 95 percent as costly as bypass surgery.[37,38]

Considerable interest was generated by a subset analysis of treated diabetics in BARI. Among the 353 diabetics treated with insulin or oral hypoglycemic agents, 5-year survival was significantly better in patients who underwent surgery compared with that of patients who underwent PTCA (80.6 versus 65.5 percent; $p = 0.003$).[39] Analysis of 7-year survival for all patients in BARI revealed for the first time a significantly better survival with CABG compared with PTCA-treated patients (84.4, 80.9 percent; $p = 0.0425$) (Fig. 45-4*A*). This difference was accounted for entirely by the poorer survival of treated diabetics revascularized with PTCA (55.7 versus 76.4 percent for CABG; $p = 0.0011$)[40] (see Fig. 45-4*B*). There was no difference in the survival of nondiabetics (see Fig. 45-4*C*). Further analysis of treated diabetics in BARI revealed that the survival benefit with CABG was conferred only to those patients who received an internal mammary artery (IMA) graft. The 7-year survival of patients treated with an IMA graft was 83.2 percent compared with 54.5 percent for saphenous vein graft only patients, a figure comparable with that attained with PTCA. EAST, which initially showed no difference between PTCA and CABG in diabetics, now at 8 years shows the same trend as BARI [41] (see Fig. 45-4*D-F*). Considering the rather late manifestation of these outcome differences, it is likely that factors other than early restenosis must be operative. Development of new lesions, perhaps unrecognized, probably accounts for those events occurring many years after revascularization. Poorer outcomes also were reported for diabetics in the BARI registry[42] and in the Emory University Hospital database.[43] In these randomized trials and observational reports, balloon angioplasty was the predominant interventional strategy. Use of stents has been shown to reduce restenosis, and their use in trials of stents versus CABG (see "Stents: After a Decade of Use the Dominant Strategy," below) and in diabetic patients is discussed below. Pending clarification by these trials, caution should exercised in the use of PTCA in diabetic patients with multivessel disease[44] and use of arterial grafts emphasized in diabetic patients.[45,46]

Only recently have data become available from BARI analyzing long-term outcomes based on more specific anatomic subsets.[22] At 7 years, there was no difference in survival of PTCA-treated versus CABG-treated patients with three-vessel disease without diabetes (85 versus 87 percent; *p*

= 0.4, *n* = 592), three-vessel disease with decreased left ventricular ejection fraction (LVEF) (70 versus 74 percent; *p* = 0.6, *n* = 176), two-vessel disease with proximal LAD stenosis (87 versus 84 percent; *p* = 0.9, *n* = 352), and two-vessel disease with proximal LAD stenosis and decreased LVEF (78 versus 71 percent; *p* = 0.7, *n* = 72). Contrary to the New York State Cardiac Procedure Registry data, these findings of a prospective, randomized trial tend to support the appropriateness of PTCA in nondiabetics with multivessel disease when the anatomy is permissive and the patient prefers a percutaneous approach.

Chapter 45: PERCUTANEOUS CORONARY INTERVENTION

NEW DEVICES AND STRATEGIES FOR CORONARY INTERVENTION

Atherectomy, Laser, and Thrombectomy Devices

The directional atherectomy catheter (Fig. 45-5*A*) developed by Simpson[47] was, in 1990, the first nonballoon device approved for coronary intervention and the first to undergo randomized comparison with balloon angioplasty. In native coronary artery[48,49] and saphenous vein graft lesions[50] judged suitable for either procedure, however, the more costly directional atherectomy did not show a substantive advantage over balloon angioplasty. Additional trials using techniques to achieve optimal atherectomy (<20 percent residual stenosis) have been completed.[51,52] The randomized Balloon versus Optimal Atherectomy Trial (BOAT) showed no increase in in-hospital death, Q-wave MI, or CABG with directional atherectomy, but a higher rate of non-Q-wave infarction occurred (16 versus 6 percent; $p < 0.0001$).[51] Restenosis was lower in the atherectomy arm (31 versus 39.8 percent; $p = 0.016$), but there was no difference in late clinical events. The use of directional atherectomy has declined dramatically in most but not all centers[53,54] because of its complexity, added cost, and marginal benefit. In some centers, this technique is used to debulk lesions prior to stenting with the hope of reducing restenosis[55,56] and for lesions at bifurcations and ostial lesions of the LAD coronary artery.[57,58] Excimer laser angioplasty was approved by the Food and Drug Administration (FDA) in 1992 for lesions not favorable for balloon angioplasty, but this technology has not been shown superior to balloon angioplasty[59] and is used infrequently in most centers and then primarily for treating in-stent restenosis, where it is safe and initially effective but has no proven superiority.[60] In 1994, two additional atherectomy devices, the Rotablator (Heart Technologies, Bellevue, WA; see Fig. 45-5*B*) and the Transluminal Extraction Catheter (TEC) (Interventional Technologies, San Diego, CA; see Fig. 45-5*C*) were approved for marketing by the FDA The Rotablator's principal advantage is in the treatment of calcified and undilatable stenoses, but it is also used to treat bifurcation lesions and in-stent restenosis and to debulk prior to stenting.[61-64] The TEC device is used principally in saphenous vein grafts, where aspiration of thrombus is its unique attribute. In 1999, a rheolytic thrombectomy device known as the Angiojet (POSSIS Medical, Inc., Minneapolis, MN; see Fig. 45-5*D*) also became available for treatment of intracoronary thrombus, and it has proved useful in the setting of acute coronary syndromes associated with large thrombi and in treatment of stent thrombosis.[65-69]

Stents: After a Decade of Use, the Dominant Strategy

None of the devices described earlier had the impact on interventional cardiology that was produced by the development of the stainless steel intracoronary stent. The first coronary stents were implanted in patients in 1986 by Puel in Toulouse and Sigwart in Lausanne for restenosis prevention,[70,71] an unproven hypothesis at the time, whereas the initial implantation in a patient in the United States was performed by the authors at Emory University in 1987 in the setting of abrupt closure,[72,73] following encouraging results in a canine model by Roubin et al.[74] The initial European experience was with a self-expanding mesh stent, whereas the experience at Emory was with a balloon-mounted coil stent that subsequently was marketed as the Gianturco-Roubin flex stent (Cook, Inc., Bloomington, IN) following FDA approval for abrupt or threatened closure in 1993. This stent made balloon angioplasty considerably safer by providing effective therapy for coronary dissections and reducing the need for emergency coronary bypass surgery, but the use of

this stent, despite intensive anticoagulation with heparin and warfarin, was complicated by stent thrombosis in 5 to 10 percent of patients, and bleeding was a common complication. The device that ultimately revolutionized interventional cardiology was the Palmaz-Schatz stent (Johnson & Johnson Interventional Systems, Warren, NJ) (Fig. 45-6). On the basis of two carefully conducted randomized trials that showed reduced restenosis compared with balloon angioplasty,[75,76] this device was granted FDA approval for marketing in 1994 for the elective treatment of *de novo* lesions in native coronary arteries. Over 100,000 implantations of this stent were performed in the first year of its availability. The interest in stenting was greatly heightened by a pivotal observation by Colombo that complete stent expansion by high-pressure balloon inflation, confirmed by intravascular ultrasound (Fig. 45-7), when aspirin and ticlopidine were substituted for warfarin, yielded a very low thrombosis rate.[77] A randomized trial of stent placement without ultrasound guidance comparing aspirin and ticlopidine with phenprocoumon (a warfarin derivative) (ISAR) revealed a low 30-day incidence of cardiac events and bleeding rates in the aspirin-ticlopidine patients, supporting this simplified antithrombotic strategy[78,79] (Fig. 45-8). This finding was confirmed and extended by the Stent Anticoagulation Restenosis Study (STARS) investigation, which showed that aspirin and ticlopidine resulted in a lower rate of stent thrombosis than aspirin alone or a combination of aspirin and warfarin[80] (see Fig. 45-8), by a multicenter comparison of aspirin and ticlopidine with aspirin and oral anticoagulation in medium-risk (FANTASTIC, Fig. 45-8) and high-risk patients showing better outcome with the simpler approach,[81,82] and by a report of Mayo Clinic experience suggesting that 14 days of ticlopidine and aspirin was adequate for prophylaxis against stent thrombosis in most patients.[83] However, rare reports of thrombotic thrombocytopenia purpura related to ticlopidine use accounting for at least 20 deaths[84,85] led most centers to abandon ticlopidine in favor of clopidogrel, also an antagonist of platelet ADP receptors with similar pharmacologic activity but with far fewer side effects.[86] Clopidogrel proved equal to ticlopidine in observational reports,[87,88] and in a randomized investigation, the Clopidogrel Aspirin Stent Interventional Cooperative Study (CLASSICS), it was observed that neutropenia, thrombocytopenia, or early discontinuation of the drug was more common in the ticlopidine group (9.1 versus 2.9 percent) than in the clopidogrel group, which received 300 mg as a loading dose and 75 mg subsequently,[89] and that major cardiac events were similar at 1 month.[90] Currently, most centers use a loading dose of 300 to 525 mg clopidogrel when prolonged pretreatment is not possible plus aspirin 160 to 325 mg daily and 75 mg clopidogrel plus aspirin for 15 to 30 days after stent implantation.

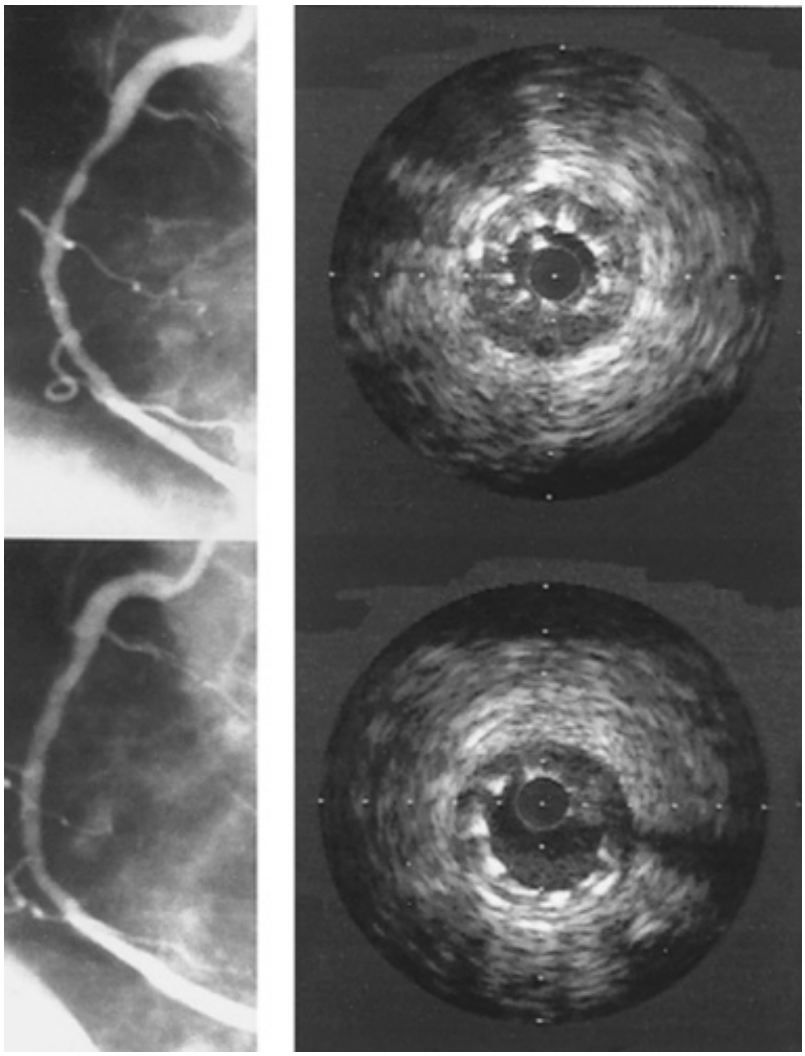

Figure 45-7: A 74-year-old woman developed early recurrence of angina after balloon angioplasty of the right coronary artery. Coronary arteriography revealed a severe, long stenosis of the right coronary artery (*top left*). Stenting was advised, and a Wallstent was deployed and dilated with a 3.5-mm balloon to 15 atm with an excellent angiographic result (*bottom left*). IVUS, however, showed that the distal end of the stent had been missed with the balloon and was poorly expanded (*top right*). This area was "redilated" to 16 atm with no change in the angiogram but much better stent expansion and wall apposition by ultrasound (*bottom right*). Following repeat dilation, the lumen cross-sectional area increased from 4.2 to 6.4 mm2.

A number of randomized trials have been conducted using the simpler antiplatelet therapy. The important Belgium Netherlands Stent II (BENESTENT II) study that randomized the heparin-coated Palmaz-Schatz stent and standard balloon angioplasty found better event-free survival at 12 months in the stent group (89 versus 79 percent; $p = 0.004$), lower restenosis (16 versus 31 percent; $p = 0.0008$), and higher costs in stent patients by $1020 at 1 year.[91] This study raised fundamental questions as to whether a strategy of elective stenting is justified in all patients, and further analysis of long-term follow-up suggested that stent implantation in some subsets was both superior and cost-effective (i.e., unstable angina, proximal LAD stenosis). To investigate these issues, the Optimal Angioplasty versus Primary Stenting (OPUS-1) trial randomized 479 patients to primary stenting or balloon angioplasty followed by provisional stenting only when necessary and reported that after 6 months the combined incidence of death, MI, and target-vessel revascularization was significantly lower in the primary stenting arm (6.1 versus 14.9 percent; $p = 0.003$), and at 6 months primary stenting was slightly less expensive ($10,206 versus $10,490).[92] This provocative study in which 99 percent of patients in the primary stent arm received a stent compared with 37 percent in the provisional stenting arm supported routine stenting when the

anatomy is appropriate as opposed to primary balloon angioplasty with stent backup, a strategy that has been advocated by some investigators[93-95] and, of course, was the dominant strategy in the early days of stenting. The use of coronary stents was reviewed extensively in a recent American College of Cardiology Expert Consensus Document[96] and in other reports.[96a,96b] This document and these newer studies provide perspectives on which to base everyday decisions regarding contemporary coronary intervention.

Stents versus CABG in Multivessel Disease

The issue of whether to recommend CABG or PTCA in patients with multivessel disease will be significantly influenced by the long-term outcome of randomized trials comparing stents with bypass surgery. Intermediate-term data are available from the Arterial Revascularization Therapy Study (ARTS), which randomized 1205 multivessel disease patients in 68 clinical centers to stent or standard CABG. At 1 year, there was no difference in death or MI; however, repeat interventions were higher in the stent group.[97] One-year survival free of death, MI, and reintervention was seen in 87.6 percent of the surgical group and 73.7 percent of the stent group ($p < 0.04$), but at a higher total 1-year cost (13,645 versus 10,860 euros). The occurrence of late events in 26 percent of ARTS stented patients was approximately one-half the incidence seen following balloon angioplasty in multivessel disease in BARI and EAST due to a reduced need for repeat revascularization in stented patients. As in BARI, the mortality rate in ARTS of diabetics treated percutaneously was significantly higher than that of nondiabetics (6.3 versus 3.1 percent; $p < 0.01$).[98] In the smaller Argentine Randomized Study of Stents versus CABG in Multivessel Disease (ERACI II), 450 patients were randomized, and at 14.7 months, survival was better in the stent group (97.4 versus 92.5 percent; $p < 0.015$) and freedom from MI was higher (97.7 versus 93.4 percent; $p < 0.017$), but repeat revascularization was needed more often in the stent group and costs were similar.[99] The Stent or Surgery Trial (SOS) will soon be completed and should offer additional insights.

Adjunctive Strategies

Intravascular ultrasound (IVUS) also has been used extensively in some centers to evaluate coronary lesions for device therapy and to assess the results of device and balloon treatment,[77,100] but the increased cost of this approach is a limiting factor. Although IVUS has had significant impact on the evolution of interventional cardiology, on the understanding of restenosis, and in evaluation of difficult lesions, its routine use in most centers is limited. See Chap. 47 for a detailed discussion.

IIb/IIIa Platelet Receptor Inhibitors

The latest arrows in the quiver of the interventionalist are the new, potent antiplatelet agents.[101-113] The first approved by the FDA was a monoclonal antibody directed against the platelet glycoprotein IIb/IIIa receptor. This agent, abciximab (ReoPro, Centocor, Malvern, PA), was shown to reduce ischemic complications and late clinical events in high-risk angioplasty.[105] The other IIb/IIIa receptor inhibitors approved by the FDA, unlike the antibody abciximab, are competitive inhibitors; eptifibatide (Integrilin, COR Therapeutics, San Francisco, CA) is a peptide, and tirofiban (Aggrastat, Merck, White House Station, NJ) is a small nonpeptide molecule. Each of these IIb/IIIa agents has been shown to consistently reduce a composite end point of death or nonfatal MI in the setting of coronary intervention and in acute coronary syndromes[79,101-105] (Fig. 45-9). Further, at 3-year follow-up in the EPIC trial, the first major study of abciximab during coronary intervention, a subgroup of 555 patients with acute coronary syndromes treated with bolus abciximab and infusion had a significant reduction in mortality at 3 years.[106] For a detailed discussion of IIb/IIIa platelet receptor inhibitors, see Chap. 44. In a recent

review of the use of the three FDA-approved IIb/IIIa receptor inhibitor agents in acute coronary syndromes, it was noted that they were each effective in reducing a composite end point of death or MI when administered prior to or at the time of percutaneous coronary intervention[107] (Fig. 45-10). In most centers, the use of these agents, slowed initially by bleeding complications and high costs, has been increasing especially in high-risk patients. Also contributing to this trend is the favorable outcome of IIb/IIIa receptor inhibitor-treated patients in the Evaluation of Platelet IIb/IIIa Inhibitors of Stenting (EPISTENT) trial, in which abciximab therapy in patients undergoing stent implantation or balloon angioplasty was evaluated.[108,109] At 6 months, the incidence of a composite end point of death or MI was 5.6 percent in patients receiving a stent and abciximab compared with 11.4 percent in those receiving a stent and placebo ($p < 0.001$) and 7.8 percent in patients treated with balloon angioplasty and abciximab (Fig. 45-11). There was a further advantage in diabetics, in whom the combination of abciximab and stenting was associated with a lower rate of repeat target vessel revascularization (8.1 percent) than was observed with stenting and placebo (16.6 percent; $p = 0.02$) or angioplasty and abciximab (18.4 percent; $p = 0.008$), and this benefit persisted through 1-year follow-up.[110] The mechanism by which target-vessel revascularization was reduced in the abciximab-treated patients is unclear.[111] Previous reports indicate that abciximab did not prevent neointimal proliferation or reduce in-stent restenosis.[112] EPISTENT does, however, raise the question regarding whether all diabetic patients and further all patients receiving stents should receive IIb/IIIa platelet inhibitors. Ongoing trials of these agents in stented patients may shed light on this important question. Clearly, however, these potent new strategies enhance the ability to provide safe and effective percutaneous revacularization.[113] Recently published data from CAPTURE indicated the presence of a gradient in the benefit obtained from IIb/IIIa receptor inhibition with abciximab in unstable angina. Death or MI was significantly less frequent in patients with elevated baseline troponin treated with abciximab compared with placebo (9.5 versus 23.9 percent; $p = 0.002$), but this end point was not different in troponin-negative patients (7.5 versus 9.4 percent; $p = 0.47$).[114] Stated differently, without an elevated troponin level, there was no benefit of treatment with respect to risk of death or MI. While there was no difference in death, MI, or urgent intervention in simple lesions, there was for complex lesions (ACC/AHA classes B2 and C) an incidence of this end point of 19.1 percent for placebo versus 11.5 percent for abciximab ($p = 0.055$).[115] The benefit gradient was steepest for bifurcation lesions in young patients. Occlusion of a side branch of more than 1.5 mm diameter, orginating from the angioplasty site, occurred in 2.8 percent of placebo-treated patients and 1.0 percent of abciximab-treated patients ($p = 0.03$). Also of interest, when flow in the culprit artery was less than TIMI grade 3 after angioplasty, the incidence of death and MI at 30 days was 11.5 percent with placebo and 4.1 percent with abciximab, supporting a role for abciximab in ameliorating the consequences of postprocedure slow flow. These observations that IIb/IIIa receptor inhibitors appear to be more effective in patients with refractory unstable angina, complex anatomy, and slow flow, results not observed previously,[104,105,116] may help in the design of trials to better determine the place of these agents.

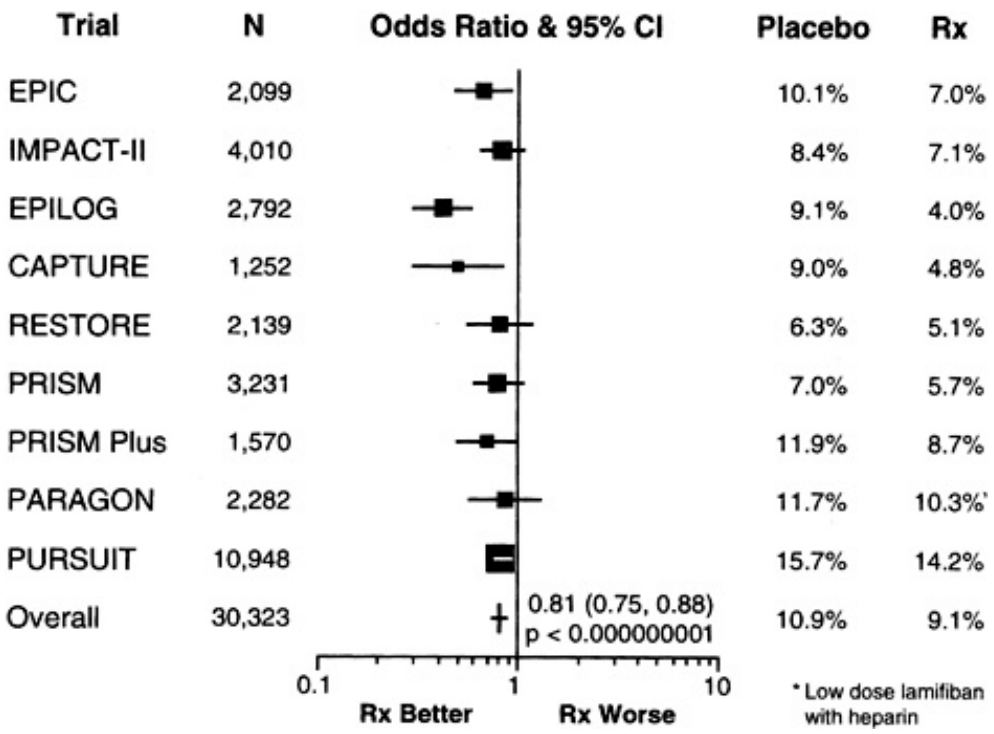

Figure 45-9: Odds ratios and 95 percent confidence intervals for nine large-scale randomized trials of IIb/IIIa platelet receptor inhibitors for percutaneous coronary interventions or unstable angina/non-Q-wave MI. Overall, in 30,323 patients, a 19 percent reduction in death or MI at 30 days was demonstrated. (From ref. 79 with permission.)

Chapter 45: PERCUTANEOUS CORONARY INTERVENTION

INDICATIONS FOR CORONARY INTERVENTION

In general, when one is selecting percutaneous coronary intervention, there should be assurance that the operator can treat, with a high probability of success, the coronary lesion(s) accounting for the symptoms or signs of myocardial ischemia. Further, the associated risk and durability of the revascularization should be acceptable as compared with bypass surgery or medical therapy during both early and long-term follow-up. The latter estimate requires consideration of the likelihood and consequences of abrupt vessel closure, restenosis, and incomplete revascularization. In addition, one cannot disregard the comparative costs of the initial intervention, its complications, and the need for subsequent revascularization procedures. The American College of Cardiology/American Heart Association Guidelines for Percutaneous Transluminal Coronary Angioplasty and Coronary Bypass Surgery provide a detailed analysis of many of these issues.[45,117,118]

Selection of Patients

SINGLE-VESSEL DISEASE

Percutaneous revascularization is an attractive option for many symptomatic patients who are anatomically suitable, having single-vessel coronary disease. It is important, however, to remember that there are no large studies comparing angioplasty with surgery in this group of patients and none that show a statistically significant survival benefit of angioplasty compared with surgery or medical therapy. Data from Emory University indicate that of 692 single-vessel disease patients newly diagnosed in 1988, a total of 46 percent underwent angioplasty, 50 percent were treated medically, and 4 percent underwent coronary bypass surgery. Of 7604 patients with single-vessel disease treated at Emory with angioplasty between 1980 and 1991, angiographic success was 90 percent and complications were infrequent (Q-wave MI, 0.8 percent; emergency CABG, 1.7 percent; and death, 0.2 percent).[119] In these patients with single-vessel disease, 1-, 5-, and 10-year survival was 99, 93, and 86 percent, respectively, whereas 80, 69, and 58 percent were PTCA-free and 92, 87, and 77 percent were CABG-free at 1, 5, and 10 years. In the Duke Data Bank experience, 5-year survival with angioplasty in single-vessel disease compared favorably with bypass surgery (95 versus 93 percent with CABG).[120]

The ACME study showed that angioplasty in single-vessel disease can lead to improved quality of life compared with medical therapy at 6 months, with reduced angina and improved exercise performance out to 3 years.[25,121,122] Clearly, it is improvement in symptoms rather than prolongation of life that is achieved by angioplasty in this patient subset. The ACME data suggest, however, that using the angioplasty techniques available at that time resulted in a slightly increased risk of acute complications (2 percent emergency CABG, 1 percent Q-wave MI) and repeat revascularization (23 versus 9 percent) at 6 months but no difference in late revascularization at 3 years.[122]

In an observational report from Kansas City of 704 patients with single-vessel LAD artery revascularization, 2-year mortality was 3.9, 2.6, and 1 percent in PTCA, stent, and LIMA-LAD revascularization groups, respectively ($p = 0.33$), and repeat procedures occurred in 30, 24, and 5 percent, respectively ($p = 0.001$).[123] In the randomized Medicine, Angioplasty, or Surgery Study (MASS) of isolated LAD disease, there was no difference in MI or mortality at 5 years but fewer late events in the surgery group.[124] In a relatively small, randomized trial of angioplasty and IMA surgery for isolated disease of the LAD artery, there was no difference in mortality or MI, but angioplasty patients had more repeat revascularizations (25 versus 3 percent; $p < 0.01$).[125] Clear superiority of stenting over balloon angioplasty for isolated LAD disease was demonstrated in a randomized comparison of these strategies in 120 patients.[126] One-year rates of event-free survival were 87 percent after stenting and 70 percent after

angioplasty ($p = 0.04$), and restenosis rates were 19 and 40 percent, respectively ($p = 0.02$).

Studies from the Cleveland Clinic analyzing the importance of repeat procedures in determining 2-year cardiac cost suggest that coronary intervention is more cost-effective than medical and surgical therapy when the probability of repeat procedures is low.[127] One would infer from this analysis that the presence of multiple or complex lesions, which are likely to recur, may tilt the scale sufficiently to modify adversely the favorable comparative cost-effectiveness of percutaneous intervention in single-vessel disease.

MULTIVESSEL DISEASE

A dramatic increase in the use of percutaneous intervention in multivessel disease, fueled by improved angioplasty technology and new devices, accounts for the growth in these procedures worldwide. *Rational selection of patients, however, requires a careful analysis of multiple issues, including a risk-benefit assessment of each ischemia-producing lesion, a projection of the possible completeness and durability of the physiologic revascularization, and an estimate of resource consumption compared with surgery and medical therapy.*

In general, as stated in "Guidelines for PTCA,"[118] patients selected for intervention are symptomatic, have evidence of ischemia, need noncardiac surgery, are recovering from cardiac arrest or malignant arrhythmia, or have compelling anatomy. Patient preferences must be considered, since repeat interventions are a common and an integral aspect of percutaneous intervention in multivessel disease (see Table 45-1). Complete revascularization, which has been shown in the surgical experience to produce superior long-term results, has been associated with fewer late interventions after angioplasty,[128] but it is not frequently attained due to the presence of total occlusions, noncritical stenoses, and diffuse disease. In the 1985-1986 NHLBI PTCA Registry, complete revascularization was achieved in 19 percent of multivessel patients.[129]

At Emory University among 10,783 patients who underwent coronary intervention, complete revascularization was achieved in 84 percent of patients with single-vessel disease and 25 percent with two-vessel disease but in only 5 percent with triple-vessel disease.[119] In the experience of EAST, 71 percent of index segments were revascularized in PTCA patients.[130] Culpritlesion angioplasty is clearly an accepted strategy, but care must be taken to avoid significant residual ischemia after intervention. This approach was reflected in EAST, where revascularization was attempted in 96 percent of high-priority lesions in PTCA patients and in 99 percent of surgical patients. (*High-priority lesions* were defined as 70 to 100 percent stenoses located proximally or in large vessels ≥ 2.5 mm). This strategy yielded similar 3-year EAST primary end points for CABG and PTCA and an identical frequency of patients with all index segments free of stenosis of 70 to 100 percent (82 versus 82 percent).[130] Recently published data from BARI indicated that planned incomplete revascularization was unrelated to 5-year risk of cardiac death or death/MI but was related to risk of CABG.[131]

The risks of percutaneous coronary intervention are increased in the presence of unstable angina, advanced age, poor left ventricular function, extensive coronary artery disease, comorbid conditions, and female gender.[132] At Emory, in-hospital mortality for one-, two-, and three-vessel disease was 0.2, 0.4, and 1.2 percent, respectively ($p < 0.0001$), and emergency bypass surgery was needed in 1.7, 3.0, and 3.2 percent, respectively.[119] In general, the risk of intervention is directly related to the probability and consequences of abrupt closure. In multivessel disease, both are frequently higher, and impaired left ventricular function is commonly present. Recent application of stenting in multivessel percutaneous intervention has improved outcomes significantly.[133-136] In a report from the Washington Hospital Center, in-hospital and long-term outcomes of 398 consecutive patients undergoing multivessel stenting were quite similar to those of patients undergoing single-vessel stenting with respect to mortality (1.4 versus 0.7 percent; $p = 0.26$), repeat revascularization (20 versus 21 percent; $p = 0.73$), and Q-wave MI (0 versus 1.2 percent; $p = 0.02$). Overall event-free survival was similar.[135] Although the major randomized trials of angioplasty versus bypass surgery also showed no overall difference in mortality on long-term follow-up, BARI reported that patients being treated for diabetes had significantly worse 5-year mortality with angioplasty compared with surgery (35 versus 19 percent).[39] In a smaller cohort of diabetic patients in EAST, however, there were no differences in outcome until almost 8 years following revascularization. The BARI findings question the safety of angioplasty in the diabetic population, who frequently have diffuse multivessel disease, more

frequent restenoses, more rapid disease progression, and in many cases a reduced recognition of recurrent ischemia.[44,137] ARTS extended this cautionary theme in multivessel diabetics with observations that stented diabetics had roughly twice the mortality of nondiabetics[98] (see "Randomized Trials of Balloon Angioplasty," above).

UNSTABLE ANGINA

Patients with unstable angina, who account for a majority of coronary interventions, are at increased risk for ischemic complications, particularly abrupt closure.[117,118,132] These complications, which are presumed to be related to the presence of thrombus and ruptured complex plaque[138] (see Chaps. 40 and 44), as demonstrated elegantly by angioscopy,[139,140] have led many operators to defer intervention for a few days while stabilizing the patient on aggressive antianginal therapy, including aspirin and heparin[141-143] (particularly in the presence of angiographic thrombus).[144] Alternatively, the favorable results achieved with angioplasty within 18 to 48 h after hospitalization in randomized trials of interventional strategies in unstable angina (96 percent angiographic success, 0.4 percent mortality, 2.9 percent MI, 0.7 percent emergency CABG, 2.2 percent abrupt closure)[145] and the recently reported FRISC II study of invasive management of non-Q-wave MI[30,31] have encouraged some to pursue a more aggressive approach, particularly in patients at highest risk of a coronary event-i.e., those with postinfarction angina[146] and angina refractory to medical therapy.[147] The use of direct antithrombins[148] and platelet glycoprotein IIb/IIIa inhibitors[105] has been shown to be effective in reducing complications of intervention in unstable angina, whereas the routine administration of thrombolytic agents has reduced the thrombus burden but with an unfavorable impact on complications (i.e., in hospital ischemic events; 12.9 versus 6.3 percent without thrombolytics; $p = 0.02$).[149] At present, the optimal adjunctive therapy in unstable angina is unclear, but recent trials of the currently available IIb/IIIa platelet receptor inhibitors and of low-molecular-weight heparin have shown important reductions in complications in patients with non-ST-segment elevation acute coronary syndromes during medical therapy[101-103,114-116,150-153] and additional protection with IIb/IIIa receptor inhibitors during coronary intervention[107,154] (see Fig. 45-10 and Chap. 41). Data from CAPTURE in patients with unstable angina indicated that the benefit of IIb/IIIa receptor inhibition was greatest in troponin-positive patients and those with complex coronary anatomy.[114,115,155]

Selection of Lesions

LESION CHARACTERISTICS

The importance of coronary stenosis angiographic morphology in predicting the outcome of coronary angioplasty is reflected in the American College of Cardiology/American Heart Association "PTCA Guidelines."[117,118] Lesions were classified as type A for anticipated high success, low risk; type B for anticipated moderate success, moderate risk; and type C for anticipated low success, high risk (Table 45-2). The general validity of this classification in predicting outcome of balloon angioplasty was confirmed in low-risk patients,[156] in patients with multivessel disease,[157] and in patients undergoing directional atherectomy, in whom success and complication rates were 93 and 3 percent for type A lesions, 88 and 6 percent for type B_1, and 75 and 13 percent when more than one B characteristic was present (type B_2).[158] More recent analysis of this lesion scoring system using balloon angioplasty technology of the 1990s suggests rates of 96, 93, and 80 percent can be achieved with type A, B, and C lesions, respectively, and that certain morphologic characteristics (i.e., long lesions, calcified lesions, stenosis severity 80 to 90 percent, angulated lesions, and presence of thrombus)[159] may have higher predictive value in determining success and complications. The ABC classification also was reported to be useful in predicting outcome after contemporary angioplasty in a population of unstable angina patients in whom early adverse events occurred in 4 percent of type A, 7.7 percent of type B_1, 15.3 percent of type B_2, and 17.9 percent of type C lesions in patients treated with heparin.[160] It does appear, however, in many centers that the complexity of lesions being attempted has increased and that new devices (especially stents) and antithrombotic strategies have, to a certain extent, weakened the prognostic value of this scoring system. In one recent report of 1085 lesions treated in the era of new devices (type A, 8 percent; type B_1, 42 percent; type B_2, 35 percent; type C, 15 percent), procedural success was 100 percent for type A, 97.3 percent for type B_1, 97 percent for type B_2, and 87.4 percent for type C lesions. Predictors of procedural failure were lesion length greater than 20

mm, TIMI-I flow, calcification, angle greater than 90 percent, and chronic total occlusion.[161] In an effort to update this classification based on results of contemporary coronary intervention using stents and IIb/IIIa platelet receptor inhibitors, Ellis and colleagues analyzed results from 10,907 lesions and proposed a new classification scheme for risk stratification.[162] Over 4000 patients treated in 1995 through 1996 constituted a training set (40.7 percent received stents, 26 percent abciximab, 18.9 percent Rotablator, 0.9 percent directional atherectomy, 0.2 percent excimer laser, and 0.2 percent TEC). Nine preintervention variables were independently correlated with adverse outcome (non-chronic total occlusion, degenerated vein graft, vein graft age greater than 10 years, lesion length greater than 10 mm, severe calcium, lesion irregularity, large filling defect, angulated greater than 45 degrees plus calcium, and eccentricity). A proposed classification (Table 45-3) validated against 2146 patients treated in 1997 had greater predictive value than the ACC/AHA classification, but not by as much as expected. Importantly, lesion characteristics previously thought to be associated with a heightened risk but absent in the new classification include lesion angulation per se, bifurcation location, ostial site, proximal tortuosity, and small thrombus. When the new model was tested against the 1997 validation set, adverse outcomes [death, MI > 3 × creatine kinase (CK) or emergency CABG] occurred in 2.1 percent of low-risk patients, 3.4 percent at moderate risk, 8.2 percent at high risk, and 12.7 at highest risk (compared with 2.5, 3.0, 5.2 and 6.6 percent for ACC/AHA types A, B_1, B_2, and C, respectively). Whether bifurcation location should be included as a predictor of complications is debatable. In our own experience, bifurcation has represented increased risk, and this was confirmed in CAPTURE, where placebo-treated patients with bifurcations had a higher rate of death, MI, or early revascularization than placebo-treated patients without bifurcations (23 versus 11.7 percent; $p < 0.05$).[115] Importantly, this increased risk of complications with bifurcations was neutralized by treatment with abciximab. It should be recognized, however, that other factors are important in determining risk in the stent and IIb/IIIa inhibitor era, including patient age, LVEF, acute MI presentation, and operator experience, and these also must be considered.[163-165]

Table 45-3: New Risk-Assessment Schema Based on Analysis of 10,907 Lesions Treated in the Stent and IIb/IIIa Era

Strongest correlates:	Nonchronic total occlusion
	Degenerated saphenous vein graft (SVG)
Moderately strong correlates:	Length ≥10 mm
	Lumen irregularity
	Large filling defect
	Calcium + angle ≥45°
	Eccentric
	Severe calcification
	SVG age ≥10 years
Highest risk:	Either of strongest correlates
High risk:	≥3 moderate correlates and the absence of strong correlates
Moderate risk:	1-2 moderate correlates and the absence of strong correlates
Low risk:	No risk factors

SOURCE: Ellis et al.[162]

LEFT MAIN CORONARY ARTERY LESIONS

Whereas percutaneous intervention in protected left main coronary artery disease has been an accepted strategy for many years,[166] significant narrowing of an unprotected left main coronary artery has been considered a contraindication to this approach since Gruentzig's early recognition of increased mortality.[9,10] With the advent of improved technology in the form of atherectomy devices and stents, percutaneous revascularization has been applied increasingly in patients with unprotected left main coronary artery lesions.[167-170] Although reports of unprotected left main angioplasty/stenting indicated reasonably good results in carefully selected patients,[168,170] CABG remains the treatment of choice according to ACC/AHA guidelines.[45] Patients considered for percutaneous intervention in an unprotected left main coronary artery lesion in our hospital include those with significant comorbidity, making CABG impractical, and patients experiencing abrupt left main coronary artery closure as a complication of coronary angiography or presenting in cardiogenic shock without immediately available surgery.[170,171]

PREDICTORS OF RESTENOSIS

Lesion characteristics that were associated with increased restenosis rates following balloon angioplasty alone or after stent implantation include length, total occlusion (Fig. 45-12), vessel size less than 3 mm, ostial location, previous angioplasty to the same site, and saphenous vein grafts.[172-174] The assessment of lesion characteristics by IVUS and angioscopy also has been shown to have prognostic value for determining angioplasty success and long-term outcome,[175-179] and in some centers these strategies are used frequently to guide therapy (see Chap. 47). Selection of lesions for intervention is strongly based on the operator's assessment of his or her ability to treat the ischemia-producing lesion safely and in a cost-conscious manner and to achieve long-term patency and symptomatic benefit.

IN-STENT RESTENOSIS

One of the most vexing lesions confronting the interventionalist is in-stent restenosis, a new "disease" created by the explosion of stent use worldwide. This lesion, solely the result of neointimal proliferation as opposed to a combination of negative remodeling and intimal proliferation seen in nonstented lesions,[179] was reported by Yokoi et al.[180] to have an overall recurrence rate of 37 percent, but this rate is up to 85 percent for diffuse in-stent restenosis. Among 288 lesions, recurrent restenosis was highly correlated with the pattern of restenosis (target lesion revascularization in 19 percent of focal lesions less than 10 mm, 35 percent for lesions larger than 10 mm but confined to the stent, 50 percent for lesion larger than 10 mm and extending beyond the stent, and 83 percent for total occlusions; $p < 0.0001$). Additional correlates were the presence of diabetes (odds ratio, 2.8) and previous in-stent restenosis (odds ratio, 2.7).[181] In-stent lesions have been shown by IVUS to have significant reintrusion of tissue shortly after catheter-based intervention not apparent by quantitative angiography.[182] Debulking with atherectomy and laser techniques has been advocated and, although safe and associated with a larger postprocedure minimal lumen diameter (MLD), has not been shown to be superior to balloon angioplasty.[183-186] Although preliminary results from a U.S.-based multicenter randomized comparison of rotational atherectomy and balloon angioplasty were encouraging,[187] results of ARTS indicated that rotablation was inferior to balloon angioplasty (restenosis in 70 percent compared with 50 percent with balloon; $p = 0.008$).[188] Yokoi[189] reported results of repeated balloon angioplasty of in-stent restenosis in 310 patients, observing a first recurrence in 51 percent and subsequent recurrences following repetitive procedures in 68, 78, 74, and 92 percent of patients. Although 98 percent of patients were free of death and 90 percent were free of death/MI/CABG at 3 years, the increasingly high restenosis rate makes this approach impractical. The investigational use of radiation to inhibit neointimal proliferation has produced the most promising strategy for potential use in the treatment of this difficult problem. In randomized trials, beta and gamma radiation has reduced restenosis rates of 50 to 60 percent to approximately 20 percent[190,191] with reduction in 2-year death, MI, or target vessel revascularization (TVR) from 52 to 23 percent ($p = 0.03$).[192]

Selection of Devices

Conventional balloon angioplasty is a simple, relatively low in cost, and effective method of reducing coronary stenosis, but new devices (especially stents) are being used with increasing frequency, particularly in conditions where balloon angioplasty has been proved not to be highly effective (Table 45-4). At Emory University Hospital in 1990, balloon angioplasty was the sole technique used in 88 percent of 1863 patients

who underwent coronary intervention (directional atherectomy, 3 percent; excimer laser, 3 percent; stents, 2 percent; laser balloon, 1 percent), whereas in 1998, a majority of lesions that were discrete and not involving bifurcations were treated with stent implantation (66 percent of all patients), and the atherectomy procedures performed were prinicipally with the Rotablator for calcified, rigid, or bifurcation lesions (accounting for 8 percent of patients). At the Cleveland Clinic in 1997, device use frequency was as follows: stents, 64 percent (62.6 percent planned and 1.6 percent bailout); rotational atherectomy, 18 percent; directional atherectomy, 0.6 percent; excimer laser, 0.5 percent; and TEC 0.1 percent.[162]

Table 45-4: New Coronary Interventional Strategies Compared with Balloon Angioplasty

Technique	Indications	Contraindications	Advantages and Limitations
Balloon angioplasty	Focal stenosis	Insignificant narrowing, no ischemia, unimportant artery	Broad applicability, lower cost; poor outcome in thrombotic, ostial, and calcified lesions; significant restenosis
Stents	Focal stenosis	Heavy calcification or thrombus, vessel diameter <2.5 mm	Reduced emergency CABG and restenosis; more expensive, rare stent thrombosis
Directional atherectomy	Focal noncalcified	Diffuse disease, severe tortuosity or bend	Debulks, reduced restenosis; more frequent non-Q-wave MI, more expensive, technically difficult
Rotational atherectomy	Focal calcified stenosis, ostial site	Thrombus, large plaque burden, severe tortuosity or bend	Effective in calcified lesions, reduced elastic recoil; more expensive, similar restenosis, transient left ventricular dysfunction
Laser	Ostial lesion, SVG, in-stent restenosis	Severe calcification, tortuosity or bend	Debulks effectively; increased cost, similar restenosis
Transluminal extraction atherectomy	Thrombotic lesion, bulky SVG lesion	Severe tortuosity or bend, calcification	Thrombus and plaque removed; high complication rate in native vessels, distal embolization
Rheolytic thrombectomy	Thrombus	No thrombus	Effective thrombus removal; no plaque removal

PROVISIONAL STENTING

The practice of performing balloon angioplasty as an initial strategy in a majority of patients and using stents for suboptimal results is supported by observations from the BENESTENT trial that stentlike results (30 percent residual narrowing) were achievable in 35 percent of patients with balloons and that they had a long-term outcome comparable with that of stented patients.[193] This strategy has been reported to be cost-

effective,[194] but the recent OPUS-1 study of primary stenting suggested that primary stenting was cost-effective after 6 months because of reduced reinterventions.[92] Adjunctive stents placed for bailout have been shown clearly to reduce Q-wave infarction and emergency bypass surgery.[72,73] Although subacute thrombosis was substantially higher in patients with stents placed emergently in the early experience, the employment of high-pressure balloon inflations in recent studies and the use of antiplatelet agents such as ticlopidine and clopidogrel plus aspirin instead of warfarin have reduced this complication substantially to about 1 percent.[195]

PRIMARY STENTING

In our hospital, stents frequently are selected for primary treatment of complex lesions, aortoostial sites, shelflike lesions, early recurrence, total occlusions, and lesions with high restenosis rates (proximal LAD artery and saphenous vein grafts) (Figs. 45-7, 45-12, and 45-13). It is important to point out that restenosis rates obtained with stents in complex lesions are not as favorable as in simple lesions[196,197] and that these applications have not been subjected to rigorous comparison with balloon angioplasty. Randomized comparison has been carried out, however, in saphenous vein grafts, where 6-month MLD was significantly larger with stents (1.75 versus 1.47 mm; $p = 0.05$), and a composite end point of death, MI, CABG, or target lesion revascularization was less frequent (26 versus 38 percent; $p = 0.05$).[198] Stents also were shown in randomized trials to be superior to balloon angioplasty in total occlusions (TVR in 8.4 versus 15.4 percent; $p = 0.03$)[199] and in restenotic lesions (TVR in 10 versus 27 percent; $p = 0.001$).[200]

Given the superb results reported in the BENESTENT II study[91] with heparin-coated stents (overall clinical success 99 percent, stent thrombosis 0.2 percent, restenosis 16 percent, and 1-year mortality 1 percent) and the large number of new stent designs currently available, one would anticipate broadened use of improved and cheaper stents due to competitive market forces. Decreased cost may permit stenting to rival or prove more cost-effective than simple balloon angioplasty for most lesions.[201-203]

ATHERECTOMY

Currently, directional coronary atherectomy (DCA) is used infrequently in most centers as primary therapy but may be applied effectively in STRESS and BENESTENT-equivalent lesions[54] or used adjunctively prior to stent implantation based on registry data indicating that this strategy can yield restenosis rates as low as 11 percent.[56] Suitable lesions are generally proximal in vessels larger than 3 mm in diameter and have features that predict poor outcome with primary stenting such as high-bulk stenoses, ostial site, proximal LAD artery lesion, and protected left main coronary lesions[170,204] and include carefully selected bifurcation lesions[205-209] and complex postinfarction lesions (where histology frequently shows partially organized thrombus; see Fig. 45-10). Pretreatment of calcified lesions with rotational atherectomy may permit successful DCA in selected patients,[209] but in general moderate angiographic calcification and significant superficial calcification on IVUS are predictors of failure.[175]

Rotational atherectomy has proved useful in the presence of calcium, in treatment of aortoostial and branch ostial lesions, and in nondilatable lesions. In some series, it has been used in long, ulcerated, and complex lesions with excellent acute results,[210,211] and in some reports, long-term outcome of stenting was improved by rotablation pretreatment.[63] Highly angulated or thrombotic lesions or those with impaired distal runoff (recent infarction, fixed thallium defect) and segments with myocardial bridging should be avoided.[210-213] Rotational atherectomy also has been used in total occlusions, but restenosis rates have not been demonstrated to be better than those of balloon angioplasty. Elective intraaortic balloon pump placement has been shown to improve systemic blood pressure and to be associated with a lower non-Q-wave MI rate in high-risk patients.[214] Care is needed in selection of rotablation in patients with reduced left ventricular function due to the transient regional ventricular dysfunction shown to persist for over 2 hours after the procedure.[215]

The TEC, which is unique in its ability to cut and aspirate plaque and thrombus, is used primarily in saphenous vein grafts containing thrombus, where acute success rates are high, but embolic MI and

restenosis are not uncommon.[216-218] In some centers, high-risk patients with MI have been treated successfully with TEC either acutely or following postinfarction angina due to thrombotic coronary occlusion with results comparable with those of balloon angioplasty.[219] When used in the treatment of complex native coronary artery lesions not associated with acute MI, the outcome also appears similar to that of balloon angioplasty,[220] but use of TEC doubles the cost. In carefully selected patients with large intracoronary thrombi and ongoing ischemia, TEC has proved useful, as has the Dispatch catheter (Scimed Life Systems, Maple Grove, MN), a device for localized intracoronary infusion.[221] The Angiojet (Possis Medical, Inc., Minneapolis, MN) is the most effective thrombectomy device currently available and is used principally to treat large intracoronary thrombi.[65-69,222]

LASER ANGIOPLASTY

Although ablative laser angioplasty (XeCl excimer and holmium Nd:YAG) has been shown to be effective in the treatment of aortoostial sites, undilatable lesions, total occlusions, calcification, long lesions, and saphenous vein grafts,[223-226] its superiority to simpler and less costly balloon strategies has not been demonstrated.[227-229] Lesions that should not be selected for ablative laser angioplasty include those on bend points or in tortuous segments, those associated with severe calcification or thrombus, or lesions with a suspected subintimal wire passage. In general, bifurcation lesions should not be selected for ablative laser therapy unless an eccentrically directed device can be used to avoid perforating at the flow divider of the vessel. The use of a laser guidewire to cross total occlusions has been advocated.[230]

Chapter 45: PERCUTANEOUS CORONARY INTERVENTION

PERFORMANCE OF CORONARY INTERVENTION

Operator Proficiency

Current guidelines recommend that cardiologists who wish to become competent in coronary intervention receive special training in diagnostic and therapeutic catheterization during an additional year after the standard fellowship training program and maintain skills by performance of a minimum of 75 procedures per year.[231-237] Adequate case mix is an important aspect of a physician's training in interventional cardiology that has not yet been addressed by practice guidelines.[238,239] Assurance of quality by surveillance of procedural outcomes is made difficult by such complex issues as a need to adjust for high-risk patients, low incidence and subjectivity of major adverse events, and low volume of many operators.[163-165,240-242]

Interventional Laboratory

Optimal conditions for performance of coronary angioplasty procedures require sophisticated imaging systems; trained personnel; a large inventory of dilation, atherectomy, and stent hardware and software; and a variety of therapeutic safety nets to protect the patient when intervention fails or is complicated. Most studies suggest that laboratory procedural volume is important and inversely related to adverse procedural outcomes.[163,243-245] The quality of the video image of the coronary arteries is an important determinant of angioplasty success. A freeze-frame storage and display capability is required for use during the procedure, as is a high-quality video replay with slow-motion and stop-frame capability. The ability to solve specific problems-such as lesion eccentricity or rigidity, vessel tortuosity, and unusual position or orientation of the coronary ostia-often depends on specific device characteristics. Consequently, it is necessary to have available dilating catheters, stents, atherectomy devices, guidewires, and guiding catheters in a variety of shapes and sizes. Cardiac surgery should be available in the institution if needed for emergency situations.

Interventional Equipment

The over-the-wire steerable catheter system used in most coronary interventions is illustrated in Fig. 45-14. In atherectomy, ablative laser, or stent procedures, the device replaces or is mounted on a balloon catheter. The balloon or device is introduced through a guiding catheter that extends through the arterial puncture site (femoral, brachial, or radial) to the coronary artery or graft ostia, where coaxial alignment of the catheter and vessel is highly desirable. In the past, the Judkins right and left coronary shapes were used most frequently, but many other shapes are currently available to address specific anatomic problems (Figs. 45-15 and 45-16). The size (5-11 French) and shape of the guide catheter may be determined by the arterial size at the entry site, the guide catheter lumen requirement of the device used, and other factors such as a need for optimal vessel opacification. Balloon catheters for coronary use are available in an array of balloon lengths (8-40 mm), diameters (1.5-5 mm), shaft sizes, and special features, including active and passive perfusion, high-pressure capability, and local intracoronary infusion.

In the United States, the most frequently used stent in early experiences, the Palmaz-Schatz stent (see Fig. 45-6), was provided with a sheath delivery system that necessitated an 8 French guide catheter, whereas most currently used stents are accommodated by 6 French catheters, and

use of these smaller catheters for radial artery or femoral approaches has increased dramatically.[246] A large number of new stent designs have cleared FDA approval and are available for use (Fig. 45-17). Although these new stent designs offer considerable advantage over first-generation devices in terms of their deliverability, profile, variety of sizes, and strength of balloon, stent versus stent comparisons have not been performed in a manner that helps the interventionalist in choosing the best device for a given problem.[247]

Figure 45-17: Currently available newer-generation stents. *A.* Nir stent (Medinol-Scimed, Maple Grove, MN). *B.* Cross-Flex LC stent (Cordis-Johnson & Johnson, Warren, NJ). *C.* Multi-Link Duet stent (Guidant, Santa Clara, CA). *D.* AVE-GFX stent (Medtronic-Applied Vascular Engineering, Santa Rosa, CA). *E.* Magic Wall stent (Schneider-Scimed, Maple Grove, MN). *F.* Radius stent (Scimed, Maple Grove, MN).

The high-speed rotational atherectomy device (see Fig. 45-5*B*), an olive-shaped burr with embedded diamond chips, requires a special 0.009-in. stainless steel guidewire, whereas the directional atherectomy cutter and laser catheters pass over conventional 0.014-in. steerable guidewires. The transluminal extraction catheter requires a unique 0.014-in. stainless steel guidewire that has a 0.21-in. ball at its tip.

The use of IVUS to guide therapy varies widely; it is almost routine practice in some centers and is rarely used in others. Ultrasound assessment of the adequacy of stent deployment (see Fig. 45-7), pioneered by Colombo and colleagues,[77] and evaluation of calcified lesions are probably the most frequent applications (see Chap. 47).

The Coronary Interventional Procedure

Prior to coronary intervention, patients receive an explanation of the procedure, including the operator's estimate of success, possible complications, risks, and benefits. A booklet and videotape describing the procedure and an explanation by the nursing staff help to reduce anxiety and ensure that both patient and family are well informed.

Antiplatelet therapy is used routinely. The therapy most widely used is aspirin 160 to 325 mg daily. Patients in whom stenting is planned also receive clopidogrel, usually in 300- to 525-mg loading dose unless pretreatment for several days has been performed. In a significant percentage of patients in our hospital, a platelet glycoprotein IIb/IIIa receptor antagonist is used when there is perceived to be an increased risk of abrupt closure or distal embolization (e.g., suspected or definite thrombus, acute coronary syndrome, complex lesion, diabetes, atherectomy procedure, or multisite intervention).[105] Restenosis trials have failed to show a clear advantage of one antiplatelet regimen over another and have not shown inhibition of restenosis by calcium channel-blocking agents, warfarin anticoagulation, angiotension-converting enzyme (ACE) inhibitors, steroids, or other agents.

Some operators administer a calcium channel-blocking agent prior to coronary intervention for prophylaxis against coronary artery spasm and to reduce ischemia during the procedure. Once the patient is in the catheterization laboratory, electrocardiographic monitoring leads are applied, a peripheral intravenous line is started, and midazolam 1 mg or an equivalent drug is given intravenously. In most laboratories, a femoral approach is employed; use of a radial artery approach, however, is increasing. Heparin is administered intravenously (100 units/kg, or 70 units/kg if IIb/IIIa receptor-inhibiting agents are used concomitantly). Maintenance of an activated clotting time (ACT) of greater than 300 s is recommended unless IIb/IIIa inhibitors are used, where 200 to 250 s is accepted. IIb/IIIa platelet receptor inhibitors are used selectively in our hospital for higher-risk patients (see "IIb/IIIa Platelet Receptor Inhibitors," above). Use of low-molecular-weight heparin during intervention is under investigation. Patients with a history of allergy to contrast material are premedicated with prednisone 40 to 60 mg orally the night before and the day of the procedure and with diphenhydramine (Benadryl) 50 mg intravenously at the time of the procedure. Ionic hyperosmolar contrast material is used commonly in our hospital for elective coronary angioplasty because of the extraordinary cost of low-osmolar agents and the lack of proved benefit to warrant their routine use.[248-250] Due to the reported increased thrombotic complications with nonionic agents (attributed to comparatively less thrombin inhibition and

enhanced platelet activation), ionic agents have been preferred in patients with unstable ischemic syndromes or frank intracoronary thrombus.[249] Recently published studies comparing ionic (Ioxglate) and nonionic (Iomeprol) agents in a randomized format,[251] ionic versus nonionic contrast material in EPIC, EPILOG, and CAPTURE in a metaanalysis,[252] and ionic versus nonionic in stenting,[253] however, revealed no increase in thrombotic complications, whereas nonionic agents were associated with more bailout stenting in a randomized study.[254] These studies reported outcomes with contrast agents with osmolalities in the 600 to 700 mosmol/kg range. Recent preliminary reports of the use of the isosmolar nonionic dimer iodixanol in high-risk PTCA were promising,[255] and further evaluation of this agent is warranted. Contrast-induced bradycardia, more common with ionic agents, is treated with atropine. Patients selected for use of a low-osmolar contrast agent include those with renal insufficiency or severe left ventricular dysfunction. Nonionic agents generally are reserved for patients with known allergy to the available ionic agents or with a history of severe bradycardia with ionic agents.

Coronary arteriograms are performed in two approximately orthogonal views selected to demonstrate the lesion(s) to be treated and the course of the parent artery without overlap by other vessels. The angles chosen are recorded, and freeze frames demonstrating the anatomy are stored and displayed during the procedure. A balloon catheter or device is selected based on the diameter of the target coronary artery to be treated and the length of the stenotic segment as determined by comparison with the guiding catheter of known diameter. The balloon diameter is chosen to approximate closely the diameter of the normal adjacent vessel, since oversizing the angioplasty balloon has been associated with increased complications and no reduction in the rate of restenosis.[256] In general, an over-the-wire catheter system is preferred because of the ability to exchange easily for alternative guidewires, balloons, or stents. The operator's impression of the difficulty of the case may influence selection of a particularly low profile catheter to cross severe stenoses, a flexible catheter or device to negotiate tortuous segments, or rotational atherectomy to treat a fibrotic, calcified lesion. Balloon-on-a-wire devices are especially useful when an ultra-low-profile balloon or simultaneous use of two balloons is required (see Fig. 45-2). Because of the current availability of very low profile and flexible balloon-mounted stents that are securely attached, direct stenting without predilating has increased dramatically in some centers. The coronary ostium is engaged with the guiding catheter, and the steerable guidewire is cautiously advanced into the target artery. In patients requiring angioplasty of more than one coronary artery, the most difficult lesion is commonly treated first. A clean crossing of the stenosis with the guidewire is critical and is accomplished by aligning the steerable wire tip with the entry point of the stenosis and gently advancing it across the lesion. The intraluminal position of the wire in the distal artery is confirmed by free rotation of the guidewire tip and by contrast angiography. If there is difficulty in crossing the stenosis with the guidewire, reshaping the tip commonly will lead to success. Changing the wire to one with different characteristics, such as a hydrophilic coating or one that is stiffer, may be necessary in the case of total occlusions.

With the steerable guidewire securely in the distal coronary artery, injections of contrast material are made through the guiding catheter to locate and mark the position of the stenosis to be treated. While fixing the position of the guidewire, the operator advances the balloon catheter or device to the lesion. If it is not possible to push the balloon or device across the stenosis, it may be wise to exchange it for rotational atherectomy or the lowest-profile over-the-wire balloon system available. If balloon angioplasty is being performed, the balloon is inflated to an initial pressure of 2 atm. Indentation of the inflated balloon by the lesion confirms proper placement. The balloon is subsequently inflated until the "waist" caused by the lesion is obliterated, and then the balloon is fully inflated. When using a compliant balloon, the operator may inflate the balloon to higher pressures to produce the balloon diameter desired. During these inflations, an attempt is made not to exceed the burst pressure of the balloon. The balloon is reinflated as needed to achieve an adequate dilation.

There is no clear evidence regarding the optimal number or duration of balloon inflations or the

maximal balloon pressure. Occasionally, if two to four inflations of 30 to 60 s do not yield the desired result, prolonged inflations up to 5 to 10 min may be helpful. Tolerance of the longer inflations may be enhanced by distal perfusion of arterial or venous blood through the dilatation catheter or by use of an autoperfusion balloon catheter.[257] Balloon inflations are limited by evidence of ischemia, as indicated by symptoms of chest discomfort or by ST-segment elevation. Some investigators have monitored intracoronary electrocardiograms from the steerable intracoronary guidewire and found these to be more sensitive in detecting ischemia than surface electrocardiograms. One also can use the intracoronary wire for temporary pacing.[258]

When performing directional atherectomy, the "window" of the atherectomy device is oriented toward the lesion, and the balloon is inflated to 1 atm. The cutter is then withdrawn, allowing the lesion to enter the open window. The motor is activated, and a cut is performed by slowly advancing the spinning cutter to the distal end of the device housing, thereby packing the shavings into the nose cone of the device. The balloon is then deflated, the window reoriented, and the sequence repeated. To minimize the possibility of perforation, the window is not oriented toward normal portions of the vessel wall. It is important to note that overzealous atherectomy may lead to an increased risk of perforation or aneurysm formation.

Intracoronary stenting may be conducted either as a primary strategy or for suboptimal outcomes after balloon angioplasty or other interventions. Deployment strategies vary depending on stent designs, since some are balloon-mounted and others are self-expanding. Stent deployment with a properly sized balloon is performed (usually to >12 atm) to expand the stent optimally throughout its length. A recently reported randomized trial of stent implantation showed no advantage to inflation to more than 15 atm.[259] Although some operators advocate IVUS guidance, there is no consensus regarding its routine use.[260,261]

With rotational atherectomy and ablative laser procedures, many operators use special infusion or flushing strategies (using saline and/or vasodilators) to optimize laser debulking by blood displacement, reduce acoustic shock and dissection with the laser, and avoid no-reflow phenomena.[210,262] Proper sizing of these debulking devices is under investigation. Recent studies suggest that lower rotational atherectomy speeds (<160,000 rev/min) produce less platelet activation and comparable atheroablation and that IIb/IIIa receptor inhibitors block this activation.[263,264]

If there is concern about the adequacy of the lumen at the treatment site, use of a Doppler flow wire, angioscopy, or pressure gradients may be helpful in addition to ultrasound in assessing the result. Studies suggest that a normal coronary hyperemic flow response and a low transluminal gradient are associated with reduced risk of restenosis. *It is clear that optimizing the lumen size is the goal, since final lumen size is an important determinant of the probability of restenosis*. When the operator is confident that the best possible result has been obtained, the patient is returned to his or her room, where an electrocardiogram is obtained and the patient is placed on telemetry. Puncture-site closure devices are used with increasing frequency. Creatine kinase determinations are performed immediately and every 8 h for three determinations. Because of the dehydrating effect of the osmotic load, most patients receive at least 1 L of intravenous fluids after the procedure. Delayed sheath removal is performed at 2 to 4 h when the ACT is below 150 s. If an intimal tear, suboptimal result, or intraluminal thrombus is present, or if multiple stents are implanted, a IIb/IIIa receptor inhibitor is often used.[265] There is evidence that routine heparin administration following uncomplicated angioplasty is not helpful in reducing acute occlusion or restenosis.[266] Postprocedure medications in-hospital include aspirin, a calcium channel-blocking agent, topical nitrates, and clopidogrel in stented patients. Most patients are discharged on the first day following the procedure after receiving instructions on lipid-lowering therapy (see Chap. 38), exercise, and cessation of smoking and are given an outline of follow-up procedures.

Chapter 45: PERCUTANEOUS CORONARY INTERVENTION

RESULTS OF CORONARY INTERVENTION

The results obtained with coronary intervention procedures have been influenced significantly by technological advances, operator experience, and the difficulty of patients selected. With pioneering equipment, Gruentzig was able to dilate 64 percent of the first 50 patients and 78 percent of the first 169 patients.[10,15] Defining primary success as less than 50 percent residual stenosis and freedom from complications, a success rate of 91 percent in over 26,000 patients treated at Emory University Hospital was seen between 1980 and 1998 (Table 45-5). Note that complication rates generally declined despite increasingly difficult cases. Experienced operators should achieve primary success rates in excess of 95 percent in ideal proximal lesions compared with a reduced success rate of approximately 75 percent in recent (<3 months) total occlusions or when attempting to treat fibrotic, calcified, eccentric stenoses located distally in tortuous coronary arteries. In all techniques, including stenting,[196] lesion characteristics are a major determinant of the outcome of the procedure.[117,118,157-162] Long-term outcome has been reported out to 10 years in patients treated in Zurich, Atlanta, and Rotterdam,[15-17,119,267] and detailed 5- to 8-year follow-up data are available from randomized trials,[25-41,130,131] (see above and Table 45-1 and Fig. 45-4).

Complications

Patients undergoing coronary intervention are subject to the same complications encountered with the performance of coronary arteriography. In addition, because instrumentation of the atherosclerotic lesion takes place, coronary artery dissection, thrombus formation, and coronary artery spasm may occur, leading to acute occlusion of the coronary artery or of side branches arising from it. Atheroembolism may occur and lead to MI in an otherwise successful procedure. Occlusion of the treated artery is the most common serious complication of coronary angioplasty and accounts for most of the morbidity and mortality related to the procedure.

Of Gruentzig's first 50 patients, 5 experienced an acute deterioration necessitating emergency bypass surgery and 3 showed electrocardiographic evidence of MI.[10] The results of 3500 patients undergoing elective balloon angioplasty at Emory were analyzed and reported in detail.[268] Angioplasty was attempted in 3933 lesions, with a success rate of 91 percent. No complications occurred in 89 percent of patients, minor complications occurred in 6.9 percent, and major complications (emergency surgery, MI, death) occurred in 4.1 percent. Emergency CABG was performed in 2.7 percent of patients, who had an MI rate of 49 percent and a Q-wave MI rate of 23 percent. In patients sent for emergency surgery, the mortality rate was 2 percent. The overall MI rate was 2.6 percent. There were two nonsurgical deaths, giving a total mortality rate of 0.1 percent (4 of 3500). *Five preprocedural predictors of a major complication were identified: multivessel coronary artery disease, lesion eccentricity, presence of calcium in the lesion, female gender, and lesion length. The strongest predictor of a major complication was the appearance of an intimal dissection during the procedure*. Intimal dissection was evident in 29 percent of patients, and its presence resulted in a sixfold increase in the risk of a major complication. Minor complications tabulated in this study included the following: side branch occlusion (1.7 percent), ventricular arrhythmia requiring dc shock (1.5 percent), emergency recatheterization (0.8 percent), femoral artery repair (0.6 percent), transfusion requirement (0.3 percent), coronary embolus (0.1 percent), cardiac tamponade (0.1 percent), and stroke (0.03 percent). This early series of patients was treated with balloon angioplasty alone. In 1995 at Emory University Hospital, over 1600

patients were treated (76 percent with balloon alone), with angiographic success in 94 percent, Q-wave MI in 1.1 percent, non-Q-wave MI in 2.9 percent, and death in 0.6 percent. Stents have played an increasing role, being used in 66 percent of patients in 1998 with an improvement in acute outcome (see Table 45-5).

Although angiographic variables are important predictors of abrupt closure, of equal or greater importance is an estimate of the consequences of abrupt closure. This estimate is determined in large part by the amount of myocardium that is supplied by the artery in jeopardy. Occlusion of a small diagonal branch is of little consequence compared, for example, with the occlusion of a large LAD coronary artery that is also supplying collateral vessels to an occluded right coronary artery. In the first case, a small non-Q-wave MI is likely, whereas in the latter, occlusion would likely result in abrupt anterior and inferior ischemia and be associated with hypotension and possibly cardiogenic shock. Immediate stenting or bypass surgery may be lifesaving, but MI will occur in up to one-half of patients, and there is a significant risk of mortality in this subgroup of patients.

An analysis of 294 acute occlusions occurring during 8207 consecutive coronary angioplasty procedures performed in two centers revealed 13 cardiac deaths (4.4 percent of acute occlusions) and an overall cardiac mortality of 0.16 percent.[269] Of 13 patients who died, 12 were women. Multivariate analysis identified three independent predictors of death: collaterals originating from the dilated vessel, female gender, and multivessel disease. In an analysis of 32 deaths associated with 8052 PTCA procedures in three centers, left ventricular failure due to vessel occlusion, the most common cause of death, was independently correlated with female sex, "jeopardy score," and PTCA of a proximal right coronary artery (RCA) site but not ejection fraction or presence of multivessel disease.[270] Right ventricular failure due to occlusion of the proximal RCA and left main coronary dissections accounted for most of the remaining deaths.

The use of stents in the course of a failing angioplasty (Fig. 45-18) and prospectively in patients with unfavorable anatomy has significantly reduced the risk of urgent bypass surgery and Q-wave MI.[72,73,113] The increasing use of stents and adjunctive measures including new, powerful antithrombotic agents may herald a "new era" of coronary intervention.[113] New complications specifically related to the use of nonballoon devices include coronary perforation, distal atheroembolization, arterial access complications, and "domino stenting" (additional stents to treat end-of-stent dissections). The risk of coronary perforation is a limiting factor in achieving optimal atherectomy and significantly restricts use of the TEC device in native vessels. Among 8932 patients treated at William Beaumont Hospital, perforation was reported in 0.4 percent (balloon, 0.14 percent; TEC, 1.3 percent; DCA, 0.25 percent; excimer laser 2 percent).[271] This risk of perforation is highest in tortuous and smaller vessels and in laser angioplasty of right coronary lesions. In patients experiencing free perforations, Ellis reported that 75 percent required surgery, 29 percent had a Q-wave MI, and 14 percent died.[272] Perforation was reported in 10 of 432 stent patients (2.3 percent), resulting in cardiac tamponade (50 percent), MI (40 percent), emergency surgery (50 percent), and death (30 percent).[273] The manifestations of perforation were delayed (5-24 h) in 20 percent of patients. Angiographic features associated with stent-related perforation were complex lesion morphology, small vessel diameter (2.6 ± 0.2 mm), oversized stents (stent/artery ratio 1.4 ± 0.1), tapering vessel (40 percent), and recrossing dissections (20 percent).[273] These results should engender a cautious approach to stenting in small vessels and when there is uncertainty regarding wire position. One of the newest causes of perforation is the hydrophilic coronary guidewire, which easily penetrates the wall of small distal arteries causing bleeding and cardiac tamponade, especially when IIb/IIIa receptor inhibitors have been used. Prompt application of strategies for the management of vessel perforation can be lifesaving, and device angioplasty operators must be facile with them.

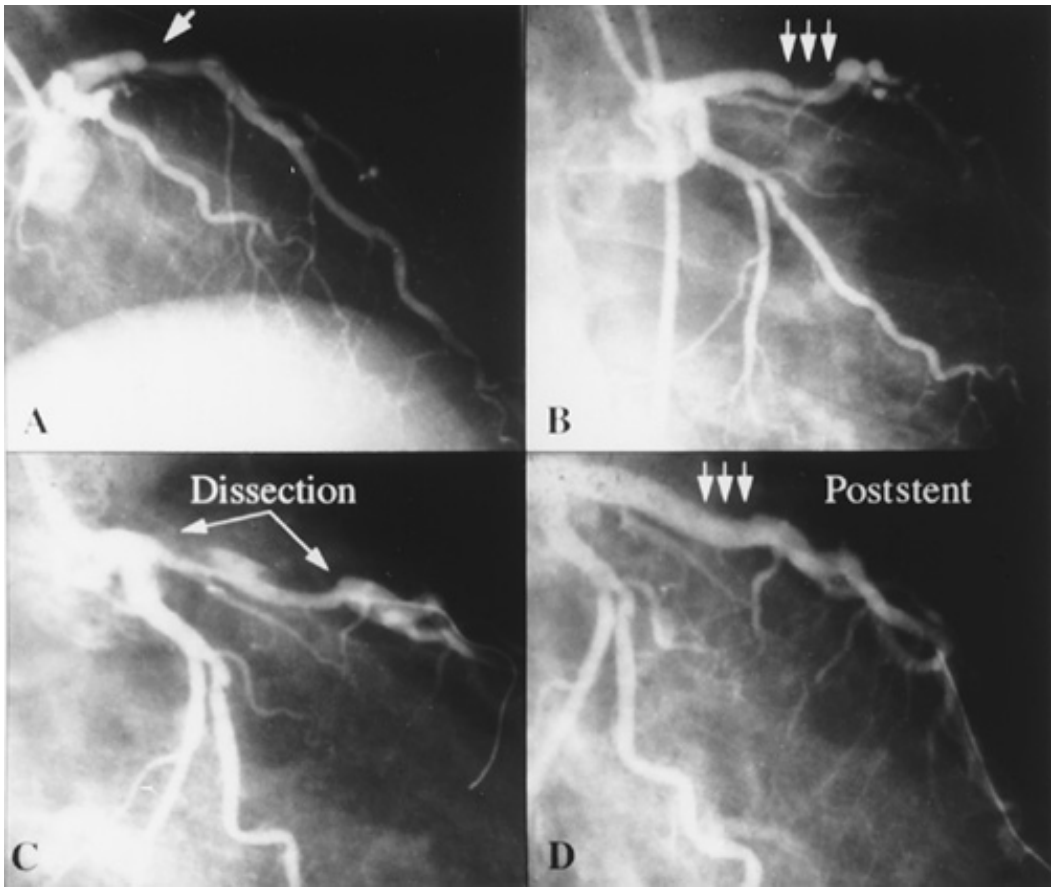

Figure 45-18: Complex stenosis of tortuous proximal LAD. *A.* Right anterior oblique, cranial angulation. *B.* Caudal angulation. Following an initial attempt at treatment of the lesion, a long dissection occurred. *C.* Prompt stent implantation stabilized the patient, preventing the need for emergency CABG (*D*).

Fortunately, the risk of vascular access-site complications, a frequent accompaniment of stenting when heparin and warfarin anticoagulation is used adjunctively, has been reduced with less aggressive antithrombotic strategies. In our experience, complications at the femoral artery puncture site were more often related to advanced age, female sex, hypertension, and postprocedure heparin use than to the size of the catheter.[274-276] Prolonged compression of pseudoaneurysms using ultrasound guidance and in some cases local thrombin injection obviates surgery in many patients with this complication.[277-279] Closure devices are used actively in some centers but add significantly to the cost of the procedure and have their own complications, including infection.

Distal coronary atheroembolization is only occasionally recognized clinically with balloon angioplasty but probably occurs moderately frequently[280] and is a clinically important limitation of debulking strategies such as atherectomy and laser ablation, where its manifestations are slow coronary flow, ischemia, and infarction.[281,282] Reports from CAVEAT indicate that creatine kinase elevations postprocedure were associated with worse long-term outcomes (death, MI, repeat intervention).[282] Although procedural modifications with rotational atherectomy appear to have reduced the immediate impact of microparticulate embolization,[210] the issue remains a source of concern and needs further study. Patients at increased risk include those with bulky or long native vessel lesions and nonfocal or thrombotic saphenous vein graft lesions, where embolization with TEC was noted in about 20 percent, and about one-third of patients with this complication died.[283,284] Atheroembolization also complicates stenting, accounting for an

increased rate of non-Q-wave MI compared with balloon angioplasty. Particulate embolism to the coronary microcirculation may lead to otherwise silent infarction reflected by creatine kinase elevation, a topic of intense interest due to the finding of adverse late outcome, even with small elevations,[285] and the recognition that IIb/IIIa platelet receptor inhibitors, filters, and "occlusion-aspiration" systems can protect against this complication.[105,106,286,287] Not all studies, however, have found a correlation between enzyme elevations and adverse late outcome,[288] and this issue of when to use IIb/IIIa platelet receptors inhibitors is actively debated.[289]

Acute contrast nephropathy requiring dialysis is a costly complication of coronary intervention, which occurred in 15 of 1828 (0.8 percent) patients and was associated with a high (33.8 percent) in-hospital mortality.[290] Independent predictors of contrast nephropathy included decreased baseline creatinine clearance, diabetes, and contrast dose (no dialysis was required in patients receiving less than 100 mL of contrast material). Adequate periprocedural hydration and limitation of contrast volume are the most important measures in high-risk patients.[291]

Chapter 45: PERCUTANEOUS CORONARY INTERVENTION

FUTURE DIRECTIONS

The future of coronary intervention is bright indeed. The problem of subacute stent thrombosis, greatly diminished by current deployment strategies, should be solved by nonthrombogenic stents and/or more effective antithrombotic agents, thus opening the arena of small-vessel stenting (2- to 2.5-mm vessels) and further expanding intervention for multiple lesions in multiple vessels. The major impediments are cost and restenosis. The former should be ameliorated somewhat by market competition. Restenosis, which has been reduced by stenting of *de novo*[75,76,201] and restenotic lesions,[292] remains a challenge that is currently being addressed on multiple fronts with good prospects for meaningful solutions,[192293-296] but new and sometimes unsuspected problems continue to arise, as in the recognition of the threat of late-late occlusion following brachytherapy.[297,298] Improved strategies to protect the microcirculation from atheroembolization are on the immediate horizon.[286]

Part 6: CORONARY HEART DISEASE
Chapter 46:

MECHANICAL INTERVENTIONS IN ACUTE MYOCARDIAL INFARCTION

Authors: William O'Neill, Bruce R. Brodie

The history of mechanical reperfusion therapy is fascinating and has important lessons concerning the application of radical new treatments in modern medicine. Confluences of pathologic, clinical, and technical advances were required for this treatment to be initiated and validated. Lack of understanding of the pathophysiologic basis for acute myocardial infarction (AMI), lack of adequate understanding of clinical subsets, and lack of adequate medical devices led to multiple early pioneering attempts that were akin to the early rocket programs of the late 1950s. Ultimately, however, this treatment modality has been refined, tested, and validated and has the promise to dramatically decrease mortality for increasingly large segments of the population. This chapter will review the historical development of mechanical reperfusion, summarize the results of randomized clinical trials, define subsets most likely to be benefited or harmed by this approach, and offer a glimpse into future research directions.

HISTORICAL DEVELOPMENT

Mechanical reperfusion had its inception with the initial treatise of Fletcher et al.[1] that described the use of intravenous thrombolytic therapy in thromboembolic disorders, including myocardial infarction. The authors presented results on their experience with treatment of 22 patients with AMI. Unfortunately, no methodology for testing efficacy existed. A suggestion that the SGOT enzyme curves peaked earlier was entertained. Crude descriptors including chest pain relief, blood pressure response, and electrocardiographic changes were highly variable and did not provide consistent patterns to demonstrate harm or benefit. Importantly, autopsies were performed in three of the four patients who died. The autopsy results were confusing. One patient who died suddenly 3 weeks after treatment had evidence of a large healing infarction but no evidence of residual thrombus in the infarct artery. A fresh thrombus in a separate artery was perceived to be the cause of death. A second patient died shortly after cessation of streptokinase infusion, and at autopsy, a very fresh microscopic thrombus was found in an ulcerated plaque in the left main artery. A third patient with a history of atrial fibrillation was found to have a massive posterolateral infarction but only mild atherosclerotic plaque and no residual thrombus. These autopsy findings failed to demonstrate that failure of therapy to recanalize vessels lead to death or that thrombus was in fact related to any of these cases. The results of this initial study helped fuel a controversy that raged for 20 years in the scientific community on the role of thrombus formation in myocardial infarction.

Bouchek et al.[2] published the second pioneering observation concerning reperfusion therapy and the initial attempt at developing a platform for local treatment in 1960. This intrepid group performed emergency brachial cut-downs and used subselective catheters to apply fibrinolytic therapy to the aortic root of patients presenting with AMI. Unfortunately, they were unaware of Sones[3] work in selective coronary angiography. Bouchek et al. were astute enough to use the electrocardiogram (ECG) as a localizing tool so that right or left coronary subselective infusions could occur. Although this group presented similar enzymatic results, like Fletcher, they could not clearly establish that their treatment was beneficial. If only their catheters could have been advanced another 3 or 4 mm and angiographic documentation of clot lysis established, the history of reperfusion therapy would have been accelerated by 20 years!

Thus the lack of consensus concerning the inciting role of thrombotic occlusion in AMI, lack of equipment to visualize thrombus in vivo, and lack of clearly defined subgroups for treatment lead investigators to abandon invasive approaches in the 1960s. Later that decade, Favaloro[4] et al. made major contributions to the development of saphenous vein aortocoronary bypass and early on applied it to patients presenting with AMI.[4,5] This group quickly realized that due to enormous logistic and time constraints, this treatment was not practical in referral centers. Fortunately, two groups, one in Spokane[6] and one in Goettingen,[7] attempted to apply emergency surgical revascularization as management for myocardial infarction in a community setting. Preoperative emergency catheterization was required, and thus, for the first time, knowledge of the coronary anatomy during AMI became available. Both groups made seminal observations that served as cornerstones for reperfusion therapy. DeWood et al.[8] described the high prevalence of total coronary occlusion in the early hours after acute transmural myocardial infarction and the decreased incidence of total occlusion in the later hours of presentation. These authors concluded that total coronary occlusion occurred early and that spontaneous lysis explained the lower prevalence during later presentation. They concluded that total thrombotic occlusion was the cause and not the consequence of AMI. Perhaps equally important, this initial report and a subsequent report[9] clearly defined the role of electrocardiographic transmural injury current in identifying a population of patients most likely to have acute total occlusion and thus most likely to benefit from emergency revascularization.

At the same time that the Spokane group was testing surgical revascularization, Rentrop and associates were developing techniques to safely catheterize and study patients with AMI and cardiogenic shock. In June 1978, based on lessons learned from balloon angioplasty, they performed emergency guidewire recanalization of a catheter-related acute thrombotic coronary occlusion.[10] The instantaneous gratifying clinical and electrocardiographic results led this group to initiate mechanical reperfusion in AMI. They reported on the first 13 patients treated with mechanical reperfusion in 1979.[11] In June 1979, this group initiated a second phase of their investigation, selective catheter infusion of intracoronary streptokinase. They presented their work at the American Heart Association Meetings in November of 1979, and the modern era of reperfusion therapy was born. American investigators were largely uninterested in thrombolytic therapy of AMI in the 1960s and 1970s. The pathologic findings of Roberts and Buja[12] and the National Heart Lung and Blood Institute (NHLBI) consensus conference[13] swayed scientific conventional wisdom. The importance of thrombotic occlusion was unclear, and attention was focused on methods to limit infarct size by decreasing oxygen demand.[14] Once the works of DeWood et al. and Rentrop et al. were disseminated, enormous research interest was generated in both Europe and the United States. Randomized trials were quickly organized. Khaja et al.[15] first demonstrated the efficacy of intracoronary streptokinase administration. The western Washington group demonstrated the mortality advantage of intracoronary streptokinase therapy.[16] Because of the necessity of selective coronary angiography for this treatment, it became apparent that a severe residual stenosis persisted in most patients after successful recanalization. The Ann Arbor group first demonstrated that balloon angioplasty could more effectively relieve the residual stenosis than could thrombolytic therapy alone.[17] This resulted in less recurrent ischemia, less exercise-induced ischemia,[18] and more effective preservation of ventricular function.[19] Lack of trained operators, lack of catheterization facilities, and logistic constraints, however, led most investigators to abandon primary angioplasty in the mid-1980s.

Both intracoronary streptokinase and primary percutaneous transluminal coronary angioplasty (PTCA) lost momentum once intravenous thrombolytic therapy was validated in the mid-1980s.[20] Research interest focused on new thrombolytic drugs that could be administered intravenously. Many investigators were still concerned about the severe underlying residual stenosis remaining after thrombolytic therapy. Therefore, three major randomized trials the TAMI, TIMI-2a, and European Cooperative trials were performed.[21-23] Each trial attempted to determine the value of

routine PTCA after thrombolytic therapy. In aggregate,[24,25] these studies gave surprising and disappointing results. Routine PTCA not only failed to improve results but actually appeared to be harmful. Angioplasty thus was abandoned as an adjunct to thrombolytic therapy in 1990.

Although routine, postthrombolytic PTCA was proven to be detrimental, interest still persisted in the use of PTCA without antecedent thrombolytic therapy and in cases of persistent chest pain after thrombolytic therapy. A great deal of the credit must be given to the pioneering work of Hartzler et al.[26] This group demonstrated that angioplasty alone may have outcomes superior to thrombolytic therapy.[27] At the same time, Brodie et al.[28] and O'Neill et al.[29] concluded that lone angioplasty had been inadequately tested as a reperfusion modality. These three groups joined forces and organized the original Primary Angioplasty in Myocardial Infarction (PAMI) study group. This group first formally compared intravenous thrombolytic therapy with primary PTCA. The results of this trial and the Zwolle and Mayo Clinic studies have largely defined the value of mechanical reperfusion in the 1990s.

Chapter 46: MECHANICAL INTERVENTIONS IN ACUTE MYOCARDIAL INFARCTION

RESCUE ANGIOPLASTY

In the early 1990s, intravenous thrombolytic therapy became the overwhelmingly preferred reperfusion strategy.[30-32] Unfortunately, with current fibrinolytic regimens, successful reperfusion after thrombolytic therapy is achieved in only 54 to 81 percent of patients, and TIMI 3 flow is achieved in only 29 to 54 percent of patients.[33] The achievement of successful reperfusion (especially TIMI 3 flow) in the infarct artery after thrombolytic therapy is the most important determinant of 30-day mortality and recovery of left ventricular function.[33] Rescue angioplasty, the mechanical reopening of an occluded infarct artery after failed thrombolysis, has been used as adjunctive therapy in an attempt to improve outcomes in patients with failed thrombolysis. Despite the intuitive benefit of this approach, the value of rescue angioplasty remains controversial, especially given the disappointing results of the TAMI, TIMI-2a, and European Cooperative studies.

Numerous observational studies have documented that rescue angioplasty can achieve successful reperfusion in 82 to 92 percent of patients with occluded infarct arteries after failed thrombolysis,[34-38] but reocclusion of the infarct artery has been common (18 percent in Ellis's meta-analysis),[39] and recovery of left ventricular function has been variable.[34,36,37] Mortality associated with unsuccessful rescue angioplasty has been very high, and mortality associated with all rescue angioplasties (successful and unsuccessful) has been no better than in patients with failed thrombolysis who do not undergo rescue angioplasty and has been higher than in patients with successful thrombolysis[3437] (Table 46-1). The lack of benefit in these observational studies with rescue angioplasty may be related to selection bias, since rescue angioplasty often is selected for higher-risk patients.[39] The relatively high mortality after rescue angioplasty compared with successful thrombolysis is not surprising because patients with failed thrombolysis are a high-risk subgroup who have demonstrated resistance to pharmacologic reperfusion, possibly due to hypotension, large thrombus burden, or extensive intimal disruption, all of which are unfavorable to the success of coronary angioplasty. Also, reperfusion after rescue angioplasty, by definition, occurs later than reperfusion by successful thrombolysis, and this inherent delay decreases the extent of myocardial salvage. It is not clear if the particularly high mortality in patients with failed rescue angioplasty is due to additional associated high-risk features or if there may be harmful effects from the rescue angioplasty procedure itself.

Table 46-1: Observational Data Comparing Mortality* in Patients Undergoing Rescue Angioplasty (PTCA) for Failed Thrombolysis versus No Rescue Angioplasty versus Successful Thrombolysis

Trial	Successful Rescue PTCA	Failed Rescue PTCA	All Rescue PTCA	No Rescue PTCA	Successful Thrombolysis
TAMI 1-5 Trials (*n* = 192)[35]	10/169 (5.9%)	9/23 (39%)	19/192 (9.9%)	3/43 (7.0%)	28/607 (4.6%)
TIMI I and II Trials (*n* = 33)[36]	2/27 (7.4%)	2/6 (33%)	4/33 (12%)	7/100 (7%)	
TIMI IV Trial (*n* = 58)[37]	5/52 (9.6%)	2/6 (33%)	7/58 (12%)	4/37 (11%)	9/307 (2.9%)

GUSTO-I Trial (n = 198)[34]	15/175 (8.6%)	7/23 (30%)	22/198 (11.1%)	21/266 (7.9%)	55/1058 (5.2%)
TOTAL	32/423 (7.6%)	20/58 (34%)	52/481 (10.8%)	35/446 (7.8%)	92/1972 (4.7%)

*Mortality is in-hospital mortality for TIMI-IV and TAMI 1-5, 21 days for TIMI-I and II, and 30 days for GUSTO-I.

Two moderately sized randomized trials have evaluated the efficacy of rescue angioplasty. The TAMI-5 trial[40] randomized 575 patients with AMI treated with tissue-type plasminogen activator (tPA) or urokinase or both to emergency angiography with rescue angioplasty for failed thrombolysis versus conservative care. Rescue angioplasty was performed in 18 percent of the emergency catheterization group with a success rate of 83 percent. At hospital discharge, the emergency catheterization group had a slightly higher infarct artery patency rate (94 versus 90 percent; p = 0.07), better regional wall motion, and less recurrent ischemia, but there were no differences in mortality, reinfarction, or global left ventricular ejection fraction.

The Randomized Evaluation of Salvage Angioplasty with Combined Utilization of Endpoints (RESCUE) trial[41] randomized 151 patients who had their first anterior wall myocardial infarction treated with thrombolytic therapy and had an occluded infarct artery demonstrated within 8 h of the onset of chest pain to rescue angioplasty versus conservative care. There was no difference in left ventricular ejection fraction at 30 days (40 versus 39 percent; p = NS), but the rescue angioplasty group tended toward a lower mortality (5.1 versus 9.6 percent; p = 0.18), less congestive heart failure (1.3 versus 7.0 percent; p = 0.11), had a lower composite of death and congestive heart failure (6.4 versus 16.6 percent; p = 0.05), and better exercise left ventricular ejection fraction (43 versus 38 percent; p = 0.04). These benefits occurred despite what the authors felt was a strong investigator bias not to randomize patients presenting very early in the course of their infarction.

Rescue angioplasty, especially after tPA, is associated with lower angiographic success rates and higher reocclusion rates than primary angioplasty and this limits its effectiveness. This may occur because infarct artery occlusion refractory to thrombolysis may have more extensive intimal disruption. In addition, platelet and thrombin activation that occurs with thrombolytic therapy may adversely affect the efficacy of PTCA.[42-44] Recent studies using coronary stenting with rescue angioplasty have reported high procedural success rates and low reocclusion rates.[45-47] The largest of these studies reported a success rate of 98 percent in 167 patients, a reocclusion rate of only 1.2 percent, and a combined end point of death or reinfarction of 1.4 percent at 30 days in nonshock patients.[47] Glycoprotein IIb/IIIa platelet inhibitors also may enhance outcomes with rescue angioplasty, but this has not been well studied, and the risk of bleeding when aspirin, heparin, ticlopidine, or clopidogrel and glycoprotein IIb/IIIa platelet inhibitors are used in conjunction with thrombolytic therapy is not established.[46]

A major limitation of the rescue angioplasty approach is the lack of a reliable noninvasive method to detect reperfusion after thrombolytic therapy. The ECG is very specific in predicting patency of the infarct artery when there is complete (>70 percent) resolution of ST-segment elevation at 90 min after thrombolytic therapy.[48] This occurs in only a minority of patients, however; in most patients there is only partial or no resolution of ST-segment elevation, and the patency status of the infarct artery is uncertain.[49] Similarly, enzyme rise or enzyme curves lack sufficient, rapid diagnostic accuracy.[50] Consequently, acute angiography is usually required to determine infarct artery patency.

Based on the available data, acute angiography with rescue angioplasty should be considered in patients with anterior or large myocardial infarction who are thought to have failed thrombolysis, as evidenced by persistent chest pain, lack of resolution of ST-segment elevation, or hemodynamic compromise 90 min or more after treatment.

The recently reported PACT trial[50a] of bolus tPA and transfer to the catheterization laboratory for rescue angioplasty for those without TIMI 3 flow showed that angioplasty could be performed safely following administration of a short-acting thrombolytic agent. Since transfer to the catheterization laboratory was very fast in this trial, no improvement in left ventricular function could be shown in the thrombolyzed cohort. An important question is whether in real-life situations, where transfer to the catheterization laboratory takes longer, will upstream thrombolysis be helpful.

Chapter 46: MECHANICAL INTERVENTIONS IN ACUTE MYOCARDIAL INFARCTION

PRIMARY ANGIOPLASTY

In the early 1990s, great controversy still existed about the routine use of angioplasty for treatment of AMI. Angioplasty after thrombolytic therapy was abandoned except for its use as a rescue after failed thrombolytic therapy. In centers where interventional programs existed, controversy existed about the use of immediate PTCA without antecedent thrombolytic therapy as an alternative to routine thrombolytic therapy. This controversy has now been largely settled based on a number of randomized trials of these reperfusion modalities.

Comparison of Outcomes with Thrombolytic Therapy

RANDOMIZED TRIALS

In 1997, Weaver et al. published a meta-analysis of 10 randomized trials[51-60] in a total of 2606 patients comparing thrombolytic therapy with primary angioplasty[61] (Fig. 46-1). The largest of these trials were the PAMI-1 trial,[52] the Zwolle trial,[53] and the GUSTO-IIb trial.[58] In this meta-analysis, primary angioplasty was associated with a lower in-hospital mortality (4.4 versus 6.5 percent; $p = 0.02$), a lower incidence of nonfatal reinfarction (2.9 versus 5.3 percent; $p = 0.002$), and a lower incidence of death or nonfatal reinfarction (7.2 versus 11.9 percent; $p = 0.001$). Primary angioplasty also was associated with a significantly lower incidence of stroke (0.7 versus 2.0 percent; $p = 0.007$) and hemorrhagic stroke (0.01 versus 1.1 percent; $p = 0.0005$). The survival benefit of primary angioplasty compared with thrombolytic therapy reported in this meta-analysis was substantial (21 lives saved per 1000 patients treated) and compared favorably with the survival benefit of thrombolytic therapy compared with placebo reported by the Fibrinolytic Therapy Trialists' (FTT) Collaborative Group (19 lives saved per 1000 patients treated).[62]

OUTCOMES IN HIGH-RISK PATIENTS

Patients with AMI at highest risk for mortality include patients with cardiogenic shock, elderly patients, patients with anterior wall myocardial infarction, and women. Data from randomized trials indicate that the greatest mortality benefit with primary angioplasty is seen in these high-risk patients (Table 46-2). The PAMI-1 investigators found a significant mortality benefit with primary angioplasty compared with tPA in non-low-risk patients (patients older than 70 years, anterior infarction, or heart rate >100 beats per minute) but no difference in mortality in low-risk patients.[52] Likewise, elderly patients showed a substantial mortality benefit with primary angioplasty compared with tPA in both the PAMI-1 trial[63] and the GUSTO-IIb trial,[64] whereas younger patients showed no mortality difference. The PAMI-1 investigators also found a substantial mortality benefit with primary angioplasty versus thrombolytic therapy in patients with anterior wall myocardial infarction but no mortality benefit in non-anterior wall myocardial infarction.[65] Garcia et al.[60] also found mortality benefit with primary angioplasty in patients with anterior wall myocardial infarction, but the GUSTO-IIb trial did not.[66] The lack of benefit in the GUSTO-IIb trial may be related to the lower rates of achieving TIMI 3 flow in the GUSTO-IIb trial.[67] Women are also at high risk for mortality with AMI partly related to more baseline risk factors. In the PAMI-1 trial, mortality in women was lower with primary angioplasty compared with tPA[68] (see Table 46-2). Patients with cardiogenic shock are the highest-risk subgroup of patients with AMI and appear to benefit most from primary angioplasty. Unfortunately, thrombolytic therapy is not very effective in patients with cardiogenic shock. In the GISSI-1 trial,[20] there was no difference in mortality in patients with cardiogenic shock treated with intravenous streptokinase versus placebo (70 percent in each), and the International Study Group found that mortality was high with both streptokinase and tPA (65 and 78 percent, respectively).[69] In contrast, pooled data from 19 observational studies with primary angioplasty for cardiogenic shock showed an overall mortality of 44 percent.[70] Recently, the SHOCK trial,[71] which randomized patients with

cardiogenic shock to emergency revascularization versus medical stabilization, found a decreased mortality rate in favor of emergency revascularization at 6 months (50 versus 63 percent; $p = 0.03$). Survival benefit was especially pronounced in patients treated within 6 h of symptom onset and in patients under age 75 years. These data and previous observational data strongly support the use of primary angioplasty to provide survival benefit in patients with AMI complicated by cardiogenic shock, especially in young patients who present early after symptom onset.

OUTCOMES IN LOW-RISK PATIENTS

While the survival benefit with primary angioplasty versus thrombolytic therapy is limited to high-risk patients, low-risk patients benefit from a reduction in the incidence of reinfarction and recurrent ischemia. In a randomized comparison, the PAMI-1 trial[65] found a lower incidence of recurrent ischemia (9.7 versus 27.8 percent; $p = 0.0002$) and the Zwolle group[57] found a lower incidence of reinfarction (0 versus 16 percent; $p < 0.01$) in patients with non-anterior wall myocardial infarction treated with primary angioplasty. Similarly, Ribichini et al.,[59] in a randomized comparison of primary angioplasty versus thrombolytic therapy in patients with inferior infarction, found a lower incidence of reinfarction (1.8 versus 9.1 percent; $p = 0.10$) and recurrent ischemia (1.8 versus 20.0 percent; $p = 0.002$), higher infarct artery patency (100 versus 71 percent; $p = 0.0001$), and better left ventricular ejection fraction (55.2 versus 48.2 percent; $p = 0.001$) at hospital discharge in patients treated with primary angioplasty.

Thus, while low-risk patients have no survival benefit with primary angioplasty, they do benefit from less reinfarction, less recurrent ischemia, higher infarct artery patency rates, and better left ventricular function without the risk of intracranial hemorrhage.

IMPORTANCE OF TIMI FLOW

The importance of achieving timely restoration of normal blood flow in the infarct artery in patients with AMI was convincingly demonstrated in the GUSTO trial.[72] Patients with normal (TIMI 3) antegrade flow in the infarct artery at 90 min after treatment had the highest left ventricular ejection fraction at follow-up catheterization and the lowest 30-day mortality (Table 46-3). Patients with slow (TIMI 2) flow had a left ventricular ejection fraction and 30-day mortality that was significantly worse than patients with TIMI 3 flow and similar to patients with no flow (TIMI 0-1). A similar relationship between TIMI flow and mortality has been found with primary angioplasty[73] (see Table 46-3). These data indicate that only restoration of TIMI 3 flow is associated with optimal outcomes and that only TIMI 3 flow should be regarded as "true patency." A comparison of the rates of TIMI 3 flow with various reperfusion strategies in the GUSTO trial and with primary angioplasty from the PAMI-1 and PAMI-2 trials are shown in Fig. 46-1.[72,73] The ability of primary angioplasty to achieve significantly higher TIMI 3 flow rates than thrombolytic therapy probably explains most of the mortality advantage seen with primary angioplasty. Indeed, there appears to be a tight inverse relationship between short-term mortality and the ability to achieve TIMI 3 flow with various thrombolytic regimens and with primary angioplasty (Fig. 46-2). Newer thrombolytic strategies combining low-dose thrombolytics with platelet glycoprotein IIb/IIIa receptor inhib-itors have shown improved TIMI 3 flow rates[74] (see Chap. 42), but these rates are still well below the TIMI 3 flow rates achieved with primary angioplasty, and these strategies remain to be tested in large clinical trials.

Table 46-3: Relationship Between TIMI Flow and 30-Day Mortality after Reperfusion Therapy for AMI

	30-Day Mortality	
TIMI Flow	GUSTO-I[72] (Lytic Therapy)	PAMI-1 and PAMI-2[73] (Primary PTCA)
TIMI 0-1	8.9%	17.2%
TIMI 2	7.4%	7.6%
TIMI 3	4.4%	2.1%

LATE CLINICAL AND ANGIOGRAPHIC OUTCOMES

A comparison of late clinical outcomes of patients with AMI treated with primary angioplasty versus thrombolytic therapy has been provided by the PAMI investigators.[75] The initial benefit of primary angioplasty in reducing death and reinfarction was maintained out to 2 years with event-free survival curves that remain nearly parallel after hospital discharge (Fig. 46-3). Primary angioplasty also was associated with lower hospital readmission rates (59 versus 69 percent; $p = 0.035$) and lower rates of target-vessel revascularization with either angioplasty or bypass surgery (33 versus 54 percent; $p = 0.001$) compared with tPA. More recently, the Zwolle group has demonstrated that the early mortality and reinfarction benefit is maintained over 5-year follow-up.[76]

Reocclusion of the infarct artery at follow-up angiography occurs frequently after thrombolytic therapy when adjunctive percutaneous coronary intervention is not employed. The Antithrombotics in the Prevention of Reocclusion in Coronary Thrombolysis (APRICOT) study performed follow-up angiography at 3 months in patients with AMI treated with intravenous streptokinase who had a patent infarct artery at catheterization at 24 to 48 h and found a late reocclusion rate of 28 percent.[77] Similarly, White et al. found that 25 percent of patients with an initially patent infarct artery after thrombolytic therapy at 4 weeks had an occluded artery at 1 year.[78] In contrast, reocclusion rates at 6-month follow-up angiography after primary angioplasty have ranged from 5 to 13 percent[29,77,79-81] (Table 46-4). In a randomized comparison of primary angioplasty with streptokinase from the Zwolle group, reocclusion rates were significantly lower with primary angioplasty (9 versus 32 percent; $p = 0.001$).[53] With the use of coronary stenting, reocclusion rates at 6-month angiography have been reduced to about 5 percent.[81] The lower rates of reocclusion with primary angioplasty are likely related to the reduction in residual stenosis, since residual stenosis after thrombolytic therapy is highly correlated with late reocclusion.[77]

Infarct artery patency is important for recovery of left ventricular function[79] and may be important for late survival. Several observational studies with thrombolytic therapy and primary angioplasty have found that both left ventricular function and infarct artery patency are strong independent predictors of late cardiac survival.[82,83] This suggests that the late angiographic outcomes after primary angioplasty may translate into better long-term clinical outcomes.

The restenosis rate at 6-month follow-up angiography after primary angioplasty is similar to that after elective angioplasty and occurs in 24 to 46 percent of patients.[29,7779-81] While this remains a significant clinical and economic problem with primary angioplasty, only about one-half of patients with restenosis require repeat target-vessel revascularization, and restenosis does not interfere with recovery of left ventricular function as long as the infarct artery remains patent.[79] The use of stents with primary angioplasty, like elective angioplasty, has significantly reduced restenosis rates. The Stent PAMI trial showed a reduction in restenosis rates from 34 percent with angioplasty to 20 percent with stenting.[81] In comparison with primary angioplasty, the frequency of significant residual stenosis (>50 percent diameter narrowing) at 3-month follow-up angiography after thrombolytic therapy remains quite high[77] (Table 46-4).

Role of Cardiac Surgery in the Primary Angioplasty Approach

Not all patients with AMI brought to the cardiac catheterization laboratory undergo percutaneous coronary intervention.[52,84] Approximately 10 percent of patients are triaged to either medical treatment or are treated with coronary bypass surgery as the primary reperfusion strategy, i.e., primary coronary artery bypass grafting (CABG). Patients may be selected for primary CABG when there is severe left main coronary artery disease or severe three-vessel coronary artery disease with preserved (TIMI 3) flow in the infarct artery that allows time for transfer to the operating room. These patients frequently undergo operation emergently and comprise a little less than half the patients not undergoing percutaneous coronary intervention. The remaining patients not treated with percutaneous coronary intervention are treated medically. These include patients with no myocardial infarction (mistaken diagnosis), patients with no significant stenosis in the infarct artery (resolution of spasm or thrombus), patients in whom the infarct artery cannot be identified, and occasionally patients with unsuitable anatomy or a very small infarct-related artery.

Bypass surgery is also performed emergently after failed angioplasty, urgently for reinfarction or recurrent ischemia, and electively for definitive treatment of left main or severe multivessel disease. With recent experience and with the availability of stents, emergency bypass surgery is rare (~0.4 percent), and the need for urgent bypass surgery for reinfarction or recurrent ischemia that cannot be managed with repeat percutaneous coronary intervention is very infrequent (<1 percent).[81] Elective bypass surgery for treatment of residual coronary artery disease after initial successful primary angioplasty has been used in about 4 to 5 percent of patients. Altogether, bypass surgery is performed in about 7 to 10 percent of patients with the primary angioplasty approach.[84,85] Considering the severity of illness of these patients, surgical mortality has been relatively low (6.4 percent with emergency or urgent bypass surgery and 2.0 percent with elective bypass surgery in the PAMI-2 trial).[85]

Cardiac surgery is also used in patients with mechanical complications of AMI. Patients with ventricular septal rupture and acute mitral regurgitation from papillary muscle rupture usually develop cardiogenic shock and have a very poor outcome without surgical intervention and are candidates for emergency surgery. Patients with cardiogenic shock with severe left main disease (without mechanical complications) also may be candidates for emergency bypass surgery.[71]

Although cardiac surgery is an integral part of the primary angioplasty approach, it has been demonstrated that primary angioplasty can be performed safely and effectively at some community hospitals without on-site cardiac surgery when rigorous program criteria are established.[86,87] These criteria include the availability of experienced interventionists, a well-stocked and well-equipped catheterization laboratory, an experienced catheterization laboratory team, rigorous case-selection criteria, the establishment of good lines of communication between the interventional cardiologist and the cardiovascular surgeon at the referring institute, and an efficient emergency transport system. In many hospitals, transfer to an angioplasty/surgical center for those requiring an intervention may be a preferable approach.

Primary Angioplasty in Thrombolytic-Ineligible Patients

In most U.S. thrombolytic trials, 70 to 85 percent of patients with AMI screened have been considered ineligible for thrombolytic therapy because of advanced age, late presentation, prior bypass surgery, cardiogenic shock, or bleeding predisposition.[88] These patients constitute a high-risk subset with a significantly increased in-hospital mortality. Despite recommendations to broaden thrombolytic therapy to patients of any age and to patients presenting up to 12 h after the onset of symptoms, data from the National Registry of Myocardial Infarction (NRMI-2) have found that only 31 percent of patients with AMI are considered eligible for thrombolytic therapy, and only 75 percent of these patients are currently receiving thrombolytic therapy[89] (Fig. 46-4).

One of the major advantages of primary angioplasty compared with thrombolytic therapy is that primary angioplasty can be applied to a majority of patients with AMI.[90] The only contraindications to primary angioplasty are lack of vascular access, renal insufficiency, and active hemorrhage. Among patients who are usually not considered candidates for thrombolytic therapy but who may benefit greatly from reperfusion therapy with primary angioplasty are patients with cardiogenic shock, elderly patients, and

patients with a predisposition to bleeding. Elderly patients are frequently excluded from thrombolytic trials, but those who have been enrolled in trials comparing thrombolytic therapy with primary angioplasty have had a substantial mortality benefit with primary angioplasty.[63,64] Patients with AMI and contraindications to thrombolytic therapy due to bleeding risk have a high mortality, and observational data suggest that mortality may be reduced by reperfusion with primary angioplasty.[91]

There are very little data supporting benefit of reperfusion therapy in patients who present more than 12 h after the onset of symptoms. One exception to this is patients who present late but have persistent ischemic chest pain. These patients frequently have collateral flow to the infarct zone and show substantial recovery of left ventricular function following reperfusion with primary angioplasty.[92] It is also possible that late restoration of patency of the infarct artery could enhance late survival independent of myocardial salvage by preventing left ventricular dilatation, promoting electrical stability, and serving as a source for collateral flow,[93,94] but this remains to be tested in prospective studies. Patients with AMI who do not have electrocardiographic ST-segment elevation or left bundle-branch block have shown no benefit with thrombolytic therapy in randomized trials[62] and appropriately are not considered candidates for thrombolytic therapy. There are little data regarding benefit from primary angioplasty in this group of patients. McCullough et al.[95] demonstrated that patients with acute ischemic syndromes, including non-ST-segment elevation infarction, randomized to triage angiography with angioplasty when appropriate versus conservative care have less recurrent ischemia but have no mortality or reinfarction benefit.

Although prior bypass surgery is not a contraindication to thrombolytic therapy, these patients frequently have been excluded from thrombolytic trials. Reperfusion rates with thrombolytic therapy in patients with AMI due to saphenous vein graft occlusion are significantly less than with native vessel occlusion (TIMI 2-3 flow in the GUSTO trial: 48 versus 69 percent, respectively; $p < 0.01$).[96] Reperfusion rates with primary angioplasty in patients with saphenous vein graft occlusion are better than with thrombolytic therapy but are not as good as with primary angioplasty in native vessel occlusion. The PAMI-2 trial achieved TIMI 3 flow in 70 percent of patients with saphenous vein graft occlusion compared with 94 percent of patients with native coronary artery occlusion.[97] Patients with prior bypass surgery also had higher in-hospital mortality compared with patients without prior bypass surgery (6.9 versus 2.6 percent; $p = 0.05$).[97] While primary angioplasty appears to have an advantage over thrombolytic therapy in treating patients with AMI due to saphenous vein graft occlusion, new approaches are still needed to improve outcomes.

Cost Issues

RANDOMIZED COMPARISONS WITH THROMBOLYTIC THERAPY

There has been the perception that a strategy of primary angioplasty is more expensive than thrombolytic therapy in the treatment of AMI because of the initial cost of cardiac catheterization and coronary intervention. There are now data from several randomized trials that provide direct cost and length-of-stay comparisons between primary angioplasty and thrombolytic therapy.[98-100] The Mayo Clinic trial,[98] the PAMI-1 trial,[99] and the GUSTO-IIb trial[100] all showed a shorter length of hospital stay with primary angioplasty, which is likely due to a less complicated hospital course with less reinfarction and less recurrent ischemia (Table 46-5). The same randomized trials have shown comparable or lower hospital costs (charges) with primary angioplasty compared with thrombolytic therapy (see Table 46-5). A breakdown of the hospital charges from the PAMI-1 trial comparing primary angioplasty with tPA is shown in Fig. 46-5).[99] As expected, catheterization laboratory charges are higher with primary angioplasty, but the differences are not as great as expected because of the high use of catheterization and angioplasty in tPA-treated patients (63 and 36 percent, respectively). Initial catheterization laboratory charges with primary angioplasty are offset by higher drug charges in tPA patients due primarily to the charge for tPA. Other charges are slightly less with primary angioplasty, reflecting a shorter, less complicated hospital course. The cost advantages are not confined to hospital stay or American centers. The Zwolle group has shown similar decreases in cost during a 5-year follow-up.[76]

Table 46-5: Hospital Length of Stay and Hospital Charges/Costs Comparing Primary Angioplasty versus Lytic Therapy with tPA

	PTCA	tPA	*p* Value
Mayo Clinic trial[98]			
Length of stay (days)	8.1	10.5	0.08
Hospital charges ($)	21,000	26,700	0.09
PAMI-1 trial[99]			
Length of stay (days)	7.6	8.4	0.04
Hospital charges* ($)	23,468	26,904	0.04
GUSTO-IIb trial[100]			
Length of stay (days)	7.0	7.7	0.0009
Hospital costs* ($)	13,337	14,236	0.004

*PAMI-1 and GUSTO-IIb do not include professional charges.

EARLY-DISCHARGE STRATEGIES

A strategy of early discharge with primary angioplasty may reduce costs further. Primary angioplasty appears to have two advantages over thrombolytic therapy in allowing a strategy for early discharge. First, the incidence of recurrent ischemic events and reinfarction is substantially less with primary angioplasty, and unlike thrombolytic therapy, ischemic events are usually confined to the first 2 days.[101] Second, angiographic data obtained at cardiac catheterization with primary angioplasty provide powerful information for risk stratification. These data include left ventricular ejection fraction, number of diseased vessels, and the reperfusion status or TIMI flow in the infarct artery after intervention. The PAMI-2 trial has documented the safety and cost savings of early discharge in low-risk patients treated with primary angioplasty.[102] Patients were classified as low risk if they met all the following clinical and angiographic criteria: age less than 70 years, ejection fraction greater than 45 percent, one- or two-vessel coronary artery disease, successful angioplasty, no saphenous vein graft occlusion, no persistent arrhythmias, and no congestive heart failure. Using these criteria, an extremely low risk group of patients was identified comprising about one-half the study population with an in-hospital mortality of 0.4 percent. The study documented that a strategy of targeting early discharge on day 3 in these low-risk patients was safe and reduced length of stay from 7.0 to 4.2 days and hospital costs from $11,604 to $9658.

COST-EFFECTIVENESS OF ADJUNCTIVE THERAPY

The impact of adjunctive treatment with coronary stents and platelet inhibitors on costs with primary angioplasty is evolving. Initial data from the Stent PAMI trial[103] suggest that the initial increased costs of stenting versus angioplasty alone ($2185) are partially recovered by decreased posthospital costs due to less target-vessel revascularization (-$974). This makes the total 1-year costs $1211 higher with stenting compared with angioplasty alone. The costs and effectiveness of stenting patients with AMI appear comparable with those of elective stenting. The incremental costs and effectiveness of glycoprotein IIb/IIIa platelet receptor inhibitors in the setting of primary angioplasty is currently being evaluated.

Importance of Time to Reperfusion

Data from a number of randomized trials have shown that the mortality benefit of thrombolytic therapy is strongly dependent on the time from symptom onset until treatment up to 12 h.[62,72,104] Recent observations suggest that time to treatment may be less important with primary angioplasty.[105-107] The PAMI-2 trial found that mortality was lowest when patients were treated very early (<2 h) but that mortality was relatively independent of time to treatment after 2 h[105] (Fig. 46-6). Brodie et al.[107] also found that mortality was significantly lower when patients were reperfused at less than 2 h with primary angioplasty but that mortality was relatively constant after 2 h regardless of further increases in time to treatment[107] (see Fig. 46-6). (One exception to this is in patients with cardiogenic shock, who continue to have increasing mortality with increasing time to reperfusion.[71]) There are several possible explanations for this. First, data from several trials suggest that TIMI 3 flow is achieved in a smaller proportion of patients with increasing time to treatment with thrombolytic therapy.[108,109] In contrast, TIMI 3 flow is achieved with primary angioplasty in more than 90 percent of patients regardless of time to treatment.[105-107] Since achieving TIMI 3 flow in the infarct artery is the strongest predictor of survival, this may partially explain why mortality continues to rise with increasing time to treatment with thrombolytic therapy but remains fairly constant after 2 h with primary angioplasty. Second, cardiac rupture occurs more frequently with increasing time to treatment with thrombolytic therapy.[110,111] In the GISSI trial, mortality due to cardiac rupture increased from 0.7 percent at 0 to 3 h to 2.0 percent at 8 to 12 h.[111] With primary angioplasty, cardiac rupture is uncommon.[112] Finally, for reasons that are not clear, the incidence of intracranial hemorrhage also increases with increasing time to treatment with thrombolytic therapy from 0.5 percent at less than 2 h to 1.0 percent at more than 6 h.[113] These data may have important implications regarding the mechanism of benefit of reperfusion therapy. The traditional paradigm regarding the mechanism of benefit of reperfusion therapy is that early reperfusion results in myocardial salvage, which results in improved left ventricular function and better survival. This paradigm has been expanded to include benefit of late reperfusion when myocardial salvage is no longer expected. An open infarct artery, even if opened too late for myocardial salvage, may result in survival benefit by preventing ventricular dilatation, promoting electrical stability, and providing a source of collateral flow.[93,94] The survival benefit due to myocardial salvage is felt to be strongly time-dependent, whereas the survival benefit due to late reperfusion not related to myocardial salvage is felt to be relatively independent of time to reperfusion. The data with primary angioplasty are consistent with this expanded paradigm, but studies with primary angioplasty suggest that the time period for significant myocardial salvage and recovery of left ventricular function is relatively short (<2 h).[107,114,115]

These data also may have important implications regarding the triage of patients for primary angioplasty. Unless patients present very early (<2 h), when substantial myocardial salvage is possible (and this occurs in only about 12 percent of patients),[107] the time delay in transferring patients from community hospitals to tertiary centers for primary angioplasty may not be prohibitive. This concept is currently being evaluated in prospective randomized trials.

Technical Aspects of Primary Angioplasty

TREATMENT IN THE EMERGENCY DEPARTMENT

When primary angioplasty is planned for patients with known or suspected AMI, only a limited history and physical examination should be performed to avoid delays in initiating the catheterization procedure. Patients are given 325 mg of soluble chewable aspirin, 5000 to 10,000 units of intravenous heparin, sublingual nitroglycerin, intravenous beta blockers unless contraindicated, and supplemental oxygen and are transported promptly from the emergency department to the catheterization laboratory. A lower weight-adjusted dose of heparin should be given if the use of a glycoprotein IIb/IIIa receptor blocker is considered.

CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Femoral access is usually preferred because this allows for the use of larger devices if necessary and facilitates the use of adjunctive therapy with intraaortic balloon pumping or transvenous pacing when indicated. Low-osmolar ionic contrast material (ioxaglate) has been recommended to minimize the risk of hemodynamic and arrhythmic disturbances, as well as thromboembolic complications.[116,117] Recent studies

also have shown that the isomolar nonionic dimer iodixanol has been associated with a very low incidence of adverse events in high-risk patients undergoing percutaneous coronary intervention.[118]

After arterial access is obtained, an activated clotting time (ACT) is measured, and additional heparin is given to prolong the ACT to more than 350 s prior to balloon inflation (200- 300 s if use of a glycoprotein IIb/IIIa receptor blocker is planned). Left ventriculography is clinically useful when performed prior to intervention, even in patients who are hemodynamically unstable, to assess the severity of ventricular and valvular dysfunction, to help in identification of the infarct artery (if this is uncertain), and to aid in making decisions regarding the need for adjunctive therapy, such as intraaortic balloon pumping and pulmonary artery catheter insertion. Occasionally, papillary muscle rupture, ventricular septal defect, or rarely even frank free wall rupture will be demonstrated, prompting urgent surgery. Alternatively, demonstration of normal left ventricular function may raise early concerns of nonischemic diagnoses such as aortic dissection or pericarditis. A femoral venous sheath may be helpful in patients with occlusion of the right coronary artery to allow access for temporary transvenous pacing if necessary. In patients with hypotension or hemodynamic instability, placement of a pulmonary artery catheter is important to define and monitor hemodynamics. The use of a pulse oximeter to monitor oxygen saturation is also useful. Following diagnostic coronary and left ventricular angiography, patients are triaged to the most appropriate therapy.

PRIMARY ANGIOPLASTY PROCEDURE

Primary angioplasty is generally performed with 7 French standard guiding catheters and soft or floppy-tipped 0.014-in. steerable guidewires. The soft tip almost always can cross the soft fresh thrombus (in contrast to chronic total occlusions) and is less traumatic than stiffer wires. If the infarct lesion cannot be crossed with a soft wire, a stiffer wire is used. The guidewire is advanced well down the infarct artery to ensure that it is in the true lumen and not in the small side branch or under an intimal dissection, since navigation is usually done blindly distal to the occlusion. If the infarct-related artery is totally occluded initially, reperfusion often will be established after the occlusion is crossed with a guidewire. If reperfusion is not established with the wire, it may be preferable to cross the occlusion with the balloon and then withdraw the balloon without inflating it ("Dottering" the lesion) to establish reperfusion. The more gradual reperfusion provided with the wire or Dottering technique may result in fewer reperfusion arrhythmias than rapidly inflating the balloon immediately after crossing. Once reperfusion is established, balloon angioplasty of the infarct lesion is performed with similar technique to conventional angioplasty. Infarct lesions usually are soft and do not require high balloon pressures. The operator should strive for an optimal result with less than 30 percent residual luminal narrowing and TIMI 3 flow. If a significant residual stenosis remains, or if there is a dissection, coronary stenting is indicated because these features are predictive of recurrent ischemia or reocclusion.[119] As soon as the decision to perform coronary stenting is made, 500 mg ticlopidine or 150 to 300 mg clopidogrel should be given as a loading dose. As an alternative to stenting for suboptimal results, or if there is large residual thrombus, a glycoprotein IIb/IIIa platelet receptor inhibitor may be used (although if glycoprotein IIb/IIIa receptor blocker use is likely, it is preferable to use this agent prior to balloon inflation). The use of intracoronary thrombolytic therapy is not recommended because this results in increased rates of infarct artery occlusion when used as an adjunct to angioplasty in acute ischemic syndromes.[120] No flow (TIMI 0-1 flow) or slow flow (TIMI 2 flow) may occur after successful opening of the epicardial infarct artery obstruction. This is generally due to microvascular dysfunction from spasm, distal emboli, or endothelial injury and should be treated with intracoronary nitroglycerin, verapamil, and/or adenosine, which often helps to improve flow. Glycoprotein IIb/IIIa receptor blocking agents also may help with no reflow. With rare exceptions (such as refractory cardiogenic shock), a cardinal rule with primary angioplasty is to dilate only the infarct artery. Tandem lesions in the infarct vessel can be dilated, but dilating a noninfarct artery places too much myocardium acutely in jeopardy.

ACUTE CATHETERIZATION LABORATORY COMPLICATIONS

With increasing operator experience, improved equipment and patient selection, and the availability of stents, major catheterization laboratory complications with primary angioplasty have become infrequent. Acute catheterization laboratory complications from the Stent PAMI trial[121] in nonshock patients are shown in Table 46-6. Laboratory death and emergency bypass surgery for failed angioplasty are rare. Ventricular tachycardia or fibrillation requiring cardioversion, asystole and bradycardia including second- and third-degree atrioventricular (AV) block, and hypotension are the most common complications and

usually occur immediately after reperfusion. These complications, which occur more often with right coronary artery infarction, historically were a problem with primary angioplasty, but with increased experience, they occur less frequently and are manageable.[84]

Table 46-6: Acute Catheterization Laboratory Complications with Primary Angioplasty (PTCA) and Primary Stenting in Nonshock Patients

Complication	Stent (*n* = 451) (%)	PTCA (*n* = 448) (%)	Combined (*n* = 899) (%)
Laboratory death	0.2	0	0.1
Emergency bypass surgery	0.2	0.2	0.2
Cardiac arrest

Sustained hypotension§	7.8	8.3	8.0

*Requiring electric cardioversion.†Requiring chest compression.‡Requiring atropine or temporary pacing.§Requiring vasopressors or intraaortic balloon counterpulsation.
SOURCE: From the Stent PAMI trial.[76]

POSTANGIOPLASTY CARE

Following the interventional procedure, heparin should be held for 2 to 4 h until the ACT is less than 170 s, at which time the sheath should be removed. Heparin is resumed 2 h after sheath removal with a bolus at 15 units/kg per hour and titrated to maintain the activated partial thromboplastin time (aPTT) at 60 to 80 s. Full-dose heparin is continued until 48 h after the intervention, then is decreased to one-half dose for 12 h to prevent a rebound hypercoagulable state, and then is discontinued. In patients who receive abciximab, no postprocedural heparin is given. When tirofiban or eptifibatide is used, low-dose heparin is recommended. Low-risk patients (as defined earlier) can be transferred from the catheterization laboratory directly to the subacute unit (rather than the coronary care unit) and can be targeted for discharge on day 3 (day 0 = day of admission).[102] Aspirin should be given routinely. Ticlopidine 250 mg orally twice daily or clopidogrel 75 mg orally daily should be given in stented patients and continued for 2 to 4 weeks. If no contraindications are present, angiotensin-converting enzyme (ACE) inhibitors should be used in patients with congestive heart failure, hypertension, or low ejection fraction (<40 percent). Oral beta blockade also should be administered routinely in the absence of contraindications. Patients who develop symptoms or electrocardiographic changes suggestive of recurrent ischemia or reinfarction should undergo emergency repeat catheterization and intervention as indicated.

Adjunctive Therapy

STENTS

The use of stenting with percutaneous coronary intervention in AMI initially was thought to be contraindicated due to the presence of thrombus in the infarct artery and concern regarding the risks of subacute thrombosis. The use of platelet inhibition with aspirin plus ticlopidine or clopidogrel and high-pressure balloon deployment have greatly reduced the incidence of subacute thrombosis, and numerous

studies have now documented the safety of stent deployment in the setting of AMI.[81,122,123] Several studies with first-generation stents have documented superior outcomes with stenting compared with angioplasty alone, with lower composite end points due primarily to less target-vessel revascularization or less recurrent ischemia[123-125] (Table 46-7). The largest randomized trial, the Stent PAMI trial[121] with 900 patients, has documented lower restenosis rates (20 versus 34 percent; $p = 0.001$), including less reocclusion (5 versus 9 percent; $p = 0.04$) and less ischemia-driven target-vessel revascularization (8 versus 17 percent; $p = 0.0001$) with stenting versus angioplasty alone but no difference in mortality or reinfarction (see Table 46-7). Currently, stenting cannot be recommended for routine use with primary angioplasty but should be used in selected patients, especially when there are suboptimal results or dissection following angioplasty. The results of large ongoing trials with newer stents may provide data that will extend these indications.

PLATELET INHIBITORS

Several trials have documented the efficacy of glycoprotein IIb/IIIa platelet receptor inhibition during elective coronary intervention.[126-128] The RAPPORT trial evaluated platelet inhibition with abciximab in patients with AMI undergoing primary angioplasty and found a significant reduction in the 30-day composite end point[129] (Table 46-8). However, by 6 months, there was no difference in outcomes (see Table 46-8). Also, the use of high-dose heparin in concert with prolonged sheath dwell times resulted in an excess of major bleeding episodes. Two European trials, the ADMIRAL trial[130] and the Munich trial,[131] have evaluated abciximab in patients with AMI undergoing primary stenting, and both have found a significant reduction in composite end points with abciximab compared with placebo (see Table 46-8). The CADILLAC trial has evaluated the efficacy of abciximab in 2000 patients with AMI undergoing either primary angioplasty or primary stenting. This study should provide efficacy as well as cost data that will help to define the role of platelet inhibition with primary angioplasty for AMI.[132]

INTRAAORTIC BALLOON COUNTERPULSATION

Clinical studies have shown that the use of intraaortic balloon counterpulsation results in augmentation of systemic pressure, reduction in preload and afterload, and an increase in coronary blood flow velocity.[133,134] This has given hope that intraaortic balloon counterpulsation may improve outcomes in patients with AMI. Unfortunately, randomized trials in high-risk patients with AMI have shown little or no benefit when intraaortic balloon counterpulsation is used alone without concomitant reperfusion or revascularization.[135,136] Several studies have evaluated the prophylactic use of intraaortic balloon counterpulsation after reperfusion with primary or rescue angioplasty in high-risk patients[137,138] (Table 46-9). Initial studies[137] suggested benefit in terms of less infarct artery reocclusion and less recurrent ischemia, but larger, more recent studies including the large PAMI-2 trial have shown little or no benefit.[138,139] The results of these trials and the advent of coronary stenting, which has reduced the incidence of reocclusion and recurrent ischemia, have diminished the role of intraaortic balloon counterpulsation after primary angioplasty in hemodynamically stable patients. Intraaortic balloon counterpulsation still has a role in hemodynamically unstable patients with congestive heart failure or shock prior to primary angioplasty and in patients with mechanical complications of AMI or anatomy that is unsuitable for percutaneous coronary intervention as a bridge to surgery. There also may be a role for prophylactic intraaortic balloon pumping before primary angioplasty in selected high-risk patients to prevent hemodynamic deterioration.[140]

Chapter 46: MECHANICAL INTERVENTIONS IN ACUTE MYOCARDIAL INFARCTION

FUTURE RESEARCH DIRECTIONS: BEYOND TIMI 3 FLOW

The superior TIMI 3 flow rates achieved by mechanical reperfusion largely explain the mortality advantage of this strategy. Today, TIMI 3 flow rates of 90 percent or more are expected for optimal clinical benefit. It must be emphasized, however, that TIMI flow is a subjective, qualitative assessment of relative contrast velocity in major epicardial coronary vessels. Observations using myocardial contrast echocardiography suggest that effective myocardial perfusion may occur in only 70 percent of patients with TIMI 3 flow.[141] Similarly, the Zwolle group has shown that myocardial contrast blush grade is impaired in a large number of patients with normal TIMI flow.[142] Finally, Tsunoda et al.[143] have shown that up to one-third of patients with TIMI 2 flow have abnormal Doppler wave flows with a systolic flow reversal and diminished diastolic flow pattern. The reason for concern is that each of these techniques measures myocardial perfusion, and each has shown that ventricular function is only improved in those patients with normal myocardial perfusion.

The cause for abnormal perfusion after PTCA is unknown. Most myocardium is stunned after prolonged ischemia, but lack of demand alone does not explain the abnormal flow. Distal embolization of macroscopic thrombotic and plaque debris and reperfusion injury after reperfusion may be contributory. Extensive myocardial edema with capillary constriction and leukoaggregation or platelet macroemboli may prevent capillary perfusion.

Exciting new research modalities will test each of these potential mechanisms. The goal is to normalize myocardial perfusion and thus optimize salvage after reperfusion. Agents such as adenosine will be tested to decrease reperfusion injury.[144] Filtered leukocytes and complement-depleted blood have been used to reperfuse patients.[145] Supersaturated oxygen is being employed to limit myocardial injury during reperfusion.[146] Mechanical traps[147] will be employed to prevent macroembolization of debris during angioplasty and stent placement. Even glucose-insulin-potassium solutions may be of value.[148] Finally, glycoprotein receptor blockade may prevent platelet-rich thrombi from impairing microcirculatory function. Two trials have demonstrated significant improvement in ejection fraction when abciximab is added to stent therapy of AMI.[130,131] Mechanical reperfusion not only has demonstrated improvement in clinical outcome but also will contribute to an understanding of mechanisms involved in myocardial injury.

Chapter 46: MECHANICAL INTERVENTIONS IN ACUTE MYOCARDIAL INFARCTION

CONCLUSION

Mechanical reperfusion therapy of AMI has developed as an alternative to thrombolytic therapy. Reperfusion rates are significantly higher, rates of death and reinfarction are significantly lower, rates of intracranial hemorrhage are dramatically lower, and long-term survival is significantly greater compared with thrombolytic therapy. This treatment thus may be the preferred therapy for patients presenting to institutions equipped to perform it. Ongoing clinical trials will further elucidate the role of mechanical reperfusion after failed thrombolytic therapy and the role of transport of high-risk patients to referral institutions. The potential for mechanical reperfusion therapy is great. The major challenge for clinicians will be to find methods to apply this treatment to larger segments of the population.

Part 6: CORONARY HEART DISEASE
Chapter 47:

CORONARY INTRAVASCULAR ULTRASOUND IMAGING

Author: Steven E. Nissen

Although angiography continues to serve as the primary imaging modality used to assess the anatomy of coronary artery disease, intravascular ultrasound has matured into an important alternative method for examination of the coronaries during diagnostic or interventional catheterization.[1-8] Studies comparing angiography and intravascular ultrasound have demonstrated important differences in quantitative and qualitative findings.[7-11] Unlike angiography, which portrays the vessel as a silhouette of the lumen, intravascular ultrasound provides tomographic images that portray not only the lumen but also the deeper intramural structures within the vessel wall. The ability of ultrasound to penetrate and image soft tissue enables direct visualization of the atheroma, providing insights into the pathophysiology of coronary disease not obtainable by any other technique. Accordingly, intraluminal ultrasound imaging is now commonly utilized to confirm, refute, or supplement angiographic data in patients with coronary disease.[8]

RATIONALE FOR INTRAVASCULAR ULTRASOUND

Limitations of Angiography

Visual interpretation of angiograms exhibits significant observer variability, and necropsy examination is often discordant with the apparent angiographic severity of lesions.[12-18] In comparison to postmortem evaluation, angiography often significantly underestimates the extent of atherosclerosis.[13,18] Angiographic assessment of lesion severity is strikingly discordant with measurements of the physiologic effects of stenoses.[19] Angiography depicts coronary anatomy from a planar two-dimensional silhouette of the contrast-filled lumen. However, coronary lesions are often complex, with markedly distorted or eccentric luminal shapes, and mechanical interventions (other than stenting) exaggerate luminal eccentricity by fracturing or dissecting the atheroma.[9,20,21] The angiographic appearance of the postintervention vessel often reveals an enlarged but "hazy" lumen. This indistinct, broadened angiographic silhouette may overestimate actual vessel diameter and misrepresent the gain in lumen size.[21]

The traditional method for characterizing angiographic lesion severity depends upon visual or computer measurements of the percentage stenosis. This process requires comparison of luminal dimensions within both the lesion and an adjacent, uninvolved "normal" reference segment. However, necropsy studies demonstrate that coronary disease is frequently diffuse and contains no truly normal reference segment.[18] In the presence of diffuse disease, calculation of percent stenosis will predictably underestimate disease severity. Diffuse, concentric, and symmetrical disease affecting the entire vessel may result in the angiographic appearance of a small but normal artery.[21] Angiography is also confounded by the phenomenon of coronary "remodeling," observed histologically as the outward displacement of the external vessel wall in segments with atherosclerosis.[22] This adventitial enlargement attenuates lumen encroachment, thereby concealing the presence of the atheroma on angiography. Although such lesions do not restrict blood flow, clinical studies have demonstrated that these minimal, nonobstructive lesions represent an important cause of acute coronary syndromes.[23] Angiographically unrecognized

disease virtually always underlies an ergonovine-positive response in symptomatic patients with a "normal" coronary angiogram.[24]

Theoretical Advantages of Ultrasound

Intravascular ultrasound has several unique properties of theoretical value in the detection and quantitation of coronary disease.[25,26] The cross-sectional perspective of ultrasound permits visualization of the full 360-degree circumference of the vessel wall. Accordingly, measurement of lumen area can be determined by planimetry independent of the radiographic projection or magnification.[7,21,25,26] The tomographic perspective of ultrasound enables evaluation of vessels difficult to assess by angiographic techniques, including diffusely diseased segments and bifurcation or ostial lesions. The ability to directly image the atheroma represents a truly unique capability not possible using any other commonly available imaging modality.

Chapter 47: CORONARY INTRAVASCULAR ULTRASOUND IMAGING

IMAGING TECHNOLOGY

Catheter Design

Intracoronary ultrasound equipment consists of two major components: a catheter incorporating a miniaturized transducer and a console containing the electronics necessary to reconstruct the image. High frequencies (20 to 50 MHz) are employed, resulting in excellent theoretical resolution (axially <100 μm and laterally <250 μm). Two dissimilar technical approaches to transducer design exist: mechanically rotated devices and multielement electronic arrays[1-5] (Fig. 47-1). Each design has yielded small intravascular devices suitable for coronary imaging, typically ranging in size from 2.6 to 3.5 Fr (diameter of 0.86 to 1.17 mm). To facilitate subselective coronary cannulation and catheter exchanges, ultrasound catheters provide a lumen for a movable guidewire. Most systems generate images at a temporal frequency of 30 frames per second for recording on videotape.

Limitations and Artifacts

Intravascular ultrasound devices generate artifacts that may adversely affect image quality, alter interpretation, or reduce quantitative accuracy.[27] Ring-down artifact arises from acoustic oscillations in the piezoelectric transducer, resulting in high-amplitude signals that preclude imaging close to the transducer surface. Accordingly, the "acoustic" size of catheters is slightly larger than their physical size. Since the minimum size of current devices is approximately 0.9 mm, some severe stenoses cannot be imaged prior to intervention. Geometric distortion can result from imaging in an oblique plane (not perpendicular to the long axis of the vessel), resulting in an elliptical rather than circular imaging plane.[28]

Mechanical, but not electronic, transducers may exhibit cyclical oscillations in rotational speed, resulting in an artifact known as nonuniform rotational distortion (NURD).[27] This artifact arises from mechanical friction within the catheter drive shaft during the portions of its rotational cycle. This speed variation produces readily visible distortion often observed as circumferential stretching of a portion of the image with compression of the contralateral vessel wall. NURD is most evident when the drive shaft is bent into a small radius of curvature by a tortuous vessel. Improvements in the mechanical precision of ultrasound devices have reduced the impact of the artifact, but it still remains troublesome during some examinations.

Chapter 47: CORONARY INTRAVASCULAR ULTRASOUND IMAGING

CORONARY IMAGING

Examination Technique

Standard interventional techniques for intracoronary catheter delivery are used for intraluminal ultrasound examination. Intravenous heparin [to maintain activated clotting time (ACT) >200 to 250 s] and intracoronary nitroglycerin (100 to 300 μg) are routinely administered, although there are no controlled studies documenting the necessity for anticoagulation. Using a 7- or 8-Fr guiding catheter, the operator advances a steerable guidewire to subselectively cannulate the vessel. A stable guiding catheter position with good support is desirable, since current ultrasound catheters have less trackability and a larger profile than modern balloon angioplasty catheters. The operator carefully advances or retracts the imaging catheter over the wire to examine the vessel in real time, recording images on videotape for subsequent quantitative or qualitative analysis.

Some centers use a motorized pullback device to withdraw the catheter at a constant speed (between 0.25 and 1 mm/s, most frequently 0.5 mm/s). However, a single pullback, even when controlled by a precise motor, may be insufficient for a complete diagnostic ultrasound examination. Accordingly, motorized pullback is most often used to "survey" the coronary prior to more prolonged and thorough examination of sites of interest. Side branches, visualized with both angiography and ultrasound, are often used as landmarks to facilitate interpretation. Some practitioners advocate use of a uniform format, electronically rotating the ultrasound image so that branches appear in a standardized orientation. For example, imaging of the left anterior descending is often performed with the septal branches at 6 o'clock and the left circumflex appearing at about 9 o'clock.

Safety of Coronary Ultrasound

Although intravascular ultrasound requires intracoronary instrumentation, studies have demonstrated few serious untoward effects.[29-31] The most frequently encountered complication is focal coronary spasm, which usually responds rapidly to intracoronary nitroglycerin. Data from European centers reported a 1.1 percent complication rate in 718 ultrasound examinations.[30] Another report from 28 centers (2207 studies) documented spasm in 2.9 percent and major complications such as occlusion or dissection judged to have a "certain relation" to instrumentation in 0.4 percent.[29] In both studies, complications (spasm, vessel dissection, or guidewire entrapment) occurred in patients undergoing angioplasty rather than diagnostic imaging.[44] In 170 cardiac transplant recipients (240 studies), there was no morbidity, but spasm occurred in 20 patients (8.3 percent) despite pretreatment with nitroglycerin.[31] Any intracoronary instrumentation carries the potential risk of intimal injury or vessel dissection. Accordingly, most laboratories limit credentialing for this procedure to personnel with interventional training.

Normal Coronary Anatomy

Studies performed either in vivo or using excised, pressure-distended vessels have characterized the appearance of normal coronaries by intravascular ultrasound.[32-36] Important determinants of vessel wall appearance include both the normal arterial structure and the inherent properties of ultrasound. An ultrasound reflection occurs at a tissue boundary whenever there is an abrupt change in acoustic impedance. Normally, two strong acoustic interfaces are visualized by

ultrasound-the leading edge of the intima (at the interface between the blood-filled lumen and the endothelium) and the outer border of the media (at the junction of media and external elastic membrane). Underlying the trailing edge of the intima, a middle sonolucent layer is usually evident, which is composed principally of the tunica media. The echodense intima and adventitia with a sonolucent medial layer often give the wall a trilaminar appearance. However, this pattern is not a universal finding; in 30 to 50 percent of normal segments, a thin intimal layer reflects ultrasound poorly, which results in a monolayer appearance[35] (Fig. 47-2).

In a necropsy study, the ultrasound-derived intimal thickness in segments with three layers was significantly greater than for monolayered sites (0.24 ± 0.1 versus 0.11 ± 0.06 mm, $p < 0.001$). The mean age in the three-layered group was greater, 42.8 ± 9.8 versus 27.1 ± 8.5 years ($p < 0.001$).[37] Other studies demonstrate that a trilaminar appearance is dependent not only on the age but also on the histologic characteristics of the vessel. A three-layered appearance is consistently observed if an internal elastic membrane state is present.[38] However, if an internal elastic membrane is absent, a trilaminar appearance is observed only when the collagen content of the media is low. In older "normal" subjects, intimal thickening usually results in a pattern of two distinct echogenic layers sandwiching a sonolucent intermediate layer. In nearly all cases, the deepest arterial layers exhibit a characteristic "onionskin" pattern, representing the adventitia and periadventitial tissues with an indistinct outer vessel border.

In both normal and abnormal arteries, the lumen exhibits faint, finely textured, swirling echoes that arise from acoustic reflections from circulating blood elements. This blood "speckle" may assist image interpretation by providing a means to confirm the communication between dissection planes and the lumen. The pattern of blood speckle is dependent on the velocity of flow, showing increased intensity and a more coarse appearance when flow is reduced. In some cases, the coarse blood speckle can mimic the appearance of tissue, complicating image interpretation.

Chapter 47: CORONARY INTRAVASCULAR ULTRASOUND IMAGING

CHARACTERIZATION OF ATHEROSCLEROSIS

Atheroma Composition

The subtle changes that occur early in the development of atherosclerosis, such as fatty streaks, are not visible using current ultrasound devices. Atherosclerotic arteries exhibit a variety of features that reflect the distribution, severity, and composition of the atheroma.[32-34] Sites with limited disease exhibit generalized or focal thickening of the intimal leading edge, while advanced lesions appear as large echogenic masses encroaching upon the lumen. A comparative study of ultrasound and histology in 1100 fresh necropsy sections demonstrated that lipid-laden lesions are usually hypoechoic.[32] Soft, low-intensity echoes most often represent fibromuscular lesions and very bright echoes are observed within dense fibrous or calcified tissues (Fig. 47-3). In highly echogenic plaques, foci of calcification are recognized by attenuation of ultrasound penetration, which obscures deeper layers, a phenomenon known as "acoustic shadowing." In lipid-laden or fibromuscular lesions, a prominent echogenic overlying fibrous "cap" may be observed.

The echogenicity of the plaque components is dependent not only on the acoustic properties of tissue but also on the acquisition settings (gain, compression, etc.). Accordingly, most classification schemes compare the echogenicity of the plaque to the surrounding adventitia to correct for differences in ultrasound technique. However, in plaques containing a zone of reduced echogenicity, it is not possible to determine whether these represent areas of lipid deposition, thrombus, or necrotic degeneration, all of which can appear as zones of low density. Plaque composition was accurately predicted by ultrasound imaging in 96 percent of 112 quadrants from 21 freshly explanted human coronary arteries.[29] Fibrous and calcified plaque quadrants were correctly identified in almost all incidences (100 of 103, or 97 percent), but only 7 of 9 quadrants (78 percent) with predominantly lipid deposits were correctly identified.

Accordingly, some caution is warranted in the intravascular ultrasound classification of atheroma composition. Although currently available devices produce detailed views of the vessel wall, interpretation employs visual inspection of acoustic reflections to determine morphology. Different histologic features may exhibit comparable acoustic properties, and methods do not yet exist for objective or automated classification of atheromatous lesions. Thus, intravascular ultrasound can delineate the thickness and echogenicity of vessel wall structures but does not provide actual histology. Despite these limitations, the classification of coronary plaques into the categories of soft, fibromuscular, and calcified has important clinical implications.

Detection of Calcification

Ultrasound imaging has shown superiority over fluoroscopy or angiography in the detection of coronary calcification. In a series of 110 patients undergoing intervention, target lesion calcification was detected by ultrasound and fluoroscopy in 84 and 50 patients, respectively (76 versus 14 percent, $p < 0.001$).[39] Another retrospective study analyzed calcification by angiography and ultrasound in 183 interventional patients.[40] Assessment by the two techniques was concordant in 92 and discordant in 91 cases. Calcification was detected in 138 patients by ultrasound and 63 by fluoroscopy, showing a sensitivity and specificity for angiography of 46 and 82 percent, respectively. When calcium was detected angiographically, calcification by ultrasound

often subtended >90 degrees and was superficial to the lumen in location. If no calcification could be visualized on the angiogram, the chance of detecting a large superficial arc of calcium by ultrasound was low (12 percent).

Ultrasound calcification is a major determinant of the arterial response to intervention, portending a greater risk of dissection following balloon angioplasty, less tissue retrieval with directional atherectomy, and greater benefit with the use of rotational atherectomy.[41,42] Because of the importance of calcium in the selection of interventional devices, most classification schemes quantify calcification, usually by measuring the circumferential angle subtended by calcified plaque.[39] Commonly, the axial length of the calcified portion of the lesion is also reported and the depth of calcification assessed, described as superficial when the calcium remains in contact with the luminal surface and deep if no portion of the calcium deposit is superficial.

Arterial Remodeling

This term refers to a change in arterial dimensions associated with the development of atherosclerosis. In a necropsy study of 136 human left main coronary arteries, Glagov et al. originally described focal arterial enlargement at atherosclerotic sites, reporting a positive correlation between external elastic membrane (EEM) area and the area occupied by atheroma ($r = 0.44$, $p < 0.001$).[22] At sites with area stenosis less than 40 percent, the increase in arterial size "overcompensated" for the plaque deposition, leading to an increase in absolute lumen area. With more advanced lesions (area stenosis >40 percent), the degree of arterial enlargement or remodeling was blunted, resulting in a smaller lumen area. The authors hypothesized that this phenomenon represented a compensatory mechanism to preserve lumen size.

The findings of Glagov et al. were later confirmed in vivo by intravascular ultrasound imaging[43,44] (Fig. 47-4). In 80 ultrasound cross sections obtained from 44 patients undergoing coronary interventions, EEM area correlated closely with plaque area ($r = 0.79$, $p = 0.0001$). In this study, lumen area increased with early atherosclerosis, confirming the phenomenon of overcompensation in early stages of the disease. With more advanced atherosclerosis, there was a correlation between increasing area stenosis and decreasing lumen area ($r = 0.58$, $p = 0.0001$).[43] Compensatory enlargement has also been demonstrated by ultrasound in superficial femoral arteries; however, there was no difference between lesions less than and greater than 40 percent stenosis.[45]

In recent years, ultrasound studies have demonstrated a new dimension to arterial remodeling: negative remodeling.[46,47] At diseased sites, the EEM area may actually be reduced in size, contributing to luminal narrowing rather than compensating for it. In 51 femoral arteries, EEM area was smaller at lesions than adjacent reference sites, with a negative correlation between stenosis severity and EEM area reduction ($r = 0.62$ by histology and 0.66 by ultrasound, $p < 0.001$ for both).[46] "Inadequate" remodeling, defined as an EEM area within the lesion less than 78 percent of a proximal reference site, has also been described in the coronaries of patients with stable angina.[47] Although 91 of 603 lesions (15 percent) fit this definition, there was a highly variable response among lesions within the same patient. However, when remodeling is defined in this fashion, there is an assumption that the reference EEM area represents the original vessel size, which may not be correct, since angiographic reference sites are invariably diseased according to ultrasound.

Although the exact mechanisms of compensatory or negative remodeling remain unclear, these phenomena have important clinical implications. Compensatory remodeling represents an important factor in the underestimation of the severity of atherosclerosis by angiography. Remodeling may influence the estimation of the vessel size during coronary interventions. Recently, negative remodeling has been implicated in restenosis following debulking and balloon

angioplasty.[48]

Unstable Plaque and Thrombi

An emerging application of intracoronary ultrasound is the characterization of the atheroma associated with acute coronary syndromes (Fig. 47-5). The typical angiographic appearance of a ruptured plaque is a stenosis with an eccentric or ulcerated lumen, often with overhanging edges (Ambrose type II lesion).[49-54] However, retrospective reviews of angiograms of patients performed before an episode of unstable angina usually reveal minimal disease within the culprit lesion segment.[51] These studies highlight the inability of angiography to identify "rupture-prone" lesions. Histologic examination of unstable plaques after rupture usually reveals a lipid-laden plaque with a thin fibrous cap.[49] Based on these observations, it has been postulated that the size of the lipid pool and the thickness of the fibrous cap are more important than severity of stenosis in predicting plaque rupture.[52]

Some intravascular ultrasound studies have confirmed the presence of an echolucent atheroma within culprit lesions in patients with acute coronary syndromes. In a small study of 22 stable and 43 unstable angina patients, type II eccentric lesions were detected on the angiograms in 18 percent of stable and 40 percent of unstable angina patients. Echolucent plaques were more frequently observed in patients with unstable than in those with stable angina syndromes (74 versus 41 percent, $p < 0.01$).[11] Recent and intriguing intravascular ultrasound studies have examined the relationship between remodeling and the type of clinical presentation. The culprit lesions in 76 patients with acute coronary syndromes were compared with lesions in 40 patients with stable angina. In the unstable patients, both EEM and plaque areas were significantly larger than the corresponding measurements in the stable patients ($p = 0.02$ for both). Positive remodeling was more prevalent in the unstable group (51 versus 18 percent, $p = 0.002$) and negative remodeling more prevalent in the stable group (58 versus 33 percent, $p = 0.002$).[55]

The formation of intraluminal thrombi at a ruptured or fissured plaque is considered to be the hallmark of acute coronary syndromes.[56] Angiographic criteria for diagnosis of a coronary thrombus, the presence of haziness, an intraluminal filling defect, and/or irregular lumen contour are not sensitive.[54] Small observational studies have attempted to differentiate the ultrasound appearance of thrombus, defined as hypoechoic material projecting into the lumen with a slight synchronous pulsation and a distinct acoustic interface, from more echogenic plaque[57,58] (Fig. 47-6). However, in vitro studies have revealed limitations in the reliability of intravascular ultrasound diagnosis of thrombi (sensitivity of 57 percent and specificity of 91 percent), considerably inferior to angioscopy (sensitivity and specificity of 100 percent).[56] Radiofrequency analysis of ultrasound signals has shown some promise in differentiating between thrombus and plaque, although the clinical application is not yet feasible.[59,60]

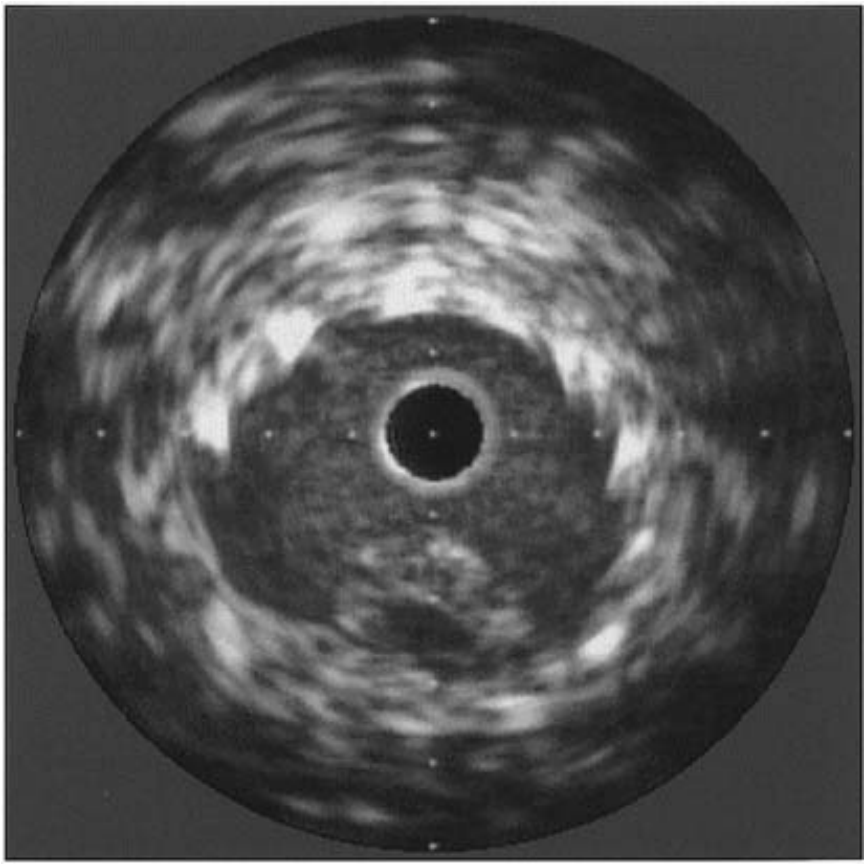

Figure 47-6: Thrombus within a coronary stent. In this intravascular ultrasound image, a stent is well visualized. There is a globular mass projecting into the lumen at 6 o'clock; it probably represents a large thrombus.

Chapter 47: CORONARY INTRAVASCULAR ULTRASOUND IMAGING

DIAGNOSTIC CLINICAL APPLICATIONS

Quantitative Luminal Measurements

A broad spectrum of therapeutic decisions hinge upon assessment of coronary luminal dimensions. Accordingly, in diagnostic and interventional practice, quantitation of vascular dimensions represents an important clinical application of intravascular ultrasound. Several studies have compared luminal measurements by intravascular ultrasound and quantitative angiography.[6,7] For vessels without atherosclerosis, most studies document a close correlation between angiographic and ultrasonic coronary dimensions, although a few studies suggest slightly larger measurements by ultrasound.[7] However, in patients with atherosclerotic arteries, most investigators report only a moderate correlation between ultrasonic and angiographic dimensions, with the greatest disparities in vessel segments with a noncircular lumen shape.[5,7,10] This reduced correlation is probably explained by the irregular, noncircular cross-sectional profile of diseased vessels, which cannot be adequately measured using angiography.[10]

Quantitation of Atherosclerosis

Analysis of intravascular ultrasound images permits quantitative measurements of the extent and severity of coronary atherosclerosis[26] (Fig. 47-7). However, the inherent properties of ultrasound require utilization of different anatomic landmarks than those serving classic histology. In all ultrasound imaging, reflections at the leading edge of any interface are located precisely at the boundary where acoustic impedance abruptly changes. However, the position of the trailing edge of any anatomic structure is determined by multiple nonanatomic factors, including ultrasound beam properties, particularly the wavelength (frequency). Thus, leading-edge measurements accurately describe the location of a boundary, whereas trailing-edge measurements are unreliable. As previously noted, strong reflections are generally produced at two locations, the leading edge of the intima and the border between the media and the external elastic membrane. The position of the trailing edge of the intima is not accurately localized in intravascular ultrasound images. Accordingly, quantitative measurements must calculate the atheroma's cross-sectional area by subtracting the area bounded by the intimal leading edge from the area enclosed by the external elastic membrane. This approach results in a slight overestimation of atheroma volume (in comparison to histology) by including the area of the media within the calculation.

NORMAL INTIMAL THICKNESS

The threshold for abnormal intimal thickness by intravascular ultrasound is controversial, particularly since the categorical classification of a continuous variable, intimal thickness, as normal and abnormal is inherently arbitrary. In various histologic and ultrasound studies, normal intimal thickness ranges between 0.10 and 0.35 mm and the normal medial thickness ranges from 0.15 to 0.25 mm. In a necropsy study, normal intimal thickness not including media was age-dependent, averaging 0.21 mm in 21- to 25-year-olds, 0.22 mm in 26- to 30-year-olds, and 0.25 mm in 36- to 40-year-olds.[37] In a comparative study, intravascular ultrasound measurements of the intima plus media averaged 20 percent greater than histological measurements.[61,62] Considering the histologic and ultrasound data, most clinical studies have defined the ultrasound measurement threshold for coronary disease as an intimal thickness ≥0.5 mm.[63-67] Currently, there

is no well-defined threshold for normal values for other measures, like intimal cross-sectional area.

The tomographic orientation of intravascular ultrasound represents an additional problem in quantifying atherosclerosis. Since each image contains information from only a thin "slice" of the vessel, global measures of atheroma burden require the integration of multiple cross sections. One successful approach to this conundrum employs a motorized device to steadily and progressively withdraw the ultrasound catheter through the interrogated vessel, typically at 0.5 to 1.0 mm/s. Since motor speed is kept constant, the operator can obtain a series of cross sections separated by a constant, recurring time interval; these are individually measured and then summated to approximate total atheroma burden using Simpson's rule. A second approach to atheroma quantitation employs three-dimensional (3D) reconstruction of the vessel from the two-dimensional ultrasound tomograms.[68] Unfortunately 3D methods are exceedingly complex, have many unresolved confounding variables, and remain largely unvalidated.

Atheroma Distribution

The circumferential distribution of the atheroma varies from nearly symmetrical plaques to very eccentric lesions in which the entire atheroma is located on one side of the artery. Assessed by ultrasound, the majority of plaques are eccentric, with a maximum atheroma thickness more than twice the minimum plaque thickness.[69] Studies have demonstrated a poor correlation between the apparent circumferential pattern by angiography and the actual plaque distribution revealed by ultrasound examination.[69] Such studies demonstrate the inaccuracy inherent in determining plaque distribution from the projected two-dimensional silhouette of the lumen (angiography). This observation has important implications for guidance of coronary interventions, particularly techniques for selective plaque removal, such as directional atherectomy.

Angiographically Unrecognized Disease

In patients undergoing angiography for clinically suspected coronary artery disease, no angiographic evidence of narrowing is present in 10 to 15 percent of cases. In these patients, intravascular ultrasound commonly detects atherosclerosis at angiographically normal sites.[21,25,26,70,71] Using intravascular ultrasound, atherosclerotic abnormalities were documented in 21 of 44 patients (48 percent) with suspected coronary artery disease and normal coronary angiograms.[70] Combining ultrasound and functional assessment (coronary flow reserve and endothelium-mediated vasodilator response), only 36 percent of patients in this cohort were completely normal. Other studies demonstrate that, if any luminal irregularity is present by angiography, ultrasound will usually demonstrate atherosclerosis at nearly all other examined sites.[21] The prevalence of atherosclerosis at angiographically normal sites confirms the finding, previously reported from necropsy studies, that coronary involvement is frequently underestimated using angiographic evaluation methods[12,13] (Fig. 47-8).

There are several mechanisms by which angiography may underestimate the presence, extent, or severity of atherosclerosis.[21] First, to detect focal narrowing, angiography relies upon comparison of the interrogated site to an adjacent uninvolved segment. However, the involved vessel is often reduced in caliber along its entire length, containing no truly normal segment for comparison. The angiographer may erroneously conclude that the vessel is simply "small in caliber." Overlapping structures and mechanical limits in x-ray positioning may prevent the angiographer from obtaining optimal radiographic projections (orthogonal to the lesion). Accordingly, eccentric plaques that occupy only a portion of the vessel circumference represent an important source of false-negative angiography. At atherosclerotic sites, compensatory enlargement of the vessel wall overlying the plaque often preserves lumen diameter, resulting in false-negative angiography because the lumen size in the involved segment is identical to that of adjacent, uninvolved segments. Finally, radiographic foreshortening can conceal short "napkin-ring" lesions.

For each of these mechanisms of false-negative angiography, intravascular ultrasound has been employed to confirm the presence and estimate the extent of atherosclerosis.[21] However, the long-term clinical implications of angiographically unrecognized atherosclerosis remain uncertain since no outcomes-based research has demonstrated a worse prognosis for patients with atherosclerosis detected only by ultrasound. However, several investigators have demonstrated that plaques with minimal to moderate angiographic narrowing are the most likely lead to acute coronary syndromes. Accordingly, the presence of angiographically occult coronary disease may have prognostic significance. Studies are currently under way to determine the value of ultrasound in predicting the clinical outcome in patients with angiographically unrecognized coronary disease.

Lesions of Uncertain Severity

Angiographers commonly encounter lesions that elude accurate characterization despite thorough examination using multiple radiographic projections. Difficult-to-assess sites include ostial or bifurcation lesions and moderate stenoses (angiographic severity ranging from 40 to 75 percent) in patients whose symptomatic status is difficult to evaluate. For ambiguous lesions, ultrasound provides a tomographic perspective, independent of the radiographic projection, that may permit quantification of the lesion. In two prospective series, intracoronary ultrasound changed the management strategy in approximately 20 percent of the examinations performed immediately prior to coronary intervention.[72,73] In both studies, however, operator selection of patients for ultrasound examination may have resulted in an overestimation of the true impact of ultrasound imaging on clinical decision making.

Angiographic assessment of left main coronary artery (LMCA) obstruction represents a particularly vexing clinical problem.[14] Radiographic contrast in the aortic cusp can obscure the ostium, and "streaming" of contrast from the injection vortex can result in a false impression of luminal narrowing. The LMCA is often short in length, leaving no normal "reference" segment. The bifurcation or trifurcation of the LMCA into daughter branches may produce vessel overlap, thereby concealing a stenosis. Intravascular ultrasound is commonly used to quantify LMCA lesions when angiographic interpretation is uncertain.[74] The technique for examination consists of subselective placement of the ultrasound transducer in the circumflex or anterior descending, followed by slow pullback to the aorta with the guiding catheter disengaged. There is no consensus regarding the threshold for critical LMCA obstruction. However, an area stenosis >50 percent or an absolute area <9 mm^2 has been proposed as a threshold.[74]

Cardiac Allograft Disease

Transplant coronary artery disease is the leading cause of death beyond the first year after cardiac transplantation, with a reported incidence of 15 to 20 percent per year.[75] Although most transplant centers perform arteriograms annually for screening, these surveillance studies often fail to detect atherosclerosis prior to a clinical event.[76,77] Necropsy studies have demonstrated that angiography systematically underestimates coronary atherosclerosis in transplant recipients.[77] Patients may have diffuse vessel involvement that, for reasons already enumerated, conceals the atherosclerosis from the angiographer. Many active transplant centers now routinely perform intravascular ultrasound at the time of annual catheterization in all recipients. Investigations using ultrasound to detect transplant vasculopathy report a very high incidence of abnormal intimal thickening in 80 percent of patients at 1 year and in more than 92 percent studied 4 or more years after transplantation.[65-67,79-83]

Recent studies have revealed two pathways to transplant-associated atherosclerosis. Some patients receive atherosclerotic plaques transmitted via the donor heart, while others develop an immune-mediated vasculopathy.[67,81] Despite a young donor age, lesions of conventional atherosclerosis

are frequently present in donor hearts. At a mean donor age of only 32 years, atherosclerosis, defined as a maximal intimal thickness ≥0.5 mm, was evident in 56 percent of patients.[67] Multivariate analysis demonstrated donor age ($p = 0.0001$) and male donor gender ($p = 0.0006$) to be important predictors of atherosclerosis. Ultrasound imaging was a necessity for accurate detection of donor lesions, since the sensitivity of angiography was only 43 percent. The natural history of donor lesions after transplantation is largely unknown. Since angiography is relatively insensitive, ultrasound remains the most important method used to study the early atherosclerotic lesion. In the first year after transplantation, progression occurred in 42 percent of patients.[82]

Chapter 47: CORONARY INTRAVASCULAR ULTRASOUND IMAGING

INTERVENTIONAL CLINICAL APPLICATIONS

Preinterventional Imaging

Several studies have demonstrated that ultrasound imaging of interventional target lesions may influence the approach to therapy. In one study (313 lesions), the intended revascularization strategy before ultrasound imaging was compared with the treatment actually performed.[42] In 40 percent of cases, the intended strategy was altered based on the ultrasound findings, most often ultrasound assessment of lesion composition or eccentricity (26 percent). Although there was a relatively close correlation between angiographic and ultrasonic lumen diameter ($r = 0.83$), a disagreement between the two methods was cited as the reason for altering the procedure in 13 percent of lesions. In another small, nonrandomized study ($n = 56$) of ultrasound guidance of balloon angioplasty or directional atherectomy, operators reclassified lesion characteristics after ultrasound in 68 percent of patients and the therapeutic approach was modified in 48 percent. Ultrasound measurements revealed a smaller lumen diameter than expected from angiography, leading to balloon upsizing in 34 percent of angioplasty cases.[84]

Several studies have purported to show benefits of ultrasound imaging prior to implantation of coronary stents.[85,86] The preliminary results of one prospective study identified vessel calcification as one of the predictors of "inadequate" stent expansion.[85] For ostial lesions, ultrasound imaging is sometimes used to determine whether the lesion involves the "true" ostium or spares the most proximal few millimeters, which may assist optimal stent positioning. When stents are used to treat dissections, ultrasound may reveal involvement of a longer segment than can be appreciated by angiography. This may be particularly relevant in "bailout" stenting for threatened abrupt closure, where it may be preferred to cover the full length of the dissection.[86] Despite promising data, reports on preinterventional imaging must be interpreted with caution. There are no prospective, controlled trials demonstrating a superior outcome using an ultrasound-guided approach. Study patients were not randomized, allowing for bias in selection of more complex cases for ultrasound guidance, which would likely emphasize the contributions of imaging. Furthermore, cases in which the operators were unable to advance the ultrasound catheter through the lesion were systematically excluded.

Imaging during Specific Interventions

BALLOON ANGIOPLASTY

Ultrasound guidance of balloon sizing has been proposed as a means to improve procedural result and late clinical outcome for percutaneous transluminal coronary angioplasty (PTCA).[87] In a study of 104 lesions, ultrasound was performed after obtaining a "satisfactory" angiographic result and revealed remodeling at the lesion or extensive plaque within the reference segment in 73 percent of the cases. In this subset, the balloon-to-artery ratio was increased from 1.12 ± 0.15 to 1.30 ± 0.17 ($p < 0.0001$) and the resulting angiographic minimal lumen diameter increased from 1.95 ± 0.5 to 2.21 ± 0.5 mm. Ultrasound lumen area improved from 3.16 ± 1.0 to 4.52 ± 1.1 mm^2 ($p > 0.0001$). Following ultrasound-guided balloon upsizing, the incidence of angiographic dissection was not increased (37 versus 40 percent, $p = 0.67$). However, the study was too small to demonstrate any effect upon intermediate or long-term clinical restenosis rates.

Intravascular ultrasound studies have evaluated the mechanisms of luminal enlargement following balloon angioplasty. Prior necropsy studies in patients who expired shortly after balloon angioplasty have described plaque fracture or disruption as the most common mechanism of dilatation.[20] Most ultrasound studies have confirmed that dissection is the most important mechanism of luminal enlargement, occurring in 40 to 80 percent of patients.[9,41,88-92] Identification of dissection or fracture is based on the visualization of blood flow in the newly created lumen, sometimes aided by injection of saline or iodinated contrast to opacify the lumen via microbubbles. Wall disruptions can be further defined by measuring the circumferential extent, length, and/or maximal depth of the dissection. One small study reported that calcified lesions had a higher incidence of dissection (67 versus 25 percent, $p = 0.03$) with a trend toward restenosis in lesions with no dissection.[41] Following iliac artery angioplasty, ultrasound evidence of dissection was noted in all 40 cases, accounting for 72 percent of the total lumen gain.[89]

Several alternative mechanisms for luminal enlargement not discernible by angiography have been identified using ultrasound, including arterial wall stretching and plaque compression, or "axial redistribution."[93-95] The contribution of vessel stretch to lumen gain following balloon angioplasty has been validated in experimental and clinical investigations. A peripheral angioplasty study reported that plaque area was reduced by 33 percent, accounting for only 20 percent of lumen gain.[89] However, studies using automatic pullback devices have shown that "compression" actually represents redistribution of plaque along the long axis of the vessel.[95] The prognostic significance of different mechanisms of luminal enlargement remains under investigation.

DIRECTIONAL ATHERECTOMY

Directional coronary atherectomy (DCA) is currently performed relatively uncommonly. DCA devices incorporate a rotating circular blade to remove atherosclerotic plaque from the luminal surface. This process requires the inflation of a balloon within the housing of the cutter, leading to invagination of the plaque into the open window on the cutting surface.[96] Because angiographic and/or ultrasound calcification is a well-documented predictor of failure of directional atherectomy, ultrasound imaging has been advocated for guidance of atherectomy, particularly for preintervention lesion selection.[97,98] Ultrasound imaging can differentiate between superficial calcium, which predicts poor tissue retrieval, and deep calcium, which does not appear detrimental to favorable results. In 70 atherectomy patients, lesion calcification was detected by ultrasound in 63 percent, compared with 22 percent by angiography. Ultrasound-detected calcification resulted in reduced lumen gain and a smaller final lumen area.[97]

The additional spatial perspective provided by ultrasound may assist in the orientation of atherectomy cuts. However, successful application is complex because precise orientation of the ultrasound image remains difficult, relying primarily upon anatomic features such as side branches to orient the image. Repeated ultrasound examinations are sometimes performed between passes of the DCA device to determine the extent of plaque removal and the need for additional cuts. Ultrasound studies before and after directional atherectomy confirm that plaque removal is the primary mechanism of luminal enlargement[91,97] (Fig. 47-9). In 25 treated lesions, plaque reduction accounted for 78 percent of total lumen gain. Plaque area was reduced from 14.3 ± 0.8 to 10.5 ± 0.7 mm^2, whereas EEM area increased only slightly, from 16.7 ± 0.8 to 17.5 ± 0.8 mm^2, $p < 0.02$. Ultrasound studies show that despite a successful angiographic result, 40 to 60 percent of the target site is still occupied by atheroma.

Some investigators have proposed that achieving a larger lumen after atherectomy using ultrasound guidance would result in a lower restenosis rate. This hypothesis was tested in a multicenter registry (the Optimal Atherectomy Restenosis Study [OARS]) in which residual stenosis was reduced from 64 to 7 percent with ultrasound guidance.[98] The angiographic

restenosis rate at 6 months was 28.9 percent and the 1-year target lesion revascularization rate was 17.8 percent. In the CAVEAT trial, DCA failed to reduce late events as compared with PTCA with or without ultrasound guidance.[99] Moreover, most atherectomy trials were performed without adjuvant therapy with GPIIb/IIIa inhibitors. It remains untested whether a larger postprocedure lumen and lower restenosis rate can be achieved using ultrasound guidance without a concomitant increase in complications.

ROTATIONAL ABLATION

Rotational ablation employs a high-speed (up to 200,000 rpm) diamond-coated burr to debulk atheroma. Theoretically, this device minimizes injury to the normal arterial wall by "differential cutting," in which normal elastic tissue is deflected away from the burr while relatively inelastic atheroma is not displaced and is therefore abraded by rotation of the burr. Clinical indications for rotational ablation include calcified segments or lesions that resist balloon dilatation. Rotational ablation is also sometimes used in long lesions, ostial lesions, and in-stent restenosis.[100-104] Demonstration of a heavily calcified vessel by angiography or ultrasound is often cited by operators as an indication for rotational ablation. However, there is a poor correlation between ultrasound and fluoroscopy in assessing the presence or extent of calcification. Accordingly, ultrasound is sometimes employed prior to rotational ablation to confirm or refute the presence of calcification. Vessels revascularized using rotational ablation are often diffusely diseased, and the "normal" dimension can be difficult to determine by angiography. Therefore, ultrasound is sometimes used to size the vessel and determine the largest burr that can be safely employed.

Intravascular ultrasound studies have confirmed the principle of selective plaque removal or differential cutting. In 48 lesions treated with rotational ablation, atheroma area decreased from 15.7 ± 4 to 13.0 ± 5 mm^2 and the arc of calcium decreased slightly from 227 ± 107 to 209 ± 107 degrees, $p < 0.05$.[104] Vessel expansion or dissection was noted in a minority of cases and did not contribute significantly to lumen gain. The residual narrowing of the cross-sectional area measured by ultrasound averaged 74 percent. Following rotational ablation, the residual lumen is usually round or ellipsoid and may have a 15 to 20 percent greater area than the largest burr used, presumably due to lateral movement of the burr during the procedure.

Luminal Measurements Postintervention

A poor correlation has been reported for comparisons of ultrasound and angiography in assessment of residual stenosis following balloon angioplasty, with measurements that are usually smaller by ultrasound than by angiography.[9,41,88-92] Two factors probably influence the overly optimistic tendency of angiographic imaging.[21] At the reference site, angiography tends to underestimate the diameter of the normal "reference" vessel because of the frequent presence of unrecognized atherosclerosis. At the target site, angiography tends to overestimate the actual gain in luminal diameter because contrast material penetrates into complex cracks and fissures produced by the intervention, giving the appearance of an enlarged lumen. To calculate a postprocedure percent diameter stenosis, the diameter at the target site (an overestimate) is divided by the reference diameter (an underestimate), resulting in a more favorable impression of the actual gain in luminal dimensions. Quantitative angiography showing a residual stenosis of 10 to 15 percent is commonly associated with a 60 to 80 percent atheroma burden.

Coronary Stent Deployment

INITIAL STUDIES OF ULTRASOUND GUIDANCE

The use of stents in percutaneous revascularization has increased exponentially over the last few years. Intravascular ultrasound imaging has played a pivotal role in understanding and optimizing the benefits of stent therapy.[105-107] In initial trials leading to FDA approval, articulated slotted-

tube stents were deployed using moderate balloon pressures (6 to 10 atm).[108,109] To reduce subacute thrombosis, patients received aggressive anticoagulation with both antiplatelet and antithrombotic agents, including warfarin, for 3 to 6 months. Initial studies demonstrated a reduction in the restenosis rate compared with balloon angioplasty but reported a high incidence of hemorrhagic complications and longer hospital stays. A pioneering report detailing the intravascular ultrasound experience of Colombo et al. in Milan, Italy, significantly altered the understanding of optimal stent deployment and prevention of subacute thrombosis.[107] Ultrasound examination revealed a mean residual stenosis of 51 percent following angiographically guided stent deployment, with frequent incomplete stent apposition (Fig. 47-10).

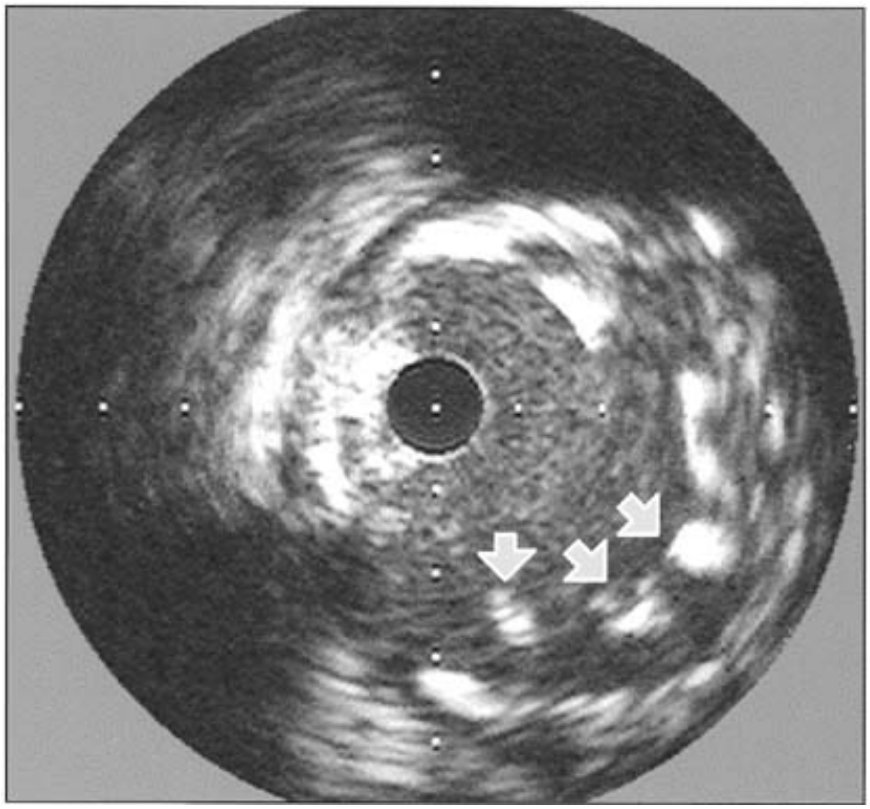

Figure 47-10: Underdeployed coronary stent. In this example, intravascular ultrasound images show several stent struts (*arrows*) that are not in full contact with the underlying vessel wall. This process is referred to as incomplete stent apposition.

Because stents are porous structures, angiographic contrast can flow outside of a partially deployed stent, resulting in the angiographic appearance of full deployment, despite the presence of incomplete apposition. In the Milan study, the operators performed additional balloon inflations at higher pressures (typically 18 to 20 atm) or used a larger balloon (or both), reducing final ultrasound residual stenosis to 34 percent and reporting a subacute thrombosis rate of only 0.3 percent with the use of no systemic antithrombotic agents (antiplatelet therapy only). It is now widely accepted that high-pressure deployment of the stents dramatically reduces the incidence of subacute thrombosis and obviates the need for acute and chronic administration of antithrombotic agents.[110,111] Subsequently, routine high-pressure deployment without ultrasound imaging became the standard of therapy.

ROUTINE VERSUS NONROUTINE ULTRASOUND

Following the widespread acceptance of high-pressure postdilatation with antiplatelet rather than

anticoagulation regimens, the further benefit of ultrasound imaging has been debated.[86,110-114] Some investigators have suggested that despite routine use of high-pressure postdilatation, ultrasound-guided therapy can improve procedural results.[86,114] In a retrospective analysis of 315 lesions treated by high-pressure stenting, ultrasound was defined as "beneficial" if imaging resulted in further interventions that increased stent area by >25 percent or identified other lesions that required treatment.[115] Prior to ultrasound, the mean inflation pressure was 14.7 ± 3.2 atm, but only 47 percent of stents were considered "optimally" deployed. Additional ultrasound-triggered inflations improved in-stent lumen area by more than 25 percent in 83 lesions (26 percent of patients), and additional procedures were performed in lesions identified by ultrasound in 51 (16 percent). Final in-stent area improved from 6.9 ± 2.2 to 8.0 ± 1.93 mm^2 ($p < 0.001$). Procedural results were "improved" in 39 percent of the cases following ultrasound imaging.[115] It is now generally accepted that after high-pressure coronary stenting, ultrasound imaging results in additional procedures in approximately 20 to 40 percent of cases.

Since in-stent restenosis is predominantly determined by the degree of intimal hyperplasia, a larger lumen can theoretically accommodate more tissue growth without flow-limiting obstruction.[116] However, it remains uncertain whether ultrasound-guided "optimal" expansion translates into better clinical outcome. A randomized trial in 164 patients of ultrasound-guided stenting demonstrated a 6.3 percent absolute reduction in restenosis rate, which was not statistically significant because the study was powered to detect a 50 percent reduction of the restenosis rate.[117] A nonrandomized substudy of 538 patients from the Stent Anticoagulation Regimen Study (STARS) compared the outcome of ultrasound and angiographically guided stenting. The ultrasound arm achieved a significantly larger lumen area and a 39 percent relative reduction in clinical restenosis.[118] However, the impact of the more aggressive dilatation on restenosis rates has not been adequately examined by prospective trials. It remains conceivable that increased vessel wall injury from a larger high-pressure balloon will yield less favorable long-term results.

ULTRASOUND IMAGING OF PERISTENT SEGMENTS

Ultrasound imaging of "reference" segments following stenting may be useful in identifying reference segment disease or dissections that require additional interventions. The presence of significant peristent flow-limiting lesions or dissections has been linked to higher likelihood of stent thrombosis.[119] These findings are often angiographically occult or appear as areas of indistinct vessel border "haziness." In 201 stent patients, 31 segments with peristent angiographic haziness were detected. Ultrasound imaging revealed an angiographically inapparent obstructive lesion in 15, a peristent wall injury in 14, and mild intimal thickening in the remaining 2 segments.[120] The extent of neointimal hyperplasia at the stent margins has been linked to preexisting reference-segment disease.[121] In stenting as a "bailout" for dissection, intravascular ultrasound is more sensitive in detecting the extent of dissection, often revealing a greater true length than is evident from angiography, which may be helpful in guiding vessel salvage.

OPTIMAL PROCEDURAL GOALS OF ULTRASOUND GUIDED STENTING

Although ultrasound guidance of stenting has been practiced for several years, there is no consensus regarding optimal procedural end points. Colombo initially recommended achieving ≥60 percent of the average proximal and distal reference areas but later altered the definition to ≥100 percent of the distal reference lumen area.[105-107] Other definitions of optimal expansion include ≥90 percent of the distal reference area, ≥80 percent or ≥90 percent of the average reference area, a "lumen symmetry index" >0.7, and/or full coverage of reference-segment disease or dissections.[122,123] In most clinical trials, procedural end points are not achieved in the majority of cases. In the Optimal Stent Implantation Trial, the target of >90 percent of the average reference or >100 percent of the smaller reference area were not achieved in half the patients at an inflation pressure of 15 atm and only 60 percent of patients at 18 atm.[122] In the Angiography

Versus Intravascular Ultrasound Directed Stent Placement (AVID) trial, the target end point of ≥90 percent of the distal reference area was not achieved in >70 percent of 225 patients.[124]

Recent reports have questioned the clinical relevance of using the stent-to-reference ratios as target for ultrasound-guided stenting. In 165 patients, target vessel revascularization was predicted by final in-stent lumen area (OR 1.4, 95 percent CI 1.1-1.9) and not the ratio of stent-to-reference area (OR 1.1, 95 percent CI 0.85-1.6).[112] Repeat revascularization was required in 30 percent of patients with a minimum in-stent lumen area <5 mm^2 but only 3 percent of cases with an area exceeding 9 mm^2. In another large cohort undergoing ultrasound-guided stenting, restenosis was inversely related to the minimum in-stent area.[125] An area of 9 mm^2 was achieved in 23 percent, but the incidence of restenosis in this subgroup was only 8 percent, compared with 29 percent in the remaining patients, $p < 0.0001$. Thus, commonly employed ultrasound end points based upon a predefined stent-to-reference ratio are both difficult to achieve and correlate weakly with clinical outcome.[125-127] Ultrasound studies have demonstrated that the degree of in-stent neointimal hyperplasia is independent of final lumen size, which may explain the higher restenosis rates in smaller vessels and poorly expanded stents.[116] If acute lumen gain is not adequate to accommodate subsequent tissue proliferation, there is significant late loss and restenosis.

Intravascular Ultrasound and Restenosis

A more complete understanding of restenosis has evolved from serial ultrasound measurements of plaque and lumen areas following balloon angioplasty and directional atherectomy.[128,129] In some studies, serial ultrasound examinations have shown that a late reduction in total vessel area (chronic negative remodeling) is an important mechanism of restenosis after interventional procedures.[129] These observations suggest that mechanical interventions to prevent chronic recoil (such as stenting) may be more important in preventing restenosis than interventions designed to prevent intimal hyperplasia. If further validated, this concept may explain the lower restenosis rate observed in randomized multicenter studies comparing balloon angioplasty and stent implantation.[108,109]

In 212 native coronary lesions in 209 patients following intervention, the ultrasound cross-sectional area with the smallest lumen area at late follow-up was compared with the matching site obtained immediately following the intervention.[129] At follow-up examination, there was a significant decrease in EEM area and an increase in plaque area ($p < 0.0001$ for both) that combined to reduce lumen area. More than 70 percent of lumen loss was attributable to the decrease in EEM area, whereas the neointimal area accounted for only 23 percent of the decrease in lumen area. The change in lumen area correlated more strongly with the change in EEM area ($r = 0.75$, $p < 0.0001$) than with the change in plaque area ($r = 0.28$, $p < 0.0001$). At lesions that demonstrated an increase in EEM area at follow-up (47 percent), there was no change or an actual gain in lumen area and a reduction in angiographic restenosis (26 versus 62 percent for lesions with a decrease in EEM area at follow-up, $p < 0.0001$).

Other investigators have suggested a bidirectional remodeling response following percutaneous coronary interventions: early adaptive enlargement and late shrinkage of the vessel. In a unique study, 61 lesions in 57 patients who underwent balloon angioplasty or atherectomy were examined by intravascular ultrasound in a serial manner-before and immediately after the intervention and after 24 h, 1 month, and 6 months.[48] The lumen area significantly improved during the first month following the intervention but significantly decreased at 6 months. Simultaneously, the EEM area increased in the first month but later decreased at 6 months. However, plaque area steadily increased from immediately postintervention to the 6-month follow-up. Thus the changes in lumen size closely tracked the changes in EEM area ($r = 0.72$, $p = 0.0001$). Although the increase in plaque area correlated with lumen loss, the correlation was not as strong ($r = 0.34$, $p = 0.0008$). The lumen gain observed during the first month was solely due to the compensatory vessel

enlargement, whereas the late lumen loss was mostly caused by vessel shrinkage but also by progressive neointimal hyperplasia.

Investigations employing quantitative angiography have demonstrated that late lumen loss is significantly greater with stents than with balloon angioplasty. This, however, is offset by the much larger acute lumen gain, such that the net gain at follow-up is significantly greater with stenting.[108,109] Intravascular ultrasound has been employed to examine the mechanism of stent restenosis. Unlike the restenotic response to other percutaneous devices, which is a mixture of arterial remodeling and neointimal growth, stent restenosis is almost exclusively due to the neointimal proliferation.[129] In a serial study using intravascular ultrasound of stented coronary segments, there was no significant change in the area bound by stent struts, indicating that stents can withstand and resist the arterial remodeling process.[130] In some cases, restenosis develops at the margins of the stent. Predictors of stent restenosis have been identified by multivariate analysis, including the smaller reference vessel and lumen size, the larger plaque burden at the reference segments, and the smaller achieved in-stent lumen area at the stent margins.[121]

Chapter 47: CORONARY INTRAVASCULAR ULTRASOUND IMAGING

FUTURE DIRECTIONS

The technology and clinical role for intravascular ultrasound examination of the coronaries continues to evolve. Technological advances in intravascular imaging are anticipated, including further reductions in the size of imaging catheters and higher-frequency ultrasound catheters, yielding significantly better spatial resolution.[131,132] Although high-frequency probes enable better axial and lateral resolution, there are significant trade-offs in moving beyond the current 30-MHz frequency. For example, penetration is likely to be impaired in comparison with more conventional devices, and greater backscatter from blood cells at high frequencies may interfere with discrimination of the interface between lumen and vessel wall. However, if catheter miniaturization continues, a shorter wavelength will be important in preserving near-field image quality. It remains apparent that the physical limits of intravascular imaging technology have not been reached. Accordingly, further improvements in the performance of these devices are anticipated.

Analysis of backscattered ultrasound signals has been used by several investigators to perform "tissue characterization" of coronary plaques. Intrinsic characteristics of the backscattered ultrasound signals-including the amplitude distribution, frequency response, and power spectrum of the signal-convey specific information about tissue types.[133] Soft plaque consists of an amorphous collection of lipid substances, fibrosis, cholesterol clefts, and a variable amount of collagen and elastin. Thrombus, on the other hand, consists of a fairly organized layering of fibrous strands packed with a dense collection of red blood cells. The ability of computer-based analysis of the unprocessed radiofrequency backscatter to differentiate the histologic layers of the normal vessel wall remains investigational.

Three-dimensional reconstruction of intravascular ultrasound has been proposed as a means to facilitate understanding of the spatial relationship between the structures within different tomographic cross sections.[134] Despite the promise of these methods, many unresolved problems remain. The algorithms applied for 3D reconstruction do not consider the presence of curvatures of the vessel and assume that the catheter passes in a straight line through the center of consecutive cross sections. The systolic expansion of the coronary vessel and the movements of the catheter within the vessel during the cardiac cycle also generate artifacts. Accordingly, the reconstructed images should not be considered faithful representations of the vessel and should not be used for volumetric plaque determination. Simultaneous digitization of biplane fluoroscopic tracking of the radiopaque transducer and catheter tip has the potential to overcome some of these limitations, but is practical only for small-scale research purposes.[135]

Chapter 47: CORONARY INTRAVASCULAR ULTRASOUND IMAGING

SUMMARY

The equipment, technique, and applications for intravascular ultrasound imaging continue to evolve, finding increasingly common usage in clinical practice and research. The insights provided by the unique ability of intravascular ultrasound to directly image coronary plaques have contributed greatly to our understanding of the nature of atherosclerosis and the effects of interventional devices.

Part 6: CORONARY HEART DISEASE
Chapter 48:

CORONARY BYPASS SURGERY

Author: Bruce W. Lytle

Coronary bypass surgery as a planned consistent approach for the treatment of patients with angiographically documented coronary atherosclerosis was begun by Sones, Favaloro, and colleagues in 1967. Many previous schemes for surgical myocardial revascularization, direct and indirect, had been attempted, including pericardial pouderage, mammary artery implantation (Vineberg operation), coronary endarterectomy, and "blind" bypass grafting without the angiographic definition of coronary lesions.[1,2] The concept behind the concerted effort undertaken by cardiologists and cardiac surgeons at The Cleveland Clinic Foundation in 1967 was that the symptoms and clinical events associated with coronary artery disease (CAD) were related to stenotic coronary artery lesions that could be specifically identified by coronary angiography, and if those lesions could be treated with bypass grafting, unfavorable symptoms and events would be less common. Experience has shown that concept to be correct but also has shown that atherosclerosis is a progressive disease.

In the early years of coronary bypass grafting, the vast majority of grafts were reversed segments of saphenous vein anastomosed to the aorta and to the coronary arteries distal to coronary stenoses (Fig. 48-1*A*). It was rapidly obvious that effective bypass surgery relieved symptoms of angina, and during the decade 1970-1980, the practice of coronary artery surgery exploded. Improvements in instrumentation, technology, and surgical training were rapid, and by 1980, bypass surgery had evolved into a microsurgical procedure usually performed with optical assistance at many hundreds of medical centers around the world.

EARLY RANDOMIZED TRIALS OF BYPASS SURGERY VERSUS MEDICAL TREATMENT

During the 1970s, multiple investigations were initiated to examine the long-term outcomes of patients receiving initial bypass grafting compared with those treated initially with medical management. The most influential were multicenter, randomized trials of patients with chronic stable angina: the Veteran's Administration study of patients with chronic stable angina (VA study),[3] the European Coronary Surgery Study (ECSS),[4] and the Coronary Artery Surgery Study (CASS).[5,6] These trials randomized patients with angiographically documented coronary stenoses to either initial medical management or initial treatment with bypass surgery, and their primary emphasis was survival. In the two largest trials (ECSS and CASS), severely symptomatic patients were excluded from randomization, and in all these trials, patients who experienced the onset or persistence of severe symptoms were allowed to change from medical to surgical treatment, a phenomenon called *crossover*. Analyses of outcomes were performed on an "intention to treat" basis. That is, patients who were randomized to the medical treatment group but who later decided to have surgery were still considered part of the medically treated group, and patients randomized to surgery who did not actually receive surgery were still considered part of the surgically treated group.

All these trials showed there were some patient subsets that experienced a higher survival rate if they received initial surgical management rather than initial medical treatment, although those subsets varied among the trials. Not surprisingly, the patients who benefited the most from surgery

in terms of survival were patients at the highest risk of death without operation. Individual trials noted improved survival rates for patients with significant left main stenosis, three-vessel disease with abnormal left ventricular (LV) function, and two- or three-vessel disease with a more than 75 percent stenosis in the proximal left anterior descending (LAD) coronary artery. The clinical descriptors of an abnormal baseline electrocardiogram (ECG) or a strongly positive exercise test helped to define patient subsets with improved survival rates with surgery. Recently, a metaanalysis that included the three major trials and some smaller ones confirmed the observations of the individual trials but also seemed to show a significant survival benefit for patients with triple-, double-, or even single-vessel disease that included a proximal LAD stenosis regardless of whether they had normal or abnormal LV function. For patients without a proximal LAD stenosis, surgery improved the survival rate for only patients with left main stenosis or triple-vessel disease. In addition, the surgically treated patients had fewer symptoms at 5 postoperative years and took fewer antianginal medications.

The degree of benefit achieved with initial bypass surgery diminished with time both in terms of survival and with regard to symptom status.[8] There were multiple reasons for this. First, the status of the surgically treated patients deteriorated based on late graft failure and the progression of native vessel atherosclerosis. Very few patients in these early trials received internal thoracic artery (ITA) grafts or were treated with platelet inhibitors or lipid-lowering agents, strategies we now know significantly improved long-term outcomes after surgery. Second, the status of the "medically treated" patients actually improved slightly because a large proportion of those patients "crossed over" and underwent bypass surgery, although they were still analyzed as part of the medically treated group. In the three major studies, 40 to 44 percent of the total medically treated patient population had undergone bypass surgery by 10 postoperative years, including 65 percent of patients with left main disease and 48 percent of patients with three-vessel disease.[7] Finally, when all-cause mortality is the end point, any two survival curves eventually will meet at zero.

Randomized clinical trials as described earlier have the advantage that they lessen the influence of bias in the selection of treatment once patients are entered into the study, but they have the disadvantage that bias may be exerted at the point of inclusion into the trial. In all these trials, a minority of patients presenting for evaluation met the criteria for entry into the trial, and of those who met the criteria for entry, a minority actually were randomized. In the case of CASS, however, patients who were not randomized were followed prospectively in a registry, and that registry has produced observational studies that continue to provide useful information.

Among the important conclusions from the CASS Registry are that asymptomatic patients with 50 percent or more of left main stenosis and patients with left main equivalent (70 percent or more stenosis of the proximal LAD and circumflex vessels) have improved survival with surgery.[9,10] For severely symptomatic patients, bypass surgery improved the survival rates of those with three-vessel disease regardless of whether they had normal or abnormal LV function, even if those patients did not have severe proximal coronary artery stenoses.[11] Also, surgically treated patients who were completely revascularized fared better than incompletely revascularized patients, particularly if they had abnormal LV function.[12]

Outcomes for patients with unstable angina based on either progressive symptoms or rest angina with electrocardiographic changes were tested in the Veterans Administration Cooperative Study. Patients with rest angina and abnormal LV function had greatly improved survival with initial surgery. Patients with progressive angina did not appear to have a worse survival rate if they were treated initially with medical therapy, but 19 percent of this group crossed over to surgery within 30 days of randomization, and by 96 months, 45 percent had crossed over to surgery.[13]

Although these trials were undertaken relatively early in the history of coronary bypass surgery and today we can expect lower operative mortality rates and improved long-term outcomes after

operation based on the use of arterial grafts, platelet inhibitors, and lipid-lowering agents, the observations from these studies provide the fundamental basis for the development of indications for bypass surgery even today.[2,14]

Chapter 48: CORONARY BYPASS SURGERY

EVOLUTION OF THE OPERATION AND PATIENT POPULATION

In the early years of bypass surgery, surgical candidates usually were relatively young, had limited coronary artery disease, good LV function, and few comorbid conditions. The operation was almost always performed through a median sternotomy with the use of cardiopulmonary bypass. To achieve a surgical field and allow operations to be done on a still heart, either cold fibrillation or intermittent ischemic arrest was a common strategy. The operation involved bypass grafts of reversed segments of greater saphenous vein from the aorta to the distal coronary arteries (see Fig. 48-1*A*). In a small number of centers, the left ITA was used as a bypass graft, usually as a graft to the LAD artery (see Fig. 48-1*B*), but this strategy was not common.

Throughout the 1970s and 1980s, operations for bypass surgery became progressively safer for multiple reasons. Surgeons became better trained, and surgical experience increased. Optical assistance became routine, and microsurgical instrumentation improved. Cardiac anesthesia developed as a subspecialty, and postoperative care protocols became more routinized. Intraoperative myocardial protection improved with the use of cardioplegia, a strategy whereby a combination of cardiac standstill and effective myocardial protection was achieved by injecting cardioplegic solution (usually containing high potassium concentrations) into the coronary circulation. The use of this strategy allowed extensive coronary reconstructions to be achieved consistent with effective myocardial protection and made surgical treatment of extensive and severe coronary atherosclerosis possible with safety.

In addition, the population of patients undergoing bypass surgery changed to an older population with more extensive coronary stenoses, a higher incidence of left main stenoses, abnormal LV function, and more frequent comorbid conditions. Table 48-1 shows the changes in preoperative descriptors for patients undergoing primary coronary surgery at The Cleveland Clinic Foundation for selected years from 1967 to 1996, and Table 48-2 shows similar changes between 1980 and 1990 in a countrywide population as recorded by the Society of Thoracic Surgeons National Database.[15] The bypass surgery population changed for multiple reasons. Improved technology and experience made it possible to operate on more complex and sicker patients with reasonable risk. Also, the randomized trials demonstrated that the patients who have the most to gain from surgery were patients with left main or multivessel disease and abnormal LV function. Furthermore, the U.S. population has been aging, and older patients have high expectations for their activity level. Finally, in the early 1980s, the advent of percutaneous anatomic treatments for coronary stenoses (i.e., PCTA) provided an alternative treatment for patients with limited coronary lesions, removing many of those patients from the surgical population.

Table 48-1: Preoperative Clinical Characteristics for the First 1000 Patients per Year Undergoing Elective Primary Isolated Coronary Bypass Grafting (The Cleveland Clinic Foundation)

Clinical Variable	1967-1970	1973	1976	1979	1982	1985	1988	1990	1994	1996
Age (yr, median)	50	53	55	56	59	62	64	65	64	65
Men (%)	85	89	89	88	84	80	78	76	75	71
Severe angina (T)	19	21	24	20	17	23	26	34	30	34
Diabetes (%)	7	7	6	7	9	13	19	24	24	27
Age ≥70 yr (%)	0.2	0.5	3	4	10	17	26	32	28	34
Single-vessel disease* (%)	56	17	15	10	8	5	3	5	9	9

Double-vessel disease* (%)	31	33	28	28	25	25	19	25	29	26
Triple-vessel disease* (%)	13	50	57	62	67	71	78	70	60	63
Left main coronary stenosis (≥50%) (%)	9	8	12	12	13	13	16	17	19	19
Left ventricular asynergy (%)	41	41	45	54	55	56	57	51	48	39

The terms *single, double-,* and *triple-vessel disease* refer to the number of the three main coronary vessels (left anterior descending, circumflex, and right coronary arteries) that have stenoses ≥50%.

Chapter 48: CORONARY BYPASS SURGERY

TYPES OF BYPASS GRAFTS AND THEIR OUTCOMES

Saphenous Vein Grafts

The most important technical change in coronary surgery has been in the types of grafts that are used. By 1980, angiographic studies at multiple centers had shown that early vein graft patency rates were favorable (80-90 percent within the first postoperative year). Early patency rates were influenced by surgical technique, gender (men experienced better patency rates), the coronary artery grafted (LAD artery patency rates were better than circumflex and right coronary artery rates), the size of the vessel grafted, and the indications for repeat study (routine studies demonstrating better patency rates than studies performed because of symptoms). Coronary risk factors did not appear to influence early patency rates.[1,16-20] However, sequential studies of patent vein grafts demonstrated substantial late attrition. Fitzgibbon et al.[17] studied 590 vein grafts that were patent at 1 postoperative year and found that when studied late (>5 years after operation) 30 percent of patent grafts had become occluded, and 76 percent had angiographic evidence of pathologic changes. Fitzgibbon et al.[17] and Bourassa et al.[16] found a 2.1 percent yearly rate of occlusion of vein grafts up to 5 years after operation, but Bourassa et al.[20] noted a 5.3 percent yearly occlusion rate between 6 and 11 years after operation. Data from sequential The Cleveland Clinic Foundation studies (Fig. 48-2) showed that of vein grafts patent without stenosis 1 to 5 years after operation, only 55 percent remained angiographically perfect 6 to 12 years after surgery.[19] In addition, the attrition rate of patent grafts was not related to the coronary vessel grafted but was related to coronary risk factors such as diabetes and hyperlipidemia.[18,19]

The pathologic changes found in stenotic or occluded vein grafts are different at different postoperative intervals.[21-25] Grafts occluded within 1 or 2 months of surgery exhibit thrombosis, often associated with endothelial disruption. Grafts examined more than a few months after surgery consistently exhibit a hypercellular, proliferative hyperplasia involving the intima-intimal fibroplasia. Intimal fibroplasia is a concentric lesion that evolves into a more fibrotic lesion. It may cause fixed stenoses and may be associated with occlusion but usually is not. However, it appears to be the substrate for the development of vein graft atherosclerosis (VGA), the process that leads to many late graft stenoses or occlusions.

VGA is different from native coronary atherosclerosis. Native coronary artery atherosclerosis is a proximal, eccentric, and intermittent lesion that usually is covered by a fibrous cap. VGA is distributed throughout the length of vein grafts, it is circumferential, it is not encapsulated, and it is extremely friable. With time, the early circumferential lesion often progresses to eccentric lesions causing severe stenoses (Fig. 48-3). Because of its friability and nonencapsulated nature, VGA is a dangerous lesion. Embolization of atherosclerotic debris is a major risk during percutaneous interventions on vein grafts and during reoperations, and it is probable that spontaneous embolization may occur.[20,26] VGA usually is not recognized before 2 to 3 years after operation and does not appear to cause much graft attrition before 5 postoperative years. However, grafts that become occluded more than 5 years after operation usually exhibit thrombosis superimposed on VGA, and the increased rate of graft attrition seen more than 5 years after operation appears to be due in large part to VGA.

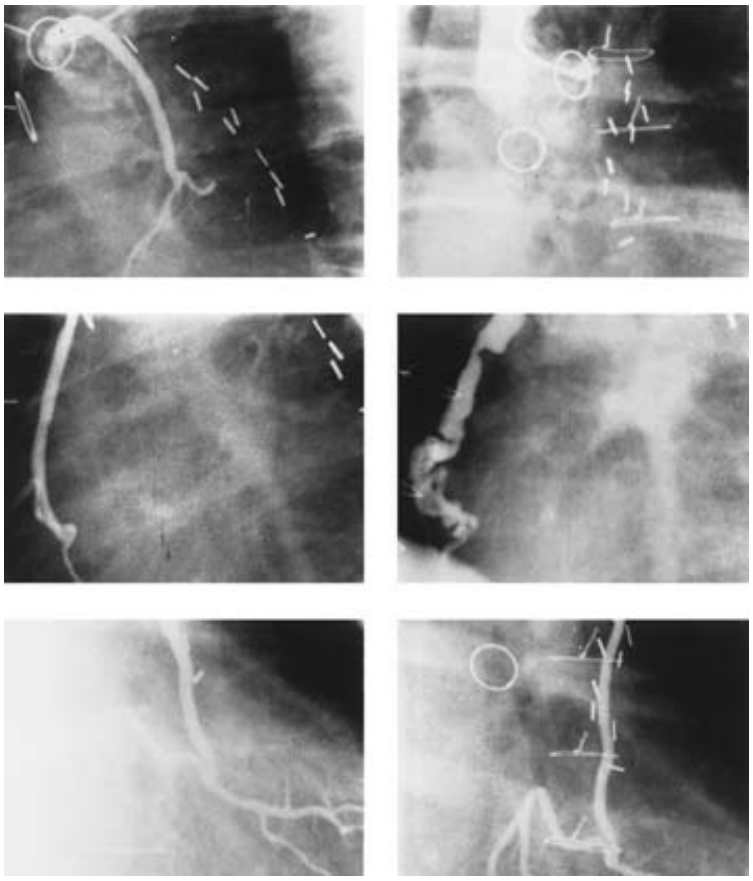

Figure 48-3: Angiographic anatomy 1 year after operation (*left*) showing patent vein grafts to the LAD artery and RCA and an ITA graft to the circumflex artery. Seven years later, the LAD artery vein graft is occluded, the RCA graft exhibits diffuse irregular stenoses characteristic of VGA, and the ITA graft is unchanged. (Used with permission from Lytle BW, Loop FD, Cosgrove DM, et al. Long-term (5 to 12 years) serial studies of internal mammary artery and saphenous vein coronary bypass grafts. *Thoracic Cardiovasc Surg* 1985; 89:250.)

Since the early studies of vein grafts cited earlier, substantial progress has been made in the prevention of vein graft attrition. First, multiple randomized, prospective trials have shown that the perioperative and long-term treatment of patients who received vein grafts with platelet inhibitors have significantly decreased the occlusion rate of saphenous vein grafts at 1 year after operation to 6 to 11 percent.[27,28] Second, lipid-lowering trials using a cholesterol-niacin combination or using an aggressive regimen of Pravastatin to lower low-density lipoprotein cholesterol levels have been shown to decrease the progression of angiographic lesions in vein grafts, including a decrease in the rate of occlusion 5 to 15 years after operation.[29,30] Importantly, a clinical trial (CARE trial) of 1091 patients who survived a myocardial infarction (MI), had average cholesterol levels, and underwent bypass surgery showed that treatment with Pravastatin decreased the risk of death and nonfatal MI over a 5-year follow-up.[31] Thus multiple studies appear to show that outcomes for patients receiving vein grafts today can be expected to be better than those noted in studies from the 1970s. Furthermore, some vein grafts provide very long-term benefit. For patients studied 16 to 20 years after operation Lawrie et al.[32] noted 46 percent vein graft patency and Fitzgibbon et al.[20] noted a 50 percent patency rate 15 years or more after operation. However, although progress has been made in decreasing the *rate* of VGA, these strategies do not eliminate VGA, and vein graft attrition remains the biggest problem associated with bypass surgery. Fortunately, other grafts are available-arterial bypass grafts.

ITA Grafts

Early in the bypass surgery era, ITA (internal mammary artery) grafts were used in a few centers, usually as a graft to the LAD artery. As the late attrition rate of vein grafts began to surface, it also became apparent that the early patency rates of ITA grafts were slightly better than the early patency rates of vein grafts, but more important, the late attrition rate of patent ITA grafts was extremely low[1,19] (Fig. 48-4). Early occlusion of ITA grafts is usually technically related, since these grafts can remain functioning even when used to graft very small coronary arteries. ITA graft stenosis or occlusion beyond 6 months after operation is usually related to competition in blood flow through a native coronary artery that is not severely stenotic and becomes manifest as a "string sign" or diffuse spasm. Atherosclerosis may involve the ITA, but it is rare, and the late development of atherosclerotic lesions in an ITA graft known to be patent is extremely rare. Patency rates of left ITA to LAD artery grafts are greater than 90 percent even 10 to 20 years after operation.[1,19] The most contemporary prospective graft patency data come from the Bypass Surgery Angioplasty Revascularization Investigation (BARI) trial angiographic studies (135 patients) that documented 1-year patency (<50 percent stenosis) of 98 percent for ITA grafts and 87 percent for vein grafts.[33]

The success of the left ITA to LAD artery graft has led to the use of the right ITA as a bypass graft, usually simultaneously with the left ITA (bilateral ITA grafting). The right ITA has been used as an in situ graft and as a "free" graft with the proximal anastomosis constructed either to the left ITA (Fig. 48-5*A*) or to the aorta (see Fig. 48-5*B*). Although patency rates of ITA grafts have been highest when used to graft the LAD artery-diagonal system, Dion et al.[34] restudied 135 pedicled ITA to circumflex artery grafts 13 months after operation and noted a 95 percent patency rate. Longer-term studies of ITA to circumflex artery grafts also have showed favorable outcomes.[1] ITA grafts to the right coronary artery (RCA) have been less frequent and prospective postoperative studies are rare, but long-term patency of ITA grafts to the RCA is possible.

Studies of aorta to coronary ITA grafts have tended to show patency rates not quite as good as those of pedicled grafts. However, these types of grafts can exhibit 20-year patency, and once they are patent, they appear to remain free from graft atherosclerosis.[1,34]

A relatively new strategy is composite arterial grafting with the right ITA used as a free graft anastomosed to the left ITA[35,36] (see Fig. 48-4*B*). This strategy allows more flexibility in the use of the right ITA, and early data show patency rates of 91 to 95 percent within a year of operation for this type of free ITA graft. Long-term data are not available, but this strategy may make the use of free ITA grafts more effective. Once experience with composite grafting is gained, the right ITA may be used to graft the circumflex and right coronary systems in selected patients, achieving total arterial revascularization with the two ITAs.

Clinical Impact of ITA Grafts

The high and stable patency rate of the left ITA to LAD artery graft also produces improved clinical outcomes. No large randomized studies have compared ITA and vein grafts, but in a large observational study published in 1986, Loop et al.[37] showed that patients who received a left ITA to LAD artery graft (with or without vein grafts to the circumflex and RCA branches) had better 10-year survival rates when compared with patients who received only vein grafts (Fig. 48-6). This observation was true for patients with single-, double-, or triple-vessel disease. In addition, the ITA graft patients underwent fewer reoperations (4 versus 8 percent) and had fewer cardiac-related hospitalizations. Data from CASS have extended the observed benefits of ITA grafting to 15 to 18 years after operation.[38]

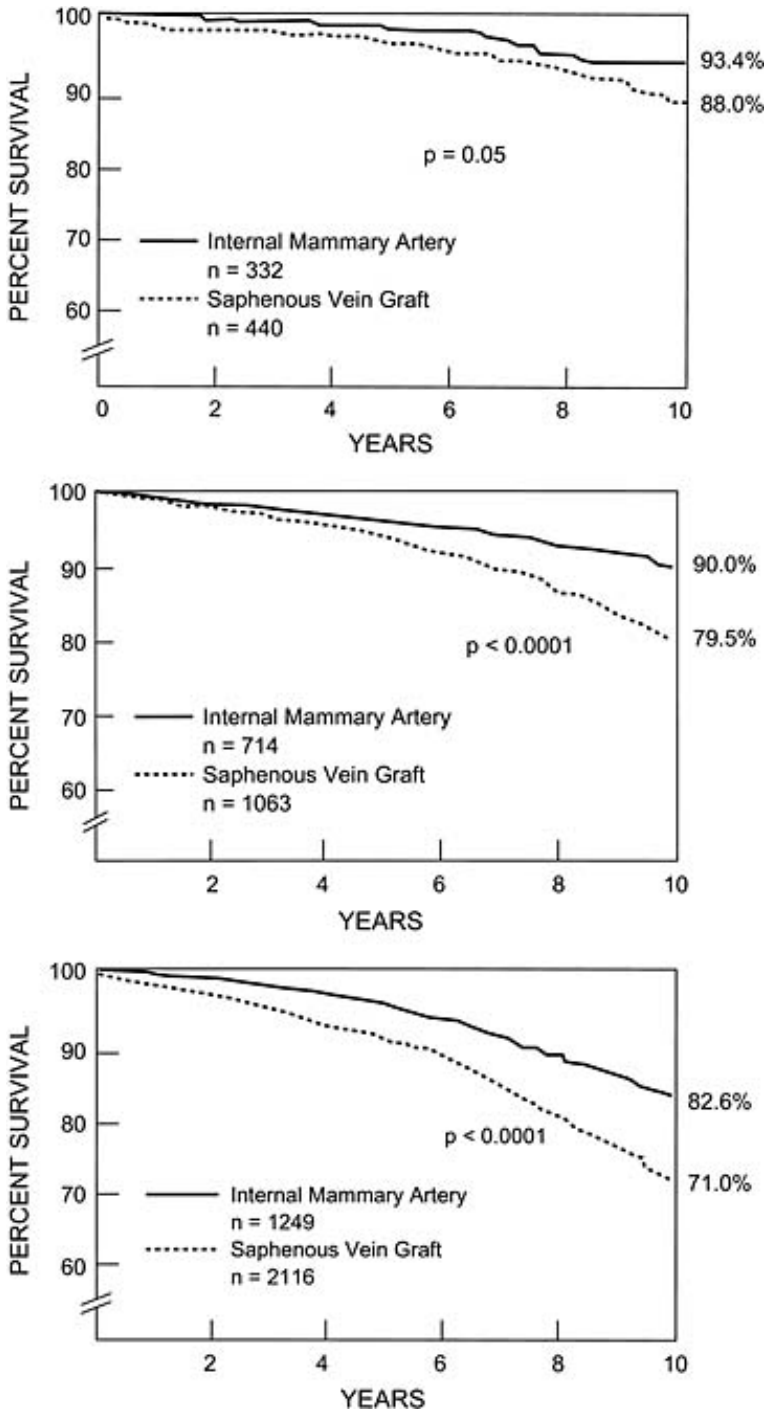

Figure 48-6: Survival for patients with an ITA to LAD artery graft with and without vein grafts to other coronary vessels compared with survival for patients with only vein grafts. An ITA to LAD artery graft was associated with significantly better survival for patients with single- (*top*), double- (*middle*), or triple-vessel (*bottom*) disease. (Used with permission from Loop FD, Lytle BW, Cosgrove DM, et al. Influence of the internal-mammary-artery graft on 10-year survival and other cardiac events. *N Engl J Med* 1986; 314:106.)

Logic seems to dictate that if one ITA graft is good, two ITA grafts may improve outcomes further. However, the strategy of bilateral ITA grafting has not become widespread. Bilateral ITA grafting makes the bypass operation more difficult, some studies have shown an increase in the risk of wound complications, and the outcomes for patients receiving a single ITA to LAD artery

graft are very good, particularly over the first postoperative decade. Furthermore, because of the importance of the LAD coronary artery in many patients, improved results may be difficult to show if LAD artery revascularization is secure. And indeed, a number of retrospective studies have shown either no benefit or relatively little incremental benefit of bilateral ITA grafting over single ITA grafting. These studies involved either small patient numbers or relatively short follow-up intervals. Recently, we retrospectively reviewed a large series of patients receiving single or bilateral ITA grafts and found an improved 12-year survival rate for the patients receiving bilateral ITA grafts, as well as a decreased risk of reoperation or percutaneous intervention over that same time frame[39] (Fig. 48-7). Another recent study that confirmed these observations also involves relatively large patient numbers.[40] It is probable that the incremental benefit of bilateral ITA grafting over single ITA grafting may be less than the benefit of a left ITA to LAD artery graft over only vein grafts. Nonetheless, it does appear that bilateral ITA grafting does offer incremental benefit.

Other Arterial Bypass Grafts

The gastroepiploic artery (GEA) was used for Vineberg-type myocardial implantation prior to the bypass grafting era, and its use as a coronary bypass graft was begun by Suma and Pym in 1986. Suma reported a 94 percent (253 of 268) patency rate within 2 months of operation and 47 of 50 GEA grafts (94 percent) patent at 2 to 5 postoperative years.[41] In situ GEA grafts have had better patency rates than free grafts. When late attrition has occurred, it has appeared to be related to native coronary artery competitive flow. Anecdotal angiographic studies have documented the patency of GEA grafts 9 to 10 years after operation and have not shown evidence of the occurrence of graft atherosclerosis. The GEA is prone to spasm, and intraluminal vasodilators have been used by many of its proponents. In situ GEA grafts function well as a graft to the posterior descending branch of the RCA or circumflex system, although in selected circumstances the distal LAD artery may be grafted. Despite good long-term patency rates, the GEA has not become a popular graft because it is more difficult to use than most other conduits.

The inferior epigastric artery (IEA) also has been used as a bypass graft. Buche et al.[42] reported on patients receiving IEA grafts and noted patency of 132 of 135 grafts studied 11 days after operation, 44 of 48 grafts at 8 months (although 8 showed a string sign), and 25 of 29 grafts studied an average of 25 months after operation. They also noted that grafts exhibiting diffuse spasm at one postoperative study may show resolution at a second. Califiore[36] reported on use of the IEA as a composite graft and noted patency in 34 of 34 grafts studied within 2 weeks of operation and 20 of 21 grafts 6 to 14 months later. Because of its relatively short length, we have most commonly used the IEA as a composite arterial graft.

The long-term usefulness of the radial artery as a coronary bypass graft is an important question that is as yet incompletely answered. The radial artery is a long graft that is easily procured and has very favorable size and handling characteristics. However, it is a thicker, more muscular artery than the ITA, and when it was used by Carpentier[44] and others[43] in the early 1970s, patency rates were not favorable. Recently, its use has been revisited along with the use of calcium-channel blocking agents to prevent postoperative spasm, and Broadman et al.[45] and Acar et al.[46] have reported early (<6 months) patency rates of greater than 90 percent. Acar et al.[46] reported 75 radial grafts studied within 2 weeks of operation with 1 occluded graft and 4 with spasm. At 1 year, 61 grafts were restudied, with 4 occluded and 2 stenotic. At 4 to 7 years after operation, 50 patients underwent repeat study, and of 64 radial artery grafts, 10 were occluded, 1 had a string sign, and 53 (83 percent) looked perfect. In the same patients, 91 percent of left ITA grafts were patent. Possati et al.[47] performed serial studies after radial artery grafting and documented an 87 percent perfect patency at 5 postoperative years, compared with 98 percent left ITA patency and 69 percent vein graft patency in the same patients. Early diffuse radial artery graft abnormalities in

7 patients disappeared by the 5-year angiogram.[47] At this point the jury is still out on radial artery grafts. They are not as reliable in terms of patency as left ITA grafts are but may be superior to vein grafts over the long term if they are resistant to late graft atherosclerosis.

Total arterial revascularization is an appealing concept, but its clinical importance is not yet certain. For some patients, total arterial revascularization can be achieved solely with the use of ITA grafts, but for many others, other arterial grafts are needed. Bergsma et al.[48] reported on a group of 256 selected patients with triple-vessel disease revascularized with two ITA grafts and a GEA graft. These relatively good-risk patients experienced an expected good survival rate, but it was also noted that over a mean follow-up period of 51 months, 85.7 percent experienced no angina, an impressive figure. Much longer-term follow-up is needed. Realistically, it is unlikely that most coronary surgeons will use GEA grafts routinely, but if the long-term patency rates of radial artery grafts are superior to vein grafts, total arterial revascularization will become common.

Chapter 48: CORONARY BYPASS SURGERY

CURRENT OPERATIVE STRATEGIES AND RISKS

Standard Operative Strategies

Currently, most operations for primary isolated coronary revascularization are still performed through a median sternotomy with the aid of cardiopulmonary bypass. Aortic occlusion and cold potassium-based cardioplegia (delivered antegrade through the aortic root or retrograde through a catheter in the coronary sinus) are used to achieve an immobile surgical field consistent with intraoperative myocardial protection. Standard revascularization techniques involve the use of an in situ left ITA to graft the coronary artery, and in most centers, vein grafts are then employed to graft the other vessels.

Hospital Mortality

Overall hospital mortality rates for primary bypass surgery vary between 1 and 4 percent. Mortality rates in the voluntary countrywide Society of Thoracic Surgeons Database ranged from 3.46 to 3.78 percent (including reoperations) from 1990 to 1994.[49] The unadjusted mortality rate for patients undergoing primary operations in New York State (a compulsory registry with subsequent public disclosure) from 1993 to 1995 was 1.9 percent,[50] and single-institution reviews have noted overall mortality rates of 1 percent or less for elective patients.[1] Multiple database analyses have been devoted to the identification of variables that can be used to predict in-hospital outcomes and adjust for patient selection. A recent review of the seven largest data sets available in the literature found that 7 variables were predictive of in-hospital death in all data sets: acuteness of operation, age, prior cardiac surgery, gender, LV ejection fraction, left main coronary artery percent stenosis, and number of coronary systems with more than 70 percent stenosis.[51] Acuteness of operation, age, and previous surgery had the greatest predictive value. Also identified were 13 variables that added some predictive value to the core variables: percutaneous transluminal angioplasty (PCTA) during the same admission, MI less than 1 week prior to operation, angina, ventricular arrhythmia, congestive heart failure, mitral regurgitation, diabetes, cerebral vascular disease, peripheral vascular disease, chronic obstructive pulmonary disease (COPD), and serum creatinine.

In the spectrum of clinical settings ranging from stable angina, to unstable angina with electrocardiographic changes, to recent subendocardial infarction, to recent Q-wave MI, and to cardiogenic shock, there has been an increased operative risk associated with increasing degrees of ischemia and decreasing degrees of LV function. Modern methods of myocardial protection have diminished the impact of unstable angina. However, operations for postinfarction ischemia and shock still generate substantial risk, and the mortality rate of bypass surgery after MI decreases with increasing post-MI interval. Thus the usual strategy for patients after MI is to control acute ischemia with medical treatment and undertake operation more electively.

The risk-stratification process has value for both doctor and patient. However, the process contains some inherent inaccuracies. First, variables are measured differently in different institutions, particularly variables related to the acuteness of operation. Second, databases record and analyze variables that can be measured. Some variables, such as the diffuse nature of distal CAD, are difficult to measure and are rarely contained in databases. Third, a variable must be able

to be measured in large numbers of patients. The presence of severe ascending aortic atherosclerosis as defined by echocardiography is a risk factor not routinely measured in most large series. Were it to be measured, it would be important, but most institutions do not have the facilities to examine this variable in all patients. Fourth, for a variable to be predictive of risk, it must be measured and recorded with enough frequency to have a statistical impact. Examples of uncommon variables that have a strong impact on operative mortality include hepatic cirrhosis, congenital clotting disorders, severe protamine allergies, and previous mediastinal radiation therapy.

Coronary bypass surgery is a very scrutinized treatment. Overall mortality rates tend to be maintained in a narrow range in part because that scrutiny engenders careful patient selection if overall mortality rates begin to rise. Burack et al.[52] studied the New York State Department of Health Cardiac Surgery Reporting System (CSRS) and found evidence that high-risk patients were being denied bypass surgery. Certainly, not all institutions should perform all operations, and it probably is of benefit for high-risk patients to undergo surgery in selected institutions. However, in a milieu of medical economics where patient mobility may be limited, care must be exerted such that high-risk patients are not denied potentially lifesaving operations.

One operation-related variable that has been associated with decreased in-hospital risk is the use of ITA grafts. At one time there was concern that ITA use would increase risk. However, multiple retrospective studies from different data sets and during different surgical periods have shown that use of the ITA graft is associated with a decrease in hospital mortality rather than an increase.[53,54]

One advantage of identifying characteristics that predict high risk is that patients who are at extremely low risk also may be identified. For example, during the years 1995-1998, the STS Database recorded 25,776 patients who underwent a primary elective bypass operation, had a LV ejection fraction of greater than 50 percent, and did not have peripheral vascular disease, carotid disease, renal failure, a prior MI, or an intraaortic balloon pump. For these good-risk patients, 98 deaths occurred for a 0.38 percent mortality rate.[55]

Hospital Morbidity

PERIOPERATIVE MI

Since the early years of bypass surgery, improved strategies for myocardial protection have evolved, and significant perioperative MI has become less frequent. Today most surgeons employ aortic occlusion combined with some type of cardioplegia injected into the cardiac vascular system to produce a still heart. Originally, cardioplegic solutions were asanguineous, cold, high in potassium, and injected into the aortic root. Modifications of this basic strategy have included addition of blood, addition of metabolic substrates, warming some or all of the cardioplegic solution, and delivery of cardioplegia retrograde through the coronary sinus into the cardiac venous system.

The definition of what constitutes a perioperative MI varies among studies but with the use of cardioplegia, the risk of hemodynamically significant perioperative MI in elective patients is very low, and it has become difficult in such patients to show incremental benefit of any of the cardioplegia modifications. For example, a trial of warm blood cardioplegia versus cold crystalloid cardioplegia in primary elective bypass operations showed that rates of MI (1.4 versus 0.8 percent), intraaortic balloon pump use (1.4 versus 2.0 percent), and death (1.0 versus 1.6 percent) were equivalent.[56] For patients undergoing operation in the face of acute ischemia based either on failed PCTA or unstable angina, blood cardioplegia does appear to provide incremental benefit.[57,58] Retrograde delivery through the coronary sinus and coronary venous system provides more effective delivery during reoperations, in the setting of acute coronary ischemia, or if the

aortic valve is insufficient.[59]

For the period of time needed to complete even extensive coronary revascularization operations using standard techniques, the metabolic environment created by these cardioplegic strategies appears to be sufficient for protection. Significant perioperative MI, when it occurs, appears to be based on anatomic causes, acute coronary occlusion, graft failure, or incomplete revascularization.

NEUROLOGIC COMPLICATIONS

Adverse neurologic events after coronary bypass surgery may negatively affect overall outcomes, and at a period in time where myocardial protection has diminished the impact of perioperative MI, the perioperative risk of cerebral complications is still under intense investigation. A recent multicenter study authored by Roach et al.[60] separated postoperative neurologic abnormalities into focal strokes (type I) and diffuse encephalopathies (type II). In this study, the total number of adverse outcomes was 6.1 percent, divided between type I (3.1 percent) and type II (3.0 percent). Advanced age and hypertension predicted an increased risk for both types of deficits.

Focal strokes (type I) appear to have multiple causes, including carotid or intracranial vascular disease, embolic phenomena based on interventricular or atrial thrombi or postoperative atrial fibrillation, and atheroembolization from the aorta, probably the most common cause. In fact, in the study by Roach et al.,[60] the greatest predictor of a type I deficit was proximal aortic atherosclerosis as noted by the surgeon. Hartman et al.[61] have associated the risk of stroke with the severity of aortic atherosclerosis as defined by transesophageal echocardiography, and Blauth et al.[62] associated the presence of ascending aortic atherosclerosis with evidence of atherosclerotic emboli to multiple organ systems. There are multiple techniques available to diminish the impact of aortic atherosclerosis, including alternative arterial cannulation sites, single aortic cross-clamping, circulatory arrest and aortic replacement, and surgery without cardiopulmonary bypass. Which strategy will produce the best outcomes will vary according to the particular pathology involved, but the most important point is recognition by the surgeon of the existence of the problem. Other predictors of type I deficit have included a history of stroke, diabetes, unstable angina, peripheral vascular disease, and a total carotid occlusion.

Variables that were predictive of type II deficits in the Roach et al. study included a history of alcohol abuse, atrial fibrillation, prior coronary artery bypass grafting (CABG), peripheral vascular disease, and congestive heart failure. The anatomic basis of type II deficits is not known, but many authors have noted some evidence of gaseous or particulate embolization associated with cardiopulmonary bypass. Strategies designed to minimize microembolization associated with cardiopulmonary bypass includes the use of membrane oxygenators, arterial filters, alpha-stat extracorporeal circulation acid-base management, and avoidance of cerebral hyperthermia. Another appealing concept is the performance of bypass surgery without the use of cardiopulmonary bypass, and logic would seem to dictate that this strategy would decrease the incidence of both types of neurologic complications. This issue is currently being intensively investigated.

The presence of carotid stenoses, symptomatic or asymptomatic, in a patient undergoing bypass surgery creates both a short- and a long-term risk of stroke. Studies of patients over age 65 with carotid Duplex scans have defined the predictors of 80 percent or more carotid stenoses as female gender, peripheral vascular disease, previous transient ischemic attack (TIA) or stroke, smoking history, and left main stenoses.[63] The majority of patients aged 65 or older had one of these characteristics, and it may be logical to screen all patients in that age group undergoing bypass surgery. Regardless of age, patients with a previous stroke, TIA, or carotid bruit should undergo Duplex screening, and any patients evidencing symptoms characteristic of vertebrobasilar insufficiency should have further studies.

The patient with simultaneous carotid and coronary disease is at higher risk than the patient with only CAD regardless of which therapeutic approach is used. Staged operations with carotid endarterectomy performed first has been shown to be safe but has been applied in very selected patients with less severe CAD. Patients undergoing bypass surgery in the face of a severe uncorrected carotid stenosis are at increased risk of stroke, and patients with bilateral stenoses are at a greatly increased risk of stroke.[64,65] Many experienced centers recommend combined carotid endarterectomy and coronary surgery for patients with carotid stenoses who are undergoing primary bypass operations, although even with this approach stroke and mortality rates are slightly worse than those for patients with isolated CAD.[66]

WOUND COMPLICATIONS

Deep sternal wound complications represent a serious adverse outcome and occur in 0.5 to 4 percent of cases depending on patient selection. Obesity and diabetes have been implicated in multiple studies as factors increasing the risk of sternal complications. There is some evidence that aggressive treatment of blood glucose levels with intravenous insulin may decrease the risk of infection in diabetic patients. No studies have shown that the use of a single ITA graft increases the risk of sternal wound complications, but some authors have implicated bilateral ITA grafting, particularly for diabetic patients.[67] Dissection of the ITA as a skeletonized artery rather than as a pedicle may leave collateral circulation to the sternum intact and diminish the impact of ITA use.

Chapter 48: CORONARY BYPASS SURGERY

DIFFERENTLY INVASIVE BYPASS SURGERY

New concepts in how bypass surgery is being performed are now under exploration: operations done through small incisions (minimally invasive bypass surgery) and operations performed without the use of cardiopulmonary bypass (beating-heart or off-pump surgery). Stimuli for these changes include the maturation of small incision or endoscopic technology for the performance of thoracic and general surgery and the desire to decrease incision-related and cardiopulmonary bypass-related morbidity (and perhaps mortality) related to coronary surgery.

Small-incision and beating-heart concepts have been combined in an operation during which a small left anterior thoracotomy is used to prepare a left ITA graft that is then anastomosed to the LAD coronary artery under direct vision (MIDCAB or LAST operation) (Fig. 48-8). Endoscopic technologies sometimes have been used for the ITA preparation but usually not for creation of the anastomosis. Early studies showed that this approach was possible but also noted an increased risk of ITA graft failure associated with this strategy. However, with increased surgical experience, results clearly have improved.[68,69] Because the left ITA-LAD operation using standard techniques (median sternotomy and cardiopulmonary bypass) is extremely safe and produces excellent 20-year outcomes, the only major risks of bypass surgery that are likely to be diminished with the MIDCAB approach are wound complications. However, it is the hope that this less invasive approach may have cosmetic, hospital stay, time loss from work, and cost advantages. The disadvantage of a limited-access, off-pump operation is that a limited number of coronary vessels can be grafted through any one incision. To approach this issue, three directions are being pursued: small-incision surgery with cardiopulmonary bypass (CPB), large-incision surgery without CPB, and robotics surgery.

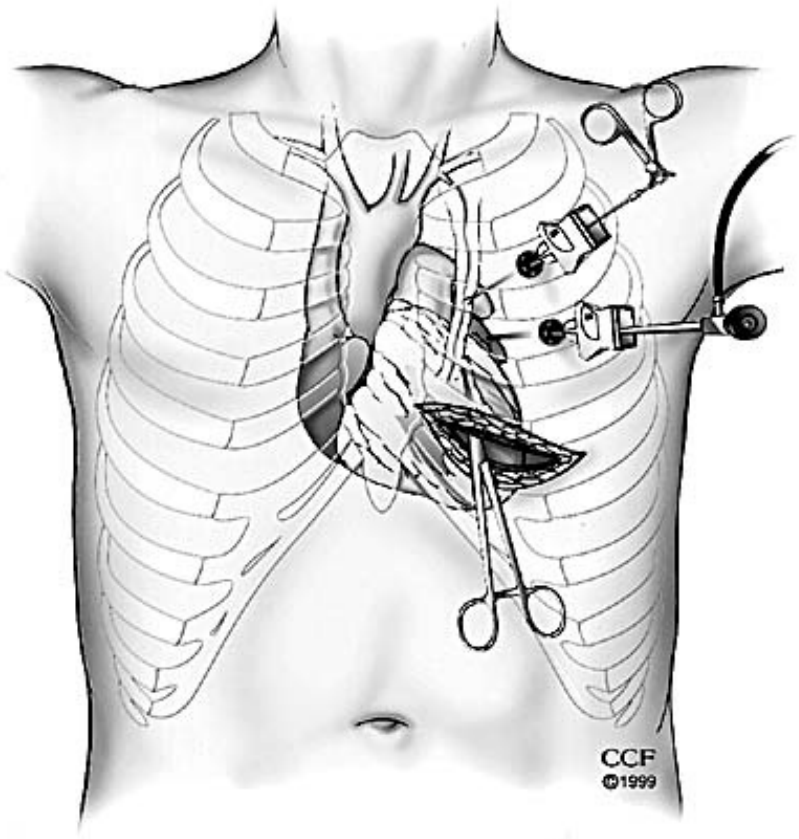

Figure 48-8: A small left anterior thoracotomy may be used to construct a limited anastomosis without the use of CPB, or with the use of percutaneous CPB, more vessels are accessible through this small incision. Endoscopic preparation of the left ITA graft may be employed.

A percutaneous CPB system has been developed that involves femoral arterial and venous cannulation and percutaneous cannulas that allow balloon occlusion of the ascending aorta and the delivery of antegrade and retrograde cardioplegia. This approach allows aortic occlusion, cardiac arrest, and decompression, making the coronary vessels more accessible through a small left thoracotomy. The disadvantages of this approach are that coronary exposure may not be ideal, the right ITA and GEA arteries are difficult to use as grafts, the patient undergoes the risks of CPB, and the patient is exposed to vascular-related risks of catheter placement such as aortic dissection and atherosclerotic embolization. Industry sources appear to show that an early increased risk of aortic dissection has lessened with experience and that the risks of death and stroke are not obviously out of line.[70] The possible benefits of this approach are a decrease in wound complications and a faster return to full activity. In carefully selected patients, these goals seem achievable.

A more common differently invasive strategy is to use a median sternotomy incision to improve coronary artery access but avoid the use of CPB, bypass surgery being performed on the beating heart. Beating-heart surgery was employed in the early years of bypass surgery, and although poor angiographic outcomes led to its decline, it never disappeared completely. Many surgeons continued to perform small numbers of off-pump operations for patients at particularly high risk for CPB, and some large series of elective off-pump operations were accumulated outside the United States.[71,72]

Differently invasive bypass operations have different risks. The disadvantages of off-pump surgery or any small-incision surgery is that coronary access and stabilization are not as optimal as is possible through a large incision with the use of CPB and cardiac arrest. However, progress

in stabilization devices and intracoronary shunts and increased surgeon experience have greatly enhanced the effectiveness of off-pump surgery, and it is a strategy that is here to stay. Current early angiographic evaluation indicates that for selected patients, favorable early graft patency rates can be achieved. Avoidance of CPB-related complications is the upside of off-pump surgery. So far, large comparative, but nonrandomized series show small differences in measurable early morbidity despite the avoidance of CPB.[73] Subgroups of patients at increased risk of a neurologic or renal complication would seem to be a group that would derive maximum benefit from off-pump surgery. However, avoiding CPB does not eliminate the risk of stroke, particularly if aortic clamps are used in the construction of aortic anastomoses. Composite grafts using the left ITA as inflow avoid aortic manipulation and are often used during off-pump surgery (see Fig. 48-5*A*, *B*).

The use of robotics-type visualization and manipulative technology is in its infancy but offers the possibility of expanding the extent of operations that can be performed through small incisions with or without CPB. The development of effective anastomotic stapling devices will greatly expand the possibilities for robotics bypass surgery.

Chapter 48: CORONARY BYPASS SURGERY

LONG-TERM OUTCOMES AFTER BYPASS SURGERY

Late survival after bypass surgery is related to the patient's cardiac status at the time of operation, the bypass operation, progression of atherosclerosis, noncardiac comorbidity, and fate. Recent follow-up of 8221 surgical patients from the CASS Registry documented overall survival of 96, 90, 74, 56, and 45 percent at 1, 5, 10, 15, and 18 postoperative years, respectively.[74] These figures are inferior to those for the age-sex-matched U.S. population. Noted in other follow-up studies is that 55 percent of deaths over the first postoperative decade were cardiac in nature.[75]

Age is a major determinant of survival. In the CASS review, very young and very elderly patients had a decreased survival rate. The lack of ITA grafting in the CASS population almost certainly had a detrimental effect on the survival of young patients, but no studies of patients 40 years of age or under have ever shown survival rates equivalent to age-matched controls. However, elderly patients, while having a diminished survival when compared with younger patients, actually have survival rates better than those for age-matched controls, an effect that begins to be observed around age 60.[74]

LV function is the cardiac-related variable most closely related to long-term survival. In addition, left main stenosis, a proximal LAD artery stenosis, and the number of significantly stenotic coronary arteries all have influenced survival in most studies. The late survival of patients treated medically is dramatically influenced by these cardiac variables, but bypass surgery at least partially ameliorates their impact.[74] In our study analyzing the impact of arterial revascularization, a proximal LAD artery stenosis had no effect on late survival, and left main disease and the number of systems diseased had minor influence.[39] In no long-term study has bypass surgery completely obliterated the impact of abnormal LV function on late survival.

Risk factors for atherosclerosis also decrease late survival, most particularly cigarette smoking, hypercholesterolemia, hypertension, and diabetes. Smoking decreases the survival rate, and stopping smoking returns the patient to a nonsmoker's prognosis.[76] High elevations in total cholesterol are related to a decreased survival in some studies,[77] and there is suggestive evidence that pharmacologic treatment may improve the survival rate for these patients. Diabetes severe enough to require treatment is associated with a decreased late survival rate, but it is not yet clear whether or not glycemic control will improve the late survival rate of surgically treated patients. However, it has been shown that close control of diabetes does improve long-term outcomes for medically treated patients, and logic would dictate the importance of this approach despite bypass surgery.

As discussed previously, the surgical strategies of the left ITA-LAD artery graft and bilateral ITA grafting incrementally improve the late survival.

The impact of incomplete revascularization on long-term outcome is of increasing importance with the emergence of PCTA and minimally invasive bypass operations, strategies that may involve less complete revascularization than can be achieved with standard bypass surgical techniques. Definitions of what *incomplete revascularization* is have varied, and it is difficult to separate incomplete revascularization as a surgical strategy from incomplete revascularization as a marker of bad coronary and noncoronary atherosclerosis. Retrospective multivariate analyses of

The Cleveland Clinic Foundation data identified incomplete revascularization as a risk factor for late death, but not a strong one.[77] A CASS Registry study by Bell et al.[12] noted a strong negative effect of incomplete revascularization on the late survival of patients with abnormal LV function who underwent bypass surgery, and Jones and Weintraub[78] observed a negative effect on patients with normal LV function.

Incomplete revascularization as a surgical strategy was examined in a study by Tasdemir et al.[72] that reviewed patients having off-pump bypass surgery. In this study, incomplete revascularization (usually of the circumflex system) was sometimes accepted in order to be able to perform bypass surgery without CPB. Failure to revascularize the circumflex system was a risk factor for early death and cardiac events, but late follow-up was not available.

Chapter 48: CORONARY BYPASS SURGERY

REOPERATION

Atherosclerosis is a progressive disease, and some patients eventually will undergo repeat bypass surgery. A study reviewing patients undergoing primary bypass surgery in the 1970s noted a cumulative incidence of reoperation of 2.7, 11.4, and 17.3 percent at 5, 10, and 12 years after bypass, respectively.[79] Young age, normal LV function, single- or double-vessel disease, severe symptoms, incomplete revascularization, and not having an ITA graft were all factors increasing the likelihood of a reoperation. Today, the availability of PCTA, use of arterial grafts, and possibly risk factor control will diminish the rate of reoperation. However, recurrent ischemic syndromes will develop in some patients with previous surgery, and reoperation will sometimes be required.

Patients who are candidates for reoperation are different from those having primary surgery. Today, the typical candidate for reoperation underwent primary surgery more than 10 years ago, had triple-vessel disease at that time, and needs reoperation at least in part because of graft failure. The atherosclerotic process is advanced, and such patients have a high incidence of noncardiac atherosclerosis. Their cardiac atherosclerosis is severe, and they have a higher prevalence of aortic atherosclerosis, left main stenosis, severe distal CAD, and abnormal LV function than patients undergoing primary surgery. They usually have the unique characteristics of having their myocardial blood supply dependent on ITA grafts, being at risk for injury, or having atherosclerotic vein grafts that create the possibility of coronary atheroembolism. In addition, few data are available that help to define the indications for reoperation, particularly for patients who are not severely symptomatic. None of the randomized trials included patients with previous bypass surgery, and since their myocardium is usually jeopardized at least in part by vascular pathology different from native coronary artery atherosclerosis, generalization from the randomized studies is unwise.

To examine outcomes for patients with prior surgery who developed recurrent ischemic syndromes, we performed two retrospective, nonrandomized studies of patients who underwent repeat angiography after primary bypass surgery. The first involved patients who did not undergo prompt reoperation and compared outcomes with patients with vein graft stenoses with patients without vein graft stenoses.[80] This study showed that late (≥5 years) stenoses in vein grafts are more dangerous lesions than are native coronary lesions. For example, patients 5 years or more after operation with a 50 percent or greater stenosis in the LAD artery vein graft had survival of 70 and 50 percent 2 and 5 years after angiography compared with survival rates of 97 and 70 percent for patients whose LAD coronary artery was jeopardized by a 50 percent or greater native vessel stenosis.

The second study involved patients with stenotic vein grafts and compared outcomes for those who underwent repeat surgery with those who were treated without initial reoperation.[81] Treatment was not randomized, and the patients who underwent repeat surgery were more symptomatic. Patients with late (≥5 years) stenoses in vein grafts had better survival rates with surgery, and the patients who particularly benefited were those with an atherosclerotic vein graft to the LAD coronary artery. The patients with a 50 percent or greater LAD artery graft stenosis had immediate and obvious benefit, but even those with a 20 to 50 percent stenosis had an improved survival rate with surgery when followed for 5 years (Fig. 48-9). Patients with late stenoses in non-LAD artery grafts also appeared to have improved late survival unless they

had a patent ITA to LAD artery graft. Patients with early vein graft stenoses did not have an improved late survival rate with surgery, although patients who underwent reoperation had fewer symptoms at late follow-up.

All studies that have examined large numbers of patients undergoing reoperation have noted an increased in-hospital risk when compared with patients undergoing primary surgery. The STS National Database noted an overall risk of 7.14 percent for reoperations from 1980 to 1990,[15] and The Cleveland Clinic Foundation studies have documented a risk of 3 to 4 percent for a first reoperation from 1967 through the present.[82-84]

The increased risk of reoperation is related in large part to an increased risk of perioperative MI. Graft injury, atherosclerotic embolization from vein grafts or the aorta, incomplete revascularization due to diffuse disease or lack of bypass conduit, and technical difficulty with severely atherosclerotic coronary vessels are anatomic causes of perioperative MI that are either unique to reoperation or more common in that setting. The use of retrograde cardioplegia has been of major benefit in the management of atherosclerotic vein grafts and patent ITA grafts, but avoiding perioperative MI during reoperation still represents a challenge.

In the reoperative setting, emergency operation produces a large increase in risk. Definitions of *emergency* vary among studies, but the lesson is the same. For example, in the STS National Database, primary operation had a risk of 2.24 percent for elective operation versus 5.7 percent for emergencies, whereas elective reoperations had a 5.33 percent risk compared with 12.69 percent for emergencies.[15] Left main stenosis, advanced age, congestive heart failure, female gender, and numbers of stenotic vein grafts have been other factors associated with increased risk.

In general, the long-term outcomes after reoperation are slightly inferior to those after primary surgery. Loop et al.[83] noted a 69 percent 10-year survival for 2429 hospital survivors of a first reoperation. LV function was the variable having the strongest impact on survival. Reoperations tend to achieve less perfect revascularization than primary procedures, and by 5 to 6 postoperative years, about 50 percent of reoperative patients have some angina, although in few patients is it severe.[82]

Chapter 48: CORONARY BYPASS SURGERY

PCTA VERSUS CABG

The advent of PCTA brought another invasive treatment for coronary atherosclerosis into the arena. Observational studies have identified many of the benefits (low procedure-related morbidity, early return to full activity, feasibility of multiple procedures) and disadvantages (not feasible for many patients, incomplete revascularization, restenosis, acute coronary occlusion) of PCTA. To compare PCTA and surgery for selected patient subgroups, multiple randomized trials have been undertaken.

A three-armed trial [The Medicine, Angioplasty or Surgery Study (MASS)] randomized 214 patients with severe (>80 percent) proximal LAD artery stenoses to medical treatment, PCTA, or bypass surgery (CABG).[85] During a 5-year follow-up, the primary end points of MI, death, and refractory angina occurred for 6 CABG patients, 29 PCTA patients, and 17 medically treated patients ($p = 0.001$). Considering repeat revascularization, death, and MI as events, event-free survival at 5 years was 98.6 percent after CABG, 93.9 percent after PCTA, and 88.9 percent for medically treated patients. The percentage of patients free of angina were CABG, 72.7 percent; PCTA, 64.7 percent; and medically treated, 25.8 percent. There was no difference, however, among the groups in the likelihood of death.

Multiple randomized, prospective trials have compared PCTA versus CABG for the treatment of multivessel CAD. The design of these trials has been to test the question of whether or not an initial strategy of PCTA compromises patient survival. The multicenter Bypass Angioplasty Revascularization Investigation (BARI) trial is the largest such trial (1792 patients randomized in 18 centers), and the single-center Emory Angioplasty Surgery Trial (EAST) is the other U.S. study.[86,87] Included in these trials were patients with stable or unstable angina who were good angiographic candidates for PCTA.

Of the spectrum of patients with coronary atherosclerosis who are considered for revascularization, a minority were included in these trials. Patients with left main stenosis of 50 percent or more were purposely excluded. In the BARI trial, more than half the patients who were potentially randomizable were excluded because of anatomy unfavorable for PCTA, and of the patients judged suitable, only half were randomized. A majority of BARI patients had two-vessel disease (59 percent) and normal LV function, and a minority (37 percent) had a proximal LAD artery lesion. Thus the BARI trial (and EAST patients had similar baseline characteristics) included very few patients who had been shown to have improved survival with CABG in the medicine versus surgery trials of the 1970s. In particular, the PCTA versus CABG trials are underpowered to detect a difference in survival for patients with multivessel disease and abnormal LV function because very few of such patients were randomized.

At approximately a 5-year follow-up interval, overall survival rates have been equivalent for the PCTA and CABG groups in both BARI and EAST. In the BARI trial, the subgroup of patients with treated diabetes had much worse survival with PCTA (Fig. 48-10). The survival advantage of the CABG group was present only if an ITA graft was used. Nondiabetic patients had equivalent survival.[88]

There were large differences between the PCTA and CABG groups in the need for repeat revascularization. Repeat revascularization was required in 54 percent of PCTA patients in both BARI and EAST versus 8 percent in the BARI CABG group and 13 percent in the EAST CABG group. There were smaller differences in symptom status and the need to take antianginal medications in favor of CABG. Detailed discussion of the limitation of these trials and the limitations in the conclusions that can be drawn from these trials have been described in detail by American College of Cardiology/American Heart Association task forces.[2,14] However, among the limitations of these trials in terms of current recommendations for the treatment of a broad spectrum of patients with multivessel CAD are the following: (1) The benefit of PCTA for high-risk patients (those subsets for whom surgery prolongs survival) has not been established because of the small number of such patients included in these randomized trials. (2) Only good angiographic candidates for PCTA were included, and the results of these trials cannot be extended to patients with more marginal suitability for PCTA. (3) Few PCTA patients received intracoronary stents. (4) Few surgical patients had extensive arterial revascularization. (5) None of the protocols included lipid-lowering therapy.

Observational studies have the disadvantage of bias in treatment selection but may have an advantage of being more inclusive. A recent large study from the New York State Cardiac Procedure Registries detailed a 3-year outcome of 29,646 CABG patients and 29,930 PCTA patients.[50] This study found a survival advantage for CABG for all patients with a proximal LAD artery lesion regardless of whether they had single-, double-, or triple-vessel disease.

Comparative trials of PCTA and CABG have involved patients with stable or unstable angina but not "beat the clock" treatment of acute MI. Currently, thrombolysis, PCTA, or both are the strategies employed for the vast majority of patients with acute MI.

There are no randomized studies of PCTA versus CABG for patients with previous bypass surgery. The percutaneous treatment of VGA usually has not been effective. Despite the use of stents, there is a high rate of restenosis and cardiac events.[89] Furthermore, it appears that these cardiac events are often serious ones, MI and/or death. Pathologies that are not based on VGA may be treated effectively with PCTA, including graft anastomotic stenoses, early vein graft stenoses, and native vessel stenoses. Patients with large amounts of myocardium jeopardized by atherosclerotic vein grafts usually should be treated with reoperation. However, generalizations are difficult for these complex patients, and therapeutic decisions are best made by interventional cardiologists, cardiac surgeons, and clinical cardiologists working in concert.

Chapter 48: CORONARY BYPASS SURGERY

INDICATIONS FOR BYPASS SURGERY

In the individual case, recommendations concerning bypass surgery may be influenced by comorbid conditions that greatly increase operative risk or that limit the patient's ultimate life span. However, some generalizations can be made.[2,14] Patients with 50 percent or greater left main stenosis or multivessel disease with a proximal LAD artery stenosis and abnormal LV function should have a recommendation of surgery regardless of their symptom status. Individual randomized trials and metaanalyses have shown clearly a survival benefit for these patients, and there is no evidence that PCTA is safe in these subgroups.

Diabetic patients with multilesion, multivessel disease including a proximal LAD artery lesion should have surgery regardless of LV function and symptom status. Survival is better with CABG than with medical treatment, and PCTA is clearly not an equivalent intervention in terms of survival.

Patients with multivessel disease that include a proximal LAD artery lesion and demonstrable ischemia should have a recommendation for revascularization. If these patients are nondiabetic with normal LV function and are good angiographic candidates for PCTA, it appears that PCTA does not compromise 5-year survival, and the options of PCTA and CABG should be discussed with the patient.

For patients with single-vessel disease based on a proximal LAD artery lesion, survival appears equivalent with medical therapy, PCTA, and CABG, and all options are reasonable, although CABG patients have had fewer events and symptoms over 5 years.

For other subsets of patients with multivessel disease, surgery may be a reasonable choice for the treatment of symptoms in the face of demonstrable ischemia. The choice between PCTA and CABG for these patients should be based on coronary vascular anatomy and patient preference.

For patients with previous bypass surgery and a significant (≥50 percent) late stenosis in a vein graft to the LAD coronary artery, surgery should be recommended regardless of symptoms. For patients in other anatomic subgroups, the risk-benefit situation is complex. Usually reoperation is undertaken to treat severe symptoms and/or large areas of ischemic jeopardy.

Chapter 48: CORONARY BYPASS SURGERY

TRANSMYOCARDIAL LASER REVASCULARIZATION

The concept of achieving myocardial revascularization by the creation of channels in the myocardium to allow perfusion of blood directly from the LV cavity to coronary sinusoids has been investigated since the 1950s. Early experiments involved mechanically created channels, but more recently, lasers of various wavelengths have been used. The increasing population of patients with severe distal native vessel atherosclerosis (usually occurring years after previous bypass surgery) who may not be well treated with either bypass surgery or PCTA has provided impetus to the search for such alternative revascularization strategies, and transmyocardial laser revascularization (TMLR) may be of value.

Recently, randomized studies of TMLR versus medical management have been conducted involving patients with angina and severe CAD judged untreatable by conventional invasive means. Both CO_2 and holmium lasers were tested, and in both studies, over 70 percent of TMLR patients noted improvement in angina at 1 year postoperatively compared with 13 to 32 percent improvement in the medically treated group ($p < 0.001$).[90,91] Survivals of the TMLR and medically treated groups were the same in both studies. In the CO_2 laser study, 20 percent of patients had improved myocardial perfusion as judged by pharmacologic stress testing with thallium-201 single-photon-emission computed tomography (versus 27 percent of the medically treated group with worse perfusion; $p = 0.002$). The holmium laser study did not show a significant improvement in perfusion.

Although there is some apparent benefit from TMLR, the mechanism of improvement is not clear. Autopsy studies have noted granulation tissue occluding the myocardial channels within a few days of operation, and angina relief may not be immediate. Denervation and microcollateral stimulation have been suggested as possible mechanisms of angina relief. TMLR appears to have a role in revascularization but currently does not appear to produce the degree or the consistency of improved myocardial perfusion that can be achieved when bypass surgery or PCTA is possible. The indications for TMLR are still in evolution.

Part 6: CORONARY HEART DISEASE
Chapter 49:

MANAGEMENT OF THE PATIENT AFTER CARDIAC SURGERY

Authors: Douglas C. Morris, Stephen D. Clements, Jr., Carl C. Hug, Jr.

The initial management of the patient following cardiac surgery is primarily focused in specialized intensive care units. The unique pathophysiologic alterations associated with hypothermia and cardiopulmonary bypass (CPB)[1] mandated that a specialized environment, including intensive monitoring and offering sophisticated electrophysiologic, hemodynamic, and mechanical intervention supervised by specially trained critical care nurses, be available. While CPB is no longer universally applied in cardiac surgery, the multiple management problems posed by cardiac patients as a consequence of their preoperative status, effects of residual anesthetic drugs, success of the operative procedure, and intraoperative complications continue to demand specialized treatment. When direct coronary artery bypass grafting is done without CPB, the primary concerns are bleeding (residual heparin, surgical hemostasis), hypothermia, myocardial ischemia, and injury. The use of CPB accentuates these concerns and adds those of a generalized inflammatory response.

ROLE OF VASCULAR CANNULAE, LIFE SUPPORT, AND MONITORING IN THE IMMEDIATE POSTOPERATIVE PERIOD

On arrival in the ICU, the patient is still under the effects of anesthesia and hypothermia, often receiving one or more drugs affecting the systemic circulation, and, in most cases, mechanically ventilated. The patient typically arrives from the operating room with the necessary apparatus for monitoring the following parameters: heart rate and rhythm; arterial, central venous, pulmonary artery, and pulmonary artery occlusion pressures (PAOP); cardiac output; urinary output; mediastinal drainage; body temperature; and arterial oxygen saturation (SpO_2) and end-tidal carbon dioxide tension ($ETCO_2$). Immediately upon arrival in the ICU, reliable monitoring of the previously mentioned variables should be instituted. Once the patient is satisfactorily connected to the bedside monitors and ventilator, all the hemodynamic measurements should be recorded, the patient's level of consciousness and comfort should be assessed, a portable supine chest x-ray should be acquired, and a 12-lead electrocardiogram obtained.

Most of the apparatus attached to the patient upon arrival in the ICU serves a dual purpose. A pulmonary artery catheter not only allows monitoring of pulmonary artery pressures but can also be used to estimate the filling pressure of the left ventricle, cardiac output, and body core temperature. The peripheral arterial cannula provides a continuous pulse-wave tracing of systemic blood pressure and ready access to arterial blood sampling for laboratory analysis. *Regular periodic assessments of arterial blood gases, especially after a major change in ventilator settings, are essential unless continuous $ETCO_2$ and SpO_2 by pulse oximetry are being monitored.* $ETCO_2$ and SpO_2 are reliable in guiding the weaning of mechanical ventilation and tracheal extubation. Monitoring of these parameters has been used very effectively in "fast-track" protocols. Assessment of volume loss is based on chest and mediastinal tube drainage plus urine output. The endotracheal tube secured in the correct position with an appropriately inflated cuff is essential for positive-pressure ventilation of the lungs. Confirmation of bilateral breath sounds and absence of tracheal air leak versus cuff inflation should be made upon arrival in the ICU and after suctioning secretions from the oropharynx. The endotracheal tube's position should be ascertained

on the initial chest x-ray. The endotracheal tube also allows for suctioning of bronchial secretions and reduces (but does not eliminate) the risk of oropharyngeal and gastric reflux secretions entering the trachea and bronchi. The endotracheal tube can often be removed the evening of surgery if the patient is conscious, is able to protect the airway, has good ventilatory mechanics and muscle strength, and is able to take on the work of breathing. Most patients can have the pulmonary artery catheter removed within 12 to 24 h if cardiovascular drug therapy is at minimum levels. The peripheral arterial cannula can be removed once cardiovascular function is satisfactory and the need for blood sampling is at a routine daily level. The urinary catheter is usually removed when the patient is ambulatory unless there is a vigorous diuresis or an increased risk of urinary retention. Chest tubes are generally removed when the total drainage is less than 100 mL per tube over 8 h.

The primary factor that differentiates cardiac surgery from other forms of surgery is CPB. With such improvements in extracorporeal technology as membrane oxygenation, arterial blood filtration, and blood sparing techniques, the noncardiac complications have been significantly reduced. Major improvements in myocardial protection technology coupled with changes in anesthetic and CPB techniques now frequently allow extubation within several hours of surgery.[2] Intraoperative management has now evolved to the point of minimizing the need for cardiopulmonary support after surgery, thereby allowing the patient to recover satisfactory vital function more rapidly than before. As a consequence, mechanical ventilation and other measures can be discontinued much earlier, and the patient can be safely and comfortably transferred from the ICU within the first 6 to 24 h, a process that has been termed *fast-tracking*.[3]

Individuals undergoing "off pump" procedures also have the potential for rapid recovery and early extubation and removal of catheters and chest tubes, and can be sitting up in the chair the next morning ready for transfer.

Fast-tracking describes efforts to minimize the duration of the patient's stay in the ICU or postanesthesia care unit and to allow the early, safe transfer of the cardiac surgical patient to a so-called step-down level of monitored care. Early extubation and transfer should require that the patient's status is characterized as follows: awake or easily aroused, neurologically intact, cooperative, and comfortable; stable, satisfactory hemodynamics; normothermia; satisfactory spontaneous ventilation; normal coagulation with minimal chest tube drainage; satisfactory urine output, electrolyte, and acid-base balance.[4]

Chapter 49: MANAGEMENT OF THE PATIENT AFTER CARDIAC SURGERY

EARLY POSTOPERATIVE MANAGEMENT

Pathophysiologic Consequences of Cardiopulmonary Bypass

The basic pathophysiology during the early postoperative period revolves around the following variables: transient left ventricular dysfunction, capillary leak, warming from hypothermia, mediastinal bleeding, and emergence from anesthesia.

The likely presence of left ventricular dysfunction during the first 24 h postoperatively with a gradual recovery to preoperative levels is suggested by studies based upon hemodynamic data, nuclear scanning, and metabolic techniques. While improvements in surgical techniques, cardioplegia delivery, and other myocardial protection measures achieved in the past decade would have been expected to lessen this complication, the reported prevalence of early ventricular dysfunction (90 percent) did not change between 1979 and 1990.[5] This transient myocardial depression has been attributed by some authors to inadequate myocardial protection or the effects of cold cardioplegia,[6,7] but the bulk of the evidence incriminates the inflammatory state induced by CPB as the primary causative factor.[1]

The inflammatory state induced by CPB involves platelet-endothelial cell interactions and vasospastic responses that result in low-flow states in the coronary circulation.[8] The inflammatory reaction causes vascular endothelial adhesion molecules to attract inflammatory cells that subsequently adhere to the vascular endothelium. These inflammatory cells mediate much of the subsequent injury by the release of oxygen radicals or proteolytic enzymes.[9] This release of oxygen-free radicals in response to reperfusion injury is now generally accepted as the explanation for the transient postoperative ventricular dysfunction.[10-12] Depressed myocardial function seems to be unrelated to CPB time, number of coronary artery grafts, preoperative medications, or postoperative core temperature. Ventricular function is generally depressed by 2 h and is at its worse at 4 to 5 h after CPB. Significant recovery of function usually occurs by 8 to 10 h, and full recovery is reached by 24 to 48 h.[13] Systemic vascular resistance, while not rising immediately after surgery, increases as ventricular function worsens. This rise in systemic vascular resistance is likely secondary to reduced ventricular function and the need to maintain systemic blood pressure and, per se, is not a major causative factor of depressed cardiac contractility. The confounding effect of vasopressor drugs used in an attempt to increase systemic blood pressure must be recognized.

The inflammation-mediated production of oxygen-free radicals and release of proteolytic enzymes by neutrophils also damages the endothelial cells. The "gatekeeper" function of the endothelium is disturbed and capillary permeability increases, resulting in edema.[9] The capillary leak syndrome may last from a few hours up to 1 to 2 days, depending to a large degree on the duration of CPB. When the capillary leak ceases and interstitial edema fluid is mobilized, intravascular volume overload is a threat. At this time, diuretics are beneficial to eliminate excessive fluid.

Hypothermia predisposes the patient to cardiac dysrhythmias, increases systemic vascular resistance, precipitates shivering (which increases O_2 consumption and CO_2 production), and impairs coagulation.[13] Hypothermia with the patient's core temperature below 35°C frequently recurs after rewarming to 37°C (98.6°F) at the end of CPB. This fall in core temperature reflects

the loss of heat from the surgical field after CPB, exposure of the patient to ambient temperature, and incomplete rewarming of peripheral tissues, especially fat and muscle. If the patient is hypothermic upon arrival in the ICU, monitoring the temperature of noncore body sites such as a finger or toe can assure complete assessment of rewarming. Hypothermia causes peripheral vasoconstriction and contributes to the hypertension frequently seen after cardiac surgery. Furthermore, hypothermia causes a decrease in cardiac output by producing bradycardia along with the increase in vascular resistance. As the patient is rewarmed, large increases in O_2 consumption, and CO_2 production can occur, with a consequent increase in demand on cardiovascular and pulmonary functions.[14]

Hypercarbia will cause catecholamine release, tachycardia, and pulmonary hypertension. If the patient cannot increase the cardiac output and O_2 delivery, venous hemoglobin desaturation and metabolic acidosis will result. Most believe that the patient should be passively rewarmed by warm air (e.g., Bear Hugger) and that shivering should be eliminated by the administration of meperidine (25 to 50 mg) and muscle relaxants.[15] As body temperature increases, the vasoconstriction and hypertension associated with hypothermia are replaced by vasodilatation, tachycardia, and hypotension. Volume loading during the rewarming process helps reduce the rapid swings in blood pressure. Vasopressors (e.g., norepinephrine) may be required to maintain an adequate systemic blood pressure.

The commonly reported prevalence of severe postoperative bleeding (more than 10 U of blood transfused) following cardiac surgery is between 3 and 5 percent. In some hospitals, 25 percent of all blood products are dedicated to cardiac surgery.[16] While approximately one-half of the patients who undergo reoperation for excessive bleeding exhibit incomplete surgical hemostasis, the remainder bleed because of various acquired hemostatic defects, most often related to acquired platelet dysfunction.[17] The factors that predispose to bleeding following CPB are residual heparin effect, platelet dysfunction (which may be intensified by preoperative drug therapy, e.g., aspirin and $GPII_bIII_a$ inhibitors), clotting-factor depletion, inadequate surgical hemostasis, hypothermia, and postoperative hypertension. CPB decreases both platelet count and function. Hemodilution causes platelet counts to fall rapidly to about 50 percent of preoperative values. Within minutes after instituting CPB, the bleeding time is prolonged and platelet aggregation is impaired. The bleeding time usually normalizes by 2 to 4 h after CPB. The platelet count usually requires several days to return to normal levels. While the exact mechanism responsible for the transient platelet dysfunction remains undefined, it appears to be related to contact of platelets with the synthetic surfaces of the extracorporeal oxygenator and to hypothermia. Reductions in the plasma concentrations of coagulation factors II, V, VII, IX, X, and XIII due to hemodilution occur during CPB, but these coagulation factors remain well above levels considered adequate for hemostasis and generally normalize within the first 12 h after surgery. Moreover, while bleeding after CPB is often attributed to excessive fibrinolysis, the decrease in both plasminogen and fibrinogen levels during CPB is due to hemodilution and not consumption.[17] Upon returning from the operating room after exploration for bleeding, a common report is that no localized site of bleeding occurred and only diffuse oozing was found. Less frequently, a specific site such as an internal mammary pedicle will be identified.

Chapter 49: MANAGEMENT OF THE PATIENT AFTER CARDIAC SURGERY

MANAGEMENT OF COMMON POSTOPERATIVE SYNDROMES

Vasoconstriction with Hypertension and Borderline Cardiac Output

Increased arteriolar resistance as a consequence of hypothermia and increased levels of circulating catecholamines, plasma renin, or angiotensin II is present in most postoperative cardiac patients. The usual criterion for pharmacologic lowering of blood pressure in postoperative patients is a mean arterial blood pressure 10 percent above the upper level of normal (>90 mmHg). Patients with a friable aorta or friable suture lines might be subjected to a lower mean arterial pressure to prevent dehiscence. The mean arterial blood pressure is monitored because it is most reflective of systemic vascular resistance. As the hypothermic patient is rewarmed, a short-acting vasodilator (nitroprusside, nitroglycerin, or nicardipine) can be infused intravenously to maintain mean arterial pressure at 80 to 90 mmHg. Intravascular volume should be maintained at a relatively high level (PAOP of 14 to 16 mmHg) in anticipation of vasodilation upon rewarming and to enhance cardiac output and peripheral perfusion. If the cardiac index is marginal (2.0 to 2.2 L/min/m^2), an inotropic drug should be administered in addition to the vasodilator.

Vasodilatation and Hypotension

This condition, which generally appears during rewarming, is most effectively prevented and best treated by fluid administration. The specific volume expander selected should be based upon a determination of the predominant factor leading to the hypovolemia. If the predominant factor is a capillary leak syndrome with generalized edema, the use of colloids could aggravate the situation as the oncotic elements pass into the interstitium and exacerbate tissue edema. If vasodilatation with increased venous capacitance is the major problem, colloids will provide longer-lasting augmentation of intravascular volume. Hetastarch (administered in 250- to 500-mL increments) provides sustained volume expansion equal to 5 percent albumin, at a significant reduction in cost. It does, however, have a tendency to increase bleeding. If fluid administration has increased PAOP appropriately (e.g., 14 to 16 mmHg for a normal ventricle or 18 to 22 mmHg for a noncompliant ventricle) and systemic blood pressure remains marginal, vasopressor or inotropic drugs should be administered. Generally, a PAOP above 15 mmHg in the postoperative period is of little benefit due to a "flattening" of the diastolic function curve, which accompanies the decline in systolic function.[18] An inotropic vasopressor should be infused if more than 1 or 2 L of fluid have been administered and the PAOP is not rising. In some patients after cardiac surgery, fluid administration produces a substantial increase in left ventricular end-diastolic volume without changing PAOP. Whether this is due to an open pericardium with overdistension of the left ventricle or some other factor is unclear.[19] If the blood pressure is marginal and the cardiac index is over 2.0 L/min/m^2, norepinephrine or dopamine is the preferable agent. If the cardiac index is less than 2.0 L/min/m^2, an inotropic agent should be administered initially.

Normal Ventricular Systolic Function and Low Cardiac Output

This set of circumstances is often noted in small women with systemic hypertension and in patients undergoing aortic valve replacement for aortic stenosis. The likely explanation is diastolic dysfunction. The problem should be managed by volume expansion with the intent to elevate PAOP to levels as high as 20 to 25 mmHg if necessary. Sinus rhythm and atrioventricular synchrony are essential and, if not present, should be restored. In the absence of other reasons for

diastolic dysfunction, the possibility of cardiac compression from clots in the mediastinum and pericardial space should be considered. If volume expansion does not lead to hemodynamic improvement, transesophageal echocardiography (TEE) should be used to establish or exclude the presence of clots or other causes of low output. If the information derived from TEE does not permit explanation and/or resolution of the problem, the patient should return to the operating room for exploration.

A rather characteristic presentation of cardiac compression is the patient who initially has significant mediastinal bleeding that ceases rather abruptly. The patient then becomes hypotensive, with high PAOP and central venous pressure and progressively increasing inotropic drug requirements. Cardiac compression from clots in the pericardial space should be suspected and, if time allows, confirmed by TEE. Rapid clinical deterioration demands immediate exploration of the pericardial space.

Chapter 49: MANAGEMENT OF THE PATIENT AFTER CARDIAC SURGERY

APPROACH TO POSTOPERATIVE CARDIOVASCULAR PROBLEMS

Low Cardiac Output Syndrome

Satisfactory cardiac performance following cardiac surgery is usually indicated by a cardiac index greater than 2.2, L/min/m^2 with a heart rate below 100 beats per minute. Marginal cardiac function is present with a cardiac index between 2.0 and 2.2 L/min/m^2. A cardiac index below 2.0 L/min/m^2 is unacceptably low, and therapeutic intervention is indicated. Clinical signs of the adequacy or inadequacy of organ perfusion must be incorporated into any assessment of cardiac performance.

ASSESSMENT

The most common causes of low cardiac output postoperatively are related to a decreased left ventricular preload. The decreased preload, in turn, can likely be attributed to hypovolemia (due to bleeding or to vasodilatation as a consequence of warming or of drugs), cardiac tamponade, or right ventricular dysfunction. Alternative explanations for low cardiac output include decreased contractility due to a preexisting low ejection fraction or to intra- or postoperative ischemia or infarction. Perioperative myocardial ischemia or infarction is usually due to poor intraoperative myocardial protection, incomplete myocardial revascularization, coronary artery spasm, coronary embolism of atherosclerotic debris or air, prolonged systemic hypotension, or severe acute anemia. Tachy- or bradyarrhythmias decrease cardiac output by reducing ventricular preload (e.g., decreased diastolic filling time, loss of atrial contraction or atrioventricular synchrony) or by reducing the number of effective ventricular contractions per minute. Substantial increases in systemic vascular resistance (i.e., vasoconstriction) impede ventricular ejection and lower cardiac output. Vasodilatation from sepsis or anaphylaxis resulting in systemic hypotension could lead to reduced coronary blood flow and myocardial ischemia. Sepsis (an unlikely occurrence in the immediate postoperative period) is also associated with the production of myocardial depressant factors. Anemia may result in reduced blood viscosity (a major determinant of total peripheral resistance) leading to hypotension and decreased oxygen delivery to the heart. The hypotension in anemia, however, is most often due to changes in effective blood volume rather than to the changes in viscosity.

ETIOLOGY AND MANAGEMENT

The multiple variables constantly monitored usually provide sufficient clues as to the cause of low cardiac output. If there is no obvious noncardiac cause such as anaphylaxis or anaphylactoid reaction, acidosis, severe anemia, or marked alterations in body temperature, then the first step is to optimize the preload (PAOP of 15 to 18 mmHg). The next step is to optimize the heart rate by either cardiac pacing or antiarrhythmic drugs. Postoperative myocardial performance is usually best at a rate of 90 to 100 beats per minute. If these measures prove unsuccessful, pharmacologic intervention with inotropic agents, vasodilators, vasopressors, or a combination of these drugs must be considered. The selection of drugs should be based upon the balance of their effects on heart rate, contractility, ventricular preload, and systemic vasculature resistance (Table 49-1). The presence of elevated left- and right-sided filling pressures, a recent cessation of mediastinal drainage, and progressively increasing inotropic drug-dosage requirements suggests tamponade, which should be relieved emergently. TEE has been very helpful in clarifying these situations.

The final therapeutic step, if the preceding measures have proved inadequate, is the use of aortic counterpulsation (i.e., intraaortic balloon pump) or another type of cardiac assist device.

Table 49-1: Medications Used in Low Cardiac Output Syndrome

Medication	Hemodynamic Properties	Dosage Range
Dopamine	Low dose-dopaminergic effect	2-20 μg/kg/min
	Moderate dose-inotropic effect	
	High dose-vasopressor effect	
Dobutamine	Positive inotropic agent	2-20 μg/kg/min
Epinephrine	Positive inotropic agent	1-4 μg/min
Amrinone	Positive inotropic agent	10-15 μg/kg/min
Isoproterenol	Potent inotropic agent	0.5-10 μg/min
	Pronounced chronotropic effect	
Norepinephrine	Potent vasopressor effect; inotropic effect	1-100 μg/min
Phenylephrine	Potent vasopressor agent	10-500 μg/min

Hypertension

MANAGEMENT

A variety of medications are available for control of hypertension, and the drug selected should depend on the hemodynamic status of the patient, the cardiovascular effects of the drug, and the patient's other medical problems. Systemic hypertension in the presence of a high left ventricular filling pressure and marginal cardiac output is most appropriately treated by an arterial vasodilator. Nitroprusside relaxes vascular smooth muscle in arterial resistance vessels (both systemic and pulmonary) and in venous capacitance vessels. The potential exists with nitroprusside for dilation of the coronary resistance vessels and production of a coronary steal syndrome by shunting blood away from any ischemic areas. The advantages of the drug are its very rapid onset and the rapid dissipation of its effects. The risks with this agent are rapid and excessive hypotension and the potential for either acute cyanide toxicity or thiocyanate toxicity with prolonged use.[19]

Nitroglycerin is primarily a venous dilator, although it produces varying degrees of arterial vasodilatation, especially at high doses. Its major role in treating systemic hypertension is in the patient with high filling pressures and active myocardial ischemia.[20] Nicardipine is a potent systemic and coronary vasodilator without the risk of coronary steal, and it has no significant effect on the venous system. It can, therefore, effectively control postoperative hypertension without reducing the filling pressures or causing a coronary steal. While its onset of action is rapid (1 to 2 min), its elimination half-life is about 40 min. Unlike some calcium channel blockers, this agent lacks a negative inotropic effect and has no effect on atrioventricular conduction.[21] Hydralazine is a direct arterial vasodilator, which is usually administered in intermittent intravenous or intramuscular doses. Hydralazine-induced arterial vasodilation may produce a compensatory tachycardia. This drug is frequently resorted to in patients who are

hemodynamically stable but remain hypertensive several days after surgery and cannot yet take or absorb oral medications.

When the hypertension is associated with a normal cardiac output and a relatively rapid sinus heart rate or a propensity toward dysrhythmias, a drug with negative inotropic and chronotropic properties is desirable. Esmolol is a cardioselective, ultrashort-acting beta blocker, which also produces a rapid and titratable control of the blood pressure accompanied by a decrease in heart rate. The drug is usually tolerated satisfactorily by patients with a history of bronchospasm because of its relatively high selectivity for $beta_1$-type adrenergic receptors. It is not ideal for patients with impaired cardiac contractility, particularly in the presence of elevated filling pressures.[22] Diltiazem is an arterial vasodilator that has a mild negative inotropic effect and a more potent negative chronotropic effect. Verapamil is a less potent vasodilator but with more potent negative inotropic, chronotropic, and dromotropic effects. It can be administered intravenously by either boluses or continuous infusion. Labetalol has both alpha- and beta-blocking properties as well as a direct vasodilatory effect. Its predominant effect is as a beta blocker, especially in the intravenous form. The angiotensin-converting enzyme inhibitor enalaprilat, which is the active form of enalapril, can be administered intermittently by the intravenous route. This agent is usually reserved for the patient who is hemodynamically stable with either a normal or reduced cardiac output but with hypertension expected to persist (Table 49-2).

Table 49-2: Intravenous Antihypertensive Agents

Drug	Peak Effect	Duration	Dosage
Nitroprusside	Immediate	2-5 min	0.3-1.0 μg/kg/min
Nitroglycerine	Immediate	2-5 min	5-100 μg/min infusion
Nicardipine	5-60 min	20-40 min	2.5 mg over 5 min; may repeat times 4 at 10-min intervals; infusion 2-15 mg/h
Esmolol	2-5 min	8-10 min	1-min loading infusion of 0.25-0.5 mg/kg; sustained infusion of 50-200 μg/kg/min
Enalaprilat	15-30 min	6 h or more	0.625-1.25 mg slowly over 5 min every 6 h
Hydralazine	15-20 min	3-4 h	5- to 10-mg bolus may be repeated every 15 min; up to total of 40 mg
Diltiazem	3-30 min	3 h	20- to 25-mg bolus may repeat; infusion of 10-20 mg/h
Verapamil	2-3 min	20-40 min	5- to 10-mg bolus; may repeat in 10 min; infusion of 3-25 mg/h
Labetalol	5-15 min	2-6 h	20-mg bolus over 2 min; then 40- to 80-mg boluses every 15 min until effect achieved (to total dose of 300 mg)

Arrhythmias

GENERAL CONSIDERATIONS AND SINUS TACHYCARDIA

The most common rhythm disturbance immediately after cardiac surgery is sinus tachycardia.

This condition is appropriately treated by searching for and correcting the underlying cause (pain, anxiety, low cardiac output, anemia, fever, or beta-blocker withdrawal). The second most common arrhythmia is ventricular ectopy. Again, an underlying cause such as myocardial ischemia, hypokalemia, hypomagnesemia, hypoxia, or administration of sympathomimetic drugs must be sought and corrected if possible. It is also important to review the patient's preoperative record to determine if the patient had preexisting ectopy. Patients with chronic ventricular ectopy frequently have their ectopy exaggerated postoperatively.[23] In the presence of active myocardial ischemia, pharmacologic suppression is advisable for complex ventricular ectopy. In the first 12 h after coronary bypass surgery, myocardial ischemia must be suspected and is difficult to exclude; accordingly, the preceding policy for ectopy suppression should be adhered to with the possible exception of those with known chronic ectopy. Lidocaine is the drug of choice in most instances. The loading dose of lidocaine is approximately 3 mg per kilogram of ideal body weight given over 20 min. One approach is to give an initial bolus of 75 mg, following by 50 mg every 5 min to a total dose of 225 mg. An alternative is to give a priming dose of 75 mg, followed by a loading infusion of 150 mg over 20 min. The usual initial maintenance infusion is 1.5 to 2.5 mg/min. If the arrhythmia is uncontrolled, one can give another bolus of 25 to 50 mg and increase the infusion rate. The chances of toxicity rise significantly at infusion rates above 4 mg/min, especially in individuals greater than 65 years of age. If the ectopy does not respond to lidocaine, the option is to not use an antiarrhythmic agent unless ventricular tachycardia occurs *or* to use intravenous amiodarone. Pacing the heart at a faster rate may prove successful in suppressing the ectopy.

VENTRICULAR TACHYCARDIA AND FIBRILLATION

After cardiac surgery, a few patients develop sustained ventricular tachycardia (either monomorphic or polymorphic) or ventricular fibrillation. These profound rhythm disturbances may develop in the absence of evidence of acute myocardial ischemia or infarction or electrolyte imbalance. In most cases the patients have had previous myocardial infarction and have undergone "complete" revascularization, including regions likely to be nonviable. Reperfusion of these areas that probably include viable as well as nonviable myofibrils embedded in the healed infarct may lead to altered dispersion of repolarization. These changes support development of reentry arrhythmias.[23] The ventricular tachycardia in these patients uncommonly responds to lidocaine and usually requires amiodarone. In some instances, a combination of amiodarone and a beta blocker is required. In a rare circumstance, aortic counterpulsation has seemed to be of benefit.

Every encounter with a wide complex tachycardia requires careful consideration as to the possibility of supraventricular tachycardia with aberrant conduction. In the presence of atrial fibrillation with a rapid ventricular response, right bundle branch aberrant conduction often mimics ventricular tachycardia. Care must be given to avoid lidocaine in these situations, because it may result in an even more rapid ventricular rate.

Wide complex tachyarrhythmias in the range of 250 to 300 beats per minute should suggest the presence of an anomalous conduction pathway. The mechanism of this arrhythmia usually involves atrial flutter, with one-to-one conduction or atrial fibrillation with a very fast ventricular response involving an anomalous pathway. Once this is recognized, procainamide becomes the drug of choice, since it does have favorable therapeutic effects on the bypass track tissue. Lidocaine and verapamil should be avoided if the presence of an anomalous pathway is suspected (see also Chap. 24).

SUPRAVENTRICULAR ARRHYTHMIAS

The most common supraventricular dysrhythmias, with the exception of sinus tachycardia, are atrial fibrillation and atrial flutter. These rhythm disturbances occur in 10 to 30 percent of patients following cardiac surgery. The predominant predisposing factor in the development of atrial

fibrillation is the patient's age. The prevalence of atrial fibrillation in postoperative cardiac patients <40 years of age is as low as 3.7 percent, while the prevalence is at least 28 percent in patients >70 years. Atrial fibrillation is most likely to appear on the second postoperative day. Within 1 to 3 days, 80 percent of these patients will return to sinus rhythm with only digoxin or beta-blocker therapy.[24-26] The prophylactic use of beta blockers has a protective effect against the development of atrial fibrillation or flutter. This beneficial effect has been demonstrated with any one of several beta blockers, administered in low or high doses and started preoperatively or postoperatively. Neither digoxin nor verapamil has demonstrated effective prophylaxis against atrial fibrillation or flutter.[27]

Preoperative oral administration of amiodarone also reduces the prevalence of postoperative atrial fibrillation.[28] The major limitation to the widespread application of this prophylactic approach is the apparent need for a 7-day preoperative treatment period. An accelerated loading regimen over 1 to 2 days may be effective, but is unproved.[29]

Intravenous infusions of either esmolol or diltiazem can be used to control the ventricular rate with atrial fibrillation or flutter. Esmolol is given as a 1-min loading infusion of 0.25 to 0.5 mg/kg, followed by a sustained infusion of 50 to 200 μg/kg/min. Diltiazem is administered as a bolus of 20 to 25 mg (which may be repeated), followed by an infusion of 10 to 15 mg/h.

Atrial epicardial pacing wires provide the means of atrial pacing to convert some cases of atrial flutter to sinus rhythm.[25] Short bursts (15 to 30 s) of atrial pacing at rates of 300 to 600 per minute may be effective in converting atrial flutter. Approximately 10 percent of patients with atrial fibrillation require electrical cardioversion to restore sinus rhythm. If hemodynamic compromise is present and aggravated by a supraventricular tachyarrhythmia, cardioversion should be used immediately rather than later.

Intravenous ibutilide (1 mg infused over 10 min to be repeated once if necessary) is the most effective pharmacologic means of converting recent-onset atrial flutter. The drug is much less effective (in the range of 30 to 50 percent) for conversion of recent-onset atrial fibrillation. The disadvantage of ibutilide is the propensity for causing torsades de pointes in 2 to 4 percent of patients.[29]

CONDUCTION DEFECTS

The prevalence of intraventricular conduction abnormalities after coronary bypass surgery is reported to be from 1 to 45 percent, with approximately 10 percent being the most commonly reported frequency. The most common conduction defect is right bundle branch block, which may be due to selective sensitivity of the right bundle to the effects of hypothermia and the extracorporeal circulation process. Only about 5 percent of the patients are left with a permanent conduction abnormality, and the prognosis for these patients is no worse than it is for comparable patients with no conduction defect.[30,31] The development of high-degree (second- or third-degree) atrioventricular block is an indication for temporary pacing via epicardial pacing wires. Atrioventricular block is not as common as either bundle branch block or fascicular block, but it does occur, especially after aortic valve surgery.

Respiratory Management

EXPECTED RESPIRATORY CHANGES AFTER CARDIAC SURGERY

Pulmonary problems are the most significant cause of morbidity following cardiac surgery. The pain associated with sternotomy and, especially, with thoracotomy has a deleterious effect on the patient's willingness to breathe deeply and cough. Pain caused by the presence of chest tubes may also interfere with normal respiratory function. Phrenic nerve damage can result in diaphragmatic

dysfunction. More commonly, the diaphragm is passively displaced cephalad by abdominal contents (gastrointestinal intraluminal air and fluid and edematous bowel) in the anesthetized, paralyzed patient supported by mechanical ventilation. Elevated left side of the heart filling pressures may cause alveolar edema and, in some patients, increased capillary permeability may exist. Insertion of an oro- or nasogastric tube by the anesthesiologist while the patient is under general anesthesia is recommended.

Atelectasis is the most common pulmonary complication, occurring in about 70 percent of patients following cardiac surgery with CPB.[32] During CPB, the lungs are not perfused and are usually allowed to collapse. Once the lungs are reexpanded, a variable amount of atelectasis remains. While the atelectasis might be microscopic, intermediate degrees (subsegmental and segmental) are common. The preponderance of atelectasis occurs in the left lower lobe because of its compression during cardiac surgery, the tendency to suction more thoroughly the right mainstem bronchus during blind naso-orotracheal suctioning, and the frequent surgical practice of opening the left pleural space to facilitate dissection of the left internal mammary artery. Evidence for a depletion of surfactant after cardiopulmonary bypass is lacking.[33]

After thoracotomy, both lung and chest wall compliance decrease significantly. The maximum decrease occurs at approximately 3 days, but the decrease persists to a lesser degree 6 or more days after sternotomy. Alterations in chest wall mechanics lead to a decrease in the forced expiratory volume (FEV_1) and the functional residual capacity (FRC). The changes in the FEV_1 may persist for 6 weeks. In addition to these changes in flows and volumes, reduced inspiratory strength and uncoordinated rib cage expansion occur. These changes result in an increase in respiratory rate and a decrease in tidal volume, a decrease in respiratory efficiency, and an increase in oxygen cost of breathing. The atelectasis and decrease in lung volume result in ventilation:perfusion mismatch and shunting. The clinical manifestation is a decrease in arterial PO_2 and hemoglobin saturation.[33]

There is little evidence of a significant increase in lung water after routine CPB. When increased capillary permeability exists, it is usually related to elevated cardiac filling pressures.[33]

BASIC CONCEPTS OF OXYGENATION AND ALVEOLAR VENTILATION

The goals of mechanical ventilation are the maintenance of satisfactory arterial oxygenation and CO_2 removal. Direct measurement of PaO_2 is generally used to assess the overall adequacy of blood oxygenation, while pulse oximetry (SpO_2) is used to monitor peripheral arterial hemoglobin saturation on a continuous basis. An $SpO_2 > 90$ percent is considered to be acceptable, but it may be associated with a marginal PaO_2. The oxygen-hemoglobin dissociation curve portrays this relationship (Fig. 49-1). The shoulder of this sigmoid curve lies at a PaO_2 of approximately 65 mmHg. A PaO_2 below this level will result in a precipitous fall in the oxygen saturation of hemoglobin. With hypothermia or with profound respiratory alkalosis, the curve will shift to the left, resulting in more avid binding of oxygen to hemoglobin and less release of oxygen to the tissues. The patient will likely be receiving 100 percent oxygen during transfer from the operating room to the ICU or postanesthesia care unit. The FIO_2 should be gradually decreased to 0.4 as tolerated to minimize adsorption atelectasis and pulmonary O_2 toxicity. Mechanical ventilation is also used to maintain alveolar ventilation, which regulates the arterial blood CO_2 tension ($PaCO_2$). Alveolar ventilation is regulated by controlling the tidal volume and the respiratory rate. Generally, the ventilator should maintain an exhaled minute ventilation of 6 to 8 L/min. Decreasing the tidal volume below 8 to 10 mL/kg may result in alveolar hypoventilation and atelectasis. Mild hypocarbia ($PaCO_2$ of 30 to 35 mmHg) is satisfactory immediately after surgery, but more profound respiratory alkalosis should be avoided because it leads to hypokalemia and a leftward shift of the oxygen-hemoglobin dissociation curve (decreased oxygen release to the

tissues). Hypocarbia is best corrected by reducing the ventilator rate.

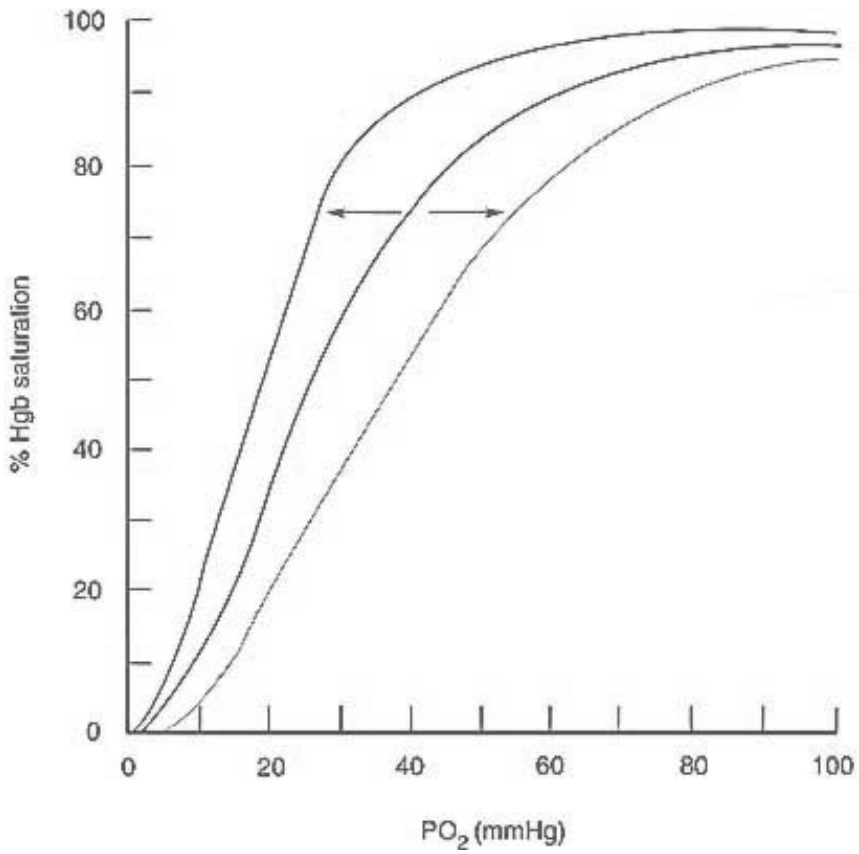

Figure 49-1: Oxygen-hemoglobin dissociation curve. The curve depicts the saturation of hemoglobin at increasing levels of PaO_2. A shift of the curve to the left increases the affinity of hemoglobin for oxygen and a shift to the right decreases the affinity.

Hypercarbia in the immediate postoperative period usually indicates that minute ventilation is inadequate. The problem can be rectified primarily by increasing the ventilator rate; in some cases it is appropriate to increase the tidal volume as well. Later, as the patient is weaned from the ventilator, hypercarbia may reflect opioid analgesia (a necessary side effect of satisfactory analgesia) or compensatory hypoventilation in response to a metabolic alkalosis, most likely due to excessive diuresis. Acetazolamide (Diamox), 250 to 500 mg intravenously every 6 h, is beneficial in correcting a primary metabolic alkalosis. Severe hypercarbia should raise a concern about mechanical problems such as ventilator malfunction, endotracheal tube malposition, or a pneumothorax.[5] Occasionally, hypoxemia and even hypotension may develop in the mechanically ventilated patient due to a tension pneumothorax or hemothorax. If the latter are suspected, assessment of breath sounds and a chest x-ray are indicated for confirmation.

VENTILATORY WEANING AND EXTUBATION

Ventilatory support should be reduced as tolerated when the cardiovascular system has become stable and the arterial oxygen tension is satisfactory [PaO_2 > 70 mmHg, with FIO_2 of 0.5 and PEEP (peak end-expiratory pressure) of 5 cm H_2O]. The patient should also be alert, normothermic, and have no active bleeding. Monitoring of SpO_2 and $ETCO_2$ is helpful and allows the weaning process to be done safely and expeditiously. Typically, the intermittent mandatory ventilation rate is decreased in a stepwise fashion to 0. Then PEEP and pressure support are reduced. Finally, a T-piece adapter is connected to the endotracheal tube and the patient is allowed

to breathe oxygenenriched air spontaneously. After 30 to 60 min, the arterial blood gases are analyzed. Weaning should be discontinued if any of the following signs appear: SpO_2 < 90; PaO_2 < 60 mmHg; $ETCO_2$ > 50 mmHg; $PaCO_2$ > 55 mmHg; pH < 7.30; 10-mmHg rise in pulmonary artery pressure; respiratory rate > 30; 20-mmHg rise in systemic blood pressure; or 20-beat rise in heart rate.[5]

Most patients require low to moderate doses of morphine or another opioid in order to tolerate the endotracheal tube. As long as the spontaneous ventilatory rate remains greater than 15 breaths per minute, the patient will almost certainly be able to maintain adequate ventilation after the endotracheal tube is removed. Common mistakes that contribute to patient discomfort and difficulty in achieving tracheal extubation are (1) trying to sedate the patient with benzodiazepines only, which have no antitussive effect and (2) avoiding opioids for fear of respiratory depression.

BRONCHOSPASM

Severe bronchospasm during CPB is an unusual event, but it can occur. A few patients cannot have their chest cavity closed at the end of surgery because of hyperinflated lungs. The most likely cause of this fulminant bronchospasm is activation of human C5a anaphylatoxin by the extracorporeal circulation. Other likely causes of bronchospasm in the postoperative period are cardiogenic pulmonary edema; simple exacerbation of preexisting bronchospastic disease triggered by instrumentation, secretions, or cold anesthetic gas; beta-adrenergic blockers in susceptible individuals; and allergic reaction to protamine.[32]

The initial therapy of bronchospasm in the postoperative patient, once a diagnosis of heart failure is excluded, should be inhaled $beta_2$-agonists (terbutaline, metaproterenol, albuterol) and/or inhaled cholinergic agents (ipratropium bromide or glycopyrrolate). In the inhaled form these rather potent bronchodilators have minimal cardiovascular effects. In addition to their bronchodilator effect, these agents may augment mucociliary transport and aid in clearing secretions. A combination of $beta_2$-agonists and cholinergic agents should be tried in the patient refractory to a single agent. Even more refractory bronchospasm requires either a short course of systemic steroids or intravenous aminophylline. In addition to being a bronchodilator, aminophylline is a mild diuretic, increases the central nervous system respiratory drive, improves respiratory muscle function, and may decrease pulmonary artery pressure. It is, however, arrhythmogenic and chronotropic.

Postoperative Oliguria and Renal Insufficiency

ETIOLOGY

The use of radiocontrast agents in the days immediately preceding cardiac surgery may embarrass renal function, as manifested by a rise in blood urea nitrogen and serum creatinine values. Following CPB, there is a substantial incidence of postoperative renal dysfunction (up to 30 percent) but a relatively low incidence of severe renal impairment requiring dialysis (1 to 5 percent). Renal blood flow and glomerular filtration rate are reduced by 25 to 75 percent during bypass, with partial but not complete recovery in the first day after CPB. This reduction in renal function is attributed to renal artery vasoconstriction, hypothermia, and loss of pulsatile perfusion during CPB. Angiotensin II levels are higher with nonpulsatile flow as compared to pulsatile flow. While renal dysfunction cannot be consistently related to the systemic blood pressure and pump flow rate during nonpulsatile bypass, there is a definite relation between the incidence of postbypass renal dysfunction and the duration of CPB. In addition to the duration of CPB, the risk of developing postbypass renal failure seems to be a function of the patient's underlying renal function (also affected by age) and the perioperative circulatory status. The histologic changes that accompany renal impairment after cardiopulmonary bypass are characteristic of tubular necrosis.

The tubular cells seem to be the most susceptible to acute reductions in renal perfusion.[33]

MANAGEMENT

There are three agents (so-called renoprotective drugs) that might be used during CPB to prevent an ischemic insult to the kidneys. Mannitol used in the CPB priming fluid may moderate ischemic insult, probably by volume expansion and hemodilution. It also initiates an osmotic diuresis, which prevents tubular obstruction and may serve as a free radical scavenger. Furosemide appears to improve renal blood flow when given during bypass. So-called renal dose dopamine (1 to 2.5 μg/kg/min based on ideal body weight) may maintain renal blood flow and urine output. Once renal failure has developed, none of these drugs is likely to offer any beneficial effect. A megadose of furosemide (200 to 300 mg) may be tried, but if there is no diuretic response, it should not be repeated. Similarly, a single dose of mannitol (12.5 to 25 mg) either with or without furosemide could be tried but not repeated if there is no effect. Whenever possible, it is advisable to avoid potentially nephrotoxic agents in the early postoperative period. Examples of such include radiologic contrast agents, aminoglycoside antibiotics, and angiotensin-converting enzyme inhibitors.

Postoperative Gastrointestinal Dysfunction

GASTROINTESTINAL CONSEQUENCES OF CARDIOPULMONARY BYPASS

The gastrointestinal consequences of CPB appear to be minimal. Reviews of the subject report a 1 percent prevalence.[32,33] Most patients eat within 24 to 48 h after an uncomplicated elective procedure. The limited investigations of the gastrointestinal tract after cardiac surgery have found a slight decrease in hepatic and pancreatic blood flow during cooling and rewarming on bypass and a decrease in gastric pH.[32,34] Transient elevations in liver function tests and hyperamylasemia may occur after cardiac surgery, and the risk factors include long CPB time, multiple transfusions, and multiple valve replacements. Appearance of jaundice portends a poor prognosis.[35] Severe gastrointestinal complications are usually ischemic in nature and are often associated with a low-output syndrome.[32] The use of opioids as part of general anesthesia and postoperative pain management contributes to gastrointestinal dysfunction (cramping, ileus, and constipation) and to postoperative nausea and vomiting. The nausea and vomiting can be minimized by use of a naso- or orogastric tube to maintain gastric decompression intraoperatively and early in the postoperative period, with the additional benefit of improving thoracoabdominal compliance to positive-pressure ventilation.

Postoperative Metabolic Disorders

POTASSIUM IMBALANCE

There are multiple factors that can produce large and rapid shifts in the serum potassium levels during and after CPB. These factors include the following: (1) high-potassium cardioplegia solution used during surgery; (2) renal dysfunction with associated oliguria and decreased clearance of potassium; (3) low cardiac output states accompanied by oliguria and acidosis; (4) hemolyzed red blood cells' release of potassium; (5) potassium lost by diuresis; and (6) diabetes mellitus interference with cellular uptake of potassium, unless insulin is infused intra- and postoperatively. The principal detrimental effects of these potassium shifts is on the electrical activity of the heart. The electrocardiographic signs of hyperkalemia and hypokalemia are described in Chap. 11. The electrocardiographic changes of hyperkalemia do not necessarily appear in the classic progressive manner; they are more related to the rate of rise in serum potassium rather than to the absolute serum concentration. The therapy of severe hyperkalemia should include counteracting the toxic cardiac effects of the elevated potassium with intravenous

calcium gluconate or calcium chloride and lowering the serum level of potassium with sodium bicarbonate and/or administration of regular insulin and glucose. Hypokalemia does not usually become clinically evident until the serum potassium concentration is <2.5 meq/L, and at these levels it can be associated with severe ventricular tachyarrhythmias. Another consequence of potassium depletion is metabolic alkalosis as the hydrogen ions replace potassium ions within the cells. Hypokalemia is treated with the intravenous administration of KCl at a rate of no more than 10 to 15 meq/h. The serum potassium rises approximately 0.1 meq/L for each 2 meq of KCl administered. Large doses of KCl should be administered by a central venous catheter because of the caustic effect of potassium on peripheral veins.

HYPOMAGNESEMIA

Hypomagnesemia is common following cardiac surgery using CPB. Magnesium mimics potassium in its effects on the electrical activity of the heart. The cause of the hypomagnesemia is unknown, but it is probably multifactorial. Many patients will be hypomagnesemic preoperatively due to the use of loop diuretics, thiazides, digoxin, or alcohol and to the effects of type I diabetes mellitus. Magnesium is usually lost in the urine during CPB. Patients with postoperative hypomagnesemia develop atrial and ventricular dysrhythmias more frequently and require more prolonged mechanical ventilatory support than do patients with normal magnesium levels.[36] Magnesium administration also seems to improve stroke volume and cardiac index in the early postoperative period.[37] Magnesium can be administered as magnesium sulfate (2 g in 100-mL solution) to raise serum levels to 2 meq/L.

HYPERGLYCEMIA

During CPB there is a rise in blood glucose levels. The elevation is modest during hypothermia and becomes more marked during rewarming. This rise in glucose is due in part to increased glucose mobilization related to dramatic increases in cortisol, catecholamine, and growth hormone levels during CPB. Also, there is an apparent failure of insulin secretion, particularly during hypothermia, probably related to inhibition of the insulin secretory response by the elevated catecholamines. This blunting of the insulin response persists for the first 24 h after surgery. These changes are exaggerated in the diabetic patient.[38] Insulin requirements are likely to be 7 times greater than the preoperative requirements during the first 4 h postoperatively. Furthermore, such insulin resistance is exacerbated by catecholamines, diuretics, and blood transfusions.[39] These multiple factors make the diabetic patient susceptible to hyperosmolar, hyperglycemia, nonketotic diabetic coma.[40]

Postoperative Fever

Fever is a common occurrence in the postoperative patient. It is generally a consequence of pleuropericarditis, atelectasis, or phlebitis. Since 70 percent of patients have atelectasis after cardiac surgery, it is the most likely etiology of postoperative fever.[32] A reasonable assumption in a patient with a core temperature <38°C (100.4°F) and no evidence of phlebitis or presence of a pericardial or pleural rub is that the source of the fever is atelectasis. The appropriate therapeutic approach is to encourage intensified efforts at incentive spirometry and coughing. Any fever >38.5°C (101.3°F) warrants blood, sputum, and urine cultures. A white blood cell count (total and differential) and a chest x-ray should also be obtained.

Sternal wound infections occur in 0.4 to 5 percent of patients after sternotomy.[41-43] Multiple factors have been identified as increasing the risk of developing sternal wound infection. These include pneumonia, prolonged mechanical ventilation (especially with tracheostomy), emergency operations, postoperative hemorrhage with mediastinal hematoma, early reexploration, obesity, diabetes mellitus, and use of bilateral internal mammary grafts. While some studies have not

found a higher prevalence of sternal wound infections with bilateral mammary grafts, the bulk of the evidence argues to the contrary. Perhaps some of the conflicting results can be explained by the fact that different degrees of devascularization of the sternum occur, depending on the particular technique used to harvest the internal mammary artery. The greatest risk for sternal infection seems to be in diabetic patients who receive bilateral internal mammary grafts.[43] Debate continues as to whether the most appropriate initial treatment is debridement and closure or open packing and subsequent plastic surgical closure with a muscle flap.

Approximately 1 percent of patients who have had coronary artery bypass surgery experience leg wound infections that necessitate extra care. Leg infections seem to occur more frequently in obese women, especially if the thigh veins are harvested.[44]

Neurologic and Neurophysiologic Dysfunction

MECHANISM

The mechanisms thought to account for most cerebral injury during cardiac surgery are macroembolization of air, debris from aortic atheroma, or left ventricular thrombus; microembolization of aggregates of granulocytes, platelets, and fibrin; and cerebral hypoperfusion. Death or disabling stroke occurs in about 2 percent of patients, with another 3 percent experiencing transient or minor functional disability secondary to cerebral infarction.[45] Focal neurologic deficits resulting from intraoperative events are usually noted within the first 24 to 48 h after surgery.

ENCEPHALOPATHY AND DELIRIUM

Alteration of mental status (encephalopathy and delirium) will be seen in approximately 30 percent of patients after cardiopulmonary bypass.[45] While the appearance of these encephalopathic symptoms likely reflects cerebral injury, other causes must be excluded, including drugs, sepsis, fever, hypoxemia, ethanol withdrawal, renal failure, and hyperosmolar state. Postoperative encephalopathic changes, varying from mild confusion and disorientation to protracted somnolence or agitation and hallucinations, may appear at any time during the hospital stay.[46] In fact, some physicians will not accept a diagnosis of postcardiotomy delirium unless the delirium develops following a lucid interval of 2 to 5 days after surgery. Studies of this condition have not identified any consistent risk factors, but advancing age, duration of CPB, and sleep deprivation have been frequently associated. The prevalence of this condition has remained rather constant since the early days of cardiac surgery involving CPB, but there has been a shift in the clinical presentation. Currently, the condition seems to present with disorientation rather than with hallucinations, paranoid ideation, and agitation noted earlier.[46] Recognition of this entity is important because the family can be assured that the patient's mental status is likely to recover. Agitation and acute psychosis in these patients usually respond to intravenous haloperidol, 2 to 10 mg, repeated as needed to produce adequate sedation.

BRACHIAL PLEXOPATHY AND ULNAR NERVE DYSFUNCTION

Another serious neurologic complication of cardiac surgery is brachial plexopathy. This neurologic dysfunction, involving C8 and T1, usually results from mechanical trauma secondary to sternal retraction but may be due to penetration by a posterior fractured segment of the first rib or injury during internal jugular cannulation. There is no specific therapy for this condition, and recovery can take as long as 6 months, with a few cases being permanent.[47] Ulnar nerve dysfunction may result from malpositioning of the upper extremities during surgery, which results in pressure being exerted on the ulnar nerve at the elbow.

Part 6: CORONARY HEART DISEASE
Chapter 50:

REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

Author: Nanette K. Wenger

Cardiac rehabilitation, an essential component of the long-term comprehensive management strategy for coronary patients, includes an individualized regimen of physical activity and health education and counseling appropriate for the individual patient's needs and specific cardiac problem.[1] *Cardiac rehabilitation* is described by the American College of Cardiology as "those exercise and counseling services which reduce symptoms or improve cardiac function"[2] and by the U.S. Public Health Service as "comprehensive, long-term programs involving medical evaluation, prescribed exercise, cardiac risk factor modification, education, and counseling." Initially, these services were recommended for patients following myocardial infarction (MI); subsequently, they were applied after coronary artery bypass graft (CABG) surgery or for patients with chronic stable angina pectoris. More recently, the U.S. Health Care Financing Administration concluded[3] that heart transplant patients and patients who had undergone percutaneous transluminal coronary angioplasty (PTCA) could benefit from prescribed cardiac rehabilitation. The Clinical Practice Guideline *Cardiac Rehabilitation*[4] documented the benefits of rehabilitative services for patients with heart failure and left ventricular (LV) systolic dysfunction and recommended their application.

The current short hospital stay for uncomplicated MI necessitates early ambulation and an accelerated educational regimen, with deferral of most teaching and counseling to the outpatient setting. Early discharge from the hospital is characteristic for patients after successful myocardial reperfusion by coronary thrombolysis or acute primary angioplasty. Patients recovering from CABG surgery typically undergo rapid ambulation, have a short hospital stay, and constitute an increasing percentage of patients referred for cardiac rehabilitation.[5] Such patients without prior MI characteristically have good ventricular function and favorable survival and are at low risk for proximate coronary events. Many require protracted guidance for coronary risk reduction; early counseling appears to aid in averting physiologic and psychological disability. Most patients following successful PTCA have brief hospital stays, good functional status, and early resumption of employment and other activities.[6,7] Patients with stable angina without recent MI constitute almost one-fourth of the total coronary population but are undeserved in terms of rehabilitative care. They are frequently not referred for formal rehabilitative services, often due to lack of insurance reimbursement. This population often has substantial loss of productivity and reduction in the quality of life and requires comprehensive medical management, with needs that may exceed those of patients after uncomplicated MI. With the aging of the U.S. population, coronary rehabilitative care is now provided to many elderly patients,[8,9] as well as to many patients with severe and complicated coronary illness. There is increasing contemporary emphasis on education and counseling as additional cornerstones of rehabilitative care, using the behavioral approach to assist patients in coronary risk reduction and other cardiovascular health-related goals[10-12]; on psychosocial assessment and interventions; and on occupational assessment and vocational counseling.

Each year almost 1 million survivors of MI are candidates for cardiac rehabilitation services in the United States, in addition to more than 7 million patients with stable angina pectoris and patients following revascularization with CABG surgery (367,000 patients in 1996, 44 percent under age

65) or PTCA and other transcatheter interventional procedures (482,000 in 1996, 51 percent younger than age 65). Of these several million patients with coronary heart disease for whom benefits can be anticipated from cardiac rehabilitation, only 11 to 20 percent participated in formal rehabilitation programs.[4,13] Among patients with acute MI enrolled in the Global Utilization of Streptokinase and tPA for Occluded Coronary Arteries (GUSTO) trial, 38 percent of U.S. patients and 32 percent of Canadian patients attended cardiac rehabilitation programs.[14] A U.S. national survey of 500 cardiac rehabilitation programs highlighted the underrepresentation of women, nonwhites, and those older than age 65.[15] Heart failure is the most common discharge diagnosis for hospitalized Medicare patients in the United States and the fourth most common discharge diagnosis for all hospitalized patients. Although coronary heart disease (CHD) is not etiologic in all these patients, it is a substantial contributor to heart failure. Application of cardiac rehabilitation services to patients with heart failure (as well as after cardiac transplantation) has gained increasing acceptance as its benefits and safety have been documented. An estimated 4.7 million patients with heart failure are potential candidates for cardiac rehabilitation.[4]

Nonetheless, this component of cardiac care is underutilized despite its efficacy and cost-effectiveness.[16,17]

EXERCISE TRAINING

Although no single randomized trial of exercise training demonstrated a reduction in mortality and morbidity in patients following MI, in part owing to inadequate sample size and/or duration of follow-up, to high dropout rates, etc., favorable trends occurred in several. Metaanalysis[16,18] of pooled data from large prospective, randomized exercise trials suggest as much as a 25 percent survival advantage for exercising subjects at 3-year follow-up following MI. This benefit cannot be attributed solely to exercise training, since many studies included coronary risk reduction as well as exercise. The reduction in mortality approaches that resulting from pharmacologic management of patients following MI with beta-blocking drugs and of patients with LV systolic dysfunction with angiotensin-converting enzyme (ACE) inhibitor therapy. The reduction in cardiovascular mortality was 26 percent in multifactorial randomized trials of cardiac rehabilitation as compared with 15 percent in trials that involved solely exercise training. There is no evidence that cardiac rehabilitation exercise training changes the rates of nonfatal reinfarction.[4,11]

The evidence-based Clinical Practice Guideline *Cardiac Rehabilitation* of the U.S. Department of Health and Human Services[4] highlights the beneficial effect of cardiac rehabilitation exercise training on exercise tolerance as one of the most clearly established favorable outcomes for coronary patients with angina pectoris, MI, CABG surgery, and PTCA and for patients with compensated heart failure or a decreased LV ejection fraction. This approach particularly benefits patients with decreased exercise tolerance.[19] Improved exercise tolerance was evident for both women and men and also occurred in elderly patients. The most consistent benefit resulted from exercise training at least three times weekly for 12 or more weeks' duration. The duration of aerobic exercise sessions varied from 20 to 40 min, at an intensity approximating 70 to 85 percent of the baseline exercise test heart rate. Improvement in exercise tolerance occurred with lower-intensity exercise as well.[20-22] Maintenance of exercise training is required to sustain improvement in exercise tolerance.

No significant increase in cardiovascular complications or other serious adverse outcomes was reported in any randomized, controlled trial of exercise training in coronary patients. These randomized, controlled trials involved 3932 patients following MI, 745 patients with catheterization-documented coronary disease, 215 patients following CABG surgery, and 139 following PTCA. No deterioration in measures of exercise tolerance was reported in any patients undergoing exercise training, nor did any controlled study document significantly greater

improvement in exercise tolerance in control patient groups compared with exercising patients.

The improvement in functional capacity with exercise training, averaging 20 percent after recovery from MI, is associated with a reduction in activity-related symptoms: angina, dyspnea, fatigue, and at times claudication. Exercise training results in (1) an improvement in oxygen transport, evident as an increase in maximal cardiac output and oxygen consumption, (2) a reduction in heart rate, systolic blood pressure, and thereby myocardial oxygen requirement at rest and at submaximal work levels, and (3) and more rapid return to normal of the exercise heart rate.

The improvement in functional capacity and decrease in activity-related symptoms following usual moderate-intensity exercise training appear to be related primarily to peripheral adaptations. These include an increase in oxygen extraction and use by trained skeletal muscle, with a decrease in myocardial oxygen demand and requirement for coronary blood flow at submaximal exercise. The redistribution of cardiac output, decrease in systemic vascular resistance, and autonomic nervous system adaptations (particularly lowering of the heart rate) result in a decreased rate-pressure product at submaximal levels of exertion. High-intensity, long-term endurance exercise may effect cardiac (central) adaptations, possibly including improved ventricular contractility and increased maximal stroke volume in selected coronary patients[23]; such intensive exercise training is feasible for only a small subset of coronary patients. There is no evidence that exercise training as a sole intervention alters the angiographic characteristics of coronary lesions, increases coronary blood flow or myocardial oxygen supply, or stimulates the formation of a coronary collateral circulation in humans. No consistent improvement in cardiac hemodynamic measurements or ventricular systolic function has resulted from exercise training.[24,25] Exercise training, however, may improve skeletal muscle functioning in patients with heart failure.[26] Exercise training can decrease evidence of myocardial ischemia, as measured by exercise electrocardiogram (ECG) testing, ambulatory ECG recording, and radionuclide perfusion imaging.[27,28] In several randomized clinical trials, apparently spontaneous improvement in resting ejection fraction after MI occurred in both exercising and control populations, rendering suspect the improvements in ejection fraction described in observational studies of exercise training. There were no consistent changes in ventricular arrhythmia related to exercise rehabilitation.

Clinical benefits of exercise training include a decrease in the symptoms of angina pectoris in patients with coronary disease[27] and the symptoms of heart failure in patients with LV systolic dysfunction.[29,30] The improvement in electrocardiographic and nuclear cardiology measures of myocardial ischemia provides objective support for the symptomatic improvement. Exercise training of patients with LV systolic dysfunction provided added symptomatic improvement to that achieved by appropriate medication.[30]

The decrease in symptoms and improvement in functional status that result from exercise training can enable a return to remunerative employment as well as to leisure and recreational activities.[31] For more impaired coronary patients, including many elderly ones, even a modest increase in functional capacity can help maintain independence.[8,9,32-35]

Guidelines for Prescriptive Exercise Training

Individualized medically prescribed physical activity is the hallmark of rehabilitative exercise training. Standards and guidelines have been promulgated by a number of professional organizations.[2,37-43] The prescriptive components of exercise training include its "dosage," determined by the intensity, frequency, and duration of exercise; the types of exercise; and the rate of progression of exercise intensity. Coronary patients should not exercise at a level higher than that documented to produce an appropriate cardiovascular response during testing. The predischarge (or early posthospitalization) exercise test, typically performed for risk stratification, can serve as the basis for initial exercise recommendations. It is inappropriate to use age-predicted

target heart rates for coronary patients; disease, therapies, and prior levels of training or fitness may influence the heart rate response to exercise.

Prescription of target heart rate range is based on the results of exercise testing. Although in prior years patients were advised to exercise to a target heart rate range between 70 and 85 percent of the highest level safely achieved at exercise testing,[44] exercise intensities in the 50 to 70 percent heart rate range have produced comparable improvement in functional capacity and endurance and may provide greater safety because of the lower risk of cardiovascular complications with unsupervised exercise.[21,22,45] These lower rates are less likely to produce discomfort that may deter long-term exercise adherence. The documented efficacy of lower-intensity exercise training to improve aerobic capacity has increased both its applicability and acceptance.[1,21,22] Particularly for unfit patients or those with lower exercise capacities, the increased comfort of lower-intensity exercise may encourage adherence, although increased duration of training may be required. Comparable favorable effects on quality of life occurred with low- and high-intensity exercise.[46] An alternative method for calculating target heart rate involves 70 to 85 percent of the difference between peak exercise test heart rate and resting heart rate, added to resting rate. This method may be advantageous in patients whose heart rate is attenuated by beta-blocking or other drugs.

The basic design of an exercise session involves an initial 5 to 10 min of warm-up exercise, i.e., stretching and range-of-motion activities that enable musculoskeletal and circulatory readiness for exercise. This is followed by a 20- to 40-min endurance component that initially involves walk-run sequences or exercise on a stationary bicycle or treadmill; for these activities, skill is a minimal component of the intensity of work demand.

When space for exercise is limited, "station" training may be preferable, with participants serially using bicycle ergometry, arm ergometry, rowing machines, and treadmills. When more space is available, gymnasium-type programs can accommodate larger numbers of patients for walk-jog activities and floor exercises; some facilities have indoor or outdoor tracks. A final 5- to 10-min cool-down period entails a gradual decrease in intensity that allows the heart rate to slow and averts postexercise hypotension. Three exercise sessions weekly appear adequate, and a greater frequency does not significantly improve aerobic capacity. Aerobic games, as a recreational component, add variety to an exercise program and improve adherence; they also provide upper body exercise. Because the oxygen cost of these activities varies with each patient's skills and competitiveness, they should be limited early in exercise training.

As the level of training increases, recreational activities in which skill often influences the intensity of work may add variety to the exercise regimen. Enjoyable, effective endurance activities include rope skipping, bicycling, skating, swimming, rowing, and aerobic dancing; both rope-skipping and swimming (for unskilled swimmers) impose higher workloads and should be undertaken carefully.

Characteristics of Aerobic (Dynamic) and Strength (Isometric) Exercise Training

Aerobic (dynamic) exercise, rhythmic repetitive movements of large muscle groups, traditionally is prescribed for coronary patients. The physiologic response, an increase in heart rate, parallels the intensity of activity, and an increase in stroke volume occurs in young and middle-aged patients. In most elderly patients, the increase in heart rate predominates, with little increase in stroke volume. Systolic blood pressure increases progressively with exercise intensity, with maintenance of or slight decrease in diastolic blood pressure and widening of the pulse pressure.

By contrast, with strength (isometric) training, the increase in heart rate is modest, and the increase in cardiac output is slight. There is a substantial increase in systolic blood pressure with high-intensity isometric activity, particularly in unfit individuals; this may provoke angina, ventricular dysfunction, and/or arrhythmias and is the basis for limiting isometric activity in

coronary patients with a low exercise capacity. Once a reasonable aerobic capacity is achieved, combined aerobic and strength training exercises in coronary patients may produce substantial training effects and improve muscle strength,[47] with resulting improvement in endurance and the ability to return to active occupational and recreational lifestyles.[48] Studies document the effectiveness of mild to moderate resistive exercise training in selected patients with coronary heart disease.[49-52] The absence of signs or symptoms of myocardial ischemia, abnormal hemodynamic changes, and cardiovascular complications suggests that resistance exercise training is safe for coronary patients who have previously participated in aerobic exercise training. A major change in contemporary exercise programs is the inclusion of strength training for appropriately selected coronary patients. Most reported studies have involved small numbers of low-risk male patients, 70 years or younger, with minimal functional aerobic impairment and with normal or near-normal LV function. The extent to which the safety and effectiveness of resistance training demonstrated by these studies can be extrapolated to other populations of coronary patients (e.g., women, older patients of both genders with low aerobic fitness, or patients at moderate to high cardiovascular risk) is not known.[4]

Arm versus Leg Exercise Training

Because exercise training is predominantly muscle-specific, both arm and leg exercises should be included in exercise rehabilitation.[53] The heart rate and blood pressure responses to leg work decrease following leg training, with only modest improvement in the response to arm work. Following arm training, the most prominent decreases in heart rate and blood pressure response occur with arm work. In one study, improvement in exercise response of the untrained limb was only 50 to 75 percent of the trained limb, suggesting that about half the increase in trained-limb performance is due to a generalized training effect; the remainder reflects predominantly improved oxygen extraction by trained skeletal muscle.

Since walk-run sequences or exercise on a stationary bicycle or treadmill train primarily leg muscles, supplementary arm exercise training is accomplished by selected repetitive calisthenics, shoulder wheels, rowing machines, and arm ergometers. When data from leg exercise testing are used to prescribe arm exercise, a reduction of about 10 beats per minute in target heart rate range is appropriate. The workload for arm training is about half that for leg training.[53] Since most occupational and recreational activities entail both arm and leg work (and often predominantly arm work), arm exercise training should be included in rehabilitative exercise.

The Effect of Cardiovascular Drugs on Exercise Training

Exercise training can occur in patients receiving antianginal drugs, which may lessen symptoms and improve the ability to exercise.[54] Although beta-blocking drugs decrease the heart rate and blood pressure response to exercise, they do not attenuate the improvement in physical work capacity that results from exercise training. Exercise testing undertaken to prescribe exercise should be performed with patients receiving medications that are planned for their training.

The Role of Exercise Testing in Coronary Rehabilitation

Graded exercise testing, using either a treadmill or a bicycle protocol, is safely performed within the initial weeks following MI.[55] Most centers currently test patients to a sign- or symptom-limited end point because heart rate limits are often inaccurate as a result of antianginal therapy effects on heart rate. Treadmill testing typically entails serial 3-min stages of walking, beginning at slow speed, initially on the level, and then at increasing speed and elevations; comparable test protocols are available for a bicycle ergometer (see Chap. 14). Arm testing may be undertaken in patients with claudication or musculoskeletal problems that make leg testing not feasible.[56]

The results of predischarge exercise tests, performed with or without radionuclide studies, contribute independent prognostic information for risk stratification.[55] High-risk patients are characterized by having a low exercise capacity [peak workload below 4 to 6 metabolic equivalents (METs)]; the occurrence of angina, ischemic ST-segment abnormalities, and/or exercise-induced hypotension at low levels of exercise; and the development of ventricular arrhythmias at low levels of exercise. Radionuclide evidence of myocardial ischemia or LV dysfunction with exercise also indicates an adverse prognosis. Predischarge exercise testing also identifies low-risk patients with a favorable prognosis who do not require additional diagnostic testing, are well-suited for accelerated rehabilitation, and for whom early discharge home and prompt resumption of preinfarction activities, including return to work, can be recommended.[55,57] The exercise test can help define safe levels of activity and guide the surveillance necessary during exercise rehabilitation. This permits simple, effective, accelerated, and less costly rehabilitation for low-risk coronary patients, reserving financial and personnel resources for high-risk patients who may derive substantial benefit from supervised exercise training. Satisfactory performance of an exercise test, coupled with explanation of its relationship to activities to be undertaken at home, may lessen the common fear of postinfarction patients that physical activity may result in reinfarction or death.[58] Such counseling also has been associated with an early return to work.[31]

Safety of Rehabilitative Exercise Training

The Clinical Practice Guideline *Cardiac Rehabilitation*[4] highlights the safety of cardiac rehabilitation exercise training in that randomized, controlled trials involving over 4500 coronary patients showed no increase in morbidity or mortality. A questionnaire survey of 142 U.S. cardiac rehabilitation programs, involving patients participating in exercise rehabilitation between 1980 and 1984, reported a low rate of nonfatal MI of 1 per 294,000 patient-hours and a cardiac mortality rate of 1 per 784,000 patient-hours.[59] Twenty-one episodes of cardiac arrest occurred, with successful resuscitation of 17 patients. A 1978 report[44] also described a low rate of fatal cardiac events during or immediately following exercise training: 1 per 116,400 patient-hours of participation. Definitive information is not available regarding the effect of levels of supervision and of ECG monitoring of exercise training on safety.

Chapter 50: REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

IMPLEMENTATION OF CARDIAC REHABILITATIVE CARE

Inpatient, or Hospital, Phase

The major components of rehabilitative care for patients hospitalized for a coronary event include progressive resumption of physical activity (early ambulation) and education and counseling of both patient and family (see also Chap. 42).

EARLY AMBULATION

Early ambulation is designed to limit the detrimental effects of deconditioning: reduced physical work capacity and maximal oxygen uptake; orthostatic intolerance, characterized by orthostatic hypotension and tachycardia (due both to hypovolemia and to a lessened cardiovascular reflex response); increase in blood viscosity owing to a decrease in plasma volume disproportionate to the decrease in red blood cell mass; and decrease in pulmonary ventilation. The decrease in muscle mass and muscular contractile strength renders muscular contraction inefficient, with more oxygen required for comparable work.

Guidelines[60] for physical activity in the coronary or surgical intensive care unit are for initial low-intensity exercise (1-2 METs), with gradual progression in work demand; supervision of progressive ambulation permits detection of inappropriate responses. Patients are encouraged to feed themselves, perform personal care, use a bedside commode, and sit in a bedside chair. Cardiac work is less in the seated than in the supine position. Sitting in a chair two or three times daily limits the hypovolemia of immobilization and resulting orthostatic hypotension. Exposure to gravitational stress, rather than physical activity intensity, appears to be the determinant in limiting hypovolemia, cardiac underfilling, and deterioration of oxygen transport capacity with effort intolerance.[61] Patients perform selected arm and leg exercises designed to maintain muscle tone and increase flexibility and joint mobility. Incentive spirometry is important for postoperative patients.

Disproportionate responses[60] to low-level activity include chest discomfort, dyspnea, or palpitations; a heart rate in excess of 100 beats per minute or lower than 50 beats per minute; ST-segment displacement on the electrocardiographic monitor; appearance of arrhythmias; or a decrease of more than 10 to 15 mmHg in systolic blood pressure. Although the latter usually indicates ischemic ventricular dysfunction, the vasodilator effect of nitrate, calcium channel blocking drugs, or ACE inhibitor therapy also must be considered. A systolic blood pressure response during low-level activity of more than 180 mmHg or a diastolic pressure response of more than 110 mmHg is an indication for antihypertensive therapy. Appropriate responses to ambulation indicate that the patient can progress to higher-intensity activity; disproportionate responses require activity restriction and clinical reassessment for unrecognized cardiac ischemia or ventricular dysfunction.

The major prescriptive hospital activity is walking, with stepwise increases in pace and distance. Patients who must climb steps at home should practice this in the hospital. Most household tasks require a work intensity of 2 to 3 METs. Electrocardiographic telemetry monitoring during ambulation is indicated for selected patients, e.g., those with serious ventricular arrhythmias or asymptomatic myocardial ischemia. A protocol for early ambulation and concomitant educational activities for patients with MI is applicable, with minor modifications, to postoperative coronary patients (Table 50-1).

Table 50-1: Inpatient Rehabilitation: Five-Step Myocardial Infarction Program (Revised 1996: Grady Memorial Hospital/Emory University School of Medicine)

Step	Date	M.D. Initials	Nurse/Exer Specialist Notes	Supervised Exercise	CCU/Step Down Unit Activity	Educational Activity
				CCU		
1	-			Active and passive ROM all extremities in bed	Partial self-care	Orientation to CCU
					Feed self	Personal emergencies, social service aid as needed
				Teach patient ankle plantar and dorsiflexion-repeat hourly when awake	Dangle legs on side of bed	
					Use bedside commode	
					Sit in chair 15 min, 1-2 times/day	Bedside teaching (CCU staff)
2	-			Active ROM all extremi-ties, sitting on side of bed or bedside chair	Sit in chair 15-30 min, 2-3 times/day	Orientation to rehabilitation team, program
					Complete self-care	Smoking cessation
						Educational literature if requested
						Planning transfer from CCU
				Step Down Unit		
3	-			Warm-up exercises, 2-2.5 METs:	Sit in chair ad lib	Normal cardiac anatomy and function
					Walk in room	
				Stretching ROM	Walk to class with supervision	Development of atherosclerosis
				Calisthenics		
				Walk in hall 50-75 ft and back at slow pace	Out of bed as tolerated	What happens when myocardial infarction occurs
						Coronary risk factors and their control
						Diet
4	-			Teach pulse counting, Borg Scale	Tepid shower or tub bath, with supervision	Heart attack management:

				Medications
		ROM and calisthenics, 3 METs	Walk in corridor prn	Exercise
				Surgery
		Practice walking few stairsteps		Response to symptoms
				Family, community adjustments on return home
		Walk 300-500 ft bid		
		Instruct on home exercise		
				Work simplification techniques (as needed)
5	-	Continue above activities	Continue all previous activities	Discharge planning
		Check pulse counting		Medications, diet, activity
		Walk up flight of steps	Predischarge exercise test (as appropriate)	
		Walk 500 ft bid		Return appointments
		Continue home exercise instruction; present information regarding outpatient exercise program		Schedules tests
				Return to work
				Community resources
				Educational literature
				Medication cards

Neither early ambulation nor early hospital discharge adversely affects the short- or long-term morbidity or mortality of appropriately selected coronary patients.[60,62] Benefits include prevention of deconditioning, decrease in pulmonary atelectasis and thromboembolic complications, lessened anxiety and depression, and an enhanced sense of well-being, related to improved functional status. Improved functional status of

patients at hospital discharge has been associated with an earlier and more complete return to work.

EDUCATION AND COUNSELING OF HOSPITALIZED PATIENTS AND THEIR FAMILIES

The current abbreviated hospital stay limits the ability of health professionals to address the informational and learning needs of the patient, spouse, and family; to assist them through recovery; and to prepare them adequately for convalescence. Answering the questions or concerns of patients in a coronary or surgical intensive care unit (or during the preprocedure phase for elective coronary angioplasty or bypass surgery) can provide reassurance. Education includes a brief explanation of the medical or surgical problem(s), tests anticipated in subsequent days, and familiarization with procedures and equipment; this information helps patients adjust to a situation perceived as life-threatening. The temporary nature of most restrictions should be emphasized, citing that improved coronary status with recovery lessens the intensity of surveillance and care.

During the remainder of the hospitalization, providing more information and planning for discharge are appropriate. Increased knowledge can lessen anxiety and improve adherence to recommendations. Patients should be instructed about medications-the purpose, dosage, desired effects, and potential adverse responses of each. Many patients have not taken medications prior to a coronary event and may be unfamiliar with the problems of taking medications. Patients and family members should be taught the appropriate response to new or recurrent symptoms and how to gain access to emergency medical care.

Outpatient, or Ambulatory, Phase

About 70 percent of contemporary survivors of MI are younger than 70 years of age[10] and many patients following successful myocardial revascularization procedures are at low risk for proximate coronary events. Exercise rehabilitation for most low-risk coronary patients, particularly following myocardial revascularization, begins shortly after discharge from the hospital; these patients usually progress rapidly in increasing their intensity and duration of exercise, often without supervision. Coronary patients who are elderly; those with significant comorbidity, myocardial ischemia, heart failure, or serious arrhythmias; those with complications of MI or CABG surgery; or those with severe angina may require exercise surveillance of variable duration.[2,37,39,55] Outpatient exercise rehabilitation is best described by the characteristics of the exercise training and the requirements, duration, and complexity of surveillance, based on the patient's clinical and risk factor status, rather than by traditional phases of earlier years that typically had fixed durations and composition. This is concordant with responding to an individual patient's needs for exercise training rather than requiring a patient to conform to program phases or requirements.

Chapter 50: REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

THERAPEUTIC EXERCISE TRAINING

Therapeutic exercise training typically lasts for 8 to 12 weeks. Initial home exercise may involve progressive walking and walk-jog sequences or serial increases in the intensity and duration of use of a stationary bicycle. Videotapes may help guide and pace home exercise and are available for varying intensities of exercise training. Home-based exercise rehabilitation optimally includes planned communication and management by rehabilitation nurses and other specially trained personnel.[10,11]

In the early years of outpatient exercise rehabilitation, few patients had continuous ECG monitoring because ECG telemetry was not widely available. In subsequent years, complication rates were described as being lower in exercise programs with continuous ECG monitoring.[44] It remains unknown, however, whether ECG monitoring, closer medical supervision, and/or differences in exercise intensity were the safety determinants. More recently, continuous ECG monitoring has not been shown to provide added safety for low-risk patients during supervised exercise[59]; as a result, ECG monitoring is currently recommended only for high-risk patients and other selected patients with problems in exercising,[1,2,4,39] although some recommend more extensive ECG monitoring. Often, ECG monitoring is undertaken solely owing to its requirement for insurance reimbursement rather than based on medical need. Many patients in supervised exercise programs without continuous ECG monitoring or patients exercising independently can be taught either to check their heart rate response intermittently to ensure that it remains in the prescribed target heart rate range or to estimate exercise intensity by the rating of perceived exertion, as described by Borg.[64] In supervised settings, heart rate response can be documented by intermittent use of defibrillator paddles as ECG leads. A technique of value in maintaining appropriate exercise intensity in unsupervised settings is the "talk test," wherein patients exercise only to the level that permits continued conversation with an exercising companion, a level generally below the anaerobic threshold at which respiratory rate accelerates.

High-risk coronary patients may require supervised and often ECG-monitored exercise. These patients are characterized by having a markedly reduced exercise capacity, severely depressed ventricular function, complex ventricular arrhythmias, exercise-induced angina, ischemia, or hypotension at low exercise intensities, and/or the inability to self-monitor exercise heart rate. Because of their increased risk for adverse events, exercise training should occur, at least initially, in a medically supervised and probably ECG-monitored setting.[65] Because exercise-related cardiac complications may be increased not only in proximity to an acute coronary event, the need and duration of ECG surveillance of exercise for these high-risk patients remain uncertain. The uniform success of resuscitation with supervised exercise, despite the rarity of its application, suggests that exercise supervision may be beneficial for selected patients.[59]

Although recent studies document the efficacy of home-based exercise training and risk reduction guided by a specialized cardiac nurse manager, data are not available as to the efficacy of long-term risk reduction or long-term compliance with unsupervised exercise in the absence of management and supervision strategies. Several studies showed that all training regimens appeared to increase functional capacity more rapidly than occurred spontaneously.[11,29,30,47] Supervision of exercise may not entail an "all or nothing" approach; intermittent supervision may be feasible in a community facility, there may be periodic telephone transmission of the exercise

ECG of patients who exercise at home, patients may use inexpensive heart rate monitors during home exercise, or a combination of these techniques may be used. It is not known whether any of these approaches improves adherence to exercise or exercise safety; several studies of independent exercise showed a lack of coronary risk reduction.

The Clinical Practice Guideline *Cardiac Rehabilitation*[4] highlights alternative approaches to the delivery of cardiac rehabilitation services, other than traditional supervised group interventions, as effective and safe for carefully selected clinically stable patients. Transtelephonic and other means of monitoring and surveillance of patients can extend cardiac rehabilitation beyond the setting of supervised, structured, group-based rehabilitation. The feasibility, safety, and efficacy of these alternative strategies for exercise rehabilitation must be assessed in more diverse populations of patients with stable coronary heart disease, particularly elderly patients, those with ventricular dysfunction, and other patients of higher risk status.

Chapter 50: REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

MAINTENANCE EXERCISE TRAINING

Once patients attain their initial exercise goals, maintenance training can be undertaken or continued in community recreational facilities or at home. Because lifetime regular physical activity is necessary to maintain physical fitness, patients must achieve reasonable independence in exercising and remain involved in an exercise regimen that is social, enjoyable, convenient, and appropriate. Most coronary patients with prior exercise restrictions who can safely attain a 7- to 8-MET level of performance can safely progress to unsupervised exercise. Patients leaving supervised exercise programs may require counseling regarding the selection and initiation of long-term exercise in the community or at home.

Chapter 50: REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

EDUCATION AND COUNSELING OF AMBULATORY CORONARY PATIENTS

The behavioral approach to coronary risk reduction encourages and enables coronary patients to manage their illness, adopt and maintain healthy lifestyles, and improve adherence to medications and other recommended regimens.[66,67] Metaanalysis of 28 controlled trials of patient education showed that "education programs have demonstrated a measurable impact on blood pressure, mortality, exercise, [and] diet" and that other parameters are positively affected, although less consistently.[68] A combination of education, counseling, and behavioral intervention strategies seems most effective in promoting health, reducing risk, and favorably altering lifestyle.[4,10,66] Whether the same interventions are equally effective for men and women and across the life span remains unanswered because few studies have enrolled patients over 70 years of age or included women.

Patients with diagnosed coronary disease are at the highest risk for disability and death and thus constitute patients for whom untreated risk factors are most damaging.[69] Cardiac rehabilitation services provide an integrating structure for the multiple risk-reduction components of secondary prevention.

There is no evidence that the performance of CABG surgery per se encourages favorable modification of coronary risk status postoperatively.[70,71] Postoperative recurrence of coronary symptoms or deterioration of function following saphenous vein CABG surgery relates predominantly to progression of the underlying atherosclerosis both in the graft vessels and in the native circulation. Control of hypertension, diabetes, hyperlipidemia, and obesity and cessation of cigarette smoking,[72,73] with adoption of a physically active lifestyle, even at advanced age, may slow progression or induce regression of atherosclerosis and decrease the occurrence of subsequent coronary events.

Community resources that may be helpful in rehabilitation should be identified: counseling and guidance services, home-care agencies, vocational rehabilitation facilities and services for job training and placement, services for financial aid, outpatient coronary rehabilitation programs, and postcoronary groups or clubs. Participation in community heart clubs or educational groups may further facilitate rehabilitation; coronary risk reduction and other skills learned and practiced in these settings may encourage health-related behaviors and aid in reinforcing maintenance of these changes. Acquisition of knowledge appears to affect favorably both behaviors involving implementing recommendations for care and coping behaviors.[63]

Chapter 50: REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

CORONARY POPULATIONS WITH SPECIAL REHABILITATION NEEDS

Elderly Coronary Patients

Elderly patients constitute a high percentage of those with MI, CABG surgery, and PTCA and other transcatheter revascularization procedures. Complications of MI and myocardial revascularization are more frequent in the elderly, with prolongation of both immobilization and hospitalization predisposing to deconditioning; early ambulation can limit functional deterioration and decrease depression. In both medical and surgical coronary intensive care settings, the major educational strategy involves concise and repeated explanations, reassurance, and time and place orientation to help avert confusion and delirium. Teaching energy-conserving techniques for self-care and performance of household tasks helps maintain independent living, an outcome valued by elderly patients. Modification of conventional coronary risk factors is feasible and warranted, given the greater prevalence and severity of coronary disease at elderly age.

Elderly patients are also at high risk of disability following a coronary event. Recent trials of exercise rehabilitation have begun to include patients over 65 years of age and to evaluate outcomes in the elderly coronary population specifically. Although few studies and no randomized, controlled trials have addressed the efficacy and safety of exercise training and multifactorial rehabilitation in the elderly, the available studies provide important new information for clinical practice.

Elderly coronary patients in posthospital exercise regimens have exercise trainability comparable with that of younger patients participating in similar exercise rehabilitation,[35,74] with elderly women and men showing comparable improvement. One report found that exercise testing before hospital discharge was feasible in about half of patients aged 70 years or older with MI, enabling accurate risk stratification and exercise prescription.[75] No complications or adverse outcomes of exercise training in elderly patients were described in any cardiac rehabilitation study. Nonetheless, rates of entry referral to and participation in exercise rehabilitation were substantially lower among elderly than among younger patients,[9,33] and older women were even less likely to be referred than were older men.[34] Elderly patients are less fit after a coronary event, in part because of decreased fitness prior to the event. Adherence to exercise training was high (90 percent) in the reported studies,[35] and significant reduction in coronary risk factors occurred in elderly patients who participated in multifactorial cardiac rehabilitation.[9]

For elderly patients who exercise independently, emphasis should be placed on the importance of warm-up and cool-down activities because of the delayed return of the exercise heart rate to normal at elderly age. Walking provides an adequate training stimulus for many elderly patients because it constitutes a significant percentage of the decreased aerobic capacity of aging.[76] Running, jumping, and other high-impact activities should be limited to avoid musculoskeletal complications. Walking, bicycle ergometry, and/or walking in a pool in shallow water can favorably modify the decreased joint mobility of aging; enhance neuromuscular coordination, balance, and stability and thereby lessen propensity for falls; and improve endurance. Elderly individuals who exercise independently should be cautioned to decrease their exercise intensity in hot and humid environments.

Coronary Patients with Heart Failure

Impairment of exercise capacity with heart failure appears in part due to inadequate nutritive blood flow to skeletal muscle; factors other than lack of increase in cardiac output with exercise seem important, including the ability to decrease peripheral vascular resistance and possibly the adequacy of right ventricular function (see also Chap. 20). Patients with heart failure and normal cardiac output responses to exercise frequently improve their functional capacity with exercise training, whereas those with severe hemodynamic dysfunction with exercise often do not.[77] A combination of LV systolic dysfunction and residual myocardial ischemia may limit trainability. The ventricular ejection fraction predicts poorly both exercise capacity and the potential for improvement of exercise performance with training; some patients with substantial ventricular dysfunction have a normal exercise capacity and no symptoms or impairment of lifestyle.[78]

Most studies of exercise training of patients with heart failure and moderate to severe LV systolic dysfunction do not demonstrate deterioration in LV volume, wall thickness, or function.[79,80] Randomized, controlled clinical trial data of exercise training in postinfarction patients with an ejection fraction less than 40 percent showed that long-term home-based exercise may attenuate the unfavorable remodeling response and even improve ventricular function over time.[79] Peripheral (skeletal muscle) adaptations appear to mediate the improvement in exercise tolerance; exercise training can substantially correct the impaired oxidative capacity of skeletal muscle in chronic heart failure.[81] Exercise training also may improve peripheral artery endothelial function in patients with chronic heart failure.[82] Exercise training can augment both the symptomatic and functional benefits of ACE inhibitor therapy.[30] Even small improvements in symptomatic status and functional capacity can exert a substantial favorable impact on quality of life. Improved clinical outcomes are also described.[83] In both the supervised and at-home settings, low- to moderate-intensity exercise regimens provide benefit, although adverse events may occur in this high-risk patient group.[4]

Although the initial exercise training programs of patients with ventricular systolic dysfunction were predominantly supervised, typically with continuous ECG monitoring, other studies have described moderate-intensity, unsupervised exercise as safe and effective.[84,85] The optimal duration of exercise supervision and the duration and need for ECG monitoring of these patients remain uncertain but should be guided by clinical evidence of exercise-related ischemia and/or arrhythmia.[29] In a study of 105 ambulatory cardiac transplant candidates, nonsupervised prescribed walking at a target heart rate range close to baseline exercise test-determined anaerobic threshold produced significant improvement in peak maximal oxygen consumption and peak exercise tolerance in 38 of 68 clinically stable patients without adverse effects. After an average of 6 months of such exercise, 31 of these 38 patients improved sufficiently to be removed from the transplant list, with improvement persisting to 2 years.[86]

Additional important components of rehabilitative care for patients with significant activity limitations include teaching work simplification, particularly the pacing of daily living activities; working in a seated rather than a standing position; and taking frequent rest periods between activities.

Patients with Implanted Pacemakers and Cardioverter-Defibrillators

Exercise prescription is determined by the characteristics of the implanted pacemaker. Because most patients likely to exercise currently receive rate-responsive pacemakers, exercise testing can ascertain the appropriateness of the sensor response to the exercise intensity,[87] and reprogramming can be undertaken as needed.

The exercise target heart rate range for patients with implanted cardioverter-defibrillators should be set at 20 to 30 beats per minute below the threshold rate of the device to fire. This also enables

appropriate work-related activities.[88] Coparticipants in the exercise setting must be reassured that they cannot be harmed by physical contact with a patient whose cardioverter-defibrillator discharges.

Chapter 50: REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

PSYCHOLOGICAL ASPECTS OF CORONARY REHABILITATION

The importance of psychosocial variables in the prognosis of patients with established coronary disease has received increasing attention during the past decade. Although the type A behavior pattern previously received emphasis, currently the hostility component of type A behavior is regarded as its most adverse feature. High levels of anger and hostility appear associated with increased cardiac morbidity and mortality.[89,90]

Other major psychological problems in coronary patients involve anxiety, depression, denial, and dependence.[91] Denial of presenting symptoms may limit or delay access to care, often with adverse outcomes. "Appropriate" denial, characterized by confidence in a favorable outcome, often an effective coping strategy of patients with a coronary event, is associated with a favorable prognosis. Anxiety, which is often the initial psychological manifestation at hospitalization, is related to a fear of dying and may progress to depression as patients contemplate their potential inability to resume former family, occupational, and community roles. Anxiety and depression, the most common psychological complications of infarction, contribute to the failure to make satisfactory life adjustments, to return to work, to return to sexual function, and to engage in social activities subsequent to hospital discharge. Depression is reported to precede MI in 30 to 50 percent of patients. Depression is associated with increased morbidity and mortality following MI and CABG surgery[92,93]; patients with depression were five times more likely to die during the initial 6 months following MI than nondepressed patients.[94] Depression may be associated with social isolation, which may serve as an independent risk factor. The 6-month mortality of patients living alone was double that of patients living with others (16 versus 8 percent), and follow-up study of patients with angiographically documented coronary disease showed a 50 percent 5-year mortality rate among those most socially isolated, compared with 17 percent among those without these characteristics. The impact of social isolation on prognosis appeared independent of ventricular ejection fraction and other physiologic prognostic factors. Interventions against depression and social isolation following MI are currently being evaluated.

Many patients with successful physical recovery following MI or myocardial revascularization often have residual psychological impairment.[91] Two major strategies that appear to limit this complication are education and counseling and the initiation of a physical activity regimen. Many patients remain psychologically disabled because, inappropriately, they perceive an excessive severity of infarction and vulnerability to sudden death; safe resumption of physical activity provides reassurance and restores self-confidence.[58] In randomized exercise trials, exercising patients returned to sexual activity, to work, and to a near-normal lifestyle more rapidly and had greater improvements in work capacity, income, and job responsibility.[95] Both physical and psychosocial benefits occurred even with low-intensity exercise, particularly among older and sicker coronary patients. Despite the paucity of controlled studies, consistent moderate psychosocial benefit appears to result from combinations of structured exercise, education, and counseling.[63,96] Although the contribution of peer support in a group program has not been ascertained, it may be helpful given the predictive power of social isolation for coronary mortality.[97]

Chapter 50: REHABILITATION OF THE PATIENT WITH CORONARY HEART DISEASE

VOCATIONAL ASPECTS OF CORONARY REHABILITATION

A major goal of rehabilitative care for nonelderly patients recovered from MI or myocardial revascularization is resumption of gainful employment, a change in occupation if needed, and the resulting economic and psychological benefits. In the 1980s, about 80 percent of patients who recovered from uncomplicated MI and who were younger than 65 years of age and employed at the time of infarction returned to work within 2 to 3 months, typically resuming former jobs.[98] Despite this favorable early return to work, subsequent cessation of employment was high, with as much as a 20 percent decrement in continued employment between 6 months and 1 year. Comparable data are not available for patients with complications of MI or residual functional impairment, although their return to work is estimated at 25 to 33 percent.

These data contrast markedly with work resumption following CABG surgery. Despite a substantial decrease in symptoms, improvement in functional capacity, and reported enhancement of life quality and participation in leisure activities, return to work following coronary bypass surgery has been much less favorable than anticipated.[99,100] No difference in 10-year employment status was described between patients randomized to medical and surgical treatment in the Coronary Artery Surgery Study (CASS).[101] Return to work following PTCA is comparable with that following CABG surgery, although PTCA patients are reported to return to work more promptly.[100] Other reports described lack of confidence in the ability to return to work following PTCA, even when patients were physically able to do so.[102]

Most studies of the return to work have involved predominantly or exclusively men; recent examination of working women with coronary disease showed them to have a longer convalescence and even lesser return to work; whether this is a gender issue or reflects older age or greater occurrence of depression among women warrants study.[103]

For patients younger than 65 years of age following MI or myocardial revascularization, the indirect health care costs of disability, including lessened productivity, loss of income, welfare payments, and unemployment insurance costs, must be considered when the cost-effectiveness of rehabilitation is determined.[57,104-106] Coronary heart disease is the leading problem in the United States for which adults receive premature disability benefits under the Social Security system; almost one-fourth of men and women receiving Social Security disability allowances have permanent disability due to coronary disease. Following both MI and myocardial revascularization, symptomatic and functional improvement correlates poorly with the return to work and resumption of preillness lifestyle, with psychosocial status appearing as a more important determinant.[99] Since only about 15 percent of the U.S. labor force currently performs manual labor and this percentage decreases with older age, the severity of angina or heart failure in coronary patients only rarely precludes or delays return to work. Many nonmedical factors negatively influence resumption of employment: older age, adequate nonwork income, anxiety or depression, activity-induced symptoms, lower social class and less education, jobs involving high-level physical activity (more common among blue-collar workers), and perception of the coronary illness as job-related. Patients who fail to resume employment within 6 months after a coronary event are unlikely ever to do so.[107]

Among the medical reasons for failure to return to work are unwarranted medical restrictions or,

even more commonly, lack of professional assurance of the safety of so doing.[107] Exercise testing performed for risk stratification also can be used for work evaluation; it permits a relatively precise assessment of function that may help allay the apprehensions of the patient,[58] family,[108] physician, and employer about the capability and safety of return to work.[109] One randomized, controlled trial of occupational work assessment in a health maintenance organization population early following MI, identifying low-risk patients and counseling them about the appropriateness of prompt return to work, effected a 32 percent reduction in the duration of convalescence.[31] Extrapolation of exercise test data to job requirements should include an analysis of the job to be performed and differences in temperature, environment, intellectual demands, relation to meals, travel requirements, and emotional stress, among others. Nonetheless, patients without evidence of ischemia or arrhythmia during a symptom-limited standard exercise test typically are free of these problems when occupational static and dynamic work are combined.[110] Arm ergometry may be preferable for occupational assessment of patients who perform predominantly arm work.[53]

Furthermore, since most occupational work is intermittent, with brief periods of strenuous activity and longer intervals of low-level activity or rest, occupational myocardial work demand is lower than for the same level of steady-state exercise; cardiac output, blood pressure, and oxygen uptake do not approach steady state until about 2 min after the onset of work, explaining the tolerance of patients with modest cardiac impairment and limitation of cardiac output for significant workloads of short duration, when adequate rest periods are interspersed. Recommendations for full-time work should be for work levels approximating 30 percent of measured physical work capacity. Guidelines are available to assist physicians in assessing and establishing the employment of patients with coronary heart disease.[111]

Other nonmedical considerations also influence postinfarction or postrevascularization employment, particularly the financial, social, disability, and compensation benefits of not returning to work. Although appropriate physician and employer attitudes may facilitate reemployment, the viewpoint of the patient appears the major determinant. In a number of studies, the patient's preoperative perception about ability to return to work appeared to be the most important determinant.

Benefits to employers of cardiac rehabilitative care for their employees include earlier return to work, less disability, less absenteeism, reduced financial expenditures for sickness and disability payments, reduced training costs for replacement of personnel, and greater productivity.[1] Employers thus should encourage coronary rehabilitative care as a component of their managed care plans.

Part 7: SYSTEMIC ARTERIAL HYPERTENSION
Chapter 51:

HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

Authors: Henry R. Black, George L. Bakris, William J. Elliott

INTRODUCTION

Hypertension is the most common disease-specific reason for which Americans visit a physician. It is currently among the leading causes of morbidity and mortality in the world and is expected to have an even greater impact on the health of the public as more of the world becomes developed.[1] In addition to the morbidity and mortality directly attributable to hypertension, high blood pressure (BP) is a powerful risk factor (a condition or characteristic of an individual or a population) that in this case increases the likelihood that an individual or population will develop a wide variety of cardiovascular (CV) diseases (Table 51-1).[2-5] Hypertension even has been associated with an increased risk of certain cancers.[6-8] Some authors have failed to appreciate this relationship when attributing certain cancers to particular antihypertensive treatments.[9]

Table 51-1: Risks Associated with Hypertension

Cerebrovascular disease	Renal insufficiency
Coronary artery disease	Peripheral vascular disease
Heart failure	Premature mortality

All health care providers routinely encounter patients whose BP is elevated. In patients with definite hypertension (see below), the paramount consideration is the choice of treatment, but in an increasing number of individuals, lowering BP may be beneficial even if definite hypertension cannot be diagnosed. In the next decade, it is expected that more and more patients will become candidates for antihypertensive therapy, especially as trials demonstrate the benefits of treatment and pharmacologic approaches become safer and more effective. Furthermore, many citizens, perhaps of the majority of those over 40 years of age, who do not yet meet the criteria for pharmacologic treatment for hypertension will benefit from lifestyle modification, a presumably safe and cost-effective public health approach to reducing BP. Many of the lifestyle habits that lower BP or slow the rate of rise of BP probably should be incorporated into everyone's lifestyle very early.

This chapter reviews the risks imparted by elevated BP, discusses the pathophysiology of hypertension, and analyzes currently available and recommended tools to measure BP and evaluate patients with hypertension. Treatment both with and without drugs is discussed in light of the explosion of information furnished by clinical trials and the newer approaches to lowering BP created by an enhanced understanding of the mechanisms responsible for raising it. The techniques of molecular biology and the contribution of genetics to hypertension have dramatically increased physicians' appreciation of the complexity of the problem.

Hypertension is a disorder of circulatory regulation. The now-classic mosaic theory of the etiology of hypertension, which first was proposed in 1949 by Page, can be endorsed even more enthusiastically in light of current knowledge.[10] No longer can one expect a simple explanation of why BP is elevated in an individual patient or expect that a single approach to therapy will be successful in the majority of those who are treated.

However, with all the progress that has been made in identifying the risks associated with elevated BP and all the efforts to develop ways to lower BP and prove that they work, the situation in the United States leaves much to be accomplished.[11,12] Only 27.4 percent of hypertensive Americans ages 18 to 74 in the period 1991 to 1994 had a BP of <140/90 mmHg, the current goal.[11] The data are still worse for those ≥75 years of age, and the goal may well be too high in some subpopulations of hypertensives, particularly those with diabetes mellitus (DM) and/or renal disease with proteinuria. The record in the rest of the world is much worse.[13-17] Although the United States does better than other countries, much still needs to be done here and elsewhere. One must understand hypertension better to give optimal care to the 1.2 billion hypertensives estimated to be living by the year 2010. Physicians must strive to prevent as much of the enormous morbidity and premature mortality that one can predict will result.

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

DEFINITION

Blood pressure is a continuous variable, and whatever number is used to define hypertension will be arbitrary. In the past several decades, the levels at which definite hypertension is defined as beginning have changed from >160/95 mmHg to >140/90 mmHg. Although there is still some disagreement, most authorities now agree on several important principles:

- Hypertension should be defined by both systolic and diastolic BP levels.
- Simply defining and consequently categorizing individuals as hypertensive or not only on the basis of their BP levels neglects the value of using the presence or absence of other risk factors, comorbidity, and target organ damage (TOD) to assess prognosis and ultimately to guide therapy. Thus, the Sixth Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC VI), the World Health Organization/International Society of Hypertension (WHO/ISH), and the British Hypertension Society (BHS) use a more comprehensive system to define hypertension (Table 51-2). These definitions are based on properly measured office readings (see below). The definitions of hypertension for home and ambulatory measurements are different. Blood pressure >135/85 mmHg for 24-h ambulatory monitoring or home monitoring is the usual level considered to be where hypertension starts. Although home or ambulatory measurements are useful, it is not appropriate routinely to use those values to diagnose most individuals. Office readings remain the standard. In certain situations, especially when an individual claims to have multiple "normal" readings outside the physician's office (see below), it may be reasonable to rely more on out-of-office measurements.
- The treatment approach to individuals with elevated BP should not focus simply on the BP level, which assesses the relative risk that is imparted by that BP, but also on the remainder of the CV risk profile, which estimates the absolute risk of events that an individual with that particular BP and risk profile will face. In the JNC VI classification and stratification of hypertension, for example, the stages (optimal to normal to high normal through stages 1 to 3) represent increasing relative risk as BP rises, while risk group A-C denotes increasing absolute risk as other risk factors and TOD are superimposed on the level of BP (Table 51-3).

It is not of major significance whether hypertensives are classified as being in a stage as recommended by JNC VI or a class per WHO/ISH.[11,18] What is important is that one base the evaluation and care of hypertensive patients on more than the BP number. Black and Yi have suggested that reimbursement for care of a hypertensive patient be based on the stage and risk group into which that patient falls, but to date such a system has not been implemented.[22]

Table 51-2: Threshold Values for 'Normal' versus 'Abnormal' BP (in mmHg)

Source	Office Readings	Home Readings	ABPM Readings
JNC VI	140/90		
Ohasama	140/90	137/84	
French	140/90	127/83	
ASH	140/90	135/85	135/85
Staessen	140/90		133/82

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

EPIDEMIOLOGY AND RISK

Physicians generally do not concern themselves with reducing BP when it is elevated because of the specific clinical problems they can attribute to that elevation. Instead, hypertension is treated because of the increased risk of mortality and CV disease that results from having an elevated BP (Table 51-1).

These risks have been well documented in numerous epidemiologic studies, beginning with the Framingham Heart Study and many others in the 1950s and 1960s and extending to the present.[23-29] More recently, meta-analyses of pooled data have confirmed the robust, continuous relationship between BP level and cerebrovascular disease and coronary artery disease (CAD) in both western and eastern populations.[30,31] In addition, BP is directly related to left ventricular hypertrophy (LVH) and heart failure (HF), peripheral vascular disease (PVD), carotid atherosclerosis, renal disease, and "subclinical disease."[4,5,32,33] Kannel and colleagues in the Framingham Heart Study have documented the fact that CV risk factors tend to cluster in hypertensives.[34] Hypertensives are more likely to have dyslipidemias, especially elevated serum triglycerides and low levels of high-density lipoprotein cholesterol (HDL-C), and type 2 DM. The common denominator may be insulin resistance, perhaps as a result of the frequent association of hypertension and obesity.[35]

In the last several years, it has become increasingly clear that the risks attributed to hypertension are much more strongly related to the level of systolic BP than to diastolic BP, especially in those over age 50 or 60 years.[36,37] The observation that systolic BP predicts events and TOD better than diastolic BP was persuasively argued in the early 1970s, but it took until 1993, in the Fifth Report of the Joint National Committee on the Detection, Evaluation and Treatment of Hypertension, before systolic BP was given even equal weight to diastolic BP in classification systems.[36,38]

Some have argued that one should not measure diastolic BP other than perhaps to calculate pulse pressure (PP).[39,40] Pulse pressure, the difference between systolic and diastolic BP, is an even better predictor of risk than is systolic BP in most of the epidemiologic studies done to date.[41-46] A wide PP, unless it is a result of aortic insufficiency or an arteriovenous malformation, is a simple clinical indicator of stiffer and less compliant large central arteries and significant arterial damage. Franklin and colleagues, again using data from the Framingham Heart Study cohort, showed that at all levels of systolic BP (even as low as 110 to 130 mmHg), risk is less with higher diastolic BPs.[46] More recent analyses by this group have suggested that these findings may be relevant only in those over age 60, and so it is not appropriate to ignore those with elevated diastolic BP level if their systolic readings are not above normal. The classification systems cited above have been careful not to include PP either in defining the risks of hypertension or in recommending treatment. A recently published position paper from the National High Blood Pressure Education Program has cautioned physicians not to rely on PP measurements until more support is gathered for this position.[47]

With the exception of hypertensive encephalopathy, it has long been felt that few, if any, clinical symptoms can be attributed to increased BP levels. This may have to be reevaluated, however, as newer and very well tolerated drugs are developed and as improved methods of assessing subtle

symptoms are perfected. Clinical trials with angiotensin receptor blockers (ARBs), for example, consistently show that the members of the actively treated group have fewer adverse reactions than do those given placebo.[48,49] Furthermore, in the Treatment of Mild Hypertension Study (TOMHS) and the Hypertension Optimum Treatment (HOT) trial, the group with the lowest BP had the fewest complaints.[50,51] These trials utilized a wide variety of drugs to reduce BP and clearly showed not only that lowering BP is safe but that hypertensives treated to lower levels feel better. Hypertension may not be the asymptomatic condition it has long been thought to be.

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

ECONOMICS

Cost considerations are playing an increasingly important role in the pharmacologic management of hypertension in the United States, and they have always been a major consideration in the rest of the world. No regimen, no matter how carefully and appropriately selected, will be effective if the patient cannot afford it. Moreover, if antihypertensive agents do not appear on the national formulary or the formulary of the insurance company from which a patient gets medication, the cost will not be covered and the patient may not be willing or able to purchase them. Generic preparations are available for every class of antihypertensive agent except ARBs, and these generic preparations tend to be the least expensive options for initial therapy. In general, branded calcium antagonists (CAs) are the most expensive, with ARBs and angiotensin-converting enzyme inhibitors (ACE-Is) the next most expensive drugs. For many of the fixed-dose combinations now available, the cost is less than what would be paid for the individual components if they were purchased separately. It is also customary for fixed-dose combinations that include a thiazide diuretic to cost no more than does the nondiuretic component alone.

A careful analysis of the economics of hypertension treatment has to include more than what is spent on drugs, patient visits, or laboratory tests.[52,53] For many affected (and especially high-risk) patients, the extremely expensive complications of under- and/or untreated hypertension far outweigh the inconvenience and costs associated with effective treatment.[53] Current estimates are that in the United States in the year 2000, hypertension will cost approximately $37.2 billion.[54] Nearly half this total is spent on indirect costs (death benefits for the families of those who die from untreated hypertension, disability payments for stroke survivors, time away from work, and transportation costs, to name a few) and payments to hospitals and nursing homes.[54] Both of these expenses could be reduced if hypertension treatment were more effective in controlling BP and reducing the risk of the clinical sequelae of hypertension, including myocardial infarction (MI), HF, stroke, and end-stage renal disease (ESRD).[55]

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

PATHOPHYSIOLOGY

Hypertension is a disorder of BP regulation and results from a multitude of causes. Control of BP involves a complex interaction among the kidneys, the central nervous system (CNS) and peripheral nervous system (PNS), and the vascular endothelium thoughout the body as well as a variety of the other organs, such as the adrenal and pituitary glands. The heart is the organ that responds to many of the changes mediated by these systems. It also secretes hormones locally and systemically that interact with substances produced elsewhere and help regulate BP levels. In those genetically predisposed to develop hypertension, an imbalance occurs among the various systems that modulate the level of BP. The sympathetic nervous system (SNS), the renin-angiotensin-aldosterone (RAA) system, vasopressin (VP), nitric oxide (NO), and a host of vasoactive peptides, including endothelin, adrenomedullin, and others produced by the heart and a host of different cells (endothelial and vascular smooth cells, for example), modulate the responses of these systems and help maintain BP over a range commensurate with optimum physical and mental activity. Additionally, these systems affect the ability of the kidney to handle sodium (Na^+) and volume, which Guyton and colleagues feel is the primary controller of BP.[56]

Sympathetic Nervous System and Renal Sodium Handling

Guyton and colleagues noted that while the SNS and the RAA system are important for short-term changes in BP, ultimately it is the kidney that is responsible for long-term blood volume and BP control.[56] High-pressure baroreceptors in the carotid sinus and aortic arch respond to acute elevations in systemic BP by causing a reflex vagal bradycardia that is mediated though the parasympathetic system and inhibition of sympathetic output from the CNS. Low-pressure cardiopulmonary receptors in the atria and ventricles likewise respond to increases in atrial filling by increasing heart rate (HR) through inhibition of the cardiac SNS, increasing atrial natriuretic peptide (ANP) release, and inhibiting VP release.[57-59] These reflexes are largely controlled centrally, particularly in the nucleus tractus solitarii of the dorsal medulla. This vasomotor center also receives input from the limbic system and hypothalamus in response to emotional or psychological stress.

The consequences of SNS stimulation are peripheral vasoconstriction, an increase in HR, release of norepinephrine from the adrenals, and a resultant rise in systemic BP. The increase in SNS activity also plays a role in mediating local vascular hypertrophy and stiffness. Renal efferent sympathetics also are activated and cause internal vasoconstriction with a fall in renal blood flow and an increase in renal vascular resistance.[60] The renal SNS also directly stimulates Na^+ reabsorption and renin release from the juxtaglomerular apparatus.[60-62] Thus, the SNS and CNS have effects on renal handling of Na^+.

Hyperactivity of the SNS has been described in patients with essential hypertension, particularly in the young and those with "high-normal" BP (130 to 139/80 to 89 mmHg).[63,64] Elevated plasma norepinephrine levels with increased HR and cardiac indexes have been described in people with newly diagnosed hypertension.[64] These individuals frequently show exaggerated BP responses to emotional (mental arthimetic) and physical stressors such as ice-water immersion. Additionally, a

subset of these patients exhibit elevated plasma renin levels that may reflect beta-adrenergic stimulation of renin secretion.

A defect in baroreceptor sensitivity has been postulated to be responsible for abnormal responsiveness of the SNS and thus may contribute to the increase in BP and HR variability noted in some hypertensive patients.[65] SNS activity also is increased in certain high-risk groups with hypertension, including African-Americans, those with obesity, those with insulin resistance, and those who ingest or inhale certain agents, such as nicotine, alcohol, cyclosporine, and cocaine.[66-68] A very small subset of patients may have hypertension caused by compression of the lateral medulla by cranial nerves and/or vessels.[60] This results in increased SNS activity. Selective decompression of these nerves may ameliorate the hypertension in rare instances. Activation of the CNS/SNS also may result from renal afferent sympathetics from the kidney in hypertensive patients. In experimental models of hypertension, renal sympathectomy resulted in a reduction in BP.[60,64]

The influence of the SNS on Na^+ handling in the kidney also has been examined in detail.[69] Several studies have linked SNS hyperactivity with greater than normal increases in BP in response to a given Na^+ load.[70-73] Indeed, Dahl and Heine were the first to show that hypertension can be transferred from a hypertensive Dahl salt-sensitive rat to a nonhypertensive Dahl salt-resistant rat by transplantation of the kidney.[70] Patients with essential hypertension and associated renal failure have been cured of the underlying hypertension by renal transplantation from a normotensive donor.[74]

Most authorities believe that the mechanism by which the kidney causes hypertension is impairment in the excretion of Na^+.[60,61,71,75-78] This impairment may be related to genetic changes in various Na^+ exchangers in the proximal and distal tubules that result in altered responses to stimulation by the SNS and the RAA system. Epidemiologic studies have linked the relative Na^+ content in the diet with the prevalence of hypertension in various populations, although the value of dietary Na^+ restriction in reducing BP remains controversial (see below).[79,80] Interventional studies with Na^+ restriction and/or loading have revealed that the BP responses in many hypertensive patients are "salt-sensitive": Their BP rises with a salt load.[81,82] In addition, several studies have shown that salt loading of patients with essential hypertension results in a net total body Na^+ accumulation. Three genetic diseases associated with hypertension in childhood (Liddle's syndrome, the syndrome of apparent mineralocorticoid excess, and glucocorticoid-remediable aldosteronism) all are associated with increased reabsorption of Na^+ by the kidney.[83]

A genetically mediated defect in the ability of the kidney to excrete Na^+ does not readily explain certain observations:

- Young hypertensive subjects appear to excrete Na^+ normally or supernormally.
- Individuals with high-normal BP may have a low blood volume.
- As many as 40 percent of people with hypertension do not show a change in BP with Na^+ loading ("salt resistance").
- With aging, salt sensitivity increases both in frequency and in degree such that by age 70, the majority of hypertensive patients are salt-sensitive.

In fact, it has been argued from meta-analyses that salt restriction is not important either in normotensives or in patients with hypertension under age 40.[84,85] All these findings are consistent with the possibility that the defect in Na^+ excretion in hypertensive patients is acquired rather than genetically determined. It should be kept in mind, however, that abnormal Na^+ handling is a

mechanism that contributes to elevating BP in many but probably not all patients with hypertension.

The Renin-Angiotensin-Aldosterone System

The RAA system is one of the most important physiologic mediators that regulate blood volume and BP. Plasma angiotensinogen, which is released primarily from the liver, is acted on by renin from the kidney to generate angiotensin I, which is further degraded in the presence of angiotensin-converting enzyme to angiotensin II (AII). In addition to the systemic RAA system, there is now evidence that a local RAA system is present in blood vessels, the heart, the kidney, and elsewhere, where it may mediate local effects (such as tissue remodeling) independent of circulating renin or angiotensinogen levels.

Most of the actions of AII are mediated by the AT_1 receptor and include stimulating vascular smooth muscle contraction and hypertrophy, increasing cardiac contractility, stimulating the SNS in the CNS and PNS, increasing NO production, causing aldosterone and VP release, and increasing thirst (Table 51-4).[86] Within the kidney, stimulation of the AT_1 receptor by AII also causes renal vasoconstriction (especially of the efferent arteriole and vasa rectae), a fall in renal blood flow, and an increase in renal vascular resistance.[87] Angiotensin II also increases Na^+ reabsorption both by increasing aldosterone release and through direct effects on the proximal tubule. Additionally, AII increases the sensitivity of the tubuloglomerular (TG) feedback response.

Table 51-4: Characteristics and Functions of AT_1 and AT_2 Receptors

AT_1 Receptors
Always expressed
Mediate vasoconstriction
Mediate growth
Smooth muscle proliferation
Stimulate connective tissue deposit in media
Facilitate low-density lipoprotein cholesterol transport to media
Inhibit endothelial function
Mediate renal tubular sodium reabsorption
AT_2 Receptors
Increased expression during stress or injury
Mediate vasodilatation
Inhibit growth (antiproliferation)
Decreased renal absorption of sodium

Angiotensin subtype 2 (AT_2) receptors also are stimulated by angiotensin II. These receptors produce virtually opposite actions in some experimental systems and are clearly active during fetal development (Table 51-4). Their role in healthy adults and even in those with cardiac or vascular damage is still uncertain.

The role of the RAA system in essential hypertension is complex. Whereas plasma renin activity (PRA) is elevated in 20 percent of hypertensive patients, PRA is either normal (50 percent) or low (30 percent) in the majority. However, in many patients with normal plasma renin levels, PRA may be inappropriately high in relation to total body Na^+. This has been suggested by the observation that Na^+ depletion accentuates and Na^+ infusion blunts changes in PRA levels in patients with hypertension. Additional evidence to support this concept comes from the observation that BP in these patients frequently is reduced after the use of ACE-Is or ARBs.[88]

Sealey and colleagues have suggested that the reason for widely varying PRA levels may be nephron heterogeneity within individual kidneys, in which there are some ischemic nephrons that make excess renin and other hyperfiltering nephrons in which renin secretion is suppressed.[89] They postulated that the increased renin release from the ischemic nephrons enters the circulation and then leads to AII generation, which causes inappropriate vasoconstriction and Na^+ reabsorption in the other hyperfiltering nephrons. This results in Na^+ retention and the development of hypertension.

Unfortunately, this is only part of the explanation, since PRA is relatively low in African-Americans and the elderly, two populations with a high prevalence of hypertension and a high rate of complications from hypertension. Low PRA, however, does not necessarily mean that the RAA is not active, since tissue effects and local actions are not necessarily evident from PRA alone.

Vasopressin

While VP has been clearly shown *not* to play a role in the genesis of essential hypertension, it does play an important role in the maintenance of established hypertension, especially in African-Americans.[90] In African-Americans, studies have shown that selective inhibition of V_1A receptors reduces systolic BP by an additional 8 to 12 mmHg in the presence of a high-salt diet (suppression of the RAA system) and clonidine (suppression of SNS).[91,92] Interestingly, this is not observed in whites. In light of the interaction between arginine vasopressin (AVP), AII, and endothelin on cellular growth and vascular responsiveness, it appears that AVP may have a potentiating effect on one of these other hormones.[93]

Endothelin

Endothelin is known to be the most potent vasoconstrictor in humans.[94] Comparative studies with AII have demonstrated not only that the endothelin family of hormones has cellular actions similar to those of AII but that the two hormones work in concert to potentiate each other's vascular and cellular effects.[95] Given this, however, the specific role of endothelin in the etiology of essential hypertension is minimal.[96] It plays a far more important role in cyclosporine-induced hypertension and decreased renal function as well as in maintaining BP in people with HF.[97]

Endothelin is the major mechanism by which cyclosporine constricts the afferent arteriole of the kidney and reduces renal function. Calcium antagonists and endothelin receptor blockade prevent this reduction. Additionally, endothelin A receptors have been shown to play a major role in contributing to the maintenance of elevated renal perfusion pressure in patients with HF.[98]

Nitric Oxide

Nitric oxide is the vasodilator produced by the endothelium in response to vasoconstrictor hormones, and so the contribution of NO to the maintenance of normal BP is vitally important.[99,100] Defects in NO release or synthesis that are induced by atherosclerosis or that are genetically programmed are a major determinant in predisposing individuals to the development of atherosclerosis and hypertension.[101] NO serves as a major counterbalancing factor that maintains BP within the range necessary to maintain organ perfusion but avoid injury. It counterbalances vasoconstrictive hormones, cytokines such as AII, platelet-derived growth factor (PDGF), tumor necrosis factor-alpha, and other hormones that stimulate its release. Transgenic animal models that do not have the ability to synthesize NO have very high BP and die of CV causes earlier than do animals that can produce NO.

Additionally, NO plays a major role in the genesis of hypertension in people who are insulin-resistant. The underlying mechanisms and the factors that may govern the interaction between insulin and NO have been studied extensively in healthy people and insulin-resistant subjects. It appears that a genetic and/or acquired defect of NO synthesis could represent a central defect that triggers many of the metabolic, vascular, and sympathetic abnormalities characteristic of insulin-resistant states, all of which may predispose to CV.[102]

Ion Transport Abnormalities

A number of dietary factors affect the SNS, the CNS, and the RAA system in those genetically predisposed to develop hypertension. These dietary factors, such as high Na^+ intake and low potassium (K^+), Ca^{2+}, and/or magnesium (Mg^{2+}) intake, may produce, worsen, or attenuate changes in BP. Substantial evidence from animal models of hypertension as well as diabetic and nondiabetic hypertensive individuals supports an association between the hypertension and changes in intracellular pH as well as electrolyte composition.[103-121] These observations have led to various hypotheses regarding the importance of one ion relative to others.

Numerous investigators have documented increases in cytosolic free Na^+ concentrations in cells of hypertensive or diabetic patients compared with age- and sex-matched normotensive or nondiabetic controls.[103-105] These increases result from altered activity of the Na^+/H^+ antiporter and the Na^+/Li^+ countertransporter. These increases in intracellular Na^+ are highly correlated with the presence of an elevated diastolic BP.

The relationship between intracellular Mg^{2+} and BP is less clearly defined. Data from experimental models of hypertension as well as from patients with hypertension demonstrate an inverse relation between intracellular Mg^{2+} concentration and BP elevation.[106,107] The primary mechanism responsible for this relative reduction in intracellular Mg^{2+} relates to Na^+-dependent Mg^{2+} efflux through the plasmalemma membrane.[112]

Increases in the intracellular Ca^{2+} concentration are seen commonly in obese and essential hypertensive subjects.[105,110] Like Na^+, these changes reflect altered membrane ion transport activity. Early clinical studies demonstrated that oral Ca^{2+} ingestion reduces BP, but the results from clinical trials do not consistently show a reduction in BP after Ca^{2+} supplementation.[120,121]

Increased K^+ intake is well known to have effects on BP control through multiple mechanisms, including opening K^+ channels in the vasculature, altering sympathetic neuronal output, and increasing vasodilatory prostaglandins.[122-125] This is exemplified by the fact that hypokalemia in

patients will blunt reductions in blood pressure by antihypertensive medication, perhaps because it results in the closure of K^+ channels.

Potassium also plays a role in modulating vascular responsiveness in salt-sensitive individuals. In a recent clinical study, increasing dietary K^+ for 3 weeks in 16 predefined salt-sensitive subjects and 42 salt-resistant subjects resulted in the conversion of all salt-sensitive subjects from nocturnal nondipping to dipping status[126] (see below). These results suggest that a positive relationship between dietary K^+ intake and BP modulation can exist even when daytime BP is unchanged by a high-K^+ diet.[126]

Taken together, these data suggest that both univalent and divalent cations affect vascular responses to stimuli such as those mediated by the RAA and the SNS. Changes in vascular responses are linked to altered function of membrane ion transporters (Na^+/H^+ antiporter, Na^+/K^+/ATPase, Mg^{2+}/Na^+ exchanger, Ca^{2+}/H^+ exchanger, Ca^{2+} ATPase, and others). Both the Na^+/K^+/ATPase and the Ca^{2+}/ATPase pumps are important in maintaining the Ca^{2+} homeostasis of the cell.

Extracellular Volume Homeostasis

Whereas an acute infusion of saline administered to animals with experimentally induced hypertension will initially raise blood volume and cardiac output, the increase in cardiac output is transient and is replaced by a rise in systemic vascular resistance (SVR).[71,72]

There are several potential mechanisms for this observation. First, the normal response to a salt load is inhibition of the SNS. However, it is known that in salt-sensitive patients, the SNS is not inhibited and even may be activated with a salt load.[127,128] A possible explanation is that in the setting of renal dysfunction or intrarenal ischemia, salt loading triggers an intense tuboglomerular feedback signal that activates the renal afferent SNS. This renal response subsequently triggers a CNS response. Indeed, there is evidence that renal afferent nerves activate CNS sympathetic activity in both experimental hypertension and chronic renal disease.

Second, parabiotic experiments have suggested there may be circulating factors in salt-loaded animals with hypertension that are responsible for some of the increase in SVR. One class of factors is circulating Na^+/K^+/ATPase inhibitors, which have been documented in some patients with essential hypertension.[129-131] These substances, one of which is ouabain, are digitalis-like and adrenally derived. Blaustein has suggested that these substances, which presumably are secreted in an attempt to facilitate Na^+ excretion, may have the adverse consequence of increasing intracellular Na^+ and thus facilitating Na^+-Ca^{2+} exchange in vascular smooth muscle cells. This would lead to a rise in intracellular Ca^{2+} and stimulate vascular smooth muscle contraction, vasoconstriction, and a rise in SVR.[110]

A third mechanism is the loss of a vasodepressor substance. There is good evidence that a lipid-like vasodepressor factor termed adrenomedullin is expressed in some of the interstitial cells in the renal medulla and the juxtamedullary region. Release of this factor into the circulation appears to depend on medullary blood flow and can be inhibited if activation of renal SNS or inhibition of NO reduces blood flow.[60] Thus, one might expect to see lower circulating levels of this substance in the setting of tubulointerstitial (TI) injury and intrarenal ischemia.

Fourth, the increase in pressure associated with a saline load could cause increased tension in the peripheral vasculature, leading to microvascular rarefaction (which has been observed in the forearms and nail beds of patients with essential hypertension) that could raise the SVR. An increased pressure load on the vessels also could result in compensatory vascular hypertrophy

mediated by local growth factors and the local RAA system. Indeed, there is evidence that AII, PDGF, and basic fibroblast growth factor are involved in these processes.

Mechanisms of Na^+ Retention in Essential Hypertension

A rise in systemic BP normally is associated with brisk natriuresis. This is thought to be due to a transient rise in pressure in the peritubular capillaries in the juxtamedullary region, with a subsequent increase in interstitial pressure and a backflow of Na^+ through the paracellular space of the proximal tubule. Numerous studies have confirmed that most patients with essential hypertension have a defect in the pressure natriuresis curve, in which higher systemic pressures are required to excrete a Na^+ load.[132,133]

A second mechanism for decreased Na^+ excretion is an enhancement of TG feedback. Tubuloglomerular feedback is a reflex vasoconstriction that occurs with chloride delivery to the macula densa, and the vasoconstrictive response will reduce glomerular filtration and Na^+ excretion. TG feedback can be enhanced in the setting of increased local vasoconstrictors such as AII and adenosine or by a reduction in local vasodilators such as NO. TG feedback appears to be enhanced in models of experimental hypertension.[132,134]

Finally, alterations in intrarenal vasoactive mediators may be involved in the impairment of Na^+ excretion in patients with hypertension. In both experimental and human hypertension, there may be low levels of renal vasodilators, such as prostaglandins, dopamine, and NO as well as elevated levels of renal vasoconstrictors such as AII and adenosine and increased activity of the renal SNS. In addition to their effects of enhancing TG feedback, alterations in the levels of these agents could contribute to net Na^+ reabsorption because of their direct effects on tubular Na^+ transport.

Some studies have shown that TI injury can be induced in rats with either catecholamine (phenylephrine) or AII infusion and that subsequently these animals will develop hypertension when placed on a high-salt diet.[134] Evaluation of these biopsies demonstrated focal areas of peritubular capillary rarefaction. This also has been observed in kidney biopsies of patients with essential hypertension. The loss of peritubular capillaries could help explain the impairment of pressure natriuresis. The ischemia related to the vasoconstriction and capillary loss could lead to alterations in the various vasoactive mediators. Indeed, there is some evidence that NO levels fall and adenosine levels rise with TI injury and ischemia, and this could contribute to the enhanced TG feedback that has been observed.[135,136]

While this pathway links a hyperactive SNS or RAA system with TI injury and salt-dependent hypertension, it is likely that TI injury induced in other ways could result in salt-sensitive hypertension. Indeed, it is of interest that TI disease is associated with reflux nephropathy, chronic pyelonephritis, DM, cyclosporine, radiation, lead and analgesic nephropathy, hypercalcemia/nephrocalcinosis, and gout, all of which are strongly associated with hypertension. In addition, it is noteworthy that many high-risk groups associated with salt-dependent essential hypertension, such as aged persons, obese persons, and African-Americans, have a high prevalence of TI disease.

Insulin Resistance

Insulin resistance is a metabolic disorder that is manifested by a reduction in peripheral skeletal muscle utilization of glucose.[35] To fully understand the contribution of insulin resistance to the genesis of hypertension, one has to evaluate the effects of insulin resistance and hyperinsulinemia on factors that contribute to BP elevation. High levels of insulin cause sodium retention and other

vascular effects, such as cellular proliferation and matrix expansion.[137] In the presence of hyperinsulinemia, neurohumoral factors such as AII, endothelin, and VP also potentiate proliferation of endothelial and vascular smooth muscle cells.[138] Lastly, the effect of insulin on various growth factors contributes to the development of vascular injury through its potentiation of the atherosclerotic process.[139] These factors in a person genetically predisposed to develop nephropathy can potentiate injury to the vasculature and end organs.

It should be noted, however, that not all subjects with insulin resistance have all the associated components of insulin resistance syndrome or syndrome X, i.e., lipid abnormalities, hyperuricemia, type 2 DM, glucose intolerance, hypertension, microalbuminuria, left ventricular hypertrophy, salt sensitivity, and obesity, among others. Studies in the normotensive offspring of hypertensive nondiabetic parents demonstrate the presence of insulin resistance.[140,141] This is also true for nondiabetic first-degree relatives of patients with type 2 DM.[142] Thus, a genetic predisposition seems to be needed to develop this syndrome.

Genetic Factors

Commonly accepted candidate genes associated with the genesis of hypertension are summarized in Table 51-5. Insulin resistance is clearly associated with hypertension. A possible genetic link between the presence of insulin resistance and the development of hypertension has been proposed.[143-146] Recent studies also have identified insulin resistance in the normotensive offspring of parents with essential hypertension. Saad and coworkers evaluated the association between insulin resistance and the propensity to develop hypertension in different racial groups.[147] Those investigators examined Pima Indians, whites, and blacks who were normotensive and nondiabetic. They noted that Pima Indians had higher fasting plasma insulin concentrations than did whites or blacks and lower whole body glucose disposal. They also noted a strong correlation between fasting plasma insulin concentrations and the rate of glucose disposal in whites but not in Pima Indians or blacks. Thus, the development of hypertension does not necessarily correlate with the presence of either hyperinsulinemia or insulin resistance in certain racial groups.

Table 51-5: Candidate Genes Associated with Hypertension and Cardiovascular Risk

Monogenic forms
Glucocorticoid-remediable aldosteronism
Liddle's syndrome
Polygenic forms that affect
Angiotensinogen gene
Na^+-Li^+ countertransport
Epithelial amiloride-sensitive sodium channel
Nitric oxide generation
Alpha-adducin
G_3 beta subunit (intracellular signal transduction)
Insertion/deletion of ACE gene

Work by various investigators to isolate a "hypertensive gene" or group of genes has been ongoing for many years. Abnormalities in the angiotensinogen gene identified by Caufield and coworkers provide evidence to link mutations in the angiotensinogen gene to the pathogenesis of essential hypertension.[148] A study of 179 hypertensive sibpairs from 69 type 2 diabetic kindreds showed that specific changes in the linkage of the angiotensinogen gene were highly correlated with the presence of hypertension.[149]

The delineation of a gene profile that will predict who will develop hypertension is near. A number of federally funded studies to gather sib pairs and families to identify candidate genes that predispose individuals to the development of hypertension are under way. Data from these studies may lead to the identification of such genes within the next 5 to 10 years. Thus, until these genetic profiles are delineated, it will be necessary to rely on the data garnered from epidemiologic studies to identify subjects at risk for the development of hypertension and CV events.

These are several clear examples of genetic influences in hypertension.

GLUCOCORTICOID-REMEDIABLE ALDOSTERONISM

This is an inherited autosomal dominant disorder that mimics an aldosterone-producing adenoma.[150] An important clinical clue to diagnosing this disease is the age at onset of hypertension. Patients with glucocorticoid-remediable aldosteronism (GRA) typically are diagnosed with high BP as children, whereas patients with other mineralocorticoid excess states, such as aldosterone-producing adenomas (APA) and idiopathic adrenal hyperplasia, usually are diagnosed in the third through sixth decades of life. A strong family history of hypertension is the rule, often associated with early death of affected family members from cerebrovascular accidents, as is seen characteristically in some GRA families.

In GRA, the RAA system is suppressed and aldosterone secretion is regulated solely by ACTH. As a result, plasma aldosterone levels usually decline during the course of an upright posture study, similar to what is seen in patients with APA.[151-153] The administration of exogenous ACTH to patients with GRA is associated with aldosterone hyperresponsiveness compared with normal subjects.[153] Moreover, in contrast to normal subjects in whom continuous ACTH administration is associated with a rise and a subsequent fall in aldosterone to basal levels over days, patients with GRA exhibit an exuberant aldosterone response that is sustained as long as ACTH is infused.

GRA is caused by a genetic mutation that results in a hybrid or chimeric gene product fusing nucleotide sequences of the 11-hydroxylase and aldosterone synthase genes.[154,155] Characterization of this chimeric gene indicates that it arose from unequal crossing between 11-hydroxylase and aldosterone synthase genes.[155] These two genes are located in close proximity on human chromosome 8, are 95 percent homologous in nucleotide sequence, and have an identical intron-exon structure. The structure of the duplicated gene contains the 5′ regulatory sequences that confer the ACTH responsiveness of 11-hydroxylase fused to more distal coding sequences of the aldosterone synthase gene.[153,154] Therefore, this hybrid gene is expected to be regulated by ACTH and have aldosterone synthase activity. This hybrid gene allows ectopic expression of aldosterone synthase activity in the ACTH-regulated zona fasciculata, which normally produces cortisol.[156,157] This abnormal gene duplication can be detected readily by southern blotting, allowing for direct genetic screening for this disorder with a small blood sample.

GLUCOCORTICOID RESISTANCE

The structure, growth, and secretory activity of the adrenal cortical zona fasciculata are regulated largely by ACTH. Only cortisol can inhibit ACTH release. An increase in ACTH release raises the levels of cortisol, which then inhibits the release of ACTH. This continuous inhibitory feedback effect of cortisol on ACTH release is interrupted in patients with glucocorticoid resistance. In this disorder, although cortisol levels are exceedingly high, ACTH release is not inhibited, leading to uninhibited ACTH secretion, which in turn stimulates the adrenal cortex to produce 11-deoxycorticosterone (DOC).[157] If sufficient DOC is secreted, salt and water retention ensue, precipitating hypertension and hypokalemia. Animal studies indicate that the mechanism for this may in part be related to changes in hippocampal steroid receptor building.[158]

Animal studies also indicate that an expressional downregulation of endothelial cell nitric oxide synthase (NOS III) may contribute to the hypertension caused by glucocorticoids. Ingestion of dexamethasone by telemetrically instrumented rats increased BP progressively over 7 days. Plasma oxidation products of NO decreased to 40 percent, and the expression of endothelial NOS III was found to be downregulated in the aorta and several other tissues in glucocorticoid-treated rats. Dexamethasone treatment significantly attenuated the relaxation to the endothelium-dependent vasodilator acetylcholine but not to the endothelium-independent vasodilator S-nitroso-*N*-acetyl-D,L-penicillamine. Additionally, incubation of human umbilical vein endothelial cells or bovine aortic endothelial cells with several glucocorticoids reduced NOS III mRNA and protein expression to 60 to 70 percent of control, an effect that was prevented by the glucocorticoid receptor antagonist mifepristone.[159]

LIDDLE'S SYNDROME

Liddle's syndrome is an autosomal dominant disorder that mimics the signs and symptoms of mineralocorticoid excess.[160] The fault appears to lie with continuously avid Na^+ channels in the distal nephron, resulting in excessive salt absorption and K^+ wasting (despite negligible aldosterone production) and severe hypertension.[161,162] A prominent feature is premature death from stroke or HF. The clinical manifestations can be corrected by triamterene and amiloride but not by spironolactone. Triamterene and amiloride directly block the Na^+ channel, whereas spironolactone inhibits Na^+ absorption by binding the aldosterone receptor.

The cellular defect associated with this syndrome is located on the apical portion of the tubule where the epithelial Na^+ channel (EnaC) located on the apical membrane plays a critical role in Na^+ absorption. Mutations in this channel cause diseases of Na^+ homeostasis, including a genetic form of hypertension (Liddle's syndrome inhibits cAMP-mediated stimulation of EnaC). Thus, the apical Na^+ channels and transepithelial Na^+ current are inhibited. Experimental data indicate that cAMP-mediated translocation of EnaC to the cell surface is defective in patients with Liddle's syndrome.[163]

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

DIAGNOSIS OF HYPERTENSION

Estimation of the pressure generated by the heart during its normal contractile cycle has been measured for more than 100 years. The value of such readings in predicting prognosis was recognized in the early 1930s by insurance companies, which probably have the best data correlating causal BP measurements and the risk of future disability and death.[164] Since the second half of the 1800s, palpation of the pulse and appreciation of the contour and pressure within a peripheral artery were skills learned only through extensive experience. Such subjective observations were supplanted by objective (albeit indirect) measurements after the introduction of the Riva-Rocci sphygmomanometer in the late nineteenth century.[165,166] This instrument was refined by Janeway and Korotkoff, who characterized the sounds heard when using a stethoscope placed over the compressed artery in 1906.[167-169] Even today, the terminology introduced by Korotkoff is still used: Systolic BP is recognized when clear and repetitive tapping sounds are heard; diastolic BP is recorded when the sounds disappear. Exceptions to these general rules are still recognized among patients who have audible sounds even down to zero mmHg and in obstetric patients: In both situations, the "muffling" of the sounds (Korotkoff phase IV) is recorded either in addition to the phase V measurement or as the diastolic BP, respectively.[170]

Techniques of Measuring Blood Pressure

The proper technique for accurate BP measurement typically is taught very early during medical training but then seldom is followed.[171-173] Many expert panels have made recommendations regarding the methodology of BP measurement, that frequently do not agree in all details, but several general principles can be extracted[174-177]:

- There are six sizes of commonly available BP cuffs (Table 51-6). Using a smaller than recommended cuff on a larger arm typically results in an overestimation of casual BP. In obese or muscular persons, the large adult-size cuff is required for all those with an arm circumference at the mid-humerus over 38 cm. In very large individuals, a "thigh" cuff is often necessary.
- In accurately measuring BP, the deflation rate of the column of mercury should be 2 to 3 mmHg/s. The lower rate of deflation should be used for persons with HRs less than 72 beats per minute (bpm); the more rapid deflation is appropriate only for those with resting tachycardia. If the precision of measurement is to be at least 2 mmHg, the observer should have the opportunity to hear at least one Korotkoff sound at each 2-mmHg gradation of the mercury column. Thus, the proper deflation rate depends on the HR of the subject and is unlikely to be more than 3 mmHg/s if a precise BP measurement is desired.
- It is unusual for a single BP measurement to be an accurate indicator of future CV risk; multiple measurements made on different occasions are more likely to be helpful in deciding whether a particular person ought to have his or her BP lowered. Although it is traditional to average the second and third of a series of BP measurements in a single position (e.g., supine, seated, or standing) and record this as the "average BP" at a given visit, recent "quality care guidelines" mandate instead the recording of individual BP measurements, with the lowest on a given date being the one of greatest interest to auditors. For these reasons, it is quickly becoming "standard practice" to record individual readings and is especially important to measure BP in several positions (including standing), since the auditors record only the lowest BP reading (in any position) as the "BP taken at that visit." The BP readings of many physicians participating in managed care audits are being judged as a "quality of care" indicator, and recording the largest number of BP measurements in several positions offers the greatest opportunity to have at least one which is deemed "acceptable."

- Most of the long-term data on hypertension and its treatment were derived from "casual" measurements made with a mercury sphygmomanometer and stethoscope in a health care provider's office. Physicians and patients often are more interested and impressed by BP readings taken in other settings (e.g., home monitors or ambulatory BP monitoring devices, both of which are discussed further below), but the great majority of data linking BP measurements to adverse clinical sequelae (including MI, stroke, and death) were made in the traditional fashion in the physician's office, and for now, office readings taken by a trained professional should be the BP used for diagnosing and treating hypertensives in all but a few special situations.

Blood pressure is subject to a large degree of intrinsic variability. Several steps can be taken to minimize this variability, including the following:

Table 51-6: Blood Pressure Cuff Names and Sizes

Cuff	Width, cm	Length, cm
Newborn	2.5-4.0	5.0-9.0
Infant	4.0-6.0	11.5-18.0
Child	7.5-9.0	17.0-19.0
Normal adult	11.5-13.0	22.0-26.0
Large adult	14.0-15.0	30.5-33.0
Thigh	18.0-19.0	36.0-38.0

- Taking multiple measurements, especially when the pulse is irregular (e.g., atrial fibrillation). This is necessary because ventricular filling pressures vary considerably as a result of variability of diastolic filling time. Blood pressure variability is especially pronounced in older persons with primarily or exclusively systolic BP evaluations.
- Centering the bladder of the cuff over the brachial artery with its lower edge within 2.5 cm of the antecubital fossa. This leaves enough space so that the stethoscope head can be applied inferiorly without touching the cuff (and generating background noise).
- Having the subject rest silently and comfortably (with back support if seated) for at least 5 min before the measurement.
- Abstaining from drinking caffeine or alcohol-containing beverages or tobacco use within 30 min before a BP measurement.
- Questioning the subject regarding the most recent meal or evacuation of bowels or bladder. Distended abdominal viscera not only are painful but routinely cause elevations in BP, presumably related to anxiety and pain. Older persons typically have a lower BP postprandially; thus, it is often necessary to inquire about and record when the last meal was eaten.
- Assuring that the arm is supported at the level of the heart. Both muscular work (of tensed muscles around the elbow) and hydrostatic pressure caused by a "dangling arm" increase the pressure necessary to obliterate the pulse and lead to overestimates of systolic BP.
- Listening over the brachial artery by using the bell of the stethoscope with minimal pressure exerted on the skin. At the conclusion of the BP measurement, there should be no lasting indentations in the area where the head of the stethoscope was placed. Otherwise the systolic BP is likely to be overestimated and the diastolic BP to be underestimated because too great a pressure was exerted directly over the artery.
- The "peak inflation level" of the mercury column should be determined by using palpation of the radial artery before the stethoscope is applied. For all subsequent BP measurements, the cuff typically should be inflated 20 mmHg higher than the pressure at which the palpable pulse at the radial artery disappears. Important prognostic information may be missed if the "auscultatory gap" is not detected; this risk is minimized by determining the peak inflation level by palpation before the

stethoscope is applied.

- Although mercury columns traditionally have been used in the measurement of BP, environmental concerns associated with elemental mercury are increasing. In Sweden and many other countries, elemental mercury is forbidden in the workplace. Nonetheless, sphygmomanometers used in the measurement of BP should be calibrated frequently and routinely against such standards (typically every 6 months) to assure accuracy.
- Attempting to avoid "terminal digit preference." Traditionally, BP measurements have been made to the nearest 2 mmHg (the typical markings on a mercury sphygmomanometer). Theoretically, in a large collection of systolic and diastolic BP measurements, there should be an equal number of readings ending in 0, 2, 4, 6, or 8 mmHg. It is often instructive to compare the actual distribution of terminal digits with the 20 percent expected for each one. This typically reveals a preference for 0 (in inpatient medical services, where BP readings are typically precise to ±10 mmHg) or 8 (for outpatients in a managed care organization being graded on how many people are <140/90 mmHg).
- Measurements of BP in both arms typically are obtained at the initial visit, and the arm with the higher BP is used thereafter if the difference is greater than 10/5 mmHg. In such situations, there is often concern about coarctation of the aorta or Takayasu's arteritis or moyamoya disease, but seldom is this seen on ultrasonography or other confirmatory testing. Blood pressure measurement in a leg should be commonplace in all young hypertensives at the first visit and may be useful in older people as a peripheral indicator of aortic insufficiency ("Hill's sign").
- Assuring that the equipment used to measure BP is in good working order. Many sphygmomanometers (even in hospitals) are in poor repair and should be cleaned, calibrated, and fitted with nonleaking tubing and properly sized cuffs. The interest in BP measurements recently demonstrated by agencies that certify health systems for quality has improved the chance that any given patient will be hospitalized in a bed with properly maintained BP-measuring equipment.

Home Blood Pressure Measurements

The technology for obtaining accurate and reproducible BP measurements outside the traditional medical environment has improved greatly in the last 20 years. Many types of machines now exist (Table 51-7) that are convenient, inexpensive, and relatively accurate. Even persons with hearing difficulties, problems with hand-eye coordination, and other disabilities can operate semiautomatic devices with digital readouts and printers to estimate BP. Some authorities feel that such devices should be provided to every person with elevated BP, but others are concerned about overinterpretation of the data, which generally have not been used commonly in clinical decision making in clinical trials and should not be used routinely in practice to make diagnostic or therapeutic decisions.

Table 51-7: Advantages and Disadvantages of Methods of BP Measurement Available to Patients in the Outpatient Setting

Attribute	Anaeroid with Stethoscope	Oscillometric with Stethoscope	Oscillometric with Digital Readout
Coordination necessary	Yes	Yes	Less so
Affected by presbyacusis	Yes	Yes	No
Affected by presbyopia	Yes	Less so	Less so
Widely available	Yes	Less so	Increasingly
Inexpensive	Yes	Less so	Increasingly
Good-quality results	Yes, with effort	Yes, with effort	Yes
Increases patients' interest in managing BP	Yes	Yes	Yes
Battery-powered	No	Yes	Yes

Affected by impaired grip strength	Yes	No	No
Independently validated by prospective studies	No	No	No

Home BP readings are typically lower (by an average of 12/7 mmHg) than measurements taken in the traditional medical environment, even in normotensive subjects.[21] Home readings tend to be better correlated with both the extent of TOD and the risk of future mortality than are readings taken in the physician's office.[182] Home readings can be helpful in evaluating symptoms suggestive of hypotension, especially if the symptoms are intermittent or infrequent. During treatment, reliable home readings can lower costs by substituting for multiple visits to health care providers.[183] Persons who routinely measure BP at home probably have a better prognosis than do those who do not because of both selection bias (they tend to be more interested in their BP than are those who refuse to purchase and use a home BP machine) and social support (when a friend or spouse becomes involved in measurement and overseeing pill-taking and appointment-keeping behaviors).

Home BP readings should be interpreted cautiously, carefully, and conservatively.[184] There are no data from long-term clinical studies that based all treatment decisions solely on home readings, but several preliminary reports show benefit from supplementing office BP measurements with home readings.[185-186] Several studies have shown that prognosis is better predicted by home readings than by one or two "casual" BP measurements.[187-189] Many of the factors that contribute to BP variability are more difficult to control in the home environment, including intrinsic circadian variation, food and alcohol ingestion, exercise, and stress. The possibility that home BP measurements will become an obsession is also a disadvantage. If home readings are to be taken, most authorities recommend that the instrument be calibrated against a mercury sphygmomanometer by using a Y-tube and that the technique of the measurer be checked. Home readings can be a useful adjunct to information obtained in the physician's office, especially when the two are widely disparate. One long-term study showed that people with much lower home BP readings (compared with those in the physician's office) suffer fewer major CV events than do people who have elevated readings both in the office and at home.[187,190] The authors recommend that patients who are interested in and capable of measuring their BP at home do it at a fixed time of the day and record all the readings obtained. The physician then can review them during the office visit and strive to educate the patients about the difficulties of interpretation of the readings.

Ambulatory Blood Pressure Monitoring

Extensive research has led to a better definition of the role of automatic recorders that measure BP frequently over a 24-h period during a person's usual daily activities (including sleep). Despite the acquisition and dissemination of excellent data, however, the use of these devices by practitioners in the United States has been extremely limited, mostly because of a lack of reimbursement by third-party payers. As a research tool, however, the advantages and disadvantages of ambulatory blood pressure monitoring (ABPM) have been well documented (Table 51-8), normal values have been defined (Table 51-2), and multiple publications correlating abnormal patterns of ABPM with adverse outcomes have appeared.[191,192] Several expert panels have defined the special situations in which ABPM is particularly useful (Table 51-9).

Table 51-8: Advantages and Disadvantages of Ambulatory Blood Pressure Monitoring

ADVANTAGES
Many BP and pulse measurements during 24-h period
Measures diurnal variation (including during sleep)
Measures BP and pulse during daily activities
Can identify 'white coat' hypertension
No 'alerting response'
No placebo effect
Better correlation with target organ damage than other methods
DISADVANTAGES
Cost
Limited availability of equipment
Disruption of daily activities from noise/discomfort (e.g., sleep quality, flaccid arm during measurement)
Limited 'normative' data
Limited guidelines (or consensus) for interpretation of data in individuals
Few long-term prospective studies demonstrating utility compared with traditional (and much less expensive) BP measurements

Table 51-9: Situations in Which ABPM is Useful

'High-normal' blood pressure without target organ damage
Office or 'white coat' hypertension
Refractory hypertension
Episodic hypertension
Symptoms consistent with hypotension associated with antihypertensive medication
Hypertension with autonomic dysfunction
Nocturnal hypertension
Evaluation of efficacy of antihypertensive drugs in clinical research

SOURCE: Adapted from the National High Blood Pressure Education Program's Working Group Report on Ambulatory Blood Pressure Monitoring. *Arch Intern Med* 1990; 150:2270-2280.

Several varieties of ABPM devices are currently available. In the United States, those which measure BP indirectly (i.e., without arterial cannulation) use either an auscultatory or an oscillometric technique. The former type uses a microphone placed over the artery to detect Korotkoff sounds in the traditional fashion.

The latter measures biophysical oscillations of the brachial artery, which are compared (using a standardized algorithm) with those observed with a mercury sphygmomanometer: Systolic BP is determined directly from the threshold oscillation, mean arterial pressure is estimated, and diastolic BP is calculated. Both types of monitors are small (<450 g), simple to apply and use, accurate, relatively quiet and tolerable, and powered by two to four small batteries. Data from 80 to 120 measurements of BP and pulse typically are stored in a small microprocessor and then downloaded into a desktop computer, which then edits the readings and prints the report.

None of the currently available ABPM devices is completely without problems. Devices that rely on direct measurements require 24 h of arterial cannulation, which is potentially dangerous, and rarely are used even for research. Indirect measurements of BP using auscultatory techniques can be confused by ambient noise levels even if R-wave gating is used (this requires the electrocardiographic leads to be attached to the chest). Oscillometric techniques require that the subject keep the arm straight and flaccid during the measurement and can be completely confused if the subject has a tremor. The interpretation of ABPM readings may be enhanced by a diary of the subject's activities, but such diaries are not always completed.

ABPM makes it possible to measure BP routinely during sleep and has reawakened interest in the circadian variation of HR and BP. Most normotensives and perhaps 80 percent of hypertensives have at least a 10 percent drop in BP during sleep compared with the daytime average. Although there may be some important demographic confounders (blacks and the elderly have less prominent "dips"[193,194]), several prospective studies have shown an increased risk of CV events among those with a "nondipping" BP or pulse pattern.[195-197] However, there is concern, based on several Japanese studies, that elderly persons with more than a 20 percent difference between nighttime and daytime average BPs ("excessive dippers") may suffer unrecognized ischemia in "watershed areas" (of the brain and other organs) during sleep if their BP declines below the autoregulatory threshold.[198]

During the last 15 years, research has demonstrated an important correlation between ABPM readings and the prevalence and extent of TOD in hypertensives. Compared with "casual" BP measurements (obtained in the health care provider's office), ABPM measurements clearly are a better predictor of LVH, cardiac function, and overall scores summing optic, carotid, cardiac, renal, and peripheral vascular damage resulting from elevated BP.[199-201] Ambulatory BP monitoring also may be useful in identifying the small minority of typically unrecognized patients [61 of 234 (26 percent) in New York City] with "white coat normotension" who have normal BP readings in the physician's office but elevated ABPM readings with LVH and carotid wall thickening similar to that usually seen in sustained hypertensives.[202]

Perhaps the most important data demonstrating the value of ABPM have come from recent end-point studies of CV events (death, MI, stroke). In the first published study of outcomes in central Italy, ABPM was the best predictor of future CV events; "nondipper hypertensives" had approximately three times the risk of hypertensives whose BP was ≥10 percent lower at night compared to daytime ("dippers").[195] A population-based study involving 1572 men and women of ABPM versus casual and home BPs has been ongoing since 1987 in Ohasama, Japan.[188] After an average of approximately 5 years of follow-up, there was no significant relationship between one casual BP measurement and future CV mortality. However, there was a highly significantly increased risk of CV death in the quintile with the highest ABPM, and the lowest risk was found in those in the lowest quintile of ABPM.[189] The value of ABPM in refractory hypertension was demonstrated in a study of 86 hypertensive people taking on average three antihypertensive medications daily.[203] Follow-up data were collected approximately 4 years after an ABPM was performed; the patients having ABPM results in the lowest tertile had significantly lower rates of CV complications: 2.2 versus 9.5 versus 13.5 events per 100 patient-years. These data suggest that ABPM may be helpful in sorting out which patients with elevated office BP measurements who already are taking multiple antihypertensive medications ought to have intensified treatment and which ones can be spared the additional expense and risk. A subsidy of the Systolic Hypertension in Europe (Syst-EUR) trial involved 808 patients who had ABPM in addition to the usual clinic BP measurements before randomization to placebo or active treatment.[197] In the group randomized to placebo, ABPM was clearly a better predictor of future CV events than was the office BP measurement. Active treatment reduced the difference in prognosis

among ambulatory and office measurements. Furthermore, the risk of a CV event was much higher in patients who did not display a nocturnal decline in BP. These data suggest (but do not prove) that the poor prognosis seen with nondipping hypertension can be mitigated by active antihypertensive treatment.

White Coat Hypertension

Since the advent of technology that allows accurate BP measurement outside the health care provider's office, it has been estimated by many but not all reports that 10 to 20 percent of American hypertensives have substantially lower BP measurements in other settings.[204] The name *white coat hypertension* has been given to the situation in which BP measurements outside the health care setting are considerably lower than those in it even though the "white coat" itself is unlikely to be the only factor that increases BP. Careful studies originally done in Italy and later corroborated in other countries show that BP rises in response to an approaching physician who is not previously known to the subject. This apparently does not happen if the subject is approached by a nurse even if she or he is wearing a white coat.

The clinical consequences and prognostic significance of white coat hypertension have been hotly debated in the medical literature for some years. One school of thought suggests that if a person has an acute rise in BP caused by stress related to an approaching physician, similar elevations in BP are likely whenever a stressful stimulus is encountered. Thus, some of the literature supports the concept that the white coat response is merely a precursor to "more substantial and more sustained hypertension."[205] This point of view is buttressed by the realization that in several clinical and population-based studies, white coat hypertension also is found in people with a greater prevalence of subclinical risk factors for CV, including LVH, a family history of hypertension and heart disease, hypertriglyceridemia, elevated fasting insulin levels, and lower HDL-C levels.[205-208]

A second school of thought, based on more careful and conservative definitions of the white coat effect, proposes that some individuals consistently show a similar and marked elevation in BP in response to the health care environment. Using somewhat more stringent criteria than the studies cited above, several long-term studies have shown a greatly reduced risk of either TOD or major CV sequelae among people with lower BPs measured either at home or by 24-h BP monitoring compared with measurements taken in the same person in the physician's office.[187,190,195] Whether the future risk of such individuals for CV events is similar (or even identical) to that of completely normotensive people is open to question. A third group has claimed that white coat hypertension simply represents regression to the mean in those with considerable BP variability.[204]

The best approach to the treatment of white coat hypertension is unresolved. Clearly, such individuals would benefit from lifestyle modification, which presumably would reduce the probability of progression to sustained hypertension. Completely abstaining from antihypertensive medication in "white coat hypertensives" appears unwise. Verdecchia and colleagues have published data indicating that in the long term, the risk of future CV events did not differ between white coat and sustained hypertensives when both were treated with antihypertensive medications.[209] Whether intensive treatment with continuous antihypertensive medication is warranted for only temporary increases in BP is debatable. Clearly, the treatment and repeated ABPM sessions required to monitor therapy would not be very cost-effective. The cost-effectiveness of ABPM to diagnose and monitor people with white coat hypertension has been estimated by several groups, primarily because 10 to 20 percent of hypertensives might be spared the cost of treatment and close follow-up.[210-212] One ABPM session annually has been set as the upper limit of what most American health plans could afford.[213] Several authoritative groups have recommended that ABPM be used sparingly in the general antihypertensive population but may be more widely used in managed care, veterans' hospitals, and other situations where minimal incremental direct costs are involved.[213,214]

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

EVALUATION OF THE HYPERTENSIVE PATIENT

Six key issues must be addressed during the initial office evaluation of a person with elevated BP readings:

- Documenting an accurate diagnosis of hypertension (see above)
- Defining the presence or absence of TOD related to hypertension
- Screening for other CV risk factors that often accompany hypertension
- Stratifying risk for CVD (according to risk Group A, B, or C in JNC VI)
- Assessing whether the person is likely to have an identifiable cause of hypertension (secondary hypertension) and should have further diagnostic testing to confirm or exclude the diagnosis
- Obtaining data that may be helpful in the initial choice and subsequent choice of therapy

There are many diagnostic possibilities for explaining a single set of elevated BP readings (Tables 51-10 and 51-11). Aside from those who take one of several types of drugs known to elevate BP, many persons with only one elevated BP reading will have their BP decline and return to the normal range. This is the reason for recommending multiple encounters (at least two or three) before a diagnosis of hypertension is firmly established.

Table 51-11: Drugs Known to Elevate Blood Pressure

Nonsteroidal anti-inflammatory drugs
Sympathomimetic amines (e.g., phenylpropanolamines)
Estrogen and estrogen analogs (e.g., oral contraceptive pills and hormone replacement therapy)
Methylxanthines (e.g., theophylline, caffeine, theobromine)
Cyclosporine
Erythropoietin
Cocaine
Nicotine
Phencyclidine ('angel dust')
'Herbal ecstasy' (and other ephedra-containing substances)
Withdrawal from certain drugs (e.g., beta blockers, alpha agonists, opioids, ethanol, calcium antagonists)

Routine Evaluation in All Hypertensive Patients

The recommendations of JNC VI and other national and international expert panels limit the number of and the expense related to initial tests for the routine evaluation of a hypertensive patient[11,18,19] (Table 51-12). Those which are used in assessing the presence or absence of TOD include physical examination, blood urea nitrogen (BUN)/creatinine, electrolytes, urinalysis, and an electrocardiogram (ECG). Assessing the number of CV risk factors can be accomplished with the medical history, chemistry panel [glucose, total

cholesterol (TC), triglycerides], and urinalysis. The JNC VI suggests stratifying patients' risk for CV into three risk groups (Table 51-3). Other national expert panels have even more elaborate systems for linking the assessment of CV risk and the intensity of antihypertensive treatment.[19,215]

Table 51-12: Routine Tests Recommended by JNC VI for the Initial Evaluation of a Hypertensive Patient

Serum chemistry (glucose, potassium, creatinine)
Urinalysis
Electrocardiogram

Several elements of the evaluation of a hypertensive patient warrant further comment. The physical examination needs to be "directed" toward looking for clues that might indicate an identifiable secondary cause of hypertension such as an abdominal or flank bruit, which would be a sign of visceral atherosclerosis or perhaps renal artery fibromuscular disease, or an abdominal or flank mass that might be a pheochromocytoma or a polycystic kidney.

Proper examination of the optic fundus often is neglected even though it is a valuable tool for evaluating hypertensive patients. In the years before effective antihypertensive drug therapy became available, the most important predictor of future CV mortality and morbidity was not the level of BP but in the appearance of TOD in the optic fundi.[216] Although the prognosis of hypertensive patients has improved greatly since that time, the appreciation of hypertension-related changes in the optic fundus is still important in the assessment of both the severity and the duration of elevated BP. The optic fundus is the only site in the entire body where blood vessels can be examined directly. Very few patients with a recent onset of hypertension have Keith-Wagener-Barker (KWB) grade III or IV fundi (Table 51-13).

Table 51-13: Keith-Wagener-Barker Classification of Optic Fundi

Grade	Characteristic Finding
I	Arterial tortuosity, localized arterial spasm or narrowing (relative to neighboring vein), 'silver wiring'
II	Extensive or generalized arteriolar narrowing, resulting in arteriovenous crossing changes ('arterial nicking')
III	Hemorrhages or exudates
IV	Papilledema

Arteriosclerosis can be directly recognized, and the severity and duration of previous hypertension can be estimated through the appreciation of abnormalities of the retinal arteries.[217] The normal yellowish-white color of the retinal arteries gradually changes to a reddish-brown tone ("copper wire"), and the ratio of artery/vein diameters is reduced from the normal 2:3 to less than 1:3. Over time, the column of blood within the artery gradually diminishes and the artery is reduced to a whitish thread ("silver wire") despite a persistent (albeit reduced) flow of blood. "AV nicking" is perhaps the most easily recognized ocular abnormality in hypertension. When the thickened artery containing blood at elevated pressure compresses a low-pressure, thin-walled vein within the shared adventitial sheath, the vein disappears from view. Hypertension is therefore both epidemiologically and pathophysiologically a risk factor for retinal vein occlusion, although this is not a common occurrence.[218,219] When arterial blood flow is reduced sufficiently to cause infarction of underlying retinal tissue, round to oval white patches with fluffy borders are formed ("cytoid bodies" or "cotton-wool spots"). When there is breakdown in the blood-retinal barrier

(caused by a ruptured aneurysm, neovascularization-typically in diabetics-or "blowout" hemorrhages resulting from hypertension), intraretinal "flame-shaped" hemorrhages can be recognized on direct ophthalmoscopy. The leakage of plasma into the macular space often causes an acute reduction in vision and leaves behind the "macular star figure" for years thereafter. Grade IV retinopathy (papilledema), which is the hallmark of either retinal vein occlusion or a hypertensive emergency, usually is caused by ischemia in the optic nerve circulation resulting from increased intraocular or intracranial pressure and diminished axoplasmic flow in the optic nerve fibers. In some cases, particularly when BP is not exceedingly high and there is no other evidence of acute TOD from a hypertensive emergency, another cause should be sought. Papilledema without other evidence of hypertensive retinopathy generally is due to another etiology.

The impact of controlling hypertension on ophthalmic end points (e.g., vision loss, retinal hemorrhages, and laser photocoagulation procedures) has not received much attention in the general medical literature. There are nonetheless several reports of reduced risk of these end points in several clinical trials that assessed their incidence prospectively, particularly among diabetic hypertensives.[220-222]

Cardiac Evaluation

One of the most important elements of the physical examination of hypertensive patients is the cardiac examination. An atrial (S_4) gallop is an extremely common finding and may be a vital clue to the presence of hypertensive heart disease.

A key part of the laboratory evaluation is directed at determining whether LVH is present. The ECG is currently recommended by nearly all authorities as part of the initial evaluation of persons with hypertension. Not only is the ECG useful in documenting previously undetected MI, myocardial ischemia, and/or cardiac rhythm disturbances, it is the least expensive and possibly the most cost-effective way to diagnose and/or exclude LVH. Although several studies have suggested that compared with echocardiography, computed axial tomography (CAT), or magnetic resonance imaging (MRI) of the heart, the ECG is perhaps only 10 to 50 percent sensitive (depending on which criteria are used) and at best 80 percent specific, the expense of these more accurate methods of screening for LVH limits their use.[223-225] A "limited echocardiogram" that accurately calculates left ventricular (LV) size at a very affordable price and also provides information about ventricular geometry has been recommended by several authorities but has not been commonly endorsed by third-party or other payers.[226]

The prognostic significance of LVH among hypertensive patients is well established. Left ventricular hypertrophy often is thought of as the "hemoglobin A_{1c} of BP," since it is an objective measure of both the severity and the duration of elevations in BP. In the Framingham Heart Study, ECG evidence of LVH was associated with an approximately threefold increase in the incidence of CV events.[227] Echocardiographically detected LVH appears to predict an even greater incremental increase in the risk of future CV events, although the geometry of the ventricle also may play a role.[228,229] Hypertension typically is associated with concentric hypertrophy of the ventricle, perhaps as a result of concentric remodeling, which in one series carried a fourfold increased risk of cardiac morbidity and mortality (compared with nonhypertrophied hearts).[230] Eccentric hypertrophy, which is seen in response to exercise in athletes, imparted only a twofold increased risk of events in the same series.[229] In several reports from various locales, in both univariate and multivariate models, LVH was the most powerful of any of the traditional CV risk factors in predicting not only death or MI but also stroke, HF, and other CV end points.[228,229,231,232] Although research studies including thousands of people have demonstrated the importance of echocardiographically determined measurements of LV mass, there is concern that the intrinsic variability of a single echocardiogram is sufficiently high (perhaps 10 to 15 percent) that serial determinations in a usual hypertensive individual are unlikely to be cost-effective. The exception may be a person with stage 1 hypertension, in whom the presence of this form of LVH would lead to a reclassification of the patient and indicate the need for antihypertensive drug therapy earlier than it might have been given if the clinician had thought the patient was free of TOD.

LVH is associated both epidemiologically and pathophysiologically with intimal hyperplasia of the epicardial coronary arteries, increased coronary vascular resistance, increased severity and frequency of ventricular dysrhythmias, decreased flow reserve, and reduced diastolic relaxation. At the extreme, diastolic

dysfunction and restrictive cardiomyopathy result clinically in "flash pulmonary edema" despite a normal ejection fraction. Although this phenomenon is not well understood, some feel that hypertension plays the major role in the pathogenesis of this syndrome, which has been identified in up to 40 percent of patients presenting to the hospital with HF.[233] The important prognostic role of LVH was demonstrated and separated from possible subclinical coronary disease in a consecutive series of 785 patients who had cardiac catheterization.[234] After 4 years of follow-up in patients with echocardiographically documented LVH, the risk of dying was increased twofold if there was coronary artery disease (CAD) but more than fourfold if CAD was not present.[234] Echocardiographically defined LVH was the most powerful risk factor for death.

The most contentious aspect of LVH is the importance of its reversal and how to achieve it. While early data from several centers indicate a better prognosis among patients with echocardiographically determined LVH whose LV mass index is reduced (typically by pharmacologic treatment of hypertension) compared with those whose index increases over time, the large therapeutic trials directed primarily at this question are still ongoing. There are major controversies, supported by separate meta-analyses with differing conclusions, about whether certain classes of antihypertensive drug therapy are more effective at quickly reducing LV mass, but these changes have not been correlated with a reduced risk of CV events in large numbers of patients.[235-237] Most studies agree that LVH is unlikely to regress without reducing BP; most authorities therefore recommend spending resources on achieving BP control rather than on serial echocardiograms to see if the LV mass index is returning toward normal.

Renal Evaluation

Current recommendations for the evaluation of renal function include just a measure of BUN and serum creatinine and a dipstick to detect heavy proteinuria. A more extensive search for microalbuminuria (MA), as defined by the presence of albumin in the urine above the normal range of less than 30 mg/day but below the detectable range with the conventional dipstick methodology, i.e., 300 mg/day, is also warranted.[238] Data from several pioneering studies done over the last two decades have demonstrated that MA is not only a predictor of diabetic complications but also a powerful independent risk factor for CV disease.[238-240] Moreover, MA predicts the development of ischemic CV events related to the development of atherosclerosis. Numerous clinical studies in persons with either type 1 or type 2 DM as well as those with renal disease have demonstrated higher CV mortality in those with MA.[239-244]

The prevalence of MA in patients with type 2 DM is about 20 percent (range, 12 to 36 percent) and affects about 30 percent of people with type 2 DM older than 55 years of age.[242-244] The prevalence of MA ranges from 5 to 40 percent among nondiabetic persons with essential hypertension.[244] The reason for this high variability in MA prevalence among those with essential hypertension relates to both the duration of BP control and associated lipid abnormalities, especially low-density lipoprotein cholesterol (LDL-C) levels.[245] A second related predictor is the duration of hypertension.[246] In this way, MA may be a marker of BP control, since BP control with all agents, except dihydropyridine CA and central or peripheral sympathetic blockers, reduces albuminuria.[247] Subsequent chronic renal failure occurs at a rate of 1 percent per annum in those with type 2 DM; the risk for those with type 1 DM approaches 75 percent after 10 years, while for those with essential hypertension, it is less than 1 percent over 5 years.[247,248]

Some studies have shown that the amount of MA present in a person is proportional to the severity of systolic, diastolic, and mean BP elevation as measured by either clinic or 24-h ambulatory BP monitoring.[249,250] This observation has been corroborated by the results of a clinical study of 211 untreated men with MA and essential hypertension.[251] This study agreed with the findings of previous investigators and showed that patients with MA had higher BP levels.[249] Another Italian population study with 1567 participants revealed an 18-mmHg higher systolic BP in the group of nondiabetic people with MA.[252] Lastly, circadian abnormalities of BP seen in nondippers (see above), who are known to be at higher risk for CV, also have a higher prevalence of MA.[253,254]

The exact pathophysiology of how MA contributes to or accelerates the atherosclerotic process is uncertain. The current understanding, however, suggests that MA is an indicator of increased vascular permeability

and, hence, altered barrier function of the endothelium.[249,250,252-,255] People with MA have an elevated transcapillary escape rate of albumin regardless of whether they have preexisting DM. Moreover, it has been argued that when albumin leaks into the interstitial space, cellular injury occurs secondary to free radicals and cytokine production enhanced by the presence of albumin. More recently, some authors have suggested that MA is another element of the metabolic components of syndrome X[256-258] (see above).

Simply using a conventional dipstick that can detect only higher levels of urinary protein (>300 mg/24 h) means that the clinician will miss the opportunity to characterize a patients' prognosis more precisely at the initial visit. Dipsticks that detect MA are available and inexpensive. Perhaps all hypertensives with "trace" proteinuria (generally 300 to 500 mg/day) when measured by conventional dipsticks should have a spot urine measurement of the albumin/creatinine ratio.[238] Routine assessment of MA in diabetic patients is well advised, but in hypertensives without DM, its value is still debatable. In part, this is due to the relatively low prevalence of MA in the nondiabetic population and the uncertainty of the significance of its modification in these groups.

Studies found that subjects with MA and type 2 DM have approximated total mortality of 8 percent and CV mortality of 4 percent annually. These values are up to four times higher than those of patients without MA.[258] Similar increases in CV mortality also are present in people with MA and without diabetes. In several series, the CV event rate in nondiabetic people with MA and hypertensives was twofold to fourfold higher than it was in those without MA.[259]

In several studies, people with MA had larger LV mass and higher degrees of LVH.[260-262] This has been documented by both ECG and echocardiographic criteria. However, this finding was not consistent in other populations that were relatively young (age between 18 and 45) and had stage 1 hypertension. This association of MA with LVH may be related to a higher BP load.

Evaluation of the Vasculature

One of the hallmarks of the hypertensive circulation is decreased vascular compliance. Acutely, elevated BP affects the elastic behavior of both large and small arteries such that the muscular layers of the arterial wall are unable to relax as quickly and transmit pressure waves as easily and reproducibly as they can when BP is lower. This is a passive and reversible phenomenon that typically lasts minutes to hours. Over a prolonged period, however, there is a gradual infiltration of the internal elastic lamina of blood vessels with thinned, split, and frayed elastic fibers and a laying down of new intercellular matrix; in extreme cases, medial necrosis is found within the arterial wall. This process, which is attributed to aging, hypertension, or a combination of the two, often is described as "arteriosclerosis," since it leads to chronic and generally irreversible stiffening of the arterial tree.[263]

There are several methods of assessing arterial compliance (Table 51-14), but most are invasive, expensive, or not widely used in clinical medicine.[264] Several new methods for calculating total arterial compliance are based on pulse contour analysis but have not been tested in large population-based studies to prove their value in estimating CV risk.[265,266] Blacher and associates showed in 710 subjects from the Framingham Heart Study that pulse wave velocity is higher in subjects with known atherosclerotic CV.[267] Whether this measure will be used routinely to evaluate hypertensives remains to be seen.

Table 51-14: Methods for Determining Arterial Compliance

	Measured in	Invasive?	Drawbacks
Direct methods			
Angiography	Aorta	Yes	Expensive
Echocardiography	Aorta	No	Expensive
Echo tracking	Peripheral arteries	No	Not widely available
Intravascular ultrasound	Peripheral arteries	Yes	Expensive
Venous occlusion plethysmography	Peripheral arteries	No	Time- and operator-intensive
Indirect methods			
Stroke volume/pulse pressure ratio	Total arterial compliance	No	Reproducibility questionable
Pulse wave velocity	Segmental arteries	No	Limited to large arteries
Fourier pulse analysis	Peripheral arteries	No	Reproducibility questionable
Total compliance	Total arterial compliance	No	Expensive
Pulse contour analysis	Total arterial compliance	No	Time- and operator-intensive

Pseudohypertension is the name given to the rare circumstance in which BP measurements by the usual indirect sphygmomanometry are much higher than direct intraarterial measurements; these differences usually are attributed to very "stiff" and calcified arteries that are nearly impossible to compress with the bladder in the usual BP cuff. The "Osler maneuver" (palpating the walls of the brachial artery when blood flow has been interrupted by inflating the cuff higher than systolic pressure) has been recommended as a simple measure to diagnose this condition, but several reports have found it less sensitive and specific than was reported initially, and the authors do not recommend using it.[268] Because making the diagnosis of pseudohypertension requires a potentially dangerous and expensive intraarterial measurement (and perhaps an infusion of an intravenous antihypertensive agent to "calibrate" the difference between indirect and direct BP measurements), few clinicians routinely check for and diagnose pseudohypertension.

The benefits of lowering BP in older patients with "stiff" arteries, however, are well established. Three clinical trials specifically in isolated systolic hypertension [systolic blood pressure (SBP) ≥160 mmHg with diastolic blood pressure (DBP) <90 or <95 mmHg] proved that older individuals with BP elevations only in systolic BP (a typical finding in patients with reduced vascular compliance) have a reduced risk of CV events with pharmacologic treatment.[269-271] Whether arterial compliance should be measured as a predictor of CV risk and measured serially over time is controversial; perhaps it would not be as cost-effective as serial BP determinations during treatment.

Other Evaluation

Other blood tests such as PRA and serum insulin or newly appreciated markers of CV risk such as C-reactive protein have been abandoned for routine or even specialized evaluation or have not been proved to be sensitive or specific enough to warrant inclusion in the evaluation of all hypertensive patients.[272]

Evaluation for Identifiable Causes of Hypertension

There are many identifiable causes of hypertension (secondary hypertension). In patients with some of these causes, the elevation of BP can be eliminated with specific treatment such as angioplasty or surgery therapy or by removing the agent that caused the hypertension. By far the most common identifiable cause

is chronic renal failure. Although chronic renal disease almost never can be cured, the hypertension associated with it often can be controlled with adequate dialysis without the use of drugs. Renal artery stenosis, pheochromocytoma, and primary aldosteronism, however, are potentially curable. These conditions are encountered commonly enough that the clinician seeing a hypertensive patient must have a high index of suspicion in the appropriate clinical setting and should order the specialized tests necessary to screen for and confirm the diagnosis. Other etiologies, such as specific enzyme deficiencies, coarctation of the aorta, and Ask-Upmark kidney, are distinctly rare. This section will cover only the most common etiologies listed in Table 51-10. If a secondary cause of hypertension is suspected, a referral to a hypertension specialist may be appropriate.[11,19]

RENOVASCULAR HYPERTENSION

Patients with this form of secondary hypertension often have stage 3 hypertension and considerable TOD and are at risk of losing renal function. At least 90 percent of cases of renovascular hypertension now are due to renal artery atherosclerosis, with only 10 percent being due to fibromuscular dysplasia or unusual causes.[273,274] Atherosclerotic renal artery stenosis is a disease of older individuals. Characteristically, these patients develop hypertension after age 50 or have a history of hypertension that had been relatively easy to control and became refractory. A large proportion of these patients have evidence of vascular disease elsewhere (carotids, coronaries, and peripheral circulation, in particular), and the majority are cigarette smokers, often heavy smokers.[275] Although it is more common in whites, blacks also can develop atherosclerotic renovascular hypertension.[276,277] Fibromuscular dysplasia tends to affect young white women in whom BP tends to rise abruptly to stage 3 during the third decade of life. Abdominal or frank bruits are heard commonly, and renal function is usually normal when the diagnosis is entertained.

Laboratory Testing

The objective of laboratory testing in patients suspected of having renovascular hypertension is not only to verify that arterial lesions are present but also to determine that the lesion that is discovered is in fact the cause of the patient's hypertension.[273] The clinical situations in which renovascular disease should be suspected are listed in Table 51-15.

Table 51-15: Testing for Renovascular Hypertension: Clinical Index of Suspicion as a Guide to Selecting Patients for Workup

Low (should not be tested)
Stage 1 or 2 hypertension in the absence of clinical clues
Moderate (noninvasive test recommended)
Stage 3 hypertension
Hypertension refractory to standard therapy
Abrupt onset of sustained stages 2-3 hypertension at age <20 years
Hypertension with a suggestive abdominal bruit (long, high-pitched, and localized to the region of the renal artery)
Stages 2-3 hypertension (diastolic BP exceeding 105 mmHg) in a smoker, a patient with evidence of occlusive vascular disease (cerebrovascular, coronary, peripheral, vascular), or a patient with unexplained but stable elevation of serum creatinine
High (may consider proceeding directly to arteriography)
Stage 3 hypertension with either progressive renal insufficiency or refractoriness to aggressive treatment, particularly in a patient who has been a smoker or has other evidence of occlusive arterial disease

Accelerated or malignant hypertension (grade III or IV retinopathy)
Hypertension with recent elevation of serum creatinine, either unexplained or reversibly induced by an angiotensin-converting enzyme inhibitor
Moderate to severe hypertension with incidentally detected ansymmetry of renal size

SOURCE: Modified from Mann SL, Pickering TG. Detection of renovascular hypertension: State of the art: 1992. *Ann Intern Med* 1992; 117:845.

The tests used to confirm the clinical suspicion that a patient has renovascular hypertension are biochemical or depend on a variety of imaging techniques (Table 51-16).

Table 51-16: Detection of Renovascular Hypertension

Biochemical
Serum K^+
PRA
Renal vein renin activity
Split renal function tests
Imaging
Rapid-sequence intravenous pyelography
Renography
Captopril or enalaprilat renography
Intraarterial digital substraction angiography
Standard angiography
Duplex renal ultrasound
Magnetic resonance angiography

Biochemical

Measurement of serum K^+ (which, if low, may indicate hyperaldosteronism) or PRA (which, if high, may confirm activation of the RAA system) plays no role in the further case finding for renovascular hypertension because the sensitivity and specificity are too low.[278] Even measuring the PRA after captopril (the so-called captopril test) has a sensitivity of only 60 to 70 percent, although better results have been obtained in some series.[278] Measuring the concentration and activity of renin simultaneously from each renal vein and computing the renal vein renin ratio was a very popular approach at one time, but the sensitivity and specificity for detection of renovascular hypertension with this test are both approximately 75 percent, unacceptably low for an invasive procedure that requires special expertise and sophisticated measurements.[278] This ratio may still be useful to help prove that an anatomic lesion is also the cause of a patient's hypertension but should not be used as a screening tool.

Imaging

Rapid-sequence intravenous pyelography and standard renal scanning were the earliest noninvasive imaging studies used for diagnosing renovascular hypertension.[278] Even though in expert hands each has reasonable sensitivity (65 to 70 percent for scanning and 75 percent for pyelography), neither has a place in the diagnostic approach any longer. Renal duplex ultrasound has the advantage of being noninvasive and widely available. In some laboratories, the sensitivity of this test approaches 90 to 95 percent.[279] However, the presence of abdominal gas or fat may make it difficult to visualize the renal arteries, and the test is very operator-dependent. In specialized centers with special expertise and in selected patients, it may be a useful test. In most settings, however, little is gained by using this technique. Magnetic resonance angiography with gadolinium is a new approach to visualization of the renal arteries that is becoming widely available and is noninvasive.[280] However, until the quality of the images improves and the cost becomes lower, this technique is not likely to replace angiography when visualization of the renal arteries is felt to be necessary.

The two imaging modalities currently favored are isotopic renography with labeled dethylenetriamine pentaacetic acid (DTPA) (a measure of glomerular filtration) of MAG-3 (a measure of renal blood flow) with captopril and intraarterial digital subtraction angiography.[273] Isotopic renography with captopril is a minimally invasive test that detects a discrepancy between perfusion and function of the kidneys. The overall sensitivity and specificity are 90 percent when done carefully, especially in patients whose prior probability of having renovascular hypertension is judged to be high.[273,278] Only ACE-Is and ARBs need to be stopped before the test is performed, and adverse reactions from the single dose of captopril are rare. Isotopic renography with captopril also provides functional information. If the time to peak activity is initially normal and becomes abnormal after captopril ("captopril-induced changes"), the likelihood of cure or improvement after revascularization is high.[273]

Intraarterial digital subtraction angiography has become the invasive procedure of choice to demonstrate definitively the renal artery anatomy and determine whether an arterial lesion is present. Although an arterial puncture is required, the needle used is small and the dye load is modest. In addition, the type of lesion (ostial, nonostial, or branch) can be determined. In some centers, percutaneous renal angioplasty is done at the same time if it is felt to be indicated. The authors are not in favor of doing revascularization unless evidence has been obtained (a positive captopril renogram with captopril-induced changes or a renal vein renin ratio >1.5) that the lesion is functionally significant. The presence of anatomic renal artery stenosis does not mean that the lesion is responsible for the elevation in BP (functional renal artery stenosis).[273]

When considering whether to proceed with these studies, the clinician must consider how the data will be used. In a number of hypertensive patients with renovascular hypertension, BP is controlled adequately with medical therapy. If the risk of surgery or angioplasty is viewed as unacceptably high or if the patient will not consent to having a revascularization procedure if a remediable lesion is discovered, any specific further evaluation may not be appropriate.

PHEOCHROMOCYTOMA

Patients with pheochromocytoma are almost always symptomatic on presentation.[281] These patients usually have a characteristic cluster of complaints that occur in paroxysms or "spells." The description of the spell tends to be typical and is usually the same in each patient. The spells may occur many times a day or may be separated by weeks or months.[282] Often there is a characteristic trigger (change in position, certain foods, trauma, pain, or drugs) that if present should greatly increase the clinician's index of suspicion of pheochromocytoma. Hypertension is not usually paroxysmal, as has often been stated, with some BP readings elevated and some normal. Most measurements are in fact in the hypertensive range, although wide variability is the rule. The three most common symptoms of pheochromocytoma are headache, diaphoresis, and palpitations[282] (Table 51-17). Many other symptoms, particularly anxiety, weakness, and tremulousness, are also quite common. The pattern of symptoms can provide guidance about the predominant hormone secreted by the tumor. When norepinephrine is the primary hormone produced, pallor is usually the symptom. Flushing is more likely if substantial amounts of epinephrine are produced.

Laboratory Testing for Pheochromocytoma

Whereas it is possible and sometimes desirable to manage hypertensive patients with renovascular hypertension or mineralocorticoid-excess states with medical therapy, it is almost always imperative to remove a pheochromocytoma. As with renovascular hypertension, once the clinical presentation suggests that a pheochromocytoma may be the cause of a patient's hypertension, a variety of tests are available to confirm the diagnosis (Table 51-18). If a pheochromocytoma is suspected, the next step is to obtain biochemical confirmation of an increase in catecholamine production. The authors prefer to measure 24-h urinary excretion of total catecholamines (norepinephrine, epinephrine, or dopamine) or their metabolites (vanillylmandelic acid or metanephrine).[282] In some laboratories, 24-h urinary metanephrines are the most sensitive and specific in the diagnosis (both approximately 85 percent and 90 percent), but when done precisely, there is little to choose in regard to which should be measured. When the two or three of these compounds are quantitated and several samples are analyzed, both the sensitivity and the specificity of the tests improve. Attention must be paid to the conditions under which the sample is collected, and urinary creatinine also should be measured to verify that the collection represents the 24-h excretion. To reduce the number of false-positive results, the patient should be in a nonstressful situation when the sample is obtained.

Table 51-18: Diagnostic Tests for Pheochromocytoma

Biochemical
Urinary free catecholamines
Urinary vanilylmandelic acid
Urinary metanephrines
Plasma catecholamines (or metanephrines)
Clonidine suppression test
Imaging studies
Computed axial tomography
Magnetic resonance imaging
^{131}I-meta-iodobenzylguanidine
Abdominal ultrasound
Adrenal vein or vena caval drainage
Angiography

In the authors' view, only when the urinary assays are borderline can the measurement of plasma catecholamines be useful. If plasma catecholamines (norepinephrine plus epinephrine) levels exceed 2000 pg/mL in the basal state, the presence of a pheochromocytoma is highly likely. If the levels are less than 1000 pg/mL, the diagnosis is very unlikely, whereas in patients with plasma catecholamine levels between 1000 and 2000 pg/mL, the clonidine suppression test may be useful.[283] If plasma catecholamine levels do not suppress after the administration of 0.3 mg of oral clonidine in an appropriately prepared and monitored patient, a further aggressive search for a pheochromocytoma is warranted.

The choice of which initial imaging procedure to obtain is also somewhat controversial. CT scanning is a highly sensitive imaging modality that will locate nearly all pheochromocytomas, especially those in the adrenal gland or the abdomen. MRI has the advantage of not requiring contrast material (which is sometimes necessary with CT scanning) and is also helpful in localizing nonadrenal or nonabdominal pheochromocytomas. Enhancement of the T2-weighted images happens virtually only with pheochromocytomas and adrenal carcinomas, helping distinguish adrenal masses that are not biochemically

active (so-called incidentalomas) from metabolically active or malignant tumors.

The use of I-meta-iodobenzylguanidine scanning has been particularly helpful when a pheochromocytoma is suspected but is not clearly located with CT or MRI. This radiopharmaceutical is a guanethidine analog that is concentrated in pheochromocytomas and other neural crest tumors.[284] Using total-body scanning helps localize the tumor if the initial CT or MRI scans are negative or equivocal. The sensitivity of this test exceeds 90 percent, but it is not uniformly available.

PRIMARY ALDOSTERONISM

In a hypertensive patient receiving no treatment who demonstrates significant hypokalemia (serum $K^+ \leq 3.2$ meq/L) with renal K^+ wasting (24-h urinary $K^+ > 30$ meq), PRA below 1 ng/mL, and elevated plasma or urinary aldosterone values, the diagnosis is unequivocal. Often, however, the diagnosis is not obvious because the values are not as definitive; in such cases, multiple measurements are needed during salt loading.

The single best test in people with normal renal function for identifying patients with primary aldosteronism is the measurement of 24-h urinary aldosterone excretion during salt loading[285,286] (Table 51-19). An excretion rate of >14 μg of aldosterone in 24 h after 3 days of salt loading (greater than 200 meq/day) distinguishes most patients with primary aldosteronism from those with essential hypertension. Only 7 percent of patients with primary aldosteronism have values that fall within the range for essential hypertension. In contrast, a substantial number (about 39 percent) of patients with primary aldosteronism have plasma aldosterone values that fall within the range for essential hypertension.[287] The findings of hypokalemia and suppressed PRA provide corroborative evidence, but the absence of either or both does not preclude the diagnosis.

Table 51-19: Diagnostic Studies for Mineralocorticoid Excess States

Biochemical
Serum potassium
Plasma renin activity
Plasma aldosterone
Plasma aldosterone/renin ratio
24-h urinary aldosterone excretion
Plasma 18-hydroxycorticosterone
Plasma 18-oxocortisol
Plasma 18-hydroxycortisol
Adrenal vein sampling for aldosterone
Imaging studies
Abdominal ultrasound
Computed axial tomography
Iodocholesterol scanning
Adrenal venography

A substantial number of patients with primary aldosteronism, however, do not present with hypokalemia; serum K^+ concentration is normal in 7 to 38 percent of reported cases.[288,289] In addition, 10 to 12 percent of patients with proven tumors may not have hypokalemia during short-term salt loading. Plasma renin activity <1 ng/mL per hour or one that fails to rise above 2 ng/mL per hour after salt and water depletion and upright posture has been used as an additional test to exclude primary aldosteronism.[288] However, a significant number (about 35 percent) of patients with the disease have values that rise >2 ng/mL per hour when appropriately stimulated.[286] In addition, about 40 percent of subjects with essential hypertension have suppressed PRA, and 15 to 20 percent of these patients have values <2 ng/mL per hour under conditions of stimulation.

The plasma aldosterone/renin ratio has been used to define the appropriateness of PRA for the circulating concentrations of aldosterone.[286] It is assumed that the volume expansion associated with excessive aldosterone production inhibits the synthesis of renin without affecting the autonomous production of aldosterone. Both tests are subject to the same limitations: First, there is inherent variability of plasma levels of aldosterone even in the presence of a tumor, and this translates into variability in the absolute value of the ratio; second, the use of drugs that result in marked and prolonged stimulation of renin long after their discontinuation may alter the ratio.

The most common cause of primary aldosteronism is an aldosterone-producing adenoma (70 to 80 percent of all proven cases). Approximately 20 to 30 percent of cases are caused by hyperplasia of the zona glomerulosa layer of the adrenal cortex (bilateral adrenal hyperplasia). Some reports suggest the occurrence of a syndrome intermediate between adenoma and hyperplasia.[288] The distinction between these two processes is important because surgical intervention is likely to be curative in the majority of adenomas and fails to reduce BP in patients with bilateral adrenal hyperplasia.

An adenoma is likely in the presence of spontaneous hypokalemia <3.0 meq/L, plasma 18-hydroxycorticosterone values >100 ng/dL, and an anomalous postural decrease in plasma aldosterone concentration.[289,290] In addition, adenomas are largely unresponsive to changes in sodium balance and appear to be exquisitely sensitive to ACTH, unlike hyperplasias, which are more sensitive to angiotensin II infusions.[290] Plasma 18-hydroxycorticosterone values <100 ng/dL, a postural increase in aldosterone, or both, are findings usually associated with hyperplasia, but they do not completely rule out the presence of an adenoma.[291]

An adrenal CT scan should be considered the initial step in tumor localization. It is noninvasive, and all adenomas ≥1.5 cm in diameter can be located accurately. Only 60 percent of nodules measuring between 1 and 1.4 cm in diameter are detected by CT scanning. Nodules <1 cm in diameter are very difficult, if not impossible, to demonstrate. The overall sensitivity of localizing adenomas by high-resolution CT scanning exceeds 90 percent.[292] Adrenal venous aldosterone levels should be measured when the biochemical findings are highly suggestive of an adenoma, but the adrenal CT scan is ambiguous.[293]

Medical therapy is indicated in patients with adrenal hyperplasia, patients with adenoma who are poor surgical risks, and patients with bilateral adrenal adenomas that may require bilateral adrenalectomy. Total bilateral adrenalectomy has no place in the management of primary aldosteronism.

The long-standing experience has been that the hypertension associated with primary aldosteronism is salt- and water-dependent and is best treated with sustained salt and water depletion.[294] The usual doses of diuretic agents are hydrochlorothiazide 25 to 50 mg/day or furosemide 80 to 160 mg/day in combination with either spironolactone 100 to 200 mg/day or amiloride 10 to 20 mg/day. These combinations usually result in prompt correction of hypokalemia and normalization of BP within 2 to 4 weeks.

In the majority of these patients, surgical excision of an aldosterone-producing adenoma leads to normotension as well as reversal of the biochemical defects. One year postoperatively, about 70 percent of patients are normotensive, but 5 years postoperatively, only 53 percent remain normotensive. The restoration of normal K^+ homeostasis is permanent. Patients undergoing surgery should receive drug treatment for a least 8 to 10 weeks both to decrease BP and to correct metabolic abnormalities. These patients have a significant K^+ deficiency that must be corrected preoperatively because hypokalemia

increases the risk of cardiac arrhythmias during anesthesia.

After the removal of an aldosterone-producing adenoma, selective hypoaldosteronism usually occurs even in patients whose PRA had been stimulated with chronic diuretic therapy. Potassium supplementation therefore should be given cautiously, and serum K^+ values should be monitored closely. Sufficient residual mineralocorticoid activity often is left to prevent excessive renal retention of K^+ provided that Na^+ intake is adequate. Abnormalities in aldosterone production can persist for as long as 3 months after tumor removal.

OTHER FORMS OF IDENTIFIABLE SECONDARY HYPERTENSION

In addition to these three most common and potentially curable forms of identifiable secondary hypertension, there are a vast number of rare conditions in which the cause of the hypertension cannot be found (Table 51-10). These include enzyme deficiencies such as 17-β-hydroxylase deficiency and 17-α-hydroxylase deficiency, other congenital disorders such as the Ask-Upmark kidney, trauma such as the Page kidney, urologic causes such as hydronephrosis, endocrine abnormalities such as Cushing's syndrome and Cushing's disease, and even infectious etiologies such as renal tuberculosis.[274] Although the practicing clinician may never encounter a patient with any of these disorders, it is incumbent on him or her to know that these unusual conditions may present with hypertension and that the elevated BP may be the first clue to the diagnosis. Two causes of identifiable hypertension are not rare, and all clinicians will see patients with iatrogenic hypertension and those with sleep apnea (Table 51-11). Any of the drugs or other substances listed in the table should be stopped before one concludes that a patient has hypertension. The relation of sleep apnea to hypertension and obesity has long been recognized.[295,296] The typical clinical presentation of sleep apnea (daytime drowsiness, snoring) in an obese hypertensive should alert the clinician to this disorder.

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

TREATMENT OF HYPERTENSION

Patients with JNC VI stage 2 or 3 hypertension (SBP ≥160 mmHg or DBP ≥100 mmHg) and those in risk group C (those with DM and those with clinical CV) should receive drug therapy once their hypertension has been diagnosed and confirmed.[11] Furthermore, the length of time the clinician should rely on lifestyle modifications before starting drug therapy has been clarified in JNC VI and is based on risk estimates, not just on the level of BP (Table 51-3). Those with stage 1 hypertension (SBP 140 to 159 mmHg and/or DBP 90 to 99 mmHg) who have no other risk factors or end-organ damage (so-called risk group A) can be treated only with lifestyle modification for up to 1 year even if goal BP is not reached before drug therapy should be considered necessary. Since male sex and age over 60 years are considered risk factors, only women under 60 years of age are in group A.

Patients with stage 1 hypertension who are in risk group B (other CV risk factors but no TOD or DM) should receive pharmacologic therapy after only a 6-month trial of lifestyle modification unless goal BP is achieved without drugs. Those in risk group C [TOD, clinical cardiovascular disease (CVD), and/or DM) should be treated with pharmacologic agents and lifestyle modification even if they have high-normal BP (SBP 130 to 139 mmHg and/or DBP 85 to 89 mmHg).

Lifestyle Modification

The JNC VI recommended weight loss for obese hypertensive patients, modification of dietary Na^+ intake to ≤100 mmol/day, and modification of alcohol intake to no more than two drinks per day.[11] It also recommended an increase in physical activity for all patients with hypertension who have no specific condition that would make such a recommendation not applicable or safe. However, for many of the authors' patients these suggestions are not practicable or already are being implemented. For such patients, drug therapy may be indicated even sooner in group A and group B hypertensive patients.

There is little doubt that lifestyle factors such as diet, exercise, and stress can affect BP. There is a strong positive correlation between the level of body weight and body mass index (weight/height) and the level of BP.[297] The relationship of dietary Na^+ and BP is equally clear, especially at low and modest intakes of Na^+ and in those deemed to be salt-sensitive. Other nutrients, such as K^+, the omega-3 fatty acids present in fish oil, and possibly Ca^{2+} and Mg^{2+}, are inversely related to BP level. Sedentary individuals who do little, if any, aerobic exercise usually have higher BPs than do appropriately matched controls even when one controls for other confounding variables.[298] The relationship of stress to BP is somewhat less clear. Physical or mental stress will raise BP temporarily, but the relationship of chronic anxiety and stress has been more difficult to demonstrate.

The appreciation of these relationships has naturally led to numerous attempts to lower BP by modifying lifestyle (Table 51-20). The most important trial that evaluated the benefits of lifestyle modification, including weight loss, was the Trial of Hypertension Prevention (TOHP-1).[299] This study was large (n = 2182) and randomized and compared the benefits of weight loss, Na^+ reduction, or stress reduction to usual care and also compared K^+ supplements at 60 meq/day or Ca^{2+} at 1.0 g/day or Mg^{2+} at 15 mmol/day or fish oil at 3.0 g of omega-3 fatty acid to placebos. The weight loss, Na^+ reduction, and stress management were given to 308, 327, and 240 participants, respectively, for 18 months. The group assigned to supplementation (Mg^{2+}, Ca^{2+}, or placebo) then was rerandomized to fish oil, K^+, or placebo. In addition, 589 participants received usual care, giving this trial the ability to judge the efficacy of these treatments more objectively than any prior studies could. The nutritional treatments were delivered by trained nutritionists using group and individual sessions to maximize the adherence to the regimen and presumably its efficacy. The long

period of treatment and observation in TOHP-1 also provided important information about the "natural history" of the efficacy of these therapies. TOHP-1 showed that weight loss was the most effective lifestyle modification, reducing BP by 2.9/2.3 mmHg in association with an average weight loss of 3.9 kg. Sodium reduction was the only other therapeutic modality that reduced BP a significant amount (1.7/0.9 mmHg) with a reduction of 44 meq/day of Na^+. All the other arms of the study (K^+, Ca^{2+}, Mg^{2+}, fish oil supplements, and stress management) failed to demonstrate any reduction in BP compared with placebo or usual care. Whereas there were physiologic markers that indicated that the nutritional approaches and weight loss did at least partially achieve their objectives, the stress management techniques used were not effective. Perhaps successful stress management might lower BP.

Table 51-20: Lifestyle Modifications That Lower Blood Pressure

PRIMARY LIFESTYLE MODIFICATIONS

1. Reduction of body weight (5-kg threshold; 10 kg reduces BP ~10/8 mmHg)
2. Reduction in dietary salt consumption (target 100 mmol/day; can lower BP ~12/10 mmHg, but individual responses vary)
3. Increase physical activity to 30-45 min, four times a week (can lower BP 8/4 mmHg and often helps control weight)
4. Increased consumption of fruits and vegetables (at least 4 servings/day; can lower BP ~6/3 mmHg and often helps reduce salt consumption)
5. Moderation of alcohol consumption (target 10-20 g ethanol for women, 20-30 g for men; can lower BP up to 8/4 mmHg in those who have more than 5 drinks/day)
6. Stress management (randomized clinical trials outside the workplace have been unconvincing, but many psychologists still recommend the approach despite a lack of detailed protocols that uniformly lower BP)

OTHER LIFESTYLE MODIFICATIONS THAT ARE ROUTINELY RECOMMENDED

1. Tobacco avoidance (lowers cardiovascular risk independently of any effect on BP)
2. Fish consumption (improves lipid profiles and cardiovascular risk more than expected if BP effect alone is operative)
3. Increasing dietary fiber (improves lipid profiles and cancer risk independently of effect on BP)

LIFESTYLE MODIFICATIONS THAT ARE NOT ROUTINELY RECOMMENDED

1. Biofeedback
2. Dietary calcium supplementation
3. Dietary magnesium supplementation
4. Micronutrient supplements

TOMHS also evaluated the long-term benefit of lifestyle modification.[300] This study compared five classes of antihypertensives (diuretics, CAs, ACE-Is, alpha blockers, and beta blockers) to placebo in middle-aged

subjects with minimal elevations of BP (average BP of 140/91 mmHg when the study started) and superimposed these pharmacologic treatments on a comprehensive lifestyle regimen that included weight loss, Na^+ restriction, alcohol reduction, and exercise. A subgroup of the cohort got lifestyle modification with placebo. In TOMHS, the nutritional advice and the exercise program were presented to the participants and monitored by certified nutritionists and trained exercise physiologists. The subjects were seen frequently in group and individual sessions. The group given placebo reduced BP from 140/91 to 132/82 mmHg (a reduction of 9.1/8.6 mmHg) and sustained that level for the 4.4 years of study follow-up, even though the reduction of the Na^+ intake, amount of weight loss, and the increase in exercise did not reach study goals. Perhaps the most important finding in TOMHS was the statistically significantly fewer number of CV events (p <.03), in the group given pharmacologic treatment plus lifestyle modification. These patients achieved an average BP of 125/79 mmHg, a reduction of 16/12 mmHg. Even though the lifestyle modification was successful and sustained, the group given drugs had statistically significantly fewer CV events (p <.03), probably because their BP was lower.

The inevitable conclusion from this trial is that even successful lifestyle modification that brings BP to the current goals does not reduce morbidity and probably mortality as well as does the combination of drugs and lifestyle adjustments that brings BP down even further. The fact that the value of BP reduction in preventing CV complications with pharmacologic agents could be demonstrated in a group at such low risk calls into question the current emphasis on delaying treatment with drugs even in low-risk individuals while the patient and provider try to get BP to goal without them. In a subsequent paper, Grimm and colleagues also showed that quality of life, as assessed by a very extensive questionnaire delivered on multiple occasions during TOMHS, showed that subjects felt best in all the ways studied when their BP was lowest.[50] This result was seen whether they were on active pharmacologic treatment with lifestyle modification or on lifestyle modification alone. These data lead the authors to believe that physicians should strive to get the maximum BP reduction that can be achieved safely and do so by combining treatments and not restrict their approach to one modality or the other.

More recent studies have combined the two most successful lifestyle modifications (weight loss and Na^+ restriction) in prospective, randomized, and well-controlled long-term trials. The Trials of Hypertension Prevention-2 (TOHP-2) studied the value of weight loss and Na^+ restriction in a 2 × 2 factorial design against usual care.[301] The group assigned to both Na^+ reduction and weight loss did the best at 6 months [BP fell 4.0/2.8 mmHg (usual care subtracted)], while those receiving a single modality did not experience as much of a BP reduction (3.7/2.7 mmHg for the weight loss only group, 2.9/1.6 mmHg for the Na^+ reduction only group, also usual care subtracted). The disturbing finding here was that most of this reduction was gone by the 3-year follow-up, with the combined treatment having reduced BP by only 1.1/0.6 mmHg at that time. This finding highlights another difficulty with lifestyle modification: the high recidivism rate seen in virtually all long-term studies. While adherence to a drug regimen is notoriously poor, adherence to lifestyle modification is, if anything, even worse. As in TOHP-1, the regimen was delivered by highly trained nutritionists in group and individual sessions and is consequently not an inexpensive way to reduce BP.

The second long-term, randomized, and well-controlled study directly assessing the value of lifestyle modification was the Trial of Nonpharmacologic Interventions in the Elderly (TONE).[302] This study also evaluated the efficacy of weight loss and Na^+ reduction, but in a different population and with a somewhat different objective. Only hypertensives 60 to 80 years of age were enrolled, and all already were on single-drug pharmacologic treatment. The objective of TONE was to see whether the imposition of a formal lifestyle approach, again taught by highly trained professionals, would allow hypertensives to go off their medications. The results were equally disappointing. After 30 months, when the study ended, 44 percent of the actively treated subjects were able to stay off antihypertensives (they did not have a CV event or have BP rise to levels that were considered too high not to be given drugs: >150/90 mmHg) compared with 38 percent of those not getting active lifestyle modification. While this was statistically significant (p <.001), it means that 56 percent of successfully treated hypertensives needed to resume drug therapy even when given the best possible lifestyle regimen available administered by experts.

The value of alcohol reduction also has been addressed by a recently published clinical trial (PATHSI).[303] This study took 641 patients at seven Department of Veterans Affairs clinics who were actively employed

and completely functional but had at least six alcoholic drinks per day. The subjects reduced their alcohol intake nearly 20 percent once they entered into the study and before their randomization to intensive counseling or usual care was done. Those in the intensive counseling group were seen frequently and were able to reduce their average alcohol consumption to 2.0 drinks per day, which was significantly better than the usual care group (3.3 drinks per day). In spite of this, BP and events were not different at the end of this 2-year trial.

Appel and associates showed in the Dietary Approaches to Stop Hypertension (DASH) trial that a diet rich in fruit and vegetables lowered BP by 2.8/1.1 mmHg more than did the control diet.[304] The fruit and vegetable diet was designed to contain K^+ and Mg^{2+} at the 75th percentile of the usual American diet, while the control diet was at the 25th percentile. A "combination" diet that also contained foods rich in Ca^{2+} and was lower in total and saturated fat content lowered BP by 5.5/3.0 mmHg more than did the control diet. In the hypertensive subjects in DASH (*n* = 133 of 459), the BP reduction was impressive (11.4/5.5 mmHg). Although this study was short (only 8 weeks) and may not be generalizable to the population since it was carried out in four centers with special expertise, this approach offers great promise for using nutritional management to prevent hypertension in individuals with high-normal BP. The DASH diet provides high amounts of K^+, Mg^{2+}, and Ca^{2+} in the food eaten, not as supplements, and also limits the dietary fat and saturated fat intake in a diet only modestly low in Na^+ (3000 mg/24 h). Further studies done over longer periods in a less highly selected cohort will be needed to verify these results and determine whether the DASH diet will be a valuable therapeutic tool for the general population.

While treatment modalities such as K^+, Ca^{2+}, and/or Mg^{2+} supplements, fish oil, and garlic have advocates, careful and objective assessment of the data leads one to the conclusion that lifestyle modification should be primarily adjunctive to drug therapy in hypertensives, especially now that so many well-tolerated agents have been developed and it has been proved that lowering BP with drugs reduces morbidity and mortality.[305-309] No study of lifestyle modification in hypertensives has demonstrated that life is prolonged or CV events prevented.

The recommendations for lifestyle modification from JNC VI and other guideline committees also include smoking cessation.[11] The reason for the inclusion of this recommendation was to improve CV health rather than because of a proven direct relationship between smoking and hypertension. A direct relationship between smoking and BP, in fact, had not been demonstrated in epidemiologic studies, and often the opposite (BP lower in smokers) was observed.[310] It is now clear, however, that cigarette smoking increases BP and HR transiently (for about 15 min) and that the rise in both is gone by 30 min. The mechanism is the increase in catecholamine secretion induced by smoking. Since the authors recommend that office readings be taken no sooner than 30 min after smoking and caffeine ingestion (another substance that transiently raises BP), one may well miss the elevation of BP caused by smoking if it is measured when the patient has not smoked. Indeed, ABPM studies have shown that smokers have significantly higher BP on days when they smoke compared with days when they do not.[311] The recommendation not to smoke is clearly appropriate, and it is worthwhile not only because of enhanced CV health but also because smoking induces a rise in BP.

The lack of proof of efficacy or effectiveness when using lifestyle modification to treat or even prevent hypertension does not mean that physicians should abandon their efforts to encourage patients to lose weight; restrict their Na^+ intake; eat generous amounts of K^+, Mg^{2+}, Ca^{2+}, and fish; exercise regularly; drink only moderately if they wish to; stop smoking; and reduce stress. What one needs to realize is that the most important thing is to lower BP, perhaps to the lowest tolerable level, and to do so safely and without excessive personal or societal cost. The tension between advocates of lifestyle modification and those who consider it at best no more than an adjunct is not useful. The recommendations for modifying lifestyle are still very appropriate for the general population. If adopted, they will prevent or delay the virtually inevitable rise in BP that occurs with age and many hypertensives will be able to reduce BP further than might be achieved with drugs alone. Lifestyle modification is the primary public heath approach to trying to reduce the prevalence of hypertension and the average BP in the society. If successful, such modification is likely to save more lives and prevent more MIs, strokes, and episodes of HF than can be prevented by using drugs in those who are already hypertensive.

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

PHARMACOLOGIC THERAPY

The primary goal of BP reduction is to achieve the recommended goal BP by using the least intrusive means possible.[11] *Intrusive* has several interpretations: economic, office visits, adverse effects, and convenience. The choice of the drug with which to begin therapy is probably the most important decision the clinician must make when treating hypertensive patients. Approximately half the patients physicians treat will respond to the first choice and can tolerate most rational options. If physicians choose wisely, the first choice will be successful in getting BP to goal, and that will be the drug on which the patient remains for what is usually an indefinite period of therapy. Since the remainder will need additional treatment, the choice of the first drug must be done with an eye toward what can be added to achieve that goal.

Classification of Antihypertensive Agents

Antihypertensive agents can be classified in a number of ways. Some are effective parentally and are indicated only for a hypertensive crisis, and others (the overwhelming majority) are used orally for chronic therapy. Antihypertensive agents are further classified by pharmacologic class and alleged primary mechanism of action (Table 51-21). There are more than 80 effective antihypertensive drugs and 40 fixed-dose combinations from which to choose. This provides physicians with many options but can make the choice seem more perplexing than it should be. All the drugs that are available lower BP safely and, in appropriate doses, essentially to the same degree. Some classes are more likely than others to reduce BP to goal with monotherapy and with acceptable tolerability. Those agents are appropriate choices for initial treatment.

Table 51-21: Pharmacologic Properties of Commonly Used Antihypertensive Agents

Drug	Dose, mg/day	Doses per Day	Mechanisms of Action	Special Considerations
Diuretics				
Thiazides and related drugs	12.5-25	1	Decreased body sodium and extracellular fluid volume	More effective antihypertensive agents than loop diuretics unless serum creatinine is ≥2.0 mL/min or creatinine clearance is ≤50 mL/min
Hydrochlorothiazide				
Loop diuretics				
Furosemide	20-320	2	Inhibit $2Cl^-Na^+$ pump	Effective even in patients with advanced renal or congestive heart failure
Bumetanide	0.5-5	2	Ascending loop of Henle	

Ethacrynic acid	25-100	2		
Torsemide	5-20	1		
Fixed-dose diuretics (potassium-sparing)			Increase K^+ reabsorption	Weak diuretics
Hydrochlorothiazide/amiloride				
HCTZ/triamterene				
Spironolactone	25-100	2-3	Aldosterone antagonist	May cause hyperkalemia in patients with serum creatinine >2.5 mg/dL, particularly when combined with ACE inhibitors, K^+ supplements, or NSAIDs
Triamterene	50-100	2		
Adrenergic inhibitors				
Beta blockers				
Cardioselective			Inhibit $beta_1$ receptors, decrease CO	In higher doses, also inhibit $beta_2$ receptors
Atenolol	25-100	1	Increase SVR, decrease plasma renin activity	
Metoprolol	50-200	1-2	(PRA)	
Noncardioselective			Inhibit $beta_1$ and $beta_2$ receptors	More likely to cause metabolic side effects
Nadolol	20-240	1		
Propranolol	40-240	1-2		
Timolol	20-40	2		
With intrinsic sympathomimetic activity (ISA)				
Acebutolol	200-1200	2	Partial agonist activity on beta-adrenergic receptors	No clear advantage except for less bradycardia and metabolic side effects than other beta blockers
Pindolol	10-60	2		
Antiadrenergic agents				
0x002003 *Centrally acting*				

α-Methyldopa	250-1500	2	Stimulate $alpha_2$-adrenergic receptors in the brainstem, resulting in inhibition of efferent sympathetic activity; decrease SVR	Sudden withdrawal may result in hypertensive crisis
Clonidine	0.1-0.6	2		
Clonidine TTS	0.1-0.3	Once a week		
Guanfacine	1-3	1		
Peripherally acting				
Guanethidine	10-100	1	Inhibit norepinephrine release from sympathetic nerve terminals	Frequently cause orthostatic hypotension and sexual dysfunction
			Decrease SVR	
Reserpine	0.05-0.25	1	Depletion of norepinephrine	Causes frequent neurologic symptoms; $alpha_1$-receptor blockers
Doxazosin	2-16	1	Inhibit $alpha_1$-adrenergic receptors.	First-dose effect; postural hypotension; useful for prostatic hypertrophy
Prazosin	2-20	1-2	Decrease SVR; CO same or increases	
Terazosin	1-20	1		
Alpha/beta blockers				
Labetalol	200-800	2-3	Blocks alpha- and beta-adrenergic receptors (7:1 beta:alpha blockade)	Same as beta blockers
Carvedilol	3.75-25	2	Blocks alpha- and beta-adrenergic receptors (3:1 beta:alpha blockade)	Same as beta blockers
ACE inhibitors				

Benazepril	10-40	1-2	Block conversion of angiotensin I to angiotensin II; decrease aldosterone; may increase bradykinin and vasodilatory prostaglandins; decrease SVR; no change in CO	When added to diuretics, may cause hypotension; may cause hyperkalemia in patients with renal failure, those with hypoaldosteronism, those receiving K-sparing diuretics or NSAIDs
Captopril	12.5-100	2-3		
Cilazapril	2.5-5	1-2		
Enalapril	2.5-40	1-2		
Fosinopril	10-40	1		
Lisinopril	5-40	1		
Perindopril	1-16	1-2		Can cause acute renal failure in patients with bilateral renal artery stenosis, renal artery stenosis of a solitary kidney, creatinine >3 mg/dL, or severe heart failure
Quinapril	5-80	1-2		
Ramipril	1.25-20	1		
Spirapril	12.5-50	1-2		
Trandolapril	1-4	1		
Calcium antagonists			Blocks entry of calcium into smooth muscle cells, resulting in vasodilation; decreases SVR; blunts increases in exercise heart rate	
Diltiazem	90-360	3-4		
Diltiazem CD	180-360	1		
Verapamil	80-480	2-3		May cause heart block, particularly when combined with beta blocker
Verapamil SR	120-480	1-2		
Verapamil-Covera HS	180-240	1 (at bedtime)		

Dihydropyridines				
Amlodipine	2.5-10	1	Same as diltiazem and verapamil	More potent vasodilators than diltiazem and verapamil; may cause dizziness, headache, tachycardia, flushing, edema
Felodipine	5-20	1	Do not blunt increase in exerise heart rate	
Isradipine	2.5-10	2		
Nicardipine	60-120	3		
Nifedipine	30-120	3		
Nifedipine (GITS)	30-120	1		
Nisoldipine	10-10	1-		
Direct vasodilators				
Hydralazine	50-200	2-4	Direct relaxation of smooth muscle cells, causing arteriolar vasodilation secondary to opening [K^+] channels	Limited efficacy if given alone due to fluid retention and reflex vasodilation; should be combined with a diuretic and a beta blocker to prevent edema and tachycardia
Minoxidil	2.5-80	1		

COMBINATION DRUGS FOR HYPERTENSION

Drug	Trade Name
Beta-adrenergic blockers and diuretics	
Atenolol 50 or 100 mg and chlorthalidone 25 mg	Tenoretic
Bisoprolol fumarate 2.5, 5, or 10 mg, and hydrochlorothiazide 6.25 mg	Ziac[a]
Metoprolol tartrate 50 or 100 mg and hydrochlorothiazide 25 or 50 mg	Lopressor HCT
Nadolol 40 or 80 mg and bendroflumethiazide 5 mg	Corzide
Propranolol hydrochloride 40 or 80 mg and hydrochlorothiazide 25 mg	Inderide
Propranolol hydrochloride (extended release) 80, 120, or 160 mg and hydrochlorothiazide 50 mg	Inderide LA

Timolol maleate 10 mg and hydrochlorothiazide 25 mg	Timolide
ACE inhibitors and diuretics	
Benazepril hydrochloride 5, 10, or 20 mg, and hydrochlorothiazide 6.25, 12.5, or 25 mg	Lotensin HCT
Captopril 25 or 50 mg and hydrochlorothiazide 15 or 25 mg	Capozide[a]
Enalapril maleate 5 or 10 mg and hydrochlorothiazide 12.5 or 25 mg	Vaseretic
Lisinopril 10 or 20 mg and hydrochlorothiazide 12.5 or 25 mg	Prinzide, Zestoretic
Angiotensin II receptor antagonists and diuretics	
Losartan potassium 50 mg and hydrochlorothiazide 12.5 mg	Hyzaar
Calcium antagonists and ACE inhibitors	
Amlodipine besylate 2.5 or 5 mg and benazepril hydrochloride 10 or 20 mg	Lotrel
Diltiazem hydrochloride 180 mg and enalapril maleate 5 mg	Teczem
Verapamil hydrochloride (extended release) 180 or 240 mg and trandolapril 1, 2, or 4 mg	Tarka
Felodipine 5 mg and enalapril maleate 5 mg	Lexxel
Other combinations	
Triamterene 37.5, 50, or 75 mg, and hydrochlorothiazide 25 or 50 mg	Dyazide, Maxide
Spironolactone 25 or 50 mg and hydrochlorothiazide 25 or 50 mg	Aldactazide
Amiloride hydrochloride 5 mg and hydrochlorothiazide 50 mg	Moduretic
Guanethidine monosulfate 10 mg and hydrochlorothiazide 25 mg	Esimil
Hydralazine hydrochloride 25, 50, or 100 mg, and hydrochlorothiazide 25 or 50 mg	Apresazide
Methyldopa 250 or 500 mg and hydrochlorothiazide 15, 25, 30, or 50 mg	Aldoril

Reserpine 0.125 mg and hydrochlorothiazide 25 or 50 mg	Hydropres
Reserpine 0.10 mg, hydralazine hydrochloride 25 mg, and hydrochlorothiazide 15 mg	Ser-Ap-Es
Clonidine hydrochloride 0.1, 0.2, or 0.3 mg, and chlorthalidone 15 mg	Combipres
Methyldopa 250 mg and chlorothiazide 150 or 250 mg	Aldochlor
Reserpine 0.125 or 0.25 mg and chlorthalidone 25 or 50 mg	Demi-Regroton
Reserpine 0.125 or 0.25 mg and chlorothiazide 250 or 500 mg	Diupres
Prazosin hydrochloride 1, 2, or 5 mg, and polythiazide 0.5 mg	Minizide

[a]Approved first-line medications.

Surrogate versus Clinical End Points

Physicians are no longer willing simply to look at the degree of BP reduction when making a choice of antihypertensive therapy. Clinical end points are the events that physicians are trying to prevent in treating hypertension. So-called surrogate (or intermediate) end points are factors that may contribute to clinical end points and can be affected favorably or unfavorably by treatment. Blood pressure reduction is a surrogate or intermediate end point, since the reason for treating hypertension is to reduce the morbidity and mortality associated with elevated BP, not simply to lower BP. Physicians now expect and demand proof that the selection made will prevent hypertension-related clinical end points. Data from large and prospective clinical trials that are designed to evaluate the ability of a drug to reduce hypertension-related CV events as well as or better than an otherwise reasonably alternative drug are the reliable means to use in choosing from among the otherwise bewildering number of options.

Before 1997, only diuretics and beta blockers had been shown to reduce the morbidity and mortality in clinical trials in hypertension. Dihydropyridine (DHP), CAs, and ACE-Is were added to the list after the Syst-EUR trial was completed.[270] This trial used the DHP CA nitrendipine, followed by enalapril and hydrochlorothiazide, if needed, to get BP to goal. It was only in 1999, when the Captopril Prevention Project (CAPPP) was published, that the ability of an ACE-I to reduce morbidity and mortality in a trial that enrolled subjects because they were hypertensive was demonstrated.[312] That project showed that a regimen starting with the ACE-I captopril achieved the same overall benefit in reducing morbidity and mortality as did one that began with diuretics or beta blockers (so-called conventional therapy).[312] Certain interesting findings need further study. For example, the group randomized to conventional therapy had statistically significantly fewer strokes, and the group given the ACE-I had a lower incidence of new DM and better outcomes in those with known type 2 DM. A more recent active comparison study, the second Swedish Trial of Hypertension in Older Persons (STOP-2), again confirmed that both ACE-Is and DHP CA reduce morbidity and mortality as well as but clearly not better than do diuretics and beta blockers.[313] In STOP-2, conventional treatment was not better than newer agents at preventing strokes, and the ACE-I group did not have less incident DM. This trial failed to confirm the intriguing findings from CAPPP.

Numerous studies have shown the value of ACE-Is in saving the lives of patients with HF, in those with an MI, and in those with type 1 DM with nephropathy and proteinuria.[314-317] Many of the subjects in these

trials had hypertension but were enrolled in the studies because they had these other conditions, and so one needs to be cautious about whether these data can be extrapolated to hypertensives who do not have these complications. A major new trial, the Heart Outcome Prevention Evaluation (HOPE) trial, was published in 2000.[318] This trial demonstrated that treatment with the ACE-I ramapril significantly reduced CV events compared with placebo in participants with multiple CV risk factors who had an average BP of 138/78 mmHg.[318] However, HOPE did not have an active comparator, and the group on ramapril did have a modestly lower BP (3/2 mmHg). Although the investigators claimed that this small difference in BP could not explain most of the benefit of ramapril, it is still possible that it was the reduction in BP rather than the ACE-I that was responsible for the dramatic reduction in events.

In the next few years, approximately 30 more events trials will be completed.[319] Table 51-22 lists some of the more important trials in progress. When some or all of these trials are published, it should be known with some degree of certainty whether lowering BP is all that matters or whether a particular drug or class of drugs should be selected because it or they prevent hypertension-related events more effectively. The largest of these trials (42,448 subjects), the Antihypertensive and Lipid Lowering Trial to Prevent Heart Attack (ALLHAT), is due to be completed in 2003.[320] ALLHAT compares diuretics to DHP CAs, ACE-Is, and alpha blockers. Acute MI in the primary end point. In February 2000, the alpha-blocker arm of the ALLHAT trial was stopped because of a 25 percent higher CV mortality and twofold increase in HF when doxazosin was compared to chlorthalidone.[321] The primary end point was not different between the two groups. Here too, there was a difference in BP control. The chlorthalidone group had a 3/0 mmHg lower BP almost from the start compared with those getting doxazosin. Thus, the question of the degree BP reduction versus how one chooses to achieve it remains open.

Table 51-22: Long-Term Outcome-Based Clinical Trials of Antihypertensive Agents in Progress

Acronym (Name)	First-Line Agent	Comparator	Patients	Comments
ALLHAT (Antihypertensive and Lipid Lowering Prevention of Heart Attack Trial)	Amlodipine, Doxazosin, Lisinopril	Chlorthalidone	42,448 in 625 centers in United States and Canada	Doxazosin arm stopped prematurely; 6-year follow-up planned
ANBP-2 (Australian National Blood Pressure Trial No. 2)	ACE inhibitor	Diuretic	6000 65-84-year-old Australians	5-year follow-up planned
ASCOT (Anglo-Scandinavian Cardiac Outcomes Trial)	Calcium antagonist or ACE inhibitor	Diuretic or beta blocker	18,000 residents of Scandinavia or United Kingdom	5-year follow-up planned
CONVINCE (Controlled-Onset Verapamil Investigation of Cardiovascular Endpoints)	COER-verapamil	HCTZ or atenolol	16,602 in 661 centers worldwide	5-year follow-up planned
ELSA (European Lacidipine Study of Atherosclerosis)	Lacidipine	Beta blocker	2251 European patients with known atherosclerosis	4-year follow-up planned
HYVET (Hypertension in the Very Elderly Trial)	ACE inhibitor (± diuretic)	Placebo	2100 patients >80 years old	5-year follow-up planned

INSIGHT (International Nifedipine GITS Study Intervention as a Goal in Hypertension Treatment)	Nifedipine GITS	HCTZ plus amiloride	6592 patients in nine European countries	3-year minimum follow-up planned
LIFE (Losartan Intervention for Endpoint Reduction)	Losartan	Atenolol	9194 patients in >300 centers worldwide	ECG LVH only; 4-year follow-up planned
NICS-EH (National Intervention Cooperative Study in Elderly Hypertensives)	Calcium antagonist	Diuretic	1000 Japanese >60 years old	5 year follow-up planned
NORDIL (Nordic Diltiazem Study)	Diltiazem	Diuretic or beta blocker	11,000 patients in 480 centers in Sweden and Norway	5-year follow-up planned
SHELL (Systolic Hypertension in the Elderly Long-Term Lacidipine Trial)	Lacidipine	Diuretic	4800 Europeans with isolated systolic hypertension	Compares 3.5-year incidence of cardiovascular morbidity/mortality
VALUE (Valsartan Amlodipine Long-Term Utilization Evaluation)	Valsartan (±HCTZ)	Amlodipine (±HCTZ)	14,400 patients in 1000 centers in 31 countries	6 years follow-up, 1450 primary end points expected

It is of great interest that the participants receiving the alpha blocker had lower TC, triglycerides, and serum glucose and higher serum K^+ than did those on the diuretic.[321] If metabolic surrogate end points are important, all these changes would predict that alpha-blocker-treated subjects should have fewer events than do those on chlorthalidone. The opposite was the case. Another trial, the Controlled ONset Verapamil INvestigation of Cardiovascular Endpoints (CONVINCE), will be completed in 2002.[322] This study compares a nondihydropyridine CA (verapamil) to diuretics/beta blockers in 16,600 older hypertensives. This trial will indicate whether this class of CA will prevent mortality and morbidity as well as or better than conventional therapy does. It also will evaluate the importance of circadian variation in BP since the verapamil preparation used is designed to be given at night and released in concert with the morning rise in BP (see below). Event trials of ARBs in older high-risk hypertensives [Valsartan Amlodipine Long Term Use Evaluation (VALUE)] in hypertensives with ECG LVH (the Losartan Intervention for End Point Reduction-LIFE), and in those with diuretic nephropathy are in progress and will be finished in the next few years.[319,323]

Individualizing Therapy

In view of the many effective options available, the physician must pay very close attention to each patient's needs and plan his or her regimen accordingly. Each patient must be treated as an individual, not as a member of a population, and so the drug chosen must be compatible with that individual patient's preferences, lifestyle, and job requirements. Whatever is selected, it must be affordable. No amount of therapeutic wisdom will be effective if the patient does not have the funds to purchase the physician's choice.

Goal of Therapy

One must strive to reduce SBP to below 140 mmHg and to reduce DBP to below 90 mmHg, the goal currently articulated by several guidelines committees.[11,18,19] In diabetic patients, the recommended goal is lower (SBP <130 mmHg and DBP <85 mmHg). JNC VI recommended these more stringent goals for those with DM without proof from a clinical trial to support this aggressive approach. The subsequent publication of the HOT study and the United Kingdom Diabetes Prevention Study (UKDPS) provided the solid evidence that was needed to support this recommendation.[324,325] In patients with renal disease and at least 1 g of proteinuria per day, JNC VI recommended an even lower goal (SBP <125 mmHg and DBP <75 mmHg). This too was not an "evidence-based" recommendation but was based on the expectation that a still lower BP would be helpful in preventing morbidity and mortality in this population of hypertensives.[326] The African-American Study of Kidney Disease (AASK) will provide definitive evidence for or against this very stringent goal.[327] Whether this more aggressive goal should be extended to other subpopulations, such as those with prevalent CVD, remains to be proved.

One of the perceived limitations to achieving this lower level of BP control was the fear that lowering BP too far might be harmful, the concept of the "J" curve. Several investigators had pointed out that subjects treated to diastolic BP level below 85 mmHg had higher rates of MI than did those whose on-treatment diastolic BP was between 85 and 90 mmHg.[328,329] However, an increased risk for those with low diastolic BP is also evident in populations and in the placebo groups of several trials.[330,331] Furthermore, the Systolic Hypertension in the Elderly Program (SHEP) treated individuals down to an average diastolic BP of 67 mmHg and prevented MIs compared with those with an average of 71 mmHg.[269] Definite proof that aggressive treatment is not harmful has come from the HOT and UKPDS trials.[324,325] These studies showed no increase in the incidence of CV events in the groups randomized to the lowest levels of BP control, but HOT could not show that those treated to the lowest goal necessarily did the best. Both demonstrated reduced risk in hypertensives with DM and did not support the contention that hypertensives with known CAD would be at risk if treated aggressively. Both support the more aggressive BP treatment goals now recommended by guidelines committees (Table 51-23).

Table 51-23: Goal Blood Pressure

General population without diabetes or renal disease	<140/90 mmHg
Diabetes	<130/85 mmHg
Renal disease with >1 g proteinuria	<125/75 mmHg
Isolated systolic hypertension	<140 mmHg

While the benefits of this level of aggressive therapy have not been proved conclusively, clinical trial results suggest that more events would be prevented with these treatment goals than with higher levels, with little if any harm to the patient. Another aspect, that of cost, was addressed in an analysis by Elliott and colleagues.[332] They compared the putative cost/effectiveness ratio of treating to a goal of [140/90 mmHg (JNC V) compared with 130/85 mmHg (JNC VI)] in hypertensives with type 2 DM.[11,38] Their theoretical analysis suggested that the aggressive approach would save money. Even though more drugs would be needed, the reduction in both direct costs (hospitalization for the greater number of events that would occur in those with higher BP) and indirect costs (lost work) would more than balance the money spent for additional antihypertensives, any costs related to adverse reactions, and the extra visits to providers necessary to get BP to the lower goal.

Factors to Consider in Choosing an Initial Antihypertensive Agent

There are 10 factors that should always be considered when initial therapy is chosen and other drugs are added (if additional agents are needed to reduce BP to goal) (Table 51-24).

Table 51-24: Factors in the Choice of Agents for Antihypertensive Therapy

1. Efficacy
2. Comorbidity and other risk factors
3. Safety (adverse reactions and side effects)
4. Demographic considerations
5. Special situations
6. Dose schedule (dosage and chronotherapy)
7. Drug interactions
8. Adherence
9. Mechanism of action of drug and pathophysiology of patient's hypertension
10. Cost

EFFICACY

JNC VI made the distinction between surrogate and clinical end points when it provided guidelines for selecting treatment that were based on efficacy, defined as the reduction of morbidity and mortality. Now four classes of drugs (thiazide diuretics, beta blockers, long-acting DHP CAs, and ACE-Is) have been shown to reduce CV end points when used as the initial therapy for hypertension in appropriately designed and implemented clinical trials. Other agents, such as peripheral sympatholytics (reserpine and guanethidine), centrally acting alpha agonists (alpha-methyldopa), and vasodilators (hydralazine), also have been used in clinical trials as the second, third, or even fourth agent to be added to get BP under control. None is an option for initial therapy because they are relatively poorly tolerated compared with the agents that are recommended as initial therapy or need to be taken together with diuretics to lower BP effectively in the long term. Other drugs, such as alpha/beta blockers and ARBs, that are effective as monotherapy and are well tolerated, have not yet been shown to reduce clinical end points. Alpha blockers are valuable as adjunctive therapy, but the early data from ALLHAT have shown that this class should not be used as the initial treatment for hypertension unless symptomatic relief of benign prostatic hypertrophy (BPH) is needed.[321] Many would now recommend that a man with hypertension and BPH get another drug along with the alpha blocker as part of an antihypertensive regimen.

COMORBIDITY AND OTHER RISK FACTORS

JNC VI has recognized two other factors that may alter the correct choice of initial treatment in an individual hypertensive patient:

- Data from events trials that were conducted in subjects with other conditions (e.g., type 1 DM, acute MI, HF, and after HOPE, those considered to be at high risk for CV events) but in which many subjects with hypertension were enrolled. These trials were the basis for the JNC VI designation of a "compelling" indication (Table 51-25)
- Individual patients may have certain comorbid conditions for which a specific agent may be appropriate even though no trial has been completed in which that agent has been compared to drugs for which clinical trial data are currently available. This was the basis of the JNC VI recommendation for a drug to be indicated or contraindicated as a "specific" indication even though randomized clinical trials might not be available to support that decision (Table 51-26). A "specific" indication tries to codify clinical judgment, or that which any reasonable clinician would do to care for all the health needs of his or her patients. For the most part, these recommendations do not add classes of drugs to the list of those which are favored because of a reduction in clinical end points but instead alter the choice of which class should be selected for initial therapy. Good examples are osteoporosis and thiazide diuretics and angina pectoris and beta blockers.

The factors that influence the specific indications are generally the presence of other risk factors and active clinical problems. These conditions may and often should alter the initial and subsequent choice of antihypertensive therapy in an individual patient. An appreciation of the fact that the drugs prescribed to

reduce BP can improve or adversely affect other clinical conditions is the basis for the JNC VI recommendation that although diuretics and beta blockers should be used when a patient has "uncomplicated" hypertension, the presence of these comorbid conditions clearly affects that decision.

Table 51-25: Considerations in Individualizing Antihypertensive Drug Therapy

Indication[a]	Drug Therapy
DM (type 1) with proteinuria	ACE-I
HF (systolic)	ACE-I, diuretics, beta blockers, aldosterone receptor blockers
Isolated systolic hypertension (older patients)	Diuretics (preferred), DHP CAs
MI	Beta blockers (non-ISA), ACE-Is (systolic dysfunction)

[a]Compelling indications unless contraindicated.

SOURCE: Modified from JNC VI.

Table 51-26: Drugs That May Have Favorable or Unfavorable Effects on Comorbid Conditions

Favorable

- Angina
- Atrial tachycardia and fibrillation
- Cyclosporine-induced hypertension
- DM (types 1 and 2) with proteinuria
- HF
- Liver disease
- Peripheral vascular disease
- Pregnancy
- DM (type 2)
- Dyslipidemia
- Essential tremor
- Hyperthyroidism
- Migraine
- MI
- Osteoporosis
- Preoperative hypertension
- Prostatism (benign prostatic hyperplasia)
- Renal insufficiency (caution in renovascular disease)

Unfavorable

- Bronchospastic disease
- Depression
- DM (types 1 and 2)
- Dyslipidemia
- Gout
- Second- or third-degree heart block
- Renal insufficiency, renovascular disease
- Beta blockers, Ca^{2+} antagonists
- Beta blockers, CA nondihydropyridines
- Ca^{2+} antagonists (caution with the dose of cyclosporine)
- ACE-Is (preferred), CAs (nondihydropyridines), low-dose diuretics
- ACE-Is, losartan, K^{+}-sparing agents, beta-blockers
- Beta blockers
- Alpha-blockers, CAs
- Labetalol hydrochloride, methyldopa
- ACE-Is
- Alpha blockers
- Beta blockers
- Beta blockers
- Beta blockers (noncardioselective), Ca^{2+} antagonists (nondihydropyridine)
- Beta blockers (cardioselective)
- Thiazide diuretics
- Beta blockade
- Alpha blockers
- ACE-Is, ARBs, K^{+}-sparing agents for hypertension and creatinine >3 mg/dL
- Beta blockers
- Beta blockers, central alpha agonists, reserpine
- Beta blockers, high-dose diuretics
- Beta blockers (non-ISA), diuretics (high-dose)
- Diuretics
- Beta blockers, Ca^{2+} antagonists (nondihydropyridine)
- ACE-Is, ARBs

This approach was also used by the BHS.[19] In those guidelines, similar language to that in JNC VI was used, but the BHS considered the presence of some of these comorbid conditions to be a compelling reason rather than a specific one to choose a particular class of drugs even though a trial had not been completed proving the value of those agents in patients with these conditions. The lessons from the Evaluation of Losartan in the Elderly II trial (ELITE II), which failed to show any advantage of an ARB over an ACE-I (see below), and ALLHAT are that it is best to demand and wait for evidence that an agent prevents events before recommending to clinicians that they should feel "compelled" to prescribe that class.

Dyslipidemias

Hypertensive patients who have lipid abnormalities (which may be present in as many as 50 percent of those treated for hypertension) probably should not be treated with drugs that worsen their particular dyslipidemia. Although it has not been proved that the changes in serum lipids caused by certain classes of antihypertensive agents are harmful, it is certainly reasonable to choose an equally effective drug that is lipid-neutral or one that may improve the lipid profile.[333] In large doses (>25 mg/day), thiazide diuretics and related compounds such as chlorthalidone raise TC and LDL-C 5 to 10 percent at least transiently and may lower HDL-C 2 to 4 percent. Serum triglycerides are increased 15 to 30 percent.[334] With the doses that are currently recommended (using up to but no more than 25 mg of hydrochlorothiazide), there is little if any alterations in these parameters. The beta blockers that do not have intrinsic sympathomimetic activity lower HDL-C even more (10 percent) and also raise triglycerides (approximately 20 percent) without affecting TC or LDL.[335] Beta blockers that do have intrinsic sympathomimetic activity and alpha/beta

blockers are lipid-neutral.

Conversely, one could choose to add to therapy using a peripheral alpha blocker in patients with dyslipidemias who are already being treated with agents known to reduce CV events, such as beta blockers, ACE-Is, and diuretics.[333,336] These drugs reduce TC and LDL cholesterol approximately 8 to 10 percent, triglycerides 15 percent, and HDL-C 10 to 15 percent. The ALLHAT results mentioned above call into question the wisdom of this approach.[321] ACE-Is do not affect serum lipids, and in some studies benefits similar to those seen with alpha blockers have been observed. ARBs and CAs are lipid-neutral.[334,335]

Other sympatholytics do not affect the lipid profile, and direct vasodilators (e.g., hydralazine) raise HDL-C and lower triglycerides and TG even when used in combination with thiazide diuretics.

Glucose and Insulin and Diabetes Mellitus

Antihypertensive drugs may affect glucose metabolism and worsen or improve insulin sensitivity.[333] The magnitude and direction of the drug-induced changes seen in glucose and insulin are very similar to what occurs with lipids. Peripheral alpha blockers and some ACE-Is (captopril, enalapril, trandolapril, and perindopril) may improve insulin sensitivity.[337] Not only do some ACE-Is improve insulin sensitivity, all have been shown to reduce urinary protein excretion, which may contribute to the renal benefit seen in patients with DM. Both moderate- to high-dose thiazides and beta blockers worsen insulin sensitivity and occasionally precipitate glucose intolerance. Beta blockers increase the risk of developing clinical DM by up to 25 percent.[338] In spite of these metabolic changes, in SHEP, treatment with low-dose chlorthalidone (plus atenolol or reserpine in some volunteers) reduced clinical events in the diabetic subgroup even more than it did in nondiabetics.[339] In the HOPE trial and in CAPPP, incident diabetes was prevented.[312,318] These findings, if confirmed by ALLHAT (STOP-2 did not demonstrate that ACE-Is prevented new DM), indicate that patients at high risk of becoming diabetic (the obese and those with glucose intolerance or other components of syndrome X) also might benefit from treatment with ramapril or an ACE-I.

Hypertensives with Diabetes Mellitus

The combination of hypertension and DM confers much more risk for CV events and renal failure than does either one alone. Angiotensin-converting enzyme inhibitors, diuretics, and beta blockers have been shown consistently to reduce CV and renal risk. There are very few data on other classes of antihypertensive agents, although there are some preliminary studies with ARBs and CAs. JNC VI recommended that clinicians should feel "compelled" to give hypertensive patients with type 1 DM an ACE-I only because the only randomized clinical trial that has clearly demonstrated the utility of ACE-Is in reducing clinical events was done in a group of type 1 diabetic patients with hypertension.[316] Although no large, long-term events trials have been completed that have proved the special value of ACE-Is in patients with type 2 DM, many feel that the benefit shown for type I diabetic patients also can be assumed to occur for type 2 diabetic patients, and so ACE-Is were recommended by JNC VI as a specific indication.[11] Others argue that if BP control is achieved, it does not matter what drug or drugs are used. In UKPDS, the group that received the ACE inhibitor captopril did no better than did the group that received atenolol. This lends some support to the argument that BP control, not how it is accomplished, is the key factor in reducing events in type 2 diabetic patients.[325]

Although some experts have raised concern about the safety of DHP CAs in type 2 diabetic patients, the Syst-EUR study, in which these drugs were the initial therapy, demonstrated that the benefit accrued was greater in diabetic patients than it was in other patients.[340] Just as with SHEP, the results of a properly done clinical trial disproved surrogate end-point-based hypotheses from other sources of data such as observational studies, case-control studies, and meta-analyses of smaller trials.

Trials of CV mortality involving nondihydropyridine CAs in high-risk hypertensive patients have not been completed. However, nondihydropyridine CAs have been shown to reduce CV mortality after an MI and slow the progression of diabetic nephropathy.[341,342] Moreover, their use in combination with ACE-Is

lowers urinary protein excretion, and unlike DHP CAs, they have additive effects to reduce proteinuria independent of BP reduction.[343,344] This combination appears to be particularly useful in diabetic patients with nephropathy and proteinuria.

From the available data, it would appear that in people with DM, the most important factor in reducing mortality and preserving renal function is reducing BP to goal (Table 51-23).

Left Ventricular Hypertrophy and Heart Failure

Left ventricular hypertrophy results from chronic elevations in arterial pressure that cause cardiac myocyte hypertrophy and remodeling of the coronary resistance vessels. This leads to perivascular fibrosis of the intramyocardial arteries and arterioles. Over time, these changes in the myocardium contribute to the development of ventricular wall stiffness and diastolic dysfunction.[345]

Left ventricular hypertrophy is a robust independent risk factor for CV and premature mortality.[227] It is especially common in the elderly, particularly in elderly women, and often is associated with diastolic dysfunction. It appears that all antihypertensive agents that are recommended for initial therapy reduce LV mass. Data from meta-analyses have suggested that agents that block the RAA system reduce LV mass better than do other antihypertensive agents.[235] However, TOMHS and the Veterans Administration (VA) study of monotherapy found that there was no difference among antihypertensive agents in their ability to regress LVH.[236,237] Moreover, in TOMHS, nutritional hygienic measures such as weight loss, reduced Na^+ and alcohol intake, and exercise were effective by themselves in regressing LV mass. Perhaps the most important factor responsible for LV mass regression is the prolonged reduction of systolic BP.

Heart Failure

Hypertension has been identified as a major risk factor for the subsequent development of HF, the onset of which typically occurs many years later.[346] For many un- or undertreated hypertensives, LVH is an important intermediate step, resulting in "hypertensive heart disease" with impaired LV filling and increased ventricular stiffness. This type of HF (which has been seen in up to 40 percent of hospitalized patients with an antecedent history of hypertension) is commonly called diastolic dysfunction.[233] The more common type of "systolic dysfunction" associated with a reduced LV ejection fraction most often is due to previous MI (for which hypertension is also an important risk factor). In a meta-analysis of clinical trials in hypertension, there was a 42 percent reduction in HF incidence among hypertensives randomized to either a low-dose diuretic or a beta blocker.[342]

Distinguishing between the two subtypes of HF is most easily done by quantitation of the LV ejection fraction.[347] The results dictate the therapy. Patients with low ejection fractions ("systolic HF") improve both BP and long-term prognosis with ACE-Is and diuretics, to which are sometimes added beta blockers, spironolactone, and/or other drugs.[314,347-349] The role of ARBs is controversial unless cough or other adverse effects preclude an ACE-I. In the first (but small) direct comparison of captopril and losartan [Evaluation of Losartan In The Elderly (ELITE)], there was a survival benefit (a tertiary hypothesis) attributed to the ARBs, which the larger study (ELITE II), with exactly the same protocol, did not confirm.[350] If cough or other adverse effects of an ACE-I preclude its use, an ARB becomes the rational choice. Ongoing research may define the benefit of using both an ACE-I and an ARB simultaneously in patients with systolic HF. The role of DHP CAs and other direct-acting vasodilators (e.g., hydralazine in combination with isosorbide dinitrate) remains controversial.[351] Most authorities recommend these drugs as second- or third-line therapy (after maximum doses of ACE-Is and/or ARBs) if BP is still elevated. Recently, in the Randomized Aldactone Evaluation Study (RALES) trial, spironolactone, an aldosterone antagonist, in doses that do not lower BP reduced morbidity and mortality in patients with HF, most of whom were already taking ACE-Is, aspirin, and diuretics.[349] Many of these patients were also on beta blockers.

Treatment of hypertension with diastolic dysfunction and HF has not been as well studied, but most

authorities recommend using drugs that reduce HR, increase diastolic filling time, and allow the heart muscle to relax more fully: beta blockers or nondihydropyridine CAs.[352,353] Although these options make physiologic sense, no randomized clinical trials have had outcomes that demonstrate their long-term efficacy.[352]

Valvular Disease

The coexistence of hypertension and valvular heart disease is, for most affected patients, simply an occurrence of two common conditions in the same person. There are few syndromes or scenarios in which the two are pathophysiologically connected, but there are some circumstances in which their coexistence has clinical importance, especially in regard to choosing antihypertensive drug therapy.

A murmur of aortic sclerosis is found in approximately 21 to 26 percent of adults over 65 years of age. Recent data from the CV Health Study showed that 29 percent of the 5621 subjects age 65 and over had this valvular abnormality detected on echocardiography; it was found much more commonly among hypertensives and those with LVH.[354] Perhaps most important, its presence was associated with a 50 percent increased risk of CV events over an average of 5 years of follow-up. After adjustment for risk factor differences at baseline (e.g., hypertension), only one of four studied end points retained statistical significance. Calcific aortic stenosis is about 10 times less common but often must be evaluated more extensively, usually with an echocardiogram. Aortic insufficiency in hypertensives is found almost exclusively in patients with isolated systolic hypertension and is most easily recognized by the murmur and several peripheral signs.[355] Unloading the LV with arteriolar vasodilators has long been recommended on a pathophysiologic basis and has been shown in a long-term trial against digoxin to prolong the time until valvular replacement surgery was required.[356] Although nifedipine was used in the study, it is likely that any vasodilator would be more effective than a weakly positive inotropic agent.

Mitral valvular disease is less common than it was in past decades, primarily because of efforts to treat streptococcal pharyngitis. Mitral stenosis is still seen occasionally in citizens of developing countries but is not commonly associated with systemic hypertension. Since digoxin typically is used to control the ventricular rate in atrial fibrillation, antihypertensive drugs that interfere with the excretion of digoxin should be used cautiously. Mitral insufficiency is also less common than it was in the past, but there are few problems specific to this disease that affect hypertension and its therapy.

The right-sided cardiac valves seldom need be considered in the treatment of patients with systemic hypertension. In patients with primary (or secondary) pulmonary hypertension (which can be treated with the usual antihypertensive drugs, although with less success), the status of the right-sided heart valves takes on increased significance.[357] Occasionally, insufficiency of the tricuspid valve is the major diagnostic clue to carcinoid heart disease (associated with weight loss drugs but rarely associated with hypertension).[358]

Microalbuminuria

MA is a predictor of CV and renal death in patients with DM.[359-361] The class of antihypertensive medications known to have the most potent effects on reducing MA is the ACE-Is.[317,359-363] These agents reduce albuminuria by reducing intraglomerular pressure as well as decreasing glomerular size selectivity and partially restoring membrane charge.[362,363] The effects of different classes of antihypertensive agents on MA as well as related metabolic parameters are summarized in Table 51-27.

Table 51-27: Effects of Drugs on Microalbuminuria and Proteinuria

Decrease levels
ACE inhibitors
Angiotensin receptor blockers
Alpha/beta blockers
Nondihydropyridine CAs
Beta blockers
Diuretics
Increase levels
Short-acting dihydropyridine CAs
Minoxidil
No effect
Dihydropyridine CAs (long acting)
Alpha blockers
Central alpha agonists (clonidine, methyldopa)

Both ACE-Is and nondihydropyridine CAs reduce albuminuria and together have additive antialbuminuric effects, in part independently of further reductions in BP.[359,364,365]

The ACE-Is and ARBs are the antihypertensive agents that most consistently reduce proteinuria in response to their BP-lowering effect. Moreover, in the absence of hypertension, these agents prevent the increase of MA to proteinuria and in many cases normalize protein excretion in patients with MA.[366] Nondihydropyridine CAs (diltiazem and verapamil) also have some utility in reducing urinary protein excretion in hypertensive patients with kidney disease.[364] In two studies, these drugs had antiproteinuric effects similar to those of ACE-Is in hypertensive diabetic patients with chronic renal disease and heavy proteinuria.[367,368] Some studies have shown that a high Na^+ intake blunts the antiproteinuric and antihypertensive effects of an ACE-I.[369,370] Increasing dietary salt despite not affecting BP appears to abolish the antiproteinuric effect of the nondihydropyridine CA diltiazem, and so attention should be paid to Na^+ intake in patients with MA/or proteinuria.[368,369] Since there are so many more data, including events data, about ACE-I than about any other agents, including ARBs, ACE-Is should be the first-line treatment of hypertension in DM and should be included in all antihypertensive regimens in such patients if tolerated.

Renal Dysfunction

Any agent or group of agents that adequately lowers BP to levels <130/85 mmHg will slow the progression of nephropathy. Aggressive BP reduction (<125/75 mmHg) is needed to maximally slow the progression of renal disease, especially among patients with elevated serum creatinine. Aggressive BP reduction (<125/75 mmHg) is needed to maximally slow the progression of renal disease, especially among patients with an elevated serum creatinine ≥1.4 mg/dL.[11] ACE-Is will slow the progression of diabetic and nondiabetic nephropathy, assuming BP reduction to levels below 140/90 mmHg.

In spite of the evidence from many long-term clinical trials, there is a general hesitancy among clinicians to use ACE-Is in such patients. This stems from a rise in serum creatinine that predictably occurs when the

drug is given. It is common to see increases in serum creatinine of up to 25 percent above baseline within 2 to 3 months of ACE-inhibitor initiation. An analysis of long-term clinical trials has confirmed that this reduction in renal function plateaus within a month.[371] In a study from Scandinavia, ACE-Is were discontinued after an average follow-up of 6 years of therapy. The glomerular filtration rate (GFR) returned to levels not significantly different from baseline even though within the first 4 months after ACE-I initiation there was a clear initial reduction in GFR by an average of 8 to 10 percent below baseline.[372] This return to baseline GFR has not been reported with any other class of antihypertensive agent studied and suggests that ACE-Is prevented the expected deterioration of renal function over time. If the serum creatinine continues to rise, especially after 1 month of therapy, evaluation for renal artery stenosis may be indicated.

There are also concerns about hyperkalemia. This should be worrisome only if the serum K^+ rises ≥0.5 meq/L.

The role of ARBs in the treatment of nephropathy and reducing CV events has not been settled. All animal studies and one completed clinical trial in patients with HF suggest that these agents are as good as ACE-Is in slowing the progression of renal disease and reducing proteinuria and CV events.[360,365] Whether ARBs are better than ACE-Is or even equivalent remains to be proved. Two ongoing clinical trials in subjects with diabetic nephropathy are scheduled to be completed by 2002 and will answer the question definitively.[319]

Thus, while any class of antihypertensive agent may be used to achieve this new recommended lower level of BP to preserve renal function, certain principles should be kept in mind.

- BP will never be controlled adequately in patients with significant renal insufficiency (serum creatinine >1.8 mg/dL) without the use of a diuretic (usually a loop diuretic).
- Long-acting loop diuretics are preferred, or if furosemide is used, it needs to be given twice a day.
- Various combinations of medications will be needed to achieve BP reduction. One of these drugs should contain an ACE-I. If side effects are noted with the ACE-I, an ARB may be substituted to ensure renal protection and BP reduction.

Since CV is the most common cause of death in people with renal disease, beta blockers clearly also have a role in therapy. These agents do not have synergistic or additive effects on BP in the presence of agents such as clonidine.[373]

Coronary Artery Disease

Since hypertension is a major risk factor for CAD, it is not surprising that a large number of patients have both conditions. It is unlikely on ethical grounds that a placebo-controlled trial will be done with any single antihypertensive drug in such patients. The presence of CAD in a patient with hypertension is likely to influence both the choice of drugs used to treat the patient and the BP goal to be achieved. Because both beta blockers and CAs are effective antihypertensive agents with major antianginal efficacy, they are often the preferred agents for initial treatment, especially in the common setting of unstable angina pectoris.[374] A recent meta-analysis suggested that the former are more effective, although the latter are more commonly used.[375] The recent HOPE trial showed a large survival benefit for high-risk hypertensives (most of whom had known CAD) treated with ramapril.[318] None of the volunteers in HOPE had known HF at enrollment in which this degree of benefit would have been expected. This has been interpreted by some as evidence in favor of this class of medication or even for this specific agent for all hypertensive patients with CAD.

The issue of how low to reduce BP in the setting of CAD is controversial. The concept of the J-shaped curve has been supported by data in patients with coronary disease, mostly using beta blockers.[328] Diastolic pressures less than 82 mmHg were associated with a higher risk of coronary events, and the rationale proposed was that since coronary artery filling occurs during diastole, reducing perfusion pressure during this time might increase coronary ischemia. These and other data led to the HOT study, in which 18,790 hypertensive patients without known coronary disease were randomized to one of three diastolic BP goals: ≤90, ≤85, and ≤80 mmHg.[324] After 3.8 years, there were no significant differences in major CV events

across the groups, suggesting that there is no increase in risk from lowering diastolic BPs below 80 mmHg. It is unlikely that a similar study in patients with CAD will be done, but some still recommend caution in lowering BP below 85 mmHg in patients with angina and/or known CAD. JNC VI indicates that "BP should be lowered to the usual target range (<140/90 mmHg), and even lower BP is desirable if angina persists."[11] The World Health Organization/International Society of Hypertension's Collaborative Trialists' Group is collecting patient-specific outcome data and eventually may have sufficient power from the clinical trials in this registry for a post hoc analysis comparing levels of achieved BP control among 270,000 hypertensives with or without CAD.[319] Even after such data become available, it probably will be advisable to use beta blockers, CAs, and perhaps nitrates for hypertensive patients with CAD to achieve a slightly lower than usual BP target and to recommend aspirin and intensive treatment of dyslipidemias. Appropriate precautions must be taken for hypertensives also using sildenafil citrate (Viagra). To date, no antihypertensives seem to confer any increased risks when used with this agent, but all nitrate-containing preparations are contraindicated.

After Stroke

Although hypertension is perhaps the most powerful risk factor for acute stroke and "clinically evident cerebrovascular disease is an indication for antihypertensive treatment," optimal BP management depends on the nature, cause, and chronology of the neurologic symptoms.[376] In the immediate setting of acute ischemic stroke, there is controversy about the optimal level of acceptable BP. Appropriate concern has been expressed about possible reduction in blood flow to "watershed" areas of the brain that are already poorly perfused if BP is reduced pharmacologically.[377] Many neurologists have observed acute worsening of cerebrovascular function and evolving neurologic deficits when BP has been reduced "too much" or "too quickly." Most physicians therefore are uncomfortable reducing BP to <180/100 mmHg. Many do not institute treatment until mean arterial pressure is >130 mmHg (e.g., BP >200/100 mmHg), except in the setting of concomitant hemorrhagic transformation or another hypertensive emergency (e.g., aortic dissection, MI, renal failure with bleeding).[378] This level of BP is at least supported by the exclusion criterion from the National Institutes of Health (NIH)-sponsored rt-PA for acute stroke trial; patients with BP >185/110 mmHg were prohibited from getting the thrombolytic agent and were instead suggested to receive antihypertensive therapy.[379] The optimal drug therapy for acute stroke-related hypertension is also ill defined, but most authorities prefer intravenously administered, short-acting agents because they can be discontinued quickly if a patient's neurologic condition deteriorates acutely.[378]

SAFETY (ADVERSE REACTIONS AND SIDE EFFECTS)

The two primary types of adverse reactions and side effects that occur with antihypertensive therapy are clinical and biochemical (Table 51-21). Clinical side effects are directly evident to the patient and are perceived by the patient or the clinician to be related to the drug. The appearance of these adverse reactions requires that the drug be stopped, the dose be reduced, or the patient be willing to remain on therapy until he or she becomes able to tolerate the side effect or until it disappears. The drugs recommended for initial therapy generally cause fewer clinical side effects than do other drugs at doses that lower BP.[11,18,19]

Biochemical side effects may lead to clinically evident adverse reactions (e.g., hypokalemia from thiazide diuretics causing muscle weakness, palpitations, nocturia, or polyuria), but usually the biochemical problems that occur with antihypertensive agents are more troublesome to the clinician than they are to the patient.

The importance of biochemical side effects is usually not that they result in clinically evident problems but the danger that these drug-related permutations of lipids, glucose, or insulin may aggravate other risk factors and accelerate the clinical impact of dyslipidemias, glucose intolerance, or insulin resistance. Whether the minor and often short-term effects on triglycerides, HDL-C, or TG that result from therapy with thiazides or beta blockers are responsible for an increase in ischemic heart disease remains to be proved. It is of great interest that in ALLHAT the biochemical profile of the group receiving the alpha blocker seemed favorable (lower triglycerides, TG, and glucose and higher K^+) compared with the group on chlorthalidone, yet the diuretic prevented CV events more successfully.[321] The remaining treatment arms of

ALLHAT (DHP CA and ACE-I versus diuretic) should definitely delineate the role of these metabolic changes.

At the doses that are now recommended, these changes and the electrolyte disturbances noted with thiazides are modest, although it is still possible that at high doses, thiazides could reduce serum K^+ sufficiently to increase the rate of sudden cardiac death. Whether the increases in insulin resistance that are seen with thiazide diuretics and beta blockers and the hypokalemia that is seen with thiazide diuretics have precipitated DM sooner or in patients who would not otherwise have become diabetic also remains to be proved. Although it is not certain that these metabolic adverse reactions are clinically relevant, it may be prudent to select another option for patients with DM or a dyslipidemia so long as BP is reduced to goal. Certain types of dual therapy also may ameliorate biochemical adverse reactions. Angiotensin-converting enzyme inhibitors and ARBs and thiazides, when given together, produce few, if any, of the metabolic abnormalities associated with thiazides alone.[380] Several fixed-dose combinations or these classes of drugs are available and may be appropriate as initial therapy[11] (Table 51-21).

The incidence of clinical side effects tends to rise with increasing doses with all classes of drugs, with the exception of ACE-Is and ARBs. Patients who develop an adverse reaction on a high dose of a drug or on a dose they previously tolerated do not necessarily need to have that drug discontinued. Instead, the dose can be lowered and another antihypertensive can be added to reduce BP to goal. The primary problems with ACE-Is are cough and angioedema, both of which tend to be idiosyncratic and occur with all representatives of that class of agents. Reducing the dose or changing to a different ACE-I is rarely helpful. Angiotensin-converting enzyme inhibitors should be increased to the maximum recommended dose before therapy is abandoned or another agent is added unless a low-dose fixed-dose combination is felt to be more appropriate. Angiotensin II receptor blockers as a class appear to be the best tolerated of all currently available antihypertensive agents.[381] Although some experts feel that they should be reserved for initial therapy only in patients who have developed a cough with ACE-Is, they are also an excellent option for patients who have no complaints when treatment is started and patients in whom a drug that primarily blocks the RAA system appears to be a good option. When VALUE and LIFE are completed, it will be known whether ARBs are as good a choice as the other four classes of antihypertensives available.

DEMOGRAPHIC CONSIDERATIONS

Blacks and Other Ethnic Minorities

Some classes of antihypertensive agents reduce BP more or less effectively in certain ethnic groups. Thiazide diuretics, for example, are more effective in blacks than in whites, whereas ACE-Is, ARBs, and beta blockers are more effective at lower doses in whites. Many blacks respond to agents that block the RAA system, but they often need higher doses than do whites or Asians.[382] Studies in African-Americans have demonstrated that starting with higher doses of an ACE-I makes this class quite efficacious in lowering BP in this population.[383] Therefore, if a black hypertensive patient would benefit from the special properties that these drugs may have in type 1 diabetic patients or in HF, for example, they definitely should be used even if additional agents will be needed to get BP to goal. Peripheral alpha blockers, alpha/beta blockers, and CAs are equally effective in all types of hypertensive patients in all ethnic groups. In general, the response rates to antihypertensive agents in Hispanics is intermediate between that seen in whites and that seen in blacks, while east Asians, though not necessarily south Asians (patients from the Indian subcontinent), often need lower doses than do whites.

The Elderly

All classes of antihypertensive agents lower BP effectively in older persons, although the doses needed to reach goal are often lower than the doses necessary in young and middle-aged hypertensive patients.[384,385] Certain drugs and certain classes of drugs, however, should be avoided or used with caution in older hypertensives. These include agents, such as peripheral alpha blockers, that can exacerbate the postural fall in BP seen more frequently in older individuals with baroreceptor dysfunction; nondihydropyridine CAs and beta blockers that may aggravate subtle or subclinical conduction defects or precipitate systolic

dysfunction and HF; and verapamil, which may not be well tolerated in some older persons already bothered by constipation. Cough from an ACE-I may be more common in older women. Diuretics and dihydropyridine DHP CAs have both been shown to reduce morbidity and mortality in older persons with stage 2 or 3 isolated systolic hypertension, making them excellent choices in such patients.[269-271] What is often forgotten in regard to many classes is that the benefits of effective treatment are more evident in older hypertensives who are at higher risk than are younger hypertensives.[385] Therapy should not be withheld for fear of toxicity or lack of efficacy in the elderly.

Children

The diagnosis and treatment of hypertension in children are different from those in adults, primarily because of the limited experience with antihypertensive drug therapy in children and the low risk of CV events in younger individuals.[386,387] Most pediatricians are very comfortable measuring and monitoring BP in their patients, but few nonnephrologists commit the expected 1 percent of their patients to drug therapy. Because of a higher incidence of secondary hypertension than there is in adults, most hypertensive children have at least an evaluation of the kidneys and urinary tract before beginning treatment.[387]

The diagnosis of hypertension in pediatric patients is truly population-based, since the 5 percent of children with the highest BP are diagnosed with "significant hypertension" and the highest 1 percent are deemed eligible for pharmacologic treatment.[387] The diagnostic cutoffs for hypertension in youth are age- and weight-dependent, and "growth charts" for plotting the progress of a child's BP against age often are completed by pediatricians for height, weight, and, more recently, BP. More frequent measurements and attention to BP are warranted when a child's BP exceeds the 90th percentile. Treatment of hypertension in children begins with lifestyle modifications, since they are likely to be beneficial as a child grows into adolescence and adulthood.[386,387] Because few registration studies of antihypertensive drugs include children (owing to informed consent complexities and risk management issues), there are limited data on the benefits of specific drugs in hypertensive children. Although the recommended treatment algorithm is based on time-tested drug use in adults, there is a growing awareness of the possibility of long-term adverse effects with diuretics and especially beta blockers (which make exercise more difficult and may lead to weight gain) and a growing use of both ACE-Is and CAs. Antihypertensive drugs that are used frequently in children are shown in Table 51-28; the doses typically are based on the body weight of the child.

Table 51-28: Antihypertensive Drugs Frequently Used in Children

Drug	Initial Dose	Usual Maximum Dose
Intravenously administered		
Sodium nitroprusside	0.5 μg/kg/min	8 μg/kg/min
Labetalol	1 mg/kg/h	3 mg/kg/h
Orally administered		
Hydrochlorothiazide	1 mg/kg/day	2-3 mg/kg/day
Furosemide	1 mg/kg/day	12 mg/kg/day
Bumetanide	0.02-0.05 mg/kg/day	0.3 mg/kg/day
Propranolol	1 mg/kg/day	8 mg/kg/day
Atenolol	1 mg/kg/day	8 mg/kg/day
Captopril (for neonates)	0.03 mg/kg/day	2 mg/kg/day
Captopril (for children)	1.5 mg/kg/day	6 mg/kg/day

Enalapril	0.15 mg/kg/day	40 mg/day
Nifedipine (extended release)	0.25 mg/kg/day	3 mg/kg/day
Prazosin	0.05-0.1 mg/kg/day	0.5 mg/kg/day
Minoxidil	0.1-0.2 mg/kg/day	1 mg/kg/day

SPECIAL SITUATIONS

Pregnancy

Hypertension is found in about 10 percent of pregnancies and is the major cause of perinatal morbidity and mortality in most developed countries. Because of the unique patient population, hypertension in pregnancy has a special definition, four specific types, and a treatment algorithm that recognizes the need to assess outcomes in both mother and baby. Since most pregnancies are managed by obstetricians, most of the authoritative pronouncements about this condition have been advanced by expert panels drawn from that discipline.[388,389] In the United States, hypertension in pregnancy is defined as either BP >140/90 mmHg on two measurements at least 4 h apart or a diastolic BP >110 mmHg at any time during pregnancy or up to 6 weeks postpartum.[389]

The classification of hypertension in pregnancy typically requires some knowledge of BP status before conception. If there was preexisting hypertension, the patient is said to have "chronic hypertension," which can be diagnosed before 20 weeks' gestation and persists at least 42 days postpartum. Preeclampsia is hypertension appearing after 20 weeks' gestation, associated with proteinuria (at least 300 mg per 24-h collection or 2+ on a random dipstick), which typically resolves within 42 days after delivery. Hypertension with superimposed preeclampsia is a combination of the two. The term *Hypertension unclassified* typically is used only when none of the above criteria are met and the BP status before conception or during the first trimester is unknown.

There has been a great effort to elaborate both the cause and the effective treatment for preeclampsia, but neither has been identified. A large number of demographic, genetic, laboratory parameters, and other factors have been associated with a higher risk of preeclampsia, but none has been accepted as the underlying "cause" (Table 51-29). Even more interesting are recent clinical trials that attempted to prevent preeclampsia with low-dose aspirin or Ca^{2+} supplementation.[390,391] Despite a great deal of evidence in smaller studies, typically in high-risk women, the large NIH-sponsored megatrials have been unsuccessful in showing benefit from these inexpensive preventive measures. In addition, since aspirin tends to delay parturition and increase the likelihood of bleeding, few obstetricians routinely recommend it.

Table 51-29: Factors Associated with Altered Risk of Preeclampsia

Genetic markers
Angiotensinogen gene polymorphism
Tumor necrosis factor-alpha gene polymorphism
Mitochondrial transfer RNA gene mutation
Congenital thrombophelias
Resistance to activated protein C (factor V Leiden, perhaps the most common form of hereditary prothrombotic disorder)
Mutation in gene for prothrombin factor II
Hyperhomocysteinemia (mutation C677T)
Protein S deficiency
Antiphospholipid antibody syndrome
Protein C and antithrombin deficiencies

SOURCE: Adapted from Shear R, Leduc L, Rey E, Moutquin J-M. Hypertension in pregnancy: New recommendations for management. *Curr Hypertens Reports* 1999; 1:529-539.

Treatment of elevated BP during pregnancy traditionally has begun with bed rest, followed by methyldopa as the primary drug, based on its long history of efficacy and lack of adverse effects on babies. For severe hypertension (BP >160 or 169/109 mmHg) in outpatients that is not controlled with these measures to a diastolic BP between 90 and 100 mmHg, hydralazine, labetalol, and nifedipine routinely are added in succession.[392,393] Angiotensin-converting enzyme inhibitors and ARBs are contraindicated because of renal abnormalities in the fetus, and diuretics typically are avoided because of the risk for oligohydramnios. For intrapartum management, until delivery can be achieved, intravenous Mg^{2+} sulfate has been a mainstay for the prevention of progression of preeclampsia to seizures and other more serious complications.

Hypertension during pregnancy also carries prognostic significance for future health problems as the woman ages. Sixty percent of women with early-onset preeclampsia have abnormalities on renal biopsy and a higher risk of persistent hypertension after delivery. Women who develop hypertension during pregnancy not only are at higher risk for hypertension later in life but also have a roughly twofold increase in the risk of death from CAD.

Hypertensive Emergencies and Urgencies

Although great strides have been made in the treatment of hypertension since the First Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure in 1977, some patients still present to physicians' offices and emergency departments with hypertensive crises.[393] Fortunately, there now are excellent medications available for both acute, in-hospital treatment and outpatient management; these improvements have led to a decrease in the 1-year mortality rate after a hypertensive emergency from 80 percent (1928) to 50 percent (1955) to only 10 percent (Fig. 51-1).

The primary pathophysiologic abnormality in patients who experience hypertensive crises is the alteration of autoregulation in certain vascular beds (especially cerebral and renal), which often is followed by frank arteritis and ischemia in vital organs.[394] Autoregulation is the ability of blood vessels to dilate or constrict to maintain normal organ perfusion. Normal arteries from normotensive individuals can maintain flow over a wide range of mean arterial pressures, usually 60 to 150 mmHg. Chronic elevations of BP cause compensatory functional and structural changes in the arterial circulation and shift the autoregulatory curve

to the right; this allows hypertensive patients to maintain normal perfusion and avoid excessive blood flow at higher BP levels.[395] When BP increases above the autoregulatory range, tissue damage occurs. An understanding of autoregulation is also important for therapy, since the sudden lowering of BP into a range that would otherwise be considered normal may reduce BP below the autoregulatory capacity of the hypertensive circulation and lead to inadequate tissue perfusion (Fig. 51-2). In the later stages of a hypertensive crisis, pathologists can demonstrate cerebral edema and both acute and chronic inflammation of the medium and small arteries and arterioles, often associated with necrosis.

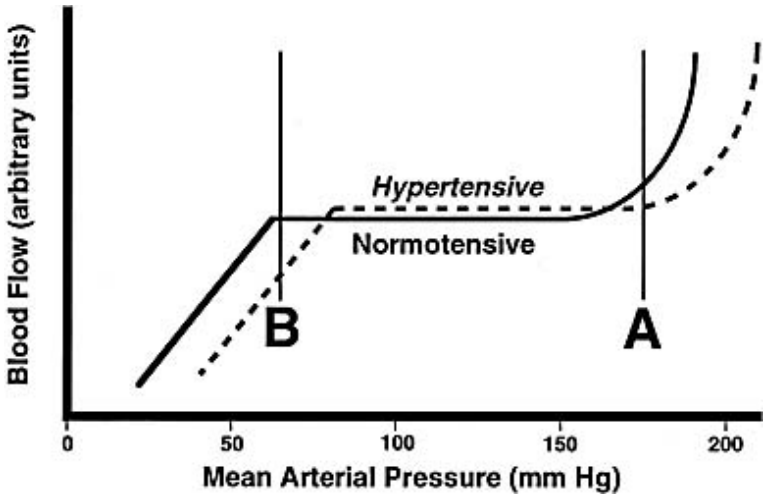

Figure 51-2: Blood pressure versus flow relationships in normotensive (*dark curve*) and hypertensive (*dotted curve*) persons, based on cerebral blood flow data of Strandgaard et al.[395] Chronically hypertensive persons can autoregulate their blood flow within the normal range despite higher blood pressures (e.g., vertical line "B"). Lowering BP in the setting of a hypertensive emergency to what might be considered "normal" (in a normotensive person, e.g., vertical line A) probably will put BP below the autoregulatory threshold and may compromise local circulation.

Hypertensive crises occur in a variety of clinical settings. The most common is a chronic and often untreated patient with stage 3 essential hypertension (i.e., usual BP ≥ 180/110) whose BP rises above the autoregulatory range, triggering the pathophysiologic sequence outlined above. Identical crises can occur, however, any time there is an acute or rapid rise in BP in a normotensive or minimally hypertensive individual, such as a child or a woman during pregnancy. Hypertensive crises can most easily be recognized by the association of an extremely elevated BP with physical examination or laboratory findings that indicate acute TOD. The actual levels of BP are of little import.

The initial evaluation of a severely hypertensive patient includes a thorough inspection of the optic fundi (looking for acute hemorrhages, exudates, or papilledema); a mental status assessment; a careful cardiac, pulmonary, and neurologic examination; a quick search for clues that might indicate secondary hypertension (e.g., abdominal bruit, striae, radial-femoral delay); and laboratory studies to assess renal function (dipstick and microscopic urinalysis, serum creatinine).[394]

There are several different types of common clinical presentations of hypertensive emergencies.

The neurologic crises are the most difficult to distinguish from one another (Table 51-30). Hypertensive encephalopathy is typically a diagnosis of exclusion; hemorrhagic and thrombotic strokes usually are diagnosed after focal neurologic deficits are corroborated by CT. Subarachnoid hemorrhage is diagnosed by the typical findings on lumbar puncture. The management of each of these conditions is somewhat different in that nimodipine may be the drug of choice for most neurologic crises because of its antihypertensive and anti-ischemic effects. Many physicians still prefer nitroprusside or another intravenous vasodilator because it can be discontinued rapidly if BP goes too low.[396] Goal BP also depends on the presenting diagnosis and is usually lower for encephalopathy than it is for acute stroke in evolution (

Table 51-30).

Patients who present with hypertensive crises involving cardiac ischemia/infarction or pulmonary edema can be managed with either nitroglycerin or nitroprusside, although typically a combination of drugs (including an ACE-I when there is HF) is used in these settings.[396] Efforts to preserve myocardium and open the obstructed coronary artery (by thrombolysis, angioplasty, or surgery) also are indicated.

Patients with aortic dissection are managed in a somewhat different fashion.[397] A beta blocker is added to the intravenous vasodilator, and the goal BP is much lower: Typically 120 mmHg systolic is recommended, but 100 mmHg systolic may be even better. Pharmacologic therapy is only a temporary adjunct to definitive surgical therapy, which should be planned with dispatch, although long-term medical therapy may be more appropriate in some patients.[398]

Hypertensive crises involving the kidney commonly are followed by a further deterioration in renal function even when BP is lowered properly. Some physicians prefer fenoldopam to nicardipine or nitroprusside in this setting because of its lack of toxic metabolites and specific renal vasodilating effects.[396,399,400] Blood pressure should be reduced about 10 percent during the first hour and a further 10 to 15 percent during the next 1 to 3 h. The need for acute dialysis often is precipitated by BP reduction, but many patients are able to avoid dialysis in the long term if BP is carefully and well controlled during follow-up.

Hypertensive crises resulting from catecholamine excess states [pheochromocytoma, monoamine oxidase (MAO) inhibitor crisis, cocaine intoxication, etc.] are best managed with an intravenous alpha blocker (phentolamine), with the beta blocker added later, if necessary. Many patients with severe hypertension caused by sudden withdrawal of antihypertensive agents (e.g., clonidine) are easily managed by reinstituting such therapy.

Hypertensive crises during pregnancy must be managed in a more careful and conservative manner because of the presence of the fetus. Magnesium sulfate, methyldopa, and hydralazine are the drugs of choice, with oral labetalol and nifedipine being drugs of second choice in the United States. Delivery of the infant often assists in the management of hypertension in pregnancy and often is hastened by the obstetrician under these conditions.

Hypertensive urgencies are situations in which acute TOD is not present; they require somewhat less aggressive management and nearly always can be handled with oral antihypertensive agents without admission to the hospital. Nifedipine, clonidine, captopril, labetalol, and several other short-acting antihypertensive drugs have been used for this problem. Nifedipine has been reported to cause precipitous hypotension, stroke, MI, and death and, according to the U.S. Food and Drug Administration, "should be used with great caution, if at all."[401,402] Otherwise, none of these drugs seems to have a major advantage over all the others, and all are effective in most patients.[403] *The most important aspect of managing a hypertensive urgency is to assure compliance with antihypertensive therapy during long-term follow-up.*

Patients presenting with a hypertensive emergency should be diagnosed quickly and started promptly on effective parenteral therapy (often nitroprusside 0.5 μg/kg per minute) in an intensive care unit. BP should be reduced about 25 percent gradually over 2 to 3 h. Oral antihypertensive therapy (often with an immediate-release CA) can be instituted after 6 to 12 h of parenteral therapy; evaluation for secondary causes of hypertension may be considered after transfer from the intensive care unit. Because of advances in antihypertensive therapy and management, "malignant hypertension" should be malignant no longer.

The situation in hemorrhagic stroke is slightly more complex because acute hypertension often is seen in such patients even if there has been no antecedent history of elevated BP. It is not clear if acute BP lowering will reduce or increase the complication rates (from worsened cerebral ischemia in other areas or making a zone surrounding the hemorrhage ischemic). As a result, it is recommended not to treat hypertension beyond a mean arterial pressure of >130 mmHg, and even then it is controlled rather more slowly into an intermediate range (e.g., 160/100 mmHg). Some have claimed that previously hypertensive patients with acute intracerebral hemorrhage should be managed even less aggressively.

Appropriate BP reduction in the setting of acute subarachnoid hemorrhage is even more controversial.[379] Even associating higher BP levels with higher rates of rebleeding has been difficult. If BP lowering is desired (e.g., if mean arterial pressure is >130 mmHg), a short-acting intravenous drug (e.g., nitroprusside) typically is recommended, since it can be discontinued quickly and the patient can be given fluids to restore the previous BP level if the neurologic status worsens.

DOSE SCHEDULE (DOSAGE AND CHRONOTHERAPY)

It is clear that BP needs to be controlled for 24 h. Preparations that are active once a day are easier for patients to remember to take, but adherence to treatment may not be substantially worse if twice-a-day preparations are used. In fact, patients may be better protected if they fail to remember to take one dose of a twice-a-day medication and be uncovered for 12 hours than if they skip a once-a-day pill and are unprotected for a considerably longer period.

In addition to "controlling BP" over 24 h, regimens should pay some attention to the circadian rhythm of BP and HR. Many of the sequelae of hypertension have a strong circadian variation, with a peak incidence in the early morning. Recent meta-analyses have quantitated the excess risk of heart attack during the period from 6 A.M. to noon at 40 percent, sudden cardiac death at 29 percent, and stroke at 49 percent compared with what would be expected if these events happened evenly or randomly throughout the day.[404,405] Since most patients administer antihypertensive agents in the morning, most authorities recommend long-acting drugs that should cover the early-morning period, when blood pressure, pulse, and cardiovascular risk are highest. Although many of the currently used medications have short intrinsic elimination half-lives, pharmaceutical technology has made available several methods of making sustained-release compounds from short-acting drugs.[406,407]

Recently, a chronobiological approach to antihypertensive therapy has become available.[407] This is currently available only for two preparations of verapamil.[408] These drug-delivery systems release active drug for 18 to 20 h, beginning between 2 A.M. and 4 A.M., leaving the patient with no active drug in the circulation from about 10 P.M. to 2 A.M. The rationale for this approach is that BP falls normally at night coincident with the usual circadian rhythm and active drug might cause excessive lowering of BP during the middle of the night.[409] These sustained-release preparations provide adequate active drug as the BP rises before awakening and during the peak time of CV events (the period between 6 A.M. and noon). The same matching of drug delivery to BP is not achieved by giving "homeostatically" designed drugs (i.e., all the others) at night. Such agents were designed for morning use, and giving them at night causes the risk of lowering BP too far during sleep.[198]

The putative advantage of such a system is that it would not excessively lower BP during sleep (when BP is typically at its nadir anyway) and would deliver an agent that is both hypotensive and HR-lowering at the time of day when BP, HR, and CV risk are nearly maximal.[198] The long-term consequences of this strategy are being tested in the CONVINCE trial with 16,602 subjects; conclusions may be available in 2002.[322]

DRUG INTERACTIONS

The selection of the initial agent to treat hypertension must be done with the understanding that many hypertensive patients may not reach goal BP on that agent alone and will therefore need additional antihypertensive therapy. Furthermore, many hypertensive patients need to take medications for other conditions, and so the problem of drug-drug interactions is particularly pertinent.

Certain combinations of antihypertensive agents are particularly effective, such as thiazide diuretics with beta blockers, ACE-Is, or ARBs.[380] Combinations of ACE-Is with CAs (both DHP and non-DHP) are also effective. Moreover, combinations of the two subtypes of CAs are synergistic with regard to BP reduction.[409] Dihydropyridine CAs and beta blockers are also very effective combinations. Nondihydropyridine CAs and beta blockers should not be used because of the risk of excessive bradycardia and conduction defects. Thiazide diuretics are also effective with all other antihypertensive drugs, including CAs, and always should be included in a triple-drug regimen. Little is known about the efficacy of

combining alpha blockers with central and peripheral sympatholytics or with ACE-Is or ARBs.

Recently, a series of low-dose fixed-dose combinations have been introduced that have fewer clinical side effects than occur when the components are used as monotherapy (Table 51-21). The best example is the combination of a DHP CA with an ACE-I. These fixed-dose combinations have a significantly lower incidence of edema than that seen when a DHP CA is given alone.[380] The incidence of cough, however, is not lessened when these drugs are combined. The appeal of a low-dose fixed-dose combination is that BP can be reduced further with fewer adverse reactions with two drugs at lower doses than might occur when one or the other component is pushed to the full dose. The added advantage is that the patient needs to take fewer pills to get BP to goal and so adherence to the regimen tends to improve (see below).

Most commonly used antihypertensives do not have any serious drug-drug interactions with anticoagulants, platelet inhibitors, or antibiotics. Nondihydropyridine CAs, beta blockers, and possibly telmisartan (an ARB) must be used with care in patients who are taking digitalis preparations.[381] Nonsteroidal anti-inflammatory agents may raise BP and interfere with the activity of all antihypertensive agents because of their Na^+-retaining properties.[410]

ADHERENCE

Fewer than 50 percent of patients continue taking the initially prescribed antihypertensive drug therapy for a year.[411,412] The proportion who properly adhere to therapy improves only modestly when the drugs and medical care are provided free of charge. Recent estimates indicate that about 10 percent of the overall expenditures on hypertension in the United States are wasted because of nonadherence to medical advice and antihypertensive drug therapy.[413] Patients who do not follow the advice of their physicians and do not take their medications correctly have an *infinite* cost/benefit ratio because they incur all the cost associated with the therapy but derive *none* of the benefits of treatment.

Assessing adherence with antihypertensive medications is generally difficult, but several simple measures often are recommended.[11,38,414] Some medications induce physical signs that are absent in those who have not recently taken them, e.g., bradycardia with beta blockers, orthostatic BP change with alpha blockers, and an increase in serum urate with diuretics. A telephone call to the patient's pharmacy generally will reveal how many times the prescribed medications have been refilled during the last year.[415] Several interventions have been advocated to improve adherence with medications (Table 51-31).

Table 51-31: Strategies to Improve Medication Adherence

Educate patient regarding proper use of medications
Improve patient's social support network (e.g., spouse or caretaker)
Increase patient's autonomy and involvement in decision making (when appropriate)
Remove barriers to compliance with pill taking
Integrate into activities of daily living (e.g., brushing teeth)
Avoid large ('horse') pills
Avoid bad-tasting formulations (e.g., lactulose, quinine)
Simplify the therapeutic regimen
Minimize number of pills
Minimize frequency of pill taking
Minimize inconvenience of pill taking

Provide positive attitude and positive reinforcement about achieving therapeutic goals
Maintain continuity of care with same practitioner
Use well-tolerated antihypertensive drug therapy individualized for each patient

There is concern, however, that administering long-acting drugs will lower blood pressure to a relatively constant degree during the day and night. This may lead to hypoperfusion of vital organs during the night that will not be symptomatic.[408]

MECHANISM OF ACTION OF THE DRUG AND PATHOPHYSIOLOGY OF THE PATIENT'S HYPERTENSION

Some have felt that physicians could be much more successful in treating hypertensive patients if they could base therapy on the reason why the patient is hypertensive (the pathophysiologic abnormality responsible for the patient's hypertension) and match that information to the mechanism of action of antihypertensive drugs. If physicans truly could know precisely why an individual was hypertensive and easily and safely obtain such information, treating hypertension would be not be complicated. If it really were known exactly how drugs work, those decisions would be much simpler. This approach, while intellectually appealing, has problems.

The first difficulty is that attempts to profile patients either biochemically using PRA, for example, or hemodynamically by measuring cardiac output and peripheral vascular resistance are too expensive and potentially invasive to do in everyone. In addition, these methods are not precise enough to provide the kind of necessarily definitive information needed to predict the response to therapy in a particular patient. Furthermore, trying to base therapy on the presumed pathophysiology in an individual or group of individuals would be expected to have is also imprecise. This approach runs the risk of denying certain patients the potential benefits of certain classes of drugs. Although it is true that blacks and older persons tend on the average to have low or suppressed PRA, many do not. Also, many patients with a low PRA will respond to drugs, such as ACE-Is or ARBs, that are less effective on the average in hypertensives with this renin profile. In the VA trial of monotherapy, selecting initial treatment on the basis of PRA was less effective than simply using age and ethnicity (thiazide diuretics and CAs for older patients and blacks and ACE-Is and beta blockers for whites and in those less than 60 years of age).[382] However, neither method correctly predicted a good response in more than 63 percent of the patients.

The second issue that complicates this approach is that many, if not all, drugs have more complex mechanisms of action than they were originally thought to have and work well in patient subgroups in whom they were supposed to be ineffective. For example, thiazide diuretics not only reduce plasma volume but also are vasodilators after 4 weeks of therapy. It should not have been surprising that these agents are effective and very well tolerated in older persons even though many of those patients tend to have a modestly decreased plasma volume compared with younger hypertensives. Although it is true that ACE-Is usually suppress the endocrine RAA system, the antihypertensive effect is still evident even when plasma AII concentration returns to pretreatment levels. This is good evidence that there is a tissue site of action for these drugs or that other mechanisms, perhaps the stimulation of bradykinin or NO, participate in how ACE-Is lower BP and that the initial formulation of their mechanism of action was incomplete. This also explains why some patients with low PRA (a measure of the activity of the *endocrine* RAA system) respond well to these agents or to ARBs, which suppress the RAA system at the angiotensin AT_1 receptor in tissues throughout the body. Calcium antagonists were presumed to work best in older hypertensives and in those with suppressed PRA, but these agents are equally effective in all subgroups of hypertensives.[237]

Perhaps the major flaw in the reasoning that drugs can be used to "probe" the pathophysiologic abnormality causing a patient's hypertension is the concept that there is one overriding abnormality responsible for that patient's elevated BP. In all likelihood, more than one, if not many, of the systems that control BP, many of which are discussed in this chapter, are dysfunctional simultaneously and single or combinations of pharmacologic agents that reduce BP do so by correcting more than one abnormality.[10]

The choice of initial therapy therefore should be based primarily on evidence from clinical trials that document a reduction in CV events and/or renal disease progression. However, despite the fact that one cannot precisely determine the mechanism or mechanisms of action of drugs and that it is impossible to elucidate precisely why a particular patient is hypertensive, the empirical approach to treating hypertension dramatically reduced the rate of stroke and CAD after physicians began to treat hypertension aggressively. This approach, though far from perfect, has paid dividends.

COST

The economics of hypertension and its therapy are complex, but the simple fact is that if a person cannot afford to pay for the drug chosen by the health care provider, the completed prescription will do little good in the long term.[52,53] Many pharmacists and businesspeople associated with health care believe that the agent with the lowest purchase price is the best, but this oversimplification omits the costs of extra visits to health care providers, laboratory testing, and adverse drug experiences that result in emergency room visits or hospitalization.[415] Such global evaluations of the economics of hypertension and its therapy are rare. It is possible for a more expensive but better-tolerated drug (e.g., an ARB) to actually be less expensive in the long term than another agent that produces many side effects, some of which must be evaluated by laboratory testing, physician visits, and even hospitalization. There is also the possibility that some of the newer (and currently more expensive) agents are more effective in lowering BP and reducing cardiovascular events (which currently account for 82 percent of expenditures related to hypertension in the United States) than are some of the older agents; this alone may be sufficient to make them more cost-effective than the time-tested agents.

Generically available drugs are usually less expensive to purchase than their branded counterparts and are strongly favored in most managed care pharmacy plans by both mandates to physicians and lower copayments by patients.[416] Some organized health care plans insist that the first month of antihypertensive therapy always involve a low-dose thiazide diuretic because of its proven efficacy and low cost. Although JNC VI "favored" low-dose diuretics and beta blockers for uncomplicated hypertension, it did, for the first time, suggest that hypertensives with another "compelling condition" would benefit even more from other classes of antihypertensive agents. There are now more data to suggest that in the long term it matters more what BP level is achieved during treatment than which agent is chosen initially to begin the lowering.

Many authorities are concerned that achieving the new, lower target BPs for diabetic and renally impaired hypertensives will cost more, as it will require more visits to health care providers and more antihypertensive medications. These increases in short-term expenditures are likely, however, to be offset by a lower future incidence of expensive outcomes, including heart attack, stroke, ESRD, and HF, at least for diabetic patients over age 60 in the United States.[332]

Many proposals for reducing the high cost of antihypertensive therapy have been advanced. JNC VI has suggested withholding drug therapy for 6 to 12 months from those at low risk (risk groups A and B) with stage 1 hypertension and giving it instead to patients in risk group C with BP ≥130/85 mmHg.[11] In stage 2 to 3 hypertension, wider use of combination drug tablets has been advocated, as these tablets typically cost much less than two separate prescriptions for the same doses of individual agents. Some formularies and pharmacy benefits managers prefer agents that have all doses priced identically, with the theory that a pill splitter can then be used to divide one tablet into two or more days' treatment. Aggressive health care plans have implemented strategies that prohibit the use of more expensive medications (e.g., ARBs) unless two physicians independently ascribe an adverse effect to a less expensive drug (e.g., an ACE-I), and others require three separate ACE-Is to be administered sequentially before an ARB can be dispensed.

Until a universal pharmacy benefits program is instituted, there are likely to be wide variations in the pricing and cost of antihypertensive agents. Although it is difficult for physicians to stay abreast of fluctuations in these costs, it is important that all health care providers attempt to provide tolerable antihypertensive medications at the lowest possible cost for the benefit of the patient, the health plan, and the national budget.

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

SUMMARY AND RECOMMENDATIONS

Although there are numerous options and many sources of error, the successful pharmacologic treatment of a hypertensive patient need not be too complicated, although it also should not be oversimplified. Once the diagnosis has been established and the routine evaluation and any more complex tests believed to be necessary have been completed, lifestyle modification should begin. Lifestyle modification should be given time to work unless the patient is in a group for which drug therapy is indicated (together with lifestyle modifications at the initiation of treatment). Drug therapy is indicated in all hypertensive patients if goal BP is not reached with lifestyle modification alone.

The following steps are recommended for choosing a regimen and then altering it until the goal is reached:

- Deal first with cost. If the patient is unable to afford any but the least expensive drugs or cannot pay for the one that is selected, price becomes the primary issue.
- Ascertain whether other risk factors or comorbidity is present. Avoid drugs that may worsen these factors or conditions and choose the ones that may tend to improve them.
- Find out what clinical adverse reactions the patient would find the most troublesome and avoid agents that are more likely to cause or exacerbate these problems. Some patients are not concerned by certain side effects that are very troublesome for others.
- Consider demographic issues and select the class of drug with a higher probability of success if options are available.
- Start with the lowest effective dose and plan to see the patient within 2 to 4 weeks unless the severity of the patient's hypertension or another problem warrants an earlier visit. Carry out appropriate biochemical monitoring when necessary. In some patients, start with a fixed-dose combination when it appears appropriate.
- Increase the dose if goal BP has not been reached or if there has been only a minimal response. Do not increase the first dose or any dose prematurely. Give each dose adequate time to be fully effective. If intolerable side effects occur and are likely to be drug-related or if there has been no response, only then switch to another appropriate agent for monotherapy.
- Continue the process of dose titration and monitoring until the maximum recommended dose has been reached. Stopping before the full dose has been reached leads to a situation in which the patient is treated with multiple agents at subtherapeutic doses when only one or two drugs are necessary.
- If the drug of first choice fails to reduce BP to goal, add a second agent that has a different mechanism of action and is known to have additive antihypertensive effects to the first-choice agent. A fixed-dose combination that combines two drugs in the desired doses also could be used at this time.
- Titrate the second drug to the full dose, as was done for the first drug, and continue appropriate monitoring. If the two-drug combination fails, consider a specific cause for the patient's refractory hypertension, and if none is evident, add a third drug, being sure that a diuretic is part of the regimen. Consider a referral to a hypertension specialist.
- Plan to see a patient who is at goal at least once every 3 months to be sure that BP control is sustained.
- Reinforce the need for adherence to the regimen and always question each patient carefully

about adverse reactions. Although some patients will not reach goal with this approach even with the many effective treatment options that are available, most will come under control or close to it. Patients who do this can anticipate substantial long-term benefit with an extended life expectancy and a much reduced risk of stroke, ischemic heart disease, HF, and probably renal failure and dementia.

Chapter 51: HYPERTENSION: EPIDEMIOLOGY, PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT

CONCLUSION

Although treating high BP can be costly and at times seem unrewarding, the benefits to individual patients and to society make the effort worthwhile. Physicians must be careful not to become apathetic about hypertension. The problem has not been solved and will not be solved until all hypertensive patients are able to avail themselves of what has been among the most successful examples of preventive medicine.

Part 8: PULMONARY HYPERTENSION AND PULMONARY DISEASE
Chapter 52:

PULMONARY HYPERTENSION

Author: Lewis J. Rubin

Pulmonary hypertension is a hemodynamic abnormality common to a variety of conditions that is characterized by increased right ventricular (RV) afterload and work. The clinical manifestations, natural history, and reversibility of pulmonary hypertension depend heavily on the nature of the pulmonary vascular lesions and the etiology and severity of the hemodynamic disorder. For example, subacute or chronic hypoxia predominantly causes increased muscularization of the small muscular pulmonary arteries and arterioles while leaving the intima relatively intact. Relief of the hypoxia improves or occasionally reverses the process with little or no pathologic residue.[1,2] In contrast, the lesions of systemic sclerosis (scleroderma), which tend to be confined to the intima of the small pulmonary arteries and arterioles, are usually progressive and irreversible. In contrast to scleroderma and chronic hypoxia, which spare the pulmonary capillary bed, the pulmonary capillaries are the primary site of involvement in pulmonary capillary hemangiomatosis.[3] Because of its large capacity, its great distensibility, its low resistance to blood flow, and the modest amounts of smooth muscle in the small arteries and arterioles, the pulmonary circulation is not predisposed to become hypertensive. When total cross-sectional area is decreased, such as by destruction or obliteration of lung tissue or occlusive lesions in the resistance vessels, pulmonary arterial pressures increase. The degree of pulmonary hypertension that develops is a function of the amount of the pulmonary vascular tree that has been eliminated. Pulmonary hypertension is usually secondary to cardiac or pulmonary disease. Although primary pulmonary hypertension (PPH) is uncommon, it has attracted considerable attention as a distinctive clinical entity in which intrinsic pulmonary vascular disease is free of the complicating features of secondary pulmonary hypertension contributed by diseases of the heart and/or lungs. Mild or even moderate pulmonary hypertension can exist for a lifetime without becoming evident clinically. For example, native residents at high altitude, in whom mild to moderate pulmonary hypertension is a natural result of sustained exposure to hypoxia, can function normally. When pulmonary hypertension does become manifest clinically, the symptoms tend to be nonspecific (Table 52-1).

Table 52-1: Symptoms of Primary Pulmonary Hypertension

Dyspnea	Palpitations
Fatigue	Orthopnea
Dizziness	Cough
Syncope	Hoarseness
Chest Pain	

DEFINITIONS

Pulmonary *arterial* hypertension can be either acute or chronic. The acute form is usually a result

of either pulmonary embolism (see Chap. 53) or the adult respiratory distress syndrome. This chapter deals with *chronic* pulmonary arterial hypertension.

Pulmonary *venous* hypertension usually is encountered clinically as a consequence of left ventricular (LV) failure or mitral valvular disease. Occasionally, it may occur in the course of fibrosing mediastinitis. Only rarely is the entity known as pulmonary veno-occlusive disease (PVOD) encountered. Even though pulmonary hypertension may be confined, at the outset, to the pulmonary veins (e.g., in acute mitral insufficiency), sooner or later pulmonary arterial hypertension supervenes. The hallmarks of pulmonary venous hypertension are pulmonary congestion and edema. For practical purposes, pulmonary venous hypertension is said to exist when pulmonary venous (or left atrial) pressure rises above 15 mmHg.

Cor pulmonale signifies the presence of pulmonary hypertension in the setting of chronic respiratory disease.[4] The degree of pulmonary hypertension that develops in patients with chronic lung disease tends to be less severe than in connective tissue diseases, chronic thromboembolic disease, or primary pulmonary hypertension. Pulmonary hypertension may be severe, however, in some patients with interstitial lung disease.

Chapter 52: PULMONARY HYPERTENSION

NORMAL PULMONARY CIRCULATION

Structure

Immediately before birth, pulmonary and systemic arterial blood pressures are about equal and on the order of 70/40 mmHg, with a mean of 50 mmHg. Immediately after birth, with closure of the ductus arteriosus and initiation of ventilation, pulmonary arterial pressure falls rapidly to about one-half of systemic levels. Thereafter, pulmonary arterial pressures gradually decrease over several weeks to reach adult levels[5] (see also Chap. 70).

In some neonates, the normal pulmonary hypertension of the fetus fails to recede normally, generally due to either a developmental anomaly or a relentless increase in pulmonary vascular tone. In such infants, the persistent pulmonary hypertension and RV failure may become life-threatening. Surgical intervention or temporizing measures, such as the use of inhaled nitric oxide (NO) or extracorporeal membrane oxygenation (ECMO), may be useful in reversing the pulmonary vascular abnormalities.[6]

In the normal adult at sea level, the small muscular arteries and arterioles in the lungs are thin-walled and contain very little smooth muscle. In contrast, in the fetus or the adult who has lived under hypoxic conditions (e.g., native residents at high altitude), the media of the arterioles are thickened, and the muscle extends distally into precapillary vessels that are ordinarily devoid of muscle; i.e., the precapillary vessels undergo "remodeling."[7]

Endothelium and Endothelium-Smooth Muscle Interactions

In addition to its role as a semipermeable barrier between blood and interstitium, the endothelium serves a wide array of biologically important functions, the net effect of which is the processing of blood flowing through the lungs. Among these functions are the synthesis, uptake, storage, release, and metabolism of vasoactive substances; transduction of blood-borne signals; modulation of coagulation and thrombolysis; regulation of cell proliferation; engagement in the local inflammatory and proliferative reactions to injury; involvement in immune reactions; and angiogenesis (see also Chap. 4). Some of the enzymes involved in these processes, such as the angiotensin-converting enzyme, are found on the surface of endothelial cells; others, such as 5′-nucleotidase, are found within the cell.[8] Hence it is appropriate to regard endothelium as an organ with diverse metabolic and endocrine functions, one that is unique because of its strategic location as a continuous, monolayered lining of blood vessels throughout the body. It is also important to bear in mind that the lungs contain the largest expanse of endothelium in the body.

The cells that comprise the monolayered endothelial lining communicate not only with each other by anatomic junctions and bridges but also with the underlying smooth muscle by way of biologically active substances.[9] This interaction participates in regulating normal vasomotor tone as well as in response to the administration of vasoactive substances. It is not difficult to imagine that damage to the lining cells, proliferation of the intima, or hypertrophy of the smooth muscle will upset the normal interplay.

Hemodynamics

For the adult pulmonary circulation, the definition of *normal* depends on the altitude. The normal pulmonary hemodynamics of adults residing at sea level and above sea level are compared in Table 52-2. At *sea level*, a cardiac output of 5 to 6 L/min is associated with a pulmonary arterial pressure of about 20/12 mmHg, with a mean of about 15 mmHg. At an altitude of 15,000 ft, the same level of blood flow is associated with somewhat higher pressures (see Table 52-2). Pulmonary arterial pressures also tend to increase somewhat with age.

Table 52-2: Values of Normal Pulmonary Circulation at Sea Level and Altitude

	Sea Level	Altitude (~15,000 ft)
Pulmonary arterial pressure (P_{PA}), mmHg	22/12, 15	38/14, 25
Cardiac output (Q), L/min	6.0	6.0
Left atrial pressure (P_{LA}), mmHg	5.0	5.0
Pulmonary vascular resistance (PVR),[a] (mmHg/L)/min (R units)	1.7	3.3

[a]> To convert T units to CGS units (dynes·s/cm^2), multiply R units by 80.

A pressure drop of only 5 to 10 mmHg between the pulmonary artery and left atrium accompanies the cardiac output of 5 to 6 L/min (see Table 52-2). Determination of pulmonary vascular resistance, calculated as the ratio of the difference in mean pressure at the two ends of the pulmonary vascular bed (pulmonary arterial pressure minus left atrial pressure divided by the cardiac output; see Table 52-2), has proved to be a practical clinical tool for assessing the hemodynamic state of the pulmonary circulation and for distinguishing between active and passive changes in the pulmonary resistance vessels (e.g., the effect of administering a vasodilator agent to a patient with pulmonary hypertension). In practice, since the left atrium may not be readily accessible, pulmonary wedge pressure generally is substituted for left atrial pressure.

Another approach to defining certain characteristics and the behavior of the pulmonary arterial tree, i.e., elastic properties and geometry, is the calculation of pulmonary arterial input impedance. This approach has more physiologic than clinical value. It takes into account the pulsatile nature of pulmonary arterial pressures and flow. Like vascular resistance, it is defined as a ratio. But instead of a ratio involving *mean* pressures and blood flow, the ratio is of the amplitudes of pulsatile pressure to oscillatory flow near the beginning of the pulmonary artery at a particular frequency. Values for the ratio are obtained by resolving mathematically the pulsatile pressure and flow curves into their sinusoidal components.

Although calculated pulmonary vascular resistance has proved useful in assessing the state of the normal and abnormal pulmonary circulation, and even though a change in calculated resistance often can be helpful in deciding whether pulmonary vasoconstriction or vasodilatation has occurred, translation of a calculated ratio into vasomotor activity has to be made with caution.[4] For example, changes in calculated pulmonary vascular resistance are not readily interpretable when a vasodilator agent evokes multiple hemodynamic changes simultaneously (e.g., simultaneous changes in pulmonary vascular pressures and blood flow). Also, a clinical shortcut, such as the substitution in the numerator of the pulmonary arterial pressure for the pressure *drop* between the pulmonary artery and left atrium, may be useful empirically but deprives the calculation of any physiologic meaning. Finally, the clinical significance of a value calculated for pulmonary vascular resistance depends heavily on the implications of the hemodynamic changes on the work of the right ventricle. For example, the same decrease in calculated pulmonary vascular resistance brought about by two different pulmonary vasodilators may affect the work of the right ventricle differently: Should one agent elicit a *decrease* in pulmonary arterial pressure along with an *increase* in cardiac output (an ideal response), it is more apt to be of long-term benefit than another agent that, while increasing the cardiac output, fails to decrease the pulmonary arterial pressure.

In the normal lung, a considerable increase in cardiac output, i.e., two to three times that at rest, generally increases pulmonary arterial pressure by only a few millimeters of mercury. On the other hand, in pulmonary hypertensive states, in which the distensibility and extent of the pulmonary vascular bed have been restricted by disease, pulmonary arterial pressure increases along with even small increments in pulmonary blood flow. Changes in pulmonary blood volume are much more subtle than changes in blood pressure or flow in their hemodynamic effects; they are also much more difficult to quantify. Clinical clues

can be helpful in recognizing that the pulmonary blood volume has increased. Often a fullness of the pulmonary vascular pattern on the chest radiograph along with evidences of interstitial edema suggests that pulmonary blood volume has increased acutely. In chronic mitral stenosis or LV failure, the pulmonary blood volume is not only increased but is also redistributed toward the apices of the lungs, i.e., "cephalization."

Autonomic innervation of the pulmonary vascular tree plays much less of a role in modulating vasomotor tone than do local stimuli, particularly hypoxia. Indeed, hypoxia can exert its pulmonary pressor effect in the isolated lung, i.e., one that is devoid of external innervation. The mechanism by which hypoxia exerts its local pressor effect is not fully characterized but appears to involve altered smooth muscle cell membrane ion channel activity.[2] Acidosis potentiates the hypoxic pressor effect. Hypercapnia also exerts a pulmonary pressor effect, presumably by way of the local acidosis that it generates, but it is less powerful than hypoxia as a pulmonary vasoconstrictor agent.

Chapter 52: PULMONARY HYPERTENSION

PULMONARY HYPERTENSION: GENERAL FEATURES

Clinical Manifestations

Pulmonary hypertension is a final common hemodynamic consequence of multiple etiologies and diverse mechanisms. As noted earlier, most cases of pulmonary hypertension are secondary (Table 52-3). Among the underlying causes of pulmonary hypertension are mechanical compression and distortion of the resistance vessels of the lungs (e.g., by diffuse pulmonary fibrosis), hypoxic vasoconstriction (e.g., in severe obstructive airways or diffuse parenchymal diseases), intravascular obstruction (e.g., thromboemboli or tumor emboli), and combinations of mechanical and vasoconstrictive influences. The significance of pulmonary hypertension, however, is that if it is uncontrolled, it leads to RV failure. Once pulmonary arterial pressures reach systemic levels, RV failure becomes inevitable.

Table 52-3: Nomenclature and Classification of Pulmonary Hypertension

Diagnostic Classification
1. Pulmonary arterial hypertension
1.1 Primary pulmonary hypertension
(a) Sporadic
(b) Familial
1.2 Related to
(a) Collagen-vascular disease
(b) Congenital systemic to pulmonary shunts
(c) Portal hypertension
(d) HIV infection
(e) Drugs/toxins
(1) Anorexigens
(2) Other
(f) Persistent pulmonary hypertension of the newborn
(g) Other
2. Pulmonary venous hypertension
2.1 Left-side atrial or ventricular heart disease

- 2.2 Left-side valvular heart disease
- 2.3 Extrinsic compression of central pulmonary veins
  - (a) Fibrosing mediastinits
  - (b) Adenopathy/tumors
- 2.4 Pulmonary veno-occlusive disease
- 2.5 Other

3. Pulmonary hypertension associated with disorders of the respiratory system and/or hypoxemia

- 3.1 Chronic obstructive pulmonary disease
- 3.2 Interstitial lung disease
- 3.3 Sleep-disordered breathing
- 3.4 Alveolar hypoventilatory disorders
- 3.5 Chronic exposure to high altitude
- 3.6 Neonatal lung disease
- 3.7 Alveolar-capillary dysplasia
- 3.8 Other

4. Pulmonary hypertension due to chronic thrombotic and/or embolic disease

- 4.1 Thromboembolic obstruction of proximal pulmonary arteries
- 4.2 Obstruction of distal pulmonary arteries
  - (a) Pulmonary embolism (thrombus, tumor, ova and/or parasites, foreign material)
  - (b) In-situ thrombosis
  - (c) Sickle cell disease

5. Pulmonary hypertension due to disorders directly affecting the pulmonary vasculature

- 5.1 Inflammatory
  - (a) Schistosomiasis
  - (b) Sarcoidosis
  - (c) Other
- 5.2 Pulmonary capillary hemangiomatosis

Special Studies

The "gold standard" for the diagnosis of pulmonary hypertension is right-sided heart catheterization. This technique enables the direct determination of right atrial and ventricular pressures, pulmonary arterial pressure, pulmonary wedge pressure (as an approximation of pulmonary venous pressure), pulmonary blood flow (cardiac output), and the responses of these parameters to interventions (vasodilators, oxygen, exercise). From the measurements and samples obtained during cardiac catheterization, pulmonary vascular resistance can be calculated (see Table 52-2). As a rule, noninvasive methods are less reliable and less informative.

CHEST RADIOGRAPHY

The findings on the chest radiograph depend on the duration of the pulmonary hypertension and the etiology. The characteristic findings of pulmonary hypertension are enlargement of the pulmonary trunk and hilar vessels in association with attenuation (pruning) of the peripheral pulmonary arterial tree (Fig. 52-1). Right-sided heart enlargement can be best detected radiographically on the lateral view as fullness in the retrosternal airspace. In secondary pulmonary hypertension, changes in the lungs (e.g., hyperinflation, fibrosis) and in the position of the heart and diaphragm often mask the radiologic changes of pulmonary hypertension. Contrast angiography has a role in the workup for pulmonary hypertension when chronic thromboembolic disease, which may be treated surgically, is suspected.[8]

THE ELECTROCARDIOGRAM

The electrocardiogram (ECG) can disclose hypertrophy of the right ventricle and is more reliable in respiratory disorders that do not involve the parenchyma of the lungs (e.g., alveolar hypoventilation and sleep apnea) than in obstructive airways disease or parenchymal lung disease.

ECHOCARDIOGRAPHY

The amount of reliable information obtained by Doppler and two-dimensional echocardiography depends greatly on the commitment of individual clinics to standardizing and perfecting these noninvasive techniques. In general, echocardiographic techniques have proved useful in providing a measure of RV thickness as an index of RV hypertension. In some clinics, reliable estimates of the level of pulmonary hypertension have been obtained by determining regurgitant flows across the tricuspid and pulmonic valves using continuous-wave Doppler echocardiography.[9] In patients in whom the pulmonic valve has been visualized, its behavior during the cardiac cycle also has been used to estimate the level of pulmonary arterial pressure. Probably one of the more rewarding applications of echocardiography has been as an alternative to repeated cardiac catheterization in tracing the course of the disease and in assessing the effects of therapeutic interventions (e.g., pulmonary vasodilators) in some patients (see also Chap. 13).

LUNG SCANS

Ventilation-perfusion scans are of most value in the diagnosis and exclusion of pulmonary thromboembolic disease (see below).

RADIONUCLIDE STUDIES

The response of the RV ejection fraction to exercise is assessed in some clinics using radionuclide angiography. Scintigraphy using thallium-201 also has been useful in detecting hypertrophy of the right ventricle due to pulmonary hypertension (see also Chap. 16).

LUNG BIOPSY

The sampling of lung tissue by open thoracotomy or thoracoscopy occasionally is helpful in identifying the etiology of the pulmonary hypertension, e.g., in the setting of suspected pulmonary vasculitis. However, the procedure carries substantial risk in these hemodynamically compromised individuals. Attempts to predict responsiveness to vasodilators on the basis of lung biopsy have met with limited success.[10]

Chapter 52: PULMONARY HYPERTENSION

SECONDARY PULMONARY HYPERTENSION

Cardiac and/or respiratory diseases are the most common causes of secondary pulmonary hypertension. Pulmonary thromboembolic disease ranks third. Cardiac disease leads to pulmonary hypertension by increasing pulmonary blood flow (e.g., large left-to-right shunts) or by increasing pulmonary venous pressure (e.g., LV failure). Almost invariably, secondary influences such as intimal proliferation in the pulmonary resistance vessels add a component of obstructive pulmonary vascular disease.[11] In respiratory disease, the predominant mechanism for the pulmonary hypertension is an increase in resistance to pulmonary blood flow arising from perivascular parenchymal changes coupled with pulmonary vasoconstriction due to hypoxia. In pulmonary thromboembolic disease, clots in various stages of organization and affecting pulmonary vessels of different size increase resistance to blood flow.[11]

Cardiac Disease

The mechanisms of pulmonary hypertension usually are quite different in acquired disorders of the left side of the heart than in those of congenital heart disease.

ACQUIRED DISORDERS OF THE LEFT SIDE OF THE HEART

LV failure is the most common cause of pulmonary hypertension. Among the various etiologies, myocardial disorders and lesions of the mitral and aortic valves predominate. Both categories of lesions lead to an increase in pulmonary venous pressure that, in turn, evokes an increase in pulmonary arterial pressure. Presumably, the increase in pulmonary arterial pressure is reflex in origin. In time, three types of morphologic changes supervene: (1) occlusive intimal and medial changes not only in pulmonary venules and veins but also in the precapillary vessels, (2) perivascular interstitial edema and fibrosis that, under the influence of gravity, cause vascular and perivascular changes to be most marked in the dependent portions of the lungs, and (3) occlusion of small pulmonary vessels by emboli or thrombi when the right ventricle fails and cardiac output decreases. The medical management of myocardial failure is considered in Chap. 21. The treatment of congenital heart disease and of mitral valvular disease is usually mechanical (e.g., surgical or balloon mitral valvuloplasty). The prospect for relief of the pulmonary venous hypertension, such as by mitral valve commissurotomy or replacement, depends on the reversibility of the pulmonary vascular and perivascular lesions.

Although LV failure is the most common cause of RV failure, rarely is the level of pulmonary hypertension that accompanies LV failure sufficient to account for the RV failure. RV failure, secondary to LV failure, is usually attributed to failure of the muscle in the shared ventricular septum.

CONGENITAL HEART DISEASE

Pulmonary hypertension is part of the natural history of many types of congenital heart disease and is often a major determinant of the clinical course, the feasibility of surgical intervention, and the outcome (see Chaps. 63 and 64). Congenital defects of the heart associated with large left-to-right shunts (e.g., atrial septal defect) or abnormal communications between the great vessels

(e.g., patent ductus arteriosus) are commonly associated with pulmonary arterial hypertension. Pulmonary hypertension occurs in both "pretricuspid" congenital defects (e.g., secundum atrial septal defect) and "posttricuspid" congenital defects (e.g., ventricular septal defect). Important differences exist in the natural history of these two categories. Their differences are considered elsewhere in this book (see Chap. 70). The major cause of pulmonary hypertension in congenital heart disease is an increase in blood flow, an increase in resistance to blood flow, or most often, a combination of the two. In congenital heart disease with right-to-left shunting (systemic hypoxemia), pulmonary vasoconstriction adds to the resistance to blood flow. Erythrocytosis, acting by way of increased viscosity and propensity to thrombosis, also contributes to the increase in resistance. Although the increase in pulmonary vascular tone elicited by hypoxia contributes to the increase in pulmonary vascular resistance, the predominant resistance is offered by anatomic changes in the walls of the small muscular arteries and arterioles. Patients with congenital heart disease and pulmonary hypertension who become pregnant are at increased risk of sudden death both in the course of delivery and in the immediate postpartum period.

Depending on the nature of the congenital cardiac defect, vasodilators sometimes are helpful in diminishing heightened pulmonary vasomotor tone. Caution is required in administering such agents to patients with congenital heart disease because of the potential to increase right-to-left shunting by reducing systemic vascular resistance to a greater degree than its pulmonary counterpart. Phlebotomy, with replacement of fluid (e.g., plasma or albumin), is helpful in congenital cyanotic heart disease in which severe hypoxemia has evoked a large increase in red cell mass. Once again, caution is required to avoid depletion of iron stores and to avoid reduction in the circulating blood volume.

THROMBOEMBOLIC DISEASE

Thromboembolic disease is a form of occlusive pulmonary vascular disease. It may be acute or chronic. In the United States and Europe, clots originating in peripheral veins represent a common cause of chronic occlusive pulmonary vascular disease. Elsewhere in the world, other intravascular particulates may cause pulmonary vascular occlusive disease. For example, in Egypt, where schistosomiasis is endemic, pulmonary vascular disease stemming from ova lodged in pulmonary vessels and hypersensitivity reactions to the organism (usually situated outside the lungs) is not uncommon. In some parts of Asia, filariasis is reputed to be an important cause of pulmonary hypertension. Tumor emboli to the lungs from extrapulmonary sites (e.g., the breast) can cause pulmonary hypertension by invading the adjacent minute vessels of the lungs. Intravenous drug use may be associated with talc or cotton fiber embolism to the lungs, which can result in a granulomatous pulmonary arteritis.

The *syndromes of thromboembolic pulmonary hypertension* can be categorized according to the segments of the pulmonary arterial tree that are primarily affected: (1) small (muscular pulmonary arteries and arterioles), (2) intermediate, and (3) large central arteries. Some overlap among these categories is inevitable because clots lodged in large vessels are fragmented by the churning motion of the heart, and both the parent clot and its derivatives tend to move peripherally for final lodging.

Occlusion of Small Muscular Arteries and Arterioles by Organized Thrombi

At autopsy, small thrombi, predominantly recent in origin, are commonplace in the small pulmonary vessels of patients with pulmonary hypertension who have developed heart failure preterminally. In contrast is the syndrome of widespread pulmonary vascular occlusion by organized thrombi in the small pulmonary arteries and arterioles. Once attributed to multiple pulmonary emboli, these lesions are now regarded as organized, in situ thrombi.[12] The syndrome is rare and indistinguishable during life from primary pulmonary hypertension except by lung biopsy. Histologic identification of these lesions serves little purpose in management. After a

ventilation-perfusion scan has excluded chronic proximal thromboembolism (see below), treatment consists of long-term anticoagulation to prevent further clotting using warfarin or related agents, antiplatelet agents, or both.

Occlusion of Intermediate Pulmonary Arteries by Emboli

This syndrome is by far the most common of the three.[12] It is thought to be caused by multiple emboli released from vessels in the upper legs and thighs that progressively amputate the pulmonary arterial tree. Ventilation-perfusion scans and selective angiography demonstrate the pulmonary vascular occlusion, although both studies tend to underestimate the degree of obstruction compared with direct inspection of the vascular tree at surgery or postmortem (see Chap. 53). The major therapeutic concern in these patients is to exclude chronic proximal pulmonary thromboembolism (see below) and to prevent recurrent thromboemboli. Treatment involves the use of anticoagulants of the warfarin type and antiplatelet agents.

Chronic Proximal Pulmonary Thromboembolism

In some patients who have survived large to massive pulmonary emboli, resolution fails to occur, and the clots become organized and incorporated into the walls of the major pulmonary arteries, leading to pulmonary hypertension (Fig. 52-2). Overwhelming the capacity of the local fibrinolytic mechanisms also allows the clot to propagate, to obstruct large segments of the pulmonary vascular bed, and to decrease the compliance of the central pulmonary vessels. By the time the diagnosis is made, the obstructing lesions in the central pulmonary arteries have become an integral part of the vascular wall through the processes of endothelialization and recanalization.[12]

The importance of recognizing *proximal* pulmonary thromboembolism as a cause of pulmonary hypertension is the possibility of relieving the pulmonary hypertension by surgical intervention, i.e., by pulmonary thromboendarterectomy. Ventilation-perfusion lung scanning is the critical diagnostic test. As a rule, patients with proximal pulmonary thromboembolism show two or more segmental perfusion defects. If the perfusion defects are segmental or larger, selective pulmonary angiography is called for to define the location, extent, and number of pulmonary vascular occlusions.[13] [14] Cardiac catheterization for selective pulmonary angiography also enables hemodynamic assessment. Fiberoptic angioscopy, helical computed tomographic scanning, and magnetic resonance imaging may be helpful in defining the lesions of proximal thromboembolic pulmonary hypertension[15] (see also Chap. 53).

Surgery is advocated for patients with pulmonary hypertension who have persistent clot in lobar or more proximal pulmonary arteries after at least 6 months of anticoagulation. Thromboendarterectomy is done via a median sternotomy using deep hypothermic cardiopulmonary bypass with intermittent periods of circulatory arrest. Postoperatively, hemodynamic improvement is usually quite dramatic.[8,14] Reperfusion pulmonary edema can be a severe complication immediately after the obstruction has been relieved. In experienced hands, mortality is on the order of 5 percent. After the operation, patients are placed on lifelong anticoagulants. A filter is usually placed in the inferior vena cava to further prevent recurrence.

Respiratory Diseases and Disorders

In addition to intrinsic pulmonary diseases, disturbances in respiratory muscle function or in the control of breathing also can lead to pulmonary hypertension. Among the intrinsic lung diseases are those affecting the airways (e.g., chronic bronchitis) as well as those affecting the parenchyma (i.e., emphysema, pulmonary fibrosis). Among the ventilatory disorders are the syndromes of alveolar hypoventilation due to respiratory muscle weakness and sleep-disordered breathing.

INTRINSIC DISEASES OF THE LUNGS AND/OR AIRWAYS

Diseases that affect the parenchyma of the lungs or the tracheobronchial tree can elicit pulmonary hypertension in different ways depending on the underlying disease (Fig. 52-3). In obstructive airways disease, ventilation-perfusion abnormalities cause vasoconstriction due to arterial hypoxemia. In diffuse fibrosis, several mechanisms act in concert: Loss of vascular surface area due to lung destruction, loss of vascular compliance due to hyperinflation-induced vascular compression, and vascular remodeling due to hypoxic vasoconstriction all promote an increased pulmonary vascular resistance.

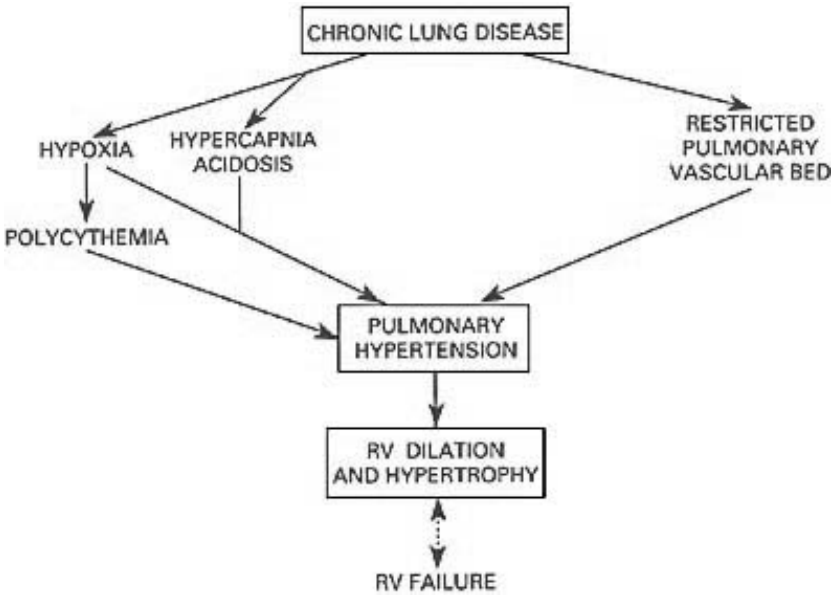

Figure 52-3: The evolution of RV failure in chronic obstructive airways disease (chronic bronchitis and emphysema; COPD). The factors on the left arise primarily from the bronchitis; those on the right from emphysema.

INTERSTITIAL FIBROSIS

Pulmonary sarcoidosis, asbestosis, and idiopathic and radiation-induced fibrosis are common causes of widespread pulmonary fibrosis that culminates in cor pulmonale. Dyspnea and tachypnea generally dominate the clinical picture of interstitial fibrosis; cough is rarely prominent. As a rule, severe pulmonary hypertension occurs toward the end of the illness, when hypoxemia and hypercapnia are present at rest (see Fig. 52-1). RV failure is a common sequel.

Systemically administered vasodilators have no proven place in dealing with the pulmonary hypertension associated with interstitial fibrosis and may worsen intrapulmonary gas exchange. Recent experience with inhaled vasodilators, such as the prostacyclin analogue iloprost, is encouraging and suggests the possibility of producing selective pulmonary vasodilator and/or antiproliferative effects in this population.[16] Oxygen therapy, particularly during daily activity or sleep, can be important in attenuating the hypoxic pulmonary pressor response. Glucocorticoids and other potent immunosuppressive agents are the mainstay of therapy and often effect some symptomatic relief. The advent of lung transplantation has widened greatly the therapeutic horizons for dealing with widespread interstitial fibrosis.

CHRONIC OBSTRUCTIVE AIRWAYS DISEASE

Chronic bronchitis and emphysema [chronic obstructive pulmonary disease (COPD)] are the most common causes of cor pulmonale in patients with intrinsic pulmonary disease.[17,18] Cystic fibrosis is an example of a mixed airways and parenchymal lung disease in which pulmonary hypertension plays a significant role in outcome.

Cor pulmonale is encountered in two different settings: *acutely* in the setting of decompensation, which is often due to an acute respiratory infection, and *chronically* when progressive lung disease and worsening gas exchange lead to unremitting vascular remodeling.

The "gold standard" for diagnosing pulmonary hypertension in patients with COPD is right-sided heart catheterization. Noninvasive studies, such as echocardiography, have proved useful in some centers.[19,20] RV enlargement, the cardinal sign of pulmonary hypertension, can be difficult to discern in obstructive airways disease because of hyperinflation and cardiac rotation.[21] Once suspicion is raised that the clinical picture of RV failure stems from gas exchange abnormalities, an arterial blood sample will confirm that the P_{O_2} is low (P_{O_2} < 40-50 mmHg) and the P_{CO_2} is high (P_{CO_2} > 50 mmHg). Derangement in gas exchange to this degree is rare in LV failure unless overt pulmonary edema is present.

Electrocardiographic evidence of RV hypertrophy is also often equivocal in patients with chronic obstructive airways disease (chronic bronchitis and emphysema, COPD) because of rotation and displacement of the heart, widened distances between electrodes and the cardiac surface, and the predominance of right-sided heart dilatation over hypertrophy. Because of these limitations, it is not surprising that standard electrocardiographic criteria for RV enlargement apply in about only one-third of patients with COPD who prove to have cor pulmonale at autopsy. Consecutive changes in the ECG are often more useful than a single ECG in detecting RV overload. As the arterial P_{O_2} drops to abnormal levels (e.g., <60-70 mmHg while awake), T waves tend to become inverted, biphasic, or flat in the right, precordial leads (V_1 to V_3); the mean electrical axis of the QRS shifts 30° or more to the right of the patient's usual axis; ST segments become depressed in leads II, III, and aV_F; and right bundle-branch block (incomplete or complete) often appears. These changes tend to reverse as arterial oxygenation improves (see also Chap. 11).

In the patient with COPD with acute cor pulmonale precipitated by a bout of bronchitis or pneumonia, the goal of therapy is to maintain tolerable levels of arterial oxygenation while waiting for the upper respiratory infection to subside. Supplemental oxygen, such as 28% oxygen delivered by a Venturi mask, generally suffices to relieve arterial hypoxemia and to restore pulmonary arterial pressures to normal. Considerable improvement also may be accomplished even in the individual who has chronic pulmonary hypertension by sustained (>18 h/day) breathing of oxygen-enriched air.

Once the right ventricle has failed, inotropic agents should be used cautiously because of the threat of arrhythmias posed by arterial hypoxemia and respiratory acidosis. Moreover, after adequate oxygenation has been achieved, the need for digitalis and diuretics often decreases because the hemodynamic burden on the right ventricle decreases. Even though acute cor pulmonale is largely reversible, each bout appears to leave behind a slightly higher level of pulmonary hypertension after recovery.[17]

Arterial blood gas composition is the therapeutic compass to the control of pulmonary hypertension in COPD. The degree of hypoxia may be underestimated by blood sampling while the patient is awake and at rest, since hypoxemia is more marked during sleep and with physical activity. Determinations of the oxygen saturation during sleep or with ambulation using pulse oximetry are helpful in optimally prescribing supplemental oxygen.

Ensuring the return of arterial oxygenation toward normal is much more vital than is the administration of inotropic agents.[22] When respiratory infection has triggered the episode of pulmonary hypertension, a vital strategy for achieving a lasting improvement in arterial oxygenation is the administration of an appropriate antibiotic. While awaiting the salutary effects of antibiotic therapy, attention is paid to hydration, to postural drainage, and to adequate alveolar ventilation.

Phlebotomy, once popular because of the prospect that increased blood viscosity contributes importantly to the pulmonary hypertension, has fallen into disuse. Polycythemia is rarely severe enough to be a serious problem in cor pulmonale associated with bronchitis and emphysema, and when its is present, it is usually indicative of inadequate relief of hypoxemia with optimal use of supplemental oxygen.

Vasodilators recently have been tried in various types of secondary pulmonary hypertension, including that due to COPD.[23] The agents tried are the same as those outlined for *primary* pulmonary hypertension. They run the risk of aggravating arterial hypoxemia by exaggerating ventilation-perfusion abnormalities. Unfortunately, the efficacy of vasodilator agents in secondary pulmonary hypertension has proved to be far less impressive or predictable than in primary pulmonary hypertension. To date, the safest and most effective approach to pulmonary vasodilatation in obstructive lung disease with arterial hypoxemia is the use of supplemental oxygen.[23]

CONNECTIVE TISSUE DISEASES

Pulmonary vascular disease is an important component of certain connective tissue diseases. Among these, the more common are systemic lupus erythematosus (SLE), the scleroderma spectrum of diseases, and dermatomyositis.[24] The lesions may take the form of interstitial inflammation and fibrosis, obliterative disease, or vasculitis, either singly or in combination. Although pulmonary hypertension can complicate many connective tissue diseases, it has been documented most often in SLE and progressive systemic sclerosis (scleroderma) and its variant syndromes. The possibility has been raised that primary pulmonary hypertension is an inflammatory, or autoimmune, disease. This prospect has gained support from the occasional instances in which the lesions are confined to the pulmonary arterial tree without interstitial involvement and similarities in the histologic appearance of the vascular lesions. The high frequency of both collagen-vascular disease and primary pulmonary hypertension in women and the occurrence of Raynaud's phenomenon in up to 20 percent of patients with primary pulmonary hypertension has been used as additional evidence.[25] Finally, there is a high incidence of positive serologic tests for antibodies (ANA, anti-Ku), particularly in women with primary pulmonary hypertension. With respect to the pathogenesis of the two disorders, the idea has been raised that both the Raynaud's phenomenon and an increase in pulmonary vascular tone represent a widespread vasoconstrictive pulmonary-systemic disorder. However, this hypothesis has not gained universal support.

The lungs and pleura are frequently involved in SLE, with a reported frequency of up to 70 percent. Patients with pulmonary hypertension and SLE are predominantly women; most of these patients also exhibit Raynaud's phenomenon.

The histopathologic lesions in these patients resemble those of primary pulmonary hypertension. Pulmonary hypertension in these patients may originate in microthrombi secondary to the hypercoagulable state caused by lupus anticoagulant or anticardiolipin antibodies in the blood. Less likely is the hypothesis of generalized vasoconstriction noted earlier. Unfortunately, treatment of pulmonary hypertension associated with SLE using either anticoagulants or pulmonary vasodilators has had only modest success. This poor outcome contrasts with the results obtained in patients with active pulmonary vasculitis, who may either improve or stabilize their

vascular disease with immunosuppressive agents.

In progressive systemic sclerosis (scleroderma) and its variants, such as the CREST syndrome (*c*alcinosis, *R*aynaud's syndrome, *e*sophageal involvement, sclerodactyly, and *t*elangiectasia) and in overlap syndromes (e.g., mixed connective tissue disease), the incidence of pulmonary vascular disease is high. In these patients, pulmonary hypertension is the cause of considerable morbidity and mortality. In a prospective study involving cardiac catheterization of patients with progressive systemic sclerosis or the CREST syndrome variant, pulmonary hypertension, either as an isolated finding or in association with pulmonary parenchymal or cardiac disease, was found in up to one-third of patients with progressive systemic sclerosis and in up to one-half of patients with the CREST syndrome.[26] The pulmonary vascular disease may be independent of pulmonary or other visceral disease. As in the case of SLE, the pathology of these lesions is often indistinguishable from that of primary pulmonary hypertension. Vasodilator therapy has not proved to be highly effective; however, continuous intravenous epoprostenol recently has been shown to improve hemodynamics and exercise tolerance.[27]

ALVEOLAR HYPOVENTILATION IN PATIENTS WITH NORMAL LUNGS

In patients who hypoventilate despite normal lungs (alveolar hypoventilation), the primary pathogenetic mechanism is alveolar hypoxia potentiated by respiratory acidosis.[28] These abnormal alveolar and arterial blood gases play the same role in eliciting pulmonary hypertension in patients with alveolar hypoventilation as in those in whom the abnormal alveolar and blood gases are the result of ventilation-perfusion abnormalities. In individuals with normal lungs, the alveolar hypoventilation generally originates from an inadequate ventilatory drive (e.g., after encephalitis), covert obstruction of the upper airways (e.g., in the sleep apnea syndromes), an ineffective chest bellows (e.g., after poliomyelitis or polymyositis), or lungs entrapped by neoplasm or fibrosis (e.g., in trapped lung caused by asbestosis).

Regardless of etiology, whether pulmonary hypertension will occur in patients with alveolar hypoventilation and normal lungs depends on the whether there is sufficient alveolar and arterial hypoxia to raise pulmonary arterial pressures considerably. In the sleep apnea syndromes, severe arterial hypoxemia and pulmonary hypertension that develop initially only during sleep may become self-perpetuating and carry over into wakefulness, although this only occurs in those with severe disturbances in respiration during sleep.[29]

For the patient with alveolar hypoventilation with combined respiratory and cardiac (right ventricular) failure, the highest therapeutic priority is to improve oxygenation. Assisted ventilation, particularly during sleep, may be particularly helpful in improving oxygenation and reducing hypercapnia (e.g., continuous positive airway pressure) breathing. Pharmacologic therapy is rarely needed for patients with alveolar hypoventilation because of the efficiency of assisted ventilation coupled with oxygen therapy in promoting pulmonary vasodilatation.

Chapter 52: PULMONARY HYPERTENSION

PRIMARY (UNEXPLAINED) PULMONARY HYPERTENSION

Definition

PPH is a disorder intrinsic to the pulmonary vascular bed that is characterized by sustained elevations in pulmonary artery pressure and vascular resistance that generally lead to RV failure and death.[25] The diagnosis of PPH requires the exclusion on clinical grounds of other conditions that can result in pulmonary artery hypertension[30] (see Table 52-3). PPH is a rare disease, with an incidence of 1 to 2 per million.[31] Its prevalence is about 0.1 to 0.2 percent of all patients who come to autopsy.

The clinical diagnosis of PPH rests on three different types of evidence: (1) clinical, radiographic, and electrocardiographic manifestations of pulmonary hypertension, (2) hemodynamic features consisting of abnormally high pulmonary arterial pressures and pulmonary vascular resistance in association with normal left-sided filling pressures and a normal or low cardiac output, and (3) exclusion of the causes of secondary pulmonary hypertension.

SPECIAL TYPES

Certain associations of PPH have attracted interest because of their prospects for shedding light on some etiologies. These include so-called anorexigen-induced pulmonary hypertension, familial pulmonary hypertension, human immunodeficiency virus (HIV) infection-associated pulmonary hypertension, and portal-pulmonary hypertension.[30-33] In each of these, the clinical findings and the histologic appearance of the lungs at autopsy are identical to those which characterize the sporadic form of PPH. This diversity in associations underscores the likelihood that so-called PPH is the final common expression of heterogeneous etiologies.

General Features

After puberty, females predominate, those between 10 and 40 years of age being most often affected. Before puberty, no sex difference is discernible. The textbook picture of a patient with PPH is that of a young woman in the prime of life who develops one or more of the symptoms in Table 52-1 without discernible cause. Sex and age are sometimes useful in distinguishing clinically between the likelihood of PPH and pulmonary thromboembolic disease. The latter generally favors men, particularly in their later years.[25]

As a rule, median survival of patients can be predicted on the basis of the New York Heart Association functional classification: 6 months for class IV, 2½ years for class III, and 6 years for classes I and II. Unless interrupted by sudden death, which occurs in approximately 15 percent of patients, the usual downhill course terminates in intractable RV failure.[34]

Etiology

The common denominator in the pathogenesis of PPH appears to be injury to the layers of the vascular wall of the small muscular pulmonary arteries and arterioles.[35] In response to injury, the

intima of these vessels proliferates so that the endothelium changes from a single flat layer to a piled-up projection that narrows the caliber of the vascular lumen. Along with intimal proliferation, the media of the affected vessels hypertrophy.[36]

The primary site of injury in PPH remains uncertain. Recent studies have implicated an intrinsic defect in ion channel function and calcium homeostasis in vascular smooth muscle,[37] whereas others have shown that endothelial function is disturbed, leading to altered production or handling of a variety of endothelial-derived vasoactive substances.[35] These abnormalities, coupled with altered platelet-endothelial interactions that predispose to intravascular thrombosis, lead to an inexorable course of enhanced vascular reactivity, proliferation and remodeling, and progressive obliterative vasculopathy. Diverse etiologies seem to be capable of eliciting PPH[38] (Table 52-4). For example, ingestion of the anorexigens fenfluramine and its isomer dexfenfluramine has been demonstrated to markedly increase the risk of PPH,[31] ingestion of toxic oil elicited an outbreak of pulmonary hypertension in Spain,[39] and HIV infection, even in the absence of the acquired immune deficiency syndrome, also has been implicated.[32]

Table 52-4: Suggested Mechanisms for Primary Pulmonary Hypertension

Proposed Mechanism	Evidence
Early/sustained vasoconstriction kinetics	Altered smooth muscle cell calcium
	Endothelial dysfunction
Genetic predicposition identified	Familial disease with gene locus
	?Susceptibility with exposures, e.g., anorexigens, HIV, portal hypertension
Pulmonary thrombosis/embolism arteries/arterioles	Widespread occlusion of ?Altered endothelial-platelet interaction
Autoimmune disease	Raynaud's phenomenon and antinuclear antibodies common, female gender predilection

For a long while, virtually all reports of PPH dealt with sporadic cases. An epidemic in Europe between 1967 and 1970 that was linked to the use of Aminorex, an anorectic agent, raised the prospect of hereditary predisposition, since only 1 in 1000 who took the drug developed pulmonary hypertension. More recently, the fenfluramines have been associated with both severe pulmonary hypertension and valvular heart disease.[31,40] The recent toxic oil epidemic in Spain has reinforced the concept of individual susceptibility to pulmonary vasotoxic agents.[39]

In recent years, an increasing number of patients have been identified in whom PPH is genetically linked.[41] In these individuals, the hereditary pattern is that of autosomal dominance with incomplete penetrance. The locus of the familial gene recently has been localized to the long arm of chromosome 2.[42] One major insight provided by the families with PPH is the diversity of pulmonary vascular lesions in members of the same family.[41]

Pathology

The evolution of PPH depends on progressive attenuation of the pulmonary arterial tree, which gradually increases pulmonary vascular resistance to the point of eliciting RV strain and failure. The seat of the disease is in the small pulmonary arteries (between 40 and 100 mm in diameter) and arterioles. The obliterative lesions can affect one or more layers of these vessels. In some instances, medial hypertrophy predominates; in others, it is the intima that proliferates. In addition, evidence of inflammation also may be present[36] (Fig. 52-4).

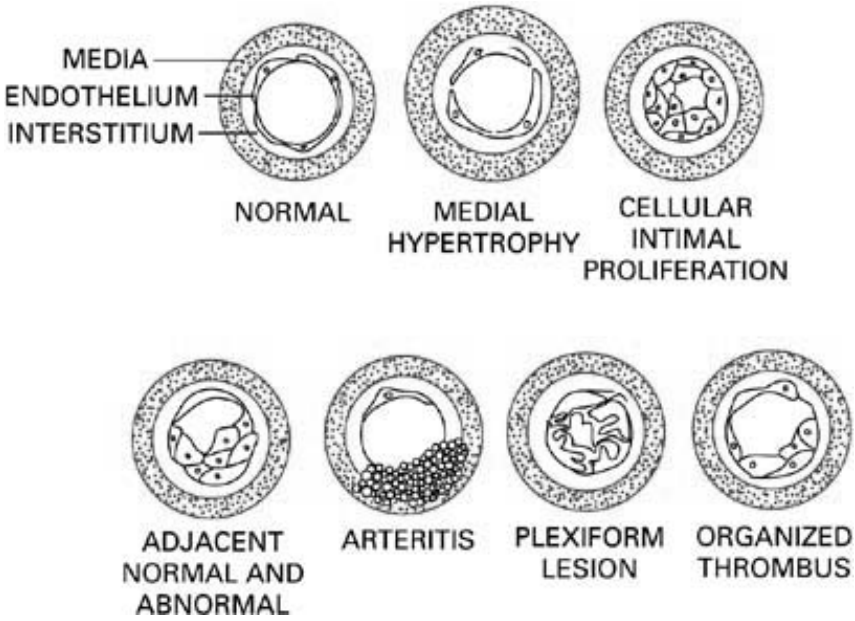

Figure 52-4: Vascular lesions in primary pulmonary hypertension. The plexiform lesion, once believed to be the histologic hallmark of primary pulmonary hypertension, has emerged as only one feature of a constellation of lesions.

Histologic examination of the lung identifies a constellation of pulmonary precapillary lesions that are consistent with the clinical diagnosis of PPH, i.e., plexiform lesions, angiomatoid lesions, concentric intimal fibrosis, and necrotizing arteritis. The pathologist is often hard-pressed to distinguish between organized clots in small vessels that initiate the pulmonary hypertension and those which result from the obliterative pulmonary vascular disease. Recent clots in small pulmonary arteries and arterioles are common at autopsy in patients with PPH, particularly when the right ventricle has failed and cardiac output falls. Although similar clots may not have initiated the pulmonary hypertension process in PPH, it seems reasonable that more often they are complicating features that aggravate and exaggerate pulmonary vascular obstruction.

Pathophysiology

The hemodynamic hallmarks of PPH in the resting patient were indicated earlier: a combination of a high pulmonary arterial pressure, a normal or low cardiac output, and a normal left atrial (pulmonary wedge) pressure. As a result of this hemodynamic pattern, calculated pulmonary vascular resistance is high, generally leading to the logical conclusion that the resistance vessels, i.e., the small muscular arteries and arterioles, are the predominant sites of vascular obstruction. During exercise, as cardiac output increases, pulmonary arterial pressures increase further; the increments in pressure in the pulmonary hypertensive circuit are much more striking than in the normotensive pulmonary circulation owing to the inability to dilate existing vasculature or recruit unused vessels to accommodate the rise in pulmonary blood flow.

Pulmonary vasodilators are currently administered acutely for testing the responsiveness of the pulmonary circulation.[30] Among these, inhaled NO and intravenous prostacyclin have become the "gold standards." Several clinical and hemodynamic changes are sought as desirable end points: (1) improvement in exercise tolerance and in the quality of life; the increase in physical capacity, attributable to an increase in cardiac output, in turn improves oxygen delivery to peripheral organs and tissues; (2) a decrease in the level of pulmonary arterial hypertension, with evidence of regression of RV hypertrophy or dilatation, or both; (3) a decrease in calculated pulmonary vascular resistance; optimally, this decrease should entail an increase in cardiac output (with minimal increase in heart rate) accompanied by a decrease in pulmonary arterial pressure; and (4) since pulmonary vasodilators are also systemic vasodilators, pulmonary vasodilatation has to be effected without evoking undue systemic hypotension and tachycardia.

The combination of right-sided heart catheterization and vasodilator testing is particularly useful not only for defining the hemodynamic state of the patient but also in providing a hemodynamic baseline for future invasive and noninvasive studies, such as serial echocardiograms.

Clinical Picture

In its early stages, the disease is difficult to recognize. In the sporadic case, the first clue is often an abnormal chest radiograph (see Fig. 52-1) or ECG indicative of RV hypertrophy (Fig. 52-5). Both are late manifestations. The existence of RV enlargement is generally confirmed by echocardiography. By the time these changes appear, however, pulmonary hypertension is moderate to severe. Initial complaints, particularly easy fatigability and dyspnea, tend to be discounted, i.e., attributed to being "out of shape," except when the index of suspicion is high, e.g., with a history of ingestion of anorectic agents or of familial pulmonary hypertension (see Table 52-1).

When the disease is advanced, the activities of daily life are progressively circumscribed by increasing nonspecific discomfort. Dyspnea, particularly during physical activity, becomes incapacitating. Some patients develop an angina type of chest pain along with breathlessness. Other common symptoms are weakness, fatigue, and exertional or postexertional syncope (see Table 52-1). Infrequently, an enlarged pulmonary artery causes hoarseness because of compression of the left recurrent laryngeal nerve. In time, right-sided heart failure develops.

Patients with severe pulmonary hypertension seem prone to sudden death. Death has occurred unexpectedly during normal activities, cardiac catheterization, and surgical procedures and after the administration of barbiturates or anesthetic agents. The mechanisms for sudden death are not clear and may include arrhythmias or acute pulmonary thromboembolism. In a few instances, severe bradycardia and atrioventricular (AV) dissociation have preceded cardiac arrest.

It was noted earlier that as far as clinical manifestations and physical examination are concerned, PPH has an advantage over secondary pulmonary hypertension in that its manifestations are not obscured by those of underlying cardiac or respiratory disease. On physical examination, the jugular venous pulse usually shows a prominent *a* wave. RV hypertrophy causes a heave along the left sternal border, and a distinct systolic impulse is palpable over the region of the main pulmonary artery (see Chap. 10). The pulmonic component of the second sound is markedly accentuated, the second heart sound is narrowly split, and an ejection click is heard in the pulmonic area. Often a fourth heart sound emanating from the hypertrophied right ventricle is heard at the lower left sternal border. The murmur of tricuspid regurgitation is best heard along the sternal border with the patient in the supine position and can be accentuated with inspiration. In some patients, a midsystolic murmur is audible at the pulmonic area; as pulmonary arterial pressures approximate systemic arterial levels, the murmur of pulmonary valvular regurgitation often appears (see also Chap. 10).

The onset of RV failure is accompanied by jugular venous distention and a gallop (S_3); inspiration intensifies the gallop. The liver becomes enlarged and tender, and hepatojugular reflux can be elicited. Hydrothorax and ascites are seen as RV failure progresses.

Special Studies

Direct determination of pulmonary circulatory pressures by right-sided heart catheterization is the only way to definitively establish the diagnosis of pulmonary hypertension; however, other studies that are less direct can strongly suggest that it is present. Since the diagnosis of "primary" is one of exclusion, a number of tests are undertaken, usually in the hope of identifying a more treatable disease than PPH.[38]

CHEST RADIOGRAPHY AND ELECTROCARDIOGRAPHY

In the early stages, the chest radiograph is generally normal. Later it shows cardiac enlargement in association with enlargement of the pulmonary trunk, while the peripheral pulmonary arterial branches are attenuated; the lung fields appear oligemic (see Fig. 52-1). Although fullness of the central pulmonary arterial trunks and peripheral "pruning" are distinctive, appearances vary somewhat from patient to patient in accord with the level and pace of the pulmonary hypertension and the age of the patient. Radiographic evidence of RV enlargement usually becomes overt only late in the course of the pulmonary hypertension. The ECG almost always shows right axis deviation, RV hypertrophy, and, usually, right atrial enlargement (see Chap. 11).

THE ECHOCARDIOGRAM

Two-dimensional echocardiography confirms the enlargement and hypertrophy of the right atrium and ventricle, tricuspid regurgitation, and pulmonic valvular regurgitation. At the same time, LV structure and function are normal. The magnitude of the velocity of the tricuspid regurgitant jet using Doppler techniques can provide a noninvasive estimate of RV peak systolic pressure. The determination of RV ejection fraction using radionuclide techniques can be helpful in evaluating the extent to which the excessive RV afterload has compromised the right ventricle. This applies not only to PPH but also to other disorders that lead to severe pulmonary hypertension (e.g., COPD and congenital heart disease) (see also Chap. 14).

Lung Scans

Lung scans are particularly helpful in suggesting the possibility of large, long-standing organized clots in the major pulmonary arteries that may be amenable to surgical removal (thromboendarterectomy). The lung scan in PPH fails to disclose major perfusion defects. Angiography is done to exclude pulmonary emboli in cases where the scan is equivocal. Scanning over the brain or kidneys may disclose the presence of an intracardiac or intrapulmonary right-to-left shunt.

RIGHT-SIDED HEART CATHETERIZATION

Cardiac catheterization is invaluable in quantifying the hemodynamic abnormalities, in excluding cardiac causes of pulmonary arterial hypertension, and in assessing the hemodynamic responses of the heart and pulmonary circulation to vasodilator agents.[4]

Diagnosis

The diagnosis of PPH rests on two pillars: (1) the detection of pulmonary hypertension and (2) the exclusion of known causes of high pulmonary arterial pressure. The history is of utmost importance. Before categorizing pulmonary hypertension as "primary" or "unexplained," due regard must be paid to the exclusion of known etiologies (see Table 52-3), particularly thromboembolic disease and connective tissue disorders. Account also should be taken of the likelihood of familial disease. Pulmonary function tests are useful in excluding diffuse pulmonary disorders, particularly interstitial fibrosis and granuloma. Serologic testing can point the way to covert connective tissue disorders. Abnormal liver function tests can signal the coexistence of portal and pulmonary hypertension. The value of cardiac catheterization in eliminating acquired or congenital heart disease was indicated earlier. Unfortunately, by the time pulmonary hypertension complicating heart disease is recognized, the anatomic lesions often are too far advanced for the obliterative pulmonary vascular disease to be reversible. One notable exception is the dramatic improvement that often follows surgical removal of organized clots from the walls of major pulmonary arteries.

Treatment

For the past few decades, treatment of PPH has repeatedly turned to the use of vasodilators in the hope that an increase in pulmonary vascular tone contributed importantly to the high pulmonary arterial pressures. Although the bulk of the pulmonary vascular obstruction was clearly anatomic, vasodilators offered the prospect not only of decreasing pulmonary arterial pressures somewhat, and therefore the hemodynamic burden on the right ventricle, but also of prompting reversibility of the anatomic lesions, such as muscular hypertrophy, that resulted simply from the high pulmonary arterial pressures. Unfortunately, the use of vasodilators, which could affect the systemic as well as the pulmonary circulation and which often were accompanied by undesirable side effects, led to progressive disenchantment with one agent after another.

The situation has changed considerably during the past decade. The introduction of acute vasodilator testing for responsiveness helped to confirm the idea that in about one-third of patients, heightened pulmonary vasomotor tone helped to sustain the pulmonary hypertension. An optimal "responder" to acute testing manifested an increase in cardiac output along with a decrease in pulmonary arterial pressure and in pulmonary vascular resistance without affecting systemic arterial pressure unduly. Improvement in exercise tolerance accompanied the increase in cardiac output. Another landmark was the introduction of calcium channel blocking agents that could be taken orally, and in general, those who were highly responsive during acute testing could be maintained at lower pulmonary arterial pressures by these agents. A third insight was that even patients who failed to satisfy the criteria for a good hemodynamic response to acute vasodilator testing might respond to continuous infusion of epoprostenol. Indeed, a substantial number of such patients have been treated in this way for years, and even more have used continuous intravenous epoprostenol as a transition to transplantation of the lung or lungs or of heart and lungs. During this evolution, heart-lung and then lung transplantation became increasingly feasible and available, although the donor supply is still a limiting factor.

As a result of these advances, a patient with PPH has several therapeutic options, ranging from oral calcium channel blocking agents to continuous infusion of prostacyclin to lung transplantation. However, none of these modalities is free of complications. The oral calcium channel blocking agents generally have to be administered in large doses that are often accompanied by undesirable side effects.[43] The continuous infusion of a vasodilator, such as prostacyclin, runs the risks not only of a permanently placed intravenous catheter but also of drug-related side effects that can preclude dose increases.[44,45] Transplantation offers the substitution of immunosuppression and its attendant risk of infection as a better option than chronic cor pulmonale and RV failure.[46] Despite the limitations of each of these therapeutic modalities, together they provide a graduated therapeutic approach that has provided, at each stage, a better quality of life for many individuals with PPH. Moreover, they have prompted the search for

agents that can be used in place of prostacyclin, which, until now, has required intravenous infusion; prostacyclin analogues that are delivered subcutaneously and by aerosol are currently under investigation. Other novel approaches include chronic ambulatory NO, which can be administered by inhalation.

VASODILATOR AGENTS

Various agents have been tried over the years as pulmonary vasodilators. These include α-adrenergic antagonists, β-adrenergic agonists, diazoxide, hydralazine, nitrates, and angiotensin-converting enzyme inhibitors. In general, these have not withstood the test of time. Experience has taught that untoward reactions can occur with any pulmonary vasodilator, even when low doses are used. Three categories of agents continue to hold promise, however: calcium channel blocking agents, arachidonic acid metabolites, and NO.

DRUGS THAT BLOCK CALCIUM TRANSPORT

The designation *calcium channel blocker* refers to a heterogeneous group of agents of different structural, pharmacologic, and electrophysiologic properties. The agents in this category currently receiving the most clinical attention as potential pulmonary vasodilators are nifedipine and diltiazem. Of the two, nifedipine is the more popular. Verapamil generally is not used because of its undesirable negative inotropic effect.

Nifedipine

Note that this use is not listed in the manufacturer's directive. Nifedipine is a synthetic agent that is unrelated to other vasoactive or cardiotonic drugs. It is a potent systemic vasodilator that is used for the treatment of coronary vasospasm. Although it has significant direct negative inotropic effects, these are usually not prominent clinically because of the reflex sympathetic stimulation of the heart; it does not possess antiarrhythmic properties. It is now the preferred agent for therapy of patients who manifest acute vasoreactivity when tested with short-acting agents under hemodynamic monitoring.

Sustained-release preparations are used, with the dosage generally titrated to the maximal tolerable level based on avoiding untoward systemic effects, i.e., hypotension, headache, dizziness, and flushing. Considerable caution is necessary in administering the higher dosages, however, because side effects can occur precipitously and be life-threatening. In one study, 64 patients with PPH were treated acutely with high doses of calcium channel blockers. Seventeen patients responded to treatment with nifedipine (13 patients) or diltiazem (4 patients) and were alive after 5 years.[46]

In experienced centers, the trial of nifedipine or diltiazem orally is preceded by use of testing of acute vasoreactivity using one or more of three agents: (1) inhaled NO, in concentrations of 10 to 40 ppm for 5 to 10 min, (2) prostacyclin (PGI_2, Epoprostenol, Flolan), administered intravenously in increasing doses (starting dose of 1-2 ng/kg/min followed by successive increments every 15 min of 2 ng/kg/min until a maximal dose of 12 ng/kg/min is reached or until side effects preclude further increases), and (3) adenosine (50-200 ng/kg/min). Only patients who manifest significant reductions in pulmonary vascular resistance (usually >20-30 percent), resulting from a fall in pulmonary artery pressure without systemic hypotension and accompanied by an unchanged or increased cardiac output, are considered candidates for chronic therapy with oral calcium channel antagonists.

Arachidonic Acid Metabolites

Epoprostenol (Flolan, prostacyclin, PGI_2), a metabolite of arachidonic acid, and its analogues continue to be a major focus of attention as treatments for a variety of forms of pulmonary hypertension. The pulmonary endothelium elaborates prostacyclin into the bloodstream, where it has a short biologic half-life, i.e., 2 to 3 min. In principle, it is attractive for the treatment of pulmonary hypertension on several accounts: (1) it is a pulmonary vasodilator, (2) it inhibits platelet aggregation, and (3) it inhibits proliferation of vascular smooth muscle. Unfortunately, it suffers the disadvantage of requiring continuous intravenous infusion, which is currently being done using portable pumps.[44,45] Analogues that can be given orally, subcutaneously, or by the inhaled route are under investigation. Success in long-term management recently has been reported using aerosolized iloprost, a stable prostacyclin analogue.[16,47] Currently, its most effective use is for long-term management in patients with severe (NYHA classes III or IV) primary pulmonary hypertension who are unresponsive to or are not candidates for therapy with calcium channel blockers.[44,45,48]

Nitric Oxide

NO is synthesized in endothelial cells from one of the guanidine nitrogens of L-arginine by the enzyme NO synthase. It has proved to be the endothelial-derived relaxing factor that contributes to the low initial tone of the pulmonary circulation. It has the advantage of other vasodilators of selectively relaxing pulmonary vessels without affecting systemic arterial pressure. It is currently being used as a test of vasoreactivity in a wide variety of pulmonary hypertensive states including PPH and also has been used to control pulmonary hypertension in the syndrome of persistent pulmonary hypertension in the newborn.[49, 50-51]

Anticoagulants

Since 1984, when Fuster et al.[52] in a nonrandomized clinical trial showed that long-term survival was improved in patients with PPH by anticoagulant therapy (warfarin in low doses), the use of anticoagulants has been incorporated into the therapeutic regimen in patients with PPH. This practice is supported by the high incidence of antemortem clots found at autopsy in the small pulmonary arteries and arterioles of patients with PPH. Moreover, in a recent trial that separated "responders" from "nonresponders" to calcium channel blockers, survival was significantly better in those given warfarin than in those who were not anticoagulated.[43] The advent of RV failure increases the propensity for clotting in the pulmonary circulation. The usual goal of anticoagulation is to achieve and maintain an INR of 2 to 2.5.[53]

ATRIAL SEPTOSTOMY

Blade-balloon atrial septostomy has been performed in patients with severe RV pressure and volume overload refractory to maximal medical therapy.[54] The goal of this approach is to decompress the overloaded right heart and improve systemic output of the underfilled left ventricle. Improvements in exercise function and signs of severe right-sided heart dysfunction such as syncope and ascites have been observed. Since the creation of an interatrial communication will result in an increased venous admixture, worsening hypoxemia is an expected outcome. The size of the septostomy that is created should be monitored carefully to achieve the ideal balance of optimizing systemic oxygen transport and reducing right-sided heart filling pressures without overfilling a noncompliant left ventricle or producing extreme degrees of venous admixture.

LUNG TRANSPLANTATION

Only one-third of patients with PPH are responsive to long-term oral vasodilator therapy. Of the

remainder, approximately 65 to 75 percent maintain sustained clinical improvement with long-term continuous intravenous therapy using prostacyclin. When pulmonary hypertensive disease has progressed, or threatens to progress, to the stage of RV failure, the physician and patient are left with few therapeutic options other than lung transplantation. Lung transplantation is currently being done at specialized centers and is almost invariably handicapped by a shortage of donor lungs, which can lead to long delays. Single- or double-lung transplantation has largely replaced heart-lung transplantation. Often, hemodynamic improvement is dramatic,[55] but transplantation for PPH poses not only a considerable surgical risk but also the prospect of opportunistic infections that accompanies lifelong immunosuppression.[56] Rejection phenomena, notably bronchiolitis obliterans, are the major limiting factor to prolonged survival. The median survival after lung transplantation is approximately 3 years.[46] Recurrence of PPH after transplantation has not been reported.

Prognosis

The diagnosis of PPH carries with it a poor prognosis unless medical or surgical therapy succeeds in decreasing pulmonary vascular resistance. Although death usually occurs within a few years after the onset of symptoms, instances of long-term survival do occur. Although sudden death accounts for 10 to 15 percent of all PPH-related deaths, the prognosis is largely determined by the severity of pulmonary hypertension and right-sided heart dysfunction.[34]

Chapter 52: PULMONARY HYPERTENSION

PULMONARY VENO-OCCLUSIVE DISEASE AND PULMONARY CAPILLARY HEMANGIOMATOSIS

These are the least common of all types of unexplained pulmonary hypertension. Not infrequently, the patient is thought to have primary pulmonary hypertension until manifestations inconsistent with pulmonary precapillary disease, such as pulmonary congestion and edema or severe hypoxemia, redirect attention to the vascular bed distal to the arterioles, i.e., the capillaries, pulmonary small veins, and venules. The pathogenetic mechanism of POVD is unknown but may begin as an inflammatory-thrombotic process in the small pulmonary veins and venules and ends in fibrous obliteration of the venous and venular lumens. Presumably as a secondary phenomenon, the distal pulmonary arterial tree also develops obstructive lesions that are generally proliferative ("reactive") rather than inflammatory in nature; the intervening capillary bed is generally normal. The pulmonary veno-occlusive lesions have been attributed to an inflammatory response to vascular injury, followed by thrombosis and scarring. Among the postulated etiologies (based on exceedingly sparse evidence) are viral illness, chemotherapy, toxins, autoimmune disease, and mediastinal fibrosis.[36]

Both POVD and capillary hemangiomatosis can be familial. When the pulmonary hypertension is suspected of originating distal to the pulmonary capillary bed, mitral valve disease, myocardial dysfunction, or even left atrial myxoma has a greater likelihood of being the cause than does POVD.

Clinical Picture

Predominantly children and young adults are affected, but the age has ranged from infancy to 48 years. Clinical suspicion of this disorder generally arises when a patient with congested and edematous lungs proves to have a normal mitral valve and left ventricle.

The cardinal signs are dyspnea and fatigue on exertion in conjunction with evidence of pulmonary hypertension; the pulmonary venous rather than pulmonary arterial etiology is suggested by radiologic evidence of postcapillary pulmonary hypertension without evidence of involvement of the left side of the heart (Fig. 52-6*A*). Pleural effusions are common. Cyanosis, syncope, hemoptysis, and finger clubbing have been inconsistent findings. Moderate to severe hypoxemia, due to intrapulmonary shunting through the abnormal capillary network, is a hallmark of capillary hemangiomatosis. Rarely, systemic embolization may occur.

Figure 52-6: POVD proven by open lung biopsy. *A*. Chest radiography. Pulmonary interstitial edema is marked at both bases. *B*. Lung biopsy. In addition to obliterative pulmonary venular disease, the pulmonary arterioles (*arrow*) showed intimal proliferation and medical hypertrophy. (Courtesy of Dr. G. G. Pietra.)

Hemodynamics

Cardiac catheterization discloses a high pulmonary arterial pressure with a normal pulmonary wedge (and LV end-diastolic) pressure. The low wedge pressure has been attributed to discontinuities and channels of high resistance between the pulmonary capillaries and the pulmonary and bronchial venous channels so that wedging interrupts all sources of flow distal to the area blocked by the catheter.[30] When epoprostenol is administered to a patient with POVD, an acute pulmonary edema pattern may ensue, resulting from increasing pulmonary blood flow in the face of downstream vascular obstruction.[48,57] Although not universally present, this response is virtually diagnostic of POVD. Patients with capillary hemangiomatosis may experience worsening

hypoxemia with epoprostenol, attributable to increased shunting through the low-resistance capillary meshwork.

Pathology

Few lung biopsies have been done during life. At autopsy, both lungs are involved. The lungs are the seat of congestion, edema, and focal fibrosis, which may become extensive. The venous lesions may be more marked in one region than in another. Although the small pulmonary arteries as well as the small pulmonary veins are affected, the lesions are different (see Fig. 52-6*B*). Most striking are the morphologic changes in the pulmonary veins and venules, which are narrowed or occluded by intimal proliferation and fibrosis; up to 95 percent of the veins and venules may be affected in this way, but complete occlusion is uncommon. Bronchial veins and bronchopulmonary anastomoses share in the occlusive process. Hypertrophy in the walls of the pulmonary arteries may be quite striking. POVD, to varying degrees, also may coexist with capillary hemangiomatosis. Thrombi in the pulmonary arteries are common.[36]

Treatment

Medical management has been disappointing, since the lesions generally are irreversible. An occasional patient has been reported to do well with medical therapy,[58] although most experienced clinicians consider both POVD and capillary hemangiomatosis to be contraindications to the use of oral vasodilators or intravenous epoprostenol. The usual duration after recognition ranges from a few weeks in infants to several years in adults, with 7 years being the maximum. The treatment of choice is probably lung transplantation.

Part 8: PULMONARY HYPERTENSION AND PULMONARY DISEASE
Chapter 53:

PULMONARY EMBOLISM

Author: Victor F. Tapson

Approximately 100,000 patients in the United States die each year directly due to acute pulmonary embolism (PE), with another 100,000 deaths occurring in patients with concomitant disease in whom PE contributes significantly to the demise of the patient.[1,2] A substantial number of patients die from PE prior to being diagnosed. Many of these deaths appear to be preventable. Autopsy studies have repeatedly documented the high frequency with which PE has gone unsuspected and undetected.[3] Despite advances in diagnostic technology and therapeutic approaches, PE remains underdiagnosed and prophylaxis continues to be dramatically underutilized. Pulmonary embolism nearly always results from deep venous thrombosis (DVT) of the proximal deep veins of the legs, that is, including the popliteal veins, and their vicinity, although axillary and subclavian vein thrombi may also embolize. Venous thromboembolism (VTE) represents the clinical spectrum of DVT and PE and occurs extraordinarily commonly in hospitalized patients, particularly after major surgery.

Because DVT and PE are so commonly clinically unsuspected, considerable diagnostic and therapeutic delays result and substantial morbidity and mortality are the ultimate consequence. The risk factors for DVT are discussed below, followed by the pathophysiology of acute PE. Because of the potential overlap with regard to the diagnostic approach to suspected DVT and PE, these are discussed in the same section. The principles of management of DVT and PE are addressed. Finally, the less common entity of chronic thromboembolic pulmonary hypertension is reviewed.

ACUTE DEEP VENOUS THROMBOSIS: RISK FACTORS AND PATHOGENESIS

Virchow proposed that the pathogenesis of DVT was based upon several potential initiating events, including stasis, venous injury, and hypercoagulability. Risk factors for DVT are based upon these processes (Table 53-1). Thrombosis may develop within the lumen of any vein as well as in the right side of the heart. Extensive investigation has been undertaken of the veins of the lower extremities, since most significant PE originate from this location. Although thrombi may form at any point along the vein wall, most originate in valve pockets. The veins of the calf are the most common site of origin, with subsequent extension of the clot prior to embolization.[4] If the clot does propagate, it usually remains attached at its base and floats in the vein more proximally. Eventually, it may expand to fill the vessel entirely, with both retrograde and further proximal extension. If embolization does not occur, the thrombosis can partially or completely resolve via three mechanisms, which include recanalization, organization, and lysis. Fatal PE is the most feared complication of DVT. Chronic thrombophlebitis with recurrent pain and swelling can be incapacitating. Frequently more than one risk factor for venous thrombosis is present and knowledge of these risk factors provides the rationale for both prophylaxis and clinical suspicion.

Table 53-1: Risk Factors for Venous Thromboembolism

Acquired factors
Age greater than 40
Prior history of venous thromboembolism
Prior major surgical procedure
Trauma
Hip fracture
Immobilization/paralysis
Venous stasis
Varicose veins
Congestive heart failure
Myocardial infarction
Obesity
Pregnancy/postpartum period
Oral contraceptive therapy
Cerebrovascular accident
Malignancy
Severe thrombocythemia
Paroxysmal nocturnal hemoglobinuria
Antiphospholipid antibody syndrome (including lupus anticoagulant)
Inherited factors
Antithrombin III deficiency
Factor V Leiden (activated protein C resistance)
Prothrombin gene (G20210A) defect
Protein C deficiency
Protein S deficiency
Dysfibrinogenemia
Disorders of plasminogen
Hyperhomocysteinemia

Acquired Risk Factors

Most venous thrombi arise in venous valves, where blood flow tends to stagnate. The increased frequency of thrombosis with advanced age and immobilization further emphasizes the importance of stasis in thrombogenesis. Immobility, regardless of the cause, discourages venous return and contributes to stasis. Acute paraplegia significantly increases the risk of DVT (particularly in the paralyzed limb), and the period of highest risk appears to be the first 2 weeks after the onset of the paralysis.[5] Prolonged bed rest or long automobile or airplane trips may be the only obvious risk factors in patients developing thromboemboli. Obesity also appears to increase the risk of VTE. Information extrapolated from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) suggests that the relationship of obesity and VTE are not entirely understood and that further clarification would be useful.[6] Although obesity is commonly believed to be a significant risk, it is likely that immobility and stasis are contributing factors. Age appears to increase mortality due to PE,[7] and it appears that PE is suspected less commonly prior to death in the elderly patient.[8] The risk of VTE is particularly high in those of the elderly with concomitant cardiac disease or cancer.

Antecedent pulmonary thromboembolism forecasts an appreciable risk of recurrence in the hospitalized patient. Surgical patients with a previous history of VTE who do not receive prophylaxis develop postoperative DVT in more than 50 percent of cases.[9] Surgery itself significantly enhances the risk. Even surgery patients without significant additional risk factors develop venography-proven DVT in nearly 20 percent of cases if neither pharmacologic nor mechanical prophylaxis is applied.[10] Prophylactic anticoagulation is initiated either prior to surgery or shortly thereafter to prevent the development of intraoperative and early postoperative thrombosis. Total hip and total knee replacement patients not receiving prophylaxis develop DVT in more than 50 percent of cases.[11] These orthopedic settings have been comprehensively investigated, prompted by the increasing use of low-molecular-weight heparin (LMWH). Spinal or pelvic surgery place patients at particularly high risk for VTE.

Trauma, particularly of the lower extremities and pelvis, heightens the risk of DVT. Pulmonary embolism has been identified at autopsy in as many as 60 percent of patients with lower extremity fractures,[12] and mortality has been attributed to PE in as many as 50 percent of patients dying after hip fracture.[13] The incidence of VTE increases with time after the traumatic event. Autopsy-confirmed PE in patients surviving for less than 24 h after trauma has been demonstrated in 3.3 percent, increasing to 5.5 percent in those surviving up to 7 days. Pulmonary emboli occurred in 18.6 percent of those surviving for a longer period.[14] Venous catheters (particularly in the jugular, subclavian, or femoral veins) traumatize veins as well as serving as potential nidi for thrombosis. Associated cancer or immobility is often present in these individuals. Symptomatic PE can originate from catheter-induced (or non-catheter-induced) upper extremity thrombi, although this appears much less commonly than when the leg or pelvic veins are the source. Upper extremity (axillary-subclavian) thrombosis may also occur due to the effort-induced syndrome described by Paget-Schroetter.[15]

Recent epidemiologic analyses as well as autopsy data suggest that patients with cardiac and malignant disease are particularly predisposed to VTE.[7,16] Although myocardial infarction without anticoagulation has been associated with a significant incidence of DVT, more recent therapeutic strategies have had a beneficial impact.[17] Several of the large, multicenter, placebo-controlled acute myocardial infarction trials have indicated that the use of thrombolytic therapy has reduced the incidence of VTE.[18,19]

Malignancies clearly augment the risk of VTE, although the precise pathogenesis of

thromboembolism in cancer is not well understood.[16] It is clear, however, that numerous mechanisms-including intrinsic tumor procoagulant activity and extrinsic factors such as chemotherapeutic agents and indwelling access catheters-contribute to this process. The thrombophilic tendency associated with cancer is often amplified by weakness and reduced ambulation with venous stasis. A recent analysis, based upon data from the PIOPED trial, revealed that of 399 patients with PE, 73 (18.3 percent) had cancer.[7] Pancreatic, lung, gastric, genitourinary tract, and breast malignancies are associated with a particularly high risk of DVT and PE. It appears that about half of all cancer patients and about 90 percent of those with metastases exhibit abnormalities of one or more coagulation parameter. The most common abnormalities include elevation of clotting factor levels (fibrinogen, factors V, VIII, IX, and XI), fibrinogen and fibrin degradation products, and thrombocytosis.[16]

Most tumor cells produce both tissue factor and cancer procoagulant.[16,20] Tissue factor appears to be the primary coagulant factor implicated in promoting fibrin deposition and is expressed in situ as well as in isolated cells of numerous cancers.[21] Tumor cell expression of tissue factor also promotes metastatic dissemination.[21] Cancer procoagulant is a cysteine protease that activates factor X. Mucin, a glycoprotein produced by certain tumors, possesses a sialic acid moiety that may nonenzymatically cleave factor X to Xa. Plasminogen activator inhibitor type 1 (PAI-1) is secreted by numerous tumor cells and inhibits plasmin generation, augmenting the thrombophilic state as well as possibly also promoting tumor metastasis dissemination.[21] Other procoagulant properties of tumor cells include expression of cytokines such as IL-1β and tumor necrosis factor alpha (TNF-α), which, in turn, regulate expression of procoagulants and mediate interactions between tumor cells, platelets, leukocytes, and endothelial cells. Thrombin, certain cytokines, and growth factors such as vascular endothelial growth factor (VEGF) can stimulate endothelial cells to synthesize tissue factor, further potentiating a procoagulant surface and leading to fibrin deposition on vessel walls. Activated protein C inhibitor may contribute to a prothrombotic state, as it can inhibit both fibrinolysis and the protein C anticoagulant pathway.[21]

Chemotherapy, with resulting neutropenia and sepsis, often necessitates hospitalization and bed rest, which contributes further to the high risk of VTE. Following the administration of various chemotherapeutic agents, changes in the levels of coagulation factors, suppression of anticoagulant and fibrinolytic activity, and direct endothelial damage have been documented clinically and experimentally.[22] Hormonal therapy, particularly tamoxifen in breast cancer adjuvant therapy, is also associated with an increased risk of thromboembolism, particularly when combined with chemotherapy. The thrombophilic state induced by chemotherapeutic agents has recently been reviewed.[22] Further comprehensive research will more clearly elucidate the mechanisms underlying thrombophilia in cancer patients. In spite of the clear association, there is no convincing evidence that an aggressive search for cancer is warranted in patients presenting with apparently idiopathic DVT.[23]

Pregnancy and the postpartum period are the most common settings in which women under age 40 acquire thromboembolic disease. Venous thrombosis develops in these settings five times more often than in age-matched women not on oral contraceptives.[24] Although DVT appears to be more common in the third-trimester and postpartum than prior to delivery, the risk is clearly considerable throughout pregnancy.[24] Cesarean section further augments the risk. Oral contraceptives are associated with the development of VTE, although the precise risk has been controversial.[25] The risk increases with third-generation agents (agents containing desogestrel or gestodene as the progestogen component).[26,27] Results from a clinical trial evaluating hormonal replacement therapy indicated that such therapy increased the incidence of VTE in women 45 to 64 years of age. A yearly total of 16.5 cases of VTE per 100,000 women may be attributed to hormonal replacement therapy.[28] The risk of VTE also appears to be highest during the first year of exposure to hormonal replacement.[29] It has not been clearly established that previous use

increases the risk.[30] Although such therapy is associated with obvious benefits, physicians must consider other potential risk factors for VTE before prescribing hormonal replacement therapy.

Other disease states and clinical settings enhance the risk of VTE. Most intensive care unit patients can be considered at risk for VTE because of their multiple risk factors, including significant underlying disease, immobility, and venous injury due to trauma or central venous catheters. These patients should receive some form of DVT prophylaxis and a high index of suspicion for VTE should be maintained in appropriate clinical circumstances.

Inherited Risk Factors

Inherited thrombophilias result in variable degrees of VTE risk. Individuals with, for example, antithrombin III or factor V Leiden deficiency without significant superimposed risk factors such as surgery or immobilization often do not suffer from VTE until an additional risk factor develops. The factor V Leiden mutation is a common genetic polymorphism associated with activated protein C resistance and appears to be present in approximately 4 to 6 percent of the general population.[31] The relative risk of a first idiopathic venous thrombosis among men heterozygous for the mutation has been shown to be three- to sevenfold higher than that of those not affected.[31] Another thrombophilic mutation has been identified in the 3′ untranslated region of the prothrombin gene (substitution of A for G at position 20210), and this mutant allele is present in 2 percent of the general population.[32] This prothrombin gene defect increases the risk of DVT by a factor of 2.7 to 3.8.[32,33] It appears that carriers of both factor V Leiden and the prothrombin G20210A defect have an increased risk of recurrent DVT after a first episode and are candidates for lifelong anticoagulation.[34] There has been increasing interest in the potential role of homocysteine in VTE. In vitro, homocysteine has potentially thrombogenic effects, including injury to vascular endothelium and antagonism of the synthesis and function of nitric oxide.[35] Coexisting hyperhomocysteinemia has been shown to increase the risk for thrombosis in patients with factor V Leiden.[36] However, the thermolabile methylenetetrahydrofolate reductase gene variant is not independently associated with thrombosis, emphasizing that the precise role of homocysteine in venous thrombosis is unclear. Thus, interactions between the genetic factors (defects in enzymes) that control homocysteine metabolism and nutritional factors (folate, vitamin B_6, and vitamin B_{12} deficiencies) that affect homocysteine metabolism appear to warrant additional investigation with regard to VTE. It would appear certain that additional inherited thrombophilic disorders will be identified that may explain some of the "idiopathic" cases.

Chapter 53: PULMONARY EMBOLISM

ACUTE PULMONARY EMBOLISM: PATHOPHYSIOLOGY

Gas-Exchange Abnormalities

The effect of PE on oxygenation and hemodynamics depends upon the extent of obstruction of the pulmonary vascular bed and the severity of underlying cardiopulmonary disease. Hypoxemia develops in the preponderance of patients with PE and has been attributed to various mechanisms. When no previous cardiopulmonary disease is present, lung regions with low ventilation/perfusion ratios and shunting due to perfusion of atelectatic areas appear to be the predominant mechanisms of hypoxemia. Hypoxemia leads to an increase in sympathetic tone with systemic vasoconstriction and may actually increase venous return with augmentation of stroke volume, at least initially, if there is no significant underlying cardiac or pulmonary pathology already present.

Hemodynamic Alterations

Massive emboli can cause profound hemodynamic compromise. In the setting of massive emboli, cardiac output is diminished but may be initially sustained as the mean right atrial pressure increases. The increased pulmonary vascular resistance impedes right ventricular outflow with a reduction in left ventricular preload. When no underlying cardiopulmonary disease is present, occlusion of 25 to 30 percent of the vascular bed by emboli results in a rise in pulmonary artery pressure (PAP). As the extent of vascular obstruction increases, hypoxemia worsens, stimulating vasoconstriction and a further rise in PAP. Greater than 50 percent obstruction of the pulmonary arterial bed is generally present before there is substantial elevation of the mean pulmonary artery pressure. When the extent of embolic occlusion approaches 75 percent, the right ventricle must generate a systolic pressure in excess of 50 mmHg and a mean PAP of greater than 40 mmHg to preserve pulmonary perfusion.[37] Although a hypertrophied right ventricle (in an otherwise normal patient) may theoretically be capable of achieving pressures this high, a normal right ventricle is unable to and will fail.[37] In reality, individuals with significant underlying cardiopulmonary disease and superimposed PE are more inclined to develop a more profound deterioration in cardiac output than normal individuals with PE, whether or not right ventricular hypertrophy is present. Furthermore, a depressed cardiac output in the absence of an elevated right atrial pressure suggests that the PE is superimposed upon preexisting cardiac disease. Right ventricular failure develops more frequently in the setting of PE when the patient has underlying coronary artery disease.[38] Aggressive hemodynamic support may sustain some patients with massive embolism at least temporarily, even when the right ventricle is dilated and hypocontractile, but any further increment in embolic burden may be fatal.

Chapter 53: PULMONARY EMBOLISM

DIAGNOSIS OF DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

Venous thromboembolism represents the spectrum of one disease. Most clinically significant PE arise from the prior development of DVT in the lower extremities, with subsequent embolization to the lungs. Patients may present with symptoms of either DVT, PE, or both. At the present time, the diagnostic strategy involves recognition of certain symptoms and signs of DVT and/or PE and usually involves an imaging study directed at either the legs or the lungs, depending upon the presentation. Ventilation/perfusion (/) scanning has been the diagnostic cornerstone for patients with suspected PE for decades. However, the contrast-enhanced computed tomography (CT) scan is being used increasingly as experience and technology improve. The diagnostic approach to acute DVT and PE has recently been exhaustively reviewed and presented as clinical practice guidelines by the American Thoracic Society.[39]

Lower extremity ultrasound is the most common leg study utilized, and the / scan still appears to be the most frequently utilized lung imaging study. It is important to realize that an increasingly common diagnostic strategy in patients presenting with suspected PE but with a nondiagnostic lung imaging study is to perform a lower extremity study in hopes of proving that DVT is present.

History and Physical Examination

The clinical diagnosis of both DVT and PE, based upon the history and physical examination, are insensitive and nonspecific. Patients with lower extremity DVT may be asymptomatic or may have erythema, warmth, pain, swelling, and/or tenderness. These findings are not specific for DVT but suggest the need for further evaluation. The differential diagnosis of DVT includes cellulitis, edema from other causes, musculoskeletal pain, or trauma (some of these may be concomitant and may or may not be related). Pulmonary embolism must always be considered when unexplained dyspnea is present. Dyspnea as well as pleuritic chest pain and hemoptysis are common in PE but are nonspecific. Coughing may be present, and while sometimes caused by PE, it more commonly occurs with bronchitis or pneumonia. It is far less common than shortness of breath. Anxiety, light-headedness, and syncope are all symptoms that may be caused by PE but may also be due to a number of other entities that result in hypoxemia or hypotension. Tachypnea and tachycardia are the most common signs of PE but are also nonspecific. Syncope or sudden hypotension should suggest the possibility of massive PE. The cardiac and pulmonary physical examinations are both nonspecific. A pleural rub or accentuated pulmonic component of the second heart sound may suggest PE but can also be explained by other disorders. In spite of the limitations of the history and physical examination for DVT and PE, the index of clinical suspicion becomes a more useful parameter when considered in conjunction with additional studies and / scanning.[40] Dyspnea, tachypnea, clear lung fields, and hypoxemia may often be attributed to a flare of chronic obstructive disease or asthma when underlying PE is present. Thus, diagnostic efforts aimed at possible VTE should still be considered despite alternative explanations if risk factors and the clinical setting are suggestive.

Laboratory Testing

Routine laboratory testing is not useful in proving or refuting the presence of DVT or PE but may

be helpful in confirming or excluding alternative or concomitant diagnoses. For example, leukocytosis and pulmonary infiltrates may suggest pneumonia, and worsening hypercapnia in a patient with known chronic obstructive lung disease may suggest a flare of the underlying lung disease. It is important to realize, however, that acute PE can develop in the setting of other cardiopulmonary disorders that do not exclude the possibility of concomitant PE.

D-DIMER TESTING

The D-dimer is a specific derivative of cross-linked fibrin. Measurement of circulating plasma D-dimer has been comprehensively evaluated as a diagnostic test for acute VTE, both independently and together with other diagnostic measures. A normal enzyme-linked immunosorbent assay (ELISA) appears to be sensitive in excluding PE. When the D-dimer level is 500 μg/L or greater, the sensitivity and specificity for PE have been shown to be 98 and 39 percent, respectively.[41] The sensitivity of the plasma D-dimer appears to remain high up to 1 week after presentation. In another prospective analysis, 96 percent of 79 patients with high-probability / scans had an elevated D-dimer concentration.[42] Thus, increased levels of cross-linked fibrin degradation products are an indirect but suggestive marker of intravascular thrombosis in addition to indicating fibrinolysis. Although the sensitivity of the D-dimer appears high, the specificity is not high enough to be diagnostic. Patients with both suspected and proven DVT and PE often have underlying disease states that also cause the D-dimer to be elevated.

When clinical studies comparing D-dimer with the results of other diagnostic tests for VTE are reviewed, there appear to be appreciable differences in assay performance, heterogeneity among the patient population, and inconsistent use of definitive diagnostic criteria for venous thromboembolism.[43,44] The number of available D-dimer assays, including rapid bedside assays, is increasing. It appears that results of clinical studies utilizing one manufacturer's D-dimer assay cannot be extrapolated to another study using another manufacturer's assay. No single assay has been established as superior to all the others. The ELISA assays are sensitive but cannot be performed rapidly. The latex tests, while rapid, have not been proven to be sufficiently sensitive. A rapid, quantitative, immunoturbidimetric technique has been evaluated that recognizes the D-dimer epitope by using antibody-coated latex particles.[45] In at least one study, the degree of abnormality of this D-dimer test appeared to correlate with the extent of the DVT, with proximal thrombosis producing higher D-dimer levels.[45] In addition, patients presenting immediately after the onset of symptoms were found to have higher D-dimer levels than patients examined after a few days. Thus, certain quantitative D-dimer tests may prove to offer additional information regarding the acuity and extent of thromboembolic disease. Future studies of D-dimer techniques should be rigorous with regard to the definitive presence or absence of DVT and/or PE as well as addressing issues such as duration of symptoms, presence of comorbid disease, and extent of thrombosis.

Recently, both DVT and PE management studies have been performed, with therapeutic decisions based, to some extent, upon D-dimer results. When a bedside whole-blood agglutination D-dimer assay and impedance plethysmography were both negative in patients with suspected DVT and anticoagulation was withheld, the negative predictive value was 98.5 percent (95 percent confidence interval, 96.3-99.6) based upon 3 months of follow-up.[46] For the D-dimer test alone, the negative predictive value was 97.2 percent. A diagnostic protocol including an assessment of clinical probability, / scan, ELISA plasma D-dimer, and lower extremity ultrasound (US) was utilized in 308 consecutive patients presenting to the emergency room with suspected PE.[47] Of these patients, 106 (34 percent) had diagnostic / scans (high probability in 63 and normal in 43). The noninvasive evaluation was diagnostic in 125 patients (62 percent). In 48 patients, PE was ruled out by a nondiagnostic lung scan together with low clinical probability. In 53 cases, it was ruled out by a quantitative D-dimer of less than 500 μg/L. Only 77 of the 202 patients with

nondiagnostic / scans required pulmonary angiography. At 6 months follow-up, only 2 of the 199 patients in whom the diagnostic protocol had ruled out PE had a VTE event. Using the same cutoff value for the quantitative D-dimer, these investigators subsequently reported that of 198 patients with suspected PE and a D-dimer <500 μg/L, 196 were free of PE, one had PE, and one was lost to follow-up.[48] Thus, the negative predictive value of the D-dimer was approximately 196 of 198 (99 percent). Although these data represent the work of only one group of investigators, they are promising. Rapid bedside assays are becoming more available and additional outcome studies will help to clarify their role. At present, plasma D-dimer measurements should be interpreted with caution and in the context of other diagnostic tests.

ARTERIAL BLOOD GAS ANALYSIS

Hypoxemia, while not universal, is extremely common in acute PE. Some patients, particularly young individuals without underlying cardiopulmonary disease may have a normal Pa_{O_2}. In a retrospective study of hospitalized patients with PE, the Pa_{O_2} was greater than 80 mmHg in 29 percent of patients less than 40 years old, compared with 3 percent in the older group.[49] However, the alveolar-arterial (A-a) difference was elevated in all patients. Thus, as age increases, it becomes even less likely that a patient with PE will have a normal room air Pa_{O_2}. In the PIOPED, a subset of patients suspected of PE without a history or evidence of underlying cardiac or pulmonary disease was evaluated, and the Pa_{O_2} and A-a difference values were compared.[50] Patients with and without PE could not be distinguished based upon either of these values. However, the A-a difference was elevated by more than 20 mmHg in 76 of 88 (86 percent) patients with PE. The diagnosis of acute PE cannot be excluded based upon a normal Pa_{O_2}, and although the A-a difference is usually elevated, it may very rarely be normal in patients without preexisting cardiopulmonary disease. An important tenet should be that unexplained hypoxemia, particularly in the setting of risk factors for DVT, should suggest the possibility of PE.

Electrocardiography

Electrocardiography (ECG) cannot be relied upon to rule in or rule out PE, though ECG proof of a clear alternative diagnosis, such as myocardial infarction, is useful when PE is among the possible diagnoses. The potential coexistence of PE together with another process must, however, be a consideration. ECG findings in acute PE are generally nonspecific and include T-wave changes, ST-segment abnormalities, and left- or right-axis deviation. The changes that do occur are likely caused by right ventricular dilation. The "classic" S1Q3T3 pattern described by McGinn and White[51] in 1935 in seven patients with acute cor pulmonale secondary to PE was subsequently demonstrated to be present in about 10 percent of PE cases.[52] In patients without underlying cardiac or pulmonary disease from the Urokinase Pulmonary Embolism Trial (UPET), electrocardiographic abnormalities were documented in 87 percent of patients with proven PE.[53] These findings were not specific for PE, however. In this clinical trial, 26 percent of patients with massive or submassive PE and 32 percent of those with massive PE had manifestations of acute cor pulmonale, such as the S1 Q3 T3 pattern, right bundle-branch block, P-wave pulmonale, or right axis deviation. Such changes are thus seen in a minority of patients. The low frequency of specific ECG changes associated with PE was confirmed in the PIOPED study.[50] It has been recently suggested that the anterior subepicardial ischemic pattern is the most frequent ECG sign of massive PE.[54]

Chest Radiography

The chest radiograph is abnormal in the majority of patients with PE, but the findings are

nonspecific. Atelectasis, pulmonary infiltrates, pleural effusion, and mild elevation of a hemidiaphragm may be present.[50] Classic radiographic evidence of pulmonary infarction (Hampton's hump) or decreased vascularity (Westermark's sign) are suggestive but uncommon. A normal chest radiograph in the presence of significant dyspnea and hypoxemia without evidence of bronchospasm or anatomic cardiac shunt is strongly suggestive of PE. In most situations, however, the chest radiograph cannot be used to definitively diagnose or exclude PE. Although exclusion of other processes such as pneumonia, congestive heart failure, pneumothorax, or rib fracture (which may cause symptoms similar to acute PE) is important, PE often coexists with other underlying lung diseases.

Imaging Studies for Pulmonary Embolism

VENTILATION/PERFUSION SCANNING

Ventilation/perfusion scanning has been the pivotal diagnostic test for approaching suspected PE for many years. However, even in patients in whom PE is ultimately proven, the / scan is most commonly nondiagnostic. Certain / scan readings are of substantial utility, however. Normal and high-probability scans are considered diagnostic. A normal perfusion scan excludes the diagnosis of PE with enough certainty that further diagnostic testing is unnecessary. Matching areas of decreased ventilation and perfusion in the presence of a normal chest radiograph suggests a process other than PE. However, low- or intermediate-probability (nondiagnostic) scans are commonly found with PE, and particularly when clinical suspicion is high, additional testing is necessary. In the PIOPED study, the utility of / scanning combined with clinical assessment of patients with suspected PE was prospectively evaluated.[40] Patients with PE had scans that were of high, intermediate, or low probability, but so did most individuals without PE. Although the specificity of high-probability scans was 97 percent, the sensitivity was only 41 percent. Of interest, 33 percent of patients with intermediate-probability scans and 12 percent of patients with low-probability scans were diagnosed definitively with PE by pulmonary arteriography. When the clinical suspicion of PE was considered very high, the positive predictive value of high-probability scans for PE was 96 percent. More interestingly, in those with high clinical suspicion and intermediate- and low-probability scans, it was 66 and 40 percent, respectively. Thus, further diagnostic testing for PE should be performed even when the lung scan is of low or intermediate probability if the clinical setting suggests PE. Although the / scan may sometimes be diagnostic of PE or exclude the possibility with sufficient certainty, it is often nondiagnostic. The latter fact emphasizes the need to further improve our diagnostic resources.

PULMONARY ARTERIOGRAPHY

Pulmonary arteriography is the established "gold standard" diagnostic technique for the diagnosis of PE. It is a very sensitive and specific test. However, for smaller (subsegmental) emboli, it appears less accurate. Two referee readers from the PIOPED agreed on the presence or absence of subsegmental emboli in only 66 percent of cases.[55] In another study, using selective pulmonary arteriography, there was excellent agreement on main, lobar, and segmental emboli but only 13 percent agreement on subsegmental emboli.[56] The significance of such emboli is unclear, however, and may depend upon the presence of underlying cardiopulmonary disease, the extent of concurrent DVT, and the continued presence or absence of risk factors for DVT. Arteriography is safe in most instances. Complications related to this technique among 1111 patients suspected of PE in the PIOPED study included death in 0.5 percent and major nonfatal complications in 1 percent.[55] An increasingly utilized alternative to pulmonary arteriography is to perform lower extremity studies when the / scan is nondiagnostic; if DVT is discovered, the therapeutic approach is generally the same as if an arteriogram were positive for PE. If serial lower extremity testing is

negative, the chances of significant PE or morbidity from a subsequent event appears unlikely.[57] However, the ease with which serial testing can be performed is variable, and arteriography is often the best alternative when the leg test is negative, since the sensitivity of ultrasound for DVT is substantially lower in patients with asymptomatic DVT. Lower extremity testing is being increasingly utilized in patients with nondiagnostic lung scans and in stable patients; this appears to be appropriate.[39] Pulmonary arteriography has also been performed at the bedside utilizing a Swan-Ganz catheter.[58] However, accurate interpretation of arteriography, particularly in the case of submassive emboli, is crucial.

ECHOCARDIOGRAPHY

Echocardiography is not usually used for approaching the patient with suspected PE, although it may suggest its presence in some clinical settings, and it has been suggested as a potential means by which to determine the need for thrombolytic therapy.[59] Echocardiography can often be performed more rapidly than either / scanning or pulmonary arteriography and may suggest hemodynamically significant PE.[60] Studies of patients with documented PE have revealed that more than 80 percent of patients have imaging or Doppler abnormalities of right-ventricular size or function that may suggest acute PE.[60,61] However, patients who are acutely ill with suspected PE often have underlying cardiac or pulmonary disorders such as chronic obstructive lung disease, and neither right-ventricular dilation nor hypokinesis can be reliably used even as indirect evidence of PE in these settings. Intravascular ultrasound imaging has been utilized in both the experimental and clinical setting to image large emboli.[62-64] This technique can be performed at the bedside. Although the technique may be less sensitive and specific and more time-consuming in the setting of smaller emboli, further investigation may be warranted.

COMPUTED TOMOGRAPHY

Contrast-enhanced spiral (helical) CT scanning has been increasingly investigated and utilized in patients with clinically suspected acute and chronic PE. This technique involves continuous movement of the patient through the scanner with concurrent scanning by a constantly rotating gantry and detector system.[65] A helix of projecting data is obtained. Continuous volume acquisitions can be obtained during a single breath, and with newer scanners, breath-holding may be less important. Rapid scans can be obtained, facilitating imaging in critically ill patients. Limitations of helical CT scanning in early clinical studies included poor visualization of horizontally oriented vessels in the right middle lobe and lingula because of volume averaging.[66] The peripheral areas of the upper and lower lobes may be inadequately scanned and the presence of inter-segmental lymph nodes may result in false-positive studies. Multiplanar reconstructions in coronal, sagittal, or oblique planes aid in distinguishing lymph nodes from emboli (see also Chap. 17).

Computed tomography scanning may reveal emboli in the main, lobar or segmental pulmonary arteries with >90 percent sensitivity and specificity.[66-69] Accurate results have been reported for large PE.[70,71] However, for subsegmental emboli, the sensitivity and specificity appear to be lower. The incidence of isolated subsegmental emboli appears to be approximately 6 to 30 percent, with the former figure likely being more representative.[55,72] Of note, even with the gold standard diagnostic test (arteriography), two referee readers from the PIOPED agreed on the presence or absence of subsegmental emboli in only 66 percent of cases.[55] Another study, using selective pulmonary arteriography, indicated excellent agreement on main, lobar, and segmental emboli but only 13 percent agreement on subsegmental emboli.[56] Thus, this apparent limitation with spiral CT scanning is also a concern with angiography. The incorporation of CT scanning into diagnostic algorithms for PE is being endorsed increasingly.[73] However, no prospective

multicenter randomized clinical trials large enough to unequivocally prove the sensitivity and specificity of contrast-enhanced CT scanning in patients with suspected PE have been performed. Most have been single-center trials of moderate size. The value of CT for large emboli appears clear, however.

Sensitivity and specificity data from several large studies evaluating helical CT scanning for acute PE are shown in Table 53-2. Contrast-enhanced electron-beam CT also appears useful in diagnosing acute PE.[69,74] In one comparison with pulmonary angiography, only 8 of 720 vascular zones (1.1 percent) were considered inadequately visualized with electron-beam CT. As with spiral CT, three-dimensional reconstruction techniques can be applied to the pulmonary vessels to better define vessels located within the plane that has been sectioned. Another important advantage of these CT techniques over the / scan is the concomitant ability to define nonvascular structures such as airway, parenchymal, and pleural abnormalities, lymphadenopathy, and cardiac and pericardial disease. Prospective randomized clinical trials comparing these techniques with the standard diagnostic approach to PE will help to determine their precise role. It appears that CT scanning is being increasingly utilized.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is also being utilized to evaluate clinically suspected PE at some centers.[75,76] One clinical trial compared MRI with spiral CT: the average sensitivity of CT for five observers was 75 percent and of MRI 46 percent.[77] The average specificity of CT was 89 percent, compared with 90 percent for MRI. Sensitivity and specificity values for expert readers were higher, however. Spiral CT may be somewhat more useful than MRI for detecting PE at the present time, but MRI has several attractive advantages, including excellent sensitivity and specificity for the diagnosis of DVT. As in the case of CT scanning, the diagnosis of entities other than PE using MRI is a major advantage over the / scan.

Diagnostic algorithms for patients presenting with suspected DVT and PE have been recommended in the American Thoracic Society Consensus Statement and allow for a certain degree of flexibility with regard to specific diagnostic modalities utilized.[39]

Imaging Studies for Deep Venous Thrombosis

A number of diagnostic techniques can be utilized to evaluate the patient with suspected DVT. Compression US is the most common technique used in the United States and in many other areas of the world. Impedance plethysmography is used at some centers, and a number of important clinical trials have been performed utilizing this technique. MRI appears to have some important advantages, but it has not generally been used as a first-line test. Venography remains the gold standard, but has been necessary less often at many centers in view of the accuracy of US. Each diagnostic technique has advantages and limitations. Although diagnostic algorithms may be suggested for suspected DVT, these are institution-specific, depending upon resources and available expertise with certain techniques. Newer diagnostic testing modalities, such as scanning with technetium 99m-labeled glycopeptide IIb/IIIa receptor antagonists, appear promising but will not be discussed.[78]

CONTRAST VENOGRAPHY

Although contrast venography remains the gold standard for the diagnosis of DVT, it has been less commonly used since the advent of US. Venography should be performed whenever noninvasive testing is nondiagnostic or impossible to perform. It is an invasive procedure that may

result in superficial phlebitis or hypersensitivity reactions, but it is generally safe and accurate.

IMPEDANCE PLETHYSMOGRAPHY

Impedance plethysmography has been carefully studied in patients presenting with suspected acute DVT. It has proven reliable for the detection of proximal DVT (including that occurring in and above the popliteal vein). Preliminary studies suggested greater than 90 percent sensitivity and 97 percent specificity for DVT involving the proximal lower extremity, although less than 30 percent of isolated calf vein thromboses were detected.[79,80] Although this modality is sometimes portable, it does require access to the calf and thigh for electrode and cuff placement. The specificity of IPG is affected by disorders that obstruct venous outflow, such as tumor or hematoma. Plaster casts or external fixation of extremities limits the utility of this technique. Some investigators have emphasized the potential limitations of IPG.[81] Among the limitations of the technique are its inability to detect asymptomatic/nonobstructive proximal DVT, or calf DVT and its lack of utility for diagnoses other than DVT.[39] It is used much less commonly than compression US.

ULTRASONOGRAPHY

Compression US with venous imaging is a portable, accurate, and widely available diagnostic technique for proximal lower extremity DVT. Combined with a Doppler reading, this technique is referred to as *duplex ultrasonography*. Ultrasound technology has been further sophisticated by the development of color duplex instrumentation that display Doppler frequency shifts as color superimposed on the gray-scale image. The color duplex images display both mean blood flow *velocity*, expressed as a change in hue or saturation, and *direction* of blood flow, displayed as red or blue. US imaging techniques can also identify or suggest the presence of pathology other than DVT-for example, Baker's cysts, hematomas, lymphadenopathy, arterial aneurysms, superficial thrombophlebitis, and abscesses may be suggested or diagnosed.[82] The sensitivity and specificity of US for symptomatic proximal DVT has been well above 90 percent in most recent clinical trials.[83,84] There are limitations, including insensitivity for asymptomatic DVT (less than 50 percent), operator dependence, the inability to accurately distinguish acute from chronic DVT in symptomatic patients, and insensitivity for calf vein thrombosis.[85-87] Compared with other technology, it is relatively inexpensive and is the preferred diagnostic modality for the straightforward case of symptomatic suspected proximal DVT.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) has clear advantages as a diagnostic test for suspected DVT and appears to be an accurate noninvasive alternative to venography.[88] A major feature of this technique is excellent resolution of the inferior vena cava and pelvic veins.[89,90] Preliminary experience with MRI suggests that it is at least as accurate as contrast venography or US imaging and more sensitive than US for pelvic vein thrombosis.[88-90] Simultaneous bilateral lower extremity imaging can be accomplished, and MRI appears to accurately distinguish acute from chronic DVT. This technique appears to be useful in distinguishing other entities such as cellulitis or a Baker's cyst from acute DVT. As with many other diagnostic techniques, its utility depends to a certain degree on the experience on the part of the reader. There is the additional advantage of evaluating a patient for the entire spectrum of VTE in one imaging session by scanning the legs and pelvis as well as the lungs. MRI is used by some medical centers when the initial diagnostic test (usually US) is nondiagnostic (see also Chap. 18).

Chapter 53: PULMONARY EMBOLISM

PREVENTION OF DEEP VENOUS THROMBOSIS

Background

Prophylaxis for DVT is effective.[91] A substantial reduction in the incidence of DVT can be accomplished when individuals at risk receive appropriate preventive care, as such measures appear to be grossly underutilized. A review of the use of prophylaxis for DVT in 16 Massachusetts hospitals revealed that such therapy was administered to only 44 precent of high-risk patients in teaching hospitals and only 19 percent in nonteaching hospitals.[92] The frequency of prophylaxis ranged from 9 to 56 percent among hospitals. Another retrospective analysis revealed that only 97 of 250 patients (39 percent) at *very high risk* for DVT received any form of prophylaxis and that of these 97, only 64 (66 percent) received appropriate care.[93] Prophylaxis can be pharmacologic (anticoagulation) or nonpharmacologic. Low-molecular-weight heparin (LMWH) products have been increasingly utilized in clinical practice for both prevention and treatment of established VTE. Extensive literature is now available supporting the use of these preparations for DVT prevention. The LMWH preparations are advantageous in that they produce a more predictable dose response and are administered subcutaneously only once or twice daily (without monitoring) depending on the preparation (see "Management of Established Venous Thromboembolism," below).[94] Early ambulation whenever possible is always recommended in postoperative patients.

General Medical Patients

Patients are stratified according to DVT risk, and certain prophylactic measures are more appropriate for some patients than for others. Generally, low-dose anticoagulation with standard, unfractionated heparin or LMWH is indicated in medical or surgical patients deemed at risk for DVT. When standard heparin is used for prophylaxis in general medical patients, 5000 U delivered subcutaneously every 8 to 12 h is generally adequate. LMWHs have also been studied in general medical patients. In a large double-blind, randomized clinical study comparing two different doses of subcutaneous LMWH (enoxaparin) delivered once daily to acutely ill medical patients, the higher dose (40 mg) proved more effective than the lower dose (20 mg).[95] The incidence of DVT was 5.5 percent in the former group and 14.9 percent in the latter.

When prophylactic anticoagulation is contraindicated, mechanical devices (intermittent pneumatic compression) are utilized. Anticoagulation together with pneumatic compression is appropriate in patients deemed at exceptionally high risk or with multiple risk factors for DVT.

General Surgical Patients

In general surgery patients, a number of prophylactic strategies have been employed. An overview of the results of randomized trials in surgical patients demonstrated the substantial benefit of DVT prophylaxis.[91] In this review of more than 70 randomized trials involving 16,000 patients, it was demonstrated that perioperative use of subcutaneous heparin could prevent about half of all PE and about two-thirds of all DVT. In a large meta-analysis, the value of prophylaxis to reduce the incidence of DVT was confirmed; it was also suggested that intermittent pneumatic compression

plus the use of gradient compression stockings may result in the lowest incidence of postoperative DVT.[96] Other combined treatments were associated with lower rates than heparin alone and appear appropriate in patients at exceptionally high risk. For those patients undergoing minor operations who are less than 40 years old and have no additional risk factors for DVT, no prophylaxis other than early ambulation is recommended. Older patients undergoing major operations without additional risk factors should receive either standard, unfractionated heparin, LMWH, or intermittent pneumatic compression. When additional risk factors are present in the latter group, standard heparin every 8 h or LMWH should be administered. Enoxaparin has been FDA-approved for prophylaxis in patients undergoing elective abdominal surgery (40 mg subcutaneously once daily). A second preparation, dalteparin, has also been approved in the United States for once-daily use as prophylaxis for elective abdominal surgery.

Other High-Risk Patients

Certain orthopedic populations at particularly high risk for acute DVT have been carefully studied with well-designed randomized clinical trials, which led to the approval of enoxaparin by the FDA for prophylaxis against DVT in patients undergoing elective total hip or knee replacement. The approved dosing regimens are 30 mg subcutaneously twice daily initiated within 12 to 24 h after surgery, and 40 mg once daily initiated preoperatively. The duration of prophylaxis depends upon whether the patient is ambulatory and upon additional risk factors. At least one large randomized, placebo-controlled clinical trial suggested a lower incidence of DVT with more prolonged (1 month) outpatient prophylaxis in this patient population.[97] LMWHs have also been evaluated in trauma patients at risk for DVT and have proven efficacious in this patient population.[98] Intermittent pneumatic compression should be utilized if anticoagulation prophylaxis is contraindicated.

A number of LMWH preparations are currently being investigated. It is important to realize that these preparations are not identical and the results of clinical trials with one agent cannot be extrapolated to another. Detailed recommendations for DVT prophylaxis are published and updated every 2 to 3 years (American College of Chest Physicians Consensus).[99]

Chapter 53: PULMONARY EMBOLISM

MANAGEMENT OF ESTABLISHED VENOUS THROMBOEMBOLISM

Assuring adequate oxygenation and hemodynamic support for PE is of paramount importance. Such supportive measures for massive PE are discussed further on in this chapter (see "Hemodynamic Management of Massive Pulmonary Embolism," below). Pain control and elevation of the leg are recommended for DVT, particularly severe, symptomatic acute iliofemoral DVT. Certain recommendations, such as bed rest in patients with established DVT, have not been well substantiated, but this measure should be instituted when significant symptoms are present. The major focus for effective therapy of VTE involves anticoagulation.

Anticoagulation

When DVT or PE is diagnosed or strongly suspected, anticoagulation therapy should be initiated immediately unless contraindications exist. The diagnosis must be confirmed if anticoagulation is to be continued.

STANDARD, UNFRACTIONATED HEPARIN

Standard heparin has been the time-honored parenteral anticoagulant based upon its prompt antithrombotic effect in preventing thrombus growth. The major anticoagulant effect of heparin is accounted for by a unique pentasaccharide with a high-affinity binding sequence to antithrombin III, which is present on only one-third of heparin molecules.[100] The interaction of heparin with antithrombin III markedly accelerates its ability to inactivate thrombin, factor Xa, and factor IXa. Heparin also catalyzes the inactivation of thrombin by a second plasma cofactor, heparin cofactor II. Heparin does not directly dissolve thrombus, but it allows the fibrinolytic system to act unopposed and more readily reduces the size of the thromboembolic burden.[100] Although thrombus growth can be prevented, early recurrence can develop even during therapeutic anticoagulation.

When intravenous standard, unfractionated heparin is instituted, the activated partial thromboplastin time (APTT) should be aggressively followed at 6-h intervals until it is consistently in the therapeutic range of 1.5 to 2.0 times control values.[101] This range corresponds to a heparin level of 0.2 to 0.4 U/mL as measured by protamine sulfate titration. Heparin can be administered by several protocols, but a weight-based approach has been shown to substantially enhance the chances of attaining the therapeutic range quickly. Heparin can be administered as an intravenous bolus of 5000 U followed by a maintenance dose of at least 30,000 to 40,000 U every 24 h by continuous infusion.[102] The lower dose is administered if the patient is considered at high risk for bleeding. This aggressive approach decreases the risk of subtherapeutic anticoagulation and, although supratherapeutic levels are sometimes achieved initially, bleeding complications do not appear to be increased.[102] More recent data continue to support aggressive heparin dosing. An alternative regimen consisting of a bolus of 80 U/kg followed by 18 U/kg/h has been recommended.[103] [104] Subsequent adjusting of the heparin dose should also be weight-based (Table 53-3). This approach was recommended by the recent American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic Therapy.[104] Warfarin therapy may be initiated as soon as the APTT is therapeutic and heparin should be maintained until a therapeutic International Normalized Ratio (INR) of 2.0 to 3.0 has been overlapped with a

therapeutic APTT for 2 consecutive days. This initial anticoagulation approach applies to both acute DVT and PE. Although proximal lower extremity thrombus is more likely to result in PE, calf thrombi should still be treated aggressively with anticoagulation or followed with noninvasive testing over 10 to 14 days for extension into the popliteal vein.[105,106] The spectrum of upper extremity venous thrombosis is variable and includes patients with peripherally and centrally placed intravenous catheters as well as those with underlying malignancy. Symptomatic patients with documented upper extremity DVT should be anticoagulated.[107] Prophylacticanticoagulation in patients with long-term indwelling catheters should also be instituted.[104,108]

LOW-MOLECULAR-WEIGHT HEPARIN

Mechanisms of Action and Pharmacology

Low-molecular-weight heparin is being utilized increasingly for acute venous thromboembolism. These agents differ in a number of respects from standard, unfractionated heparin. Standard heparin consists of lengthy glycosaminoglycan polymers that are heterogenous in size, with a mean molecular weight of approximately 15,000 Da. LMWHs, also glycosaminoglycans, are prepared by chemical or enzymatic depolymerization and are approximately one-third of the size of unfractionated heparin. These LMWH fractions are also diverse, with a mean molecular weight of 4000 to 5000 Da. The difference in size between unfractionated heparin and LMWH results in an altered anticoagulant profile.[109] Only one-third of the LMWH molecules contain the pentasaccharide required for antithrombin III binding. Maximal inhibition of thrombin requires the binding of heparin to both antithrombin III and the activated enzyme. In contrast, the accelerated inactivation of factor Xa by the heparin/antithrombin III combination requires only the binding of unfractionated heparin to antithrombin III and does not require the formation of the ternary complex. Heparin molecules smaller than 18 saccharide units are unable to bind thrombin and antithrombin III simultaneously, precluding maximal acceleration of the inactivation of thrombin by antithrombin III. These smaller LMWH molecules do, however, retain their ability to catalyze the inhibition of factor Xa by antithrombin III. For this reason, LMWH fractions appear to have relatively more anti-Xa than antithrombin activity and significantly less effect upon the APTT. While the ratio of anti-Xa to antithrombin of heparin is 1:1, the LMWH preparations have significantly higher ratios. In addition, other anticoagulant properties such as stimulation of tissue factor pathway-inhibitor release appear to be responsible for the effect of these agents, suggesting more reason for variability among them.[109] While the different preparation methods result in products with similar molecular profiles, structural variations remain, which impart significant differences in their biologic actions. Chemical modifications of various portions of the molecules, charge density, and the degree of desulfation all affect the characteristics of the final product. Because of these differences, antithrombin III activity, the effects on tissue-factor-pathway inhibitor, platelet factor 4, and heparin cofactor II would be expected to be different for the different preparations. Other potential dissimilarities between heparin and LMWH and between the individual LMWH preparations include differences in stimulation of the release of tissue plasminogen activator and prostacyclin. A major advantage of these preparations over unfractionated heparin is substantially enhanced bioavailability. This has been shown to differ for different LMWH preparations as well. Each of the LMWH compounds should be considered a distinct agent and they should not, at the present time, be considered interchangeable. Important characteristics and advantages of the LMWH preparations are shown in Tables 53-4 and 53-5.

Clinical Trials and Indications

Numerous clinical trials have strongly suggested the efficacy and safety of LMWH for treatment of established acute proximal DVT, using recurrent symptomatic VTE as the primary outcome

measure.[110-116] Treatment with LMWH is more convenient for the patient and for the nursing staff for several reasons. A continuous intravenous line is not required, as these agents can be administered once or twice per day subcutaneously at therapeutic doses. In most cases monitoring of the APTT is not required. Patients can be monitored by measuring levels of factor X, and certain patient populations, such as significantly obese individuals or those with renal insufficiency, are probably best managed with such monitoring. There has not been complete agreement on the approach to these individuals. Outpatient therapy for stable patients with DVT is increasing significantly. In two large, randomized (Canadian and European) trials, therapy with LMWH (enoxaparin and fraxiparine, respectively) was compared with that using standard weight-based unfractionated heparin.[110,111] The LMWH patients were treated entirely as outpatients or continued at home after a brief hospitalization. The outpatient LMWH regimens proved safe and effective. Three meta-analyses examined the use of LMWH compared with unfractionated heparin in the initial treatment of acute proximal DVT.[117-119] Although there was overlap among the clinical trials included in the analyses, they have helped to confirm the efficacy and safety of LMWH for the treatment of established DVT. At the present time, only one LMWH (enoxaparin) is FDA-approved for use in the United States for treatment of established DVT in the outpatient setting or for DVT (with or without PE) in the inpatient setting. Unlike the regimen for prophylaxis, in which a fixed dose of enoxaparin is utilized, a weight-based dosing regimen is employed for treatment of established VTE. For outpatient therapy, the recommended dose of enoxaparin is 30 mg subcutaneously every 12 h, while for inpatient treatment both 30 mg every 12 h and 40 mg once daily have been studied and FDA-approved. In addition to being more convenient, the LMWH preparations appear to be cost-effective, particularly when outpatient therapy is utilized.[120] Some of the different LMWH products and their prophylaxis and treatment regimens are listed in Table 53-6. The appropriate steps in instituting anticoagulation with enoxaparin for established VTE, including outpatient therapy, are shown in Table 53-7.

LONG-TERM THERAPY FOR DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

Documented proximal DVT or PE should be treated for 3 months with oral warfarin, keeping the INR at 2.0 to 3.0. Individuals unable to take warfarin can be treated with long-term subcutaneous heparin or LMWH. More prolonged therapy is indicated when significant risk factors persist. Furthermore, patients in whom no clear risk factors exist (idiopathic VTE) appear to benefit from more prolonged anticoagulation.[121] In a double-blind study, patients completing 3 months of anticoagulation for a first episode of idiopathic VTE were randomized to receive either warfarin (INR 2.0 to 3.0) or placebo for an additional 24 months, and there was a substantial reduction in recurrences in the warfarin group without a statistically significant increase in bleeding.[121] Both short- and long-term anticoagulation guidelines are outlined in the ACCP Consensus Conference guidelines.[104]

OTHER ANTICOAGULANTS

Newer anticoagulants are being explored. Heparin works indirectly, requiring antithrombin III as a cofactor, and its effects vary considerably between patients. Hirudin is a direct thrombin inhibitor that has several advantages over heparin, including efficacy against fibrin clot-bound thrombin. It does not require any cofactors and is not inactivated by platelet factor 4 or plasma proteins. This drug, derived from the saliva of the medicinal leach (*Hirudo medicinalis*), appears promising. Data from several clinical myocardial infarction trials suggested that hirudin is at least as safe as heparin.[122,123] Recombinant hirudin has been examined for prophylaxis of DVT in patients receiving total hip replacement and resulted in a low rate of proximal DVT.[124] As with heparin, these direct thrombin inhibitors have very narrow therapeutic indices. Other direct thrombin

inhibitors and substances such as selective factor Xa inhibitors and tissue factor pathway inhibitor (TFPI) merit further investigation in the treatment of acute VTE.[125-130]

COMPLICATIONS OF ANTICOAGULATION

Complications of heparin include bleeding and heparin-induced thrombocytopenia (HIT). The rates of major bleeding in recent trials using standard heparin by continuous infusion or high-dose subcutaneous injection have been less than 5 percent.[104] Heparin-induced thrombocytopenia typically develops 5 or more days after the initiation of heparin therapy, and occurs in 5 to 10 percent of patients.[131-133] If a patient is placed on heparin for VTE and the platelet count progressively decreases to 100,000/mm^3 or less, heparin therapy should be discontinued. Although the risk of HIT appears to be lower with LMWH, it is important for clinicians to realize that HIT can occur with the use of either form of heparin.[134] Over the past decade, there have been many important advances in the pathogenesis, diagnosis, and treatment of HIT, which represents one of the most common immune-mediated adverse drug reactions.[135] This entity is caused by heparin-dependent IgG antibodies that recognize complexes of heparin and platelet factor 4, leading to activation of platelets via platelet Fc gamma IIa receptors. Formation of procoagulant, platelet-derived microparticles, and, possibly, activation of endothelium generate thrombin in vivo. The generation of thrombin helps to account for the strong association between HIT and thrombosis, including the recently recognized syndrome of warfarin-induced venous limb gangrene. This syndrome develops during warfarin treatment of HIT and deep venous thrombosis when acquired protein-C deficiency leads to the inability to regulate thrombin generation in the microvasculature. The diagnosis of HIT can be made confidently when one or more typical clinical events (most frequently, thrombocytopenia with or without thrombosis) occur in a patient with detectable HIT antibodies. The pivotal role of thrombin generation in this syndrome provides a rationale for the use of anticoagulants that reduce thrombin generation (danaparoid) or inhibit thrombin (lepirudin).

Vena Cava Interruption

In patients with established VTE in whom heparin therapy cannot be continued, inferior vena cava (IVC) filter placement can be undertaken to prevent lower extremity thrombi from embolizing to the lungs. These devices have been widely used for nearly two decades. The essential indications for filter placement include contraindications to anticoagulation, recurrent embolism while on adequate therapy, and significant bleeding complications during anticoagulation.[136] Filters are sometimes placed in the setting of massive PE when it is believed that any further emboli might be lethal.[136] A number of filter devices exist, but the Greenfield filter design has been most widely used. These devices can be inserted via the jugular or femoral vein and are effective. Complications are unusual.[137] Possible mechanisms of IVC filter failure include filter migration; improper filter positioning, allowing thrombi to bypass the filter; and formation of thrombosis proximal to the filter or on the proximal tip of the filter with subsequent embolization. Rare complications include clinically significant perforation of the IVC, migration to the heart, and displacement of the filter during insertion. Rarely, these devices may erode into the wall of the IVC. Occasionally, IVC obstruction due to thrombosis at the filter site may occur. Deaths due to filter placement are extraordinarily uncommon. Anticoagulation is generally continued when a filter is placed unless it is contraindicated. Temporary filters have been placed in individuals deemed at extremely high risk for DVT yet unable to receive anticoagulant prophylaxis, such as certain trauma patients.[138]

Thrombolytic Therapy

Acceleration of clot lysis in PE using thrombolytic therapy was first documented several decades

ago.[139-141] The prospective, multicenter, randomized UPET evaluated 160 patients with arteriographically proven PE.[53] Thrombolysis was accelerated in patients receiving urokinase compared with those on heparin when pulmonary arteriograms and lung perfusion scans were examined 24 h after treatment. Subsequently, the difference between the two groups diminished and by day 5 the improvement in each group was similar. There were no differences in the frequency of recurrent PE or mortality rate within 2 weeks of treatment. The lack of reduction in mortality may have been explained by the fact that only 7 percent of the patients in the clinical trial were classified as having massive PE with shock. The second phase of this clinical trial also documented the efficacy of streptokinase administered over 24 h.

Both urokinase and streptokinase were approved for use in pulmonary embolism. In 1980, the National Institutes of Health issued consensus guidelines for PE thrombolysis and recommended thrombolytic therapy for patients with obstruction of blood flow to a lobe or multiple pulmonary segments and for patients with hemodynamic compromise regardless of the size of the PE.[142] Recombinant tissue plasminogen activator (t-PA) was subsequently approved for use for the treatment of PE and is administered as a 100-mg intravenous infusion delivered over 2 h.[143] Even shorter infusion durations have been evaluated, and future clinical trials may lead to wider acceptance of these regimens. At present, the above t-PA regimen is the most rapidly administered protocol that is currently approved for use.

At the present time, the clearest indication for the use of thrombolytic therapy is in patients with hemodynamic instability (hypotension) when there are no concomitant contraindications.[144,145] Patients with severely compromised oxygenation should also be considered.[144] Stable patients with a significant embolic load are individualized, often receiving treatment in the absence of absolute or relative contraindications. For example, a strong case for thrombolytic therapy can be made when the embolic load visualized on the imaging study is extensive (defect involving the equivalent of half of the pulmonary vascular bed) or with echocardiographic evidence of right ventricular dysfunction without clear hemodynamic instability.[146,147] Another setting in which thrombolytic therapy may be considered is when extensive DVT accompanies a submassive PE. No clinical studies have been undertaken to support this indication. Perhaps future trials will clarify more controversial guidelines.

The recommendations for use of thrombolytic therapy in PE have been carefully reviewed.[146] Potential indications are presented in Table 53-8. Approved regimens for the treatment of PE are presented in Table 53-9. Coagulation assays are not necessary during thrombolysis, since the approved regimens are administered as fixed doses. Heparin should be withheld until the thrombolytic infusion is completed. The APTT is then determined and heparin is initiated without a loading dose if this value is less than twice the upper limit of normal. If the APTT exceeds this value, the test is repeated every 4 h until it is safe to proceed with heparin. The method of delivery of thrombolytic agents has also been investigated. Although a number of investigators have employed standard or low-dose intrapulmonary arterial thrombolytic infusions in order to deliver a high concentration of drug in close proximity to the clot,[148,149] intravenous therapy appears adequate in most settings.[150] More direct techniques, such as catheter-directed administration of intraembolic thrombolytic therapy are discussed below.

The use of thrombolytic therapy for DVT without PE is more controversial. A comprehensive review of the literature suggests that use of streptokinase may be associated with a reduction in postphlebitic syndrome when used for acute DVT, although bleeding is increased with thrombolytic therapy.[151] Future studies may clarify the role of thrombolytic therapy for DVT. It is reasonable to consider systemic thrombolytic therapy in patients with proximal occlusive DVT associated with significant swelling and symptoms when there are no absolute or relative contraindications.

The major complication resulting from thrombolytic therapy is bleeding. These agents are not fibrin-specific and any clot, whether pathologic or protective, is subject to lysis. Although hemorrhagic complications in the UPET were relatively high, further experience with thrombolytic therapy has suggested that adverse effects are reduced when venous cut-downs and unnecessary arterial phlebotomy are avoided.[152] Thus, when thrombolytic therapy is administered, invasive procedures should be minimized. The most devastating complication associated with this treatment is the development of intracranial hemorrhage.[153] Clinical trials have suggested that this occurs in significantly less than 1 percent of patients. Contraindications to systemic thrombolytic therapy in VTE are listed in Table 53-10. Bleeding related to thrombolytic therapy requires immediate management. Bleeding from vascular puncture sites should be addressed with manual compression followed by a pressure dressing. Intracranial bleeding requires immediate discontinuation of thrombolytics or anticoagulants, and emergent neurologic and neurosurgical consultation should be obtained. A noncontrasted brain CT scan should be performed. Retroperitoneal hemorrhage may develop from a vascular puncture above the inguinal ligament and may be life-threatening. Severe or refractory bleeding should be addressed with transfusion of 10 U of cryoprecipitate and 2 U of fresh frozen plasma, and heparin can be reversed with protamine. A comprehensive review of thrombolytic therapy for acute VTE has been published.[154]

Table 53-10: Thrombolytic Therapy for Acute Pulmonary Embolism: Contraindications

Absolute
Intracranial tumor or hemorrhagic stroke
Previous head trauma or cranial surgery
Active or recent gastrointestinal/internal bleeding
Relative
Thrombocytopenia or coagulopathy
Uncontrolled severe hypertension
Cardiopulmonary resuscitation
Surgery or biopsy within the previous 10 days

Catheter-Directed Techniques

The intravenous route has been the primary method of delivery, but local thrombolytic therapy has been utilized in massive PE. Intrapulmonary arterial delivery of thrombolytic agents by bolus or prolonged infusion with or without concomitant heparin has been utilized for massive PE (see "Thrombolytic Therapy," above).[148,149] These studies have generally been small and uncontrolled. Although intrapulmonary arterial delivery of thrombolytic agents appears to offer no advantage over the intravenous route,[150] *intraembolic* thrombolytic infusions may offer advantages over merely infusing the agents into the pulmonary artery. Such techniques have been applied in both animal models of PE and in patients, with enhanced thrombolysis.[155,156] Lower than conventional doses of t-PA or urokinase are delivered via a catheter imbedded directly within massive emboli over 10 to 20 min.[155,156] Combining thrombolytic therapy via direct delivery (at

low doses) with the possible mechanical benefits of direct intraembolic infusion could prove advantageous over the intravenous route, particularly in the setting of contraindications to thrombolytic therapy. Larger randomized studies would be needed to demonstrate the efficacy, potential advantages, and safety of such techniques. The implementation of these techniques, as well as the catheter-directed administration of intraembolic thrombolytic therapy described above, depend upon the experience of the medical team involved. Transvenous embolectomy without thrombolysis, via a suction-catheter device, has been proven quite effective by some[157,158] but is not widely performed. In an experience spanning 7 years, one group successfully extracted emboli in 11 of 18 patients with massive PE utilizing this technique; 13 survived their hospital stay while 5 died.[158]

Catheter-directed techniques have been successfully employed in the setting of acute iliofemoral DVT utilizing urokinase doses ranging from 1.4 to 16 million U delivered over an average of 30 h.[159,160] Results from a national registry of patients with iliofemoral thrombosis treated with local, catheter-directed therapy indicates that this approach is frequently successful.[160] Randomized trials may be appropriate.

Surgical Embolectomy

Pulmonary embolectomy may be performed in the setting of acute massive PE. The advent of thrombolytic therapy has reduced the number of potential candidates, but contraindications to these agents are relatively common. Although many patients die from PE before surgical embolectomy can be performed, some deteriorate hours after the initial episode, suggesting that surgery may occasionally be appropriate. In one case series of 71 embolectomies performed for acute PE using cardiopulmonary bypass, hospital mortality was 29 percent.[161] However, the mortality in those patients who had not sustained a cardiac arrest preoperatively was only 11 percent.

Hemodynamic Management of Massive Pulmonary Embolism

Massive PE should always be a consideration in the setting of the sudden onset of hypotension or extreme hypoxemia. Electromechanical dissociation or sudden cardiac arrest should always make massive PE suspect. If the patient is stable enough, lung imaging (generally / scan or spiral CT scan) should be performed when possible. Echocardiography may support the diagnosis of massive PE and may also suggest that aggressive intervention including thrombolytic therapy be considered.[146,147] When massive PE associated with hypotension and/or severe hypoxemia is suspected, supportive treatment is immediately initiated. Intravenous saline can be rapidly infused, but caution is recommended because right ventricular function is often markedly compromised. Dopamine or norepinephrine appear to be the favored choices of vasoactive therapy in massive PE and should be administered if the blood pressure is not rapidly restored.[162] Death from massive PE results from right ventricular failure, and dobutamine has been recommended by some as a means by which to augment right ventricular output.[163,164] A vasopressor such as norepinephrine combined with dobutamine might offer optimal results, and further exploration of such combined therapy would prove enlightening. Oxygen therapy is administered and thrombolytic therapy should be administered if hypotension is present and there are no contraindications. Intubation and mechanical ventilation are instituted as needed to support respiratory failure. Surgical embolectomy may be indicated, particularly if thrombolytic therapy cannot be administered.

Chapter 53: PULMONARY EMBOLISM

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

In the majority of cases of acute PE, the patient either dies or completely recovers; however, a substantial residual thromboembolic burden occasionally remains and/or continues to form.[165,166] In these patients, the clot becomes organized and adherent and is not amenable to thrombolysis. If the obstruction becomes extensive, pulmonary hypertension develops. At least 50 percent of patients who develop chronic thromboembolic pulmonary hypertension have no documented history of DVT or PE, and this feature greatly impedes the diagnosis. Most patients have no identifiable coagulopathy. Dyspnea with exertion and fatigue are the most common complaints. The nonspecific nature of these findings may substantially delay the correct diagnosis. The physical examination generally reveals a right ventricular heave, a loud P_2, a right ventricular S_3, and tricuspid regurgitation consistent with pulmonary hypertension. In 20 percent of patients, one or more murmurs may be auscultated over the lung fields.

The chest radiograph usually reveals right ventricular enlargement and enlarged main pulmonary arteries. ECG changes are consistent with pulmonary hypertension. Arterial blood gases generally reveal hypoxemia with a widened A-a difference, although some patients may only demonstrate exercise-induced hypoxemia. Echocardiography documents pulmonary hypertension and enlargement of the right ventricle. Chest CT scanning is prudent and may reveal other rare causes of pulmonary hypertension, such as mediastinal fibrosis, and may, in fact, demonstrate evidence of chronic thrombi. With chronic thromboembolic pulmonary hypertension, the / scan nearly always indicates a high probability of PE, but occasionally it is less impressive. Right heart catheterization and pulmonary arteriography are performed, both to establish the diagnosis with certainty and to determine operability. Pulmonary angioscopy has frequently proven complementary to arteriography in assessing these patients.

Although anticoagulation should be instituted and IVC filters are recommended in patients with chronic thromboembolic pulmonary hypertension, the only means by which to alleviate symptoms and affect survival is with surgery. The University of California at San Diego has been a leading center for the evaluation and surgical therapy of these patients. Pulmonary thromboendarterectomy is performed via median sternotomy on cardiopulmonary bypass, and the overall mortality, which has continued to improve, is now less than 5 percent. Lung transplantation can sometimes be performed in patients in whom thrombi are too distal to extract.

Chapter 53: PULMONARY EMBOLISM

SUMMARY

Venous thromboembolism represents a spectrum consisting of DVT and PE. It is a common cause of death, particularly in hospitalized patients with significant risk factors, and is frequently not diagnosed until autopsy. The history and physical examination for both DVT and PE consist of suggestive but generally very nonspecific findings. These findings, particularly in the setting of risk factors for VTE, are important in raising the level of suspicion for VTE, leading to diagnostic testing. Preventive measures in patients at risk are crucial. Anticoagulation represents appropriate therapy for most patients with VTE. Low-molecular-weight heparins are being used increasingly in established VTE as well as for prophylaxis. Thrombolytic therapy should be considered in massive PE in the absence of contraindications, and guidelines for the use of these agents is evolving. Placement of a filter in the inferior vena cava is indicated when anticoagulation is contraindicated. Newer agents such as direct thrombin inhibitors are being explored. Future clinical trials will help to clarify the roles of both the newer diagnostic modalities and therapeutic strategies.

Part 8: PULMONARY HYPERTENSION AND PULMONARY DISEASE
Chapter 54:

CHRONIC COR PULMONALE

Author: John H. Newman

DEFINITION

Cor pulmonale is a term that describes the pathologic effects of lung dysfunction on the right side of the heart. Pulmonary hypertension is the link between lung dysfunction and the heart in cor pulmonale. Cor pulmonale occurs as a late manifestation of many diseases of the lung, but the common thread in each case is increased right ventricular afterload. Cor pulmonale can be an elusive clinical diagnosis because pulmonary hypertension can exist without clinical manifestations and because clinical signs, such as dyspnea, may be shared with the underlying disease. Acute pulmonary hypertension leads to acute dilatation of the right ventricle; chronic pulmonary hypertension leads to ventricular hypertrophy followed by dilatation. The presence of overt right-sided heart failure is not essential to make the diagnosis of cor pulmonale, but right-sided heart failure is a common consequence. The clinical manifestations of cor pulmonale relate to alterations in cardiac output, salt and water homeostasis, and in most cases, gas exchange in the lung. Right-sided heart dysfunction secondary to left-sided heart failure, valvular dysfunction, or congenital heart disease is excluded in the definition of cor pulmonale.[1] Pulmonary venous obstruction is a cause of cor pulmonale; pulmonary venoocclusive disease is usually considered in the spectrum of primary pulmonary hypertension.

As a concept, cor pulmonale was introduced over 200 years ago, but the exact origin of the term is uncertain.[2] Osler[3] commented in the first edition of his textbook that "hypertrophy of the right ventricle . . . results from increased resistance in the pulmonary circulation, as in cirrhosis of the lung and emphysema." McGinn and White[4] apparently were the first to use the term *acute cor pulmonale* in the discussion of a case of acute, massive thromboembolism in 1935. William Harvey's discussion of the relationship of the lung and right side of the heart in *De Motu Cordis*[5] showed remarkable insight into the limitations of the right ventricle.

Chapter 54: CHRONIC COR PULMONALE

INCIDENCE, ETIOLOGIES, AND PATHOLOGY

Emphysema and chronic bronchitis cause over 50 percent of cases of cor pulmonale in the United States. The prevalence of cor pulmonale is difficult to determine because cor pulmonale does not occur in all cases of chronic lung disease and because routine physical examination and laboratory tests are relatively insensitive to the presence of pulmonary hypertension. The prevalence of chronic obstructive lung disease in the United States is about 15 million, directly resulting in approximately 70,000 deaths per year and contributing to about 160,000 other deaths.[6] It has been estimated that cor pulmonale accounts for 5 to 10 percent of organic heart disease. Cor pulmonale was present in 20 to 30 percent of admissions for heart failure in one study.[7] It is likely that cor pulmonale is a complication in a high percentage of cases. Gazes[8] found that 9.2 percent of cases of heart disease that came to autopsy had right heart abnormalities.

Chronic cor pulmonale occurs most frequently in adult male smokers, although the incidence in women is increasing as heavy smoking in females becomes more prevalent. A list of all diseases that may lead to cor pulmonale would be extensive and is not included in this chapter, but the major types of disease processes are listed in Table 54-1. Two important causes of cor pulmonale, thromboembolism and primary pulmonary hypertension, are discussed in Chaps. 52 and 53.

Table 54-1: Etiologies of Chronic Cor Pulmonale by Mechanism of Pulmonary Hypertension

I. Hypoxic vasoconstriction
   A. Chronic bronchitis and emphysema, cystic fibrosis
   B. Chronic hypoventilation
      1. Obesity
      2. Sleep apnea
      3. Neuromuscular disease
      4. Chest wall dysfunction
   C. High-altitude dwelling and chronic mountain sickness (Monge's disease)

II. Occlusion of the pulmonary vascular bed
   A. Pulmonary thromboembolism, parasitic ova, tumor emboli
   B. Primary pulmonary hypertension
   C. Pulmonary venocclusive disease/pulmonary capillary hemangioma
   D. Sickle cell disease/sickle crisis/marrow embolism
   E. Fibrosing mediastinitis, mediastinal tumor
   F. Pulmonary angiitis from systemic disease
      1. Collagen vascular diseases
      2. Drug-induced lung disease
      3. Necrotizing and granulomatous arteritis

III. Parenchymal disease with loss of vascular surface area
   A. Bullous emphysema, alpha$_1$ antiproteinase deficiency, hyperinflation
   B. Diffuse bronchiectasis, cystic fibrosis
   C. Diffuse interstitial disease
      1. Pneumoconiosis

2. Sarcoid, idiopathic pulmonary fibrosis, histiocytosis X
3. Tuberculosis, chronic fungal infection
4. Adult respiratory distress syndrome
5. Collagen vascular disease (autoimmune lung disease)
6. Hypersensitivity pneumonitis

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) causes cor pulmonale through several interrelated mechanisms, including hypoventilation, hypoxemia from ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, and reduction of perfused surface area.[9,10] Patients with more prominent hypoxemia and alveolar hypoventilation develop erythrocytosis, edema, and early onset of cor pulmonale ("blue bloaters").[10] Patients in whom dyspnea on exertion is the most prominent symptom have less hypoventilation and less hypoxemia at rest and therefore develop cor pulmonale later ("pink puffers"). Some of the differences between blue bloaters and pink puffers may relate to ventilatory drives; patients with low drives may be more likely to fit the blue-bloater category, whereas pink puffers strive to maintain normal arterial pH and gas tensions.[12] Another hypothesis is that blue bloaters have more inflammatory bronchitis and that pink puffers suffer more from pure emphysema.[10] *Physical examination* in advanced COPD shows an increase in the thoracic diameter, flattened diaphragms, hyperresonance to percussion, decreased breath sounds with expiratory wheezes, distant heart sounds, distended neck veins during expiration, and a palpable liver. Liver enlargement and leg edema are manifestations of fluid retention, and right-sided heart failure and may or may not be present. The *chest roentgenogram* may show characteristic changes of emphysema such as hyperlucent lungs, bullae, increased anteroposterior (AP) diameter, and flattened diaphragms. In some cases, increased bronchovascular markings and air bronchograms suggest the presence of thickened or inflamed airways. On the other hand, the chest roentgenogram may not show characteristic findings or be indicative of the severity of the physiologic impairment. Pulmonary function tests show an increased residual volume and total lung capacity, decreased forced vital capacity (FVC), and markedly decreased expiratory flow rates (FEV_1, FEF_{25-75}). Arterial blood studies at rest can be normal when disease is mild but in severe disease show decreased P_{O_2}, increased P_{CO_2}, and decreased pH. With cor pulmonale, P_{O_2} is likely to be below 55 mmHg. Desaturation increases with exercise and frequently during sleep. The $\dot{V}/\dot{Q}$ inequality and alveolar hypoventilation both contribute to the hypoxemia. A P_{CO_2} above 45 mmHg at rest defines net alveolar hypoventilation. Asthma is a form of COPD that rarely, if ever, leads to chronic cor pulmonale, probably because asthma is usually a disease of intermittent airways obstruction.

Cor pulmonale in COPD is related to the severity of lung dysfunction, and pulmonary hypertension is a manifestation of advanced disease. Exercise limitation in COPD is usually due to limitation of ventilatory capacity, not cardiac reserve, although sedentary patients develop deconditioning, which reduces exercise performance. No single test of lung function-such as spirometry, lung volumes, carbon monoxide diffusing capacity (DL_{CO}), blood gas tension, or radiography-is highly predictive of cor pulmonale because abnormalities such as reduced surface area and hypoxic vasoconstriction add independently to pulmonary artery pressure.[10]

Diffuse Interstitial Lung Disease

These patients have dyspnea, tachypnea, exercise intolerance, and occasionally clubbing of the digits. Basilar crackles are heard frequently on auscultation of the chest and may persist throughout inspiration. The *chest roentgenogram* shows diffuse reticular, reticulonodular, or

fibrotic lesions, but the appearance does not always correlate well with physiologic impairment. In some disease presentations, such as desquamative interstitial pneumonitis, there may be an alveolar filling pattern with air bronchograms. A lung biopsy frequently is required to identify the basic pathologic process, and even then the exact etiology may not always be determined. Transbronchial biopsy can be diagnostic in some interstitial diseases such as sarcoidosis, and bronchoalveolar lavage may point to a diagnosis in many cases.[13] *Pulmonary function tests* show a restrictive process with reduced lung volumes, decreased compliance, and decreased diffusing capacity without airway obstruction. The vital capacity is reduced, and the forced expiratory volume in 1 s (FEV_1) as a percentage of FVC is usually at least 80 percent. At first, P_{O_2} decreases during exercise but is kept at normal levels at rest by hyperventilation. As the disease becomes more severe, P_{O_2} is low at rest. The course and prognosis of interstitial lung disease depend on the specific etiology, and there is wide variation among and within diseases.[13]

The presence of cor pulmonale in interstitial lung disease implies extensive lung dysfunction, perhaps with vascular involvement (as in systemic lupus erythematosus), and cor pulmonale may not occur even in end-stage disease. Treatment of idiopathic pulmonary fibrosis frequently is unsatisfactory despite the use of high-dose corticosteroids and either cyclophosphamide or azathiopirine. Recent trials using interferon-alpha with corticosteroids show promise of improved efficacy.[14]

Hypoventilation Syndromes

Some disorders (i.e., kyphoscoliosis) may impair or restrict mechanisms of ventilation, causing general alveolar hypoventilation and alveolar hypoxia.[15] Extreme obesity may be associated with hypoventilation, cyanosis, polycythemia, and somnolence (without intrinsic lung disease), often called the *pickwickian syndrome*.[16] Patients with daytime somnolence, morning headaches, and personality disturbances have been found to have periodic apnea during sleep associated with sleep deprivation, loud snoring, hypoxemia, and hypercapnia caused by upper airway obstruction (i.e., by the tongue, enlarged tonsils, or collapse of pharyngeal walls). Brainstem abnormalities such as Arnold-Chiari malformation also may cause respiratory center depression and primary hypoventilation. Neuromuscular diseases such as postpolio syndrome and chronic Guillain-Barré syndrome may present with cor pulmonale and right-sided heart failure.[17] Diagnosis of hypoventilation is confirmed by blood gas analysis, a depressed ventilatory response to inhaled CO_2, tests of pulmonary hypoventilation, or sleep studies. It has become apparent that disordered ventilation during sleep is a major component of many hypoventilation syndromes.[18] In all cases of hypoventilation, the main stimulus for pulmonary hypertension is hypoxic vasoconstriction, a response of the pulmonary arterioles to alveolar hypoxia. The respiratory acidosis that may accompany hypoventilation augments the vasoconstrictor response to hypoxia. Noninvasive assisted nocturnal ventilation with continuous positive airway pressure (CPAP), with or without added O_2 is the most efficacious therapy in most patients with nocturnal hypoventilation.[17]

Pulmonary Vascular Disease

Chronic cor pulmonale is a consequence of several diseases that involve the pulmonary vessels. Primary pulmonary hypertension and recurrent (or unresolved) pulmonary emboli are described in detail in Chaps. 59 and 60. Sickle cell disease, from SS or SC hemoglobinopathy, can cause cor pulmonale after multiple episodes of pulmonary infarction from focal pulmonary sickling, fat embolism, or thromboembolism.[18,19] Pulmonary venoocclusive disease is a rare disease of the pulmonary veins that presents with pulmonary hypertension and variable pulmonary infiltrates. It occasionally occurs in human immune deficiency virus (HIV) infection and after bone marrow transplantation.[20]

Cirrhosis of the liver is usually associated with pulmonary vasodilatation, but occasionally a

disorder clinically and pathologically identical to primary pulmonary hypertension emerges.[21] HIV infection is a new cause of pulmonary vascular disease resembling primary pulmonary hypertension.[22] Collagen-vascular disease can cause cor pulmonale by primary vasculitis as well as by diffuse interstitial fibrosis. Systemic sclerosis, systemic lupus erythematosus (SLE), and rheumatoid arthritis (RA) are the collagen-vascular diseases that most commonly cause pulmonary arteritis. Patients with SLE and RA frequently present with primary interstitial lung disease. Occasionally, the presentation is that of cor pulmonale without interstitial disease but with primary pulmonary arteritis.[23] Cor pulmonale is not reported as a feature of Goodpasture's syndrome or idiopathic pulmonary hemosiderosis. Historically, dietary pulmonary hypertension has occurred as a result of the use of Aminorex in Europe, contaminated canola oil in Spain, and in eosinophilia myalgia syndrome in the United States related to contaminated tryptophan.[24] The new anorectic drug dexfenfluramine has caused pulmonary hypertension in France and recently has been banned in the United States by the Food and Drug Administration (FDA) because of its association with primary pulmonary hypertension and perhaps valvular dysfunction.[25]

Chapter 54: CHRONIC COR PULMONALE

PATHOPHYSIOLOGY

Increased pulmonary vascular resistance (PVR) and pulmonary hypertension are central mechanisms in all cases of cor pulmonale.[10] Physiologic mechanisms of pulmonary arterial pressure are shown in Table 54-2. These variables can be described in part by Poiseuille's law. Fortunately, most pulmonary diseases and disorders do not produce enough pulmonary hypertension to cause cor pulmonale.

Table 54-2: Genesis of Pulmonary Vascular Pressure: Poiseuille's Law

Flow = cardiac output (usually ↑ elevated in COPD; if PRV is fixed. ↑ CO will ↑ PAP).
= numerical constant related to tubular structure of vessels.
n = blood viscosity (increased in polycythemia vera, secondary erythrocytosis, and cryoglobulinemia).
N = number of perfused vessels of a particular radius. *N* is decreased in any occlusive or destructive disease (see Table 61-1). *N* for pulmonary capillaries is >200 million.
= radius of a vessel is a critical determinant of flow (*r* is decreased by vasoconstriction, luminal obstruction, or hyperinflation. A change in *r* from 1to 2 units changes resistance 16-fold).
Pla = left atrial pressure. Passive pulmonary hyperten- sion can result from left atrial pressure elevation due to either LV or valvular disease.

Normal Pulmonary Circulation

The primary function of this unique high-flow, low-pressure, low-resistance system is to provide blood for gas exchange, and it is ideally structured for this function. It receives and transmits the entire cardiac output at low hydrostatic pressures primarily because of three characteristics: (1) the pulmonary arteries are thin-walled with little resting muscular tone, (2) there is negligible vasomotor control by the autonomic nervous system at rest in the adult, and (3) many small arterioles and alveolar capillaries produce a high surface area that can be recruited when needed to expand the pulmonary vascular bed, resulting in a decreased PVR. Normal mean pulmonary artery pressure (PAP) is about 12 to 17 mmHg; PAP above 20 mmHg at rest suggests pulmonary hypertension. Flow of blood from the main pulmonary artery (PA) through the pulmonary capillaries to the left atrium is accomplished by a pressure drop of only 5 to 9 mmHg, compared with an arterial-to-venous gradient of 90 mmHg in the systemic circuit. Thus normal PVR is 10- to 20-fold less than systemic vascular resistance.

Pulmonary Hypertension

The effective cross-sectional area of the pulmonary vascular bed must be reduced by 25 to 50 percent before any change in PAP can be detected at rest. Exercise causes increased PAP because of increased pulmonary blood flow in the normal bed, and exercise will dramatically raise PAP if the vascular bed is reduced. Obliterative vascular diseases increase PVR by vascular luminal occlusion, whereas diffuse interstitial diseases act primarily by compression and obliteration of small vessels. Hyperinflation in COPD increases PVR partly by compressing intraalveolar vessels, reducing the cross-sectional area of the bed. It is now well established, however, that arteriolar constriction resulting from alveolar hypoxia is the predominant cause of pulmonary hypertension in chronic airways diseases.[1,10,26,27]

PULMONARY ARTERIOLAR CONSTRICTION

The most important cause of pulmonary vasoconstriction is alveolar hypoxia. The mechanism of hypoxic pulmonary vasoconstriction is unknown. It is thought to be due either to mediator release from some unknown effector cell or a direct action of hypoxia on pulmonary vascular smooth muscle K channels.[28,29] The degree of hypoxic vasoconstriction depends primarily on the alveolar P_{O_2}, and when alveolar P_{O_2} is less than 55 mmHg, PAP rises sharply (Fig. 54-1). When PAP is greater than 40 mmHg due to hypoxia, arterial oxygen saturation is very likely less than 75 percent.[26] There is large individual variability in the hypoxic pressor response, and hypoxic vasoconstriction is enhanced by acidosis and blunted by alkalosis. Acidosis also has a mild direct pressor effect on the pulmonary circulation.[28] Extensive investigations into the mechanism of hypoxic vasoconstriction have shown that many local and circulating mediators of pulmonary vascular tone are capable of modulating the hypoxic pressor response but that no single mediator yet discovered is solely or predominantly responsible[28] (Table 54-3).

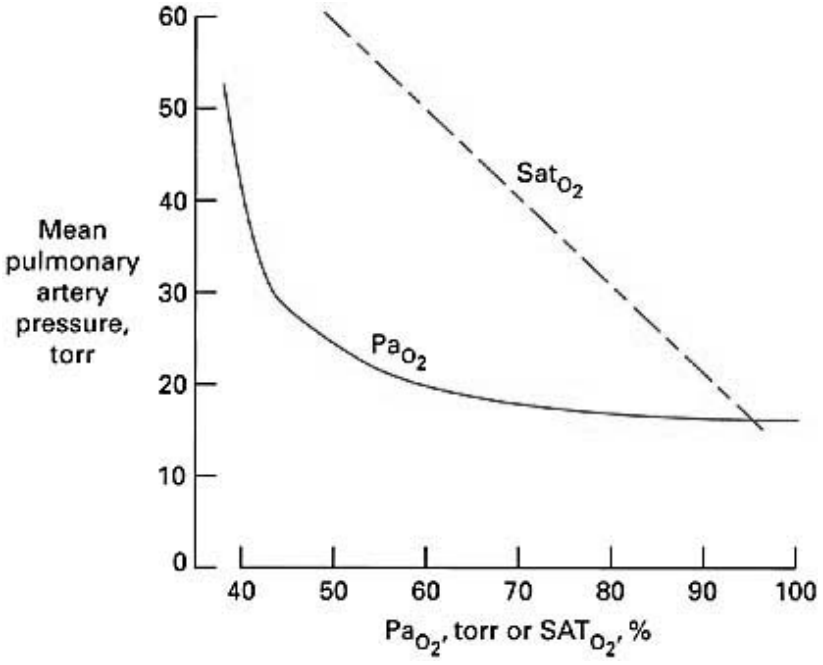

Figure 54-1: Pulmonary arterial pressure as a function of Pa_{O_2} or oxyhemoglobin saturation in humans. Pulmonary arterial pressure rises sharply as Pa_{O_2} decreases below 55 mmHg. (Redrawn from Reeves JT, Grover RF. High altitude pulmonary hypertension and pulmonary edema. *Prog Cardiol* 1975; 4:105, and from Burrows B. Anaerobic infections of the lung and pleural space. *Am Rev Respir Dis* 1974; 110:64, with permission.)

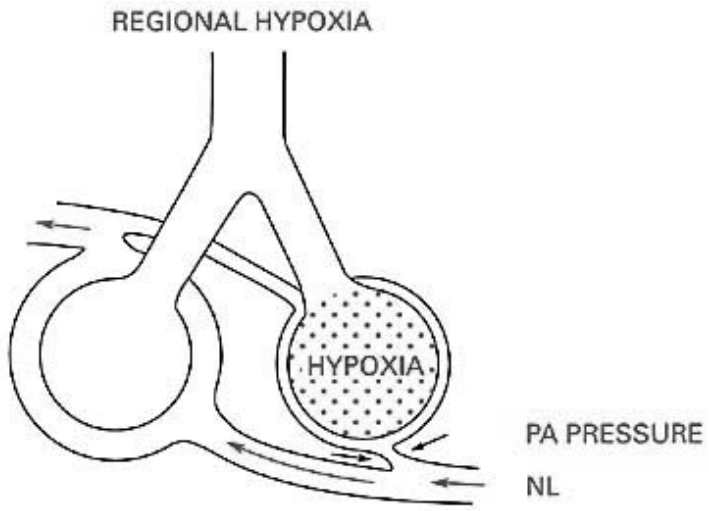
Table 54-3: Endogenous Pulmonary Vasomotor Tone

Dilator	Constrictor
Beta-adrenergic	Alpha-adrenergic agonists
Histamine H_2	Histamine H_1
Prostacyclin (PGI_2), PGE_1	PGE_2, PGF_{1a}, Thromboxane A_2 PGD_2
Acetylcholine*	Serotonin
Oxygen	Hypoxia

Bradykinin	Angiotensin II
Vasoactive intestinal polypeptide	Platelet activating factor>Endothelin
Nitric oxide	Leukotriene C_4/D_4
Atrial natriuretic peptide	Vasopressin
Adenosine	

*The response of the pulmonary vascular bed is tone-dependent. When the pulmonary circulation is preconstricted, acetylcholine is a vasodilator through the release of endothelium-derived NO.

Hypoxic vasoconstriction in a region of lung where ventilation is diminished probably serves to maximize net arterial oxygenation by diverting blood from the hypoxic region to better-ventilated areas. Because the pulmonary vascular bed is capable of significant recruitment, localized hypoxic vasoconstriction does not cause pulmonary hypertension. Generalized hypoxia causes generalized hypoxic vasoconstriction and the development of pulmonary hypertension (Fig. 54-2). In COPD, the first episodes of alveolar hypoxia may occur during sleep, and it gradually becomes more prevalent thereafter.[30] Any cause of alveolar hypoventilation (see Table 54-1) can result in chronic cor pulmonale through the mechanism of hypoxic pulmonary vasoconstriction, including entities as different as diffuse emphysema and kyphoscoliosis[9,15] (see also Chap. 59).



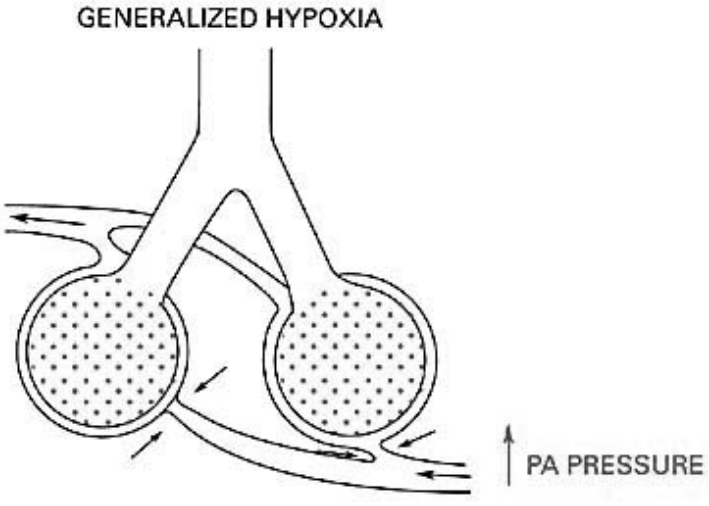


Figure 54-2: Hypoxic pulmonary vasoconstriction maximizes arterial oxygenation by diverting blood away from areas of regional hypoxia toward better-ventilated zones. Generalized hypoxia causes generalized hypoxic vasoconstriction and results in pulmonary hypertension. (From Newman JH. Pulmonary vascular reactivity in primary pulmonary edema. *Semin Respir Med* 1983; 4:299; reproduced with permission of the publisher. Courtesy of J. V. Weil.)

OTHER CONTRIBUTIONS TO PULMONARY HYPERTENSION

Increases in cardiac output and blood volume or direct effects of acidosis and/or hypoxia on the myocardium may contribute to pulmonary hypertension. Increased blood flow such as occurs with exercise engenders an increased PAP, and in such a situation, the effects of hypoxia and acidosis also will be exaggerated.[26] Sustained or repetitive severe hypoxemia causes secondary erythrocytosis. Blood viscosity increases rapidly after the hematocrit exceeds about 55 percent, raising PVR and also decreasing cerebral function. If left ventricular failure (LVF) is superimposed on an already reduced pulmonary vascular bed, pulmonary hypertension will be augmented by elevated downstream left atrial pressure. Once established, pulmonary hypertension may be self-perpetuating. A sustained increase in PAP in patients with diffuse lung disease causes muscular hypertrophy in the walls of small arteries, with extension of muscle toward alveolar vessels, further increasing PVR and PAP. Chronic hypoxia alone results in muscularization of pulmonary arterioles and exaggerated increases in PAP with stimuli.[26,31]

Right Ventricular Response to Pulmonary Hypertension

The right ventricle is thin-walled and eccentric and better able to handle an increase in volume load than to meet an increased pressure load.[10] The primary cause of right ventricular strain and failure (RVF), therefore, is a chronic pressure load (afterload). Small increases in PAP may result in large increases in right ventricular work. Pulmonary hypertension at rest indicates a high baseline resistance, and small changes in blood flow will cause large increases in PAP.

Response of the right ventricle to pulmonary hypertension depends on the acuteness and severity of the pressure load. Acute cor pulmonale (see Chaps. 59 and 60) occurs after a sudden and severe stimulus (i.e., massive pulmonary emboli) with ventricular dilatation and failure but without hypertrophy. Acute cor pulmonale may develop within minutes to hours. Chronic cor pulmonale, however, is associated with a more slowly evolving and slowly progressive hypertension,[33] and the response involves increased protein synthesis and right ventricular hypertrophy (RVH).[34] The severity of the hypertension, the rapidity with which it becomes severe, and the possible eventual onset of RVF are influenced by factors that intercede intermittently, such as (1) *alterations in ventilatory function,* causing alveolar pressure changes with effects on chamber function, (2) *alterations in gas exchange,* with more or less severe hypoxemia, hypercapnia, and acidosis, and (3) *alterations in volume load,* as influenced by exercise, heart rate, polycythemia, or renal retention of salt and water associated with cor pulmonale. At some stage, the myocardium is unable to function at the high-pressure load, dilates, and fails. RVF may occur relatively early in some patients with chronic bronchitis and emphysema because of sustained hypoxemia and hypercarbia, but it occurs later in patients with diffuse interstitial lung disease because the degree of RVH helps to maintain blood flow even when PAP is high.[33] Extreme pulmonary hypertension and RVH can occur in normal persons living at high altitude (>10,000 ft, or 3033 m) with no evidence for heart failure.[34] Thus the right ventricle can develop into an efficient high-pressure pump over time and sustain normal function for months to years.

Left Ventricular Function in Cor Pulmonale

Dysfunction of the left ventricle occurs in some patients with cor pulmonale, but the evidence available indicates that cor pulmonale per se does not cause disease of the left side of the heart. The likelihood in most cases is that left-sided heart dysfunction coexisting with cor pulmonale results from other known causes, such as coronary ischemia or systemic hypertension. Left ventricular failure is a serious complication in cor pulmonale because the increase in left atrial pressure and in lung water further impairs lung function, increases the work of breathing, increases PAP, impairs gas exchange, and may induce

respiratory failure. When underlying disease of the left ventricle is present, the direct effects of hypoxia, hypercapnia, and acidosis arising from primary lung disease may precipitate left ventricular failure.[10,35,36]

Several lines of evidence point to mechanical effects of lung dysfunction and right ventricular dilatation on performance of the left ventricle.[36,37] Wide swings in transpulmonary pressure in obstructive lung disease can reduce left ventricular filling and increase left ventricular afterload.[38] Hypertrophy and elevated end-diastolic pressure of the right ventricle in cor pulmonale can reduce left ventricular compliance and impair left ventricular filling through effects on the shared ventricular septum.[39] Despite these effects, most patients with chronic cor pulmonale demonstrate normal resting cardiac output, normal pulmonary artery wedge pressure, and normal resting left ventricular ejection fraction.[40] The majority of patients with abnormal left ventricular ejection fraction in either compensated or decompensated chronic lung disease probably have demonstrable coronary artery disease.

Edema Formation and Cor Pulmonale

Peripheral edema occurs in some cases of chronic cor pulmonale. The mechanism of edema formation is poorly understood but is probably related to increased systemic venous pressure, hypercarbia, and hypoxemia.[10,41] The presence of pulmonary hypertension per se does not appear to be sufficient to cause fluid retention until right atrial pressure becomes elevated. Decreased clearance of aldosterone from the passively congested liver contributes to salt retention but is likely not an initiating event. Plasma volume is increased, however, in chronic cor pulmonale.[10]

Hypercarbia stimulates plasma renin activity, and hypercarbic, edematous patients with COPD have increased plasma levels of aldosterone and antidiuretic hormone.[42,43] This pattern occurs despite oxygen therapy in these patients. Thus not only increased salt retention but also impaired water excretion contributes to edema in chronic hypercapnia. Atrial natriuretic peptide is elevated in cor pulmonale in response to elevated right atrial pressure and perhaps acidosis.[10] Severe hypoxemia is associated with reduced renal blood flow and glomerular filtration rate and a decrease in urine sodium excretion.[10] Other mechanisms of edema formation are increased systemic capillary hydrostatic pressure, related to increased venous pressure and blood volume; and perhaps inappropriate release of arginine vasopressin.[10] Many mechanisms appear to be operating to produce edema in chronic cor pulmonale, several of which are related to the primary pulmonary dysfunction, especially in COPD. The exact mechanisms and sequence of events leading to edema are difficult to determine in any specific case. Pulmonary edema and pleural effusion are not seen as a consequence of chronic cor pulmonale.

Chapter 54: CHRONIC COR PULMONALE

CLINICAL MANIFESTATIONS OF COR PULMONALE

Symptoms

Clinical manifestations of cor pulmonale are often obscured by the signs and symptoms of underlying disease and therefore are closely related to the pulmonary disease or disorder. It is necessary first to recognize the type and severity of lung disease and then to look for cor pulmonale.

There is no history that is specific for cor pulmonale. Episodes of leg edema, atypical chest pain, dyspnea on exertion, exercise-induced peripheral cyanosis, prior respiratory failure, and excessive daytime somnolence are all historical clues suggesting the presence of cor pulmonale. Chest pain may be due to strain or distortion of the chest wall (musculoskeletal) or may be related to right ventricular ischemia. Cough and complaints of easy fatigability are common. Some patients with nocturnal hypoventilation and sleep apnea may present with personality changes, mild systemic hypertension, and headache. Shortness of breath is nearly a universal symptom in cor pulmonale. The degree of activity that leads to dyspnea should be quantified because patients reduce activities to avoid dyspnea. Thus the naive question of whether a patient is short of breath may lead to a negative reply because the patient is less and less active. Abdominal pain may result from liver and bowel congestion if RVF is present.

Physical Examination

The earliest signs are those associated with long-standing pulmonary hypertension. The most sensitive sign for pulmonary hypertension is an accentuated pulmonary component of S_2, which also may be palpable in the pulmonic area, and right ventricular lift of the sternum may be seen. With very high PAP, characteristic diastolic and systolic murmurs of pulmonary valvular and tricuspid valvular regurgitation may be heard together with a systolic ejection sound and right ventricular S_3 gallop. In overt RVF, cardiac enlargement, distended neck veins, hepatomegaly, and peripheral edema are present. Symptoms or signs suggestive of heart failure-such as dyspnea, orthopnea, peripheral edema, palpable liver, and distended neck veins-however, can be observed in patients with COPD without RVF. But when neck veins are distended during inspiration as well as expiration, RVF is more likely present. Hyperinflated lungs alter the position of the heart and frequently make the examination difficult. The apical impulse and the right ventricular lift are often not palpable, and the right ventricular S_3 gallop may be heard in the epigastrium. In emphysema, the heart sounds may be best heard in the subxiphoid area. Extremities may be warm due to peripheral vasodilatation caused by hypercapnia, or there may be cyanosis due to low flow or hypoxemia.

ELECTROCARDIOGRAM

Electrocardiographic patterns are influenced by many factors such as PAP, rotation, and displacement of the heart by hyperinflated lungs, arterial blood gases, myocardial ischemia, and metabolic disturbances. The value of the electrocardiogram (ECG) in diagnosis of cor pulmonale, therefore, depends on the underlying disease and complicating conditions. Absence of changes indicating right ventricular disease does not rule out cor pulmonale because the ECG may be

normal in advanced cor pulmonale. An example of RVH is shown in Fig. 54-3. The standard criteria for right ventricular enlargement were absent in two-thirds of patients with COPD who had RVH on postmortem examination.[1] It has been suggested that when classic RVH changes are absent, diagnosis should be based on the combination of rS in V_5 to V_6, RAD, qR in aV_R, and P pulmonale.[44] Tall peaked P waves in leads II and aV_F may reflect positional changes rather than right atrial enlargement. Right bundle-branch block occurs in about 15 percent of patients. A pattern of S_1, Q_3, and T_3 carries reasonable sensitivity and specificity for cor pulmonale in COPD.[45] Arrhythmias are infrequent in uncomplicated cor pulmonale, but when present, they are mostly supraventricular and may reflect blood gas abnormalities, hypokalemia, or excess of drugs such as digitalis, theophylline, and beta agonists. Multifocal atrial tachycardia is associated with decompensated COPD and is best treated by attention to the underlying disease rather than by antiarrhythmic drugs. Ventricular arrhythmias, when they occur, are associated with a high mortality.

CHEST ROENTGENOGRAM

The radiographic findings of pulmonary hypertension in patients with normal lung parenchyma (such as in primary pulmonary hypertension) are well described[46,47] (Fig. 54-4). Most diseases that cause cor pulmonale have grossly abnormal chest roentgenograms, and the radiologic diagnosis of pulmonary hypertension in these diseases is more difficult. Right ventricular enlargement may be difficult to detect in the vertical heart of emphysema, and comparison with previous films may be helpful. In the most obvious cases of cor pulmonale, there is right ventricular and PA enlargement, but pulmonary hypertension precedes right ventricular dilatation. One indicator of pulmonary hypertension is measurement of the dimensions of the right and left PAs. Enlargement is considered to exist if the diameter of the right descending PA is greater than 16 mm and the left descending PA is greater than 18 mm.[48] These findings occurred in 43 of 46 patients with known pulmonary hypertension, but the true sensitivity and specificity of these measurements are not known.

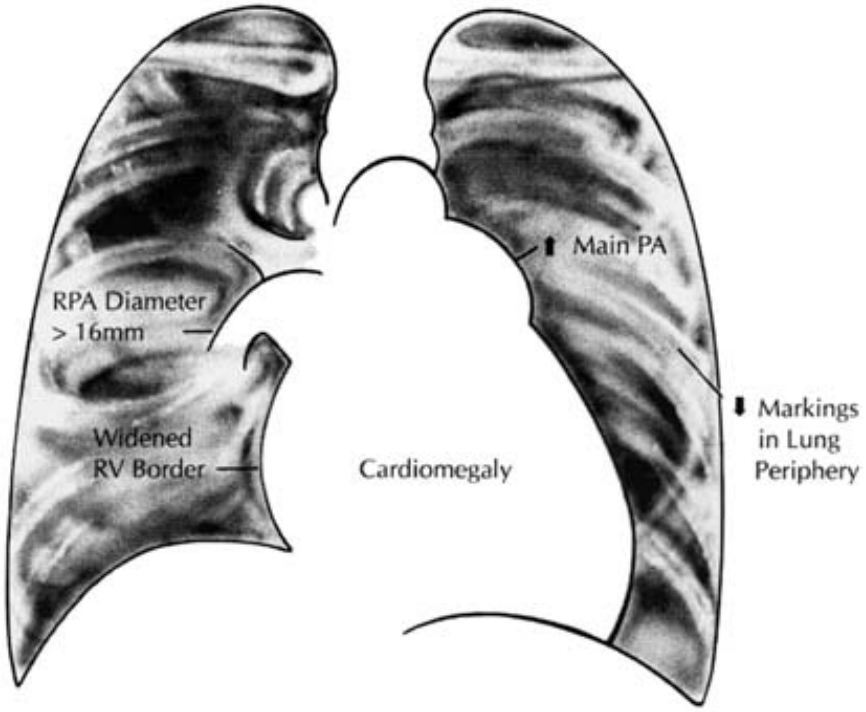

Figure 54-4: Classic features of the chest radiograph in severe pulmonary hypertension. The

enlarged pulmonary arteries can be mistaken for hilar adenopathy, and the large main pulmonary artery obscures the aortic arch. Right descending PA diameter greater than 16 mm suggests severe pulmonary hypertension.

ECHOCARDIOGRAM

Advances in echocardiography make this a useful test where cor pulmonale is suspected.[49] The standard M mode reliably detects right ventricular dilatation and is best able to display the anteriormost right ventricular wall near the interventricular septum. Two-dimensional echocardiography allows improved visualization of right ventricular chamber size and wall thickness, as well as changes in the interventricular septum resulting from RVH.[49,50] Because the right ventricle is asymmetric, measurement of right ventricular volume is difficult even with twodimensional views. Right ventricular pressure overload usually is detected by hypertrophy of the anterior right ventricular wall and by dilatation of the chamber. Hypertrophy of the septum can be found, and paradoxical septal encroachment into the left ventricular chamber can be seen in severe cor pulmonale.[53] Right ventricular volume overload, as in atrial septal defect, causes dilatation as the predominant finding, often in association with abnormal ventricular septal motion.[51]

Echo-Doppler techniques have become the noninvasive standard to detect pulmonary hypertension and to measure cardiac output. These techniques are relatively accurate when PAP is above 30 mmHg, but they may not detect milder but pathologic pulmonary hypertension.[52, 53] Echo Doppler is useful for longitudinal follow-up of pharmacologic treatment of pulmonary hypertension and cor pulmonale.

RIGHT-SIDED HEART CATHETERIZATION

Right-sided catheterization is the only technique available for the direct measurement of PAP, PA wedge pressure, and cardiac output. It is occasionally important in differentiating cor pulmonale from left ventricular dysfunction when the clinical presentation is confusing. This is especially true in patients with primary pulmonary hypertension (PPH) or unresolved pulmonary emboli, where airway function may appear normal, or with restrictive cardiomyopathy (see Chap. 75). In cor pulmonale, PA diastolic pressure is usually significantly higher than wedge pressure, unlike LVF or mitral stenosis, where the diastolic-wedge pressure gradient is smaller in most patients. Mean PAP can be very high in obliterative vascular diseases but only moderately high in interstitial lung diseases.[36] In COPD, PAP is related to the level of hypoxemia; it is not usually as severely increased as in PPH and generally will be decreased by chronic oxygen administration.[26,54,55] About 50 percent of patients with severe COPD have pulmonary hypertension at rest; in those patients with normal resting values, PAP may rise with exercise.[10,54] Serial catheterization in patients with COPD and pulmonary hypertension has revealed remarkable stability of pulmonary hemodynamics.[56]

Chapter 54: CHRONIC COR PULMONALE

USUAL STRATEGY OF WORKUP

Because of the diversity of diseases that cause cor pulmonale, no single strategy of workup exists. When lung parenchymal or airways disease is present, pulmonary function tests frequently will reveal the nature and degree of impairment.[57] Spirometry, lung volumes (functional residual capacity), DL_{CO}, and an arterial blood sample for pH, P_{O_2}, and P_{CO_2} should be obtained.

Transbronchial biopsy via a fiberoptic bronchoscope, bronchoalveolar lavage, and open lung biopsy are diagnostic options in patients with interstitial lung disease. If the hematocrit is above 50 percent, it gives a clue to the presence of chronic hypoxemia, nocturnal hypoventilation, or polycythemia vera. Patients with cryptogenic pulmonary hypertension should receive a perfusion radionuclide lung scan to detect pulmonary emboli or other causes of obstruction of the pulmonary arteries such as fibrosing mediastinitis. If pulmonary vasculitis is suspected, serum can be screened for the presence of antinuclear antibody, hepatitis B surface antigen, rheumatoid factor, and cryoglobulins. Factor V_{Leiden} is likely to be a frequent abnormality in thrombotic pulmonary hypertension,[58] and the antiphospholipid antibody syndrome may cause cor pulmonale.[59]

Polysomnography should be performed in patients with cor pulmonale and any sign or symptoms of sleep apnea. Exercise tests occasionally will reveal desaturation or ventilatory limitations that denote significant lung dysfunction not appreciated on examination at rest. Echo Doppler is an important addition to the noninvasive workup of a patient suspected to have pulmonary hypertension.

Chapter 54: CHRONIC COR PULMONALE

NATURAL HISTORY AND PROGNOSIS

Prognosis depends more on control of the underlying lung disease than on control of pulmonary hypertension in most cases. Patients with COPD have hypoxic pulmonary hypertension that is partially reversible, and RVF can be improved with appropriate therapy. Even with repeated episodes of RVF, some patients have long survivals.[1,10] The pink puffers tend to live longer than the blue bloaters.[10] Once RVF occurs, prognosis is poor; patients with COPD receiving nasal oxygen have about a 50 percent 2-year survival, but some patients survive for 5 to 8 years.[27] In patients with alveolar hypoventilation but no alteration in lung structure, the natural history is one of progressive worsening of pulmonary hypertension due to sustained hypoxemia and hypercapnia. If alveolar ventilation is improved prior to the development of nonreversible changes in vessel walls, the prognosis is good.

PREVIOUS | NEXT

Chapter 54: CHRONIC COR PULMONALE

MEDICAL TREATMENT

The underlying lung disease is the focus of therapy and is the best way to reduce the right ventricular pressure work associated with the disease. If RVF has not appeared, a major goal is to prevent its onset. When it appears, it should be treated, but the response will be poor unless cardiac work is reduced by control of pulmonary hypertension.

Treatment to Decrease Pulmonary Hypertension

Relief of hypoxia is of prime importance in reducing pulmonary hypertension, both to prevent and to treat cor pulmonale. This may be done in two ways: (1) treatment of the underlying disease and (2) O_2 administration.[55] Neither will lower PAP in all patients because hypertension is often intractable in those with an anatomic restriction of the pulmonary vascular bed. Most patients with chronic cor pulmonale have a component of hypoxic pulmonary vasoconstriction, and all patients should be treated with oxygen in amounts adequate to restore arterial O_2 tension to greater than 60 mmHg. Corticosteroids may be helpful in some patients with interstitial lung disease and in patients with a bronchospastic component of COPD. Measures should be instituted to treat the systemic disease with which obliterative vascular disease is associated or to prevent further pulmonary emboli if this is the problem.

In COPD, the primary focus is relief of hypoxemia by restoration of effective ventilation or by O_2 administration. Net alveolar ventilation may be improved by therapy, including bronchodilators for bronchospasm, antibiotics to prevent or treat acute exacerbations of bronchitis, bronchial toilet for removal of secretions, and avoidance of airway irritants such as tobacco smoke. Nocturnal aspiration of gastric fluid is now known to be a common cause of exacerbation of chronic lung disease. Tranquilizers, sedatives, and narcotics should be avoided in unstable patients and patients with hypoventilation. Correction of hypoxia and acidosis may produce a striking reduction in PAP. In diseases that alter lung function but not structure, effective alveolar ventilation must be restored by treatment of the underlying disease or by use of mechanical ventilation. Short-term ventilatory stimulants may be useful in some cases of decreased ventilatory drives, although nasal CPAP has become the first choice in most cases of sleep apnea.[10]

Adequate oxygenation may prevent the onset of heart failure, both acutely and over a long period of time. Any patient with cor pulmonale and RVF should be given sufficient O_2 to restore P_{O_2} to levels above 60 mmHg, but it should be given cautiously when P_{CO_2} is high and the threat of respiratory acidosis is present. Oxygen therapy is usually well tolerated in patients with stable lung disease but not in patients with acute acidosis or respiratory muscle fatigue. When low-flow nasal O_2 causes significant increases in P_{CO_2}, mechanical ventilation may be required to relieve hypoxia. Studies have shown conclusively that home oxygen therapy, nocturnal or continuous, is beneficial in keeping patients with severe COPD functioning better for longer periods of time; it may be effective both in treating cor pulmonale and in postponing its onset.[27,55] Continuous 24 h/day oxygen therapy is the desired goal in most patients, because desaturation occurs during both sleep and physical activity.

Treatment of Heart Failure

Cor pulmonale is heart disease, and while treatment of the lung disease and relief of hypoxia are necessary to reduce cardiac work, general principles of management of heart failure apply. Diuretics and phlebotomy can be appropriate measures for treatment of RVF. Pulmonary vasodilators are efficacious in some patients with primary pulmonary hypertension but are of unproven value in cor pulmonale from COPD.[61]

Beneficial effects of digitalis are not as obvious as in LVF, and arrhythmias caused by digitalis may occur at relatively low serum levels in patients with hypoxia and acidosis. Susceptibility to digitalis intoxication is enhanced in pulmonary disease.[62] Its use in cor pulmonale therefore has been controversial. Nevertheless, studies have shown that *digitalis improves right ventricular function in cor pulmonale, and it is an appropriate drug for treatment of RVF when given cautiously and at carefully controlled dosage levels*.[63] It should not be used during the acute phases of respiratory insufficiency when there are large fluctuations in levels of hypoxemia and acidosis but is reserved for the time when the patient is stabilized. Heart rate in this setting cannot be used as a guide for the level of digitalization. It is also reasonable to question whether or not patients with cor pulmonale who continue to have overt RVF after relief of hypoxemia in intensive therapy for the underlying lung disease will benefit from the use of digitalis. Digitalis is appropriate if there is known or suspected concurrent left ventricular systolic dysfunction.

Vasodilator therapy to reduce right ventricular afterload has been recognized as a potential treatment strategy for several years. Vasodilator therapy has the disadvantage of being secondary therapy that is not aimed at the primary lung dysfunction. Vasodilator use has not become widespread because of small observed reductions in pulmonary hypertension and occasional worsening of gas exchange.[61]

Diuretics are effective in the treatment of RVF, and indications for their use are the same as in other forms of heart disease. Pulmonary function is improved by diuretics in patients with COPD who have hypervolemia.[64] The effects of diuretics should be monitored carefully by measurement of arterial P_{O_2}, P_{CO_2}, and pH because acid-base abnormalities are often present in cor pulmonale. Contraction alkalosis can be a problem in hypercarbic patients with a large buffer base who have had vigorous diuresis.

When the hematocrit is above 55 to 60 percent, phlebotomy may reduce PAP and PVR and possibly improve right ventricular function.[65] The phlebotomy should be in small volumes (200-300 mL) and done cautiously.

Chapter 54: CHRONIC COR PULMONALE

SURGICAL TREATMENT

There is no surgical treatment for most diseases that cause chronic cor pulmonale. Pulmonary embolectomy is extremely efficacious for unresolved pulmonary emboli causing chronic thrombotic pulmonary hypertension (see Chap. 60). Adenoidectomy in children with chronic airways obstruction and uvulopalatopharyngeoplasty in selected patients with sleep apnea can relieve cor pulmonale related to hypoventilation. Single-lung, double-lung, and heart-lung transplantations are all used for salvage in the terminal phase of several diseases complicated by cor pulmonale.[66] *The diseases most commonly treated by lung transplantation are primary pulmonary hypertension, emphysema, idiopathic pulmonary fibrosis, and cystic fibrosis*. Two-year survival for single- and double-lung transplant has risen to 60 percent, still lower than the approximately 80 percent for heart transplant alone. One interesting finding is that the right ventricle can recover function after lung transplant even after the chronic stress of severe pulmonary hypertension. Volume-reduction surgery for selected patients with emphysema improves ventilatory function and gas exchange, and the long-term benefit of this approach is under study.[67]

Part 9: VALVULAR HEART DISEASE
Chapter 55:

ACUTE RHEUMATIC FEVER

Authors: Simon Chakko, Alan L. Bisno

DEFINITION

Rheumatic fever is an inflammatory disease that occurs as a delayed nonsuppurative sequel to group A streptococcal infection of the pharynx. It involves the heart, joints, central nervous system, skin, and subcutaneous tissues with varying frequency. Its clinical manifestations include migratory polyarthritis, fever, carditis, and, less frequently, Sydenham's chorea, subcutaneous nodules, and erythema marginatum. Rheumatic fever is a clinical syndrome for which no specific diagnostic test exists. No symptom, sign, or laboratory test result is pathognomonic, although several combinations of them are diagnostic. Its importance relates to involvement of the heart, which, though rarely fatal during the acute stage, may lead to rheumatic valvular disease, a chronic and progressive condition that causes cardiac disability or death many years after the initial event.

Chapter 55: ACUTE RHEUMATIC FEVER

ETIOLOGY

Antecedent infection of the upper respiratory tract with the group A streptococcus is necessary for the development of rheumatic fever. Cutaneous streptococcal infection may lead to acute glomerulonephritis but has never been demonstrated to cause rheumatic fever. The evidence establishing the group A streptococcus as the etiologic agent of rheumatic fever is only indirect, because the organism cannot be recovered from the lesions and there is no experimental animal model. Nevertheless, the evidence from clinical, immunologic and epidemiologic studies is overwhelming.

At least one-third of patients deny previous sore throat, and cultures of the pharynx are often negative for group A streptococci at the onset of rheumatic fever. However, an antibody response to streptococcal extracellular products can be demonstrated in almost all cases,[1] and the attack rate of acute rheumatic fever is strongly correlated with the magnitude of the antibody response.[2]

A clear sequential relationship between outbreaks of streptococcal pharyngitis or scarlet fever and rheumatic fever has been demonstrated in epidemiologic studies of military recruit camps, and such outbreaks can be eradicated when streptococcal infection is controlled by chemotherapy.[3] Prompt and effective penicillin therapy of streptococcal pharyngitis prevents the initial attack of rheumatic fever (so-called primary prevention),[4] and continuous chemoprophylaxis against streptococcal infection (secondary prophylaxis) prevents its recurrences.[5]

Chapter 55: ACUTE RHEUMATIC FEVER

EPIDEMIOLOGY

Rheumatic fever is a major health problem in the developing countries of Asia, Africa, the Middle East, and Latin America. It is difficult for physicians trained in North America to comprehend the magnitude of the problem. A World Health Organization survey conducted between 1986 and 1990 estimated the prevalence of rheumatic fever and chronic rheumatic heart disease per 1000 schoolchildren to be 12.6 in Zambia, 10.2 in Sudan, and 7.9 in Bolivia.[6] Hospital statistics from many developing countries reveal that 10 to 35 percent of all cardiac admissions are for rheumatic fever and rheumatic heart disease.[6,7] It has been estimated that there are at least 50,000 cases of rheumatic fever annually in India and more than 1 million people with rheumatic heart disease.[7] Exceedingly high attack rates have been reported among aboriginal populations in New Zealand and Australia.[8]

Acute rheumatic fever is most common among children in the 5- to 15-year age group. There is no clear-cut sex predilection, although there is a female preponderance in rheumatic mitral stenosis and in Sydenham's chorea. The attack rate of acute rheumatic fever following untreated exudative tonsillitis varies, depending upon the epidemiologic circumstances and the rheumatogenic potential of prevalent streptococcal strains. This rate has been reported to approximate 3 percent during epidemics in military recruit camps[9] but only 0.4 percent after endemically occurring infections in untreated children in civilian populations.[10] Acute rheumatic fever is more likely to occur after those streptococcal infections judged to be more severe by clinical and immunologic criteria (i.e., exudative tonsillopharyngitis, vigorous rises in serum titers of antistreptolysin O, and prolonged convalescent streptococcal throat carriage). Nevertheless, approximately one-third of the cases occur after asymptomatic streptococcal infections. A striking feature of the epidemiology of acute rheumatic fever is the propensity of patients who have suffered an initial attack to experience recurrences of the disease following group A streptococcal infections.

Strains of group A streptococci vary in their propensity to elicit acute rheumatic fever. Although the precise factor or factors that confer this property are unknown, highly rheumatogenic strains share certain biological characteristics. Only a limited number of the more than 90 streptococcal M-protein types have been strongly and repetitively associated with rheumatic fever.[11] These strains are often heavily encapsulated, a feature manifest by the formation of mucoid colonies on blood-agar plates. Their M-protein molecules share a particular surface-exposed antigenic domain against which rheumatic fever patients mount a strong immunoglobulin G response.[12] These characteristics were established, however, by study of rheumatic fever cases and outbreaks in the United States and Great Britain; they remain to be validated for cases occurring in third-world countries or among aboriginal populations.

The twentieth century witnessed a dramatic decline in the incidence of rheumatic fever and rheumatic heart disease in the industrialized nations.[13] The incidence of rheumatic fever and the prevalence of rheumatic heart disease are now very low in North America and western Europe. Rates fewer than 2 per 100,000 schoolchildren have been reported from several areas in the United States. The disease is very rare in affluent suburban populations[14] but persists among disadvantaged families dwelling in the crowded inner cities.[14,15] The higher incidence rates reported among blacks than among whites appear to be due to socioeconomic rather than genetic factors.

The reasons for the recent decline in the incidence of rheumatic fever in developed countries are multifactorial. One of the factors was likely an improvement in living standards, including a decrease in household crowding. Crowding favors interpersonal spread of group A streptococci and probably enhances streptococcal virulence by human passage. Although the diminution was well under way prior to the introduction of penicillin, this highly effective antimicrobial may have contributed to the decline in initial attacks of rheumatic fever and clearly contributed to a decrease in mortality by preventing repetitive attacks in patients compliant with programs of secondary prophylaxis.

There is no evidence of a decline in the frequency of streptococcal pharyngitis concomitant with the dramatic decline in rheumatic fever incidence. This strongly suggests that there have been changes in the rheumatogenicity of streptococcal strains currently prevalent in civilian populations of North America and western Europe. This concept was further validated by the isolation of strains manifesting the abovementioned rheumatogenic phenotypic characteristics during a resurgence of rheumatic fever that occurred in certain American communities toward the end of the century (see below).

In the mid-1980s, after decades of decline, outbreaks of rheumatic fever occurred in numerous cities and in two military recruit camps in the United States.[13,16] Strains of group A streptococci recovered from patients with acute rheumatic fever and their families and those found in community and training camp surveys were generally high-mucoid and often belonged to well-established rheumatogenic serotypes (serotypes 3 and 18). A survey of hospitals conducted by the American Heart Association indicated that the reported outbreaks were focal and not nationwide.[17] The largest epidemic occurred in Salt Lake City, Utah, and the surrounding intermountain area,[18] where over 500 cases were diagnosed between 1985 and 1999.

Surprisingly, the epidemiologic features of several of the civilian outbreaks-including the largest one in Salt Lake City-differed from the traditional patterns described above in that the victims were predominantly white middle-class children living in the suburbs. Only one-third of the children with rheumatic fever in Salt Lake City had a sore throat of sufficient severity that the parents considered taking them to a physician.[19] Most such outbreaks appear to have subsided during the 1990s, but that in Salt Lake City is continuing as of this writing.

Chapter 55: ACUTE RHEUMATIC FEVER

PATHOGENESIS

The exact mechanism by which the group A streptococcus causes rheumatic fever remains unexplained. Possibilities include (1) toxic effects of streptococcal products, particularly streptolysins S or O, which are capable of inducing tissue injury; (2) a serum sickness-like reaction; and (3) autoimmune phenomena induced by the similarity or identity of certain streptococcal antigens to wide variety of human tissue antigens.[20] Although no mechanism has been unequivocally proven, autoimmunity or, more precisely, molecular mimicry appears to be most likely.[21] There are shared epitopes between cardiac myosin and streptococcal M protein that lead to cross-reactive humoral and T-cell immunity against group A streptococci and the heart.[22] Epitopes of streptococcal M protein also share antigenic determinants with heart valves, sarcolemmal membrane proteins, synovium, and articular cartilage.[23] Circulating antibodies that react with neurons of the caudate and subthalamic nuclei and with group A streptococcal cell membranes have been found in many children with Sydenham's chorea.[24] Injection of streptococcal mucopeptide-polysaccharide cell wall complex can induce chronic nodular lesions in the dermal connective tissue in experimental animals.[25] These cross-reactive and toxic phenomena could explain many of the clinical manifestations of rheumatic fever, but, in the absence of a credible animal model of the disease, there is no direct proof that they do so.

During active rheumatic carditis both the number of helper (CD4) lymphocytes and the ratio of CD4 to CD8 cells are increased in the heart valves, and the production of interleukin-1 and interleukin-2 is reportedly increased.[26,27] Scarring and collagen deposition in the valves and destruction of myocytes may result.

The fact that, even in severe epidemics of exudative pharyngitis, rheumatic fever affects only a small proportion of infected persons, coupled with the known familial aggregation of rheumatic fever cases, has long suggested the possibility of a genetic predisposition to rheumatic attacks. Studies of the distribution of class 1 HLA antigens in rheumatics versus controls have been inconclusive. A statistically significant association has been reported between certain of the class II HLA antigens (HLA-DR2 in blacks[28] and HLA-DR4 in whites[29]) and rheumatic fever. An intriguing potential link between the genetic constitution of the human host and susceptibility to rheumatic fever is the identification of certain alloantigens that are expressed in a higher proportion of circulating B lymphocytes of rheumatic subjects and their family members than in those of patients with poststreptococcal glomerulonephritis or normal controls.[30]

Chapter 55: ACUTE RHEUMATIC FEVER

PATHOLOGY

Acute rheumatic fever is characterized by exudative and proliferative inflammatory lesions of the connective tissue, most notably of the heart, joints, and subcutaneous tissue. When carditis ensues, all layers of the heart are involved. Pericarditis is common and fibrinous pericarditis is occasionally present. The pericardial inflammation usually resolves over time with no clinically significant sequelae, and tamponade is rare. In fatal cases, myocardial involvement leads to globular enlargement involving all four chambers of the heart. In the myocardium, initially there is fragmentation of collagen fibers, lymphocytic infiltration, and fibrinoid degeneration. This is followed by the appearance of myocardial Aschoff nodules, which are considered pathognomonic of acute rheumatic fever. The Aschoff nodule consists of an area of central necrosis surrounded by lymphocytes, plasma cells, and large mononuclear and giant multinucleate cells. Many of these cells have an elongated nucleus with a clear area just within the nuclear membrane ("owl-eyed nucleus"). These cells are called *Anitschkow myocytes*, although histochemical studies suggest that they are of macrophage-histiocyte origin.[31] Aschoff nodules may also be found in endomyocardial biopsy specimens obtained from patients with acute rheumatic carditis.[32]

Endocardial involvement is responsible for chronic rheumatic valvulitis.[33] Small fibrinous, verrucous vegetations, 1 to 2 mm in diameter, are seen on the atrial surface at sites of valve coaptation and on the chordae tendineae. Even when no vegetations are present, there is edema and inflammation of the valve leaflets. A thickened and fibrotic patch (MacCallum's patch) may be found in the posterior left atrial wall. It is believed to be the effect of the mitral regurgitant jet impinging on the left atrial wall.[33] Healing of the valvulitis leads to granulation and fibrosis of the leaflets and fusion of the chordae. Valvular stenosis or incompetence may result. The mitral valve is involved most frequently, followed by the aortic valve. Tricuspid and pulmonic valves are usually spared.

Chapter 55: ACUTE RHEUMATIC FEVER

CLINICAL MANIFESTATIONS

Rheumatic fever may involve different organ systems such as heart, joints, skin, and central nervous system. The clinical picture depends upon the systems involved, and the manifestations may appear singly or in various combinations (Table 55-1). Five clinical features (carditis, polyarthritis, chorea, subcutaneous nodules, and erythema marginatum) are so characteristic of the disease that they are classified as major manifestations according to the Jones criteria (Table 55-2).[34] Additional findings such as fever, arthralgia, heart block, and acute-phase reactants in the blood (i.e., elevation of erythrocyte sedimentation rate and serum concentration of C-reactive protein) are commonly present in acute rheumatic fever but are nonspecific in nature and are therefore classified as minor manifestations.

Table 55-1: Clinical Manifestations of Acute Rheumatic Fever

General
High fever, lassitude, prostration, tachycardia
Cardiac
Cardiomegaly, congestive heart failure
Acute pericarditis, pericardial effusion
Apical pansystolic murmur (mitral regurgitation)
Apical middiastolic murmur (Carey Coombs)
Basal diastolic (aortic regurgitation)
Dermatologic
Subcutaneous nodules
Erythema marginatum
Rheumatologic
Arthralgia
Migratory polyarthritis
Neurologic
Sydenham's chorea

Table 55-2: Guidelines for the Diagnosis of the Initial Attack of Rheumatic Fever (Jones criteria, updated in 1992)[a]

Major Manifestations	Minor Manifestations	Supporting Evidence for Antecedent Group A Streptococcal Infection
Carditis	Clinical findings	Positive throat culture or rapid streptococcal antigen test
Polyarthritis	Arthralgia	
Chorea	Fever	
Erythema marginatum	Laboratory findings	Elevated or rising streptococcal antibody titer
Subcutaneous nodules	Elevated acute phase reactants	
	Erthrocyte sedimentation rate	
	C-reactive protein	
	Prolonged P-R interval	

[a]If supported by evidence of preceding group A streptococcal infection, the presence of two major manifestations or one major and two minor manifestations indicates a high probability of acute rheumatic fever.

SOURCE: From Dajani et al.[34] Reproduced by permission of *JAMA* 1992; 268:2069-2073, copyrighted 1992, American Medical Association.

The latent period from the onset of streptococcal sore throat to the onset of initial and recurrent attacks of rheumatic fever varies between 1 and 5 weeks with a median of 19 days. The mode of onset is quite variable. An abrupt onset with fever and toxicity is common in patients in whom acute polyarthritis is the presenting complaint. The onset may be insidious or even subclinical when mild carditis is the initial manifestation. Most attacks begin with polyarthritis, and occasionally this may be preceded by abdominal pain and fleeting signs of peritoneal inflammation, which may be misdiagnosed as acute appendicitis. Overall, arthritis occurs in approximately 75 percent of first attacks, carditis in 40 to 50 percent, chorea in 15 percent, and subcutaneous nodules and erythema marginatum in less than 10 percent.[35] These figures may vary widely, however.

Carditis

Carditis is the only manifestation of acute rheumatic fever that has the potential to cause long-term disability and death. Severe mitral regurgitation (or, possibly, severe myocarditis) may precipitate intractable heart failure and may be fatal during the acute phase of the disease. Fortunately, this complication is quite rare. Carditis, if present, usually appears within the first 3 weeks of the illness. The cardiac involvement is frequently mild or even asymptomatic, but occasionally the course can be fulminant. The diagnosis of carditis requires the presence of one of the following four manifestations: (1) organic cardiac murmurs not previously present, (2) cardiomegaly, (3) pericarditis, (4) congestive heart failure.

Valvulitis is associated with characteristic murmurs that are almost always present unless they are obscured by a loud pericardial friction rub, a large pericardial effusion, or low cardiac output. Mitral regurgitation leads to a blowing holosystolic murmur best heard at the apex and radiating to the axilla and occasionally to the base of the heart or the back. Hemodynamic and surgical pathologic studies conducted in South African patients suggest that mitral annular dilatation is usually the initial abnormality and predisposes to lengthening or rupture of the chordae tendineae and prolapse of the anterior leaflet.[36,37] Increased flow across the mitral valve in the presence of valvulitis may produce a middiastolic murmur (Carey Coombs murmur) that follows an S_3 gallop. This murmur is always accompanied by a systolic murmur of mitral regurgitation. It is not diagnostic of rheumatic fever because other conditions that lead to increased flow

across the mitral valve can cause a similar murmur, and in children an S_3 gallop can be physiologic. The Carey Coombs murmur can be differentiated from the diastolic rumble of mitral stenosis by the absence of an opening snap, presystolic accentuation, and loud first sound. A high-pitched decrescendo basal diastolic murmur of aortic regurgitation may also be heard. It is best heard along the left sternal border, over the aortic area, in expiration with the patient leaning forward (see also Chap. 57).

Myocarditis in the absence of valvulitis is not likely to be rheumatic in origin. Tachycardia is common. S_3, S_4, or summation gallops may be audible. Cardiomegaly may be noted on the chest roentgenogram or echocardiogram. In acute congestive heart failure, rapid distention of the hepatic capsule may lead to right-upper-quadrant discomfort and tenderness. Congestive heart failure is usually caused by left ventricular volume overload associated with severe mitral or aortic regurgitation.

In the presence of pericarditis, a pericardial friction rub or muffled heart sounds due to a large effusion may be noted. The presence of effusion should be confirmed by echocardiography. Large effusions leading to tamponade are rare. Pericarditis in the absence of valvular involvement is rarely due to acute rheumatic fever, and other causes should be sought.[34]

Polyarthritis

Arthritis is the most frequent major manifestation of rheumatic fever.[38] Any joint may be affected, but involvement of larger joints such as knees, ankles, elbows, and wrists is more common. The spine is only rarely affected. Several joints are involved in quick succession, and each for a brief period of time, resulting in the typical picture of migratory polyarthritis accompanied by signs and symptoms of an acute febrile illness. A striking feature of rheumatic arthritis is its dramatic response to salicylate therapy. Thus, the typical migratory polyarthritis pattern may not be present if effective anti-inflammatory therapy is administered early in the course of the disease.

The synovial fluid contains numerous white blood cells with a marked preponderance of polymorphonuclear leukocytes. Bacterial cultures are sterile. Inflammation of any one joint subsides spontaneously within a week and the entire bout of polyathritis rarely lasts more than 4 weeks. Resolution is complete with no residual joint damage. A possible exception is the so-called Jaccoud deformity of the metacarpophalangeal joints. This is a periarticular fibrosis and not a true synovitis, and its relation to rheumatic fever is unclear.[39]

Subcutaneous Nodules

These nodules are seen in only 1 to 21 percent of patients with rheumatic fever.[38] They are most often associated with carditis and rarely appear as an isolated manifestation of rheumatic fever. They are round, firm, painless, freely movable subcutaneous lesions varying in size from 0.5 to 2.0 cm. They occur in crops and are usually found over bony surfaces and over tendons such as elbows, knees, and wrists, the occiput and vertebrae (Fig. 55-1). They last for a week or two and disappear spontaneously. Similar nodules also occur in rheumatoid arthritis and systemic lupus erythematosus.

Figure 55-1: Subcutaneous nodules on the spine and elbows. (Courtesy of Dr. Benedict F. Massell.)

Erythema Marginatum

This rash is usually found on the trunk and proximal parts of the extremities, with the face being spared. It begins as an erythematous macule or papule that extends outward while skin in the center returns to normal. Lesions may merge and form serpiginous patterns. They are never pruritic or indurated, blanch on pressure, and are not influenced by anti-inflammatory therapy. The rash is evanescent, migrating from place to place and leaving no residual scarring. Individual lesions may appear and disappear in minutes to hours. Erythema marginatum has also been reported in sepsis, drug reactions, and glomerulonephritis.

Sydenham's Chorea (St. Vitus Dance)

This neurologic disorder often occurs in isolation, either unaccompanied by other major manifestations of rheumatic fever or after a latent period of several months, at a time when all other manifestations of rheumatic fever have subsided. It is characterized by rapid, purposeless, involuntary movements, most noticable in the extremities and face. The arms and legs flail about in erratic, jerky, uncoordinated movements. The speech is usually slurred and jerky. The involuntary movements disappear during sleep and may be suppressed by sedation. The patient is unable to sustain a tetanic muscular contraction. Emotional lability is characteristic of Sydenham's chorea and may often precede other neurologic manifestations. The duration of the chorea is variable, and its severity may wax and wane. Most patients recover in 6 months. Long-term sequelae such as convulsions, learning disabilities, and behavior problems are rare but have been reported in a small number of patients. Experience with brain imaging is limited but isolated case reports suggest that magnetic resonance imaging or computed tomographic scans may reveal abnormalities in the caudate nuclei, putamen, and substantia nigra.[40]

Rarely, chorea may be due to other conditions that affect the basal ganglia, including collagen vascular, endocrine, neoplastic, genetic, metabolic, and infectious disorders.[41] Perhaps the most frequent differential diagnostic consideration is systemic lupus erythematosus. The relationship of chorea occurring during pregnancy (chorea gravidarum) to acute rheumatic fever remains unclear.

Minor Manifestations

Minor manifestations of rheumatic fever include fever, arthralgia, and laboratory evidences of inflammation

(Table 55-2). Fever usually ranges from 38.4 to 40°C and rarely lasts for more than 3 to 4 weeks. Arthralgia is pain in one or more joints without objective evidence of inflammation. In diagnosing rheumatic fever using the Jones criteria, arthralgia should not be considered a minor manifestation when arthritis is present.

Other Clinical Features

Abdominal pain in rheumatic fever is the result of peritoneal inflammation and may be confused with acute appendicitis or sickle cell crisis. Because it occurs at the onset of the illness, other manifestations of rheumatic fever may not yet be present. Epistaxis has been reported as a manifestation of rheumatic fever, but it is not clear to what extent it may be attributable to the large doses of aspirin administered for treatment of the disease. Tachycardia may be out of proportion to fever and persists during sleep.

Chapter 55: ACUTE RHEUMATIC FEVER

LABORATORY FINDINGS

A mild to moderate normochromic normocytic anemia and leukocytosis with an increased proportion of polymorphonuclear leukocytes are common. Elevated serum levels of C-reactive protein and an increased erythrocyte sedimentation rate are almost always present, indicating acute inflammation. An exception is "pure" chorea, which may appear after these markers of inflammation have returned to normal.

Throat cultures are usually negative for group A streptococci by the time rheumatic fever appears. Streptococcal antibody tests provide evidence for antecedent streptococcal infection and include antistreptolysin O (ASO), anti-DNAse B, and antihyaluronidase. These antibodies reach peak titer at about the time of onset of acute rheumatic fever. The ASO is elevated in 80 percent or more of patients with rheumatic fever. A battery of these three tests will establish the presence of immunologically significant infection with group A streptococcus in 95 percent of patients.[42] The normal ranges for these titers vary depending upon the test used, patient's age, and geographic locale. ASO titers greater than 200 Todd units per milliliter in adults and 320 Todd units in children are generally considered elevated. In patients seen early during the course of rheumatic fever, rising antibody titers may be seen. An elevated streptococcal antibody titer is not diagnostic of rheumatic fever, but the diagnosis is very unlikely if all three tests (ASO, anti-DNAse B, and antihyaluronidase) are negative (see section on "Diagnosis" below (or exceptions).

Electrocardiogram

Persistent sinus tachycardia that does not resolve during sleep is common in the presence of carditis.[43] Sinus bradycardia and sinus arrhythmia may be present in some patients and can be abolished by the administration of atropine. Prolongation of the PR interval is a common abnormality. In various studies, the incidence varied from 10 to 84 percent.[43] A recent study of the resurgence of rheumatic fever[18] described the electrocardiographic findings in 232 patients. Alterations in atrioventricular conduction were noted in 74 patients (32 percent). Of these, 66 had a prolonged PR interval, 4 had transient episodes of AV block, and 4 had transient episodes of AV dissociation.

Some investigators have suggested that the AV conduction delay is a manifestation of carditis.[43] However, the response to atropine and the lack of correlation with clinical carditis suggests that this is a nonspecific finding.[34] Transient complete heart block that causes Stokes-Adams attacks has been described. Bundle-branch blocks are rare. Atrial flutter and fibrillation have been described in the presence of carditis. Low QRS voltage may be noted if a large pericardial effusion is present.

Echocardiogram

Few studies have used echocardiography to evaluate and follow up patients with rheumatic carditis.[44] During the resurgence of rheumatic fever in Salt Lake City, two-dimensional and Doppler echocardiograms were performed in children with rheumatic fever.[18] During the acute phase of rheumatic carditis, echocardiographic evidence of mitral regurgitation ws often found even when a murmur was not audible ("silent mitral regurgitation").

Valvular thickening and the presence of nodular lesions on the body and tips of the mitral leaflet have been described.[45] These are most likely echocardiographic equivalents of rheumatic verrucae. The key features of rheumatic mitral valvulitis were annular dilation and elongation of the chordae to the anterior leaflet, resulting in mitral regurgitation with a posterolaterally directed jet.[18] In an echocardiographic study of 73 patients with active rheumatic carditis and mitral regurgitation, it was noted that 90 percent of patients had elongated mitral valve chordae, 94 percent had prolapse of the anterior leaflet of the mitral valve, and 96 percent had annular dilation.[46] The resulting mitral regurgitant jet was directed toward the posterolateral wall of the left atrium. The site where this jet strikes the posterior left atrial wall corresponds with the site of endocardial thickening described at autopsy as MacCallum's patch. Rheumatic carditis can be differentiated from the common mitral valve prolapse syndrome because only the coapting portion of the anterior mitral leaflet prolapses and there is no billowing of the medial portion of the leaflet.

In the past congestive heart failure seen in acute rheumatic fever was attributed to myocarditis. Recent echocardiographic studies have shown that patients with rheumatic fever and congestive heart failure have preserved left ventricular systolic function and severe mitral regurgitation.[45,47] Thus the etiology of heart failure appears to be acute mitral regurgitation and not myocarditis.[19,44] Although these findings are interesting, experience is limited, and it is not yet clear the extent to which echocardiography has incremental diagnostic value when added to the clinical findings in the diagnosis of carditis or in ascertaining the likelihood of development of chronic rheumatic heart disease.

Endomyocardial Biopsy

Rheumatic fever is basically a clinical syndrome for which no specific diagnostic test exists. However, the presence of Aschoff nodules on histologic specimens obtained at surgery and autopsy can be considered diagnostic of rheumatic fever. Percutaneous transvenous myocardial biopsy is now feasible and may be useful in the diagnosis.[48] Aschoff nodules and interstitial mononuclear infiltrates with or without myocyte necrosis have been described in the myocardial biopsy specimens of four patients with acute rheumatic fever.[49-52] To determine the role of myocardial biopsy in the diagnosis of rheumatic carditis, a prospective study was performed in 54 patients.[32] Among 11 patients with definite clinical rheumatic carditis, 3 (27 percent) had Aschoff nodules in the biopsy specimen; the remainder had evidence of myocarditis, but the abnormalities were not diagnostic of rheumatic carditis. Among patients with suspected rheumatic carditis, myocardial specimens were diagnostic only in a minority of cases. The investigators concluded that the role of myocardial biopsy in the diagnosis of rheumatic fever was limited.

Chapter 55: ACUTE RHEUMATIC FEVER

DIAGNOSIS

The diagnostic criteria for acute rheumatic fever were originally proposed by T. Duckett Jones 1944 and have been later modified and updated by the American Heart Association (Table 55-2).[34] Based on their diagnostic importance, clinical and laboratory findings are divided into major and minor manifestations. If supported by evidence of a preceding group A streptococcal infection, the presence of two major manifestations, or of one major and two minor manifestations indicates a high probability of acute rheumatic fever. Supporting evidence of a previous group A streptococcal infection is a prerequisite for fulfilling the criteria.

There are some circumstances in which the diagnosis of rheumatic fever can be made without strictly adhering to the Jones criteria. Chorea may not occur until several months after the antecedent streptococcal pharyngeal infection. Isolated carditis that does not provoke congestive failure may not be recognized during the acute phase of illness yet may persist for months. In these situations, markers of inflammation may no longer be present and antistreptococcal antibody titers may have returned to normal by the time the illness comes to light. Moreover, in patients with previous rheumatic fever or established rheumatic heart disease, recurrences are common and a presumptive diagnosis of a recurrence may be made in the presence of a single major or several minor manifestations.[34]

Overdiagnosis must be avoided. Following well-documented group A streptococcal pharyngitis, vague signs and symptoms and nonspecific laboratory abnormalities may appear. Discomfort in the extremities, borderline temperature elevation, increased intensity of functional murmurs, tachycardia, elevated erythrocyte sedimentation rate, and prolonged PR interval may occur in the absence of major manifestations. These patients do not develop rheumatic heart disease on follow-up.[34] Thus the diagnosis of rheumatic fever should not be made in the absence of major manifestations. There is no evidence that temporarily withholding salicylates or corticosteriods has any adverse effect on the long-term prognosis. Thus premature administration of these drugs before the symptoms become distinct should be avoided.

Because acute rheumatic fever can have such diverse manifestations (acute polyarthritis, congestive heart failure, chorea, or combinations of these) and because there is no specific diagnostic test for the disease, the differential diagnostic possibilities in an individual case may be quite broad. Among the diseases that need most frequently to be differentiated are rheumatoid arthritis, juvenile rheumatoid arthritis, systemic lupus erythematosus, serum sickness, sickle cell crisis or cardiopathy, rubella arthritis, septic arthritis (especially gonococcal arthritis in adolescent patients), Lyme disease, infective endocarditis, viral myocarditis, and early stages of Henoch-Schönlein purpura. Less frequent differential diagnostic considerations include gout, sarcoidosis, Hodgkin's disease, and leukemia. Choreiform movements have been described in patients with systemic lupus erythematosus, neoplasms involving the basal ganglia, Legionnaire's disease, hypoparathyroidism, antiphospholipid syndrome, Wilson's disease, and Huntington's disease. Chorea is also seen occasionally in women taking oral contraceptives, and during pregnancy ("chorea gravidarum").

In areas of low rheumatic fever incidence, the Jones criteria are perhaps most useful in excluding the diagnosis. The specificity of the criteria is most problematic when the diagnosis is based upon acute polyarthritis as a single major manifestation plus laboratory findings indicative of acute

inflammation. In such cases, there must be clear-cut supporting laboratory evidence of recent streptococcal infection and alternative diagnoses must be carefully ruled out.

Chapter 55: ACUTE RHEUMATIC FEVER

TREATMENT

Antibiotics neither modify the course of the disease nor prevent the development of rheumatic carditis. Nevertheless, a course of antibiotics to eradicate group A streptococci remaining in the pharynx and tonsils is usually given. Penicillin G benzathine (1.2 million units intramuscularly as a single injection) is the treatment of choice for patients who are not allergic to penicillin. Erythromycin is prescribed for the penicillin-allergic patient. An oral cephalosporin is an acceptable alternative if the penicillin allergy is not of the immediate type. Following this, continuous prophylactic therapy is given to prevent streptococcal pharyngitis (see below).

Anti-inflammatory drugs provide dramatic clinical improvement but are not curative and do not prevent development of rheumatic heart disease.[53] Aspirin is very effective in reducing fever, toxicity, and inflammation of the joints. It is given as tolerated in a dosage of 90 to 100 mg/kg/day in children and 6 to 8 g/day in adults in divided doses every 4 h. A serum salicylate level of 20 to 25 mg/dL is adequate. Adverse effects include salicylism and gastrointestinal bleeding. The precise dose of aspirin is determined by the severity of symptoms, clinical response, salicylate levels, and tolerance to the drug. After 2 weeks of therapy, a reduced dose of aspirin may be used for another 6 weeks.

Corticosteroids are used in patients with carditis manifest by heart failure and in patients who do not tolerate aspirin or whose symptoms do not respond well to this drug. Prednisone 40 to 60 mg a day in divided doses is given for 2 to 3 weeks and the dosage is gradually reduced over the following 3 weeks. In some patients symptoms of rheumatic fever may reappear when the anti-inflammatory therapy, especially steroids, is stopped. Continuing aspirin therapy for 1 month after steroids are discontinued can prevent this. Although the use of nonster oidal anti-inflammatory drugs seems reasonable in patients who cannot tolerate salicylates and who do not require corticosteroids, there is a paucity of data on the use of these agents in acute rheumatic fever. Thus, their role in management remains to be defined.

Congestive heart failure is managed in the conventional manner. Digoxin should be used cautiously in the presence of myocarditis. After the acute attack subsides, the level of physical activity is determined by the cardiac status. Patients without residual cardiac disease do not require restriction of physical activity. In the rare instances in which patients with acute rheumatic fever develop intractable heart failure, mitral valve repair or replacement may be life-saving (see also Chap. 57).

Chapter 55: ACUTE RHEUMATIC FEVER

PROGNOSIS

Manifestations of chronic rheumatic heart disease include mitral and aortic insufficiency or stenosis, congestive heart failure, and atrial fibrillation. The ultimate cardiac prognosis of an individual rheumatic fever attack is rather directly related to the severity of cardiac involvement during the acute phase provided that the patient is protected from recurrent attacks (see below). In the United Kingdom-United States Collaborative Study,[54] only 6 percent of the patients with no carditis or only questionable carditis during their attack of acute rheumatic fever were found to have heart murmurs when reexamined 10 years later. Heart disease was present at follow-up in 30 percent of the patients initially found to have only apical systolic murmurs, in 40 percent of those with basal diastolic murmurs during the acute phase, and in 68 percent of those who initially suffered from congestive heart failure, pericarditis, or both. Some patients with "pure" chorea may later develop rheumatic heart disease, even though carditis was not recognized during the initial attack. In such cases, however, it may be that the initial findings of carditis were no longer prominent by the time that chorea (which often occurs after a long latent period) manifested itself.

Prevention

The risk of developing rheumatic fever following a symptomatic or asymptomatic streptococcal infection is much higher in patients who have experienced a previous attack than in nonrheumatic individuals. In some studies the recurrence rate following immunologically confirmed streptococcal upper respiratory infection has been as high as 16 percent.[2] In patients with rheumatic heart disease, recurrent attacks lead to progressive damage. Although patients who did not suffer carditis initially are less prone to develop it in the event of a recurrence, exceptions do occur. It is therefore crucial that rheumatic fever patients be protected optimally from streptococcal infections. This is accomplished by continuous antimicrobial prophylaxis.[55]

The recommended prophylactic regimens are shown in Table 55-3. The optimal duration of antibiotic prophylaxis remains controversial. The risk of acute rheumatic fever declines with age and the number of years since previous attack. The recommendations of the American Heart Association for the duration of secondary prophylaxis are given in Table 55-4. The decision to discontinue rheumatic fever prophylaxis must be individualized on the basis of risk of recurrence and the probable consequence of a recurrence. It should be noted that health care workers, individuals who have contact with schoolchildren, military recruits, and residents of areas with a high incidence of rheumatic fever are at increased risk for streptococcal infection. This fact should be taken into account when considering discontinuation of prophylaxis.

Table 55-3: Secondary Prevention of Rheumatic Fever (Prevention of Recurrent Attacks)

Agent	Dose	Mode
Benzathine penicillin G	1 200 000 U every 4 weeks[a]	Intramuscular
	or	
Penicillin V	250 mg twice daily	Oral
	or	
Sulfadiazine	0.5 g once daily for patients	Oral
	≤27 kg (60 lb)	

	1.0 g once daily for patients	
	>27 kg (60 lb)	
For individuals allergic to penicillin and sulfadiazine		
Erythromycin	250 mg twice daily	Oral

[a]In high-risk situations, administration every 3 weeks is justified and recommended.

Part 9: VALVULAR HEART DISEASE
Chapter 56:

AORTIC VALVE DISEASE

Author: Shahbudin H. Rahimtoola

The assessment and management of patients with valvular heart disease has undergone many changes in the past four decades. The incidence of acute rheumatic fever has declined, and as a result rheumatic heart disease is not the most important cause of valve disease in the developed countries. Prolapse of the mitral valve and congenital aortic valve disease are now the most common valvular lesions. Valve surgery has been the major therapeutic advance in treating patients with severe valve disease; in fact, most patients with severe valve disease are now considered candidates for surgery. Echocardiography/Doppler ultrasound has a very important role in the diagnosis and follow-up of these patients. Cardiac catheterization/angiography remains an extremely important diagnostic procedure that is needed in almost all patients being considered for interventional therapy. Catheter balloon valvuloplasty is a useful technique for the treatment of some stenotic cardiac valves.

AORTIC VALVE STENOSIS

Aortic stenosis (AS) is obstruction to outflow of blood flow from the left ventricle to the aorta. The obstruction may be at the valve, above the valve (supravalvular), or below the valve (subvalvular).[1] Supravalvular AS is a congenital lesion. Subvalvular AS results either from a discrete fibromuscular obstruction, which is a congenital lesion, or from a muscular obstruction (hypertrophic cardiomyopathy).

Etiology

The most common causes of AS are congenital,[2,3] rheumatic, and calcific (degenerative) (Table 56-1). Calcific AS is seen in patients 35 years of age or older and is the result of calcification of a congenital or rheumatic valve or of a normal valve that has undergone "degenerative" changes.[4] Recent data suggest that degenerative/calcific AS may represent an immune reaction to antigens present in the valve[5] and is related to atherosclerosis.[6]

Table 56-1: Etiology of Aortic Valve Stenosis

I. Congenital
II. Acquired
    A. Rheumatic
    B. Calcific (degenerative/autoimmune)
    C. Rare causes
        1. Obstructive infective vegetations
        2. Homozygous type II hyperlipoproteinemia
        3. Paget's disease of bone
        4. Systemic lupus erythematosus
        5. Rheumatoid involvement
        6. Ochronosis (alkaptonuria)
        7. Irradiation

Rare causes of AS include obstructive, infective vegetations that are usually large, e.g., those seen in fungal

endocarditis. Atherosclerotic AS is seen most frequently in patients with severe hypercholesterolemia and is observed in children and young adults with homozygous type II hyperlipoproteinemia.[7,8] Paget's disease of the bone,[9] end-stage renal disease,[10,11] systemic lupus erythematosus, rheumatoid involvement, ochronosis,[12] and irradiation are other rare causes of AS.

At the present time, calcific AS in the older patient is the most common valve lesion requiring valve replacement.[4,13] Among patients under the age of 70, congenital bicuspid valve accounted for one-half of the surgical cases; degenerative changes were the cause in 18 percent.[4] In contrast, in those aged 70 or older, degenerative changes accounted for almost one-half of the surgical cases and a congenital bicuspid valve for approximately one-quarter of the cases (Fig. 56-1).

Pathology

In congenital AS, the valve may be unicuspid, bicuspid, or tricuspid, depending on the patient's age.[14] In patients under the age of 15 years, over 80 percent of stenotic valves are either unicuspid or bicuspid and 15 to 20 percent are tricuspid. In patients aged 15 to 65 years, 60 percent are bicuspid, 10 percent are unicuspid, and 25 to 30 percent are tricuspid. In patients 65 years of age or over, 90 percent of the valves are tricuspid and 10 percent are bicuspid. Unicuspid valves produce severe obstruction in infancy and are the most frequent malformation found in fatal valvular AS in children under the age of 1 year.[2] Congenital bicuspid valves can produce severe obstruction to left ventricular (LV) outflow after the first few years of life.[3] The valvular abnormality produces turbulent flow, which traumatizes the leaflets and eventually leads to fibrosis, rigidity, and calcification of the valve. In a congenitally abnormal tricuspid aortic valve, the cusps are of unequal size and have some degree of commissural fusion; the third cusp may be diminutive. Eventually, the abnormal structure leads to changes similar to those seen in a bicuspid valve, and significant LV outflow obstruction often results. In calcific AS (so called "degenerative") early changes show chronic inflammatory cell infiltrate (macrophages and T lymphocytes), lipid in lesion and in adjacent fibrosa and thickening of fibrosa with collagen and elastin.[6] These patients also have a higher incidence of risk factors for coronary atherosclerosis.[15]

Rheumatic AS results from adhesions and fusion of the commissures and cusps. The leaflets and the valve ring become vascularized, which leads to retraction and stiffening of the cusps. Calcification occurs, and the aortic valve orifice is reduced to a small triangular or round opening, which is frequently regurgitant as well as stenotic. Importantly, the heart exhibits other evidence of rheumatic heart disease-namely, involvement of the mitral valve and presence of Aschoff's nodules in the myocardium.

Rheumatoid AS is extremely rare and results from nodular thickening of the valve leaflets and the involvement of the proximal part of the aorta. In severe forms of hypercholesterolemia, lipid deposits occur not only in the aortic wall but also in the aortic valve and occasionally produce AS.

The LV is concentrically hypertrophied.[16] The hypertrophied cardiac muscle cells are increased in size, with their transverse diameters ranging from 15 to 70 μm (normal, 10 to 15 μm). There is an increase of connective tissue,[17-19] and a variable amount of fibrous tissue (collagen fibrils) in the interstitial tissue. Usually, the cardiac muscle cells do not degenerate in patients with AS. Myocardial ultrastructural changes[20] may account for the LV systolic dysfunction that occurs late in the disease; such changes include unusually large nuclei, loss of myofibrils, accumulation of mitochondria, large cytoplasmic areas devoid of contractile material, and proliferation of fibroblasts and collagen fibers in the interstitial space.

Subclinical calcific emboli are commonly found in calcific AS if diligently sought at autopsy.

Pathophysiology

With reduction in the *aortic valve area* (AVA), energy is dissipated during the transport of blood from the LV to the aorta. The AVA has to be reduced by about 50 percent of normal before a measurable gradient can be demonstrated in humans.[21] When a pressure gradient develops between the left ventricle and the ascending aorta, LV pressure rises; aortic pressure remains within the normal range until end-stage heart

failure occurs. The relationship of the AVA to cardiac output and pressure gradient is discussed in Chap. 57. As LV pressure rises, ventricular wall stress increases, which leads to impaired LV function. The heart normalizes wall stress by becoming hypertrophic. Since AS develops slowly, hypertrophy develops in proportion to increased intraventricular pressure, and myocardial stress remains normal.[22] *Thus, the major compensatory mechanism by which the heart copes with LV outflow obstruction is ventricular hypertrophy*. LV mass in patients with severe AS undergoing valve replacement averages 229 g/m^2 (normal, 105 g/m^2);[22] at autopsy, left ventricles weighing as much as 1000 g have been reported. LV volume, however, is within the normal range,[22] and so there is a considerable thickening of the LV wall.

The diastolic properties of the LV are affected in AS.[23-27] This diastolic abnormality results from a combination of impaired myocardial relaxation with altered chamber compliance because the hypertrophied LV per se offers increased resistance to filling, and from increased myocardial stiffness because of structural alterations.[27] As a result, LV end-diastolic pressure is elevated, but this is not necessarily a measure of LV failure. Powerful atrial contraction produces the required LV filling and results in an elevated LV end-diastolic pressure (atrial booster pump function).[28,29] The necessary LV filling and fiber length to achieve an adequate stroke volume are achieved by atrial systole, which occupies only a small part of the cardiac cycle. Therefore there is a transient increase in left atrial pressure due to the large *a* wave, but mean left atrial pressure remains in the normal range or is only minimally increased (Fig. 56-2).

Left atrial contraction is therefore of considerable benefit to these patients. Loss of effective atrial contraction, either because of atrial fibrillation or because of an inappropriately timed atrial contraction [e.g., that associated with first-degree heart block or with atrioventricular (AV) dissociation], results in elevations of mean left atrial pressure, reduction of cardiac output, or both and may precipitate clinical heart failure with pulmonary congestion.

Patients with severe LV hypertrophy may exhibit LV diastolic dysfunction, which may produce the syndrome of clinical heart failure (paroxysmal nocturnal dyspnea, orthopnea, and even pulmonary edema) even if LV systolic pump function is normal. In patients 60 years of age or older, a higher percentage of women (41 percent) than men (14 percent) have "excessive" hypertrophy, that is, greater amounts of hypertrophy in spite of similar degrees of severity of AS.[30] They have "supernormal" LV systolic pump function (high LV ejection fraction) and a small, thick-walled chamber with lower end-systolic wall stress (Table 56-2).

LV systolic pump function is determined by myocardial (muscle) function and by a combination of LV afterload and preload. Thus, impaired LV systolic pump function (as measured by ejection fraction) may be the result of afterload-preload mismatch,[31] impaired myocardial function, or both. LV systolic pump function is normal in most patients with severe AS. When the LV hypertrophy alone is not adequate to overcome the outflow obstruction, the left ventricle uses the Frank-Starling mechanism (preload reserve) to maintain systolic pump function. When the preload reserve is no longer adequate, a reduction of LV systolic pump function occurs (Fig. 56-2). In AS, major use of the preload reserve is not a good compensatory mechanism. Even small increases in LV volume may result in major increases in LV end-diastolic pressure because the LV is on the very steep portion of its diastolic pressure-volume curve, and the corresponding increase in mean left atrial pressure produces pulmonary edema. Thus, clinical heart failure may be a result of either LV diastolic dysfunction in the presence of normal LV systolic function or impaired myocardial function producing LV systolic dysfunction, with or without associated LV diastolic dysfunction. Eventually, pulmonary artery, right ventricular, and right atrial pressures are elevated. Peripheral edema results from increases in systemic venous pressure and salt and water retention.

In most patients with AS, cardiac output is in the normal range and initially increases normally with exercise. Later, as the severity of AS increases progressively, the cardiac output remains within the normal range at rest, but, on exercise, it no longer increases in proportion to the amount of exercise undertaken or does not increase at all (fixed cardiac output). With the development of heart failure, there is a reduction in the resting cardiac output and a tachycardia. As a result, stroke volume may be so lowered that it results in a small gradient across the LV outflow tract in spite of severe AS. As the patient's age increases, there is a

progressive decrease of cardiac output with exercise and a progressive increase of LV end-diastolic pressure at equal levels of AVA. This may be related only to LV diastolic dysfunction and is most marked in the older patient.[32]

In severe AS, myocardial oxygen needs are increased because of an increased muscle mass (hypertrophy), elevations in LV pressures, and prolongation of the systolic ejection time (Fig. 56-3). Total coronary blood flow is increased because of the severe LV hypertrophy; however, coronary blood flow per 100 g of LV mass is reduced.[33] As a result, blood flow to the subendocardium[34] is inadequate at rest; and because coronary vasodilator reserve is reduced,[35] myocardial blood flow is also reduced further, relative to need, on exercise. Coronary blood flow is reduced because of a reduced coronary perfusion pressure (the elevated LV end-diastolic pressure lowers the diastolic aortic-LV pressure gradient) and also because the hypertrophied myocardium compresses the coronary arteries as they traverse the myocardium to supply blood to the subendocardium (systolic "milking" of intramural arteries). As a result, patients may have classic angina pectoris even in the absence of *coronary artery disease* (CAD). Associated obstructive CAD from atherosclerosis further increases the imbalance between myocardial oxygen needs and supply (Fig. 56-2).

Clinical Findings

HISTORY

Patients with congenital valve stenosis may give a history of a murmur since childhood or infancy; those with rheumatic ste nosis may have a history of rheumatic fever. Most patients with valvular AS, including some with severe valve stenosis, are asymptomatic. The symptoms of AS are angina pectoris, syncope, exertional presyncope, dyspnea (on exertion, orthopnea, paroxysmal nocturnal dyspnea, pulmonary edema), and the symptoms of heart failure. Once symptoms occur in a patient with severe AS, the life span of the patient is very short without surgical treatment. Sudden cardiac death is stated to occur in 5 percent of patients with AS. It occurs only in those with severe valve stenosis, most of whom have had some cardiac symptoms before the fatal episode. Typical angina pectoris occurs with or without associated CAD and results from an imbalance between myocardial oxygen needs and supply (Fig. 56-3).

Syncope is the result of reduced cerebral perfusion. Syncope occurring on effort is caused by either systemic vasodilatation in the presence of a fixed or inadequate cardiac output, an arrhythmia, or both.[36-38] Syncope at rest is usually due to a transient ventricular tachyarrhythmia, from which the patient recovers spontaneously. Other possible causes of syncope include transient atrial fibrillation or transient AV block, during which the ventricle is deprived of the powerful atrial booster pump function and/or the ventricular rate is slow.

Dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema result from varying degrees of pulmonary venous hypertension. Systemic venous congestion with enlargement of the liver and peripheral edema result from increased systemic venous pressure and salt and water retention. There is an increased incidence of gastrointestinal arteriovenous malformations.[39,40] As a result, these patients are susceptible to gastrointestinal hemorrhage and anemia. Calcific systemic embolism may occur.[41,42]

PHYSICAL FINDINGS

There is a spectrum of physical findings in patients with AS, depending on the severity of the stenosis, stroke volume, LV function, and the rigidity and calcification of the valve (Table 56-3). The arterial pulse rises slowly, taking a longer time than normal to reach peak pressure, and the peak is reduced (*parvus et tardus*);[43] the pulse pressure may be narrowed. The anacrotic notch on the upstroke is best appreciated in the carotid arteries. The more severe the valve stenosis, the lower the anacrotic notch on the arterial pulse. A systolic thrill may be felt in the carotid arteries. The jugular venous pulse is normal unless the patient is in heart failure. In the absence of heart failure, the heart size is normal. The cardiac impulse is heaving and sustained in character, and there may be a palpable fourth heart sound (S_4). An aortic systolic thrill is often present at the base of the heart. In 80 to 90 percent of adult patients with severe AS, there is an S_4 gallop

sound, a midsystolic ejection murmur that peaks late in systole, and a single second heart sound (S_2) because A_2 and P_2 are superimposed or A_2 is absent or soft. There is often a faint early diastolic murmur of minimal aortic regurgitation. In the young patient with valvular AS, a systolic ejection sound (systolic ejection click) initiates the systolic murmur but later tends to disappear as AS becomes severe. The S_2 may be paradoxically split due to late A_2, and there may be no early diastolic murmur. In many patients, particularly the elderly, the systolic ejection murmur is atypical, may be soft, is described as a seagull sound (or musical, or cooing), and may be heard only at the apex of the heart (Gallavardin phenomenon). In the presence of heart failure, the jugular venous pressure is often increased, the left ventricle is dilated, a third heart sound is present, and the systolic murmur may be very soft or absent. Thus, the clinical features on physical examination may resemble those of heart failure from a variety of causes, such as dilated cardiomyopathy, rather than AS (see also Chap. 10).

Table 56-3: Physical Examination of Patients with Varying Severity of Aortic Valve Stenosis

	Mild	Moderate	Severe + Normal LV Function	Severe + LV Dysfunction	Severe + Heart Failure[a]
Arterial pulse	Normal	Slowly rising	*Parvus et tardus*	*Parvus et tardus*	Small volume
Jugular venous pulse	Normal	Normal	Normal	Normal	±
Carotid thrill	±	±	±	±	±
Cardiac impulse	Normal	Heaving	Heaving, sustained palpable *a* wave	Heaving	Heaving or reduced
Precordial thrill	±	±	Usually ++	±	-
Auscultation					
S_4	-	±	++	+	-
S_3	-	-	-	±	+
ESS	+	±	-	-	-
Peak of ESM	Early systole	Mid-systole	Late systole	Late to mid-systole, soft	Mid-systole, soft or absent
S_2	Normal	Normal or single	Single or paradoxical	Single	Single

[a]There may be signs of mitral and tricuspid regurgitation and of pulmonary hypertension.
ABBREVIATIONS: S_4 = fourth heart sounds (presystolic gallop); S_3 = third heart sound (diastolic gallop); ESS = ejection systolic sound; ESM = ejection systolic murmur; S_2 = second heart sound.

Severe valvular AS is common in patients 60 years of age or older.[13,44] The clinical features in many of these patients tend to be somewhat different from those typical of younger patients.[44] Systemic hypertension is common, being present in about 20 percent of the patients, half of whom have moderate or severe systolic and diastolic hypertension. A fifth of the patients first present in congestive heart failure. The male:female ratio is 2:1. Because of thickening of the arterial wall and its associated lack of

dispensability, the arterial pulse rises normally or even rapidly, and the pulse pressure is wide. The S_2 is either absent or single. As noted above, the murmur may be high-pitched and musical and may radiate from the base to the apex or may be heard best at the apex, mimicking mitral regurgitation.

CHEST X-RAY

The characteristic finding is a normal-sized heart with a dilated proximal ascending aorta (poststenotic dilation). Calcium in the aortic valve can be seen on the lateral film but is better appreciated by fluoroscopy with image intensification. In the current era, calcification is most easily recognized on twodimensional echocardiography. Calcium in the aortic valve is the hallmark of AS in adults 40 to 45 years of age.[45,46] In patients aged 45 years or above, the diagnosis of severe AS is doubtful if there is no calcium in the aortic valve. The presence of calcium, however, does not necessarily mean that the valve is stenotic or that the AS is severe. In patients with heart failure, the cardiac size is increased because of dilatation of the left ventricle and left atrium; the lung fields show pulmonary edema and pulmonary venous congestion with redistribution of blood flow. In the presence of heart failure, the right ventricle and the right atrium may be dilated.

ELECTROCARDIOGRAM

The *electrocardiogram* (ECG) in severe AS shows LV hypertrophy with or without secondary ST-T-wave changes. It is important to recognize, however, that in about 10 to 15 percent of patients with severe AS, LV hypertrophy cannot be appreciated on the ECG. In fact, the ECG may be entirely normal in some of these patients. The P-wave abnormality (P = 0.12 s) of left atrial enlargement and/or hypertrophy and/or conduction delay is present in over 80 percent.[47] The ECG may show left bundle branch block, right bundle branch block with left or right axis deviation, or, occasionally, isolated right bundle branch block.[48-50] In some patients, the conduction abnormality results from aortic valve calcification extending into the specialized conducting tissue, which may even produce heart block. The patients are usually in sinus rhythm. The presence of atrial fibrillation indicates the presence of either associated mitral valve disease, CAD, or heart failure secondary to aortic valve disease. Atrial fibrillation is relatively common in the elderly with calcific AS, probably because of the increased presence of associated diseases.

Laboratory Investigations

ECHOCARDIOGRAPHY/DOPPLER ULTRASOUND

Echocardiography/Doppler (echo/Doppler) ultrasound (Chap. 13) is an extremely important and useful noninvasive test. On the echocardiogram, the aortic valve leaflets normally are barely visible in systole, and the normal range of aortic valve opening is 1.6 to 2.6 cm. In the presence of a bicuspid aortic valve, eccentric valve leaflets may be seen. The aortic valve leaflets may appear to be thickened as a result of calcification and/or fibrosis; however, the older patient without valve stenosis may also have thickened cusps. The aortic valve may have a reduced opening, but this also occurs in other conditions in which the cardiac output is reduced. The LV hypertrophy often results in thickening of both the interventricular septum and the posterior LV wall. The LV cavity size is normal. All these abnormalities are better appreciated on two-dimensional echocardiography. When LV systolic function is impaired, the left ventricle and left atrium are dilated and the percentage of dimensional shortening is reduced.

In many patients, the severity of AS is incorrectly estimated by M-mode or two-dimensional echocardiography. Neither is a completely reliable technique for assessing the severity of AS. The presence of normal movement of thin aortic leaflets on the echocardiogram, however, is strong evidence against severe AS in adults.

Echo/Doppler, when properly applied, is extremely useful for estimating the valve gradient and AVA noninvasively.[50-56] When compared with results obtained at cardiac catheterization, the standard error of the estimate of mean gradient in the best laboratories is 10 mmHg.[57] Thus, the mean gradient by Doppler can be expected to be within ±20 mmHg (95 percent confidence level) of that obtained at catheterization.[57]

Similarly, the AVA will be within ±0.3 cm^2 of that obtained at cardiac catheterization.[57] A recent study of 156 patients compared AVA obtained by cardiac catheterization with that obtained by Doppler ultrasound.[58] Of 125 patients with AVA 0.8 cm^2 at cardiac catheterization, in 36 (29 percent) Doppler-estimated AVA was ≥0.9 cm^2. In all 7 patients with AVA >1.0 cm^2 by cardiac catheterization, Doppler-estimated AVA was 1.0 cm^2; the findings in these 7 patients must be interpreted cautiously because they were likely to be a highly selected subgroup. Guidelines for assessing severity of AS based on Doppler-obtained gradients are shown in Table 56-4. In a study of 636 patients studied by cardiac catheterization, no single aortic valve gradient was found to be both sensitive and specific for severe AS. A mean gradient of ≥50 mmHg or a peak gradient ≥60 mmHg were "specific" with a 90 percent or more positive predictive value. It was not possible to find a lower limit with 90 percent negative predictive value.[59] Thus, a mean gradient of <50 mmHg is compatible with mild, moderate, or severe AS.

Table 56-4: Suggested Conservative Guidelines for Relating Severity of Aortic Stenosis to Doppler Gradients in Adults with Normal Cardiac Output and Normal Average Heart Rate

Peak Gradient, mmHg	Mean Gradient, mmHg	Severe AS
≥80	≥70	Highly likely
60-79	50-69	Probable
<60	<50	Uncertain

Transesophageal echo/Doppler ultrasound is very useful in defining the aortic valve abnormality and in assessing its severity when an adequate examination cannot be obtained with the transthoracic technique.

CARDIAC CATHETERIZATION/ANGIOGRAPHY

Cardiac catheterization remains the standard technique to assess the severity of AS "accurately." This is done by measuring simultaneous LV and ascending aortic pressures and measuring cardiac output by either the Fick principle or the indicator dilution technique. The AVA can be calculated (see Chap. 15). It is important to calculate AVA.[59] AS can be considered to be severe when the valve area is 1.0 cm^2 or less or the AVA index is 0.6 cm^2 per square meter or less (Table 56-5).[57] The state of LV systolic pump function can be quantitated by measuring LV end-diastolic and end-systolic volumes and ejection fraction. *It must be recognized that ejection fraction may underestimate myocardial function in the presence of the increased afterload of severe AS.*

Table 56-5: A Suggested Grading of the Degree of Aortic Stenosis

Aortic Stenosis	AVA, cm^2	AVA Index, cm^2/m^2
Mild	>1.5	>0.9
Moderate	>1.0-1.5	>0.6-0.9
Severe[a]	≤0.8-1.0	≤0.4-0.6

[a]Patients with AVAs that are at borderline values between the moderate and severe grades (0.9-1.1 cm^2; 0.55-0.65 cm^2/m^2) should be considered individually.
ABBREVIATIONS: AVA = aortic valve area.
SOURCE: From Rahimtoola,[57] with permission.

The presence of CAD and its site and severity can be estimated only by selective coronary angiography, which should be performed in all patients 35 years of age or older being considered for valve surgery and in those <35 years if they have LV systolic dysfunction, symptoms or signs suggesting CAD, or two or more risk factors for premature CAD (excluding gender) (Table 56-6). The incidence of associated CAD will vary considerably depending on the prevalence of CAD in the population.[57,60] It was reported to be 50 percent in patients with AS and 20 percent in patients with aortic regurgitation.[57] In general, in persons 50 years of age or older, it is about 50 percent (Table 56-7).[44,61-63]

Table 56-6: Aortic Valve Disease: Indications for Coronary Arteriography

GATED BLOOD POOL RADIONUCLIDE SCANS

Gated blood pool radionuclide scans provide information on ventricular function similar to that provided by two-dimensional echocardiography and LV cineangiography. These studies are of particular value in the occasional patient in whom LV cineangiography is unsuccessful and echocardiographic studies are suboptimal.

EXERCISE TESTS

It is usually recommended that exercise tests of any kind not be undertaken in patients with severe AS unless there is a specific reason for such studies. Exercise tests in these patients may precipitate ventricular tachyarrhythmias and ventricular fibrillation. If there is doubt about the severity of AS and concern that the patient's symptoms may not be caused by AS, it is usually wise to document the absence of severe AS before performing an exercise test. Occasionally, in a patient with severe AS who denies all symptoms, a closely monitored exercise test by experienced and skilled physician(s) may be needed to assess exercise capacity but should usually *only* be undertaken after exclusion of associated significantly obstructive CAD.

AMBULATORY ECG RECORDING

Ambulatory ECG recordings may be needed in an occasional patient suspected of having an arrhythmia[64,65] or painless ischemia. Occasionally, patients with mild or moderate AS who are symptomatic may be suspected of having an arrhythmia or painless ischemia as a cause of the symptoms. At times, in asymptomatic patients with severe AS, one may need to determine if the patient has painless ischemia (see also Chap. 25).

PROVOCATIVE DIAGNOSTIC TEST

In an occasional patient, the severity of the AS may be in doubt because of a small stroke volume and small mean aortic valve gradient. The AS may be severe or mild to moderate, and the calculated AVA may be very small because of severe stenosis or because the small stroke volume only opens the valve to a limited extent; thus, the AVA will be determined to be small even on echo/Doppler ultrasound. Infusion of an inotropic agent such as dobutamine, which results in increases of stroke volume and heart rate, usually helps one to make a correct diagnosis. In these circumstances, it is important to measure cardiac output and LV and aortic pressures simultaneously and meticulously, both before and during dobutamine infusion. Whether the AS is mild or severe the gradient increases with dobutamine infusion; however, in mild AS the AVA increases significantly; but in severe AS the AVA does not increase or increases minimally (approximately 10 percent).

Clinical Decision Making

There are a number of steps involved in clinical decision making in patients with valvular heart disease (Table 56-8).[57] The first is a complete clinical evaluation, which includes history, physical examination, ECG, and chest x-ray. Next, disease of all cardiac valves, ventricular function, and hemodynamic effects as well as CAD, other cardiovascular disease, and disease of other organs should be diagnosed and the severity assessed. Before proceeding to additional testing, it is important to list the question(s) to be answered and to be reasonably certain that these questions need to be answered. The test(s) that are most likely to provide these answers *in the clinician's own institution* should then be performed, with the following criteria being kept in mind: reliability, accuracy, lowest risk to patient, and reasonable (lowest) cost. The results of the test(s) should be reviewed as they become available, and an overall evaluation/assessment of the patient and, finally, recommendations regarding management should be made.

In a prospective, blinded study of consecutive patients with valvular heart disease, the sensitivity and specificity of diagnosis of AS and the accuracy of assessment of severity of AS were determined (Table 56-9).[66] This study revealed the following important points: (1) Clinical evaluation was sensitive, highly specific, and reasonably accurate in diagnosing AS and was very accurate in assessing its severity when AS

was moderate or severe. This emphasizes the importance of a thorough clinical evaluation of the patient. (2) Echo/Doppler ultrasound improved the accuracy of this assessment to a certain extent. (3) The reason clinical evaluation and echo/Doppler do not have a 100 percent specificity is the inability in an occasional patient to distinguish mild AS from turbulence across a normal or slightly diseased aortic valve. (4) Both clinical evaluation and echo/Doppler ultrasound are excellent in diagnosing the AS as being at least moderate or severe. (5) An important difficulty in diagnosis by clinical evaluation and by echo/Doppler is in not being able to separate accurately all patients with moderate AS from those with severe AS.

Table 56-9: Clinical Decision Making Utilizing Clinical Evaluation and Echo/Doppler in Patients with Aortic Stenosis

	After Clinical Evaluation, %	After Echo/Doppler, %
Diagnosis of AS		
Sensitivity	78	100
Specificity	92	92
Accuracy of diagnosis		
All levels of severity	48	65
Moderate or severe AS	100	100

Natural History and Prognosis

Valvular AS is frequently a progressive disease, the severity increasing over time.[67-71] The factors that control this progression and the time it takes for severe outflow obstruction to develop are unknown; however, it appears that in the older patient, AS may progress at about twice the rate that it does in the younger patient.[72] In a study of 142 patients with "mild" stenosis (catheterization-proven AVA >1.5 cm^2),[73] the rate of progression to severe stenosis was 8 percent in 10 years, 22 percent in 20 years, and 38 percent in 25 years. At 25 years, 38 percent still had mild AS (Table 56-10). The duration of the asymptomatic period after the development of severe AS is also unknown; some recent data suggest that it may be less than 2 years. The outcome of the asymptomatic patient with severe AS is not known. In the study of 123 asymptomatic patients aged 63 ± 16 years, the actuarial probability of death or aortic valve surgery was 7 ± 5 percent at 1 year, 38 ± 8 percent at 3 years, and 74 ± 10 percent at 5 years.[74] The event rate at 2 years for peak aortic jet velocity by Doppler ultrasound of >4 m/s was 79 ± 18 percent, for 3 to 4 m/s was 66 ± 13 percent, and for <3 m/s was 16 ± 16 percent. However, the limitations of gradients and of aortic peak velocity obtained by Doppler ultrasound should be kept in mind.[75] The overwhelming majority of adults with severe AS who are seen by cardiologists have symptoms.

Table 56-10: Natural History of Mild[a] Aortic Stenosis (*n* = 142)

	10 Years	20 Years	25 Years
Mild	88%	63%	38%
Moderate	4%	15%	25%
Severe	8%	22%	38%

[a]Mild stenosis is defined here as an aortic valve area >1.5 cm^2.
SOURCE: From Horstkotte and Loogen,[73] with permission.

Severe disease in adults is lethal, particularly if the patient is symptomatic, with a prognosis that is worse than for many forms of neoplastic disease.[57] The 3-year mortality is approximately 36 to 52 percent, the 5-year mortality is about 52 to 80 percent, and the 10-year mortality is 80 to 90 percent.[57] A recent study of elderly patients (average age 77 years) showed 1-year and 3-year mortalities were 44 and 75 percent, respectively.[76] With the onset of severe symptoms (angina, syncope, or heart failure), the average life expectancy is 2 to 3 years (Table 56-11).[73,77] Almost all patients with heart failure are dead in 1 to 2 years.[73,77] A combination of symptoms is much more ominous, a sign of a greatly reduced survival. Sudden death, like syncope, occurs in the presence of severe AS. Its exact incidence is difficult to determine but may be about 5 percent.[77] Most but not all of these patients have had some cardiac symptoms before the fatal episode; at times, the only symptom has been exertional presyncope. Patients with aortic valve "sclerosis" have an approximately 50 percent increase in cardiovascular mortality and myocardial infarction.[78] This incidence is lower than in patients with AS, and aortic sclerosis appears to be a marker for vascular atherosclerosis.

Table 56-11: Average Survival of Symptomatic Patients with Severe AS

	Autopsy Data,[a] Years	Post Cardiac Catheterization,[b] Months
Overall	3	23
Angina	5	45
Syncope	3	27
Heart failure	<2	11

Management

All patients with AS need antibiotic prophylaxis against infective endocarditis (see Chap. 73). Those in whom the valve lesion is of rheumatic origin need additional prophylaxis against recurrence of rheumatic fever. Patients with mild or moderate stenosis rarely have symptoms or complications and do not need any specific medical therapy (Table 56-12). In mild stenosis, the patient should be encouraged to lead a normal life. Those with moderate AS should avoid moderate to severe physical exertion and competitive sports. In patients with mild or moderate AS, if atrial fibrillation should occur, it should be reverted rapidly to sinus rhythm. In severe AS, reversion to sinus rhythm often becomes a matter of some urgency.

Table 56-12: Medical Treatment of Patients with Aortic Valve Stenosis

I. Antibiotic prophylaxis
   A. Infective endocarditis (Chap. 82)
   B. Recurrent rheumatic carditis (Chap. 62)

II. Restriction of activities
   A. Severe exercise
   B. Competitive sports

III. Arrhythmias
   A. Prevent and/or control
   B. Restore sinus rhythm, if possible

IV. Cardiac medications (only if essential)
   A. Avoid negative inotropic and proarrhythmic agents if possible
   B. Diuretics-use cautiously
   C. Arteriolar and venodilators-use cautiously

V. Follow-up of asymptomatic patients
   A. Mild AS: Every 2-5 years
   B. Moderate AS: Every 6-12 months
   C. Develop symptoms: Immediate

SOURCE: Copyright S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C. See Ref. 93.

Operation should be advised for the symptomatic patient who has severe AS. In young patients, if the valve is pliable and mobile, simple commissurotomy or valve repair may be feasible; the operative mortality is <1 percent.[79] It will relieve outflow obstruction to a major degree. In such patients, catheter balloon valvuloplasty is the procedure of choice in experienced and skilled centers. Both of these are palliative procedures that postpone valve replacement for many years. Older patients and even young patients with calcified, rigid valves need valve replacement. The natural history of symptomatic patients with severe AS is dismal, i.e., a 10-year mortality of 80 to 90 percent, but there is good outcome after surgery, particularly in patients without any comorbid cardiac and noncardiac conditions. Given the unknown natural history of the asymptomatic patient with severe AS, which may not be benign,[57] it is reasonable to recommend surgery even to the asymptomatic patient. There is, however, no consensus about valve replacement in the truly asymptomatic patient. Clearly, if the patient has LV dysfunction, then valve replacement should be performed. Some recommend valve replacement in all asymptomatic patients with severe AS, while others would recommend it in those with AVA $\leq$0.7 cm^2 and in selected patients with AVA of 0.76 to 1.0 cm^2 (Table 56-13).

The operative mortality of valve replacement is about 5 percent or less (see Chap. 61).[57,61,62] In patients without associated CAD, heart failure, or other comorbid factors, it may be 1 to 2 percent in centers with experienced and skilled staff.[62] Patients with associated CAD should have coronary bypass surgery at the same time as valve surgery because it results in a lower operative and late mortality (Table 56-14). The operative mortality in octogenarians or older is much higher: up to 6 percent for isolated aortic valve replacement and up to 10 percent for those undergoing aortic valve replacement and associated coronary bypass surgery.

In severe AS, valve replacement results in an improvement of survival (Fig. 56-4),[73,80] even in those with normal preoperative LV function. LV function remains normal postoperatively if perioperative myocardial damage has not occurred.[22,57,81,82] LV hypertrophy regresses toward normal;[22,57,81,82] after 2 years, the regression continues at a slower rate for up to 8 to 10 years after valve replacement.[82] In those with excessive LV hypertrophy preoperatively,[30] the hypertrophy may regress slowly or not at all. These patients may have persistent severe LV diastolic dysfunction, which may be a difficult clinical problem

both in the early postoperative period and after hospital discharge. Their clinical picture subsequently resembles that of patients with hypertrophic cardiomyopathy without outflow obstruction, and they may have to be treated as such. Surviving patients are functionally improved. After aortic valve replacement, the 10-year survival is 60 percent or better and the 15-year survival is 45 percent or better.[83] Approximately one-half of the late deaths are not related to the prosthesis but to associated cardiac abnormalities and other comorbid conditions.[83] Thus, the late survival will vary in different subgroups of patients. The older patients (≥65 years) have a relative 10-year survival (actual survival compared to an age- and gender-matched person in the population) after valve replacement that is significantly better than that of those who are younger (<65 years)-94 percent versus 81 percent (Fig. 56-5).[84]

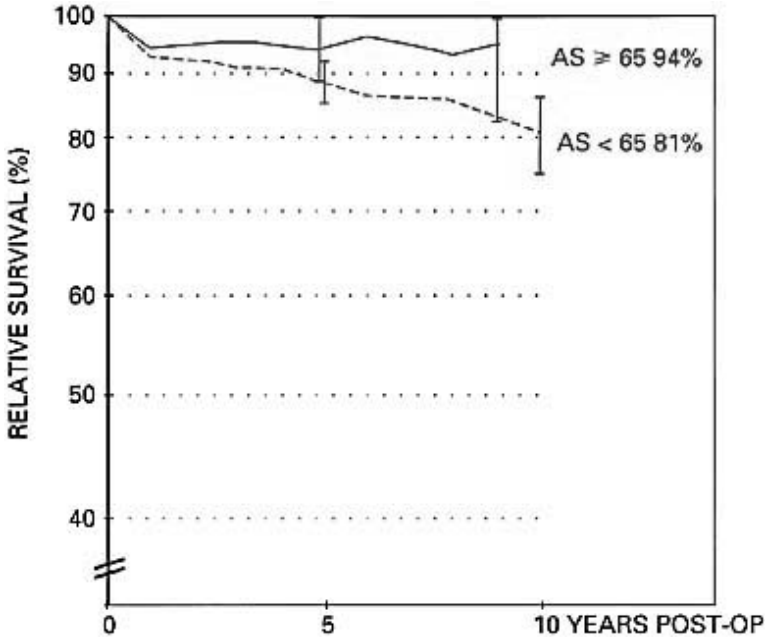

Figure 56-5: Data from the Karolinska Institute in Sweden provided an interesting perspective on the long-term survival after valve replacement in patients aged ≥65 years. They examined the relative survival, i.e., compared the survival of the patient who had undergone aortic valve replacement with another age- and sex-matched person in the same population. Patients under the age of 65 had a relative survival of 81 percent, significantly lower than 100 percent. On the other hand, patients aged ≥65 years who underwent valve replacement had a relative survival of 94 percent at the end of 10 years-not significantly different from 100 percent. These data indicate that (1) survival following valve replacement for AS in patients aged ≥65 years is identical to an age- and sex-matched individual in the population who does not have AS and (2) the late relative survival of patients aged 65 years or greater is much better than that of patients under the age of 65. (From Lindblom et al.,[84] with permission.)

Patients who present with heart failure should be hospitalized and treated with digitalis, diuretics, and *angiotensin-converting enzyme* (ACE) inhibitors and should undergo surgery as soon as possible. ACE inhibitors should be used extremely cautiously if at all. The patient must be monitored and hypotension avoided; a "significant" fall in blood pressure is an indication to discontinue or reduce the dose of ACE inhibitor. If heart failure does not respond satisfactorily and rapidly to medical therapy, surgery becomes a matter of considerable urgency.[85] Catheter balloon valvuloplasty can be an important bridge procedure in selected critically ill patients.[85] It usually improves the patients' hemodynamics and makes them better candidates for valve replacement. Valve replacement in patients with AS and heart failure can be performed at an operative mortality of 10 percent or less.[86] Although this is higher than in patients not in heart failure, the risk is justified because late survival in those who survive the operation is excellent and is far superior to that which can be expected with medical therapy; the 7-year survival of patients who survive operation is 84 percent.[87] The survival is lower in those with associated CAD.[86] The impaired LV function improves in all such patients provided that there has been no perioperative myocardial damage; it becomes normal in two-thirds of the patients (Fig. 56-6).[88] In some patients the improvement is less marked.[86] This is more

likely in those with longer duration of preoperative LV dysfunction and in those with associated CAD. In addition, the operative survivors are functionally much improved. LV hypertrophy and dilatation (if present preoperatively) regress toward normal. Despite the excellent results of valve replacements in patients with severe AS who are in heart failure, it is important to recognize that surgery should *not* be delayed until heart failure develops.

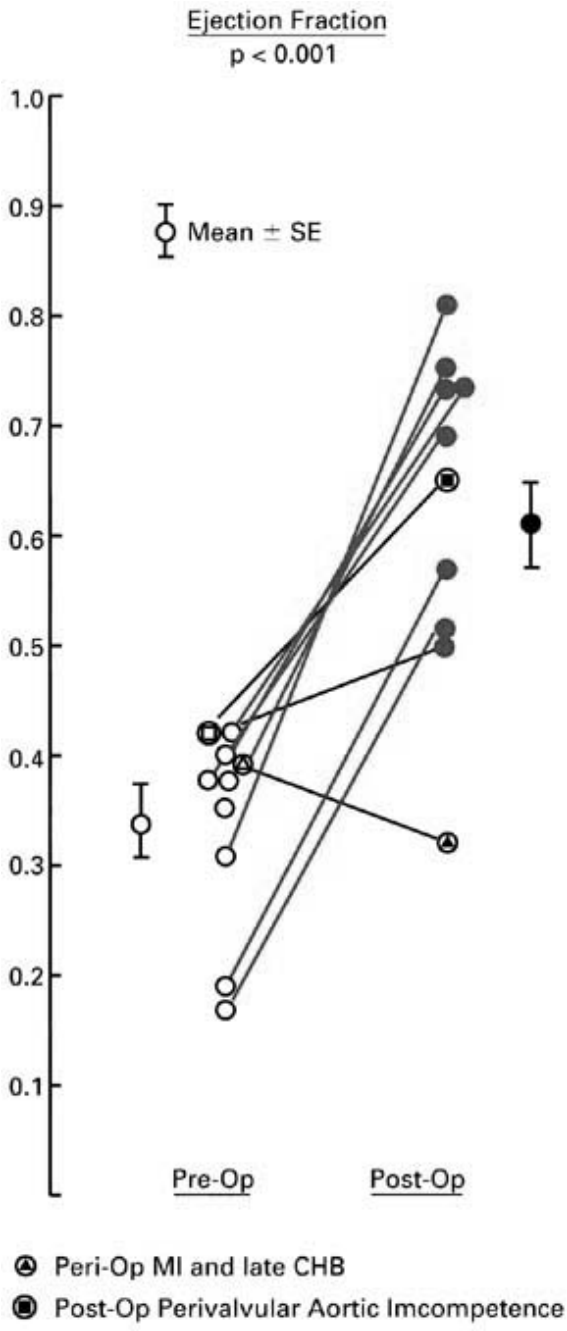

Figure 56-6: These data indicate that there is probably no lower limit of ejection fraction at which time these patients become inoperable. This also indicates that the lower the ejection fraction, the more urgent the need for valve replacement. (From Smith et al.,[88] with permission.)

In the data bases of older patients who underwent catheter balloon valvuloplasty, 6 percent of the patients were in cardiogenic shock.[89,90] The hospital mortality in such patients was very high, almost 50 percent. After hospital discharge, the subsequent mortality is also very high if the patients have not had their stenosis relieved.[90] Thus, these patients need to be treated aggressively with medical therapy with hemodynamic monitoring and need emergent surgery with or without catheter balloon valvuloplasty as a

"bridge" procedure[85] (Table 56-15).

Table 56-15: Suggested Indications for Catheter Balloon Valvuloplasty in Patients with Severe Calcific Aortic Valve Stenosis[a]

I. 'Bridge' procedure to eventual AVR
   A. Cardiogenic shock
   B. Moderate to severe heart failure
   C. Emergent/urgent need for noncardiac therapeutic procedures (e.g., operation)
II. Patient with limited life span
   A. Noncardiac reasons (e.g., carcinoma)
   B. Cardiac reason(s) other than aortic stenosis
III. Others
   A. Patient at extremely high risk for AVR
   B. AVR not desirable for noncardiac reasons or cardiac causes other than aortic stenosis
   C. Patient refuses surgery
IV. Rare
   A. 'Therapeutic test': patients with small stroke volume and small valve gradient, with valve stenosis suspected to be severe but severity in doubt even after provocative diagnostic tests

---

[a]Caution should be exercised in recommending this procedure in asymptomatic patients.

ABBREVIATIONS: AVR = aortic valve replacement.
SOURCE: Adapted from Rahimtoola,[85] with permission.

The role of catheter balloon valvuloplasty in the older patient has now been clarified.[57,85] In calcific AS after catheter balloon valvuloplasty, the average increase in AVA is 0.3 cm^2 and the final AVA usually averages 0.8 cm^2; thus, many patients continue to have severe AS.[57,85,89] The 30-day, 1-year, and 3-year mortalities average 14, 35, and 71 percent, respectively, in the older patient (average age 78 ± 9 years) with calcific AS,[89] a mortality rate that may be similar to the natural history of this lesion. This technique is indicated[85] as a bridge procedure in those who need emergent noncardiac surgery and in those who are in heart failure (or in cardiogenic shock), who have an expected limited short life span when operative risks are considered to be prohibitively high, and who refuse surgery. When performed as a bridge procedure, valve surgery should not be unduly delayed. On rare occasions, it may be considered as a therapeutic test in patients in whom AS is suspected to be severe but the severity of the AS is in doubt after all standard tests have been performed (Table 56-15), including provocative diagnostic tests to assess mean aortic gradient, stroke volume, and AVA before and after infusion of dobutamine. Catheter balloon valvuloplasty is the procedure of choice in young patients who have pliable, noncalcified valves with commissural fusion (see Chap. 63).

The recommendations of the American College of Cardiology/American Heart Association (ACC/AHA) Practice Guidelines are shown in Tables 56-16 and 56-17.[91] Guidelines *are not* and *should not* be the law. Application of these guidelines to clinical practice should be based on the following principles: (1) classes I and III applies to all patients in these classes unless there is a specific clinical circumstance not to do so; (2) class II applies to patients in this class depending on the clinical conditions of the patients and the skill and experience at the individual medical center.

Table 56-16: Recommendations for Aortic Valve Replacement in Aortic Stenosis

Indication	Class
1. Symptomatic patients with severe AS	I
2. Patients with severe AS undergoing coronary artery bypass surgery	I
3. Patients with severe AS undergoing surgery on the aorta or other heart valves	I
4. Patients with moderate AS undergoing coronary artery bypass surgery or surgery on the aorta or other heart valves (see sections III.F.6., III.F.7., and VIII.D. of the ACC/AHA Guidelines)	IIa
5. Asymptomatic patients with severe AS and	
▪ LV systolic dysfunction	IIa
▪ Abnormal response to exercise (e.g., hypotension)	IIa
▪ Ventricular tachycardia	IIb
▪ Marked or excessive LV hypertrophy (≥15 mm)	IIb
▪ Valve area <0.6 cm^2	IIb
6. Prevention of sudden death in asymptomatic patients with none of the findings listed under indication 5	III

SOURCE: ACC/AHA Guidelines,[91] with permission.

Table 56-17: Recommendations for Aortic Balloon Valvotomy in Adults with Aortic Stenosis[a]

Indication	Class
1. A 'bridge' to surgery in hemodynamically unstable patients who are at high risk for AVR	IIa
2. Palliation in patients with serious comorbid conditions	IIb
3. Patients who require urgent noncardiac surgery	IIb
4. An alternative to AVR	III

[a]Recommendations for aortic balloon valvotomy in adolescents and young adults with AS are provided in section VI.A. of the ACC/AHA Guidelines.

Chapter 56: AORTIC VALVE DISEASE

ACUTE AORTIC REGURGITATION

Etiology

The two most common causes of acute *aortic regurgitation* (AR) are infective endocarditis and prosthetic valve dysfunction.[92] Other causes include dissection of the aorta, systemic hypertension, and trauma.[93,94] AR associated with dissection of the aorta indicates that the dissection involves the ascending aorta down to the aortic valve annulus/root. AR associated with systemic hypertension is usually mild and transient; it is associated with severe elevation of aortic pressure, and, when the systemic hypertension is controlled, the AR usually disappears unless permanent changes have occurred in the aortic valve annulus/root or valve leaflets.

Pathophysiology

The LV diastolic pressure-volume relationship plays a very important role in the pathophysiology of acute valve regurgitation (Fig. 56-7).[95,96] Two features should be considered:[92] (1) The ability of the left ventricle to dilate acutely is limited; as a result, the volume overload of acute AR produces a rapid increase of LV diastolic pressure (curve B in Fig. 56-7). (2) The LV diastolic pressure-volume relationship before the onset of acute AR. If the left ventricle is already stiff or less compliant than normal from an associated lesion (e.g., AS or systemic hypertension), the LV diastolic pressure will rise more precipitously as a result of the volume overload of acute AR (curve A) than if the LV were normal (curve B). On the other hand, if the left ventricle is somewhat dilated from a previous lesion, for example, mild AR (curve C), initially the LV pressure will rise more gradually with acute AR but may subsequently rise to the same high levels as that seen with a normal or stiff LV.

Acute AR that is mild produces little or no hemodynamic abnormality, for example, when associated with systemic hypertension. Increasing severity of regurgitation produces greater degrees of hemodynamic abnormalities, and severe AR often produces the clinical picture of "heart failure."

Acute AR that is severe results in a large volume of regurgitant blood; therefore, the volume of blood in the LV in diastole is increased. In an acute situation, the LV end-diastolic volume can only increase mildly (no more than 20 to 30 percent) and the LV diastolic pressure-volume relationships are particularly important. The LV systolic pump function is initially normal (Fig. 56-8). The increased LV diastolic pressure results in increases in mean left atrial and pulmonary venous pressures and produces varying degrees of pulmonary edema.[97] The normal LV systolic pump function in the presence of LV dilatation results in an increase of LV stroke volume. A large percentage of the LV stroke volume is returned to the LV in diastole, however; as a result, the forward stroke volume is reduced. The LV uses two mechanisms: an increase of myocardial contractility and, importantly, a compensatory tachycardia to maintain an adequate forward cardiac output. As a result, the forward cardiac output may be appropriate initially. If the compensatory mechanisms are inadequate, however, forward cardiac output is reduced. Pulmonary edema, with or without an adequate cardiac output, produces the picture of clinical heart failure.[97] Subsequently, LV systolic pump function may become abnormal; when that occurs, the pulmonary edema is further increased and the forward cardiac output is further reduced, leading to more severe manifestations of clinical heart failure.

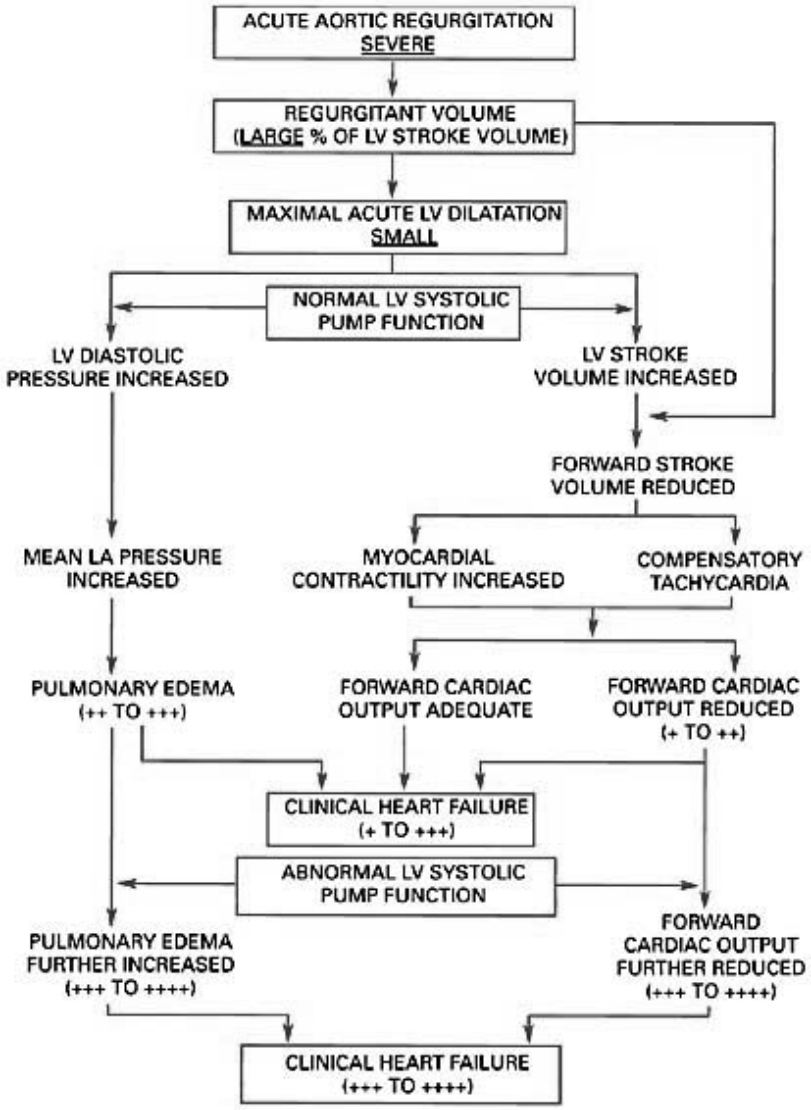

Figure 56-8: Pathophysiology of acute severe aortic regurgitation. Acute AR that is severe results in a large volume of regurgitant blood; therefore, the volume of blood in the left ventricle in diastole is increased. In an acute situation, the LV end-diastolic volume can only increase mildly (no more than 20 to 30 percent) and the LV diastolic pressure-volume relationships are particularly important (see Fig. 56-1). The subsequent findings are dependent on LV systolic pump function, LV diastolic pressure-volume relationship, myocardial contractile state, and compensatory tachycardia (see text for details). (Copyright © by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C. See Ref. 93.)

Clinical Findings

HISTORY, PHYSICAL FINDINGS

The clinical presentations of patients with acute AR are those relating to preexisting disorders that have caused the acute AR. For example, patients may have peripheral signs of infective endocarditis, a history of trauma, or severe chest pain of aortic dissection. The other clinical presentations are those related to the AR itself. If the AR is mild, the patient is usually asymptomatic. In the symptomatic patient, the symptoms are those of heart failure.

On physical examination, the symptomatic patient with acute severe AR usually has a tachycardia. The arterial pulse shows an increased rate of rise of pressure. Systolic pressure is usually normal unless there is very severe heart failure; however, the diastolic pressure is in the normal range or may be decreased. The pulse pressure is usually normal. Thus, although the classic peripheral signs of chronic, severe AR are often absent, an important diagnostic clue is the rapid rate of rise of arterial pressure. The usual clinical signs of

heart failure may be present. On examination of the precordium, the LV impulse is normal or slightly displaced to the left; it is usually hyperkinetic unless LV systolic dysfunction is present. The first heart sound is soft, and the second heart sound is often single and is soft. If pulmonary hypertension is present, P_2 is loud and there is a loud S_3 gallop sound, but an S_4 gallop sound is absent. The clinical sine qua non of AR is the AR murmur, an early or immediate, blowing, decrescendo diastolic murmur beginning after A_2 that is best heard with the diaphragm of the stethoscope. Having the patient sit up and lean forward with the breath held in expiration facilitates the audibility of the murmur in difficult cases. The murmur may be short and soft if the ascending aortic pressure equalizes with LV pressure in early or middiastole. An Austin Flint murmur, if present, occurs in middiastole (see also Chap. 10).

An important clinical picture in intravenous drug abusers[92] includes: (1) a peripheral arterial pulse that has a rapid rate of rise and fall, even though the pulse pressure is small; (2) the telltale signs of intravenous drug abuse; (3) sinus tachycardia; and (4) "normal" heart size with pulmonary edema on chest x-ray.

CHEST X-RAY

The chest x-ray shows a "normal" heart size with pulmonary edema; however, some enlargement of all cardiac chambers and the main pulmonary artery may be present. The aorta is not dilated unless aortic annular/root disease or dissection of the aorta is the cause of the acute AR. The aorta may also be dilated in the older patient and/or in those with an associated disease such as systemic hypertension. The lungs may show the signs of infected pulmonary emboli if there is associated tricuspid valve endocarditis.

ELECTROCARDIOGRAM

The ECG often shows nonspecific ST-T-wave changes and a sinus tachycardia; however, it may be normal. The ECG may show signs that are usually found in the associated causative disorder, e.g., LV hypertrophy with ST-T-wave changes in patients with severe hypertension. The ECG may show a variety of conduction abnormalities (atrioventricular and bundle branch block) including heart block, which, in the presence of infective endocarditis, is a sign of paravalvular/myocardial abscess.

Natural History and Prognosis

The natural history of this condition is variable. If the AR is mild to moderate in severity, these patients are likely to do well with medical therapy. Eventually, the changes of chronic AR will be seen. In patients with severe AR, the natural history depends on whether or not they have heart failure.[98] If heart failure is present, which is common, the prognosis is very poor without valve surgery unless the heart failure can be very easily controlled with medical therapy.

Management

DIAGNOSIS OF AORTIC REGURGITATION

In most instances, the diagnosis can be made by clinical evaluation, which includes the history, physical examination, electrocardiography, and chest x-ray. The diagnosis by physical examination in an acutely ill patient who is in extremis may be difficult.

Transthoracic echo/Doppler ultrasound is an important and valuable noninvasive procedure that should be used in every instance. It will demonstrate the AR and its severity and will provide useful information about the size and function of the left ventricle and other valvular and cardiac abnormalities. If the transthoracic method is not adequate, for example, in the very ill patient, then the transesophageal method should be used (see Chap. 13).

Echocardiography shows the diastolic flutter of the anterior leaflet of the mitral valve. In addition, the echocardiogram may show vegetations on the aortic valve, prolapse of an aortic valve leaflet into the left ventricle in diastole, and premature mitral valve closure. The mitral valve may be seen to open for only a short time because the stroke volume is limited. Occasionally, the aortic valve leaflets have been totally

destroyed, and none are seen on the echocardiogram. Doppler ultrasound can easily demonstrate the AR and provides an estimate of its severity.

Cardiac catheterization and angiography, including coronary arteriography, show the abnormal physiology described, and aortography shows gross AR. These modalities may be needed to make the diagnosis and are usually indicated before surgical intervention. Coronary arteriography is indicated in the appropriate patient (see above). In the extremely ill patient, there is often a need for clinical judgment with regard to the tests that are essential.

Other tests (cine-computed tomography, including fast cine-computed tomography, radionuclide gated blood scan, or ambulatory ECG) may be needed in very special conditions.

DIAGNOSIS OF THE ETIOLOGY OF ACUTE AORTIC REGURGITATION

The diagnosis of the etiology is usually made during the clinical evaluation by finding the usual clinical characteristics of the underlying lesion. Additional laboratory tests will be needed to confirm the diagnosis-for example, blood cultures in those with suspected infective endocarditis.

Echo/Doppler ultrasound (transthoracic and transesophageal) examination is also extremely valuable in diagnosing the underlying lesion. Its widespread availability and comparative ease of use, especially in the very acutely ill patient, make it the noninvasive procedure of choice. The availability of biplane and omniplane transesophageal probes further enhances its value as a diagnostic tool.

Magnetic resonance imaging (MRI) has a very high specificity for the diagnosis of dissection of the aorta[99,100] and, if available, should be used in all hemodynamically stable patients if the diagnosis has not already been made. The availability of biplane or omniplane transesophageal echocardiography markedly improves the specificity and diagnostic accuracy of transesophageal echocardiography. Angiography is also an effective and time-honored method of diagnosing dissection of the aorta.

In summary, clinical evaluation is available in all institutions; echo/Doppler ultrasound is available in almost all institutions. The use of the other tests depends on the availability of equipment and the skill and experience of personnel using the equipment for this purpose at each institution.

BEDSIDE HEMODYNAMIC MONITORING

In acute disorders affecting the left ventricle, there may be a phase lag between the rise in pulmonary venous pressure and the appearance of pulmonary edema on the chest x-ray film. As a result, the reliability of the chest x-ray in demonstrating the presence and severity of elevated left atrial pressure initially is less than satisfactory in the acutely ill patient.[101] If the assessment of left atrial pressure is made by physical examination and chest x-ray, a significant number of errors may be made in these patients with an acute cardiac problem. Therapeutic decisions based on incorrect assessments may result in significant problems; for example, inappropriate diuresis may result in a fall of cardiac output, or inappropriate volume loading may result in a further increase in left atrial pressure. Furthermore, the optimization of filling pressures and cardiac output may not be made accurately in acute heart failure without measuring their actual values. Thus, use of a balloon flotation catheter for bedside hemodynamic monitoring is required in most if not almost all acutely ill patients with acute AR.

TREATMENT

Treatment of the heart failure is directed toward reducing pulmonary venous pressure and increasing cardiac output. In all patients, treatment is also directed toward correcting or controlling the etiologic disease/disorder and/or the altered pathophysiologic state (Table 56-18).[92,98]

Table 56-18: Treatment of Heart Failure in Acute Valve Regurgitation

I. Correct or control altered pathophysiologic state
   A. Reduce pulmonary venous pressure
      1. Diuresis
      2. Vasodilation
      3. Control heart rate and maintain sinus rhythm (digitalis, cardioversion, antiarrhythmics)
   B. Increase cardiac output
      1. Reduction of valve regurgitation (vasodilators)
      2. Inotropic stimulation (digitalis, dobutamine)
   C. Improve left ventricular systolic dysfunction
      1. Reduce pulmonary venous pressure
      2. Increase cardiac output
      3. ACE inhibitors

II. Correct or control underlying disease or disorder
   A. Antibiotics for infective endocarditis
   B. Pharmacologic therapy for systemic hypertension
   C. Surgery for valve regurgitation in infective endocarditis, prosthetic valve dysfunction, dissection of the aorta, trauma

---

SOURCE: From Rahimtoola,[92] with permission.

Vasodilators (intravenous nitroprusside for an acute, severe condition) are useful and important in the management of these patients.[102] Vasodilators will produce a reduction of left atrial *v* wave and mean left atrial pressure. They produce a reduction in LV end-diastolic and end-systolic volumes and an increase in LV ejection fraction. The regurgitant fraction and regurgitant volume are reduced; as a result, the forward stroke volume and cardiac output are increased.[102] Digitalis therapy is of significant benefit in the management of heart failure. The combination of various agents (vasodilators, diuretics, and digitalis) tends to produce the maximum benefit in an individual patient; intravenous nitroprusside is often necessary in the acutely ill patient.

Surgical therapy (valve replacement/valve repair or appropriate surgery for dissection of the aorta) is the cornerstone of the most definitive therapy currently available for heart failure in these patients. The management of the patient with heart failure or suspected heart failure is outlined in Fig. 56-9.[98] If the valve regurgitation is due to *dissection of the aorta*, the need for cardiac surgery is an emergency, even if the regurgitation is mild or moderate, because AR indicates involvement of the ascending aorta down to the region of the aortic valve annulus/root (see also Chap. 88). The outcome of the patient with heart failure due to infective endocarditis is very poor with medical therapy but is improved with valve replacement.[103] The indications for surgery in *infective endocarditis* are listed in Table 56-19.[81] Infective endocarditis due to special organisms (e.g., fungi) can only rarely be controlled by pharmacologic therapy alone, and surgery is almost always needed. In these and some other conditions, valve surgery may be needed even if the AR is only mild or moderate. It must be recognized, however, that in 90 to 95 percent of patients needing surgery for endocarditis, the indication for valve surgery is heart failure. When the heart failure is a result of *prosthetic valve dysfunction* or *trauma*, the need for surgery can be an emergency, an urgent situation, or an elective procedure. Prosthetic valves are inherently stenotic. When regurgitation is superimposed, it produces a pressure plus volume overload on the left ventricle that the ventricle may not handle very well acutely. Furthermore, valve regurgitation may be a sign of bioprosthetic valve degeneration or prosthetic endocarditis; in both conditions, prosthetic valve replacement is usually needed even if the valve regurgitation is mild to moderate. Trauma may result in AR from damage to valve leaflets or aortic annulus/root or from dissection of the aorta. If trauma produces dissection of the aorta and AR, the need for surgery may be an emergent one.

Table 56-19: Indications for Surgery in Infective Endocarditis

Congestive heart failure
Infection
Uncontrolled by antibiotic therapy
Fungal
Usually with staphylococcal infection of aortic or mitral valves
Serratia
Usually with gram-negative bacillary infection
Recurrent septic systemic emboli despite adequate antibiotic therapy
Perivalvular and myocardial abscesses
Structural damage to valve in association with other catastrophes (e.g., ruptured sinus of Valsalva)
Very large mobile vegetation

SOURCE: From Rahimtoola,[81] with permission.

In some instances, the heart failure can be controlled completely with pharmacologic therapy, and the left ventricle and left atrium are able to dilate and adapt to the volume overload; in such instances, surgical therapy may be delayed, perhaps for a considerable period of time.

Chapter 56: AORTIC VALVE DISEASE

CHRONIC AORTIC REGURGITATION

Etiology

In North America, the most common cause of chronic, isolated severe AR is aortic root/annular dilatation that is presumably the result of medial disease. Other common causes include a congenital (bicuspid) valve, previous infective endocarditis, and rheumatic disease.[93,94] Chronic AR also occurs in association with a variety of other diseases (Table 56-20). Between 40 and 60 percent of the surgically removed valves from patients with isolated severe regurgitation are classified as idiopathic. Half of these (or 20 to 30 percent of all the valves removed) show histologic criteria of myxomatous degeneration.[104]

Table 56-20: Etiology of Chronic Aortic Valve Regurgitation

Aortic root dilatation
Congenital bicuspid valve
Previous infective endocarditis
Rheumatic
In association with other diseases
Congenital lesions, e.g., supravalvular or discrete subvalvular AS, ventricular septal defect, and aneurysm of the sinus of Valsalva
Connective tissue disease, e.g., Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome
Autoimmune diseases, e.g., ankylosing spondylitis, rheumatoid arthritis, and systemic lupus erythematosus
Various forms of aortitis and arteritis, e.g., giant-cell arteritis and Takayasu's disease
Syphilis

Pathology

During systole the aortic root/annulus expands by an increase of 14 to 16 percent of the diameter (twice the radius).[105] This causes the commissural attachments to spread apart, initiating the opening of the valves. These movements are continued during LV systole, which produces the forward motion of the blood. The length of the free edge of the cusps equals the diameter of the aortic root/annulus, or roughly one-third of the perimeter. Therefore, dilatation of the aortic root/annulus, if it is not accompanied by an enlargement of the cusps, results in AR.[104]

Depending on the cause, the valve cusps may show thickening, shortening, commissural lesions, or calcification (Fig. 56-10).[106] Regardless of the cause, the LV is dilated and hypertrophied; some of the largest ventricles have been described in association with chronic severe AR. Little pockets may be seen in the LV outflow tract. These are pouches out of the endocardial lining formed by the regurgitant jet(s) striking the left ventricle.

The myocardium is hypertrophied, with replication of sarcomeres in series, elongation of fibers, and wall thickening. The wall is not as thickened as in patients with AS. Ultrastructural changes in the myocardial cells are similar to those seen in AS; an important difference, however, is the frequent presence of degenerated cardiac muscle cells in patients with severe AR. Cardiac muscle cells with mild degeneration show focal myofibrillar lysis, with preferential loss of thick myofilament and focal proliferation of tubules of the sarcoplasmic reticulum. Moderately degenerated muscle cells show a marked decrease in the number of myofibrils and T tubules and proliferation of sarcoplasmic reticulum, mitochondria, or both. Severely degenerated muscle cells usually are present in areas of marked fibrosis; they are often atrophic, have thickened basement membranes, and have lost their intercellular connections. These degenerated cardiac muscle cells may represent the ultrastructural basis for impaired LV function, which is seen more commonly in severe AR than in severe AS.

In patients with rheumatoid arthritis and ankylosing spondylitis, nodules on the outer surface of the anterior leaflet of the mitral valve have been described.

Pathophysiology

In chronic as opposed to acute AR, the AR becomes severe over a period of time; therefore, the LV diastolic pressure-volume relationships are different from those seen in acute AR (Fig. 56-7). If the AR is mild to moderate, the LV end-diastolic volume is increased moderately, the LV diastolic pressure-volume curve is moved to the right (curve B) of normal (curve A), and the LV diastolic pressure is usually normal (Fig. 56-11). In severe AR, the LV diastolic pressure-volume curves are moved further to the right (curves C and D). If the LV systolic pump function is normal, the LV end-diastolic volume can be quite large without significant elevation of LV end-diastolic pressure (curve C). If the LV diastolic volume increases further, however, the LV diastolic pressures will be increased. If LV systolic pump dysfunction supervenes, the LV diastolic pressure-volume curve (curve D) relationships are moved even further to the right, with quite marked LV dilatation and increases in LV diastolic pressure.

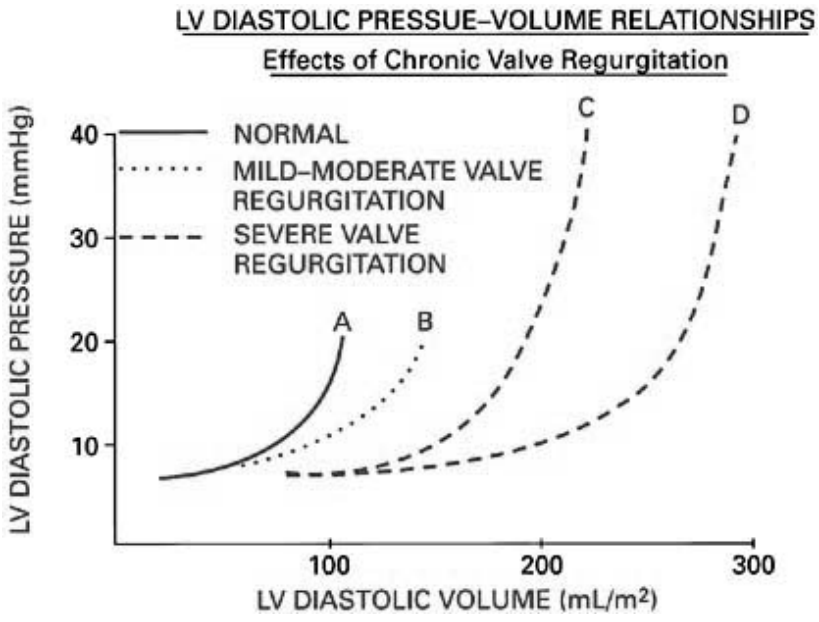

Figure 56-11: In chronic aortic regurgitation as opposed to acute AR, the AR becomes severe over a period of time; therefore, the LV diastolic pressure-volume (P-V) relationships are different from those seen in acute AR (see Fig. 56-7). If the AR is mild to moderate, the LV diastolic P-V curve is moved to the right (*curve B*). In severe AR, the LV diastolic P-V curves are moved further to the right, depending on whether the LV systolic pump function is normal (*curve C*) or abnormal (*curve D*). (From Rahimtoola,[98] with permission.)

The increase of LV end-diastolic volume[107] is a result of the regurgitant volume (and is proportional to the amount of regurgitation) and LV systolic dysfunction. As LV systolic dysfunction supervenes and increases in severity, for any severity of regurgitant volume the LV end-diastolic volume increases further in an attempt to maintain LV stroke volume.

Severe chronic AR results in a large regurgitant volume (a large percentage of LV stroke volume). The left ventricle responds by dilating (average LV end-diastolic volume in patients undergoing surgery was 205 mL/m^2);[22] the dilatation is proportional to the amount of the regurgitant volume. The subsequent large LV stroke volume produces LV systolic hypertension. Both of these increase LV wall stress (afterload), which can result in an impairment of LV function. The heart responds by becoming hypertrophied (average LV mass in patients undergoing valve surgery was 222 g/m^2),[22] and LV systolic pump function remains normal. There is also an alteration of the LV diastolic pressure-volume relationship (Fig. 63-11). As a result, some patients with normal LV systolic pump function become symptomatic[108] because of the abnormal LV diastolic function (Fig. 56-12).

In AR, the left ventricle is ejecting against systemic resistance, and the myocardial tension that is developed to open the aortic valve and eject the huge stroke volume is great. This contrasts with another volume-overload lesion, mitral regurgitation, in which there is a low-resistance chamber into which the LV is also emptying (the left atrium). Thus, for the same degree of regurgitant volume, afterload is higher in AR.

As LV afterload (a combination of LV dilatation, hypertrophy, and systolic hypertension) continues to increase, the LV utilizes two additional compensatory mechanisms, namely, increase of preload and an increase of myocardial contractility. Both of these help maintain normal LV systolic pump function.

When the limit of preload reserve has been reached (afterload mismatch)[31] and/or myocardial contractility is reduced, LV systolic pump function becomes abnormal. At this stage, correction of AR will result in normalization or marked improvement of LV systolic function. The additional LV dilatation also results in further alteration of the LV diastolic pressure-volume relationship (see Fig. 56-6). Clinical heart failure is usually a result of the abnormal LV systolic pump function. In patients with normal LV systolic pump function, clinical heart failure is a result of LV diastolic dysfunction.

Because of the leak of blood from the ascending aorta to the LV in diastole, the aortic diastolic pressure is reduced. The large LV stroke volume (a combination of forward stroke volume and regurgitant volume) results in elevation of the aortic systolic pressure, and thus the pulse pressure is considerably increased. Reduction or normalization of aortic systolic pressure is suggestive of LV systolic dysfunction in these patients.

LV stroke volume in AR consists of the forward stroke volume (blood delivered to the body tissues and the heart), which, multiplied by heart rate, makes up the forward cardiac output, and the regurgitant volume (the volume of blood that regurgitates back to the left ventricle). In the early stages, even in severe AR, the forward cardiac output and LV ejection fraction are normal at rest. During exercise, as in normal individuals, the systemic vascular resistance is decreased[109] and the heart rate is increased, which reduces the length of diastole. Both these factors reduce the regurgitant volume, and forward stroke volume and cardiac output are increased during exercise.[109] Thus, the ejection fraction on exercise is related to both the myocardial contractile state[110] and the fall in systemic vascular resistance.[109] Accordingly, a decline in ejection fraction on exercise cannot be used as a specific marker of LV function in these patients unless the change in systemic vascular resistance has also been measured. A fall of normal resting ejection fraction to less than 0.50 on exercise, however, has been shown to correlate with reduced total body oxygen consumption[103] and increased left atrial pressure during exercise.[109,111] Further impairment of LV function produces demonstrable abnormalities at rest; there is a further increase in LV end-diastolic volume, which helps to maintain forward stroke volume. The resting LV ejection fraction is reduced, and mean left atrial pressure begins to increase. Even at this stage, the forward cardiac output may be maintained in the normal range. The increases in left atrial pressure may produce various grades of pulmonary edema. Finally, in the

state of severe heart failure, the ejection fraction may be low, LV end-diastolic volume is large, and LV end-diastolic pressure is greatly increased and is associated with increases in left atrial, pulmonary, right ventricular, and right atrial pressures. Forward cardiac output is no longer normal. An increase in systemic venous pressure in association with salt and water retention produces engorgement of systemic organs (e.g., the liver) as well as peripheral edema.

In severe AR, myocardial oxygen needs are increased because of increases in LV diastolic and systolic volumes, LV muscle mass (hypertrophy), and LV pressures as well as by prolongation of systolic ejection time. Total coronary blood flow is increased. Coronary reserve, the ability of the coronary blood flow to increase with vasodilatation, however, is significantly reduced,[112-114] probably because of a reduced diastolic aortic-LV pressure gradient and compression of intramyocardial coronary arteries (systolic "milking" of intramural arteries). Therefore, myocardial ischemia is often present on stress in these patients.[112-114] Some patients with severe AR may complain of angina pectoris on effort even in the absence of epicardial CAD. Associated obstructive CAD can be expected to exacerbate further the myocardial ischemia (see Fig. 56-13).

Clinical Features

HISTORY

Patients with mild to moderate AR usually do not have symptoms that can be attributed to the heart. Even patients with severe AR may be asymptomatic. They may complain of pounding of the head or palpitations, which result from their awareness of the beating of a dilated left ventricle that undergoes a large volume change in systole, during either sinus beats or postectopic beats. The main symptoms of severe AR result from elevated pulmonary venous pressures and include dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea. When congestive heart failure occurs, patients complain of fatigue and weakness. Angina pectoris occurs in 20 percent of such patients and may be present even if the coronary arteries are normal. Angina associated with syphilitic AR may be due to associated ostial stenosis of the coronary arteries. In such patients, angina often occurs at rest and is difficult to control.

PHYSICAL EXAMINATION

A variety of interesting but not very useful clinical signs may be present in patients with chronic severe AR. These include *de Musset's sign* (bobbing of the head with each heartbeat), *Traube's sign* (pistol-shot sound heard over the femoral artery), *Duroziez's sign* (systolic murmur over the femoral artery when it is compressed proximally and diastolic murmur when it is compressed distally), and *Quincke's pulse* (capillary pulsations that can be detected by pressing a glass slide on the patient's lip or transmitting a light through the patient's fingertips).

The arterial pulse is very characteristic and consists of an abrupt distention with a rapid rise and a quick collapse *(Corrigan's pulse)*. The arterial pulse may be bisferiens, a double impulse during systole. The systolic arterial pressure is increased (in severe AR it averages 145 to 160 mmHg), the diastolic pressure is reduced (in severe AR it averages 45 to 60 mmHg), and the Korotkoff's sounds persist down to 0 mmHg. Even in such instances, however, the recorded intraarterial pressure rarely falls below 30 mmHg. The vasoconstriction that occurs in the presence of heart failure may result in some elevation of the arterial diastolic pressure and should not be interpreted as an improvement in severity of AR. Similarly, LV systolic dysfunction can produce a fall of systolic blood pressure that should not be considered to be an improvement of the AR. The fall of systolic pressure along with elevation of diastolic pressures tends to normalize the pulse pressure. The jugular venous pressure is normal except in heart failure and in those rare instances in which the greatly dilated ascending aorta obstructs the superior vena cava.

On inspection, the chest may rock and the cardiac impulse may be visible. The cardiac impulse is hyperdynamic (Table 56-21). There may be a systolic thrill at the base of the heart, over the carotids, and in the suprasternal notch. This results from a large LV stroke volume across a diseased aortic valve. A diastolic thrill signifies severe AR. The first heart sound is usually soft because the mitral valve leaflets are close to each other at the onset of systole, or there may be premature valve closure. This is exaggerated if

the PR interval is prolonged. The S_2 is usually single because the aortic valve does not close properly[115] or because the LV ejection time is prolonged and the P_2 may not be heard. Often, a systolic ejection murmur, which is sometimes very loud, is present. The clinical sine qua non of AR is an early or immediate, blowing, decrescendo diastolic murmur beginning after A_2. It is best heard with the diaphragm of the stethoscope at the left sternal border or, in difficult instances, by having the patient sit up and lean forward and by auscultating in held respiration at the end of a deep expiration. In severe AR, the murmur may be holodiastolic. When it is soft, its intensity can be increased by having the patient perform isometric exercise, for example, a handgrip, which increases aortic diastolic pressure. At times, this murmur is better heard along the right sternal border, which should draw attention to the possibility that the cause of the AR is aortic root/annular disease (see also Chap. 10). Classically, rupture of the sinus of Valsalva into the right heart chambers produces a continuous murmur.

Table 56-21: Physical Examination of Patients with Varying Severity of Chronic Aortic Valve Regurgitation

	Mild	Moderate	Severe	Severe + LV Systolic Dysfunction	Severe + Heart Failure + LV Systolic Dysfunction
Arterial pulse	Normal	Corrigan's + to + +	Corrigan's + + +	Corrigan's + +	Corrigan's +
Arterial pressure					
Systolic	Normal	Increased + to + +	Increased + + +	Increased + +	Normal/+
Diastolic	Normal	Decreased + to + +	Decreased + + + to + + + +	Decreased + + to + + +	Decreased +
Pulse pressure	Often normal	Increased + to + +	Increased + + + to + + + +	Increased + + to + + +	Increased +
Cardiac impulse	Often normal	Hyperdynamic	Very hyperdynamic visible ± chest may rock	Hyperdynamic	May be hypodynamic
Precordial thrill:					
Systolic	-	±	±	±	-
Diastolic	-	-	±	±	-
Auscultation:					
S_4	-	-	-	-	-
S_1	Normal	Often soft	Soft	Soft	Soft
S_2	Normal	Normal or single	Often single	Often single	Often single
S_3	-	+	+ + to + + +	+ + +	+ + +
ESM	±	+	+ to + +	+ to + +	+
AoDM	+	+ +	+ + + to + + + +	+ + to + + +	+ to + +

Austin Flint murmur	-	-	±	-	-

ABBREVIATIONS: S_1 and S_2 = first and second heart sounds; S_3 = third heart sound (diastolic gallop); S_4 = fourth heart sound (presystolic gallop); ESM = ejection systolic murmur; AoDM = aortic diastolic murmur; - absent; + + + + most prominent; ± present or absent.

In many patients with severe AR, an Austin Flint murmur[116] (see Chap. 10) is present in presystole and/or mid-diastole. Two inferences can be drawn from the presence of an Austin Flint murmur: (1) it signifies that the AR is severe and (2) it requires that associated mitral stenosis be excluded. The most helpful sign at the bedside is the response of the murmur to the inhalation of amyl nitrite. The vasodilatation produced by amyl nitrite increases forward flow, reduces the regurgitant volume, and results in the Austin Flint murmur becoming much softer or disappearing. On the other hand, the increased cardiac output and the tachycardia accentuate or increase the murmur of mitral stenosis. Alternatively, echocardiography can easily demonstrate the presence of organic mitral stenosis.

With severe LV dilatation and/or LV systolic dysfunction, secondary mitral regurgitation may be present with the characteristic holosystolic murmur. Heart failure may be associated with pulmonary congestion/edema, pulmonary hypertension, right ventricular enlargement, tricuspid regurgitation, elevated jugular venous pressure, hepatomegaly, and peripheral edema (see Chap. 20).

CHEST X-RAY

The LV is increased in size, and this can be appreciated on the chest x-ray by an increase in the cardiothoracic ratio. Since the upper limit of normal of the cardiothoracic ratio is 0.49, many patients with increased LV size have an enlarged ventricular volume and may still have a cardiothoracic ratio within the normal range. A better noninvasive quantification of LV size can be obtained by echocardiography. The ascending aorta is dilated throughout, and there may be calcium in the aortic valve. With increased filling pressures in the later stages, there might be evidence of an enlarged left atrium and an increased left atrial and pulmonary venous pressure, which are manifested in the pulmonary vascular shadows by a redistribution of blood flow, pulmonary congestion, and pulmonary edema. In the presence of heart failure, enlargement of the right atrium and superior vena cava may be appreciated. Calcification that is limited to the ascending aorta is strongly suggestive of luetic aortitis.

ELECTROCARDIOGRAM

The ECG shows LV hypertrophy with or without associated secondary ST-T-wave changes. In a small percentage of patients, ECG evidence of LV hypertrophy is absent in spite of severe AR. Conduction abnormalities, such as atrioventricular block or left or right bundle branch block with or without axis deviation, may be present. The PR interval may be prolonged,[117] particularly in patients with ankylosing spondylitis. The rhythm is usually sinus. The presence of atrial fibrillation should make one suspect the presence of associated mitral valve disease or heart failure.

ECHOCARDIOGRAPHY

The sign of AR on echocardiography is diastolic fluttering of the anterior leaflet of the mitral valve. Echocardiography is of particular value for excluding the presence of associated mitral stenosis in patients with an Austin Flint diastolic murmur. LV dimensions are increased, and if ventricular function is normal, the percentage of dimensional shortening is normal. Because of the increase in LV dimensions caused by volume overload, there is separation between the open anterior leaflet of the mitral valve and the endocardial surface of the interventricular septum (septal-E point separation), but this does not necessarily indicate impaired LV function when AR is present. In AR, as in other volume-overload lesions, the response in mild volume overload is an elongation of the heart. Since M-mode echocardiography takes a pencil look at the short axis of the heart, LV dimensions by M-mode echocardiography may appear to be

normal. In such patients, two-dimensional echocardiography is much superior to the M-mode technique for assessing LV volumes and systolic function. A dilated ascending aorta can be detected on echocardiography, as can an enlarged left atrium. Aortic valve vegetations suggest infective endocarditis. Some other conditions can easily be detected by echocardiography, for example, prolapse of the aortic leaflet into the left ventricle in diastole. Doppler ultrasound is useful for diagnosing and assessing the severity of AR. There is a significant incidence of false-positive mild regurgitation. There is also an overlap between the various grades of severity of assessment of AR by Doppler when compared to angiography. Transesophageal echocardiography is a useful technique when transthoracic echocardiogram is unsatisfactory and in certain instances for identifying the anatomy of the valve leaflets and aortic root/annulus; it is essential to evaluate if the valve is suitable for repair. Echo/Doppler ultrasound is also very useful for assessing disease of other valves.

CARDIAC CATHETERIZATION/ANGIOGRAPHY

Cardiac catheterization allows the measurement of intracardiac and intravascular pressures and cardiac output, both at rest and during exercise, and can demonstrate the changes described under "Pathophysiology," above. In addition, other valvular disease-for example, mitral stenosis, aortic stenosis, and mitral regurgitation-can be excluded. LV angiography demonstrates enlarged LV volumes and allows the calculation of LV volumes and LV ejection fraction. Angiography performed with injection of contrast medium in the ascending aorta demonstrates AR and allows a semiquantitative assessment of the degree of AR. In addition, the angiogram demonstrates the dimensions of the aortic root and the state of the ascending aorta. The indications for selective coronary angiography are the same as for aortic stenosis (see Table 56-6).

GATED BLOOD POOL RADIONUCLIDE SCANS

Gated blood pool radionuclide scans also allow the measurement of LV volumes and ejection fraction. In addition, with this technique, it is possible to quantify the amount of AR. These scans, however, assess regurgitation present at both the aortic and mitral valves. Thus, if both valves are incompetent, the total amount of regurgitation present at both valves will be measured. This technique also allows measurement of LV ejection fraction on exercise and on serial studies.

TREADMILL EXERCISE TEST

A treadmill exercise test provides an objective assessment of the degree of functional impairment and documentation of arrhythmias related to exertion. In some patients, however, the exercise test may remain normal despite deterioration of LV function.

AMBULATORY ECG RECORDING

Ambulatory ECG recording may be needed in an occasional patient suspected of having an arrhythmia.

MAGNETIC RESONANCE IMAGING

MRI can demonstrate AR but is rarely needed clinically.

Clinical Decision Making

Please see the equivalent section under "Aortic Valve Stenosis," above. The sensitivity, specificity, and accuracy of diagnosis of chronic AR are shown in (Table 56-22).[66] The following should be noted: (1) The sensitivity, specificity, and accuracy of diagnosing AR after clinical evaluation are good but not quite as good as in AS; (2) echo/Doppler ultrasound improves these criteria to a greater extent than in AS; (3) the difficulties lie in accurately distinguishing patients with mild AR from normal individuals and those with moderate AR and in distinguishing between moderate AR and severe AR; and (4) both clinical evaluation and echo/Doppler ultrasound are excellent in diagnosing the AR as being moderate or severe.

Table 56-22: Clinical Decision Making Utilizing Clinical Evaluation versus Echo/Doppler in Patients with Aortic Regurgitation

	After Clinical Evaluation, %	After Echo/Doppler, %
Diagnosis of AR		
Sensitivity	66	79
Specificity	76	74
Accuracy of diagnosis		
All levels of severity	43	57
Moderate or severe AR	91	100

Natural History and Prognosis

Patients with mild AR that does not progress should have a normal life expectancy. Their major risk is the development of infective endocarditis and further valve destruction. Patients with moderate AR, if their disease does not progress, would be expected to have a life expectancy that is reasonably close to the normal range. The disease does progress, however, and mortality at the end of 10 years appears to be about 15 percent.

Patients with severe AR are known to have a long asymptomatic period before the condition is discovered. In asymptomatic patients with normal LV function at rest, symptoms and/or LV dysfunction (and/or sudden death) develop at the rate of about 3 to 6 percent per year. The predictor of development of symptoms is LV systolic dysfunction at rest.[118-122] In patients with normal LV systolic function at rest (Table 56-23), the predictors of development of LV systolic dysfunction and/or symptoms are an increased LV size (LV dimension at end-diastole of ≥70 mm and at end-systole of ≥50 mm,[119-121] and LV end-diastolic volume index of ≥150 mL/m^2),[123] and abnormal LV ejection fraction on exercise of <0.50.[111] In smaller people, for example, in women,[122] these values are too large and have to be corrected for body size. The corrected dimensions for end diastole and end systole are 35 mm/m^2 and 25 mm/m^2, respectively. Sudden death in asymptomatic patients appears to occur only in those with a massively dilated left ventricle (LV end-diastolic dimension of ≥80 mm).[119] It is likely that LV dysfunction first appears on exercise and later also at rest; eventually, heart failure ensues. Severe symptoms, however, may occur even when LV systolic pump function is normal at rest (see "Pathophysiology," above). The 5-year mortality of symptomatic patients with severe AR is about 25 percent, and the 10-year mortality averages 50 percent.[118] Once symptoms occur in patients with AR, it is likely that the rate of deterioration will be rapid. Most patients with angina are dead within 4 years.[124] The 2- to 3-year mortality of those with heart failure is 50 to 70 percent. In a recent study, the mortality was 4.7 percent per year, in the symptomatic patient it was 9.4 percent per year[125] and in the asymptomatic patient 2.8 percent, which was not significantly different from age- and gender-matched individuals in the population. In the symptomatic patient, those in the New York Heart Association (NYHA) classes III and IV had an annual mortality of 24.6 percent per year, while in the class II patient it was 6.3 percent per year. In asymptomatic patients, those with LV ejection fraction <0.55, the annual mortality was 5.8 percent per year, and in those with LV end-systolic dimension ≥25 mm/m^2, it was 7.8 percent per year.[125]

Table 56-23: Chronic Severe Aortic Regurgitation: Asymptomatic + Normal LV Function at Rest

		Likelihood of Symptoms or LV Dysfunction or Death, % per Year
LV end-diastolic	≥70 mm	10
dimension	<70 mm	2
LV end-systolic	≥50 mm	19
dimension	40-49 mm	6
	<40 mm	0

Management

All patients with AR need antibiotic prophylaxis to prevent infective endocarditis. Patients with AR of a rheumatic origin need antibiotic prophylaxis to prevent recurrences of rheumatic carditis. Patients with syphilitic AR need a course of antibiotics to treat syphilis.

Patients with mild AR need no specific therapy (Table 56-24). They do not need to restrict their activities and can lead a normal life. Patients with moderate AR also usually need no specific therapy. These patients, however, should avoid heavy physical exertion, competitive sports, and isometric exercise.

The value of long-term vasodilators to produce an improvement in LV size and function has been evaluated in two placebo-controlled randomized trials. In the hydralazine trial,[126] 36 percent of the patients were in NYHA functional class II, and patients had moderate to severe AR. Hydralazine produced modest reduction of LV end-diastolic volume and a small increase in ejection fraction at the end of 2 years; however, because of side effects, long-term compliance was poor,[126] which probably accounted for the extremely modest beneficial effects.[127] In asymptomatic patients with severe AR,[128] a calcium channel blocking agent, long-acting nifedipine, produced significant reductions in blood pressure and LV end-diastolic volume and mass and major increases in LV ejection fraction at the end of 1 year. Almost all patients completed the trial. Recently, a prospective randomized trial in *asymptomatic* patients with *normal LV systolic* function[120] showed that at the end of 6 years, 34 ± 6 percent of patients treated with digoxin developed LV systolic dysfunction and/or symptoms and thus needed valve replacement, compared to 15 ± 3 percent of patients treated with long-acting nifedipine ($p < .001$) (Fig. 56-14); 90 percent (23 of 26) of those who needed valve replacement had developed LV systolic dysfunction with or without symptoms; only 3 had become symptomatic without developing LV systolic dysfunction. Accordingly, all asymptomatic patients with severe AR and normal LV systolic function should be treated with a vasodilator (calcium antagonists long-acting nifedipine) unless there is a contraindication to its use.

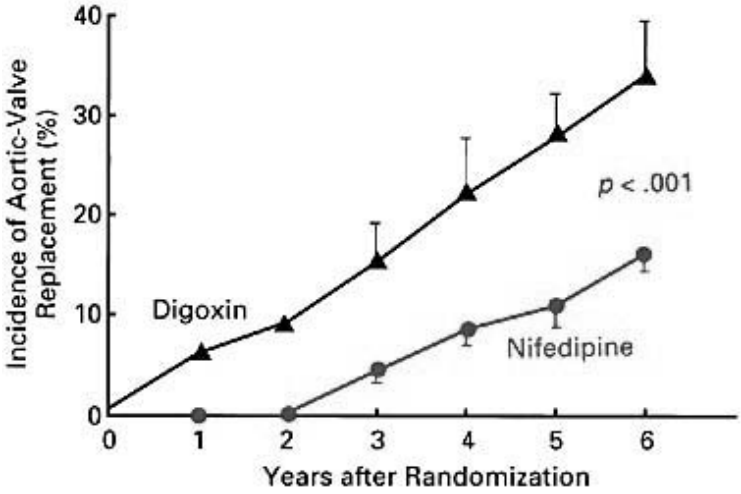

Figure 56-14: This randomized trial demonstrates that long-term vasodilator therapy with nifedipine reduces and/or delays the need for aortic valve replacement in asymptomatic patients with severe AR and normal LV systolic pump function. (From Scognamiglio et al.,[120] with permission.)

The role of nifedipine in patients with moderate AR has not been studied. In view of its beneficial effects in severe AR, long-acting nifedipine could be used in selected patients with moderate AR if there are no contraindications to its use. An acute study showed that nifedipine was superior to an ACE inhibitor,[129] and a 6-month trial showed that the results with captopril were similar to placebo.[130] One study with quinapril involved 10 patients, many of whom had moderate AR.[131] In another study with enalapril, most patients had mild to moderate AR and many had severe systemic hypertension.[132] Moreover, there are no published data to show that ACE inhibitor therapy reduces the need for valve surgery. In brief, ACE inhibitors are not of proven benefit in asymptomatic patients with AR and with normal LV systolic function.

Symptomatic patients with severe AR need medical and surgical treatment. Medical treatment (Table 56-24) consists of the administration of digitalis, diuretics, and vasodilators. Digitalis acts by increasing myocardial contractility, often reducing LV end-diastolic volume while increasing the LV ejection fraction and also the cardiac output if it is reduced in the resting state. Digitalis is clearly indicated in patients with symptoms. The need for and benefits of this therapy in asymptomatic patients have not been well documented. Diuretics are of value when the left atrial pressure is elevated and in the presence of heart failure.

Vasodilators are either arterial, venous, or both. Vasodilators act by reducing the peripheral arterial resistance, which favors forward cardiac output and reduces regurgitant volume; initially, the total LV stroke volume remains unchanged. If the left atrial pressure is elevated and LV ejection fraction reduced, vasodilators frequently result in an improvement in both.

Long-term hydralazine therapy in symptomatic patients results in significant benefit in only 20 to 35 percent of patients.[57] Those who are likely to benefit cannot be predicted. Vasodilators are indicated in patients who refuse surgery or are not operative candidates for any reason.

Vasodilators are also indicated for short-term therapy in patients awaiting valve replacement to optimize their hemodynamics (reduce filling pressures and increase cardiac output) and thus reduce their operative risks. If LV systolic function is normal, they can be given long-acting nifedipine. If they have abnormal LV systolic function, they should be treated with digitalis and ACE inhibitors; diuretics and hydralazine, with or without nitrates, can be used if needed. Small doses of hydralazine (50 mg) are without therapeutic effect in AR, and larger doses (≥100 mg) need to be given only twice daily;[133] the twice-daily regimen reduces the incidence of side effects. Hydralazine should be started in small doses and gradually increased, depending on patient tolerance of the drug.

Vasodilators are of considerable short-term benefit in patients in functional classes III and IV or heart

failure. All such patients need digitalis, diuretics, and ACE inhibitors. In patients in functional class IV with heart failure, vasodilators should ideally be started after the institution of bedside hemodynamic monitoring-that is, measurement of pulmonary artery wedge pressure and cardiac output with the use of balloon flotation catheters. Hemodynamic monitoring accurately identifies patients who need the therapy, since clinical judgments can be wrong. It establishes whether arterial dilators alone will suffice or whether additional venodilators are needed. Finally, it provides information on the optimum dosage of vasodilator therapy. After the initial hemodynamic measurements are made, arterial dilators are given in progressively increasing dosage until an optimum effect on cardiac output has been obtained. If cardiac output does not show any further increase but left atrial pressure is still very high, additional venodilator therapy should be given. If the patient is very ill or the hemodynamic abnormalities are marked, intravenous therapy (e.g., sodium nitroprusside) is the vasodilator of first choice. In this situation, intravenous vasodilator therapy should be used only with bedside hemodynamic monitoring. Inotropic agents, such as dobutamine, may be needed to improve LV function and increase cardiac output. Low-dose dopamine may be of value to increase urinary output.

Patients with severe chronic AR need valve surgery. The correct timing of surgical therapy is now better defined but is not fully clarified. Valve replacement should be performed before irreversible LV dysfunction occurs. The major problem, however, is identifying the precise point at which LV dysfunction will occur. Here, two major difficulties are encountered: (1) patients may already have impaired LV systolic pump function at rest when they first present or at the time of the first symptom and (2) patients with severe symptoms may have normal LV systolic pump function. Patients may be in NYHA functional class III (symptoms with less than ordinary activity), with a normal LV ejection fraction,[108] or they may be in functional class I (asymptomatic), with a reduced LV ejection fraction.[108] A reduced LV ejection fraction demonstrated by two-dimensional echocardiography and/or radionuclide ventriculography is the best noninvasive indicator of depressed LV systolic function.

Decisions about surgery in AR should be based on the clinical functional class and on the LV ejection fraction at rest (Table 56-25).[134] Patients with chronic severe AR who are symptomatic (NYHA functional classes II to IV) need valve replacement. Although there may be some disagreement about recommending valve replacement to patients with normal ejection fraction who are in functional class II, we currently would do so. The benefit from valve replacement has been demonstrated even when the LV ejection fraction is 0.25 or less.[135] As opposed to AS, in which there is no lower level of ejection fraction that indicates inoperability, it is likely that some patients with AR and a very low ejection fraction become inoperable. This level has not been precisely defined but may be about 0.15 or less. There is a need to individualize the need for valve replacement in those with very severe LV systolic dysfunction at rest, in those with very severe LV dilatation (LV end-diastolic volume index ≥300 mL/m^2),[136] and in those with a small regurgitant volume, with a ratio of regurgitant volume to end-diastolic volume of 0.14[137] (Table 56-25). Recent data indicate that patients with severe AR, LV end-diastolic dimension on echocardiography of ≥80 mm, and mild to moderate reduction of LV ejection fraction (mean 0.43) can obtain benefit from valve replacement.[138] Postoperatively, they are symptomatically improved, LV ejection fraction increases, and LV size is reduced; the 5- and 10-year survivals are 87 and 71 percent, respectively.

Although the issue is controversial in some countries, we believe that patients who are in NYHA functional class I (asymptomatic) and have a reduced ejection fraction at rest should be offered aortic valve replacement. If the ejection fraction is normal at rest, one should consider valve replacement in NYHA functional class I patients if they have severe obstructive CAD and/or need surgery for other valve disease (Table 56-25). It is suggested that patients undergo an exercise test during right heart catheterization if the left ventricle is large (LV end-diastolic volume ≥150 mL/m^2, LV internal dimension on M-mode echocardiography of ≥70 mm at end diastole and ≥50 mm at end systole) and/or the LV ejection fraction shows a new, persistent reduction to 0.54 to 0.60; if the patients have reduced exercise capacity on treadmill testing; or if ambulatory ECG monitoring demonstrates ventricular tachyarrhythmias. Valve replacement is recommended if the pulmonary artery wedge pressure during exercise ≥20 to 24 mmHg. Patients with associated significant CAD should have coronary bypass surgery performed at the time of valvular surgery (see "Aortic Valve Stenosis," above, and Table 56-14).

Aortic valve replacement, with or without associated coronary bypass surgery for obstructive CAD, can be performed at many surgical centers with an operative mortality of 5 percent or less (see Chap. 66). In those without associated CAD or reduced LV systolic function, the operative mortality may be in the range of 1 to 2 percent. If aortic valve replacement is successful and uncomplicated, LV volume and hypertrophy regress but do not return to normal; the beneficial effects on LV size, volume, and mass continue to be seen up to 5 years after surgery.[82,139,140] Impaired LV systolic pump function improves postoperatively in 50 percent or more of patients;[135] this improvement is more likely to occur if LV dysfunction has been present preoperatively for 12 months or less, and in this subgroup LV ejection fraction usually normalizes.[140] Even if LV systolic pump function does not improve, there is a reduction in end-diastolic volume and hypertrophy;[125] from a cardiac point of view, this is advantageous to the patient. The 5-year survival of patients undergoing aortic valve replacement in severe AR is 85 percent (this figure includes operative and late cardiac deaths).[134] The 5-year survival of patients with LV ejection fraction ≥0.45 is 87 percent, versus 54 percent in patients with an ejection fraction <0.45.[134] Late survival after valve replacement for chronic severe AR is best predicted by variables indicative of LV systolic pump function. Both the operative mortality and late survival are dependent on cardiac and LV function and associated noncardiac comorbid factors (see "Aortic Valve Stenosis," above, and Chap. 66).

Indeed, in general, the major factors influencing outcome in patients with valvular heart disease are: LV dysfunction and its magnitude, duration of LV dysfunction, degree of LV dilatation, greater NYHA functional class, older age, associated CAD, and comorbid conditions.

New techniques of aortic valve repair are being developed and evaluated, and early results are encouraging in selected subgroups.[105,141,142] It is possible that selected patients may eventually need to have valve repair rather than valve replacement for AR.

The recommendations of the ACC/AHA Practice Guidelines are shown in Table 56-26.[91] Guidelines are *not* and should *not* be the Law. Application of such guidelines to clinical practice should be based on the following principles: (1) classes I and III applies to all patients in these classes unless there is a specific clinical circumstance not to do so; (2) class II applies to patients in this class depending on the clinical conditions of the patients and the skill and experience at the individual medical center.

Table 56-26: Recommendations for Aortic Valve Replacement in Chronic Severe Aortic Regurgitation

Indication	Class
1. Patients with NYHA functional Class III or IV symptoms and preserved LV systolic function, defined as normal ejection fraction at rest (ejection fraction ≥0.50)	I
2. Patients with NYHA functional class II symptoms and preserved LV systolic function (ejection fraction ≥0.50 at rest) but with progressive LV dilatation or declining ejection fraction at rest on serial studies or declining effort tolerance on exercise testing	I
3. Patients with Canadian Heart Association functional Class II or greater angina with or without CAD	I
4. Asymptomatic or symptomatic patients with mild to moderate LV dysfunction at rest (ejection fraction 0.25 to 0.49)	I
5. Patients undergoing coronary artery bypass surgery or surgery on the aorta or other heart valves	I
6. Patients with NYHA functional Class II symptoms and preserved LV systolic function (ejection fraction ≥0.50 at rest) with stable LV size and systolic function on serial studies and stable exercise tolerance	IIa

7. Asymptomatic patients with normal LV systolic function (ejection fraction >0.50) but with severe LV dilatation (end-diastolic dimension >75 mm or end-systolic dimension >55 mm)[a]	IIa
8. Patients with severe LV dysfunction (ejection fraction <0.25)	IIb
9. Asymptomatic patients with normal systolic function at rest (ejection fraction >0.50) and progressive LV dilatation when the degree of dilatation is moderately severe (end-diastolic dimension 70 to 75 mm, end-systolic dimension 50 to 55 mm)	IIb
10. Asymptomatic patients with normal systolic function at rest (ejection fraction >0.50) but with decline in ejection fraction during	
▪ Exercise radionuclide angiography	IIb
▪Stress echocardiography	III
11. Asymptomatic patients with normal systolic function at rest (ejection fraction >0.50) and LV dilatation when degree of dilatation is not severe (end-diastolic dimension <70 mm, end-systolic dimension <50 mm)	III

[a]Consider lower threshold values for patients of small stature of either gender. Clinical judgment is required.

Chapter 56: AORTIC VALVE DISEASE

List of Figures

Figure 56-7: The left ventricular (LV) diastolic pressure-volume (P-V) relationship in acute valve regurgitation. The volume overload of acute AR produces a rapid increase of LV diastolic pressure in a patient with normal LV diastolic P-V prior to the acute AR (*curve B*). The LV diastolic pressure will rise more or less precipitously as a result of the volume overload of acute AR, depending on whether the LV is already stiff (*curve A*) or is somewhat dilated from a previous volume overload (*curve C*). (From Rahimtoola,[98] with permission.)

Figure 56-8: Pathophysiology of acute severe aortic regurgitation. Acute AR that is severe results in a large volume of regurgitant blood; therefore, the volume of blood in the left ventricle in diastole is increased. In an acute situation, the LV end-diastolic volume can only increase mildly (no more than 20 to 30 percent) and the LV diastolic pressure-volume relationships are particularly important (see Fig. 56-1). The subsequent findings are dependent on LV systolic pump function, LV diastolic pressure-volume relationship, myocardial contractile state, and compensatory tachycardia (see text for details). (Copyright © by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C. See Ref. [93].)

Figure 56-9: Role of bedside hemodynamic monitoring in acute aortic regurgitation. All patients with acute AR probably should have this procedure. If the AR is mild and there are no significant hemodynamic abnormalities, then the balloon flotation catheter can be withdrawn. On the other hand, if the AR is moderate to severe and there are significant hemodynamic abnormalities, then the balloon flotation catheter is left in place to guide therapy in the management of these acutely ill patients. If the hemodynamic abnormalities are mild, the patient is treated medically. If these abnormalities are easily controlled, medical therapy is continued and periodic reassessments are made to assess the need for elective surgery. If the hemodynamic abnormalities are not easily corrected or the hemodynamic abnormalities initially are moderate/severe, then surgery is undertaken either emergently or urgently. (From Rahimtoola,[98] with permission.)

Figure 56-10: Pathologic findings in aortic regurgitation depending on the etiology of the AR. (From Waller,[106] with permission.)

Figure 56-11: In chronic aortic regurgitation as opposed to acute AR, the AR becomes severe over a period of time; therefore, the LV diastolic pressure-volume (P-V) relationships are different from those seen in acute AR (see Fig. 56-7). If the AR is mild to moderate, the LV diastolic P-V curve is moved to the right (*curve B*). In severe AR, the LV diastolic P-V curves are moved further to the right, depending on whether the LV systolic pump function is normal (*curve C*) or abnormal (*curve D*). (From Rahimtoola,[98] with permission.)

Figure 56-12: Clinical heart failure is usually a result of the abnormal LV systolic pump function; diastolic dysfunction may also be present in some patients. Clinical heart failure in those with normal LV systolic pump function is a result of LV diastolic dysfunction. (Copyright © by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C. See Ref. [93].)

Figure 56-13: In severe aortic regurgitation, myocardial oxygen needs are increased. Total coronary blood flow is increased, but coronary reserve, i.e., the ability of the coronary blood flow to increase with vasodilatation, is significantly reduced, probably because of a reduced diastolic aortic-LV pressure gradient and compression (systolic milking) of intramyocardial coronary arteries. Therefore, myocardial ischemia is often present on stress in these patients. Associated obstructive coronary artery disease can be expected to further exacerbate the myocardial ischemia. (Copyright © by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C. See Ref. [93].)

Figure 56-14: This randomized trial demonstrates that long-term vasodilator therapy with nifedipine reduces and/or delays the need for aortic valve replacement in asymptomatic patients with severe AR and normal LV systolic pump function. (From Scognamiglio et al.,[120] with permission.)

Part 9: VALVULAR HEART DISEASE
Chapter 57:

MITRAL VALVE DISEASE

Authors: Shahbudin H. Rahimtoola, Maurice Enriquez-Sarano, Hartzell V. Schaff, Robert L. Frye

MITRAL STENOSIS

Etiology

Mitral stenosis (MS), an obstruction to blood flow between the left atrium (LA) and the left ventricle (LV), is caused by abnormal mitral valve function. In virtually all adult patients, the cause of MS is previous rheumatic carditis.[1] About 60 percent of patients with rheumatic mitral valve disease do not give a history of rheumatic fever or chorea, and about 50 percent of patients with acute rheumatic carditis do not eventually have clinical valvular heart disease.[2] Other causes of MS are all uncommon or rare and are listed in Table 57-1.[2-10] Congenital MS is uncommon. It is usually caused by a "parachute" deformity of the valve, in which shortened chordae tendineae insert in a large, single papillary muscle. MS, usually rheumatic, in association with atrial septal defect is called *Lutembacher's syndrome*. A rare cause of MS is massive mitral valve annular calcification. This process occurs most frequently in elderly patients and produces MS by limiting leaflet motion. When stenosis is present, it is usually mild in degree. Other causes of obstruction to LA outflow include a LA myxoma, massive LA ball thrombus, and cor triatriatum, in which a congenital membrane is present in the LA.

Table 57-1: Causes of Mitral Stenosis

	Involved Structure(s)			
Cause	Leaflet	Chordae	Commissures	Other
Rheumatic fever	+	+	+	
Congenital	+	+		Single papillary muscle
Active infective endocarditis	+			Vegetation
Neoplasm				Mass, pulmonary vein obstruction
Massive annular calcification	+	0	0	Rigid annulus
Systemic lupus erythematosus	+	+	+	Verrucous vegetations may extend into papillary muscles
Carcinoid				Atrial septal defect or lung tumor in order to affect left heart
Methysergide therapy	+	+		Serotonin agonist/antagonist
Hunter-Hurler syndromes				Mucopolysaccharide deposits
Fabry's disease				Aramide trihexoxide deposits
Whipple's disease				PAS-positive macrophage deposits

Rheumatoid arthritis	+	+	+	PAS-positive plasma cell infiltrate

Pathology

Acute rheumatic carditis is a pancarditis involving the pericardium, myocardium, and endocardium. In temperate climates and developed countries, there is usually a long interval (averaging 10 to 20 years) between an episode of rheumatic carditis and the clinical presentation of symptomatic MS. In tropical and subtropical climates and in less developed countries, the latent period is often shorter, and MS may occur during childhood or adolescence (see Chap. 55).

The pathologic hallmark of rheumatic carditis is an Aschoff's nodule. The most common lesion of acute rheumatic endocarditis is mitral valvulitis. In this condition the mitral valve has vegetations along the line of closure and the chordae tendineae. Mitral regurgitation (MR) may be present during the acute episode of rheumatic carditis.

MS is usually the result of repeated episodes of carditis alternating with healing and is characterized by the deposition of fibrous tissue. MS may result from fusion of the commissures, cusps, or chordae, or a combination of these.[9,10] Ultimately, the deformed valve is subject to nonspecific fibrosis and calcification. Lesions along the line of closure result in fusion of the commissures and contracture and thickening of the valve leaflets. The chordal lesions are manifest as shortening and fusion of these structures. The combination of commissural fusion, valve leaflet contracture, and fusion of the chordae tendineae results in a narrow, funnel-shaped orifice, which restricts the flow of blood from the LA to the LV. The rapidity with which patients become symptomatic may depend on the number and severity of repeated bouts of rheumatic valvulitis. Frequently, the rheumatic episodes are not clinically apparent.

In pure MS, the LV is usually normal, but there may be evidence of previous carditis with deposition of fibrous tissue. The LA is enlarged and hypertrophied as a consequence of LA hypertension. Mural thrombi are often found in the LA, particularly if atrial fibrillation has been present. Calcification of the mitral valve frequently also involves the mitral annulus.

Pathophysiology

The pathophysiologic features of MS all result from obstruction of the flow of blood between the LA and the LV. With reduction in valve area, energy is lost to friction during the transport of blood from the LA to the LV. Accordingly, a pressure gradient is present across the stenotic valve. The relationship between valve area, cardiac output, flow period, and average diastolic gradient between the LA and the LV is defined by the formula of Gorlin and Gorlin (Chap. 15).

It is readily apparent that maintaining cardiac output when the valve area is small requires a large gradient and thus an elevated LA pressure. Similarly, an increased demand for cardiac output (CO), such as occurs during exercise or pregnancy, results in an increase in gradient and high LA pressures. More subtle is the effect of the length of the diastolic flow period on the relationship between CO and gradient. The time available for diastole is that part of the cardiac cycle occupied by isovolumic contraction and relaxation or by ejection. As the heart rate increases, the total amount of time spent during systole increases despite a reduction in the systolic time per beat.[11,12] *Thus, time available for diastole decreases as the heart rate increases*. Because blood can flow through the mitral valve only during diastole, the flow rate is inversely proportional to the duration of the flow period at a constant stroke volume. Of course, a higher flow rate results in a greater loss of energy to friction and requires a larger gradient and higher LA pressures. It is important to remember that the gradient from LA to LV is a function per beat, not per minute. Thus, the gradient is dependent on the stroke volume and the diastolic filling time as well as the LV diastolic

pressure.

The pressure gradient between the LA and the LV, which increases markedly with increased heart rate or CO, is responsible for LA hypertension. The LA gradually enlarges and hypertrophies. Pulmonary venous pressure rises with LA pressure increase and is passively associated with an increase in pulmonary arterial (PA) pressure (Fig. 57-1). In up to 20 percent of patients, the pulmonary vascular resistance is also elevated,[13] which further increases PA pressure. PA hypertension results in *right ventricular* (RV) hypertrophy and RV enlargement. The changes in RV function eventually result in *right atrial* (RA) hypertension and enlargement and systemic venous congestion; frequently, tricuspid regurgitation also occurs. In a small percentage of patients, there may be regional or global LV systolic dysfunction, the cause or causes of which are not fully understood.[14-18]

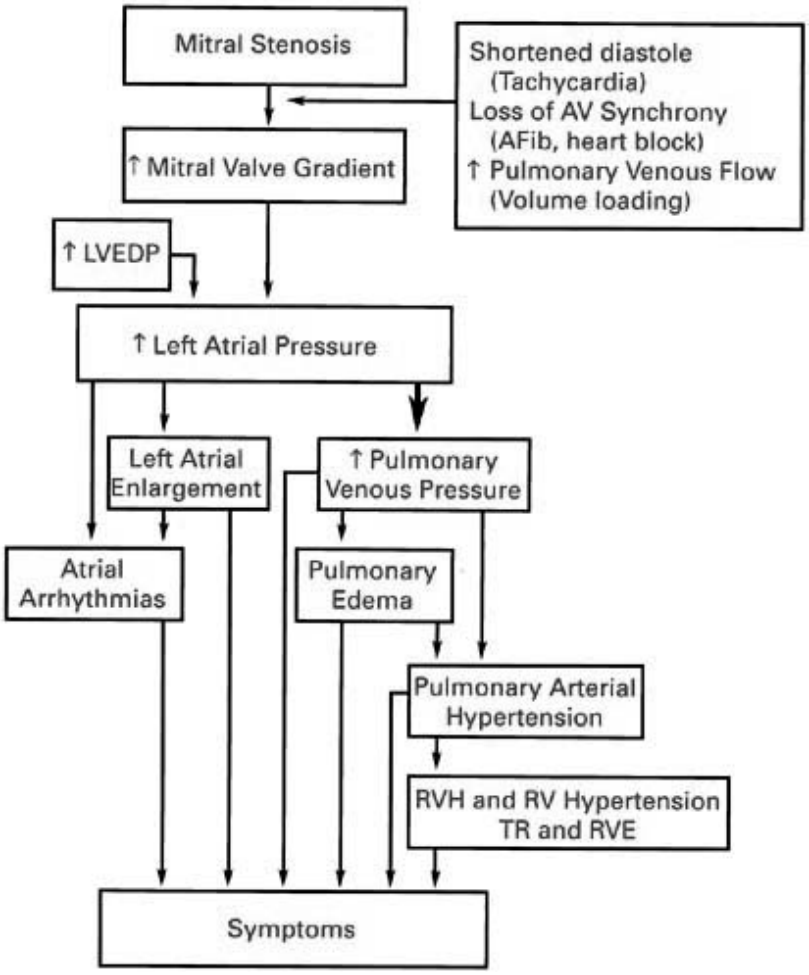

Figure 57-1: Pathophysiology of mitral stenosis. Mitral stenosis results in a diastolic pressure gradient from the LA to the LV. The actual gradient is dependent on the mitral valve area and the mitral valve *flow per diastolic second*. As a result, there is an elevation of LA pressure and therefore also of pulmonary venous pressure. Physiologic and pathologic changes-such as tachycardia and atrial fibrillation (which shorten diastole and may also result in loss of effective atrial contraction) or pregnancy, volume loading, and left-to-right shunts (at ventricular and aortopulmonary levels), which increase pulmonary venous flow-will increase the mitral valve gradient as well as LA and pulmonary venous pressures. An increased LV diastolic pressure will also result in further increase of LA pressure. An elevated LA pressure has several important effects; these include enlargement of the left atrium, atrial arrhythmias, and an increase of pulmonary venous pressure. Pulmonary venous hypertension may result in pulmonary edema and pulmonary arterial hypertension. PA hypertension and RV ventricular hypertension results in RV hypertrophy and may result in tricuspid regurgitation and RV enlargement. All of these changes contribute to producing symptoms. In addition, a fixed or even reduced cardiac output will also contribute to the

symptomatic state of the patient. [Copyright by S. H. Rahimtoola. M.B., F.R.C.P., M.A.C.P., M.A.C.C. (Ref. [10]).]

Pulmonary venous hypertension alters lung function in several ways. Distribution of blood flow in the lung is altered, with a relative increase in flow to the upper lobes and therefore in physiologic dead space. Pulmonary compliance generally decreases with increasing pulmonary capillary pressure, increasing the work of breathing, particularly during exercise. Chronic changes in the pulmonary capillaries and pulmonary arteries include fibrosis and thickening. These changes protect the lungs from the transudation of fluid into the alveoli (alveolar pulmonary edema). Indeed, it is not uncommon to find patients with severe MS whose resting PA wedge pressure (indirect LA pressure) exceeds 25 to 30 mmHg. Capillary and alveolar thickening, which help protect against pulmonary edema, further add to the abnormalities of ventilation and perfusion. Pulmonary vascular changes cause an elevated pulmonary vascular resistance.

In some patients with high pulmonary vascular resistance and RV dysfunction, CO may be low. The body maintains oxygen consumption by extracting more oxygen from the arterial blood, and the mixed venous oxygen content falls. The hemoglobin-O_2 dissociation curve is shifted to the right, facilitating the unloading of oxygen from hemoglobin to the tissues. The reduced CO may result in a *surprisingly small gradient* across the mitral valve despite severe stenosis. Although pulmonary congestion may be less striking in these patients, the CO does not increase normally with exercise, and, typically, the patients are severely limited by fatigue.

Long-standing MS with severe PA hypertension and resultant RV dysfunction may be accompanied by chronic systemic venous hypertension. Tricuspid regurgitation is frequently present, even in the absence of intrinsic disease of this valve. Functional pulmonic regurgitation may also be present. Dependent edema formation and visceral congestion directly reflect elevated systemic venous pressure and salt and water retention. Chronic passive congestion in the liver leads to central lobular necrosis and eventually to cardiac cirrhosis.

Clinical Findings

HISTORY

An asymptomatic interval is usually present between the initiating event of acute rheumatic fever and the presentation of symptomatic MS (averaging 10 to 20 years).[13,19] During this interval, the patient feels well (Table 57-2). Initially, there is little or no gradient at rest, but with increased cardiac output, LA pressure rises and exertional dyspnea develops. As mitral valve obstruction increases, dyspnea occurs at lower work levels. The progression of disability is so subtle and so protracted that patients may adapt by circumscribing their lifestyles. It becomes imperative, then, to document what activities the patient can perform without symptoms and at what activity level symptoms begin; failure to do this often results in an underestimation of disability.

Table 57-2: Symptoms Associated with Mitral Stenosis

On exertion
Dyspnea, wheezing, cough
Fatigue
Diminished activity/or pace of activity
Palpitations
Feeling faint, presyncope, syncope
At rest

Cough, wheezing
Paroxysmal nocturnal dyspnea
Orthopnea
Hemoptysis
Hoarseness (Ortner's syndrome)
From complications of MS

SOURCE: Copyright S. H. Rahimtoola, M.B., F.R.C.P, M.A.C.P., M.A.C.C. (Ref. [10]).

As obstruction progresses, the patients note orthopnea and paroxysmal nocturnal dyspnea that apparently results from redistribution of blood to the thorax on assuming the supine position. With severe MS and elevated pulmonary vascular resistance, fatigue rather than dyspnea may be the predominant symptom. Dependent edema, nausea, anorexia, and right-upper-quadrant pain reflect systemic venous congestion resulting from elevated systemic venous pressure and salt and water retention.

Palpitations are a frequent complaint in patients with MS and may represent frequent premature atrial contractions or paroxysmal atrial fibrillation/flutter. Of patients with severe symptomatic MS, 50 percent or more have chronic atrial fibrillation. Paroxysmal atrial fibrillation may produce pulmonary edema in some patients with MS. The acute increase in LA pressure that produces pulmonary edema results both from a decrease in the diastolic flow period caused by increased heart rate and from a loss of atrial transport function.

Systemic embolism, a frequent complication of MS, may result in stroke, occlusion of extremity arterial supply, occlusion of the aortic bifurcation, and visceral or myocardial infarction. Atrial fibrillation, increasing age of the patient, increasing LA size, and a previous history of embolism are associated with an increased incidence of systemic embolism[13] (Table 57-3).

Table 57-3: Complications of Mitral Stenosis

Arrhythmias
Atrial flutter/fibrillation

Chest pain/angina
Infective endocarditis

SOURCE: Copyright by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C. (Ref. [10]).

Hemoptysis may result from a variety of causes. It is usually due to increased pulmonary venous pressure. Sputum may be blood-stained with paroxysmal nocturnal dyspnea, pink frothy sputum may result from rupture of alveolar capillaries associated with acute pulmonary edema or from pulmonary infarction due to pulmonary embolism, or hemoptysis may be severe and profuse (pulmonary apoplexy). The latter results from rupture of thin-walled, dilated bronchial veins, and although usually not fatal, it may be life-threatening because of aspiration pneumonia or massive hemorrhage. The edematous bronchial mucosa is more likely to be associated with chronic bronchitis, especially in cold and wet climates; it can also result in blood-stained sputum.

Exertional chest pain, typical of angina pectoris, may be present in some patients with severe MS but normal coronary arteries. Severe PA hypertension has been postulated as a cause. Infective endocarditis is an uncommon complication of pure MS.

Progression of symptoms in MS is generally slow but relentless. Thus, a sudden change in symptoms rarely reflects a change in valve obstruction. Rather, there is usually a noncardiac precipitating event or paroxysmal atrial fibrillation. Fever, pregnancy, hyperthyroidism, and noncardiac surgery, all of which increase CO, can precipitate decompensation in patients with moderate to severe MS.

PHYSICAL FINDINGS

During the latent, presymptomatic interval, incidental physical findings may be normal or may provide evidence of mild MS. Frequently, the only characteristic finding noted at rest will be a loud S_1 and a presystolic murmur. A short diastolic decrescendo rumble may be heard only with exercise. In patients with symptomatic stenosis, the findings are more obvious, and careful physical examination usually leads to the correct diagnosis (Chap. 10).

The general appearance of the patient in MS is usually normal. The MS facies, characterized by malar flush (pinkish-purple patches on the cheeks),[13] is uncommon and is caused by peripheral cyanosis, which is usually associated with a low CO, systemic vasoconstriction, and severe PA hypertension. Tachypnea may be present if LA pressure is high. The arterial pulse is normal except for irregularity in atrial fibrillation and is of low volume when CO is reduced. All peripheral pulses should be carefully examined because of the frequency of systemic embolism. The jugular venous pressure may be normal or may show evidence of elevated RA pressure. A prominent *a* wave is a result of RV hypertension/hypertrophy or of associated tricuspid stenosis. A prominent *v* wave is caused by tricuspid regurgitation. Atrial fibrillation produces an irregular venous pulse with absent *a* waves. The chest findings may be normal or may reveal signs of pulmonary congestion with rales or pleural fluid (dullness and absent breath sounds). Marked LA enlargement may produce egophony at the tip of the left scapula.

The precordium is usually unremarkable on inspection. On palpation, the apical impulse should feel normal or is tapping (palpable mitral valve closure or RV forming the cardiac apex). An abnormal LV impulse suggests disease other than isolated MS. A diastolic thrill is usually appreciated only when the patient is examined in the left lateral position. When PA hypertension is present, a sustained RV lift along the left sternal border and pulmonic valve closure may be palpable.

On auscultation in the supine position, the only abnormality appreciated may be the accentuated S_1, which is caused by flexible valve leaflets and the wide closing excursion of the valve leaflets[20] (see also Chap. 10). Failure to examine the patient in the left lateral position accounts for most of the missed diagnoses of symptomatic MS. The diastolic rumble is heard best with the bell of the stethoscope applied at the apical impulse. Nevertheless, the murmur may be localized, and the region around the apical impulse also should be auscultated. The *opening snap* (OS) occurs when the movement of the domed mitral valve into the LV is suddenly stopped.[20] It is heard best with the diaphragm and is often most easily appreciated midway

between the apex and the left sternal border. In this intermediate region, the S_1, the pulmonary component of the second heart sound (P_2), and the OS can be identified. The auscultatory signs of MS in sinus rhythm and in atrial fibrillation are illustrated in Figs. 57-2 and 57-3.

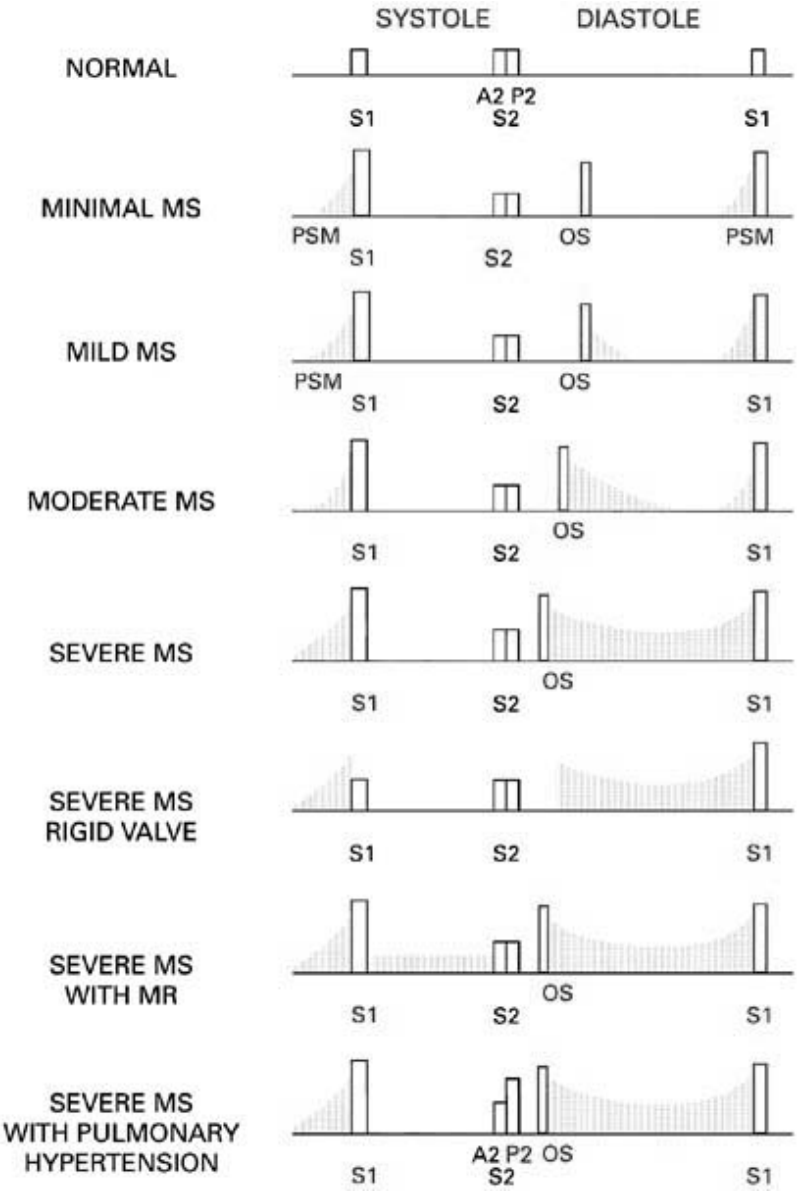

Figure 57-2: Auscultatory signs of MS in patients in sinus rhythm are illustrated. These include a presystolic murmur, loud first heart sound (S_1), an opening snap (OS), and a middiastolic murmur (low-pitched, decrescendo diastolic rumble, rumbling murmur). These signs may be accentuated or at times may be heard only by placing the patient in the left lateral decubitus position. Importantly, these signs are helpful in assessing the severity of the MS; as the MS becomes more severe, the S_2-OS interval is shortened and the length of the middiastolic rumble is increased. In mild OS, the S_2-OS interval is long and the diastolic murmur is short. In moderate MS, the S_2-OS interval is shorter, and although the diastolic murmur is longer at rest, there is usually a gap between the end of the murmur and the onset of the presystolic murmur. In severe MS, the S_2-OS interval is short (usually 0.04 to 0.06 s) and the diastolic murmur is a full-length murmur. With PA hypertension, P_2 is increased in intensity. In the presence of a rigid mitral valve (with or without calcification), S_2 is soft and the OS is usually not heard. A holosystolic murmur of mitral regurgitation may be present. (Adapted and modified from Kawanishi DT, Rahimtoola SH. Mitral stenosis. In: Rahimtoola SH, ed. *Valvular Heart Disease II*. St. Louis: Mosby; 1996:8.1-8.24. Copyright by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C.)

The OS occurs after the LV pressure falls below LA pressure in early diastole. When LA pressure is high, as in severe MS, the snap occurs earlier in diastole (Fig. 57-2). The converse is true with mild MS. The interval between A_2 and the OS varies from 40 to 120 ms. Although the OS is present in most cases of MS, it is absent in patients with stiff, fibrotic, or calcified leaflets. Thus, absence of the OS in severe MS suggests that mitral valve replacement rather than commissurotomy may be necessary.

The low-pitched diastolic rumble follows the OS and is best heard with the bell of the stethoscope. In some patients with low cardiac output or mild MS, brief exercise, such as situps or walking, is adequate to increase flow and bring out the murmur. The murmur is low-pitched, rumbling, and decrescendo. In general, the more severe the MS, the longer the murmur (Fig. 57-2). Presystolic accentuation of the murmur occurs in sinus rhythm and has been reported even in atrial fibrillation. In the latter situation, a brief "presystolic" accentuation is due to narrowing of the mitral orifice produced by ventricular systole before the final, completeclosure of the mitral valve and the mitral component of S_1. A diastolic rumble is not diagnostic of MS and may be heard with increased flow across a normal mitral valve-for example, in ventricular septal defect with a large left-to-right shunt.

The two most important auscultatory signs of severe MS are a short A_2-OS interval (usually 40 to 60 ms) and a full-length diastolic rumble. The A_2-OS interval may be longer if there is associated moderate/severe aortic regurgitation, and the OS may be absent when the mitral valve is rigid. The diastolic murmur may not be full-length in severe MS if the stroke volume is low and there is no tachycardia.

Systolic murmurs also may be heard in association with the murmur of MS. A blowing, holosystolic murmur at the apex suggests associated MR; whereas a systolic blowing murmur heard best at the lower left sternal border that increases with inspiration usually signifies tricuspid regurgitation. The Graham Steell murmur is a high-pitched diastolic decrescendo murmur of pulmonic regurgitation caused by severe PA hypertension. In most patients with MS, such a murmur usually indicates AR instead. In general, a left-sided S_3 is not compatible with severe MS with the possible exception of concomitant severe AR and/or significant LV systolic dysfunction. If an S_3 and a rumble are present, MR is usually the predominant lesion (see also Chap. 10).

ROENTGENOGRAM

The posteroanterior and lateral chest films are often so typical that experienced clinicians can make the tentative diagnosis from them. The thoracic cage is normal. The lung fields show evidence of elevated pulmonary venous pressure. Blood flow is more evenly redistributed to the upper lobes, resulting in apparent prominence of upper-lobe vascularity. Increased pulmonary venous pressure results in transudation of fluid into the interstitium. Accumulation of fluid in the interlobular septa produces linear streaks in the bases, which extend to the pleura (Kerley B lines).[21] Interstitial fluid may also be seen as perivascular or peribronchial cuffing (Kerley A lines). With transudation of fluid into the alveolar spaces, alveolar pulmonary edema is seen. These changes are not specific for MS but represent long-standing elevated LA pressure. Chronic hemosiderin deposition can result in an interstitial radiodensity that does not resolve after the relief of stenosis. PA hypertension results in enlargement of the main PA and right and left main pulmonary arteries.

The cardiac silhouette usually does not show generalized cardiomegaly, but the LA is invariably enlarged. This is manifest in the posteroanterior chest film by a density behind the RA border (double atrial shadow), prominence of the LA appendage on the left heart border between the main PA and LV apex, and elevation of the left main bronchus. The lateral film shows the LA bulging posteriorly. The LV silhouette is normal. The RV may be enlarged if PA hypertension has been present. RV enlargement is usually noted by filling of the retrosternal space, but this is an unreliable sign in adults. The combination of a normal-sized LV, enlarged LA, and pulmonary venous congestion should immediately raise the possibility of MS. Mitral valve calcification is occasionally seen on the plain chest film (see also Chap. 12).

ELECTROCARDIOGRAM

The *electrocardiogram* (ECG) is not usually as helpful as the chest x-ray. Patients in sinus rhythm may have a widened P wave caused by interatrial conduction delay and/or prolonged LA depolarization. Classically, the P wave is broad and notched in lead II and biphasic in lead V_1; it measures 0.12 s or more. Atrial fibrillation is common. LV hypertrophy is almost never present unless there are associated lesions. RV hypertrophy may be present if PA hypertension is marked (see also Chap. 11).

CLINICAL INDICATIONS OF SEVERE MITRAL STENOSIS

Some clinical features make it virtually certain that MS is severe. These include (1) moderate to severe PA hypertension as indicated by clinical and ECG evidence of RV hypertrophy or PA hypertension or both and/or (2) moderate to severe elevation of LA pressure as indicated by orthopnea, a short P_2-OS interval, a diastolic rumble that occupies the whole length of a long diastolic interval in patients with atrial fibrillation, and pulmonary edema on the chest x-ray. In both these clinical circumstances, one must be certain that there is no other cause for elevated LA pressure and that LA hypertension is not caused mainly by a correctable transient elevation of LV diastolic pressure.

Laboratory Tests

ECHOCARDIOGRAPHY/DOPPLER ULTRASOUND

Echocardiography/Doppler ultrasound has proved to be both sensitive and specific for MS when adequate studies are done (Chap. 13).[22-25] False-positive and false-negative results are uncommon. M-mode and two-dimensional echocardiography do not reliably predict the severity of MS. Doppler studies provide an estimate of mitral valve area that is within ±0.4 cm^2 (prior to interventional therapy) of that obtained by cardiac catheterization.[26] The echographic findings of MS reflect the loss of normal valve function. The fusion of commissures results in movement of the anterior and posterior leaflets anteriorly in parallel during diastole. In patients in sinus rhythm, there is an absence of the further opening of the valve that is normally seen with atrial contraction. Other findings include decreased E-to-F slope, decreased mitral valve leaflet excursion, and multiple echoes, indicating thickening or calcification of the valve. LA enlargement is seen. Abnormal pulmonary valve motion and RV enlargement may signify PA hypertension (see also Chap. 13).

Echocardiography is of great value in patients with equivocal signs, in patients with gross PA hypertension, to differentiate MS from an Austin Flint murmur of AR, and in the rare patient with "silent" MS. It is used to assess LV, RV, and atrial size and function; to evaluate the aortic and tricuspid valves; and to estimate PA pressure. When transthoracic echocardiography (TTE) is unsatisfactory, transesophageal echocardiography (TEE) is a useful technique to assess LA thrombus, the anatomy of the mitral valve and subvalvular apparatus, and to assess the suitability of the patient for catheter balloon commissurotomy or surgical valve repair.

Echocardiography/Doppler ultrasound is a most useful test in MS and should be performed in all patients. It is essential to determine suitability of the valve for commissurotomy and/or repair and to determine the likely result.

CARDIAC CATHETERIZATION/ANGIOGRAPHY

In most patients with disabling symptoms from presumed MS, right and left heart catheterization should be performed as part of a preoperative assessment. Simultaneous measurement of cardiac output and the gradient between the LA and the LV and calculation of valve area remain the "gold standard" for assessing the severity of MS (Chap. 15). LV angiography assesses the competence of the mitral valve, an important determinant of operability for mitral commissurotomy. Quantification of LV function provides a useful prognostic indicator of operative and late survival and of the expected functional result. Aortic valve function should be evaluated in all patients. Selective supraventricular aortography should be performed in all patients unless there is a contraindication. Tricuspid valve function can be assessed when there is a question of coexisting lesions. In certain circumstances-for example, in a patient with suspected severe MS

who has a small gradient and mildly elevated LA pressure-dynamic exercise in the catheterization laboratory with measurement of mitral valve gradient, CO and LA and PA pressures can be extremely useful. Another example is a patient with significant symptoms in whom the findings at rest suggest moderate (or even mild) MS. Selective coronary arteriography establishes the site, severity, and extent of coronary artery disease and should be performed in patients with angina, in those with LV dysfunction, in those with risk factors for coronary artery disease, and in those 35 years of age or older who are being considered for interventional therapy.

OTHER INVESTIGATIONS

In most clinical situations, other investigations are not needed. Occasionally, a treadmill exercise test to evaluate functional capacity may be very useful clinically-for example, when a patient denies symptoms in spite of severe hemodynamic abnormalities.

Clinical Decision Making

The reader is referred to the section on aortic stenosis in Chap. 57. In a prospective blinded study of consecutive patients with valvular heart disease, the sensitivity and specificity of diagnosis of MS by clinical evaluation was 86 and 87 percent, respectively. The accuracy of diagnosis of MS for moderate to severe stenosis was 92 percent by clinical evaluation and 97 percent by echocardiography/Doppler ultrasound.[27] This emphasizes the importance of a thorough clinical evaluation. The principal difficulty with both clinical evaluation and echocardiography/Doppler ultrasound is being able to accurately separate in all instances mild from moderate MS and moderate from severe MS.

Natural History and Prognosis

The population presenting with MS is changing because of the sharp decline in the incidence of acute rheumatic fever in the past 40 years (see also Chap. 55). Native-born American citizens with symptomatic MS are presenting at an older age. Young adults in the third and fourth decades with symptomatic MS are more likely to come from low socioeconomic backgrounds and from the inner city or to be immigrants, particularly from Latin America, the Middle East, Africa, or Asia. Therefore, the latent period between acute rheumatic fever and symptomatic MS is variable and appears to be related to the presence of repeated streptococcal infection. Women with MS outnumber men by almost two to one. The most important feature of the asymptomatic interval is the susceptibility to repeated bouts of both rheumatic valvulitis and streptococcal infection. The mechanism for the progression from no symptoms to mild to severe symptoms is progressive stenosis of the mitral valve.

With the onset of exertional dyspnea and fatigue, the valve area is usually reduced to one-half to one-third its normal size. Further small reductions in valve area markedly obstruct flow and result in symptoms with minimal exertion. The interval from initial mild symptoms to disabling symptoms may be 10 years. During this time, the patient is at some risk of death (see below). Permanent injury may result from atrial fibrillation with rapid ventricular rate, resulting in pulmonary edema, and from systemic embolus. Unfortunately, it is not possible to predict who is at risk of embolism. When late functional class II or functional class III symptoms are present, the valve area is usually 1.0 cm^2 or less (in an occasional patient the valve area is 1.2 or 1.3 cm^2), and both rest and exercise hemodynamics are deranged.[2] Further small reductions in valve area result in symptoms at rest.

The 10-year survival of patients with MS who are asymptomatic is approximately 84 percent and that of those who are mildly symptomatic is 34 to 42 percent (Fig. 57-4).[28-30] The 10-year survival of patients who are moderately or severely symptomatic and who do not have therapy is 40 percent or less, and the survival at 20 years is less than 10 percent.[28-30] Patients in the New York Heart Association functional class IV have a very poor survival without treatment[28]: 42 percent at 1 year and 10 percent or less at 5 years. All are dead by 10 years (Fig. 57-5).

Management

MS can be prevented through two approaches (Table 57-4). First, all streptococcal infections should be diagnosed rapidly and correctly treated (Chap. 55). This prevents most initial episodes of acute rheumatic fever. Second, all patients with known previous acute rheumatic fever/rheumatic carditis with or without obvious valve disease should receive appropriate antibiotic prophylaxis against recurrent streptococcal infection (Chap. 55).

Table 57-4: Medical Treatment of Mitral Stenosis

Prevention	
Primary	
Treatment of streptococcal group A infection	
Secondary (antibiotic prophylaxis)	
Recurrent rheumatic fever	
Infective endocarditis	
Restrict activities (moderate/severe MS)	
Severe exercise	
Competitive sports	
Arrhythmias	
Prevent and/or control	
Restore sinus rhythm if possible	
Cardiac medications	
Use only if essential	
Diuretics-use cautiously	
Anticoagulants for systemic/pulmonary emboli	
Elevated pulmonary venous pressure-diuretics	
Heart failure-digitalis, diuretics, ACE inhibitors	
Follow-up of asymptomatic patients	
Mild MS	Every 2-5 years
Moderate MS	Every 1-2 years
Severe MS	Every 6-12 months if interventional therapy not performed
Development of symptoms	Early or 'immediate'

Although the incidence of infective endocarditis is low in isolated MS, all patients exposed to bacteremia should receive appropriate prophylaxis against infective endocarditis (Chap. 73). Family and vocational planning should be considered. Women with this disease should consider bearing children before symptoms

occur, since pregnancy is usually well tolerated with mild MS. Occupations that require strenuous exertion in middle age and later should probably be avoided if possible. In patients with moderate or severe MS, activities such as strenuous exercise and competitive sports should be restricted.[9]

When patients reach the symptomatic threshold, medical treatment may be of some benefit. Digitalis offers no improvement for the patient with normal sinus rhythm and normal LV function. When atrial fibrillation is present, however, digitalis plays a critical role in controlling ventricular rate. In selected patients, beta-adrenergic blocking agents, diltiazem, or amiodarone may be added if digoxin alone is not satisfactory in controlling ventricular rate at rest or on exercise. Beta-adrenergic blocking agents should be used with great caution or not at all in patients with impaired LV function, associated significant aortic stenosis, or other associated severe valvular disease. Digoxin and diltiazem or digoxin and low-dose amiodarone are probably the two best combined regimens. Diuretics reduce pulmonary congestion and peripheral edema and allow most patients freedom from severe salt restriction. For the patient with mild symptoms, maintenance of sinus rhythm is desirable. Cardioversion of atrial fibrillation and maintenance of sinus rhythm using antiarrhythmic therapy with either digitalis and quinidine or digitalis and amiodarone should be offered to these patients. In patients who need interventional therapy, cardioversion is usually performed after completion of the procedure. Anticoagulation with warfarin is usually begun about 3 weeks in advance of cardioversion and for 4 weeks after the procedure.[31] Patients with chronic atrial fibrillation and those with a previous history of embolism should receive anticoagulation with warfarin (International Normalized Ratio, or INR, of 2 to 3) unless there is a specific contraindication.

There are no randomized trials of surgery versus medical therapy. Roy and Gopinath's study[29] showed that in comparable patients, surgical commissurotomy was associated with a better survival than medical therapy in patients with class II symptoms as well as in those with class III and IV symptoms (Fig. 57-6).

Unless there is a contraindication, surgery should be recommended to an MS patient with functional class III or IV symptoms (Table 57-5). For younger patients with a pliable, noncalcified valve and without important mitral regurgitation, this means valve repair. The hemodynamic results of surgical commissurotomy are excellent.[9,32,33] Because of the low morbidity and mortality of mitral commissurotomy/valve repair,[9,32-34] surgery is also offered to those patients when functional class II symptoms are present. The results of successful commissurotomy are excellent; in experienced and skilled centers, surgical mortality is less that 1 percent. Late mortality at 10 years is less than 5 percent, the thromboembolism rate is 2 percent per year or less, and the reoperation rate ranges from 0.5 to 4.5 percent per year. The return of symptoms after commissurotomy/valve repair is usually the result of an incomplete operation, other valvular lesions, refusion of mitral commissures, or deterioration of myocardial function. In less developed countries, excellent results have been reported in a very high percentage of young patients for up to 25 years.[35]

Table 57-5: Indications for Interventional Therapy for Severe Mitral Stenosis

All severely symptomatic patients (functional classes III and IV)
All mildly symptomatic patients (functional class II)[a,b]
Asymptomatic patients[a,b]
Pulmonary artery hypertension
Episodic pulmonary edema
Atrial fibrillation (persistent or repeated episodes)
Thromboembolism (systemic/pulmonary)
Severe mitral stenosis (valve suitable for CBC/surgical valve repair)

[a]Catheter balloon commissurotomy (CBC)/surgery.
[b]Individualize depending on patient characteristics; suitability of patient for CBC/surgical valve repair versus valve replacement, skill and experience of interventional team.

For the older patient with a stiff or calcified valve or when moderate mitral regurgitation is present, mitral valve replacement is usually performed. Valve replacement carries a higher operative mortality than does commissurotomy (up to 5 percent) and the morbidity associated with prostheses (see Chap. 60). Hemodynamic results of mitral valve replacement are often not ideal (Table 57-6).[36,37] Survival at 10 years after mitral valve replacement for functional class III and IV patients is better than 60 percent (see Chap. 60).

Catheter balloon commissurotomy (CBC) with use of the double balloon technique or the lnoue balloon produces immediate and 3-month hemodynamic and clinical results comparable to those obtained by surgical commissurotomy.[38-41] The mitral valve area increases from a mean of 1.0 to 2.0 cm^2.[26,32,38] There are reductions of LA and PA pressures at rest and on exercise and an increase of exercise capacity.[39] The immediate results of CBC are greatly influenced by the characteristics of the valve and its supporting apparatus, which are best determined by two-dimensional echocardiography (transthoracic and/or transesophageal).[22] Echocardiographic scores of ≤8 or of 0-1 determined by the two different methods provide a clue to the best immediate results. Repeat CBC or mitral valve replacement is needed in 20 percent of patients within 5 to 7 years. Late survival is poorer in those in whom functional class IV, higher echocardiographic score, higher LV end-diastolic pressure, or higher PA systolic pressure is present prior to the CBC.[42-47] In one study, the 7-year survival was 95 ± 1 percent and the event-free survival was 65 ± 6 percent.[47] The 7-year event-free survival ranged from 13 to 90 percent in various subgroups. The 7-year event-free survival was best predicted by the post-CBC mitral valve area (≥1.5 cm^2) and PA wedge pressure (18 mmHg); the 7-year event-free survival was 90 ± 6 percent.[47] In the appropriate patient and in centers with skilled and experienced staff, CBC is the procedure of first choice for relief of severe MS. Factors to be taken into account choosing between surgery and CBC in an individual patient are shown in Table 57-7.

Table 57-7: Some Factors to Be Considered in Choice of Type of Interventional Therapy for Mitral Stenosis[a]

Mitral valve morphology	
Low echo score:	Catheter balloon commissurotomy (CBC)
	Surgical valve repair
High echo score:	Surgery
	CBC in special circumstances
Mitral regurgitation	
≥3+:	Surgery
≤1+:	CBC
2+:	Individualize (CBC versus surgery)
Left atrial thrombus	
Surgery	

CBC in special circumstances	
Need for other cardiac surgery	
Surgery	
CBC in special circumstances

The recommendations of the ACC/AHA Practice Guidelines are shown in Tables 57-8, 57-9, and 57-10.[48] Guidelines are *not* and should *not* be the law. Application of guidelines to clinical practice should be based on the following principles: (1) classes I and III apply to all patients in these classes unless there is a specific clinical circumstance contradicting this and (2) class II applies to patients in this class depending on the clinical condition of the patient and the skill and experience at the individual medical center.

Table 57-10: Recommendations for Mitral Valve Replacement for Mitral Stenosis

Indication	Class
1. Patients with moderate or severe MS (mitral valve area ≤1.5 cm^2)[a] and NYHA functional class III-IV symptoms who are not considered candidates for percutaneous balloon valvotomy or mitral valve repair	I
2. Patients with severe MS (mitral valve area ≤1 cm^2)[a] and severe pulmonary hypertension (pulmonary artery systolic pressure >60 to 80 mmHg) with NYHA functional class I-II symptoms who are not considered candidates for percutaneous balloon valvotomy or mitral valve repair	IIa

[a]The committee recognizes that there may be a variability in the measurement of mitral valve area and that the mean transmitral gradient, pulmonary artery wedge pressure, and pulmonary artery pressure should also be considered.

SOURCE: ACC/AHA Guidelines,[48] with permission.

Table 57-8: Recommendations for Percutaneous Mitral Balloon Valvotomy

Indication	Class
1. Symptomatic patients (NYHA functional class II, III, or IV), moderate or severe MS (mitral valve area ≤1.5 cm^2),[a] and valve morphology favorable for percutaneous balloon valvotomy in the absence of left atrial thrombus or moderate to severe MR	I
2. Asymptomatic patients with moderate or severe MS (mitral valve area ≤1.5 cm^2)[a] and valve morphology favorable for percutaneous balloon valvotomy who have pulmonary hypertension (pulmonary artery systolic pressure >50 mmHg at rest or 60 mmHg with exercise) in the absence of left atrial thrombus or moderate to severe MR	IIa
3. Patients with NYHA functional class III-IV symptoms, moderate or severe MS (mitral valve area ≤1.5 cm^2),[a] and a nonpliable calcified valve who are at high risk for surgery in the absence of left atrial thrombus or moderate to severe MR	IIa

4. Asymptomatic patients, moderate or severe MS (mitral valve area ≤1.5 cm^2)[a] and valve morphology favorable for percutaneous balloon valvotomy who have new onset of atrial fibrillation in the absence of left atrial thrombus or moderate to severe MR	IIb
5. Patients in NYHA functional class III-IV, moderate or severe MS (MVA ≤1.5 cm^2), and a nonpliable calcified valve who are low-risk candidates for surgery	IIb
6. Patients with mild MS	III

[a]The committee recognizes that there may be variability in the measurement of mitral valve area and that the mean transmitral gradient, pulmonary artery wedge pressure, and pulmonary artery pressure at rest or during exercise should also be taken into consideration.

SOURCE: ACC/AHA Guidelines,[48] with permission.

Table 57-9: Recommendations for Mitral Valve Repair for Mitral Stenosis

Indication	Class
1. Patients with NYHA functional class III-IV symptoms, moderate or severe MS (mitral valve area ≤1.5 cm^2),[a] and valve morphology favorable for repair if percutaneous mitral balloon valvotomy is not available	I
2. Patients with NYHA functional class III-IV symptoms, moderate or severe MS (mitral valve area ≤1.5 cm^2),[a] and valve morphology favorable for repair if a left atrial thrombus is present despite anticoagulation	I
3. Patients with NYHA functional class III-IV symptoms, moderate or severe MS (mitral valve area ≤1.5 cm^2),[a] and a nonpliable or calcified valve with the decision to proceed with either repair or replacement made at the time of the operation	I
4. Patients in NYHA functional class I, moderate or severe MS (mitral valve area ≤1.5 cm^2),[a] and valve morphology favorable for repair who have had recurrent episodes of embolic events on adequate anticoagulation	IIb
5. Patients with NYHA functional class I-IV symptoms and mild MS	III

[a]The committee recognizes that there may be a variability in the measurement of mitral valve area and that the mean transmitral gradient, pulmonary artery wedge pressure, and pulmonary artery pressure at rest or during exercise should also be considered.

Chapter 57: MITRAL VALVE DISEASE

NORMAL MITRAL STRUCTURE AND FUNCTION

The mitral valve is a complex structure formed by four elements[49,50]:

1. The annulus is asymmetrical, with a fixed portion (corresponding to the anterior leaflet) shared with the aortic annulus and a dynamic portion (corresponding to the posterior leaflet) that represents most of the circumference of the annulus.
2. The two leaflets are asymmetrical; the anterior has the greater length of tissue but occupies a smaller portion of the circumference of the annulus than the posterior.
3. The chordae join each papillary muscle to the corresponding commissure and the adjoining halves of both leaflets and maintain the two leaflets in a position allowing coaptation.
4. The two papillary muscles and the adjacent wall attach the mitral apparatus to the LV.

Mitral competence during systole is normally ensured, first, by a large area of coaptation between leaflets allowing high friction resistance to abnormal valve movement and, second, by the systolic position to the anterior leaflet parallel to the direction of blood flow. The mechanism of MR frequently combines abnormal function of more than one anatomic element, which fact underlines the complexity of conservative surgery for restoration of normal mitral function.

Chapter 57: MITRAL VALVE DISEASE

MITRAL REGURGITATION

Mitral regurgitation (MR) is characterized by an abnormal reversed blood flow from the left ventricle (LV) to the left atrium (LA). The etiologic profile of MR is now dominated by degenerative and ischemic causes in developed countries. The development of noninvasive assessment with transesophageal echocardiography, color-flow imaging and Doppler methods of quantitation of regurgitation has transformed diagnostic approaches. With improved understanding of the impact of LV dysfunction on outcome, and most importantly with major advances in conservative surgery, the management of MR has become far more proactive.

Etiology and Mechanism (Table 57-11)

MR is often referred to as *organic* if there is an intrinsic valve disease or *functional* if the valve is structurally normal but leaks due to an extravalvular abnormality. Ischemic MR may be organic (ruptured papillary muscle) or functional (LV dysfunction). Nonischemic MR may be organic (e.g., rheumatic) or functional (e.g., cardiomyopathy).

RHEUMATIC DISEASE

Rheumatic MR is rarely pure, and in most cases is associated with stenosis and fusion of the commissures (Fig. 57-7, Plate 86). Severe rheumatic MR requiring surgical correction is still frequent in developing countries but is now rare in developed countries.[51] The underlying lesion is retractile fibrosis of leaflets and chordae, causing loss of coaptation. The secondary dilatation of the mitral annulus tends to further decrease the contract between leaflets. Elongated or ruptured chordae are infrequent.

DEGENERATIVE MITRAL REGURGITATION

These causes are often associated with valve prolapse, an abnormal movement of the leaflets into the LA during systole due to inadequate chordal support (elongation or rupture) and excessive valvular tissue. In western countries, mitral prolapse represents the most frequent causes leading to surgery for severe MR.[51] Degenerative MR can be separated in three categories:

- The mitral valve prolapse syndrome, characterized by diffuse myxomatous infiltration, discussed in detail in Chap. 58 (Fig. 57-8, Plate 87).
- The degenerative "primary" ruptured chordae, which involves the posterior more often than the anterior leaflet and occurs more often in men than in women. There is usually no excessive tissue, but enlargement of the annulus may occur as in any MR. The involved leaflet may present with a myxomatous infiltration, but the other leaflet usually remains normal. Calcification of the mitral annulus or systemic hypertension may precede the occurrence of the ruptured chordae. Isolated ruptured cord may occasionally be due to blunt thoracic trauma and endocarditis (secondary forms).
- Degenerative MR without prolapse, which is usually mild and due to valve sclerosis or isolated annular calcification; here regurgitation is secondary to deformation of the valves of annulus (Fig. 57-9, Plate 88).

INFECTIVE ENDOCARDITIS

Infective endocarditis accounts for about 5 percent of cases of severe MR. Vegetations may produce mild MR by interposition between leaflets. Severe endocarditic MR is usually related to ruptured chordae and less frequently to destruction of mitral tissue involving either the leaflet's edges or a perforation (Fig. 57-10, Plate 89).

ISCHEMIC AND FUNCTIONAL MITRAL REGURGITATION

Ischemic and functional MR-i.e., due to LV wall dysfunction secondary to ischemia, scarring, aneurysm, cardiomyopathy, or myocarditis-have in common the same mechanism: the coaptation of intrinsically normal leaflets is incomplete. Rupture of papillary muscle produces MR because of the flail leaflet and involves in 80 percent of cases the posteromedial papillary muscle and is most often associated with infarction of the adjacent ventricular wall.[53] It is the rarest form of heart rupture and of ischemic MR. Complete rupture is rapidly fatal without surgery, and partial or single-head rupture of the papillary muscle more often allows emergency surgery[53] (Fig. 57-11, Plate 90).

OTHER CAUSES OF MITRAL REGURGITATION

MR is observed very frequently with color-flow imaging, even in patients without cardiac disease. However, clinically significant MR may be found in (1) *connective tissue disorder,* Marfan syndrome, Ehlers-Danlos syndrome, pseudoxanthum elasticum, osteogenesis imperfecta, Hurler's disease, systemic lupus erythematosus, and anticardiolipin syndrome; (2) penetrating or nonpenetrating *cardiac trauma;* (3) *myocardial disease*-hypertrophic cardiomyopathy or sarcoidosis; (4) *endocardial lesions* due to hypereosinophilic syndrome, endocardial fibroelastosis, carcinoid tumors, ergot toxicity, radiation toxicity, diet or drug toxicity[54]; (5) *congenital* lesions such as cleft mitral valve isolated or associated with persistent atrioventricular canal, corrected transposition with or without Ebstein's abnormality of the left atrioventricular valve, and (6) *cardiac tumors*.

Pathophysiology

The abnormal coaptation of the mitral leaflets creates a *regurgitant orifice* during systole. The systolic pressure gradient between the LV and LA is the driving force of the regurgitant flow, which results in a *regurgitant volume*. This regurgitant volume represents a percentage of the total ejection of the LV and may be expressed as the *regurgitant fraction*. The regurgitant volume creates a volume overload by entering the LA in systole and the LV in diastole, modifying LV loading and function.

CHRONOLOGY OF REGURGITATION

The pressure gradient between the LV and atrium begins with mitral closure (simultaneous to S_1) and persists after closure of the aortic valve (S_2) until the mitral valve opens.[55] Thus, timing of regurgitant flow is determined by that of the regurgitant orifice and is most often holosystolic. Various dynamic changes in the regurgitant orifice can be observed depending on its cause.[56] With small regurgitant orifices, the regurgitant orifice declines with the ventricular volume tending to limit regurgitation to early systole.[55] Conversely, in valve prolapse, the regurgitant orifice appears or increases late in systole and variations of regurgitant flow throughout systole are the complex results of combined effects of changes of regurgitant orifice and gradient.[56,57]

DEGREE AND CONSEQUENCES OF REGURGITATION

The degree of volume overload depends on three factors, the area of the regurgitant orifice,[58] the regurgitant gradient, and the regurgitant duration. The volume overload is usually less severe in mitral than in aortic regurgitation, despite a usually larger regurgitant gradient and orifice.[58] Such differences are related to a shorter duration of MR during the cardiac cycle in mitral than in aortic regurgitation.[58]

The degree of MR is not fixed and may vary with interventions. Vasodilators may be beneficial,[59] but the change in regurgitant orifice area rather than that of ventriculoatrial gradient is the main mechanism of this effect. In functional[60] and organic MR,[61] the regurgitant orifice increases with increased afterload or ventricular volume and decreases with decreased afterload or improved contractility, but it is not influenced by changes in heart rate.[61]

The regurgitant energy produced by the LV translates into two components: the kinetic energy (regurgitant volume) and the potential energy (elevation of atrial pressure). The typical left atrial pressure change is the V wave,[62] which nevertheless, is not specific for MR. The height of the V wave and more generally left atrial pressure is mainly determined by left atrial compliance.[62] In acute MR, the LA is less compliant than in chronic MR and the MR produces a marked increase in LA pressure. The atrial V wave, in turn, decreases the ventriculoatrial gradient and, thus, for any effective regurgitant orifice,[58] tends to limit the regurgitant volume. When MR becomes chronic, the LA dilates, the V wave is less prominent, and it does not limit the regurgitant volume; the LA pressure may be normal even with severe MR.[63] At that stage, usually the cardiac output is decreased but the pulmonary pressures are often normal. Pulmonary hypertension in MR is poorly understood and mostly observed in elderly patients.

LEFT VENTRICULAR FUNCTION

With MR the LV is dilated, but less so than in aortic regurgitation of comparable degree.[64] LV end-diastolic volume and wall stress are increased,[64] and the ventricle's shape becomes spherical. End-systolic volume is increased in chronic MR but end-systolic wall stress is usually normal.[65] The myocardial mass is increased proportionately to LV dilatation.[66]

LV function is difficult to characterize because of the changes in preload and afterload. It has been suggested that normalization of ejection fraction (EF) to the preload would provide an appropriate assessment of LV function. Afterload is more difficult to assess because the MR may decrease the instantaneous impedance to ejection, but the measure of afterload provided by end-systolic wall stress is within the normal range.[65] However the usual inverse correlation between end-systolic wall stress and EF is also observed in MR.[67] Complex indices using the afterload-such as the end systolic wall stress,[68] or maximum elastance,[65] normalized to the LV volume-have been proposed and may be sensitive to subtle changes in function.

LV dysfunction is a frequent and dismal complication of MR.[69,70] The mechanism of LV hypertrophy is a reduction in protein degradation, but the mechanisms leading to interstitial fibrosis and LV dysfunction remain mysterious. Experimentally, LV dysfunction is not due to changes in coronary blood flow. The changes in myofiber contractility parallel those in LV function[71] and are associated with reduced myofiber content,[72] but the cause of the myofiber dysfunction and the explanation of its high incidence have not been clarified.

During diastole, LV relaxation is prolonged but chamber stiffness is reduced.[73] Age and decreased

systolic function[73] are associated with increased chamber stiffness. The significance of the diastolic abnormalities is unclear.

ISCHEMIC AND FUNCTIONAL MITRAL REGURGITATION

The pathophysiology of ruptured papillary muscles is poorly known. In chronic ischemic or functional MR, the primary disease involves the LV, which is often contracting poorly. However, MR may be determined more by localized LV deformation than by the systolic function. The apical and inferior traction on papillary muscles leads to leaflet tethering and tenting and subsequently to MR.[74,75] In ischemic or functional as opposed to organic (due to primary valvular disease) MR, the regurgitant volume is usually small,[76] and the LV and atrial dilatation is in excess to the degree of MR.[58] Nevertheless, MR is associated with elevated left atrial pressure[58] and poor outcome[77]; it is also a marker of sensitivity to vasodilators.

HORMONAL ACTIVATION

In organic MR, natriuretic peptides are elevated in experimental[78] and clinical[79] studies. The main determinant of elevation of atrial natriuretic peptide is the elevation of atrial pressures.[79] In our experience, brain natriuretic peptide is more a marker of LV remodeling than of altered hemodynamics. The value of natriuretic peptide levels as markers of hemodynamics, LV function, and prognosis is not established yet.

The activation of the renin-angiotensin system is not fully understood. In dogs with organic MR, systemic activation of the renin-angiotensin system is rare,[80] but tissue levels of angiotensin II are markedly elevated.[81,82] The role of angiotensin in the development of hypertrophy and fibrosis are not fully clarified.

Clinical Presentation

The sex distribution has changed in parallel to the changes in etiology of MR. With the decrease in rheumatic heart disease, severe MR is now predominantly seen in males (65 to 75 percent). The prevalence of MR increases with age[83]; therefore, patients with severe MR most often present in the sixth decade of life.[84]

The clinical presentation-including symptoms, physical findings, electrocardiographic and radiographic change-is determined by the degree, rapidity of development, and cause of MR and by LA and LV function and compliance.

SYMPTOMS

Patients with mild MR usually have no symptoms. Severe MR is diagnosed most often because of the murmur when no or minimal symptoms are present.[84] Fatigue and mild dyspnea on exertion are the most usual symptoms and are rapidly improved by rest. The administration of diuretics and progressive self-limitation of physical activity may prevent the occurrence of more severe symptoms. Severe dyspnea on exertion or, more rarely, paroxysmal nocturnal dyspnea, frank pulmonary edema, or even hemoptysis may be observed later in the course of the disease. Such severe symptoms may be triggered by a new onset of atrial fibrillation, or increase in degree of MR, the occurrence of endocarditis or ruptured chordae, or a change in LV compliance or function.

With severe MR of *acute onset*, symptoms are usually more dramatic-pulmonary edema or

congestive heart failure-but will progressively subside with administration of diuretic and increased LA compliance. A syndrome of sudden onset of atypical chest pain and dyspnea may occur with abrupt chordal rupture. Rupture of papillary muscle usually has a dramatic presentation, with cardiogenic shock or a severe pulmonary edema. Pulmonary edema may also be observed in transient severe papillary muscle dysfunction.

Sudden death as the initial presentation of MR is rare.[85]

PHYSICAL EXAMINATION

Blood pressure is usually normal. Carotid upstroke is brisk.

Cardiac palpation may show laterally displaced, diffuse, and brief apical impulse with enlarged LV. An apical thrill is characteristic of severe MR. The left sternal border lift is observed with right ventricular dilatation and may be difficult to distinguish from the left atrial lift due to the dilated, expansive LA, which is more substernal and lower.

S_1 is included in the murmur and is usually normal but may be increased in rheumatic disease. S_2 is usually normal but may be paradoxically split if the LV ejection time is markedly shortened. The presence of a third heart sound (S_3) is directly related to the volume of the regurgitation in patients with organic MR.[86] It is often associated with an early diastolic rumble due to the increased mitral flow in diastole even without mitral stenosis (Chap. 10). The S_3 and diastolic rumble are low-pitched sounds and may be difficult to detect without careful auscultation in the left lateral decubitus position. The S_3 increases with expiration. In ischemic-functional MR, S_3 corresponds more often to restrictive LV filling. An atrial gallop (S_4) is heard mainly in MR of recent onset and in ischemic/functional MR in sinus rhythm. Midsystolic clicks are markers of valve prolapse (Chaps. 10 and 11).

The hallmark of MR is the systolic murmur, most often holosystolic, including first and second heart sounds. If an opening snap or S_3 is mistakenly interpreted as S_2, the murmur may appear midsystolic. Only a careful examination beginning at the base of the heart to identify the second heart sound and progressing toward the apex will allow clear recognition of the nature of the murmur. The murmur is of the blowing type but may be harsh, especially in valve prolapse. The maximum intensity is usually at the apex, and it may radiate to the axilla in rheumatic or anterior leaflet prolapse, affecting primarily the anterior leaflet. In posterior leaflet prolapse, the jet is usually superiorly and medially directed and the murmur radiates towards the base of the heart.[87] The murmur may be heard in the back, in the neck, and sometimes on the skull. In the cases where the murmur radiates to the base, it may be difficult to distinguish from the murmur of aortic stenosis or obstructive cardiomyopathy, and pharmacologic maneuvers showing that the murmur decreases with amyl nitrite and increases with methoxamine strongly suggest MR. Murmur intensity does not increase with postextrasystolic beats and usually parallels the degree of MR,[88] but in myocardial infarction severe MR may be totally silent[89] (see Chap. 10).

Murmurs of shorter duration usually correspond to mild MR; they may be mid or late systolic in mitral valve prolapse or early systolic in functional MR.

ELECTROCARDIOGRAM

The most frequent feature of MR is atrial fibrillation which was found in approximately 50 to 60 percent of earlier series and is now present in approximately 50 percent of surgically corrected MR.[90] Patients in sinus rhythm may present with signs of left atrial enlargement (Fig. 57-

12). LV hypertrophy is more rarely seen and may be associated with secondary ST-T abnormalities.[91] Right ventricular hypertrophy is uncommon. The electrocardiogram, especially in acute MR, may be entirely normal. In ischemic MR, Q waves in the inferior leads or left bundle-branch block is often noted.

CHEST ROENTGENOGRAM

Cardiomegaly may be present in chronic MR or in ischemic/functional MR (Fig. 57-13). LA body and appendage dilatation is frequent but giant LA is rare and is usually seen in severe mixed valve disease. Although valvular calcifications are rare, annular calcification seen as a C-shaped density below the posterior leaflet is frequent. Because LA pressure is frequently normal even with severe MR, signs of pulmonary hypertension or pulmonary edema are rarely observed.

Figure 57-13: Chest roentgenogram of a patient with severe MR. Note the cardiomegaly and enlargement of the LA body and appendage.

CLINICAL SYNDROMES

The clinical presentation of patients with MR can be schematically separated in four syndromes, summarized in Table 57-12.

Table 57-12: Mitral Regurgitation: Clinical Presentations

	MVP Syndrome	Chronic MR	Acute MR	Ischemic/Functional MR
Symptoms	Chest pain	Fatigue	Pulmonary edema	CHF
Physical examination	Midsystolic click, murmur	Loud murmur S_3	Loud murmur S_4	Soft murmur S_3, S_4
Electrocardiogram	ST-T changes	Atrial fibrillation	Normal	Q waves, left bundle-branch block
Chest x-ray	Pectus excavatum	Cardiomegaly	Normal heart size, pulmonary edema	Cardiomegaly, pulmonary edema

Laboratory Tests

DOPPLER ECHOCARDIOGRAPHY

Doppler echocardiography has an important role in the assessment of MR using two-dimensional echocardiography with directed M-mode measurements, color-flow imaging, pulsed and continuous-wave Doppler, and transesophageal echocardiography (TEE). Quantitative measurements of flow and detailed hemodynamic assessment should be routinely performed. The goals of Doppler echocardiography are (1) to assess the mor phology of the mitral valve (etiology and mechanism), (2) to assess the degree of MR, and (3) to assess ventricular and atrial function (see also Chap. 13).

Morphology

The features of the most common causes are indicated below.

Rheumatic MR is characterized by thickening of the leaflets and chordae. The posterior leaflet has reduced mobility whereas the anterior leaflet may be doming if commissural fusion is associated. A valvular prolapse is usually not present unless a ruptured chordae or active rheumatic carditis are present. Similar lesions are observed in lupus or anticardiolipin syndrome, in which transesophageal echocardiography may also show small vegetations.

In *degenerative MR*, prolapse is observed with the passage of valvular tissue beyond the annulus plane in the long-axis view (Fig. 57-14). Some features are important:

- Myxomatous changes with diffusely thickened leaflets and excessive valvular tissue
- Localization of the leaflet involved (most often the posterior) confirmed by the initial direction of the jet
- The presence of mitral annular calcification, which may represent a limitation for conservative surgery if extensive and severe
- Flail segments appearing as complete eversion of the segment with or without the small floating echo of ruptured chordae (Fig. 57-15)

The usual mechanism in endocarditic MR, flail leaflets, is relatively easy to diagnose.[92] Perforations are more difficult to diagnose. Mitral annular abscesses are rare and are best detected by TEE. Vegetations can be seen on leaflets or on ruptured chords with superior sensitivity by TEE.[93]

In ischemic/functional MR, the finding of a dilated annulus[94,95] is nonspecific[76] and annular descent is reduced. The features of ischemic heart disease may be observed as regional wall motion abnormalities.[94] The leaflet tissue is normal. The mitral tenting due to the abnormal traction by the principal chordae on the anterior leaflet reduces the area of coaptation of the two leaflets and therefore allows for a central jet of MR.[94,95]

With papillary muscle rupture,[53] MR is due to the flail leaflet. The diagnosis is based on visualization of a small mass of muscle attached to chordae and floating freely during the cardiac cycle.

Assessment of Severity of Regurgitation (Table 57-13)

SEMIQUANTITATIVE METHODS

COLOR-FLOW IMAGING JET ANALYSIS

The origin and direction of the jet is related to etiology. Jet length and ratio of jet to left atrial area (or more simply jet area)[96] have been suggested as good indices of MR severity. Small jets consistently correspond to mild MR.[76] However, color-flow imaging has significant limitations, intrinsically related to the nature of regurgitant jets (Chap. 13). The extent of a jet is determined by its momentum and thus as much by regurgitant velocity as by regurgitant flow. Also, jets are constrained by the LA and expand more in large LAs.[76] The eccentric jets of valve prolapse[97] impinge on the LA wall and tend to underestimate MR[76] (Fig. 57-16, Plate 91). Central jets of functional MR expand markedly in the enlarged LA, and this tends to overestimate MR[76] (Fig. 57-17, Plate 92). TEE usually shows larger jets but does not suppress these limitations of color-flow imaging (Chap. 13).

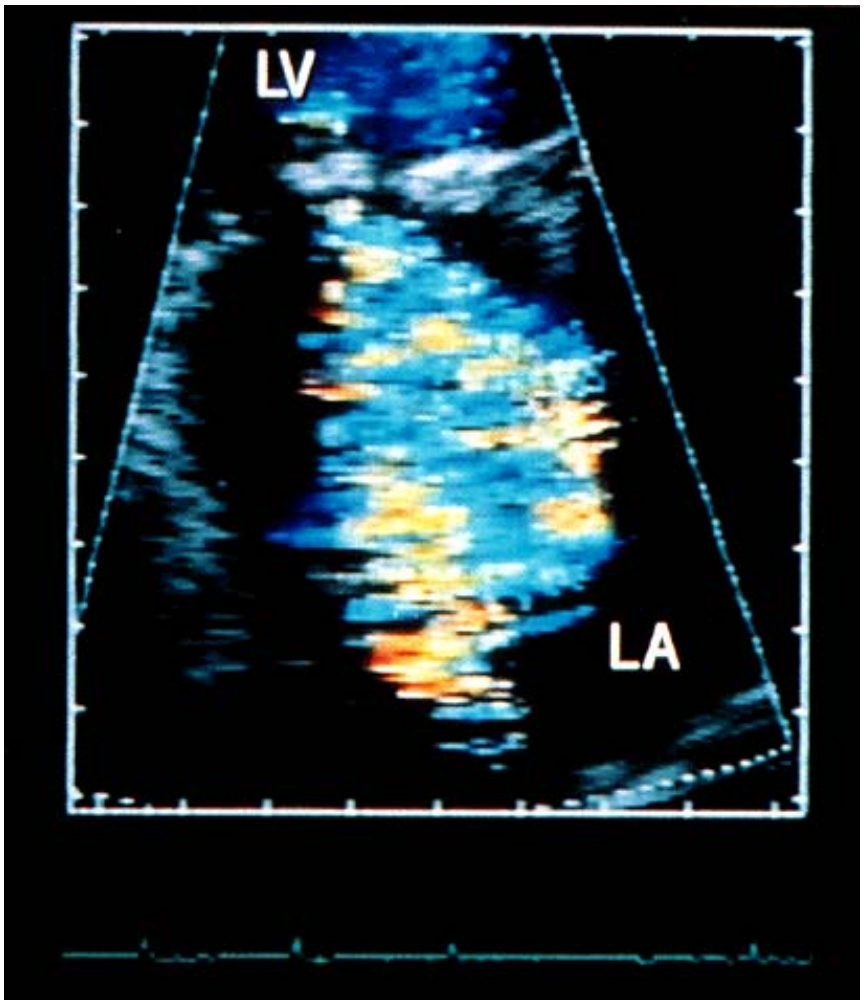

Figure 57-17: (Plate 92) Color flow imaging of a central jet of a functional mitral regurgitation by transthoracic echocardiography. Note that the jet is free, expands in the left atrium, and tends to overestimate this moderate regurgitation.

VENA CONTRACTA MEASUREMENT

The vena contracta is the region of the regurgitant flow immediately below the flow convergence through the regurgitant orifice.[98] Therefore, direct measurement of vena contracta width provides an index of the regurgitant orifice area. The vena contracta width appears superior to jet measurements and can be obtained either through transesophageal[98] or transthoracic echocardiography.[99]

The *pulmonary venous velocity profile* is useful to assess the degree of MR.[100] Systolic reversal in pulmonary veins is a strong argument for severe MR but is related not only to MR severity but also to jet direction and LA pressure.[101] Consequently, pulmonary venous reversal may be absent or asymmetric in severe MR[101] (Fig. 57-18).

QUANTITATIVE METHODS

The goal of quantitative methods is to measure the volume overload expressed as the regurgitant volume (difference between the total and forward stroke volume) or fraction (proportion of LV ejection volume regurgitated in the LA). The lesion's severity is expressed as the effective regurgitant orifice (ERO) area and calculated as follows[58,102]: ERO = regurgitant flow/regurgitant velocity or ERO = regurgitant volume/regurgitant TVI, where the TVI is the time velocity integral

of the regurgitant jet.

The *practical* quantitation of MR can be performed using various methods:

- *Quantitative Doppler* is based on the calculation of the mitral and aortic stroke volumes using pulsed-wave Doppler. The principle is simple and applicable in most cases, but the measurement of the mitral stroke volume is technically demanding, with a significant learning phase.
- *Quantitative two-dimensional echocardiography* is of similar principle but is based on measurement of LV volumes for total stroke volume calculation.
- The *proximal isovelocity surface area* (PISA) method, conversely, directly measures regurgitant flow by analyzing the flow convergence proximal to the regurgitant orifice (Fig. 57-19, Plate 93) and is based on the principle of conservation of mass. Because color-flow mapping allows precise determination of velocity in the flow-convergence region, the regurgitant flow can be calculated. Using regurgitant flow and velocity, regurgitant orifice and volume can be calculated. This method is simple and accurate if the assumptions are respected. (See also Chap. 13.)

Assessment of Left Ventricular and Atrial Function

The technique of guided M-mode diameters is used for assessment of LV size, mass, and wall stress.[90,105,106] LV volumes can be reliably measured by two-dimensional echocardiography. The EF can be calculated or estimated. M-mode diameter or volume can assess the LA size by two-dimensional echocardiography.

RADIONUCLIDE STUDIES

Radionuclide angiography can be used to estimate the LV end-diastolic and end-systolic volume as well as the right and LV EF. The detection of exercise-induced LV dysfunction is frequent. However the significance of such measurement on the long-term prognosis has not been analyzed in large series of patients. A comparison of the counts measured over the RV and LV allows the calculation of the regurgitant fraction.

CARDIAC CATHETERIZATION

Cardiac catheterization is utilized to assess hemodynamic status, the severity of MR, LV function, and coronary anatomy.

The major hemodynamic consequences of MR are reduction of cardiac output and elevation of pulmonary artery wedge pressure. Marked pulmonary hypertension is rarely present. The large V wave of the pulmonary wedge pressure is more frequent in acute than in chronic MR but can be observed in other disease such as ventricular septal defect or heart failure with reduced left atrial compliance without MR (Fig. 57-20).

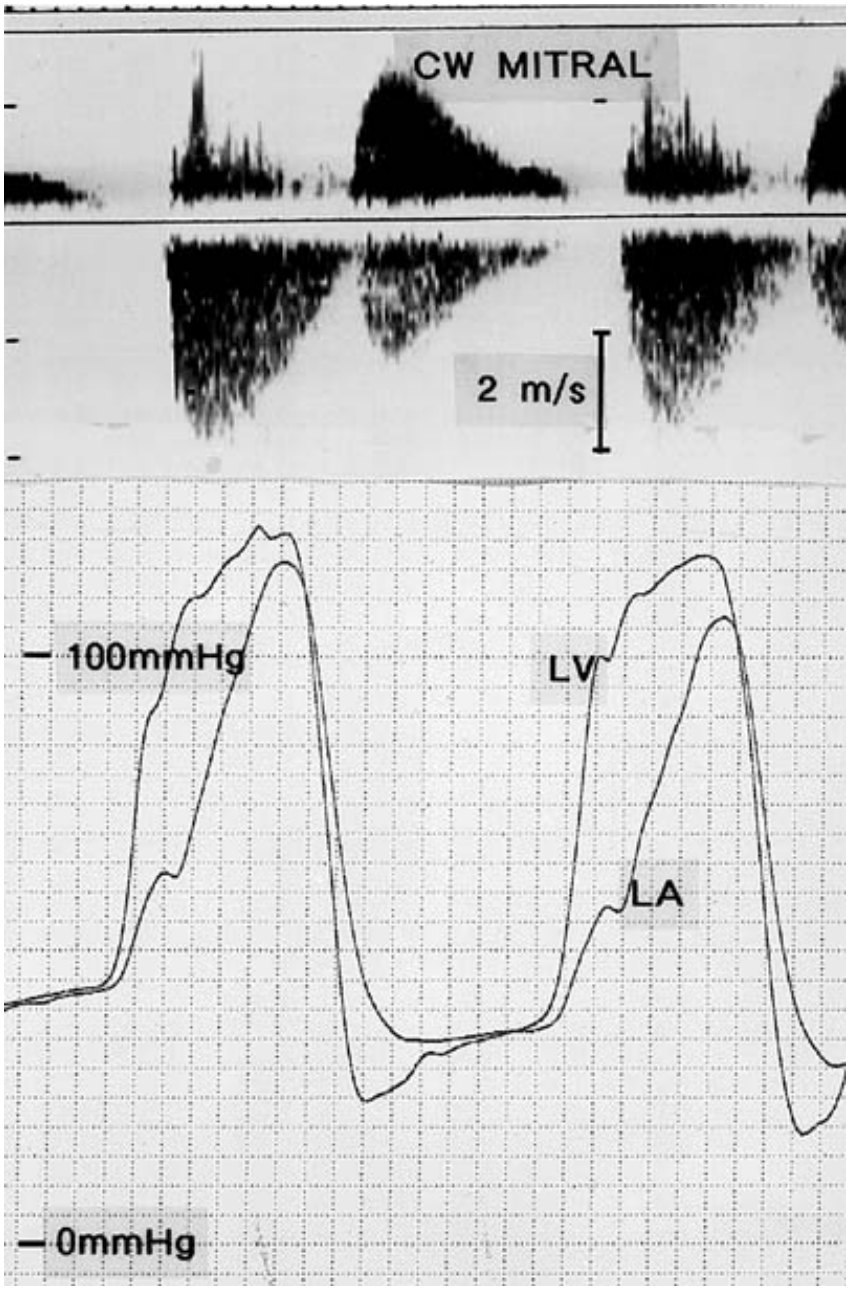

Figure 57-20: Simultaneous recording of LV and LA pressures and continuous-wave Doppler (CW) in a patient with severe MR. Note the large V wave on the left atrial pressure recording, with a triangular shape of the mitral regurgitant jet obtained by CW. (Courtesy of Dr. Rick Nishimura, Mayo Clinic.)

The assessment of MR degree can be obtained by LV selective angiography and can be qualitatively graded in three or four grades on the basis of the degree and persistence of opacification of the LA.[107] Although time-honored, this method has limitations, like all qualitative methods.[108] Quantitation of MR can be obtained by comparing the angiographic stroke volume to the forward stroke volume, calculated by the Fick or thermodilution methods,[109] to calculate the regurgitant volume and fraction. The angiographic stroke volume usually overestimates the true stroke volume and corrections have been used to minimize the overestimation of the regurgitant volume. Subtraction of two stroke volumes introduces a potentially high range of error, which cannot be verified by combined methods or by repeating the measurements; therefore this method is rarely utilized.

The assessment of LV function can be performed using quantitative angiography. LV volumes

correlate strongly to the regurgitant volume, duration and etiology of MR, and LV function. The most frequently utilized indices of LV function are end-systolic volume and EF, which are useful prognostic indices.[70,110] High-fidelity pressure recording with LV angiography allows calculation of more complex indices of LV distensibility in diastole[73] and of wall stress, maximum LV elastance, and LV systolic stiffness. The additional value of these complex measurements has been investigated in small groups of patients and remains to be defined in larger populations.

Selective coronary angiography allows definition of coronary anatomy. Obstructive coronary atherosclerosis continues to be frequent even in the absence of angina,[111] and coronary angiography is ordinarily performed in patients more than 40 to 50 years of age.

STRATEGY OF UTILIZATION OF LABORATORY TESTING

Not all the tests should be performed in all patients[112] (Fig. 57-21). Because transthoracic Doppler echocardiography confirms the diagnosis and degree of MR and of associated valvular diseases and provides a unique assessment of mitral lesions, it is performed in most cases for the initial diagnostic assessment, for follow-up, and for presurgical assessment. TEE provides superior imaging quality, but its incremental value is notable only when the transthoracic information is incomplete.[92] In our practice it is reserved preoperatively to the patients in whom a doubt persists regarding the lesions (especially if endocarditis is suspected) or regarding the severity of regurgitation, but it is utilized on a large scale intraoperatively to monitor the results of valve repair.[113]

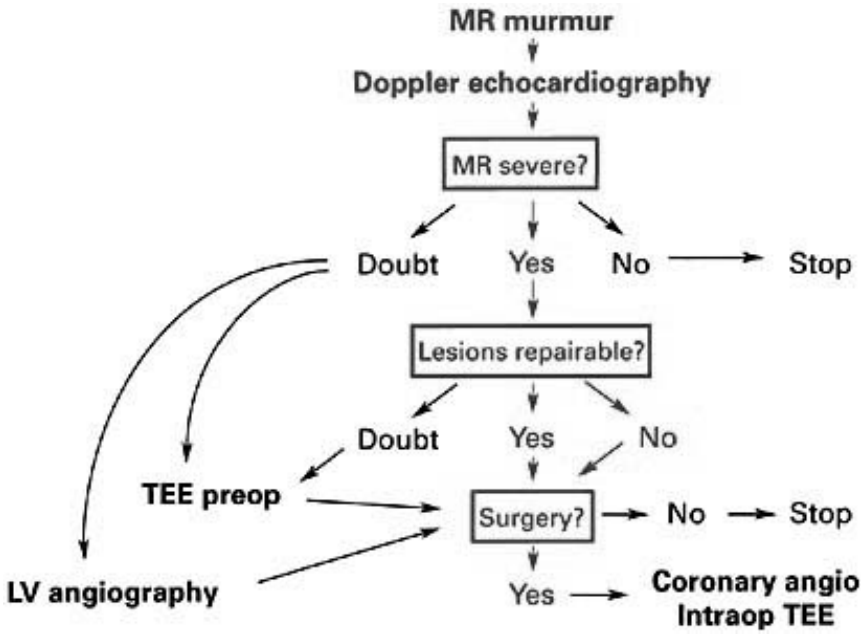

Figure 57-21: Strategy of utilization of tests in patients with mitral regurgitation.

Coronary angiography is indicated as a presurgical procedure depending on age. LV angiography is not required unless there is concern regarding validity of echocardiographic studies.[114] Although color-flow Doppler showed a significant number of discrepancies as compared to angiography,[115] the understanding of its pitfalls[76] and more recently introduced quantitative methods have reduced the need for redundant tests. Also, the analysis of LV function provided by routine LV angiography does not appear to add significant information to the noninvasive data.[90] However, the utilization of tests should be individualized based on the patient's characteristics and

the results of noninvasive studies.

Management

PRINCIPLES

Surgical treatment is reserved for patients with severe MR. Criteria most often used for severe MR are angiographic 4+ grade or color flow jet ≥8 cm^2,[96] with the intrinsic limitations of these definitions. Using quantitative techniques, thresholds for severe MR are 60 mL per beat for regurgitant volume, 50 percent for regurgitant fraction, and 40 mm^2 for effective regurgitant orifice.[116] Patients with severe MR will require surgery at some point during their follow-up. In these patients, the most relevant question is the timing of the surgical indication, which is influenced by the natural history of MR and by the outcome after surgical correction of MR. The determinants of outcome are listed in Table 57-14.

Table 57-14: Determinants of Outcome

Unoperated Patients	Operated Patients
Symptoms	Age
Pulmonary hypertension	Preoperative symptoms
LV end-diastolic volume	Coronary disease
AV-O_2 difference	End-systolic dimensions
Ejection fraction	Ejection fraction
	LA size?
	Valve repair

NATURAL HISTORY

Because of the qualitative and imprecise assessment of the degree of MR, the natural history of MR is ill defined. Patients with mild rheumatic MR appear to have a good prognosis,[117] whereas in those with more severe MR a higher mortality has been noted.[84,118] In patients with unoperated clinically significant MR, the late survival has been found as high 60 percent at 10 years[119] or as low as 46 percent[120] or even 27 percent[121] at 5 years. In our experience with flail mitral leaflets, at 10 years, survival was 57 percent, which represents an excess mortality as compared to the expected survival.[84]

The probability of sudden death is important to consider before delaying surgery. Such a devastating complication occurs more often if the ventricular function is decreased[84] but may also occur in patients with normal EF who are asymptomatic.[118] In our experience, sudden death in patients with MR due to flail leaflets occurs at a rate of 1.8 percent per year.[122] The rates are higher in patients with symptoms or reduced ejection fraction, but even in the absence of these risk factors the rate is 0.8 percent per year.[122]

Morbidity in patients with severe MR is also high. Of patients who are initially asymptomatic,

approximately 10 percent per year develop symptoms,[123] which may be hastened by atrial fibrillation. In patients with flail leaflets 10 years after diagnosis, heart failure occurred in 63 percent, and permanent atrial fibrillation in 30 percent of those initially in sinus rhythm[84] (Fig. 57-22). Also at 10 years, 90 percent of the patients had either died or undergone surgery,[84] confirming that in these patients surgery is almost unavoidable (Fig. 57-23).

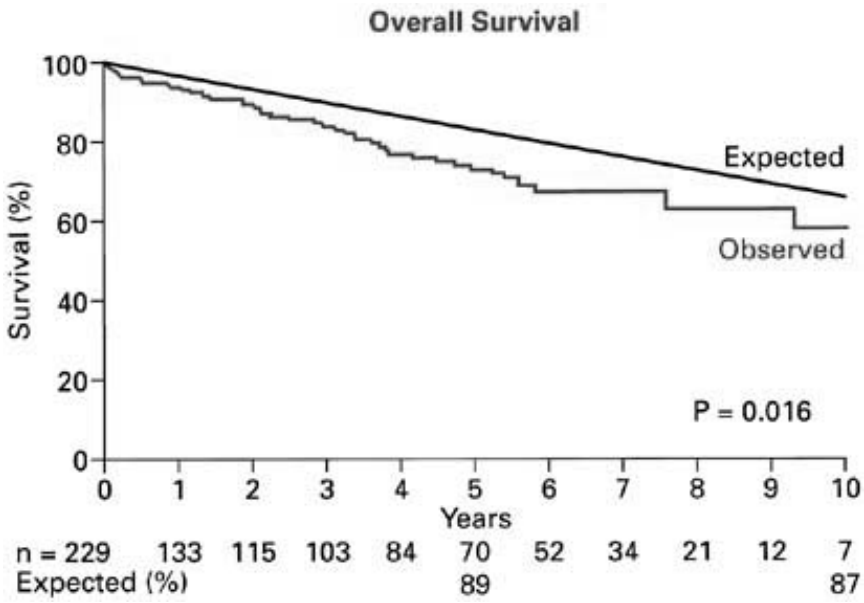

Figure 57-22: Survival with medical treatment of patients diagnosed with MR due to flail leaflets. Note the excess mortality in comparison to the expected survival. (Reprinted by permission of the *New England Journal of Medicine* from Ling LH, et al. 1996; 335:1417-1423. Copyright 1996, Massachusetts Medical Society.)

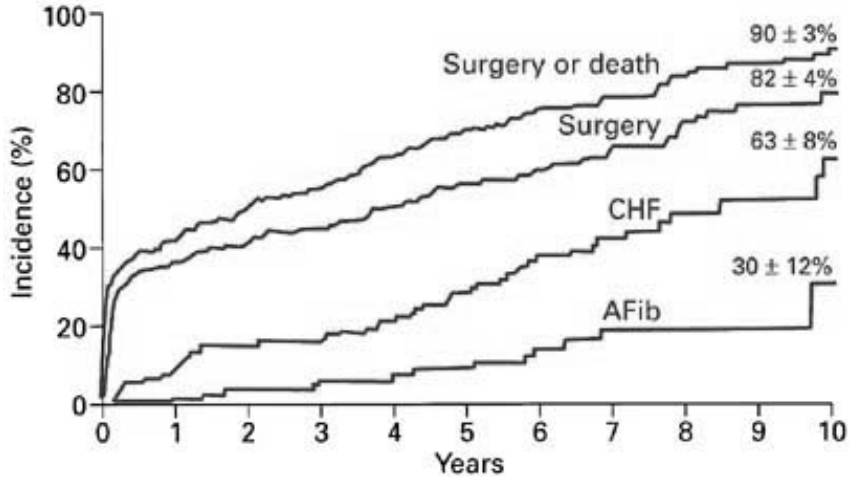

Figure 57-23: Cardiac morbidity with medical treatment in patients diagnosed with MR due to flail leaflets. CHF, congestive heart failure, Afib, atrial fibrillation. (Reprinted by permission of the *New England Journal of Medicine* from Ling LH, et al. 1996; 335:1417-1423. Copyright 1996, Massachusetts Medical Society.)

The predictors of poor outcome in patients medically treated are (1) severe symptoms (NYHA

classes III to IV),[120] even if the symptoms are transient,[84] (2) pulmonary hypertension, (3) markedly increased LV end-diastolic volume or arteriovenous difference in O_2,[124] and (4) reduced ejection fraction.[84] Comparison of prognosis in medically and surgically treated patients shows a trend in favor of the surgical treatment,[118] especially early surgery,[84] with definite improvement of outcome of patients with decreased systolic LV function.[124]

The progression of LV dysfunction in patients medically treated is not well defined. Progression of the degree of MR is usually slow, with progression of regurgitant volume of 8 mL/year, but it reaches 20 mL/year in patients with new flail leaflets.[125] The mechanism of progression of MR is an increase in regurgitant orifice without change in gradient. The major determinant of regression of MR is a reduction in afterload, whereas increase in annular size and new flail leaflet are major determinants of progression of MR.[125]

TREATMENT

Medical Treatment

Prevention of infective endocarditis using the appropriate prophylaxis is necessary in patients with MR.[126] Young patients with rheumatic MR should receive rheumatic fever prophylaxis. In patients with atrial fibrillation, rate control is achieved using digoxin and/or beta blockers. Long-term maintenance of sinus rhythm after cardioversion in patients with severe MR or enlarged LA is usually not possible in patients who are treated medically. However return to sinus rhythm after surgery is possible in patients with atrial fibrillation of short duration.[127] Oral anticoagulation should be used in patients with atrial fibrillation. Beta blockers are the drug of choice in patients with the mitral valve prolapse syndrome and palpitations or chest pain (Chap. 58). Diuretic treatment is extremely useful for the control of heart failure and for the chronic control of symptoms, especially dyspnea.

Acute afterload reduction may decrease the degree of MR.[59] This effect is achieved by reducing the LV systolic pressure but also by decreasing the effective regurgitant orifice area.[60] Acute utilization of sodium nitroprusside in unstable patients with severe MR, especially in the context of myocardial infarction, may be lifesaving in preparation for surgery.[60]

Chronic afterload reduction is more controversial. The hemodynamic effect of hydralazine,[128] has been demonstrated, but this drug is often poorly tolerated. The effect of angiotensin converting enzyme inhibitors has been analyzed in small series,[129-131] and their long-term efficacy is not defined. Furthermore, major discrepancies between series are noted regarding the effect on the degree of MR[132] and on LV remodeling.[133] Because of these uncertainties, vasoactive therapy is not recommended for chronic treatment of MR.[112]

Surgical Treatment

The approach to surgery can be the traditional median sternotomy or the more recently used "minimally invasive" approaches, which range from port-access surgery to small sternotomy to thoracotomy. These new techniques appear interesting but their long-term outcome remains uncertain. There are two main valvular surgical options: mitral valve reconstruction and mitral valve replacement.

MITRAL VALVE RECONSTRUCTION

Reconstruction of the incompetent mitral valve is almost always possible (approximately 90

percent of patients referred for primary correction of acquired MR at the Mayo Clinic). The frequency with which valve repair can be used varies with experience of the operating team and the spectrum of underlying valve disease; repair is more often feasible with degenerative valve disease than with rheumatic valvulitis or endocarditis.

The *valvular procedure* is as follows. With leaflet prolapse immobilization of this prolapsing section can be obtained by plicating or by excising it and then repairing the leaflet. This will overcome the problem of localized prolapse. However, the resulting reduction in area of the leaflet could reduce coaptation and induce residual MR; therefore, annuloplasty is a routine part of the repair. Resection or plication of prolapsing sections is most successful with posterior leaflet prolapse. With anterior leaflet prolapse the risk of residual MR is higher if the plication or resection is not combined with subvalvular procedures.[113] Other repairable leaflet abnormalities include congenital clefts and acquired perforation, which may be closed by using a patch of pericardium or synthetic material.

In the *subvalvular procedure,* chordal shortening may be necessary in patients with elongated chordae to ensure the appropriate coaptation of the leaflets, but the durability of this procedure has been criticized.[134] A major recent progress has been the introduction of transposition of chordae and of artificial chordae which have made the anterior leaflet prolapse as repairable as the posterior leaflet prolapse.[135,136]

Annular dilatation, almost constantly associated with MR, is treated by reduction of mitral circumference, i.e., *annuloplasty*. The annuloplasty should be placed in the region supporting the posterior leaflet to preserve the area of anterior leaflet. A cloth-covered rigid ring was originally developed by Carpentier. Recently, flexible annuloplasty rings have been developed to preserve the normal systolic contraction of the mitral annulus.[137] In general, results with the Carpentier ring annuloplasty have been favorable, but LV outflow obstruction associated with abnormal systolic anterior motion of the anterior mitral leaflet has been reported in 6 to 10 percent of patients.[138] This complication is mainly due to hypovolemia and excessive use of inotropes[113] but may be lower with flexible rings.[139]

It is important to assess the adequacy of mitral valve reconstruction before completion of the operation. When satisfactory repair cannot be achieved, it is preferable to replace the valve immediately. To assess adequacy of mitral repair (residual stenosis, regurgitation, or systolic anterior motion), TEE, which does not interfere with the surgical procedure, is performed routinely.[113]

Valve Replacement

When mitral reconstruction is considered impossible or is unsuccessful, replacement must be performed. The dilemma is the choice between a mechanical valve of excellent durability but with the hazard of thromboembolism and a biological valve with undefined long-term durability[140] but less tendency to cause thromboembolism. With atrial fibrillation, chronic anticoagulant therapy is necessary even with a bioprosthesis, so that avoiding anticoagulation is not relevant in choosing a prosthesis.

Postoperative Outcome

Valve repair, by preserving the normal valvular tissue, is preferable to valve replacement. Compared to prosthetic replacement, mitral valve reconstruction has a lower operative mortality.[141,142] Direct comparison of the results of valve repair and replacement is difficult[142] because the patients undergoing a valve repair are usually at a less advanced stage of the disease than patients undergoing valve replacement.[141] However, survival and LV function after valve

repair are better than after insertion of a prosthetic valve.[141] Better ventricular function with valvuloplasty may be due to preservation of chordae and papillary muscles.[143] Durability of valve repair for degenerative disease is excellent if no more than mild residual MR is accepted.[134] Valve repair has the same low rate of reoperation than valve replacement.[141] MR post-repair is due in two-thirds of the cases to new lesions and in one-third to an inadequate primary correction.[144] *Therefore valve repair should be the preferred procedure for surgical correction of MR* (Fig. 57-24).

Operative mortality has been reported between 5 and 12 percent[140] in earlier series, but most patients had prosthetic valve replacement rather than reconstruction. The operative risk is lower in the current era, around 1 to 2 percent in patients younger than 75 years with organic MR operated on at the Mayo Clinic whether they had valve repair or replacement.[90] LV function is not a predictor of operative mortality and patients with organtic MR even with markedly depressed function have a reasonable chance of surviving surgery.[90] Age symptoms and coronary disease are the most important predictors of operative mortality.[90] Some important points should be noted: First, the risk of surgery has become progressively similar in patients 65 to 75 years old as compared to younger patients. Second, operative mortality has decreased recently in patients 75 and older but remains relatively high, around 5 percent. Third, in ischemic MR the operative mortality remains high, around 10 percent.

Postoperative survival has considerably improved and in our recent experience, with a population of mean age 62, the 5- and 10-year survivals were 83 and 68 percent after valve repair and 69 and 52 percent after valve replacement. Remarkably, the survival after valve repair is not different from the expected survival, whereas it represents 77 percent of the expected survival after valve replacement.[141]

A large majority of long-term survivors after mitral valve replacement for MR show a symptomatic improvement by at least one functional class and some become asymptomatic. However, with time postoperative heart failure and symptomatic deterioration tend to occur at a progressively increasing rate (38 percent at 10 years in operative survivors) and is most often (in two thirds of the cases) due to residual LV dysfunction.[145] Valvular or prosthetic dysfunction explain the heart failure in approximately one-third of the cases.[145] Postoperative congestive heart failure has a dismal prognosis and should be prevented as much as possible[145] by early correction of the MR.

The most frequent cause of mortality after surgical correction of MR is LV dysfunction[90] due to chronic irreversible myocardial damage.[66,69,70] LV dysfunction occurs, in our experience in 40 percent of patients overall and 32 percent of those with organic MR.[69] The majority of patients demonstrate a decrease in EF after successful valve replacement.[66,69] This decline may be the result of several factors: cumulative permanent myocardial damage, occasional myocardial insult sustained at the time of operation, diminished preload, and probably increase in impedance to ejection after elimination of the MR. However, the relationships between pre- and postoperative LV function[65,66,69,70,110] and between preoperative LV function and postoperative survival[68,90,105] underline the fact that LV dysfunction is most often already present preoperatively. Because of the modified loading conditions, multiple and complex indices of LV function have been proposed.[65,67,68] Despite these altered loading conditions preoperative EF is an acceptable independent predictor of postoperative EF[66,69,70] and survival.[90] In general, one can estimate that the postoperative EF likely will decrease by approximately 10 percent early after valve replacement.[66,69,70] However, there is a significant individual variation and more decline is observed with markedly increased end-systolic diameter,[69,105] volume,[70,110] or wall stress[69] or in

patients with severe symptoms, prolonged duration of MR or coronary disease.[69] A markedly reduced preoperative EF (<50 percent) is associated with a high late mortality,[90] but nevertheless surgery provides a better outcome than medical treatment.[124] Even a "borderline" EF (50 to 60 percent) is associated with an excess late mortality.[90] Therefore, *currently the widely accepted signs of overt LV dysfunction in MR are LV diameter* ≥45 *mm or ejection fraction* <60 *percent.*[112] Nevertheless, the end-systolic diameter rarely and belatedly reaches 45 mm and the best outcome of surgery is obtained in patients with both end-systolic diameter <45 mm and ejection fraction ≥60 percent[69,90] (Fig. 57-25).

Figure 57-25

Figure 57-25: Survival after surgical correction of organic mitral regurgitation. Note the excess mortality in patients with preoperative ejection fraction above 50 percent but also in patients with preoperative ejection fractions of 50 to 60 percent. (From Enriquez-Sarano M, Tajik A, Schaff H, et al. Echocardiographic prediction of survival after surgical correction of organic mitral regurgitation. *Circulation* 1994; 90:830-837, with the authorization of the American Heart Association.)

Another issue, which has been controversial, has been the impact on postoperative outcome of preoperative symptoms. Patients with severe preoperative symptoms, NYHA class III or IV, incur an excess postoperative mortality independently of all baseline characteristics, in particular age, EF, and the type of surgery performed.[146] Importantly, patients preoperatively in class I or II incur a very low operative risk,[146,147] and an excellent long term survival, identical to the expected survival.[146] These data suggest that *in centers and patients at low operative risk, timing of surgery when there are no or minimal symptoms offers distinctive advantages*.

Atrial fibrillation when present preoperatively usually persists postoperatively, unless of brief duration[127] but the excess risk due this arrhythmia appears modest,[90,127] although it requires anticoagulation. Conversely, the association of a Maze procedure to mitral valve repair can be accomplished with minimal risk.[148]

Late risk of thromboembolism after mitral replacement for MR is not different from it as in other mitral valve diseases. Differences in thromboembolic risk after valve repair and valve replacement have been variably estimated[141,142] but appear to favor valve repair. In addition, because following valve repair, anticoagulation is recommended permanently only if atrial fibrillation persists, the occurrence of bleeding is less common than following prosthetic replacement.[141]

Indications for Surgery

Based on the most recent data regarding the natural history of MR treated with and without surgery, the indications for surgery have evolved[112] and can be outlined as follows:

TRADITIONAL INDICATIONS

Patients with severe symptoms (functional NYHA class III or IV). Patients with transient severe symptoms even if they markedly improve with medical treatment should be considered at high risk and offered surgery within that category.

ADVANCED INDICATIONS

These apply to patients with NYHA class II symptoms and to patients with no symptoms (class NYHA I) but with either signs of overt LV dysfunction (LV ejection fraction <60 percent, end-systolic diameter ≥45 mm) or with pulmonary hypertension or with atrial fibrillation.

EARLY INDICATIONS

Patients with no symptoms (NYHA class I) and no sign of LV dysfunction (ejection fraction ≥60 percent). These patients can expect the best results of surgery and in particular, after the immediate postoperative phase, a survival identical to the expected survival.[90,146] Therefore, the authors consider surgery to be a reasonable option in this subgroup. However because surgery in these patients is justified neither by symptoms nor by LV dysfunction certain conditions should be fulfilled:

- *Low operative risk:* Both the operative mortality in the institution where such an indication is contemplated and the operative risk for the individual patient involved should be minimal (1 to 2 percent).
- *Reparability:* The valvular lesions as determined by echocardiography should be in all probability repairable and the surgeon performing the intervention should have a high degree of experience with all forms of valve repair.
- *Intraoperative TEE should be performed* by experienced physicians to monitor the repair procedure and help with decisions warranted by an imperfect result.
- *Quantitation of MR should be performed* systematically in these patients preoperatively using multiple noninvasive techniques to determine objectively the degree of MR and affirm that surgery is warranted.

Therefore, despite the considerable progress recently accomplished, currently *not all patients and not all institutions* are candidates for these early indications of surgical correction of MR, but surgery should be considered early in the course of MR when severe MR has been thoroughly documented.

Chapter 57: MITRAL VALVE DISEASE

List of Figures

Figure 57-1: Pathophysiology of mitral stenosis. Mitral stenosis results in a diastolic pressure gradient from the LA to the LV. The actual gradient is dependent on the mitral valve area and the mitral valve *flow per diastolic second*. As a result, there is an elevation of LA pressure and therefore also of pulmonary venous pressure. Physiologic and pathologic changes-such as tachycardia and atrial fibrillation (which shorten diastole and may also result in loss of effective atrial contraction) or pregnancy, volume loading, and left-to-right shunts (at ventricular and aortopulmonary levels), which increase pulmonary venous flow-will increase the mitral valve gradient as well as LA and pulmonary venous pressures. An increased LV diastolic pressure will also result in further increase of LA pressure. An elevated LA pressure has several important effects; these include enlargement of the left atrium, atrial arrhythmias, and an increase of pulmonary venous pressure. Pulmonary venous hypertension may result in pulmonary edema and pulmonary arterial hypertension. PA hypertension and RV ventricular hypertension results in RV hypertrophy and may result in tricuspid regurgitation and RV enlargement. All of these changes contribute to producing symptoms. In addition, a fixed or even reduced cardiac output will also contribute to the symptomatic state of the patient. [Copyright by S. H. Rahimtoola. M.B., F.R.C.P., M.A.C.P., M.A.C.C. (Ref. [10]).]

Figure 57-2: Auscultatory signs of MS in patients in sinus rhythm are illustrated. These include a presystolic murmur, loud first heart sound (S_1), an opening snap (OS), and a middiastolic murmur (low-pitched, decrescendo diastolic rumble, rumbling murmur). These signs may be accentuated or at times may be heard only by placing the patient in the left lateral decubitus position. Importantly, these signs are helpful in assessing the severity of the MS; as the MS becomes more severe, the S_2-OS interval is shortened and the length of the middiastolic rumble is increased. In mild OS, the S_2-OS interval is long and the diastolic murmur is short. In moderate MS, the S_2-OS interval is shorter, and although the diastolic murmur is longer at rest, there is usually a gap between the end of the murmur and the onset of the presystolic murmur. In severe MS, the S_2-OS interval is short (usually 0.04 to 0.06 s) and the diastolic murmur is a full-length murmur. With PA hypertension, P_2 is increased in intensity. In the presence of a rigid mitral valve (with or without calcification), S_2 is soft and the OS is usually not heard. A holosystolic murmur of mitral regurgitation may be present. (Adapted and modified from Kawanishi DT, Rahimtoola SH. Mitral stenosis. In: Rahimtoola SH, ed. *Valvular Heart Disease II*. St. Louis: Mosby; 1996:8.1-8.24. Copyright by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C.)

Figure 57-3: Auscultatory signs of MS in atrial fibrillation are illustrated. The presystolic murmur is absent. The loud S_1 and the OS are still heard. In the short cycles, the duration of diastole is short and the middiastolic rumble occupies the whole of diastole (*left panel*). In the long cycles (*right panel*), the length of middiastolic murmur is related to the severity of MS. As the MS becomes more severe, the length of this murmur is increased. In atrial fibrillation, with a slow ventricular response and very long R-R intervals, the middiastolic rumble may not occupy the whole diastolic period and the presystolic murmur is usually absent. Thus, one may get the impression that the MS is moderate rather than severe. Increasing the heart rate-for example, with brief physical exertion-may produce more characteristic auscultatory findings. Alternatively, when the ventricular rate in atrial fibrillation is rapid or in short cycles, the auscultatory findings may suggest a more severe degree of MS than is really the case (*left panel*). (Adapted and modified from Kawanishi

DT, Rahimtoola SH. Mitral stenosis. In: Rahimtoola SH, ed. *Valvular Heart Disease. II.* St. Louis: Mosby; 1996:8.1-8.24. Copyright 1996 by S. H. Rahimtoola, M.B., F.R.C.P., M.A.C.P., M.A.C.C.)

Figure 57-4: This figure depicts the survival of patients with MS who initially where asymptomatic or had mild symptoms and were treated medically. In the 1960 study of Rowe and coworkers[30] (*dashed lines*), 52 percent of 250 patients with "auscultatory MS" who presented between 1925 and 1947 were asymptomatic; their 10-year survival was 84 percent. The lower dashed line represents the survival in the 42 percent of patients who had mild symptoms on clinical presentation; their 10-year survival was 42 percent.[30] The data of Olesen, 1962[27] (*upper solid curve connecting solid symbols*), show the survival in the 21 percent of 271 symptomatic MS patients who had class II symptoms. Their 10- and 20-year survival was 34 and 14 percent, respectively. The data of Roy and Gopinath, 1968[29] (*lower solid curve connecting open symbols*), also show the survival in patients with class II symptoms. (From Kawanishi DT, Rahimtoola SH. Mitral stenosis. In: Rahimtoola SH, ed. *Valvular Heart Disease. II.* St. Louis: Mosby; 1996:8.1-8.24.)

Figure 57-5: Survival of patients with MS and moderate or advanced (severe) symptoms is shown. Patients who were in NYHA functional class IV (Olesen, class IV, 1962)[28] had a 42 percent 1-year survival and all patients had died within 8 years. The other four survival curves are of patients who were in functional classes II to IV, and their survival curves are similar, with 5-, 10-, and 15-year approximate survivals of 60, 40, and 20 percent, respectively; at 20 years, less than 10 percent of the patients were still alive.[28-30] Thus, the survival in this group of patients with more advanced symptoms is much worse than that of patients who were initially asymptomatic or minimally symptomatic (see Fig. 57-4). (From Kawanishi DT, Rahimtoola SH. Mitral stenosis. In: Rahimtoola SH, ed. *Valvular Heart Disease. II.* St. Louis: Mosby; 1996:8.1-8.24.)

Figure 57-6: Comparison of survival of patients with class II symptoms (*left panel*) and class III and IV symptoms due to MS (*right panel*).[29] Survival of patients treated medically (unoperated) is indicated by the broken line and with surgical closed mitral commissurotomy (operated) by the solid line. In patients treated by surgical commissurotomy, there were no operative or late deaths in those with mild symptoms and no late deaths in those with class III and IV symptoms. There is a clear improvement in survival in operated patients. The 5-year mortality with medical treatment alone in those with class III and IV symptoms approaches 50 percent (also see Fig. 57-5); with surgery, there is no appreciable mortality following recovery from the procedure. [From Roy SB, Gopinath N. Mitral stenosis. *Circulation* 1968; 38(suppl v):68-76.]

Figure 57-7: (Plate 86) Anatomic example of rheumatic MR. Note the thickening of the leaflet and chordae and the retraction of the mitral tissue. (Courtesy of Dr. W. D. Edwards.)

Figure 57-8: (Plate 87) Anatomic example of MR due to mitral valve prolapse seen from the atrial view (the mitral orifice is on the left of picture). Note the redundancy of the leaflets with excess tissue. (Courtesy of Dr. W. D. Edwards.)

Figure 57-9: (Plate 88) Anatomic example of a flail posterior leaflet with ruptured chord. On the right of the picture, closeup view of the ruptured chord. Otherwise the left atrium is enlarged and the valvular tissue normal. (Courtesy of Dr. W. D. Edwards.)

Figure 57-10: (Plate 89) Anatomic example of MR due to endocarditis. Note the vegetations of the anterior leaflet and the ruptured chords. (Courtesy of Dr. W. D. Edwards.)

Figure 57-11: (Plate 90) Anatomic example of a ruptured posterior papillary muscle. Note the normal valvular tissue otherwise. (Courtesy of Dr. W. D. Edwards.)

Figure 57-12: Electrocardiogram of a patient with severe MR. Note LA enlargement, as indicated by notched p waves (lead I and rhythm strip lead II).

Figure 57-13: Chest roentgenogram of a patient with severe MR. Note the cardiomegaly and enlargement of the LA body and appendage.

Part 9: VALVULAR HEART DISEASE
Chapter 58:

MITRAL VALVE PROLAPSE SYNDROME

Author: Robert A. O'Rourke

The syndrome of mitral valve prolapse (MVP) is the most common form of valvular heart disease, occurring in 2 to 6 percent of the population, thus being more common than a bicuspid aortic valve. The incidence varies depending on the criteria used for its diagnosis.[1,2] MVP is commonly detected by cardiac auscultation, with one or more systolic clicks and/or a mid to late-systolic murmur detected on a careful physical examination. Often the auscultatory complex is the only clinical manifestation of cardiac disease, and many patients are asymptomatic.

Midsystolic clicks were first described in the late nineteenth century and originally were attributed to a pericardial or extracardiac etiology. Subsequently, late-systolic murmurs were recognized to be present in apparently healthy people and were associated with a benign natural history. Thus the murmur also was considered to be extracardiac in origin.

In 1961, Reid[3] suggested that the midsystolic click and the late-systolic murmur were due to mitral regurgitation. In 1963, Barlow et al.[4] confirmed this hypothesis by left ventricular (LV) cineangiography. Subsequently, intracardiac phonocardiogram studies documented the mitral valve origin of a systolic click and late-systolic murmur.

During the past four decades, considerable new data obtained from pathologic studies, echocardiography, and cineventriculography have demonstrated that this common syndrome is associated with prolapse of one or both mitral valve leaflets into the atrium during LV systole.

Recognition of MVP (also known as the *systolic click-late systolic murmur syndrome*) is often difficult because of the extreme variability of its clinical manifestations. It is, however, an important cause of incapacitating chest pain and refractory arrhythmias in certain patients. The abnormal components of the mitral valve apparatus are a potential site for endocarditis, and some patients, particularly males in their sixties and seventies, can develop severe mitral regurgitation (MR) due to ruptured chordae tendineae.

DEFINITION, ETIOLOGY, AND TIMING

MVP refers to the systolic billowing of one or both mitral leaflets into the left atrium, with or without MR. MVP often occurs as a clinical entity with no or only mild MR, and it is frequently associated with unique clinical characteristics when compared with the other causes of MR.[5-9] Nevertheless, MVP is the most common cause of significant MR and the most frequent substrate for mitral valve endocarditis in the United States. The mitral valve apparatus is a complex structure composed of the mitral annulus, valve leaflets, chordae tendineae, papillary muscles, and the supporting left ventricle, left atrium, and aortic walls[10] (Fig. 58-1). Disease processes involving any one or more of these components may result in dysfunction of the valvular apparatus and prolapse of the mitral leaflets toward the left atrium during systole when LV pressure exceeds left atrial (LA) pressure.

The complexity of the mitral valve apparatus provides an explanation for the presence of secondary prolapse in many conditions that affect one or more of the components of the apparatus (e.g., ruptured mitral chordae). There is, however, considerable evidence that a disorder of the mitral valve leaflets exists in which there are specific pathologic changes causing redundancy of the mitral leaflets and their prolapse into the left atrium during systole. This is the primary form of MVP (Table 58-1).

Table 58-1: Classification of Mitral Valve Prolapse

Normal variant
Inaccurate auscultation
'Echocardiographic heart disease'

In *primary* MVP, there is interchordal hooding due to leaflet redundancy that involves both the rough and clear zones of the involved leaflets[6] (Fig. 58-2). The height of the interchordal hooding usually exceeds 4 mm and involves at least one-half of the anterior leaflet or at least two-thirds of the posterior leaflet. The basic microscopic feature of primary MVP is marked proliferation of the *spongiosa*, the delicate myxomatous connective tissue between the *atrialis* (a thick layer of collagen and elastic tissue forming the atrial aspect of the leaflet) and the *fibrosa*, or *ventricularis*, which is composed of dense layers of collagen and forms the basic support of the leaflet.[6] In primary MVP, myxomatous proliferation of the acid mucopolysaccharide-containing spongiosa tissue causes focal interruption of the fibrosa. Secondary effects of the primary MVP syndrome include fibrosis of the surfaces of the mitral valve leaflets, thinning and/or elongation of chordae tendineae, and ventricular friction lesions. Fibrin deposits often form at the mitral valve-left atrial angle.

The primary form of MVP may occur in families, where it appears to be inherited as an autosomal dominant trait with varying penetrance.[11,12] No consistent chromosomal abnormalities have yet been identified in patients with MVP, which also often occurs in isolated cases.[13,14] Primary MVP has been found with increasing frequency in patients with Marfan syndrome, where it is almost always present, and in other heritable connective tissue diseases such as Ehlers-Danlos

syndrome,[15] pseudoxanthoma elasticum,[16] and osteogenesis imperfecta.[17] Marfan syndrome also has an autosomal dominant mode of inheritance. It is possible that some genetic studies of MVP may have been tracking a more general connective tissue disorder such as Marfan syndrome (see also Chap. 76).

Many observers have speculated that primary MVP syndrome represents a generalized disorder of connective tissue. Thoracic skeletal abnormalities such as straight thoracic spine and pectus excavatum are commonly associated with this syndrome.[18] The mitral valve undergoes differentiation between the thirty-fifth and forty-second days of fetal life, when the vertebrae and thoracic cage are beginning chondrification and ossification.[19] Any adverse factors in this period may affect both the mitral valve and the bones of the thoracic cage. Of possible relevance, rats fed a diet containing large amounts of peas of the genus *Lathyrus* develop both bony abnormalities and myxomatous changes in their valve leaflets. Therefore, it has been postulated that the MVP syndrome is a connective tissue disorder resulting from fetal exposure to toxic substances during the early part of pregnancy.[20,21]

Others have suggested that MVP is a result of defective embryogenesis of cell lines of mesenchymal origin. The increased prevalence of primary MVP in patients with von Willebrand disease and other coagulopathies, primary hypomastia, and various connective tissue diseases has been used to support this concept.[21]

In *secondary* forms of MVP (see Table 58-1), myxomatous proliferation of the spongiosa portion of the mitral valve leaflet is absent. Tei et al.[22] were able to produce de novo echocardiographic evidence of MVP, often with MR, in closed-chest dogs undergoing transient coronary artery occlusion; MVP was attributed to relative displacement of ischemic papillary muscles. Also, serial studies in patients with known ischemic heart disease occasionally have documented unequivocal MVP following an acute coronary syndrome that was previously absent.[23] In most patients with coronary artery disease (CAD) and MVP, however, the two entities are coincident but unrelated.

More recent studies[24-26] indicate that MR caused by MVP may result from postinflammatory changes, including those following rheumatic fever. In histologic studies of surgically excised valves, fibrosis with vascularization and scattered infiltration of round cells, including lymphocytes and plasmacytes, was found *without myxomatous proliferation* of the spongiosa.[24] With rheumatic carditis, the anterior mitral leaflet is more likely to prolapse.[26]

MVP has been observed in patients with hypertrophic cardiomyopathy, in whom posterior MVP may result from a disproportionately small LV cavity, altered papillary muscle alignment, or a combination of factors.[21] The mitral valve leaflet is usually normal, but occasionally, the changes of primary MVP are present. Since LV segmental wall motion abnormalities and sometimes depressed global LV function occur in certain patients with echocardiographic and auscultatory evidence of MVP and MR, nonhypertrophic cardiomyopathy has been listed as a cause of mitral prolapse.[27] This is probably not the case; the ventricular wall motion abnormalities usually disappear when the mitral valve is repaired or replaced. In MVP patients, atrial septal defects, pulmonary hypertension, anorexia nervosa, dehydration, or straight-back syndrome may be secondary to the relatively small size of the left ventricle in this disorder, resulting in a mitral apparatus that is relatively large and redundant.[21,28] However, atrial septal defect may be associated with primary MVP.[16] Patients with primary and secondary MVP must be distinguished from those with normal variations on cardiac auscultation or echocardiography; these variations can result in an incorrect diagnosis of MVP, particularly in patients who are hyperkinetic or dehydrated during the physical examination or two-dimensional (2-D) echocardiography. Other auscultatory findings may be misinterpreted as midsystolic clicks or late-systolic murmurs.[8,21]

Patients with mild to moderate billowing of one or more nonthickened leaflets toward the left atrium with the leaflet coaptation point on the ventricular side of the mitral annulus and no or minimal MR by Doppler echocardiography are probably normal. Unfortunately, many such patients with neither a nonejection click nor murmur of MR are frequently overdiagnosed as having the MVP syndrome.[1,2,29]

TOP

Chapter 58: MITRAL VALVE PROLAPSE SYNDROME

PATHOPHYSIOLOGY

In patients with MVP, there is frequently LA enlargement and LV enlargement, depending on the presence and severity of MR.[30] The supporting apparatus is often involved, and in patients with connective tissue syndromes such as Marfan syndrome, the mitral annulus is usually dilated, sometimes calcified, and does not decrease its circumference by the usual 30 percent during LV systole. The hemodynamic effects of mild to moderate MR are similar to those from other causes of MR.

Many studies suggest an increased prevalence of autonomic nervous system dysfunction in patients with primary MVP. In 1979, Gaffney et al.[31] reported a reduced heart rate slowing with intravenous phenylephrine and an abnormal diving reflex heart rate response in patients with MVP as compared with age-matched controls. Patients with MVP had a lesser lower extremity pooling of blood in response to lower body negative pressure. Increased vagal tone and prolonged QT intervals on the electrocardiogram (ECG) are more common in patients with MVP. Measurements of serum and 24-h urine epinephrine and norepinephrine levels are often increased in patients with symptomatic MVP as compared with controls.[32] Patients with MVP often have an increased heart rate and contractility response to intravenous isoproterenol.[33] An increased incidence of high-affinity beta receptors in the lymphocytes of patients with MVP has been reported, as well as greater than usual increases in cyclic adenosine monophosphate with isoproterenol stimulation as compared with normal individuals.[33] Patients with MVP often have postural phenomena such as orthostatic tachycardia and hypotension. Low intravascular volume and/or an abnormality in the renin-aldosterone axis may contribute to the orthostatic changes.[7,34]

Chapter 58: MITRAL VALVE PROLAPSE SYNDROME

ASSOCIATED CONDITIONS

Tricuspid valve prolapse, with similar interchordal hooding and histologic evidence of mucopolysaccharide proliferation and collagen dissolution, occurs in about 40 percent of patients with MVP.[6] Pulmonic valve prolapse and aortic valve prolapse occur in approximately 10 and 2 percent of patients with MVP, respectively.[6] The frequent findings of thoracic skeletal abnormalities in patients with MVP were noted earlier. There is an increased incidence of secundum atrial septal defect in patients with MVP and an increased incidence of MVP in patients with atrial septal defects that cannot be explained by a chance occurrence and does not represent only stretching of a patent fossa ovalis (see also Chaps. 63 and 64). An increased incidence of left-sided atrioventricular bypass tracts and supraventricular tachycardias also occurs in patients with MVP.[6,35]

Chapter 58: MITRAL VALVE PROLAPSE SYNDROME

CLINICAL MANIFESTATIONS

Symptoms

The diagnosis of MVP is most commonly made by cardiac auscultation in asymptomatic patients or by echocardiography being performed for some other purpose. The patient may be evaluated because of a family history of cardiac disease or occasionally may be referred because of an abnormal resting ECG. Some patients consult their physicians because of one or more of the common symptoms that occur in patients with this syndrome. The most common presenting complaint is *palpitation*. The source of palpitation is usually ventricular premature beats, but various supraventricular arrhythmias are also frequent, and the most common sustained tachycardia is paroxysmal reentry supraventricular tachycardia (see Chap. 24). Ventricular tachycardia occurs in some patients, and others have had symptomatic bradyarrhythmias. Palpitation is often reported by patients at a time when continuous ambulatory ECG recordings show no arrhythmias.

Chest pain is a frequent complaint in patients with MVP. It is atypical in most patients without coexisting ischemic heart disease and rarely resembles classic angina pectoris. Occasionally, it is recurrent and can be incapacitating. The etiology of the chest pain is unknown; sometimes it may represent true myocardial ischemia produced by abnormal tension on the papillary muscles and supporting ventricular wall by the prolapsing mitral leaflets.[36] Coronary artery spasm has been reported in patients with MVP, but it is unlikely to be the cause of most episodes of atypical chest pain.[37]

Dyspnea and *fatigue* are frequent symptoms in patients with MVP, including many without severe MR. Objective exercise testing often fails to show impaired exercise tolerance, and some patients exhibit distinct episodes of hyperventilation. Neuropsychiatric complaints occur in certain patients with MVP. Some have panic attacks (see Chap. 80), and others have frank manic-depressive syndromes. Transient cerebral ischemic episodes occur with increased incidence in patients with MVP, and some develop stroke syndromes.[38-42] One recent study showed no association between MVP and stroke.[43] Reports of amaurosis fugax, homonymous field loss, and retinal artery occlusion have been made; occasionally, the visual loss persists.[44] These signs likely are due to embolization of platelets and fibrin deposits that occur on the atrial side of the mitral valve leaflets.[45] *It is important to note that both MVP and panic attacks occur relatively frequently. Accordingly, the occurrence of the two syndromes in the same individual would be expected to occur frequently by chance, rather than panic attacks necessarily being part of the primary MVP syndrome.*

Physical Examination

The presence of thoracic skeletal abnormalities may suggest the diagnosis of MVP, the most common being scoliosis, pectus excavatum, straightened thoracic spine, and narrowed anteroposterior diameter of the chest.[16] Some patients with MVP may show signs, such as arachnodactyly, more typical of Marfan syndrome.

The principal cardiac auscultatory feature of this syndrome is the midsystolic click, a high-pitched sound of short duration (see Chap. 10). The click may vary considerably in intensity and location in systole according to LV loading conditions and contractility. It results from the sudden tensing of the mitral valve apparatus as the leaflets prolapse into the left atrium during systole. Multiple systolic clicks may be generated by different portions of the mitral leaflets prolapsing at varying times during systole.[46] The major differentiating feature of the midsystolic click of MVP from that due to other causes (e.g., aneurysm of the ventricular septum, atrial myxomas, or pericarditis) is that its timing during systole may be altered by maneuvers that change hemodynamic conditions (Table 58-2).

Table 58-2: Response of the Murmur of Mitral Valve Prolapse to Interventions

Intervention	Timing	Intensity
Standing upright	←	↑
Recumbent	→	↓ or 0
Squatting	→	↓ or 0
Hand-grip	←	±
Valsalva	←	±
Amyl nitrite	±	↑

NOTE: ↑ = increase; ↓ = decrease; 0 = no change; ± = variable; ← = earlier; → = later.

The midsystolic click is frequently followed by a late-systolic murmur, usually medium- to high-pitched and most audible at the apex. Occasionally, the murmur has a musical or honking quality. The character and intensity of the murmur also vary under certain conditions, from brief and almost inaudible to holosystolic and loud (Fig. 58-3).

Dynamic auscultation is often useful for establishing the clinical diagnosis of the MVP syndrome.[21] Changes in the LV end-diastolic volume lead to changes in the timing of the midsystolic click and murmur. When end-diastolic volume is decreased, the critical volume is achieved earlier in systole, and the click-murmur complex occurs shortly after the first heart sound (Fig. 58-4). In general, any maneuver that decreases the end-diastolic LV volume, increases the rate of ventricular contraction, or decreases the resistance to LV ejection of blood causes the MVP to occur early in systole, and the systolic click and murmur to move toward the first heart sound (see Table 58-2). By contrast, any maneuver that augments the volume of blood in the ventricle, reduces myocardial contractility, or increases LV afterload lengthens the time from the onset of systole to the initiation of MVP, and the systolic click and/or murmur move toward S_2. Maneuvers causing the click and/or murmur to occur earlier in systole include standing from the supine position, submaximal isometric handgrip exercise, the Valsalva maneuver, and amyl nitrite inhalation. Those which cause the click and murmur to move toward S_2 include squatting from the upright position and maneuvers that slow the heart rate.

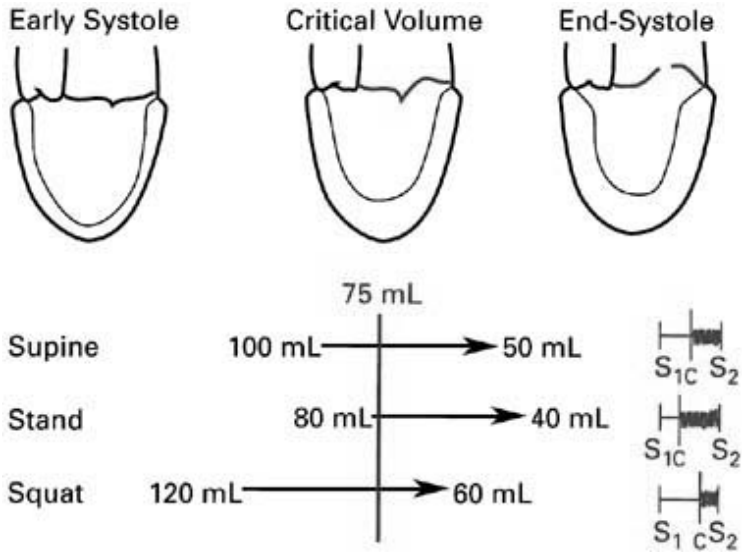

Figure 58-4: The effect of LV volume on the timing of MVP and the accompanying murmur. In the upper panel, three phases of LV systole are illustrated. In early systole, there is coaptation of the leaflets and no prolapse; when a critical ventricle volume of 75 mL is reached, valve prolapse commences and progresses until the end of systole. In the lower panel, three body positions are indicated; the corresponding change in volume and timing of the click-murmur are shown. The critical volume for prolapse remains constant. When the critical volume occurs earlier, the onset of the click-murmur is earlier. When the critical volume occurs later, the onset of the click-murmur is later. (From Crawford MH, O'Rourke RA. In: Isselbacher KJ et al., eds. *Harrison's Principles of Internal Medicine*, 9th ed. New York: McGraw-Hill; 1980:91-105. Reproduced with permission from the publisher, editors, and authors.)

Electrocardiogram

The ECG is usually normal in patients with MVP. The most common abnormality noted is the presence of ST-T-wave depression or T-wave inversion in the inferior leads (III, aV_F)[47] (Fig. 58-5). These changes may reflect ischemia of the inferior wall due to traction on the posteromedial papillary muscle by the prolapsing mitral leaflets. Sometimes ST-T-wave changes are present only during interventions that induce prolapse earlier in systole, as discussed earlier. More unusual electrocardiographic changes include prominent U waves, peaked T waves in the midprecordial leads, and prolongation of the QT interval.

MVP is associated with an increased incidence of false-positive exercise electrocardiographic results in patients with normal coronary arteries, especially females. Myocardial perfusion imaging with thallium or technetium sestamibi has been useful for differentiating false from true abnormal exercise electrocardiographic findings in patients with MVP (see Chap. 16).

Although arrhythmias may be observed on the resting ECG or during treadmill or bicycle exercise, they are detected more reliably by continuous ambulatory electrocardiographic recordings (see Chap. 13). The reported incidence of documented arrhythmias is higher in patients with MVP, ranging from 40 to 75 percent.[48] Most of the arrhythmias detected, however, are not life-threatening. Patients with ST-T-wave changes in the inferior electrocardiographic leads appear to have a higher incidence of serious ventricular arrhythmias on ambulatory recordings.[20]

Echocardiography

Echocardiography (see Chap. 13) is the most useful noninvasive test for defining MVP. The M-mode echocardiographic definition of MVP includes 2 mm or more of posterior displacement of one or both leaflets or holosystolic posterior "hammocking" of more than 3 mm (see Fig. 58-3). On 2-D echocardiography, systolic displacement of one or both mitral leaflets, particularly when they coapt on the LA side of the annular plane, in the parasternal long-axis view indicates a high likelihood of MVP[49] (see Fig. 58-5). There is disagreement concerning the reliability of an echocardiographic diagnosis of

MVP when observed only in the apical four-chamber view. The diagnosis of MVP is even more certain when the leaflet thickness is greater than 5 mm during ventricular diastole. Leaflet redundancy is often associated with an elongated mitral annulus and elongated chordae tendineae. On Doppler velocity recordings, the presence or absence of MR is an important consideration, and MVP is more likely when the MR is detected as a high-velocity jet midway or more posterior in the left atrium.[29]

At present, there is no consensus on the 2-D echocardiographic criteria for MVP. Since echocardiography is a tomographic cross-sectional technique, no single view should be considered diagnostic. The parasternal long-axis view permits visualization of the medial aspect of the anterior mitral leaflet and middle scallop of the posterior leaflet. If the findings of prolapse are localized to the lateral scallop in the posterior leaflet, they would be best visualized by the apical four-chamber view.[49,50] All available echocardiographic views should be used, with the provision that anterior leaflet billowing alone in the four-chamber apical view is not evidence of prolapse; however, a displacement of the posterior leaflet or the coaptation point in any view including the apical views suggests the diagnosis of prolapse. The echocardiographic criteria for MVP should include structural changes such as leaflet thickening, redundancy, annular dilatation, and chordal elongation.

Patients with echocardiographic criteria for MVP but without evidence of thickened/redundant leaflets or definite MR are more difficult to classify. If such patients have auscultatory findings typical of MVP, the echocardiogram confirms the diagnosis. On the other hand, a patient with typical auscultatory findings but a negative echocardiogram likely also has MVP; in the past, as many as 10 percent of patients with MVP have had a nondiagnostic echocardiographic study. Currently, this percentage is lower because of more careful and complete echocardiographic studies. In clinical practice, a false diagnosis of MVP occurs too frequently. The use of echocardiography as a screening test for MVP in patients with and without symptoms who have no systolic click or murmur on serial, carefully performed auscultatory examinations *is not recommended*. The likelihood of finding a prolapsing mitral valve in such patients is extremely low. Most patients with or without symptoms who have negative dynamic cardiac auscultation and "mild mitral valve prolapse" by echocardiography should not be diagnosed as having MVP. Recommendations for echocardiography in MVP are listed in Table 58-3.[51]

Table 58-3: Recommendations for Echocardiography in Mitral Valve Prolapse

Indication	Class
1. Diagnosis, assessment of hemodynamic severity of MR, leaflet morphology, ventricular compensation in patients with physical signs of MVP.	I
2. To exclude MVP in patients who have been given the diagnosis where there is no clinical evidence to support the diagnosis.	I
3. To exclude MVP in patients with first-degree relatives with known myxomatous valve disease.	IIa
4. Risk stratification in patients with physical signs of MVP with no or mild regurgitation.	IIa
5. To exclude MVP in patients in the absence of physical findings suggestive of MVP a positive family history.	III
6. Routine repetition of echocardiography in patients with MVP with no MR and no changes in clinical signs or symptoms.	III

Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.

Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a proce-dure or treatment.

Class IIa: Weight of evidence/opinion is in favor ofusefulness/efficacy.

Class IIb: Usefulness efficacy is less well established byevidence/opinion.

Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful.

SOURCE: From ACC/AHA clinical practice guidelines for valvular heart disease. *J Am Coll Cardiol* 1998; 32:1486-1588.

Echocardiography is useful for defining LA size, LV size and function, and the extent of mitral leaflet redundancy, as well as for detecting associated lesions such as secundum atrial septal defect. Doppler echocardiography is helpful for the detection and semiquantitation of MR as well. Serial echocardiograms are often useful for following patients with murmurs, especially holosystolic murmurs, since quantitation of MR by examination alone is more difficult. In a carefully performed study comparing auscultatory findings with echocardiographic results in patients with clinical evidence of MVP, the amount of billowing of one or both mitral leaflets into the left atrium, the level of the leaflets' coaptation point, and the presence or absence of moderate or severe MR were each important considerations in deciding on the likelihood of MVP.[29]

Chest Roentgenogram

Posteroanterior and lateral chest x-ray films usually show normal cardiopulmonary findings. The skeletal abnormalities described earlier can be seen.[19] When severe MR is present, both LA and LV enlargement often results. Various degrees of pulmonary venous congestion are evident when left-sided heart failure results. Acute chordal rupture with a sudden increase in the amount of MR may present as pulmonary edema without obvious LV or LA dilatation. Calcification of the mitral annulus may be seen, particularly in adults with Marfan syndrome (see Chap. 12).

Myocardial Perfusion Scintigraphy

Exercise myocardial perfusion imaging with thallium or technetium sestamibi has been recommended as an adjunct to exercise ECG for determining the presence or absence of coexistent myocardial ischemia in patients with MVP.[52] Most MVP patients *with clinical evidence of CAD* have an abnormal exercise scintigram. On the other hand, a negative scintigram in these patients does not exclude ischemia as the basis for the chest pain, nor does it completely exclude CAD as the etiology (see Chap. 16).

Cardiac Catheterization

Cardiac catheterization is rarely used as a diagnostic technique for MVP. Also, contrast ventriculography is unnecessary for determining LV function because it usually can be quantitated by 2-D echocardiography or radionuclide ventriculography. While contrast cineventriculography is often useful for assessing the severity of MR, cardiac catheterization and angiography are used most commonly in patients with MVP to exclude the possibility of CAD.

Intracardiac pressures and cardiac output are usually normal in uncomplicated MVP; however, these measurements become progressively more abnormal as MR becomes more severe.

LV cineangiography usually confirms the presence of prolapse of the mitral valve.[5,8] The right anterior oblique projection is best for observing prolapse of the three scallops of the posterior leaflet. The left anterior oblique view is necessary for the adequate evaluation of prolapse of the anterior leaflet.

LV wall motion is usually normal in patients with primary MVP, but some patients show abnormal

contraction patterns in the absence of CAD.[5,27] These contraction abnormalities usually represent indentation of the left ventricle at the point of attachment of the papillary muscles; it is thought to be due to abnormal traction on the papillary muscles and buckling of the ventricular wall. Patients with the most severe prolapse more commonly exhibit misshapen ventricular cavities during systole, and wall motion abnormalities frequently disappear after successful mitral valve replacement or repair.[27]

Coronary arteriography is usually normal in patients with primary MVP, and no congenital anomalies of the coronary vessels have been associated with this syndrome.

Electrophysiologic Testing

The indications for electrophysiologic testing in a patient with MVP are similar to those in other patients (i.e., recurrent unexplained syncope, sudden death survivors, symptomatic complex ventricular ectopy, and the presence of the preexcitation syndromes) (see Chap. 26). Upright tilt studies with monitoring of blood pressure and rhythm may be valuable in patients with light-headedness or syncope and in diagnosing autonomic dysfunction (see Chap. 32).

Chapter 58: MITRAL VALVE PROLAPSE SYNDROME

NATURAL HISTORY, PROGNOSIS, AND COMPLICATIONS

In most patient studies, the MVP syndrome is associated with a benign prognosis[6,53-60] (Fig. 58-6). The age-adjusted survival rate for both males and females with MVP is similar to that in patients without this common clinical entity. The gradual progression of MR in patients with mitral prolapse, however, may result in progressive dilatation of the left atrium and ventricle. LA dilatation often results in atrial fibrillation, and moderate to severe MR eventually results in LV dysfunction and the development of congestive heart failure. Pulmonary hypertension may occur with associated right ventricular dysfunction. In some patients with an initially prolonged asymptomatic interval, the entire process may enter an accelerated phase as a result of LA and LV dysfunction, atrial fibrillation, and in certain instances, ruptured mitral valve chordae. The latter occurs more commonly in males and with increasing age.[6,7]

Several long-term prognostic studies suggest that complications occur most commonly in patients with a mitral systolic murmur, thickened redundant mitral valve leaflets, or increased LV or LA size[30,57,58,62] (Fig. 58-7 and Table 58-4).

In a prospective follow-up study of 237 asymptomatic or minimally symptomatic patients with MVP documented by echocardiography, sudden death occurred in 6 patients.[55] In a multivariant analysis of the echocardiographic findings, the presence or absence of redundant mitral valve leaflets by M-mode echocardiography was the only variable associated with sudden death. Ten patients sustained a cerebral embolic event, six of whom were in atrial fibrillation with LA enlargement. Marks et al.[49] confirmed these data in a retrospective 2-D echocardiographic study from 456 patients with MVP. Two groups of patients were compared; those with thickening and redundancy of the mitral valve leaflet and those without leaflet thickening. Complications or a history of complications was more prevalent in those with leaflet thickening and redundancy compared with those without leaflet thickening. The incidence of stroke, however, was similar in the two groups. Long-term follow-up studies in patients with MVP associated with a floppy, myxomatous mitral valve permit several conclusions.[7] Serious complications occur in some patients with MVP, predominantly in those with diagnostic auscultatory findings. Also, redundant mitral valve leaflets and increased LV size are associated with a frequency of serious complications. Finally, men and those over 50 years of age are at increased risk of complications, including severe MR requiring surgery.

Sudden death is the least common but obviously the most severe complication of MVP (Table 58-5). While infrequent, the highest incidence of sudden death has been reported in the familial form of MVP. Some of these patients have been noted to have QT-interval prolongation. Also, patients with MVP with severe autonomic dysfunction and excessive vagotonia resulting in bradyarrhythmias and asystole have been reported.[63,64] Therefore, arrhythmias are likely to be the usual cause of sudden death in patients with MVP, so it seems prudent to limit ambulatory electrocardiographic recordings to those patients at highest risk. Many believe that patients with electrocardiographic ST-T-wave changes are more likely to have complex ventricular arrhythmias.[6,7] Certainly, any patients with symptoms suggestive of arrhythmia or who have arrhythmias noted during physical examination or on the resting ECG should be evaluated further (see Chap. 24).

Table 58-5: Mitral Valve Complications in 102 Hearts with Mitral Valve Prolapse

	No.	Percent
Sudden death	0	0
Primary rupture of chordae	7	7
Bacterial endocarditis	7	7
Mitral valve regurgitation	18	18
Primary rupture of chordae	(7)	-
Bacterial endocarditis	(4)	-
Severe prolapse	(4)	-
Entrapped chordae	(3)	-
Fibrin deposits	4	4

SOURCE; Modified from Lucas RV Jr, Edwards JE. The floppy mitral valve. *Curr Probl Cardiol* 1982; 7:1-48.

Infective endocarditis is a serious complication of MVP, and MVP is the leading predisposing cardiovascular diagnosis in most series of patients reported with endocarditis.[6,7,65] Since the absolute incidence of endocarditis is extremely low for the entire MVP population, there has been much discussion concerning the risk of endocarditis in MVP.[66] While there is general agreement that MVP patients with murmurs and/or thickened redundant valves confirmed by echocardiography or cineangiography should receive antibiotic prophylaxis, some authorities state that patients with isolated systolic clicks and no murmurs do not need antibiotic prophylaxis for endocarditis.[67] The dynamic nature of MVP, with variable physical findings on different examinations, makes it difficult to make judgments on the basis of the presence or absence of a systolic murmur. With the increasing use of color-flow echo-Doppler studies, MR often has been observed in patients in whom no murmur is heard.[68] Recommendations for antibiotic endocarditis prophylaxis for patients with MVP undergoing procedures associated with bacteremia are listed in Table 58-6.

Table 58-6: Recommendations for Antibiotic Endocarditis Prophylaxis for Patients with Mitral Valve Prolapse Undergoing Procedures Associated with Bacteremia

Indication	Class
1. Patients with characteristic systolic click-murmur complex.	I
2. Patients with isolated systolic click and echo evidence of MVP and MR.	I
3. Patients with isolated systolic click, echo evidence of high-risk MVP.	IIa
4. Patients with isolated systolic click and no or equivocal evidence of MVP.	III

SOURCE: From ACC/AHA guidelines for the clinical application of echocardiography. *Circulation* 1997; 95:1686-1744.

As indicated earlier, progressive MR occurs frequently in patients with long-standing MVP. Fibrin emboli are responsible in some patients for visual problems consistent with involvement of the ophthalmic or

posterior cerebral circulation. Several studies have indicated an increased likelihood of cerebral vascular accidents of various types in patients under age 45 who have MVP than would have been expected in a similar population without MVP. Therefore, it has been recommended that antiplatelet drugs such as aspirin be administered to patients who have MVP and suspected cerebral nervous system emboli; however, neither antiplatelet drugs nor anticoagulants should be prescribed routinely for patients with MVP because the incidence of embolic phenomena is very low. Recommendations for aspirin and oral anticoagulants in MVP are listed in Table 58-7. *It is important to avoid the incorrect diagnosis of MVP syndrome. This mistake is especially likely to occur in patients with neuropsychiatric symptoms, in whom an incorrect diagnosis of MVP is made from the ECG. Such an improper diagnosis can form the foundation of a chronic, often disabling cardiac neurosis. Even if the diagnosis of MVP is properly made, it is not necessarily correct to attribute neuropsychiatric symptoms to the MVP* (see also Chap. 80).

Table 58-7: Recommendations for Aspirin and Oral Anticoagulants in Mitral Valve Prolapse

Indication	Class
1. Aspirin therapy for cerebral transient ischemic attacks (TIAs).	I
2. Warfarin therapy for patients in atrial fibrillation with age ≥65 yr, hypertension, MR murmur, or history of heart failure.	I
3. Aspirin therapy for patients in atrial fibrillation <65 years old with no history of MR, hypertension, or heart failure.	I
4. Warfarin therapy for poststroke patients.	I
5. Warfarin therapy patients for TIAs despite aspirin therapy.	IIa
6. Aspirin therapy in poststroke patients with contraindications to anticoagulants.	IIa
7. Aspirin therapy for patients in sinus rhythm with echocardiographic evidence of high-risk MVP	IIb

Chapter 58: MITRAL VALVE PROLAPSE SYNDROME

TREATMENT

The majority of patients with MVP are asymptomatic and lack the high-risk profile described earlier. These patients with mild or no symptoms and findings of milder forms of prolapse should be assured of a benign prognosis. A normal lifestyle and regular exercise are encouraged.[5,7] For most patients in whom the *diagnosis of MVP is definite*, we recommend antibiotic prophylaxis for the prevention of infective endocarditis while undergoing procedures associated with bacteremia. Patients with MVP and palpitation associated with sinus tachycardia or mild tachyarrhythmias and those with chest pain, anxiety, or fatigue often respond to therapy with beta blockers.[5,7,69] In many cases, however, the cessation of catecholamine stimulants such as caffeine, alcohol, cigarettes, and certain drugs may be sufficient to control symptoms.

Orthostatic symptoms are best treated with volume expansion, preferably by liberalizing fluid and salt intake. Mineralocorticoid therapy may be needed in severe cases, and wearing support stockings may be beneficial.[7] In sudden death survivors and those patients with symptomatic complex arrhythmias, specific antiarrhythmic therapy should be guided by monitoring techniques, including electrophysiologic testing when indicated[7] (see Chap. 26).

Daily aspirin therapy (80-325 mg/day; see Table 58-7) is recommended for MVP patients with documented focal neurologic events. Such patients also should avoid cigarettes and oral contraceptives. Some clinicians use long-term anticoagulant therapy with warfarin in poststroke patients with prolapse, particularly when symptoms occur on aspirin therapy (see also Chap. 89).

Restriction from competitive sports is recommended when moderate LV enlargement, LV dysfunction, uncontrolled tachyarrhythmias, long QT interval, unexplained syncope, prior sudden death survival, or aortic root enlargement is present, individually or in combination.[7]

The familial occurrence of MVP should be explained to the patient and is particularly important in those with associated disease, who are at greater risk for complications. Screening relatives can uncover high-risk individuals and potentially prevent some complications. There is no contraindication to pregnancy based on the diagnosis of MVP alone.

Patients with severe MR with symptoms and/or impaired LV systolic function require cardiac catheterization studies and evaluation for mitral valve surgery.[70] The thickened, redundant mitral valve often can be repaired rather than replaced, with a low operative mortality and excellent long-term results.[71-79] Follow-up studies also suggest lower thromboembolic and endocarditis risk than with prosthetic valves.

Asymptomatic patients with MVP and no significant MR can be evaluated clinically every 2 to 3 years. Echocardiography has been suggested every 5 years in such patients to help determine the natural history and the likelihood of complications. Patients with MVP who have high-risk characteristics, including those with moderate to severe MR, should be followed more frequently, even if no symptoms are present.

Surgical Considerations

Management of the patient with MVP may require valve surgery, particularly in those patients who develop a flail mitral leaflet due to rupture of chordae tendineae or their marked elongation.[79] Most such valves can be repaired successfully by surgeons experienced with mitral valve repair, especially when the posterior leaflet valve is predominantly affected. Symptoms of heart failure, the severity of MR, the presence or absence of atrial fibrillation, LV systolic function, LV end-diastolic and end-systolic volumes, and pulmonary artery pressure (rest and exercise) all influence the decision to recommend mitral valve surgery. Recommendations for surgery in patients with MVP and MR are the same as for those with other forms of nonischemic severe MR and include class III-IV symptoms, LV ejection fraction less than 60 percent, and/or marked increases in LV end-diastolic and end-systolic volumes. If mitral repair is likely to be successful, severe MR with class II symptoms or atrial fibrillation may be an appropriate reason for surgical referral.[51]

Part 9: VALVULAR HEART DISEASE
Chapter 59:

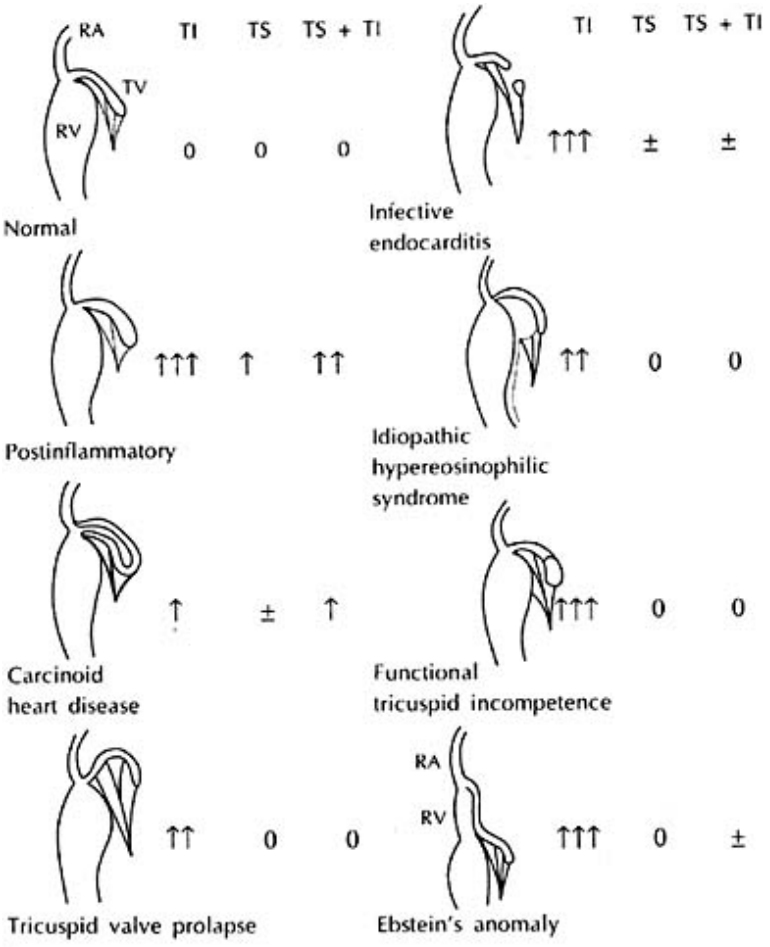
TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

Author: Robert A. O'Rourke

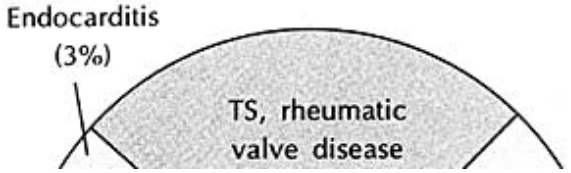
DEFINITION, ETIOLOGY, AND PATHOLOGY

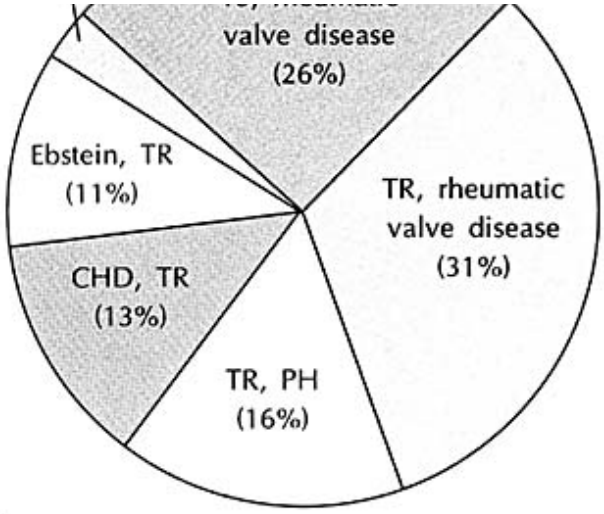
Tricuspid Valve Disease

Tricuspid valve dysfunction can occur with normal or abnormal valves.[1] When normal tricuspid values develop dysfunction, the resulting hemodynamic abnormality is almost always pure regurgitation. Tricuspid regurgitation (TR) occurs when the tricuspid valve allows blood to enter the right atrium (RA) during a right ventricular (RV) contraction. Tricuspid stenosis (TS) results from obstruction to diastolic flow across the valve during filling of the RV. A diagrammatic illustration of tricuspid valve disease and the prevalence of various pathologic etiologies are shown in Fig. 59-1*A* and *B*.



A





B

Figure 59-1: *A.* Tricuspid valve (TV) disease. Diagrammatic illustration of TV; TI, tricuspid insufficiency; TS, tricuspid stenosis; RA, right atrium; RV, right ventricle. *B.* Pathologic findings in TV. TR, tricuspid regurgitation; TS, tricuspid stenosis. [From Virmani R et al. Pathology of valvular heart diseases. In: Rahimtoola SH, ed. Philadelphia: Mosby (Current Medicine, Inc.), 1997:116, with permission.]

Diseases causing TR are more numerous than those causing TS. It is important to note that the normal tricuspid valve often does not completely coapt in systole, as is shown by the frequent occurrence of TR jets on Doppler ultrasound. Usually the volume of regurgitant blood is so small that the TR is silent; this finding occurs in 24 to 96 percent of normal individuals by Doppler ultrasound and thus must be considered a variant of normal.[2-4] Pathologic TR is most commonly due to diseases that cause RV dilatation and failure;[5] left ventricular (LV) failure and/or pulmonary hypertension can result in tricuspid regurgitation (Table 59-1). Primary diseases of the tricuspid valve apparatus, which includes the tricuspid annulus, the leaflets, the chordae, the papillary muscle, and the RV wall, also cause TR (Table 59-1).[6-8] The most common etiology of isolated TR is infective endocarditis in drug addicts[9] (see Chap. 73). Less common causes include myocardial infarction, trauma, carcinoid, leaflet prolapse, and such congenital abnormalities as atrial septal defect and Ebstein's anomaly[10-15] (see Chap. 63). TR also occurs in patients with rheumatoid arthritis, radiation therapy, and Marfan's syndrome.[6] Primary involvement of the tricuspid valve due to rheumatic fever results in TS, usually in association with TR (Fig. 59-2).

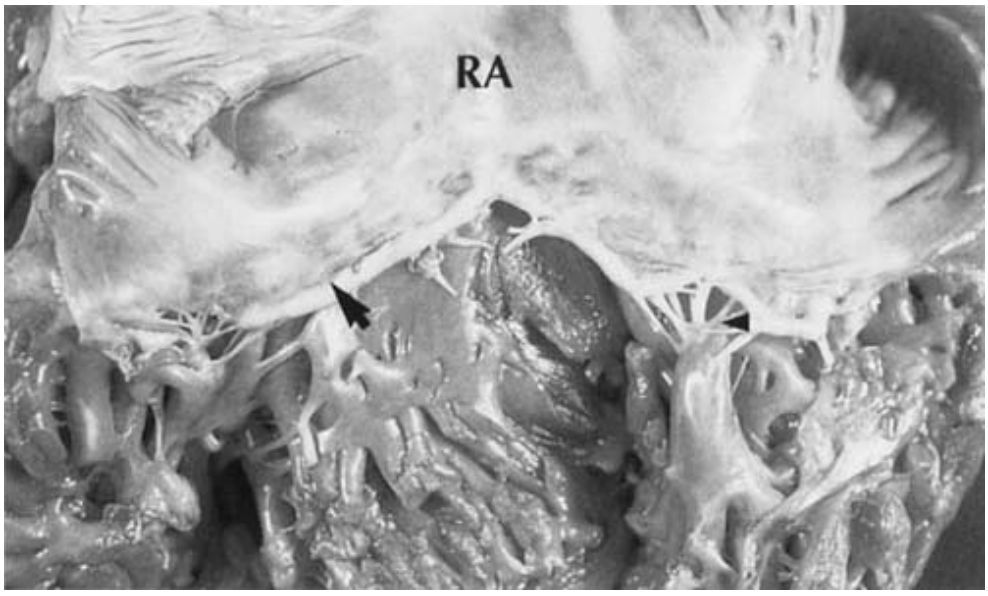


Figure 59-2: Heart displaying a tricuspid valve with fused, shortened chordae and rolled, thickened, fibrotic edge, consistent with chronic rheumatic heart disease. Isolated rheumatic TR or TS is very rare; it occurs almost always in the presence of concomitant MS. RA, right atrium. [From Farb A et al. Anatomy and pathology of the right ventricle (including acquired tricuspid and pulmonic valve disease). *Card Clin North Am* 1993; 10:1-2, with permission.]

Table 59-1: Diseases Causing Acquired Tricuspid Valve Regurgitation

DISEASE CAUSING PULMONARY HYPERTENSION
❍ All LV diseases with LV failure
❍ Mitral stenosis or mitral regurgitation
❍ Pulmonary venous obstruction
❍ Diseases causing an increase in pulmonary vascular resis- tance
❍ Primary pulmonary hypertension
❍ Acquired pulmonary vascular disease (atrial septal defects), ventricular septal defects, and patent ductus arteriosus
❍ Intrinsic pulmonary disease (chronic obstructive pulmonary disease, pulmonary fibrosis, and pulmonary resection)
❍ Collagen vascular diseases
❍ Pulmonary emboli, acute and chronic
PRIMARY DISEASES OF THE TRICUSPID VALVE
❍ Rheumatic heart disease
❍ Rheumatoid arthritis
❍ Trauma, penetrating and nonpenetrating
❍ Radiation therapy
❍ Carcinoid heart disease
❍ RA myxoma
❍ Infective endocarditis
❍ Eosinophilic myocarditis
❍ Prosthetic and bioprosthetic valve malfunction, including thrombosis and calcification
❍ RV myocardial infarction
❍ Myxomatous tricuspid valve (tricuspid valve prolapse)

SOURCE: Modified from Cheitlin and MacGregor,[22] with permission.

The most common cause of TS is rheumatic fever. This is usually associated with concomitant mitral stenosis (MS). Isolated TS can be seen with the carcinoid syndrome, infective endocarditis, endocardial fibroelastosis, endomyocardial fibrosis, and systemic lupus erythematosus, among other conditions[6-8] (Table 59-2). It has also been reported to occur in patients with Fabry's disease, or Whipple's disease and in patients receiving methysergide therapy.[6] Mechanical obstruction of the valve can be due to a RA myxoma, tumor metastases, and thrombi in the RA, each resulting in the hemodynamic abnormalities of TS.[16,17] In addition, RV inflow tract obstruction can result from thrombosis endocarditis, degeneration, or calcification affecting a prosthetic tricuspid valve.

Table 59-2: Diseases Causing Acquired Tricuspid Valve Stenosis

- Rheumatic heart disease (usually with mitral stenosis)
- Carcinoid heart disease
- Fabry's disease
- Whipple's disease
- Endocardial fibroelastosis
- Endomyocardial fibrosis
- Methysergide therapy
- Systemic lupus endocarditis
- RA myxoma or thrombus
- Prosthetic valve thrombosis
- Prosthetic valve infective endocarditis
- Paraprosthetic valve degeneration and calcification

SOURCE: Modified from Cheitlin and MacGregor,[22] with permission.

In rheumatic tricuspid valve disease, alterations in the valve are characterized by fibrosis, with contracture of the leaflets and commissural fusion. The former leads to TR and the latter to TS.[18] The stenotic component of rheumatic tricuspid valve disease is often minor and would go unrecognized clinically if it were not for the high flow across the valve caused by the coexistent regurgitation. Whenever the tricuspid valve is affected by rheumatic disease, there is also involvement of left-sided valves.[19] Flammang and associates observed that 9.5 percent of cases requiring surgical replacement of *both* the mitral and aortic valves also had rheumatic involvement of the tricuspid valve.[20]

Carcinoid heart disease is present in up to 53 percent of patients with malignant carcinoid tumor (usually originating in the ileum) with extensive metastases[15] (see Chap. 77). Carcinoid usually causes TR and TS and, less often, pulmonic stenosis (PS) and pulmonic regurgitation (PR).[21,22] Changes include deposits of fibrous tissue on the surfaces of these valves. Fibrous plaques can also develop on the endocardial surfaces of the RA and RV as well as on the intima of the coronary sinus and the pulmonary artery.[23] The hemodynamic effects result from the rigidity and contracture of the fibrous tissues deposited on the valves. Although TS may result, the major functional abnormality is usually TR.

The most common type of TR is the secondary type that results from the enlargement of the orifice and annulus secondary to congestive heart failure with RV dilation due to LV disease (Table 59-1). TR may diminish when the heart failure is treated successfully but can be permanent with long-standing dilatation of the RV.[24-26] In infective endocarditis, the TR results from improper coaptation of the leaflets because of interposed vegetations (Table 59-1). Major degrees of regurgitation may be due to rupture of chordae tendineae of the RV or perforation of the valve leaflets.

Until recently, myocardial infarction was not considered a common cause of TR except when secondary to chronic congestive heart failure.[27] Rare cases have been described from rupture of an RV papillary muscle.[28,29] Currently, RV infarction is being recognized more often and is frequently associated with TR, as documented by echocardiography (see Chap. 42).

Various degrees of tricuspid valve prolapse are commonly present in the general population and may occur in 3 to 54 percent in patients with mitral valve prolapse[22] (see Chap. 58). The reported incidence of *severe* TR from prolapse is low.[30]

External blunt trauma, most often in motor vehicle accidents, is a classic cause of TR. Isolated instances of rupture of a tricuspid papillary muscle have been described from external cardiopulmonary resuscitation.[31] Traumatic TR usually results from rupture of one or more of the components of the tensor apparatus, with disruption of the papillary muscle occurring more often than rupture of the chordae.[13] Less frequently, there

is a laceration of leaflet tissue.[32,33] Occasionally, traumatic TR and ruptured ventricular septum coexist[34] (Chap. 79). TR can also occur from iatrogenic trauma produced during an endomyocardial biopsy.[35,36] Mild TR often results when a pacemaker is placed across a normally functioning tricuspid valve or after extraction of permanent pacemaker leads.[37]

Tolerance to traumatic TR varies, with up to 39 years of survival reported.[38-40] Patients with rupture of a papillary muscle tend to tolerate the TR less well than do those in whom the trauma resulted in rupture of chordae.[39] Among reported cases of TR resulting from the rupture of the chordae, a traumatic etiology is more common than is infective endocarditis.[41] Primary congenital lesions of the tricuspid valve that cause regurgitation are Ebstein's malformation and valvular dysplasia, as discussed in Chap. 64.

Pulmonic Valve Disease

Acquired lesions of the pulmonic valve generally cause PR (Table 59-3). On rare occasions, an inflammatory process can create stenosis and regurgitation of the valve. Pulmonary hypertension from any cause, such as MS, chronic lung disease, or pulmonary emboli, can produce PR. Inflammatory diseases, such as endocarditis, rheumatic fever, and, rarely, tuberculosis, can result in PR.[42-45]

Table 59-3: Acquired Lesions of the Pulmonic Valve

- Pulmonary hypertension with pulmonic regurgitation
- Mitral stenosis
- Chronic lung disease
- Pulmonary emboli
- Inflammatory lesions
- Endocarditis
- Rheumatic fever
- Tuberculosis
- Tumors
- Sarcoma
- Myxoma
- Previous surgery or angioplasty for congenital lesions
- Mediastinal lesions
- Tumor
- Aneurysm
- Constrictive pericarditis
- Miscellaneous
- Carcinoid syndrome

PS is created by obstruction of systolic flow across the valve and is most commonly congenital (Fig. 59-3; see Chaps. 63 and 64). Sarcomas and myxomas can sometimes extend to the pulmonic valve, causing PS.[46] Previous cardiac surgery on a congenital pulmonic valve lesion can result in PR. The carcinoid syndrome with cardiac involvement can create mild PS and associated PR[44] (Fig. 59-4). Compression of the pulmonary artery can stimulate valvular stenosis and is rarely produced by tumor, aneurysm, or even constrictive pericarditis.

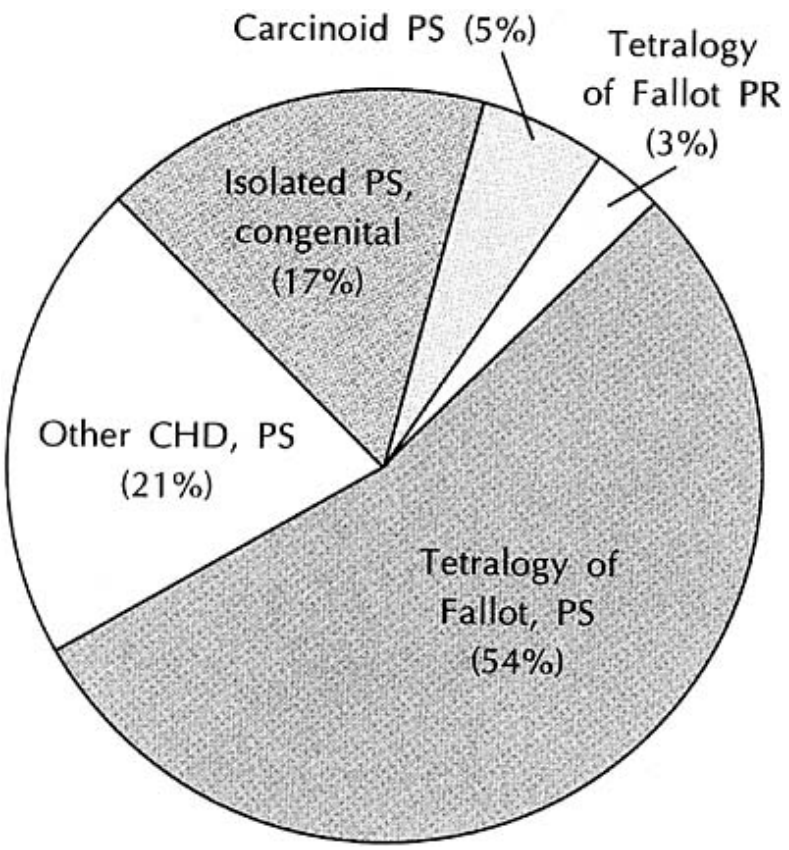

Figure 59-3: Pathologic findings in pulmonary valve (PV) replacement. CHD, congenital heart disease; PH, pulmonary hypertension; PR, pulmonary regurgitation; PS, pulmonary stenosis; TR, tricuspid regurgitation; TS, tricuspid stenosis. (Adapted from Altricher PM et al. Surgical pathology of the pulmonary valve; a study of 116 cases spanning 15 years. *Mayo Clin Proc* 1989; 64:1352-1360, with permission.)

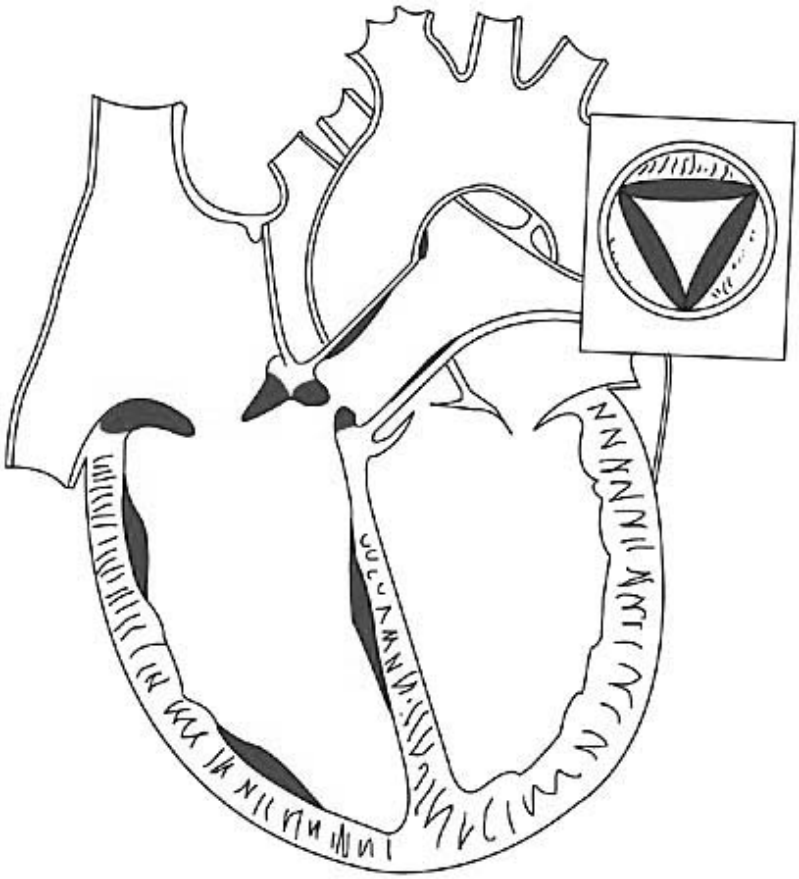

Figure 59-4: Carcinoid heart disease. The insert shows PS. The leaflets of the tricuspid valve are thickened. The valve is predominantly incompetent and causes PR. Fibrous plaques are deposited on the lining of the right ventricle and pulmonary trunk. (From Edwards JE. Effects of malignant noncardiac tumors upon the cardiovascular system. *Cardiovasc Clin* 1971; 4:282. Reproduced with permission from the publisher and author.)

Multivalvular Disease

Multivalvular disease includes mixed single valve disease [e.g., aortic stenosis (AS) plus aortic regurgitation (AR)] or combined disease affecting two or more values (e.g., MS plus TR). Rheumatic fever remains an important cause of combined disease of the mitral and aortic valves. Primary involvement of the tricuspid valve in the rheumatic process is unusual, and more commonly TR results from RV failure secondary to LV decompensation in valvular heart disease. A high prevalence of anatomic lesions involving two or more valves is present when the characteristic Aschoff body is observed at necropsy.[47] Connective tissue diseases (see Chap. 76) can affect both the aortic and the mitral valves. For example, in Marfan's syndrome mitral valve prolapse, resulting in MR, often occurs together with the frequently observed changes in the aortic valve and ascending aorta. In the aging patient, calcification can develop in the aortic valve and the mitral valve apparatus as well as in the mitral annulus. Finally, infective endocarditis of the aortic or mitral valve can extend to the adjacent valve apparatus. In an autopsy series, combined aortic and mitral valve disease was observed in 33 percent of 996 patients with rheumatic fever.[48] In a 30-year follow-up of 1042 children with a history of rheumatic fever, multiple-valve involvement became apparent in 50 percent of the individuals.[49] Bland and Jones followed 699 patients with cardiac involvement due to rheumatic fever for 20 years; 99 percent eventually exhibited aortic and mitral valve abnormalities.[50]

Rheumatic fever, myxomatous proliferation and prolapse, calcification in the aged, and infective endocarditis can impair both the aortic and mitral valves. The inflammatory process of rheumatic fever thickens and scars valve leaflets, which leads to fusion, fibrosis, and calcification (Fig. 59-5).

Myxomatous proliferation and valvular prolapse occur in the aortic, tricuspid, and pulmonic valves as well

as in the mitral valve (Fig. 59-6). Fusiform aneurysms of the aortic sinus and ascending aorta can develop in Marfan's syndrome; a dilated annulus, prolapse, ruptured chordae, and annular calcification can affect the mitral valve (Fig. 59-7). Annular dilatation, with or without prolapse, is a major cause of mitral regurgitation (MR) in Marfan's syndrome,[51] and most of the patients with Marfan's syndrome have mitral valve prolapse (see Chaps. 60 and 76).

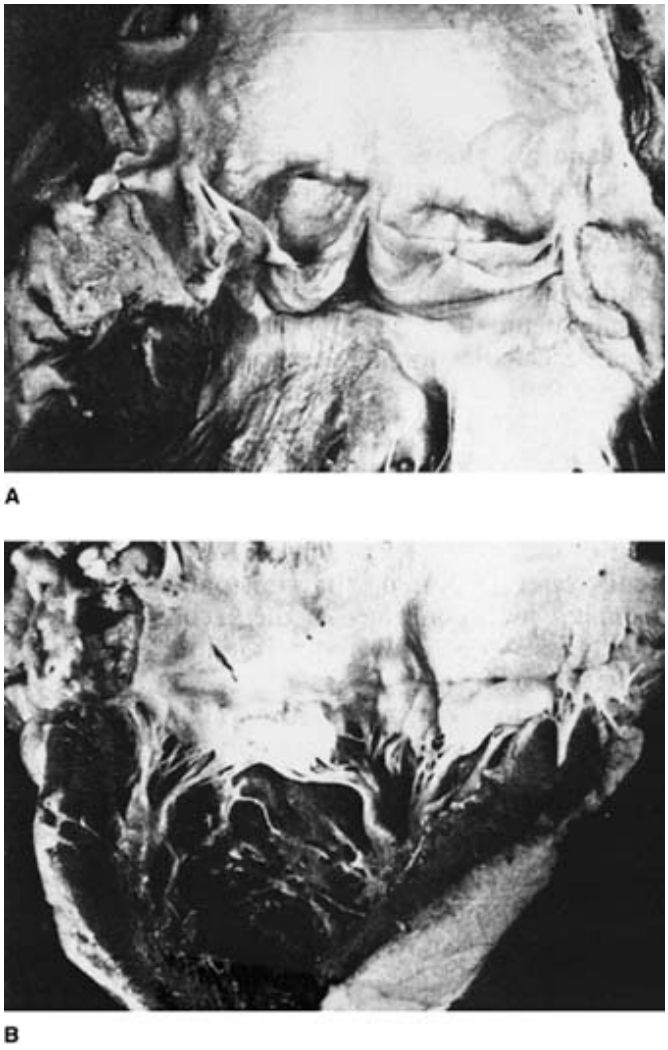

Figure 59-6: Prolapsed mitral valve and prolapsed aortic valve. *A.* Specimen of aortic valve from a 61-year-old man. The aortic valve shows redundance or prolapse of its right cusp. *B.* Specimen of mitral valve from a 73-year-old woman. The mitral valve shows prominent evidence of prolapse involving the posterior leaflet (right) and the posterior half of the anterior leaflet.

A

B

Figure 59-7: Floppy mitral valve and limited dissecting aneurysm of the ascending aorta, leading to aortic regurgitation, in a specimen from a 60-year-old man. *A.* Ascending aorta and aortic valve. The ascending aorta exhibits a laceration leading to a false channel within the aortic wall in which a hematoma is present (seen on each side of the opened aorta). Secondary distortion of the aortic valvular mechanism caused aortic regurgitation. *B.* Mitral valve, LA, and a portion of the LV. The posterior leaflet of the mitral valve (right) shows several areas of prolapse.

In aging patients, calcification can involve the aortic and mitral valves. Aortic stenosis is common, whereas mitral annular calcification usually creates regurgitation (Fig. 59-8). Infective endocarditis can extend from either the aortic or the mitral valve to the adjacent valve through the inflammatory process (Fig. 59-9).

Chapter 59: TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

PATHOPHYSIOLOGY

Tricuspid Valve Disease

In TR, the systolic blood flow into the RA elevates the mean RA pressure.[52] Regurgitant flow produces a prominent *cv* wave reflected through the venous system. Diastolic volume overload of the RV causes further dilatation of the RV and movement of the intraventricular septum toward the LV during diastole. RV failure further raises the mean RA and vena caval pressures and results in systemic venous congestion and signs of RV failure.[22]

TR decreases diastolic flow across the valve, elevates the RA pressure, and reduces the cardiac output.[1,53,54] With TS, there is stiffening of the valve by fibrosis and commissural fusion, both of which narrow the effective valvular orifice.[1,22] Flow from systemic veins or RA into the RV is obstructed, and a pressure gradient develops in diastole between the RA and RV. The normal area of the tricuspid valve is 7 cm^2, and impairment of RV filling occurs when the valve area is reduced to less than 1.5 cm^2. Elevation of the mean RA pressure above 10 mmHg usually results in peripheral edema. Development of atrial fibrillation produces a higher RA pressure in TS than when sinus rhythm and normal RA contraction are present. The hemodynamic abnormalities in TS can be further influenced by coexisting MS. Reduced RV flow in tricuspid valve obstruction has been proposed as a mechanism for protection against severe pulmonary hypertension.

Pulmonic Valve Disease

Pulmonic regurgitation is the most frequently acquired lesion of the pulmonic valve (Table 59-3). Regurgitation may be secondary to pulmonary hypertension or may be caused by primary abnormalities in the leaflets. PR imposes a volume overload on the RV, and if pulmonic hypertension preexists, the overload is superimposed on hypertrophied myocardium. Volume overload of the RV may cause an increase in diastolic volume of the chamber, an increase in RV stroke volume, and subsequent RV failure, resulting in TR.[1,22] Fortunately, isolated PR can usually be tolerated for a long time without cardiac decompensation.[55]

Multivalvular Disease

Multiple valve diseases affecting the mitral and aortic valves can produce a pressure overload, volume overload, or combinations of the two.[1,22] In the presence of combined valvular lesions, the pressure overload will cause concentric LV hypertrophy, even if myocardial failure develops.[1,23] An LV volume overload will result from AR and MR, and further dilatation will follow, with development of heart failure.[1,22] The combination of MS and AR usually results in a volume overload on the LV associated with LV pressure-volume work and myocardial oxygen consumption.[56,57]

Important physiologic considerations in combined valvular disease are the predominance of a single valvular lesion in altering hemodynamics and the potential failure to identify the presence of a second abnormal valve. MS produces left atrial (LA) and pulmonary venous hypertension,

with eventual pulmonary hypertension and RV failure, even though aortic stenosis may also be present. Despite the presence of MS, concomitant AS can create pressure overload and hypertrophy of the LV. When MR accompanies AS, the pressure and volume overloads create both LV dilatation and hypertrophy. LA enlargement and elevation of pulmonary artery pressure eventually accompany this condition. In regurgitation of both mitral and aortic valves, severe LV dilatation develops, accompanied by compensatory LV hypertrophy.[58] LV compliance increases in MR and AR, resulting in small elevations of end-diastolic pressure in the LV and LA for larger end-diastolic volumes.[59] Abnormalities in both early and late diastolic filling can accompany valvular regurgitation.[60]

In all combinations of aortic and mitral valve lesions, pulmonary congestion and elevated pulmonary capillary pressure usually follow significant depression of the contractile state of the LV. LA enlargement produced by either MS or MR is often associated with atrial fibrillation. Alterations in pulmonary blood flow and cardiac rhythm commonly accompany the LV pressure-volume overload in combined mitral and aortic valve disease.

TR usually accompanies RV dilatation secondary to pulmonary hypertension from any combination of mitral or aortic valve diseases. TS almost invariably is accompanied by disease of the mitral valve and can create significant elevations of the RA and central venous pressures.

Chapter 59: TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

CLINICAL MANIFESTATIONS

Symptoms

TRICUSPID VALVE DISEASE

Since TR generally accompanies LV failure or MS, presenting symptoms include dyspnea, orthopnea, and peripheral edema.[61] Even though LV failure is usually present, paroxysmal nocturnal dyspnea is often absent. TR under these conditions may occasionally ameliorate the pulmonary symptoms and provide a physiologic basis for the alleviation of left-sided heart failure by the development of right-sided heart failure. Some patients also have less pulmonary edema due to the development of pulmonary arteriolar disease. If the TR is produced by infective endocarditis, symptoms of febrile illness may be accompanied by fatigue and peripheral edema.

The most frequent symptoms in TS are dyspnea and fatigue. When MS coexists, the development of significant TS can diminish the paroxysmal symptoms of dyspnea, pulmonary congestion, and pulmonary hypertension.[16,17] Occasionally, patients with TS complain of prominent pulsations in the neck veins, which may precede the development of peripheral edema.

PULMONIC VALVE DISEASE

Clinical manifestations of acquired pulmonic valvular lesions depend on the severity of the hemodynamic impairment as well as on the extent of the underlying disease. Isolated PR can be tolerated without symptoms. Severe pulmonary hypertension may cause syncope in addition to shortness of breath and fatigue. With inflammatory lesions of the pulmonic valve, febrile manifestations and pulmonary infection may be present. The carcinoid syndrome is characterized by episodes of facial flushing, increased intestinal activity, diarrhea, and bronchospasm (see Chap. 77). Tumors involving the pulmonic valve may exert pressure from expansion and metastases that affect the heart and lungs.

MULTIVALVULAR DISEASE

Dyspnea is the most frequent complaint of patients with combined mitral and aortic valve disease.[1,22,62] With combined MS and AS, chest discomfort, palpitations, and syncope are frequent clinical manifestations. Symptoms of heart failure result from pulmonary congestion and usually include fluid retention. Although angina pectoris is uncommon in patients with predominant MR, this symptom is more frequent with regurgitation of both the aortic and mitral valves. Also, syncope is rare in predominant MR but may develop when AR and MR coexist; palpitations are present in the majority of patients.

Angina, dizziness, syncope, and palpitations are common symptoms in AS when it is associated with MR. Angina may also be a symptom when AR and MS are the predominant lesions; but the more frequent symptoms, dyspnea and fatigue, are attributed to pulmonary congestion and heart failure (see Chaps. 56 to 58).

Physical Examination

TRICUSPID VALVE DISEASE

In patients with primary TR not due to pulmonary hypertension, there are large *v* waves in the jugular venous pulse (JVP). There is a dilated RV with a precordial lift and right-sided third or fourth heart sounds. There is usually a long systolic murmur in the third and fourth intercostal space at the left sternal border that increases with inspiration. The murmur is often confined to early and mid-systole or may not be heard at all when there is small gradient between the RV and RA during systole and a large regurgitant orifice (see Chap. 10). When a large amount of blood returns to the RV in diastole, a short diastolic rumble along the left sternal border may be heard. All of these findings are increased with inspiration (Rivero Carvallo's sign).[63] When RV failure occurs, the mean central venous pressure becomes elevated, and the jugular veins are pulsatile and engorged. When TR is due to pulmonary hypertension, there is an accentuated P_2, and a high-pitched decrescendo diastolic murmur of PR is often heard that is louder during inspiration in the second and third left intercostal spaces. In patients with TR and atrial fibrillation, there is a prominent *cv* wave in the jugular veins, produced by the regurgitant flow into the RV (see Chap. 10). The characteristic physical finding of TR due to pulmonary hypertension is a holosystolic murmur at the left sternal border that increases during inspiration; there is a RV-RA pressure gradient throughout systole. Although the murmur of MR may also be present, respiration exerts a predominant influence on the TR murmur (see Chap. 10).

Tricuspid stenosis is frequently associated with lesions of the mitral and aortic valves. When sinus rhythm is present, the JVP will display the prominent *a* wave indicative of impaired RV diastolic filling with atrial systole. The *a* wave in the neck may be of moderate height and sometimes reaches the mandible. Auscultation of the heart is required to confirm that the rise of the venous *a* wave is simultaneous with the first heart sound. The *cv* wave is small, and the *y* descent is slow and insignificant (see Chap. 10).

PULMONIC VALVE DISEASE

If RV failure and TR have developed as a result of PR, a prominent *cv* wave will be present in the JVP. Increased RV activity may be visible and palpable along the left sternal border. If pulmonic hypertension is present, the pulmonic second sound will be accentuated over the left upper sternal border. The murmur of acquired PR is a high-pitched diastolic blow along the left sternal border. Thus, the murmur may be difficult to differentiate from the murmur of AR, but the absence of peripheral findings of AR is useful in identifying regurgitation of the pulmonic valve as the source of the diastolic murmur. Congenital PR characteristically is associated with a low-pitched, decrescendo murmur along the left sternal border, the peak of the murmur occurring shortly after P_2 (see Chap. 10).

MULTIVALVULAR DISEASE

In combined MS and AS, the LV apical impulse may not be displaced, but a palpable parasternal RV systolic lift is usually present. A mitral diastolic rumble is audible in most patients and can vary from grade I to III in intensity (on scale of I to VI). The aortic systolic murmur is usually loud, but occasionally may be faint with severe MS. A mitral opening snap may not be audible, and in some patients the diastolic rumble of MS cannot be heard.

When both AR and MR exist, the diastolic arterial blood pressure is usually less than 70 mmHg. In those with a diastolic blood pressure above 70 mmHg, there is usually a loud holosystolic

mitral murmur. If AR is the dominant lesion, the early diastolic murmur is usually prominent, whereas when MR prevails, the aortic murmur becomes less intense. MR may diminish the AR due to the increased LV diastolic filling from the enlarged LA. Depending on the contractile state of the myocardium, loud regurgitant murmurs may be associated with mild regurgitation, whereas faint murmurs may accompany severe valvular regurgitation if myocardial failure has developed. A diastolic "flow murmur" across the mitral valve is heard in the majority of patients with combined MR and AR. If AR is important, a systolic murmur produced by the large forward flow across the aortic valve often is present (see Chap. 10).

When AR and MS are both present, the LV impulse is also displaced, sustained, and forceful. The early diastolic murmur at the apex may be prominent and may be accentuated by the AR flow striking the anterior leaflet of the stenotic mitral valve. Although the low-pitched diastolic murmur of MS and the diastolic flow murmur with AR are usually reliable diagnostic parameters, neither murmur correlates with the hemodynamic measurements when the two lesions coexist.

When AR is combined with MS, the systemic pulse pressure does not necessarily reflect the severity of AR. A prominent apical impulse in apparently pure MS indicates the likelihood of associated AR but may not indicate its severity. Finally, the intensity of the aortic diastolic murmur is of little value in predicting the severity of AR in the presence of MS (Chap. 10).

In the presence of AS and possible MR, an apical holosystolic murmur is reasonable evidence for associated MR, but the intensity of the murmur is not a reliable indicator in estimating severity.

While the murmur of TR often increases with inspiration, distinction from a concomitant MR murmur may be difficult. Identification of the rumble of TS requires careful auscultation during inspiration at the left lower sternal border. Detection by auscultation is more difficult because of the frequent association of MS and TS.

Electrocardiogram

TRICUSPID VALVE DISEASE

Atrial fibrillation is frequent in patients with TR. When TR results from myocardial infarction, acute or chronic electrocardiographic (ECG) changes will be seen in the inferior leads, and ST-segment elevation indicating RV infarction may be present in the right-sided precordial leads. The characteristic ECG finding in TS is a large P wave of RA enlargement in the absence of RV hypertrophy[1,22,64] (see Chap. 11).

PULMONIC VALVE DISEASE

Although there are no characteristic changes with pulmonic valvular lesions, preexisting pulmonary hypertension will produce RV hypertrophy, right-axis deviation, and changes in the *p* wave, suggesting RA enlargement. If pulmonary hypertension is secondary to mitral stenosis, P mitrale, with characteristic notches, will be present in lead II (see Chap. 11).

MULTIVALVULAR DISEASE

In combined MS and AS, ECG evidence of LV hypertrophy, LA enlargement, and atrial fibrillation is often present. Similar findings are observed in MR and AR, with a high likelihood of LA and LV enlargement along with atrial fibrillation. With AS and MR, LV hypertrophy is accompanied by a moderate incidence of atrial fibrillation. MS with severe AR also produces LV

hypertrophy.

Chest Roentgenogram

TRICUSPID VALVE DISEASE

TR may produce some degree of RA enlargement, but there will usually be accompanying RV enlargement.[61] In TS, the most characteristic radiographic finding is prominence of the RA without significant pulmonary arterial enlargement or changes due to pulmonary hypertension[1,22] (see Chap. 12).

PULMONIC VALVE DISEASE

Patients with PR have pulmonary artery prominence along with an increase in RV dimensions. If PS is acquired, there may be poststenotic dilatation or prominence of the main pulmonary artery.

MULTIVALVULAR DISEASE

With combined MS and AS, the LA is always enlarged. LV chamber size may be significantly enlarged; however, prominent RV dimensions are usually present. Valvular calcification at either site is relatively uncommon. In AS accompanied by MR, heart size is increased, with both LV and LA enlargement. In MS with AR, marked LV enlargement is often present.

Echocardiogram

TRICUSPID VALVE DISEASE

With TR, there may be echocardiographic evidence of systolic prolapse, rupture of the chordae or papillary muscle, or vegetative lesions on the valve.[65] Increased RV dimensions indicate impaired RV function and the likelihood of secondary TR (see Chap. 13). Contrast echocardiography with peripheral venous injection can identify the back-and-forth flow across the valve.[66] The echo-Doppler technique can estimate the severity of the regurgitation and the systolic pressure in the RV[67] (Fig. 59-10). Color-flow Doppler imaging can delineate the patterns and sites of regurgitation across the valve apparatus[71] (see Chap. 13).

Figure 59-10

Figure 59-10: A continuous echo-Doppler recording in a patient with tricuspid valve disease illustrates TR in the lower portion and TS in the upper portion of the tracing. (Reproduced with permission from and courtesy of Dr. Pamela Sears-Rogan.)

A characteristic pattern of TS can often be recorded with the echocardiogram. Fibrosis and calcification of the valve can be identified. Obstructive lesions, such as myxoma, thrombus, or other tumors, can be recognized echocardiographically. The two-dimensional echocardiogram of a patient with carcinoid syndrome with both TR and TS is shown in Fig. 59-11*A* and *B*. The echo-Doppler technique can be used to estimate the diastolic gradient across the valve with generally good accuracy (see Chap. 13).

Figure 59-11

Figure 59-11: *A.* Two-dimensional echocardiogram of a 40-year-old patient, with carcinoid tumor of the testes without metastases. He presented with a testicular mass and was found to have a grade III/VI pansystolic murmur and grade III/VI diastolic murmur; both increased with inspiration. This four-chamber view shows a thickened stenotic tricuspid valve (TV) in diastole. The RA is enlarged, and the atrial septum bulges to the left, indicating a higher RA than LA pressure, which is consistent with tricuspid stenosis. The liver was normal because the humoral products of the carcinoid tumor bypassed the liver by the testicular venous drainage flowing directly to the inferior vena cava and renal veins. Carcinoid tumors arise from neuroendocrine cells known as enterochromaffin cells, which are found in organs derived from the embryonic gut. Because the liver detoxifies the humoral products of the carcinoid tumor, which most often arises in the ileum, it is extremely rare to see carcinoid heart disease in the absence of liver metastases, making this case extremely unusual.4,5 Only about 20% of patients with carcinoid tumors develop cardiovascular symptoms. RV, right ventricle; SL, septal leaflet. *B.* Two-dimensional echocardiogram in diastole. This is from the same patient as in (*A*). Note the thickened tricuspid valve (TV) and the lack of excursion of the TV from diastole to systole. This washer-like, thickened TV is characteristic of carcinoid heart disease. It is common for a carcinoid TV to be both stenotic and insufficient. With carcinoid TV disease the valve becomes thickened, and its mobility and flexibility are reduced. RA, right atrium; RV, right ventricle. (From Cheitlin and MacGregor,[22] with permission.)

PULMONIC VALVE DISEASE

Echocardiography can delineate the anatomy of the pulmonic valve as well as intrinsic or extrinsic lesions impinging on the valve apparatus. Sometimes a vegetative lesion or tumor can be detected in the pulmonic valve area. The echo-Doppler technique can estimate both the severity of both the regurgitation and the stenosis of the valve,[68] and analysis of echo-Doppler recordings can provide estimates of pulmonary artery pressure[69-71] (Fig. 59-12). Color-flow imaging can further confirm the patterns of regurgitation in the RV outflow tract (see Chap. 13).

Figure 59-12

Figure 59-12: An echo-Doppler continuous tracing in a patient with TR. By employing the equation, the systolic gradient across the tricuspid valve can be calculated, and the addition of 10 mmHg yields an estimate of the pulmonary systolic pressure. Thus, in this patient, the level of pulmonary hypertension could be estimated from the echo-Doppler tracing of the TR. (Reproduced with permission from and courtesy of Dr. Pamela Sears-Rogan.)

MULTIVALVULAR DISEASE

Echocardiography provides information on valve anatomy, chamber dimensions, pressure gradients, valve size, patterns of regurgitation, and estimates of ventricular function. MS and AS produce characteristic echoes (see Chap. 13). Prolapse of mitral, aortic, and tricuspid valves can be characteristically recognized with echocardiography.[72] The number of aortic cusps can be identified, as can the presence of calcium in the aortic or mitral valve apparatus. Dimensions of the LA, LV, and RV, together with LV wall thickness measurements and determinations of mass, are useful in estimating the extent of volume and pressure overload. Two-dimensional and Doppler echocardiographic techniques can assess the orifice size of the aortic and mitral valves and estimate the valve gradients accurately.[73,74] Even in the presence of AR, appropriate

modifications in the mathematical analysis of the pressure gradient can yield reasonably accurate estimates of the aortic valve gradients (see Chap. 13). Color-flow Doppler readings can identify patterns and sites of valvular-regurgitation across the aortic and mitral valves.[75,76] Also, thrombus formation in the LA and LV can be detected with various echocardiographic methods. Transesophageal echocardiography can accurately assess prosthetic valve function and valvular repair during the operative procedures.

Nuclear Techniques

A radionuclide ventriculogram (RNV) can delineate dimensions of the RA and RV, which may help differentiate between TS and TR (see Chap. 16). RV size and function can be evaluated in stenotic and regurgitant lesions of the pulmonic valve. Myocardial perfusion imaging techniques are useful in detecting RV infarction as a cause of TR as well as in providing estimates of RV function. RV size and function can be evaluated in stenotic and regurgitant lesions of the pulmonic valve.

Quantitative information on LV function at rest and during exercise can be provided by RNV (see Chap. 16). Segmental wall motion can be assessed at rest and during exercise and may assist in the recognition of underlying coronary artery disease. Since combined lesions of the aortic and mitral valves often create pulmonary hypertension and RV dysfunction, RNV is useful in estimating the RV ejection fraction[77] (see Chap. 16).

Cardiac Catheterization

TRICUSPID VALVE DISEASE

Accurate angiographic documentation of TR is difficult to obtain because the catheter overrides the tricuspid valve, and ventricular irritability with an RV injection can induce TR. A prominent *cv* wave in the RA suggests TR, and an intracardiac phonocardiogram may record a regurgitation murmur in the absence of Rivero Carvallo's sign.[78]

If TS is clinically suspected, simultaneous pressures should be recorded in the RA and in the RV in order to measure the gradient across the valve accurately.[59] Since the normal gradient across the tricuspid valve is less than 1 mmHg, small gradients may not be detected if pullback pressure is recorded from the RV to the RA. The area of the tricuspid valve in TS is usually less than 1.5 cm^2; in severe TS, it is less than 1 cm^2.

PULMONIC VALVE DISEASE

PR is not readily demonstrated angiographically, but a right-sided injection can outline the pulmonary valve as well as show poststenotic dilatation. An aortic root injection can be helpful in the elimination of AR as the etiology of a diastolic murmur along the left sternal border. Nevertheless, this distinction is usually best made by echo-Doppler studies.

MULTIVALVULAR DISEASE

Cardiac catheterization is appropriate for most patients with combined valvular heart disease in order to calculate the stenotic and regurgitant status of each valve as well as to identify the predominant valvular lesion. Gradients across the valve can be measured with precision and the valve area calculated. Pulmonary hypertension is commonly present in these patients, and LV end-diastolic pressure is often elevated despite the presence of MS (see Chap. 15).

In MR plus AR, the LV end-diastolic pressure is elevated in most patients, and the central aortic pressure is generally greater than 40 mmHg. As noted, however, in approximately one-third of the patients the central aortic diastolic pressure may be above 70 mmHg. The *v* wave of MR can be recorded in the wedge position, and capillary and pulmonary arterial pressures are abnormally elevated in most of these patients.

In AS with MR, LV end-diastolic and pulmonary artery pressures are elevated; however, the extent of pressure elevation does not necessarily reflect the severity of the MR. When it is severe, forward cardiac output may be reduced; thus, a spuriously small pressure gradient may be recorded across a significantly stenotic aortic valve. In MS with AR, the LV end-diastolic pressure is abnormal and the central aortic diastolic pressure is usually less than 70 mmHg.

In combined valvular lesions, the measurement of total angiographic LV stroke volume is useful in calculating the regurgitant volume across each valve.[1,22] When both valves are regurgitant, it is more difficult to calculate the regurgitant volume across each valve.

Assessment of ventricular function is important in patients with combined valvular lesions; yet the ejection fraction may be spuriously normal or elevated in MR and, to a lesser extent, in AR. Measurements of LV end-systolic pressure, volume, and wall thickness permit calculation of end-systolic wall stress.[79] This parameter has been particularly helpful in pressure and volume overload conditions, since the end-systolic pressure-volume wall stress calculation is relatively independent of loading conditions.

Finally, coronary arteriography should be performed at the time of cardiac catheterization in patients above the age of 35, since coronary artery disease may be present without symptoms and may contribute to LV dysfunction. Coronary artery bypass grafting at the time of valve surgery is an important consideration.

Chapter 59: TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

USUAL STRATEGY OF WORKUP

Tricuspid Valve Disease

The history should identify underlying conditions, such as rheumatic fever, systemic disorders, and left-sided heart failure, as etiologies for tricuspid valve disease. The physical examination should carefully define the waveforms in the JVP. The auscultatory changes of systolic and diastolic murmurs at the left lower sternal border during the respiratory cycle should be carefully evaluated. In addition, physical findings of left-sided valvular abnormalities, particularly MS or evidence of LV failure, should be observed. Peripheral edema as evidence of impaired right-sided filling should be identified.

Echocardiography is the most useful noninvasive technique for identifying the presence, severity, and potential etiologies of TS and/or TR (see Chap. 13). If the patient undergoes cardiac catheterization for assessment of left-sided heart disease, right-sided hemodynamics should be recorded and, if clinically indicated, simultaneous pressures recorded in the RA and the RV (see Chap. 15).

Pulmonic Valve Disease

The clinical history is important in delineating causes of left-sided heart failure that can lead to pulmonary hypertension and PR. Symptoms of the carcinoid syndrome, tumors, or infectious etiologies involving the pulmonic valve should be determined. The physical examination is important in evaluating the venous pulsations in the neck veins as well as the pulmonic murmurs. RV prominence should be carefully evaluated, as should concomitant left-sided valve lesions and evidence of heart failure. Although an ECG and chest x-ray should be obtained to assess the pulmonic artery, RV outflow tract, and body of the RV, the most useful noninvasive technique is echocardiography. The anatomy, competence of the valve, extent of the regurgitation, and stenosis can be recognized and assessed by an echo-Doppler sudy. In addition, other valve lesions affecting the left side of the heart can be documented. Since PR can be relatively well tolerated, this specific lesion does not require such frequent follow-up, but underlying mechanisms for pulmonary hypertension or left-sided heart failure should be monitored closely.

Multivalvular Disease

Symptoms of dyspnea, exercise intolerance, chest discomfort, or syncope should be elicited during a carefully taken clinical history. On physical examination, special attention should be directed to the peripheral and central arterial pulses and the JVP. Heart size, precordial movement, and auscultatory findings should be carefully noted. A 12-lead ECG and posterior-anterior and lateral chest films should be obtained. Echocardiography is indicated to delineate valve anatomy, measure valve gradients, recognize regurgitant patterns, calculate orifice size, and estimate ventricular function and wall motion (see Chap. 13). A limited exercise test with or without radionuclide studies may help determine the exercise capacity as well as detect functional deterioration, chest pain, arrhythmias, deterioration of ventricular ejection fraction, or segmental wall motion abnormalities. If symptoms are atypical and the extent of valvular or LV function cannot be satisfactorily evaluated by noninvasive techniques, cardiac catheterization is indicated.

Chapter 59: TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

NATURAL HISTORY AND PROGNOSIS

Tricuspid Valve Disease

With TR due to RV hypertension, the symptoms and clinical course are primarily related to the left-sided heart conditions that produce a pressure-volume overload on the RV. TR virtually always develops with severe RV failure. In infective endocarditis of the tricuspid valve, the type of organism may significantly influence the course and the response to antibiotics (see Chap. 73).

With TS, the symptoms are usually those of MS, and the absence of pulmonary congestion in the presence of peripheral edema should raise the possibility of underlying TS. Significant TS may slow the development of characteristic symptoms of MS and result in an underestimation of the severity of mitral valve obstruction.

Pulmonic Valve Disease

In pulmonic valve lesions, the course will be more prolonged if there is chronic pulmonary hypertension due to mitral stenosis or chronic lung disease. Inflammatory conditions and tumors that affect the valve usually result in a much shorter clinical course.

Multivalvular Disease

When combined aortic and mitral valve disease are due to rheumatic fever, 10 years or more may elapse before the development of significant murmurs, and an additional decade (or more) may elapse before symptoms become manifest. If lesions of the aortic and mitral valves are due to degenerative collagen changes, symptoms may develop later in life. When combined lesions are due to calcific changes in the aortic valve and annulus as well as the mitral valve annulus, symptoms develop much later in life. There may, however, be rapid progression of degenerative aortic calcific stenosis over a 2- to 3-year period (see Chap. 56).

Chapter 59: TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

MEDICAL MANAGEMENT

Tricuspid Valve Disease

With TR, treatment of RV failure requires digitalis and diuretics, and vasodilating agents are also required for the management of LV failure (see Chap. 21). If failure of the right side of the heart is caused by MS, early intervention to enlarge or replace the mitral valve is appropriate (see Chap. 57).

In TS, the usual precautionary measures of antibiotic coverage and prevention of endocarditis apply. Peripheral edema may not respond well to administration of digitalis, diuretics, and vasodilator therapy, thus emphasizing the clinical importance of detecting underlying TS. Tricuspid balloon valvuloplasty has been used successfully in patients with predominant TS.[80]

Pulmonic Valve Disease

Patients with congenital pulmonic valve stenosis are usually best treated by catheter balloon valvotomy (see Chaps. 63 and 64).

Prophylaxis and Medical Therapy

Antibiotic prophylaxis against endocarditis (see Chap. 73) is appropriate for patients with either tricuspid or pulmonic valve lesions. If pulmonary emboli contribute to the pulmonary hypertension, anticoagulation is indicated (see Chap. 53). Furthertreatment of pulmonary hypertension may require managementof left heart failure, correction of MS, or the use of vasodilating agents that can lower pulmonary artery pressure. Vasodilating agents are often ineffective in treating primary pulmonary hypertension (see Chap. 52).

If rheumatic fever is the likely etiology of combined aortic and mitral valve disease, prophylactic penicillin should usually be continued until age 35 years (see Chap. 55). Dental prophylaxis with antibiotic coverage, using either amoxicillin or erythromycin, should be provided in all patient groups prior to dental procedures. For genitourinary or other abdominal procedures, gram-negative antibiotic coverage should be provided (see Chap. 82).

Atrial Fibrillation

If atrial fibrillation develops, chronic anticoagulation with low-dose warfarin [International Normalized Ratio (INR) 2.0 to 3.0] is warranted, since the accompanying incidence of systemic and cerebral emboli is estimated at 10 to 20 percent (see Chap. 61).

The early development of atrial fibrillation associated with hemodynamic deterioration warrants an initial attempt at electrical cardioversion. If this is successful, digitalis as well as antiarrhythmic preparations should be administered thereafter for prophylaxis against recurrence (see Chap. 24). Chronic atrial fibrillation should be controlled with digitalis, beta blockers, and calcium blockers as indicated. The development of symptoms, particularly dyspnea, limited exercise activity, chest

pain, and syncope, warrants consideration for surgery. It is usually recommended for New York Heart Association (NYHA) class III symptoms despite adequate medical therapy.

Chapter 59: TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

SURGICAL MANAGEMENT

Tricuspid Valve Disease

The decision to proceed with valvular heart surgery is usually based on the severity of the aortic and mitral valve disease, rather than on the severity of the disease of the tricuspid valve. The usual decisions to be made regarding the tricuspid valve are (1) whether a procedure should be added to the mitral and/or aortic valve procedures and, (2) if so, which procedure-annuloplasty or valve replacement-should be performed. Patients may present with mild mitral valve disease but severe tricuspid valve dysfunction. Such patients may require an operation on the tricuspid valve only.

The severity of the symptoms and clinical signs of tricuspid valve disease are used to determine the indications for tricuspid valve surgery. If there are signs of TS and, particularly, if stenosis is demonstrated by cardiac catheterization and two-dimensional echocardiography, the tricuspid valve is directly visualized at operation with the anticipation of performing commissurotomy or valve replacement. Tricuspid valve balloon valvulotomy has been advocated for[80-84] TS of various etiologies.[82] However, severe TR is a common consequence of this procedure, and results are poor when severe TR develops.

When there are signs of severe TR secondary to MS, it is important to document the duration of the regurgitation and the severity and duration of pulmonary artery hypertension. If the TR is severe and long-standing and if there is chronic pulmonary artery hypertension, it is unlikely to resolve in the early postoperative period after mitral valve surgery alone. In this circumstance, tricuspid valve surgery is usually indicated. In contrast, if TR and pulmonary artery hypertension are of short duration, mitral valve replacement will usually reduce pulmonary artery pressure in the early postoperative period, and this will result in a decrease in the TR. Occasionally, severe TR will be present with only modest elevation of pulmonary artery pressure. In this circumstance, the tricuspid valve leaflets are usually deformed and valve replacement is necessary.[83]

The appearance of the heart at the time of surgery is helpful in assessing the severity of tricuspid valve disease. A thinned-out RA wall together with moderate to marked enlargement of the RA and venae cavae are indications of significant disease. The degree of stenosis and regurgitation can be estimated by palpation through the RA appendage. Intraoperative transesophageal echocardiography (see Chap. 13) provides more precise information as to the degree of residual valvular regurgitation after repair. The ACC/AHA guidelines recommendations for surgery for TR are listed in Table 59-4.

Table 59-4: Recommendations for Surgery for Tricuspid Regurgitation

Indication	Class
Annuloplasty for severe TR and pulmonary hypertension in patients with mitral valve disease requiring mitral valve surgery	I
Valve replacement for severe TR secondary to diseased or abnormal tricuspid valve leaflets not amenable to annuloplasty or repair	IIa
Valve replacement of annuloplasty for severe TR with mean pulmonary artery pressure <60 mmHg when symptomatic	IIa
Annuloplasty for mild TR in patients with pulmonary hypertension secondary to mitral valve disease requiring mitral valve surgery	IIb
Valve replacement or annuloplasty for TR with pulmonary artery systolic pressure <60 mmHg in presence of a normal mitral valve in asymptomatic patients or in symptomatic patients who have not received a trial of diuretic therapy	III

TS may be treated successfully by commissurotomy, which is usually performed under direct vision. The procedure may be combined with annuloplasty to correct valve regurgitation. Valve replacement is occasionally necessary if the changes in the leaflets and subvalvular structures are advanced or if severe TR cannot be relieved by annuloplasty. For TR, three basic reconstructive techniques have been described. The first procedure is used widely and consists of plication of the posterior leaflet,[84,85] thus converting the tricuspid valve into a functionally bicuspid valve.[84,85] De Vega described a second type of annuloplasty that narrows the annulus along the anterior and posterior leaflets with a pursestring suture.[86,87] The third major technique, described by Carpentier et al., consists of placing a carefully sized semiflexible ring along the anterior and posterior aspects of the annulus.[88] It draws in and supports the tissue evenly. Follow-up studies have shown that annular dilatation occurs in these areas rather than along the leaflets.[89]

When the leaflets and subvalvular apparatus are severely deformed as a result of rheumatic fever, reconstruction may not be feasible. In such cases, replacement is performed with either a mechanical or tissue valve. Anticoagulation with warfarin (see Chap. 52) is generally advisable in patients with tricuspid valve replacement, and therefore the major advantage of a bioprosthetic valve is negated. If a mechanical valve is preferred and the cavity of the RV is not capacious, a low-profile, tilting disk-type prosthesis seems appropriate. Usually, however, if TR is severe, a ball-cage prosthesis functions better.

Mild TR does not seem to increase the risk of surgery involving the mitral valve or both aortic and mitral valves. When the TR is moderate to severe, however, the risk of operation is significantly increased. Although long-term improvement in TR after mitral valve replacement alone has been documented, a tricuspid procedure is generally employed in the setting of moderate to severe TR to enhance cardiac function in the critical early days after operation.[90] Mitral valve replacement alone does not invariably decrease TR, even several months after operation.[91]

In general, the early and late results of tricuspid annuloplasty have been superior to those of valve replacement, and valve replacement should be avoided when possible. There is a significant incidence of thrombosis with tricuspid prostheses, and the long-term functional results have been less favorable than those of aortic and mitral valve replacements.[92] Good early results have been obtained with all three methods of annuloplasty.[93-97] When tricuspid valve replacement is necessary, the 30-day perioperative mortality increases to 15 to 20 percent. Two preoperative

factors-severity of edema and mean pulmonary artery pressure-as important predictors of long-term survival.[98] A variety of prostheses have been used for tricuspid valve replacement with variable results.[98-103]

Infective endocarditis of the tricuspid valve is relatively common because of the increased incidence of drug abuse. In general, the treatment of tricuspid valve endocarditis is medical. When septic pulmonary embolization occurs despite intensive antibiotic treatment, tricuspid valve surgery is indicated. Excision of the valve without replacement has been recommended, and reinfection of the new valve in intravenous drug users is an important risk.[104] Nevertheless, since valvulectomy alone carries an important risk of heart failure, tricuspid valve replacement has been recommended by others.[105]

The cardiac output is often marginal after tricuspid valve surgery, a reflection of persistent pulmonary arterial hypertension and long-standing RV dysfunction. Measurements of cardiac output and pulmonary artery pressure are used to guide postoperative care. If annuloplasty is performed, a pulmonary artery catheter can be used for such measurements (see Chap. 15). Nitroglycerin infused through a central venous catheter is a valuable adjunct in reducing pulmonary artery pressure. Prostaglandin E_1, in combination with pressor agents, may also be employed to treat severe postoperative pulmonary hypertension.[106] Intravenous dopamine and dobutamine may be used to enhance myocardial contractility. If cardiac output remains marginal, an intraaortic balloon pump may be used to reduce left-sided pressures. Pulmonary artery balloon counterpulsation has been employed for acute RV failure.[107] The use of a temporary circulatory assist device, such as a centrifugal pump, to bypass the RV may sustain adequate circulation when RV failure is unresponsive to other measures.

Digitalis and diuretics are usually employed for several months after tricuspid valve surgery. For patients with tricuspid valve replacement, warfarin and dipyridamole are used as anticoagulants.[108] The additional use of antiplatelet agents in this setting may improve the long-term results.[109] A serious late complication of tilting disk valves in the tricuspid position is thrombosis. Thrombolytic therapy with streptokinase has been used successfully to restore valve function.[110] Prophylaxis against infective endocarditis is also required (see Chap. 73).

Pulmonic Valve Disease

Pulmonic valve surgery for acquired disease is performed infrequently. PS on an acquired basis is rare. Although there are a variety of causes of PR, this hemodynamic condition is relatively well tolerated if pulmonary vascular resistance is normal. Pulmonic valve replacement may be performed for acquired conditions, such as carcinoid heart disease and infective endocarditis, but it usually is limited to cases where RV dysfunction has become severe after congenital heart disease surgery[111,112] (see Chaps. 63 and 64). In general, bioprosthetic valves have been preferred because of the tendency for mechanical valve thrombosis in this position. Pulmonic valve surgery is currently being performed earlier and more commonly, since studies indicate that RV dysfunction may be present in asymptomatic postoperative patients with PR.[113]

Infective endocarditis involves the pulmonic valve in about 1 percent of cases seen at autopsy. Isolated pulmonic valve infective endocarditis is even more uncommon but may be the cause of metastatic pulmonary infections. In a review of 28 cases of this entity, the overall mortality rate was 24 percent, with all those treated by operation surviving.[114] Valvulectomy in combination with antibiotic therapy is sometimes the most effective treatment (see Chap. 77).

Multivalvular Disease

Many patients with clinical evidence of combined disease of the mitral and aortic valves have severe and progressive symptoms. Experience indicates that both valves can be replaced, with a hospital mortality rate that is now between 5 and 10 percent.

Commonly, in the presence of aortic and mitral valve disease, repair, rather than replacement, of the stenotic or regurgitant mitral valve can be accomplished (see Chap. 57). Disease of the aortic valve in adults usually requires valve replacement. The combination of aortic valve replacement with mitral valve repair probably decreases early mortality rates and improves long-term survival. There have been marked subjective and objective improvements in surviving patients. When tricuspid valve replacement is added, the risk of the operation is higher (up to 20 percent), but even then the long-term results are considerably better than the life history of surgically untreated patients with triple-valve disease. The use, when possible, of tricuspid annuloplasty rather than replacement has greatly improved the early results of operation in this group of patients.

When hemodynamic derangement is significant at both mitral and aortic valves, the decision to repair or replace both is easily made, and the principles of surgical treatment are the same as when one valve alone requires operation.[115,116]

MULTIVALVULAR SURGERY

Combined MS and AR

When mechanical correction is anticipated in predominant MS, balloon mitral valvotomy followed by aortic valve replacement (AVR) obviates the need for double-valve replacement, which has a higher risk of complications than does single-valve replacement.[117] In most cases, it is advisable to perform mitral valvotomy first and then follow the patient for symptomatic improvement. If symptoms disappear, correction of AR can be delayed.

Combined MS and TR

If the mitral valve anatomy is favorable for percutaneous balloon valvotomy and there is concomitant pulmonary hypertension, valvotomy should be performed regardless of symptom status. After successful mitral valvotomy, pulmonary hypertension and TR almost always diminish.[118]

If mitral valve surgery is performed, concomitant tricuspid annuloplasty should be considered, especially if there are preoperative signs or symptoms of right-heart failure, rather than risking severe, persistent TR, which may necessitate a second operation. However, TR that seems severe on echocardiography but does not cause elevation of RA or RV diastolic pressure will generally improve greatly after mitral valve replacement (MVR). If intraoperative assessment suggests that TR is functional without significant dilatation of the tricuspid annulus, it may not be necessary to perform an annuloplasty.

Combined MS and AS

If the degree of AS appears to be mild and the mitral valve is acceptable for balloon valvotomy, this should be attempted first. If mitral balloon valvotomy is successful, the aortic valve should then be reevaluated.

Combined AS and MR

Noninvasive evaluation should be performed with two-dimensional and Doppler

echocardiography to evaluate the severity of both AS and MR. Attention should be paid to LV size, wall thickness and function, LA size, right-heart function, and pulmonary artery pressure. Patients with severe AS and severe MR (with abnormal mitral valve morphology) with symptoms, LV dysfunction, or pulmonary hypertension should undergo combined AVR and MVR or mitral valve repair. However, in patients with severe AS and lesser degrees of MR, the severity of MR may improve greatly after isolated AVR, particularly when there is normal mitral valve morphology. Intraoperative transesophageal echocardiography and, if necessary, visual inspection of the mitral valve should be performed at the time of AVR to determine whether additional mitral valve surgery is warranted in such patients.

In patients with mild to moderate AS and severe MR in whom surgery on the mitral valve is indicated because of symptoms, LV dysfunction, or pulmonary hypertension, preoperative assessment of the severity of AS may be difficult because of reduced forward stroke volume. If the mean aortic valve gradient is greater than 30 mmHg, AVR should be performed. In patients with less severe aortic valve gradients, inspection of the aortic valve and its degree of opening on two-dimensional or transesophageal echocardiography as well as visual inspection by the surgeon may be important in determining the need for concomitant AVR.

Chapter 59: TRICUSPID VALVE, PULMONIC VALVE, AND MULTIVALVULAR DISEASE

List of Figures

Figure 59-9: Bacterial endocarditis in specimens from a 36-year-old man. *A.* Aortic valve. The base of the aortic valve shows major destruction of a cusp with extension of inflammation onto the subjacent mitral valve. Near the free edge of the mitral valve, its ventricular aspect shows an ostium of a nonruptured mycotic aneurysm. *B.* Mitral valve, LA, and LV. The lobulated mycotic aneurysm of the mitral valve lies near its free edge.

Figure 59-10: A continuous echo-Doppler recording in a patient with tricuspid valve disease illustrates TR in the lower portion and TS in the upper portion of the tracing. (Reproduced with permission from and courtesy of Dr. Pamela Sears-Rogan.)

Figure 59-11: *A.* Two-dimensional echocardiogram of a 40-year-old patient, with carcinoid tumor of the testes without metastases. He presented with a testicular mass and was found to have a grade III/VI pansystolic murmur and grade III/VI diastolic murmur; both increased with inspiration. This four-chamber view shows a thickened stenotic tricuspid valve (TV) in diastole. The RA is enlarged, and the atrial septum bulges to the left, indicating a higher RA than LA pressure, which is consistent with tricuspid stenosis. The liver was normal because the humoral products of the carcinoid tumor bypassed the liver by the testicular venous drainage flowing directly to the inferior vena cava and renal veins. Carcinoid tumors arise from neuroendocrine cells known as enterochromaffin cells, which are found in organs derived from the embryonic gut. Because the liver detoxifies the humoral products of the carcinoid tumor, which most often arises in the ileum, it is extremely rare to see carcinoid heart disease in the absence of liver metastases, making this case extremely unusual.4,5 Only about 20% of patients with carcinoid tumors develop cardiovascular symptoms. RV, right ventricle; SL, septal leaflet. *B.* Two-dimensional echocardiogram in diastole. This is from the same patient as in (*A*). Note the thickened tricuspid valve (TV) and the lack of excursion of the TV from diastole to systole. This washer-like, thickened TV is characteristic of carcinoid heart disease. It is common for a carcinoid TV to be both stenotic and insufficient. With carcinoid TV disease the valve becomes thickened, and its mobility and flexibility are reduced. RA, right atrium; RV, right ventricle. (From Cheitlin and MacGregor,[22] with permission.)

Figure 59-12: An echo-Doppler continuous tracing in a patient with TR. By employing the equation, the systolic gradient across the tricuspid valve can be calculated, and the addition of 10 mmHg yields an estimate of the pulmonary systolic pressure. Thus, in this patient, the level of pulmonary hypertension could be estimated from the echo-Doppler tracing of the TR. (Reproduced with permission from and courtesy of Dr. Pamela Sears-Rogan.)

Part 9: VALVULAR HEART DISEASE
Chapter 60:

CLINICAL PERFORMANCE OF PROSTHETIC HEART VALVES

Authors: Gary L. Grunkemeier, Albert Starr, Shahbudin H. Rahimtoola

A heart valve functions as a check valve: opening to permit forward blood flow and closing to prevent retrograde flow, about 40 million times per year. Heart valve prostheses consist of an orifice, through which blood flows, and an occluding mechanism that closes and opens the orifice. There are two classes of heart valves: *mechanical prostheses*, with rigid, manufactured occluders, and *biological* or *tissue valves*, with flexible leaflet occluders of animal or human origin. Among the mechanical valves there are three basic types, depending on whether the occluding mechanism is (1) a reciprocating ball, (2) a tilting disk, or (3) two semicircular hinged leaflets. The biological valves include those whose origin is from (1) the patient, (2) another human, or (3) another species. For each type there are several models available from different manufacturers. Selected frequently used valves are described.

PROSTHETIC HEART VALVES

Mechanical Valves

Ball valves appeared in the early 1960s, disk valves in the early 1970s, and bileaflet valves predominantly during the 1980s.

BALL VALVES

The first successful valve replacement devices, which led to long-term survivors and a design that has endured until today, used a ball-in-cage design.[1,2] Several modifications of this design have been used, but only the *Starr-Edwards* valve (Fig. 60-1, Plate 94) has endured; it has been used about 200,000 times.

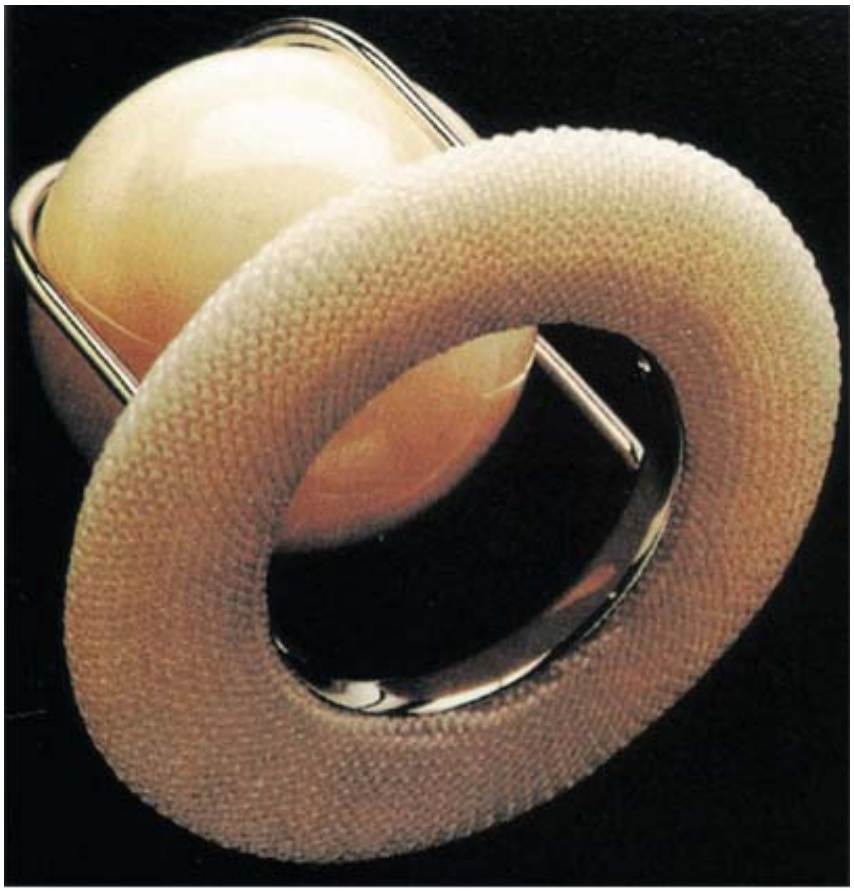

Figure 60-1: (Plate 94) Starr-Edwards caged ball valve. The ball is a silicone rubber polymer, impregnated with barium sulfate for radiopacity, which oscillates in a cage of cobalt-chromium alloy. When the valve opens, blood flows through the circular primary orifice and a secondary orifice between the ball and the housing. In the aortic position, there is a tertiary orifice between the ball and the aortic wall.

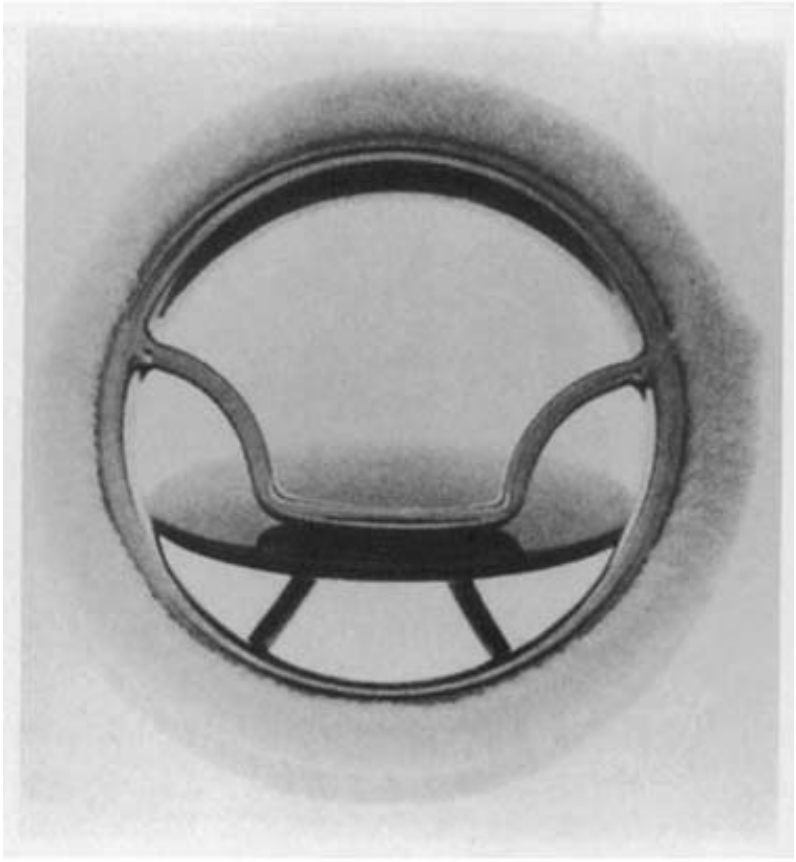
DISK VALVES

Improvement on the clinical success of the ball valves was sought by developing designs with reduced height. The first successful low-profile design was the *Björk-Shiley* tilting-disk valve, introduced in 1969.[3] It evolved through several design refinements,[4] and about 360,000 valves were implanted. These refinements also introduced a structural failure mode caused by strut fracture in the Convexo-Concave model. Some results with the discontinued Björk-Shiley models are included because many patients are still alive with these valves. Tilting-disk valves employ a circular disk as an occluder. It is retained by wirelike arms or closed loops that project into the orifice. The disks are graphite with a coating of pyrolytic carbon, and the housings are stainless steel or titanium. With the disk open, the primary orifice is separated into two unequal (major and minor) orifices. The *Medtronic Hall* valve has been used clinically since 1977.

BILEAFLET VALVES

Current development in mechanical valves is based on the bileaflet design, introduced by St. Jude Medical in 1977. Unlike the free-floating occluders in ball and disk valves, the two semicircular leaflets of a bileaflet valve are connected to the orifice housing by a hinge mechanism. The leaflets swing apart during opening, creating three flow areas: one central and two peripheral. The *St. Jude* bileaflet valve (Fig. 60-2, Plate 95) has been used over 900,000 times and the *Carbomedics* valve has been used about 300,000 times since its clinical introduction in 1986.



A

B

Figure 60-2: (Plate 95) Bileaflet valves. The St. Jude Medical valve (*A*) has leaflets that open to an angle of 85 degrees from the plane of the orifice and travel from 55 to 60 degrees to the fully closed position, depending on valve size. The original version, whose housing did not rotate within the sewing ring, has been supplemented by a model that does rotate for intraoperative adjustment. The Carbomedics valve (*B*) has flat leaflets that open to 78 to 80 degrees and close at

an angle of 25 degrees with the horizontal and has a carbon-coated surface on the sewing ring to inhibit thrombus formation.

Biological Valves

Biological valves include as wide a variety of models, as do mechanical valves:

1. An *autograft* valve is one that is translocated within the same individual-e.g., the pulmonary valve in the aortic valve position.
2. A *homograft* (or allograft) valve is one that has been transplanted from a donor of the same species-when, for example, a donor's aortic or pulmonary valve has been placed in a recipient's aortic or pulmonary position.
3. *Heterograft* (or xenograft) valve is a transplant from another species, either an intact valve (e.g., a porcine aortic valve) or a valve fashioned from heterologous tissue (e.g., bovine pericardium).

The point of using biological valves is to reduce the complications associated with thromboembolism and the need for anticoagulation. The first successful biological valves were homografts, pioneered by Ross[5] and Barratt-Boyes[6] in 1962.

AUTOGRAFT

The pulmonary autograft procedure consists of an autotransplant of the pulmonary valve to the aortic position; the pulmonary valve is then replaced by an aortic or pulmonary homograft. This operation was first described in 1967[7] and is called the Ross procedure; it is currently undergoing increased popularity,[8-12] but this operation involves a double valve replacement, with the attendant early and late risks. This procedure uses double valve replacement to solve a single valve problem; however, subsequent problems with pulmonary valve replacement may be easier to remedy and those related to autograft will be similar to those of aortic valve re-replacement.

HOMOGRAFT

The homograft valve is considered to be a preferred substitute for aortic valve replacement, especially in younger patients. It achieves excellent hemodynamics; there is no need for anticoagulation and it has low thrombogenicity. The drawbacks are a more technically demanding operation and a low availability; however, the latter drawback has been alleviated by its commercial availability from cryopreservation services. Several methods of procurement, sterilization, and preservation have been used.[13] Three surgical techniques are used for aortic valve replacement: (1) replacement of the valve only into the subcoronary position, (2) complete aortic root replacement with reimplantation of the coronary arteries, and (3) miniroot replacement with part of the donor aortic wall inserted within the host aorta.

PORCINE HETEROGRAFT

Glutaraldehyde sterilizes valve tissue, renders it bioacceptable by destroying antigenicity, and stabilizes the collagen cross-links for durability. The use of glutaraldehyde for tissue preservation was pioneered by Carpentier,[14] who introduced the term *bioprosthesis*[15] for nonviable valves of biological origin, such as the *Hancock II* and *Carpentier-Edwards SupraAnnular* (SAV) porcine valves (Fig. 60-3, Plate 96).

Figure 60-3: (Plate 96) Stented porcine valves. The Carpentier-Edwards SupraAnnular Valve is designed to be implanted above rather than within the aortic annulus. It has low-pressure fixation and a cone-shaped stent which flares out at the top to improve leaflet durability.

Most porcine valves are mounted on rigid or flexible stents, to which the leaflets and the sewing ring are attached. Unstented versions have also been devised by several manufacturers.[16-20] Their goal is to achieve some of the potential benefit of a homograft valve, especially hemodynamics and perhaps durability, with an easily available commercial product. The valve, however, is porcine and can be expected to have the same problems of primary valve failure as the stented porcine valve. As with homografts, there are potentially three ways of implanting a stentless porcine valve (valve only, aortic root replacement, and cylinder inclusion). The St. Jude Medical Toronto SPV (Fig. 60-4, Plate 97) and the Medtronic Freestyle (Fig. 60-5, Plate 98) stentless porcine valves were approved for marketing by the FDA in 1997.

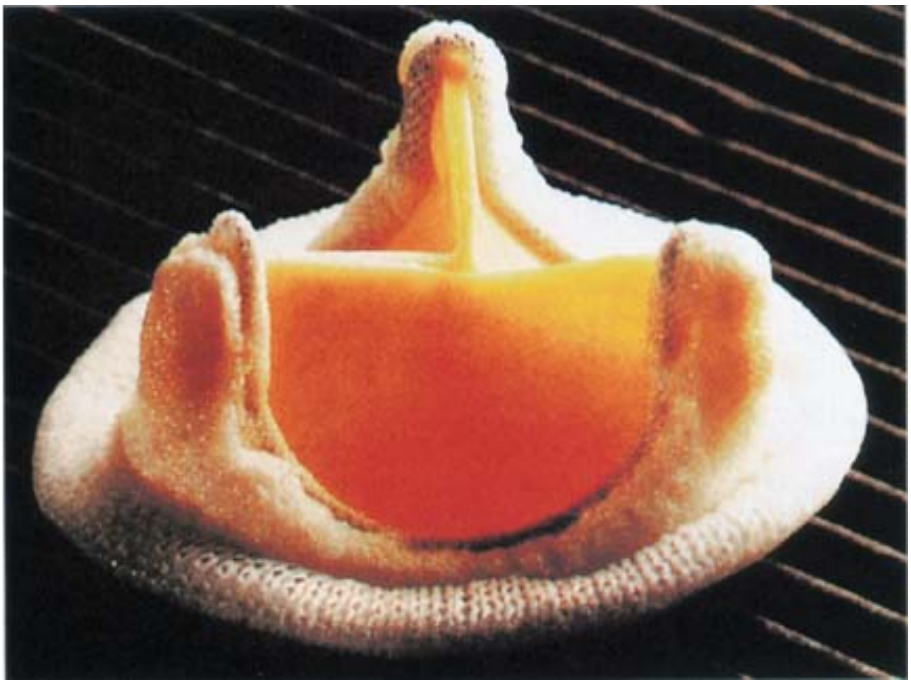


Figure 60-5: (Plate 98) The Carpentier-Edwards Perimount pericardial bioprosthesis uses a method of mounting the leaflets to the stent, which does not depend on retaining stitches passed through the pericardium-a design weakness of previous pericardial valves. Instead, the leaflets are anchored behind the stent pillars.

BOVINE PERICARDIAL VALVE

Pericardial valves that are tailored and sewn into a valvular configuration using bovine pericardium as a fabric result in a valve that opens more completely than a porcine valve, providing better hemodynamics. They might also be expected to have better durability, because there is extra tissue to allow for shrinkage and a higher percentage of collagen to be cross-linked during fixation. Unfortunately, the lonescu-Shiley, the first commercially available pericardial valve, did not bear out this promise and was taken off the market, as was the Hancock pericardial valve. These failures were due to aspects of the design, however, rather than to an intrinsic problem with pericardial tissue. The Carpentier-Edwards Perimount pericardial bioprosthesis (Fig. 60-6) has a method of construction that overcomes these design issues. It has been used clinically since 1982 and received FDA approval, for the aortic position only, in 1991.

Repair

When possible, valve repair[21-23] is generally preferable to replacement (see discussion below).

Chapter 60: CLINICAL PERFORMANCE OF PROSTHETIC HEART VALVES

GUIDELINES FOR REPORTING CLINICAL RESULTS

The analytic aspects of the reporting of clinical results of heart valves have evolved consistently since the first successful implants in 1960. As late (posthospital) experience accumulated near the end of the first decade of implants, the need to analyze time-related events resulted in the introduction of actuarial analysis,[24] which had previously been used to analyze the results of cancer therapy.[25] Later, the use of linearized (constant hazard) rates,[26,27] Cox regression,[28] and multivariable parametric models[29] was advocated. The effectiveness of these refined statistical methods in comparing results from different series, however, was limited by the lack of standardization in definitions and follow-up methods.

AATS/STS Guidelines for Clinical Reporting

In 1988, standards that specified which complications should be collected and how they should be defined were proposed by the Ad Hoc Liaison Committee for Standardizing Definitions of Prosthetic Heart Valve Morbidity, a joint committee of the American Association for Thoracic Surgery (AATS) and the Society of Thoracic Surgeons (STS).[30] These guidelines were revised in 1996.[31,32] The complications that were determined to be of critical importance by these guidelines are as follows:

1. *Structural valvular deterioration*, or any change in function of an operated valve resulting from an intrinsic abnormality that causes stenosis or regurgitation.
2. *Nonstructural dysfunction*, a composite category that includes any abnormality that results in stenosis or regurgitation of the operated valve that is not intrinsic to the valve itself, exclusive of thrombosis and infection. This includes inappropriate sizing, also called *prosthesis-patient mismatch*.[33]
3. *Valve thrombosis* is any thrombus, in the absence of infection, attached to or near an operated valve that occludes part of the blood flow path or that interferes with the function of the valve.
4. *Embolism* is any embolic event that occurs in the absence of infection after the immediate perioperative period (when anesthesia-induced unconsciousness is completely reversed). These include any new, temporary or permanent, focal or global neurologic deficits and peripheral embolic events; emboli proven to consist of nonthrombotic material are excluded.
5. *Bleeding event*is any episode of major internal or external bleeding that causes death, hospitalization, or permanent injury (e.g., vision loss) or requires transfusion. The complication "bleeding event" applies to all patients, whether or not they are taking anticoagulants or antiplatelet drugs.
6. *Operated valvular endocarditis* is any infection involving an operated valve. Morbidity associated with active infection-such as valve thrombosis, thrombotic embolus, bleeding event, or paravalvular leak-is included under this category but is not included in other categories of morbidity.

The *consequences* of the above morbid events include reoperation, valve-related mortality, sudden unexpected unexplained death, cardiac death, total deaths, and permanent valve-related impairment.[31,32]

FDA Guidelines for New Valve Approvals

In 1976, medical devices including prosthetic heart valves came under the jurisdiction of the FDA,[34] which subsequently issued various guidelines for submission of premarket approval (PMA) applications for heart valves. The FDA issued a guidance document in December 1993[35] that used the analytical approach to clinical studies adapted from the work of Gersh et al.[36] These authors proposed a method for premarket clinical testing of heart valves that emphasizes confidence interval estimation and comparisons to objective performance criteria (OPC). *OPC are linearized rates for critical complications, representing averages achieved by the best currently used valves*. A *linearized rate* is calculated as the number of events divided by total patient-years and multiplied by 100 to convert it to units of "events per 100 years" or "percent per year."[27]

To determine OPC for contemporary use, the FDA screened the literature plus data submitted by clinical investigators of approved devices and identified OPC for the major morbidity categories.[35] They determined that these rates were similar for aortic and mitral positions but varied for some complications between mechanical and biological valves. The OPC for complications are given in Table 60-1 for mechanical and biological replacement heart valves. Several observations on these data are significant.

The category *Structural deterioration* was not included in the list of OPC because the clinical PMA investigation is not designed to detect intrinsic valve failure. Structural durability should be evaluated by in vitro testing, and the clinical realization of structural failure should be so small (mechanical valves) that the clinical study is of insufficient size or so long-term (tissue valves) that the clinical study is of insufficient duration to assess it adequately.

From the *Nonstructural dysfunction* category, the FDA included only leak, the most common and the most frequently reported subcategory, and derived OPC for major leaks ("as defined by AATS/STS, 1988")[30] and for all leaks.

The FDA separated *Thromboembolism* into the separate categories of valve thrombosis and thromboembolism, as had been strongly advocated,[37,38] and the FDA derived OPC both for major *Anticoagulant-related hemorrhage* events ("as defined by AATS/STS, 1988")[30] and for all bleeding events.

Based on the OPC values given in Table 60-1, the FDA has set the minimum amount of follow-up required for a PMA study at 800 valve-years.[39] The assumption of constant risk for heart valve complications, as embodied by the OPC formulation, is only an approximation; but if operative events are excluded (the intent of the FDA guidelines) and maximum follow-up is in the 2- to 3-year range, this assumption may be acceptable, at least for the purpose of sample size estimation.

Chapter 60: CLINICAL PERFORMANCE OF PROSTHETIC HEART VALVES

VALVE-RELATED COMPLICATIONS

Actuarial valve failure-free curves[25] are used to describe tissue valve durability, and linearized rates[27] are used for all other complications.

Structural Deterioration

This category, the first one considered in the guidelines for reporting, virtually always results in death or valve explant. There is a dual standard with regard to this complication: for biological valves, structural deterioration is probably inevitable if the patient lives long enough; whereas for mechanical valves, the only acceptable rate is a very low one (near zero).

MECHANICAL VALVES

The durability of currently used mechanical valves is remarkable, given the harsh biological environment in which the valve must perform. For example, the current Starr-Edwards ball valve, now in use for 35 years and in over 200,000 patients, has had fewer than a dozen structural problems reported to the manufacturer, most of which did not cause clinical problems. Even the discontinued Björk-Shiley Convexo-Concave valve, whose strut fracture failures have been highly publicized, had fewer than 1 percent failures reported after 15 years of experience.[40] The Medtronic Hall valve had three leaflet fractures in a version that is not used in the United States. The problem was determined to be related to unequal coatings of pyrolytic carbon on the two faces of the leaflet and to be limited to a very small subset of valves. Since the manufacturing specifications were changed to ensure more equal coatings, the problem has not recurred. The St. Jude valve has had only 12 reported postoperative fractures of the disk or housing, which resulted in leaflet escape reported to the FDA-an excellent record considering that over 900,000 valves have been implanted.

BIOLOGICAL VALVES

Data on freedom from structural deterioration for several series of aortic porcine and pericardial bioprostheses and homografts are shown in Fig. 60-6. The mean age of patients in these older series is around 50 years. The current series of porcine valves, together with the tendency to select older patients,[41-44] should have improved durability. Design changes in some porcine valves,[45,46] such as stentless configurations,[16-20] may possibly improve durability.

Although the Carpentier-Edwards pericardial valve has been available for over 15 years, relatively few long-term results on the valve are available. Those that have been reported, however, show improved durability in the aortic position, as compared with the previously discontinued lonescu-Shiley pericardial valve. The durability of the Carpentier-Edwards pericardial valve also compares favorably with that of porcine valves (Fig. 60-6; Table 60-2). The patients in the Carpentier-Edwards pericardial valve series were older than patients in previous series of pericardial and porcine valves, however, and it is unknown to what extent this has resulted in apparent improvement in the durability of the Carpentier-Edwards pericardial valve.

Table 60-2: 14-Year Results with Carpentier-Edwards Pericardial Valve

		FDA-Mandated Patients[a] (*n* = 267) Actuarial (%)
Thromboembolism/thrombosis		19 ± 4
Anticoagulant-related bleeding		6 ± 2
Endocarditis/sepsis		7 ± 2
Valve dysfunction		70 ± 4
Explant due to structural valve deterioration:	Total	15 ± 3
	≤65 years of age	24 ± 5
	>65 years of age	4 ± 2
Mortality:	Total	60 ± 3.1
	Valve-related	21 ± 3.2

[a]FDA approval was based on 719 patients at 7 years. Data from FDA-mandated longer follow-up of selected patients are from Frater et al.[85]

Structural durability is considered to be better with *homografts* than with other bioprostheses. From various published reports[13] for homografts used primarily in the aortic position, it is apparent that the variation among series is wide, the current methods of sterilization/preservation provide better results than those which have been discontinued, and the results do not appear better than those for porcine bioprostheses (Fig. 60-6).

The pulmonary autograft is considered an excellent aortic valve substitute, especially for young patients[10] and in the treatment of patients with endocarditis.[47] Freedom from reoperation has been reported as 100 percent in 33 patients from 8 to 47 years old followed to a maximum of 48 months[11] and 93 percent at 5.5 years in 51 patients from 2 to 21 years old.[10] Data from one center showed 48.5 percent freedom from reoperation at 19 years[47] and, after excluding patients from three hospitals, 85 percent freedom from reoperation at 20 years.[48] To evaluate complications of this procedure fully, problems with the valve used to replace the pulmonary valve must be combined with complications of the pulmonary autograft itself.

VALVE REPAIR

Mitral valve repair is considered preferable to replacement, when practicable. It has been shown to improve ejection fraction[49] and to provide good results for treating bacterial endocarditis[50] and valve problems in elderly patients.[51,52] It has been strongly suggested that it improves survival; however, there are problems associated with the comparisons.[53]

The weakness of valve repair is durability. The 10-year actuarial reoperation rate has been reported to be 15

percent in nonrheumatic mitral disease.[54] The reoperation rate for patients with rheumatic mitral disease varies from 25 percent reoperation at 5 years[55] to 17 percent at 10 years in a large series in which calcium debridement[56] and anterior leaflet procedures were performed.[57] The reoperation rate at 10 years was 24 percent for patients less than 20 years of age and 9 percent at 10 years for patients over 20 years of age.[58]

Early results of aortic valve repair have been published,[23,59,60] but further follow-up is needed to assess the long-term results.

Other Valve-Related Complications

Linearized rates are often used to describe the complications required by the AATS/STS guidelines for reporting.[30-32] The use of such rates assumes that the risks are constant, which is usually only approximately true. A review of a large number of published reports of the performance of prosthetic heart valves reveals a wide spread of results for every complication for every valve. In 172 series of heart valves covering 335,485 valve-years accumulated by 63,531 valves of 20 different models implanted in two positions (aortic, mitral), the linearized event rates ranged from 0 to 7.5 percent per year for thromboembolism, 0 to 0.6 percent per year for thrombosis, 0 to 9.3 percent per year for bleeding, 0 to 1.7 percent per year for infection, and 0 to 2.8 percent per year for paravalvular leak.[61] Caution must be exercised in directly comparing event rates among valves for many reasons, including the simplifications involved in the use of linearized rates, varying definitions of complications (many of these reports predate the standardized definitions), and differences in patient characteristics between series.[53,62]

Chapter 60: CLINICAL PERFORMANCE OF PROSTHETIC HEART VALVES

DIFFICULTIES IN MAKING COMPARISONS BETWEEN PUBLISHED SERIES

As noted above, there is wide variation in the reported complication rates of series using the same valves. Figures 60-7, 60-8, 60-9 and 60-10 illustrate the wide range of embolism with use of the same heart valve in different series. This variation must be due to variations between series other than the *valve model*. These include factors associated with the following:

1. *Patients*-age, ventricular function, comorbidities, etc.
2. *Reporting center*-surgical variables, postoperative medical management, method, frequency and thoroughness of follow-up, definitions of complications, etc.
3. Problems with *data analysis*[63,64]-many patient-related factors are known to influence thromboembolism,[53,65] stroke rates in patients with atrial fibrillation and in the elderly are equal to those observed in prosthetic valve series,[66] and standardized definitions[30-32] were not in effect or were not employed when many of the available series were reported, etc.
4. *Published data*-these reports describe only a small fraction of the valves implanted and are probably not a representative subset.

Several types of bias can affect reported results. As examples, selection bias occurs in the collection and analysis of data and the decision to report them;[63] publication bias describes the fact that published series tend to be those with the best (or worst, but not typical) results.[67] If a random allocation of valves had been made among patients within a center, statistical methods could theoretically assess the effect on complication rates due to valve model. For logistic, financial, and ethical reasons, however, the number of randomized studies of valves is small, and the available studies are usually of insufficient size to show differences among valves. Although randomized studies provide the best internal validity or valve-specific comparison within centers, they may lack external validity or generalizability to patients outside of the study.[68]

A theoretically preferable way to answer this bias is to allocate patients randomly to different treatments (valves). Randomized trials, however, also have difficulties,[69] and as noted, there are logistic, financial, and ethical arguments against randomization of patients to different heart valves.[70] Consequently, the number of randomized studies of valves is small, and those that exist are usually of insufficient size to add to the knowledge already obtained from careful observational studies except for comparison of survival data with use of different types of prosthesis.

Major Randomized Trials

The two major randomized clinical trials that have been reported are the Edinburgh Heart Valve Trial[71] and the Veterans Administration (VA) Cooperative Study on Valvular Heart Disease.[72] Both studies compared mechanical valves to porcine bioprostheses.

The Edinburgh trial compared the Björk-Shiley Standard valve to porcine valves-initially the Hancock and later the Carpentier-Edwards.[71] It contains actuarial comparisons at 5 and 12 years for the 211 aortic and 261 mitral valve patients. The authors concluded that survival with a mechanical valve was better than with the bioprosthetic valve, but that this was somewhat offset by the increased risk of bleeding.

The VA trial compared the standard Björk-Shiley valve to the Hancock Modified Orifice (size 21 to 23 mm aortic) or Hancock Standard (other sizes) porcine valves.[72] Table 60-3 contains actuarial comparisons of the endpoint variables at 15 years. The principal long-term findings of this randomized trial[73] are: (1) Use of a mechanical valve resulted in a lower mortality and a lower reoperation rate after aortic valve replacement (AVR); (2) The mortality after mitral valve replacement (MVR) was similar with

use of the two prosthetic valve types; (3) There were virtually no primary valve failures with use of a mechanical valve; (4) Primary valve failure after AVR and MVR occurred more frequently in patients with a bioprosthetic valve especially in patients aged <65 years; (5) The primary valve failure rate between bioprosthesis and mechanical valve was not significantly different in those aged ≥65 years; (6) Use of a bioprosthetic valve resulted in a lower bleeding rate; and (7) There were no significant differences between the two valve types with regard to other valve related complications including thromboembolism, and all complications.

Comparison of the 12-year actuarial event rates between these two trials[72] showed that the bleeding and thromboembolism rates were higher in the VA study but that reoperation rates were higher in the Edinburgh study. These differences could be partially accounted for by the composition of the two patient populations: The Edinburgh patients (1) were younger and less heavily anticoagulated, (2) included women and those with double valve replacements, and (3) had a higher percentage of porcine valves in the mitral position. Late results show a better survival with mechanical valves than with bioprostheses in the mitral position with the original valve in the Edinburgh trial (42 versus 24 percent, $p < .05$), probably because of the high rate of bioprosthetic degeneration, and in the aortic position in the VA trial (23 versus 0 percent; $p = 0.0001$).

VALVE SELECTION CRITERIA

Because of the wide variation in results among and between various valve models, it is impossible to rank valves within valve types on the basis of complication rates. Some general recommendations, however, can be made with regard to valve selection (Table 60-4).[74]

Table 60-4: Recommendations for Valve Replacement with a Mechanical Prosthesis

Indication	Class
1. Patients with expected long life spans	I
2. Patients with a mechanical prosthetic valve already in place in a different position than the valve to be replaced	I
3. Patients in renal failure, on hemodialysis, or with hypercalcemia	II
4. Patients requiring warfarin therapy because of risk factors[a] for thromboembolism	IIa
5. Patients ≤65 years for AVR and ≤70 years for MVR[b]	IIa
6. Valve rereplacement for thrombosed biological valve	IIb
7. Patients who cannot or will not take warfarin therapy	III

[a]Risk factors: atrial fibrillation, severe LV dysfunction, previous thromboembolism and hypercoagulable condition.
[b]The age at which patients may be considered for bioprosthetic valves is based on the major reduction in rate of structural valve deterioration after age 65 and the increased risk of bleeding in this age group.

SOURCE: ACC/AHA Guidelines,[74] with permission.
ABBREVIATIONS: AVR = aortic valve replacement; LV = left ventricle; MVR = mitral valve replacement.

A biological valve should be used when the patient cannot or will not take anticoagulants or has a short life expectancy. Its use in relation to subsequent pregnancy is controversial (see Chap. 61). A mechanical valve should be used if the patient needs anticoagulant therapy (e.g., because of atrial fibrillation), has a

mechanical valve in another position, previously had a stroke, requires double valve replacement, or has a long life expectancy. Mechanical valves should be considered for double valve replacement because the risk of structural deterioration for two porcine valves is additive,[75] whereas the thromboembolic risk of two mechanical valves is not additive.[76]

Chapter 60: CLINICAL PERFORMANCE OF PROSTHETIC HEART VALVES

MANAGEMENT OF PATIENTS WITH PROSTHETIC HEART VALVES

Patients who have undergone valve replacement are *not* cured but still have serious heart disease. They have exchanged native valvular disease for prosthetic valvular disease and must be followed with the same care as patients with native valvular disease.[77] The clinical course of patients with prosthetic heart valves is influenced by several factors.[78]

Ventricular Dysfunction

Despite relief of valvular obstruction or regurgitation, some patients fail to improve after valve replacement or even deteriorate because of ventricular dysfunction. The cause of dysfunction may be carditis associated with rheumatic disease, myocardial degeneration and fibrosis from long-standing pressure or volume overload, ischemic damage at the time of valve replacement, coronary artery disease, or other associated diseases such as systemic hypertension or idiopathic dilated cardiomyopathy. Perioperative myocardial damage is an important cause of postoperative ventricular dysfunction. The importance of myocardial protection at the time of valve surgery is now recognized, and current operative techniques reduce myocardial oxygen consumption by hypothermic cardioplegia and use a variety of means for maintaining adequate myocardial perfusion and protection.

Other Cardiac Lesions

Cardiac diseases affecting primarily one valve often affect other valves, the conduction system, the coronary arteries, and the pulmonary vasculature. With the exception of pulmonary hypertension and functional tricuspid regurgitation, these disorders usually do not improve after isolated valve replacement. Rheumatic disease typically affects both mitral and aortic valves but not necessarily with the same severity at the same time. Therefore, patients who have mitral valve replacement may subsequently, years later, require aortic valve replacement, or vice versa. Calcification of the aortic and mitral valve annuli may extend to the conduction system. High-degree or complete atrioventricular block may occur at the time of surgery or during the late postoperative period, requiring pacemaker implantation. Coronary artery disease is very common in the age range of patients requiring valve replacement. Preoperative coronary arteriography should be performed in all patients with myocardial ischemic pain, in those with left ventricular dysfunction, in those with risk factors for coronary artery disease, and in those about 35 years of age or older.[78,79] Coronary bypass surgery of technically suitable vessels should be performed at the time of valve surgery if the patients have associated significant coronary artery disease.

Prosthesis-Related Problems

The incidence of problems with each prosthesis (see Tables 60-5 and 60-6) was discussed earlier. *Operative mortality* is related to older age of patient, New York Heart Association functional class III or IV, increased left ventricular size, left ventricular dysfunction, heart failure, pulmonary hypertension, low cardiac output, and presence of associated diseases such as systemic arterial hypertension, diabetes mellitus, peripheral and cerebral vascular disease, prior heart surgery, prior myocardial infarction, chronic obstructive pulmonary disease, and renal and hepatic failure. Coronary bypass surgery performed at the same time as valve replacement increases the operative mortality modestly (from 1.4 to 4.0 percent), but associated coronary artery disease, if not bypassed, significantly increases the operative mortality to 9.4 percent and the 10-year mortality to 64 percent.[80] Other very important factors include the occurrence of perioperative myocardial infarction, the duration of the operation, aortic cross-clamp time, and whether or not the patient needed reoperation within 1 to 2 weeks after the initial operation, and on an elective or emergency basis.

Table 60-5: Recommendations for Valve Replacement with a Bioprosthesis

Indication	Class
1. Patients who cannot or will not take warfarin therapy	I
2. Patients ≥65 years[a] needing AVR who do not have risk factors for thromboembolism[b]	I
3. Patients considered to have possible compliance problems with warfarin therapy	IIa
4. Patients >70 years[a] needing MVR who do not have risk factors for thromboembolism[b]	IIa
5. Valve rereplacement for thrombosed mechanical valve	IIb
6. Patients <65 years[a]	IIb
7. Patients in renal failure, on hemodialysis, or with hypercalcemia	III
8. Adolescent patients who are still growing	III

[a]The age at which patients should be considered for bioprosthetic valves is based on the major reduction in rate of structural valve deterioration after age 65 and increased risk of bleeding in this age group.
[b]Risk factors: atrial fibrillation, severe LV dysfunction, previous thromboembolism, and hypercoagulable condition.

Table 60-6: Major Complications of Valve Replacement

1. Operative mortality
2. Perioperative myocardial infarction
3. Prosthetic endocarditis
4. Prosthetic dehiscence
5. Prosthetic dysfunction
    a. Obstruction: Usually thrombotic, occasionally due to item 3, 4, or 8
    b. Regurgitation
    c. Hemolysis
    d. Structural failure
6. Thromboemboli
7. Hemorrhage with anticoagulant therapy
8. Valve prosthesis-patient mismatch
9. Prosthetic replacement often caused by item 3, 4, or 5, occasionally caused by item 6, 7, or 8
10. Late mortality, including sudden, unexplained death

SOURCE: Rahimtoola.[64] Reproduced with permission of the publisher and author.

The risk of *prosthetic endocarditis* is about 3 percent in the first year and 0.5 percent in subsequent years. Infections in the early postoperative period (up to 2 to 12 months) are due to hospital-based organisms. Despite therapy, the infections are difficult to cure and have a high mortality (about 80 percent);[81,82] early reoperation is usually recommended. The mortality rate from late (2 to 12 months or later) postoperative infection is approximately 40 percent;[81,82] about half the patients can be treated successfully with medication alone. The infected valve should be replaced in patients who do not respond to medical

treatment or who have evidence of heart failure, annular invasion, embolism, prosthetic dysfunction, unstable prosthesis, or gram-negative, staphylococcal, or fungal infection.[64] The importance of adequate antibiotic prophylaxis for the prevention of endocarditis cannot be overemphasized; the prevention and treatment of prosthetic valve endocarditis are discussed in Chap. 82.

Long-term anticoagulant therapy is associated with *bleeding* episodes. The incidence of minor bleeding is about 2 to 4 percent per year or less. The incidence of major bleeding is about 1 to 2 percent per year or less, with a mortality rate of about 0.5 percent per year or less. The incidence of these complications is lower in patients who take their medications reliably, in those in whom smooth long-term anticoagulation can be achieved, and in those who receive low-dose warfarin therapy (INR 2 to 3 versus >3). With oral anticoagulants, low- or mid-dose warfarin therapy is combined with low-dose aspirin. Higher degrees of anticoagulation increase the incidence of bleeding without reducing the incidence of thromboembolism. The management of antithrombotic therapy is discussed in Chap. 68.

Prosthetic dehiscence is the result of sutures pulling out of the cardiac tissues. It may result from infection, inadequate surgical technique, or diseased cardiac tissue (e.g., edema, necrosis, calcification).

Because of the continued proliferation of new types and models of prostheses and their relatively brief history of clinical use, the natural history of *structured valve deterioration* is incompletely determined. Although some mechanical prostheses had initial problems with component failure, the most common cause for dysfunction of mechanical prosthetic valves is thrombotic obstruction. The incidence of thrombotic obstruction with the Björk-Shiley spherical occluder valve is higher than that seen with the Starr-Edwards or St. Jude valves, particularly in the mitral position. Failure of biological valves is more common than failure of mechanical prostheses because of leaflet deterioration or calcification; progressive prosthetic regurgitation and/or stenosis is the rule. Bioprosthesis failure is greater in younger patients, in older patients with chronic renal insufficiency, and in the mitral position. In younger patients (average age <60 years), failure of mitral prostheses usually starts at 5 to 8 years and of aortic prostheses at 8 to 10 years. It is unlikely that the tissue valves currently in use will be able to provide the long-term performance demonstrated by the ball-valve mechanical prosthesis.

Red cells are fractured by turbulence and contact with foreign surfaces. Some degree of *hemolysis* is present with all mechanical prostheses but not with bioprostheses. Important hemolysis, however, may occur with a perivalvular leak or severe prosthetic obstruction regardless of prosthesis type. Serum lactic dehydrogenase (LDH) is usually the simplest and most reliable index of hemolysis to follow in patients with prosthetic valves. A sudden increase in LDH may indicate prosthesis dysfunction, perivalvular leak, or cloth tear. Iron and folate therapy usually correct the anemia. Valve rereplacement may be required for severe, refractory hemolytic anemia.

Important *systemic embolization* is an unfortunate complication of prosthetic valve replacement. Anticoagulation is recommended for all patients with mechanical prostheses. *Despite long-term anticoagulation, patients with prosthetic valves face an embolic rate from aortic prostheses of 1 to 2 percent or less per year and from mitral prostheses of 3 to 4 percent or less per year*.

No prosthesis currently employed has an effective orifice as large as that of the native valve, and valve prosthesis-patient mismatch[33] may occur. *All patients with prosthetic heart valves have mild to moderate stenosis*. Patients with aortic valve prostheses have obstruction to left ventricular outflow (aortic stenosis), and patients with mitral valve prostheses have obstruction to left atrial emptying (mitral stenosis). This is most important in a large patient in whom a prosthesis that is considered "small" in relation to body size must be placed for technical reasons. The resulting patient-prosthesis mismatch[33] contributes to incomplete relief of symptoms. The long-term effect of intrinsic prosthetic stenosis on survival and ventricular dysfunction is unknown but may lead to long-term effects similar to those of aortic or mitral stenosis.[83] The presence of intrinsic prosthetic stenosis must be considered when patients with prosthetic heart valves are being advised concerning activity.

Reoperation to replace a prosthetic heart valve is a serious complication. It is usually required for moderate to severe prosthetic dysfunction and dehiscence, prosthetic valve endocarditis, and occasionally recurrent thromboembolism, severe recurrent bleeding from anticoagulant therapy, or valve prosthesis-patient mismatch.

Late cardiac death may result from ventricular dysfunction, other cardiac lesions, or prosthesis-related causes. Late, sudden death is not uncommon. It may result from a bradyarrhythmia; a tachyarrhythmia that is often associated with ventricular dysfunction, prosthetic dysfunction, or mismatch; coronary artery disease; or a combination of these.

Management

All patients with prosthetic valves need appropriate antibiotics for prophylaxis against infective endocarditis (Chap. 82). Patients with rheumatic heart disease continue to need antibiotics as prophylaxis against the recurrence of rheumatic carditis (Chap. 62). Adequate antithrombotic therapy is needed for appropriate patients (Chap. 68).

During the first 4 to 6 weeks after surgery, the physician and surgeon jointly manage the patient, directing their attention toward relieving postoperative discomfort, readjusting cardiac medications, and instituting anticoagulation if not contraindicated. A graduated plan of activity is started that, in most cases, enables the patient to return to full activity in 4 to 6 weeks.

Several syndromes are peculiar to the postoperative period. The *postperfusion syndrome* usually appears in the third or fourth postoperative week. It is characterized by fever, splenomegaly, and atypical lymphocytes; it is benign and self-limited. The *postpericardiotomy syndrome* is characterized by fever and pleuropericarditis. It usually develops in the second or third postoperative week but can appear as late as 1 year after surgery and sometimes recurs. Although this syndrome is usually self-limited, most patients benefit from taking anti-inflammatory drugs, such as aspirin or indomethacin; a short course of glucocorticoids is also occasionally required.

Even though the pericardium is left open at the end of surgery, *cardiac tamponade* has been known to occur during the first 6 weeks. The fact that a critically ill patient may improve promptly with pericardial drainage underscores the need to consider this uncommon postoperative complication. Usually, anticoagulants have been given and the fluid is hemorrhagic.

The *4- to 6-week postoperative visit* is critical, because by this time the patient's physical capabilities and expected improvement in functional capacity can usually be assessed. At this time, the physician should assemble essential records and data for the subsequent office follow-up, including the preoperative history, physical examination, chest roentgenogram, electrocardiogram (ECG) and indication for surgery, preoperative echocardiographic/Doppler ultrasound and cardiac catheterization/angiographic reports, surgeon's operative report, postoperative complications, and hospital discharge summary. The prosthesis model, serial number, and size should be recorded.

The workup on this visit should include an interval or complete initial history and physical examination, ECG, chest x-ray, echocardiography/Doppler ultrasound, complete blood count, and measurement of electrolytes, LDH, and international normalized ratio (INR) if indicated (Table 60-7). The examination's main focus is on physical signs that relate to functioning of the prosthesis or suggest the presence of a myocardial, conduction, or valvular disorder. The auscultatory findings to expect with some normally functioning prostheses have been described.[84] Severe perivalvular mitral regurgitation can be inaudible on physical examination, a fact to remember when considering possible causes of functional deterioration in a patient.

Table 60-7: Recommendations for Follow-up Strategy of Patient with Prosthetic Heart Valves

Indication	Class
1. History, physical exam, ECG, chest x-ray, echocardiogram, complete blood count, serum chemistries, and INR (if indicated) at first postoperative outpatient evaluation[a]	I
2. Radionuclide angiography or magnetic resonance imaging to assess LV function if result of echocardiography is unsatisfactory	I
3. Routine follow-up visits at yearly intervals with earlier reevaluations for change in clinical status	I
4. Routine serial echocardiograms at time of annual follow-up visit in absence of change in clinical status	IIb
5. Routine serial fluoroscopy	III

[a]This evaluation should be performed 3 to 4 weeks after hospital discharge. In some settings, the outpatient echocardiogram may be difficult to obtain: if so, an inpatient echocardiogram may be obtained before hospital discharge.

SOURCE: ACC/AHA Guidelines,[73] with permission.
ABBREVIATIONS: INR = international normalized ratio; LV = left ventricle.

The interval between routine follow-up visits depends on the patient's needs. Anticoagulant regulation usually does not require office visits.

Multiple noninvasive tests have emerged for assessing valvular and ventricular function. Fluoroscopy can reveal abnormal rocking of a dehiscing prosthesis or limitation of the occluder if the latter is opaque as well as strut fracture of a Björk-Shiley valve. Radionuclide angiography, which is useful for determining whether or not functional deterioration is the result of reduced ventricular function, is performed if the same data cannot be obtained by echocardiography.

Echocardiography/Doppler ultrasound is the most useful noninvasive test. It provides information about prosthesis stenosis/regurgitation, valve area, assessment of other valve disease(s), pulmonary hypertension, atrial size, left ventricular hypertrophy, left ventricular size and function, and pericardial effusion/thickening. It is essential at the first postoperative visit because it allows an assessment of the effects and results of surgery and serves as a baseline for comparison should complications and/or deterioration occur later. Subsequently, it is performed as is needed in both symptomatic and asymptomatic patients at 1- to 2-year intervals. We recommend that in patients with a bioprosthesis in the mitral position, echocardiography/Doppler ultrasound should be performed annually after 5 years and in the aortic position annually after 8 years because of the increasing incidence of bioprosthetic structural valve deterioration.

"Heart failure" after valve replacement may be the result of (1) preoperative left ventricular dysfunction that improved partially or not at all, (2) perioperative myocardial damage, (3) progression of other valve disease, (4) complications of prosthetic heart valves, and (5) associated heart disease such as coronary artery disease and systemic arterial hypertension.

Any patient with a prosthetic heart valve who does not improve after the surgery or who later shows deterioration of functional capacity should undergo appropriate testing to determine the cause. Such studies are also usually necessary for patients who require reoperation for endocarditis or repeated embolism to determine the hemodynamics and anatomy.

The indications for reoperating on a patient with prosthetic valve endocarditis have already been discussed. A patient in stable condition, without prosthetic valve endocarditis, can usually undergo reoperation with only slightly greater risk than that of the initial surgery. For the patient with catastrophic dysfunction, surgery is clearly indicated and urgent. The patient without endocarditis or severe dysfunction requires careful hemodynamic evaluation; the decision about reoperation should then be based on the hemodynamic abnormalities, the symptoms, ventricular function, and current knowledge of the natural history of the

particular prosthesis.

Part 9: VALVULAR HEART DISEASE
Chapter 61:

ANTITHROMBOTIC THERAPY FOR VALVULAR HEART DISEASE

Authors: John H. McAnulty, Shahbudin H. Rahimtoola

INTRODUCTION

The most important reason to address the issue of protection against thromboemboli in every patient with valve disease is the risk of a stroke. In addition, the consequences of valve thrombosis and of emboli to other organs make the risk of antithrombotic therapy reasonable to assume in many patients with valve disease. Treatment has to be individualized, but some issues and principles are widely applicable (Table 61-1).[1,2] Although some recommendations are appropriate for affluent American communities, the risk, benefit, and cost ratio may not be applicable in poorer areas, where the resources are simply not available. Thromboemboli are not ignored, but alternative therapy-for example, a greater use of antiplatelet agents, in particular aspirin-may, on balance, be more appropriate.

Table 61-1: Valve Disease and Antithrombotic Therapy[a,b]

1. Prevention of thromboemboli should be addressed each time a patient with valve disease is seen.
2. Lifelong antithrombotic therapy is required in patients with atrial fibrillation (paroxysmal or persistent) (Table 61-2).
3. Warfarin therapy is required in all patients with a mechanical prothesis (Table 61-3).
4. Antithrombotic therapy should be started early after valve surgery.
5. Warfarin should be avoided in the first trimester of pregnancy.
6. Antithrombotic therapy should be individualized during noncardiac surgery and cardiovascular procedures (Table 61-5).

[a]See text for discussion.
[b]In general, whenever warfarin/aspirin therapy is recommended it is assumed that there is no specific contraindication to its use.

Intracardiac thrombosis most often presents as an embolic cerebrovascular event in over 80 percent of cases. Rarely, thrombosis becomes manifest by causing valve dysfunction. The physical examination should include careful attention to the peripheral pulses and to the skin, fundi, and soft tissues (mouth, conjunctiva), looking for clues of an embolus. A detailed neurologic assessment for focal deficits is essential. Although thrombosis most often occurs without any change in the cardiac examination, auscultation to assess for a change in a murmur or in the quality of heart sounds is important. Intracardiac thrombosis often is first diagnosed when cardiac catheterization or echocardiography is performed for other reasons.

Thrombus is the most common but not the exclusive cause of an embolus. Infective endocarditis must be considered and excluded as a cause, particularly in individuals with valve disease. Disruption of a vascular plaque in the ascending aorta, arch, or descending aorta and in the cerebral vessels may be a common cause of peripheral and cerebral emboli in patients with atherosclerotic disease. Intracardiac tumors or calcified emboli from the heart or aorta are other rare causes.

Chapter 61: ANTITHROMBOTIC THERAPY FOR VALVULAR HEART DISEASE

NATIVE VALVE DISEASE

The risk of thromboembolism in patients with native valve disease is most directly related to certain risk factors, including atrial fibrillation, a history of thromboembolism, left ventricular (LV) dysfunction, and known hypercoagulability. The risk is increased by the presence of certain types of native valve disease (e.g., mitral stenosis) and with prosthetic heart valves, particularly mechanical prostheses, which put a patient at risk even without other associated risk factors (Fig. 61-1).

Risk Factors for Thromboemboli with Native Valve Disease

ATRIAL FIBRILLATION

Most is known about the stroke risk with atrial fibrillation, which is common even without valve disease. Six recent large prospective randomized trials have assessed the value of antithrombotic therapy for primary prevention in patients with nonvalvular atrial fibrillation.[3-8] The term *nonvalvular* is not completely accurate, as at least some patients with aortic valve disease and with mitral regurgitation were included in the studies if the valve lesions were considered hemodynamically "insignificant."

In these trials, the embolic rate (essentially the rate of a stroke in untreated patients with nonvalvular atrial fibrillation) ranged from 3 to 8 percent per year. This was true whether the atrial fibrillation was constant or paroxysmal. Importantly, these trials indicated that warfarin therapy reduced the stroke rate to approximately 0.5 to 2 percent per year. One study, SPAF II,[7] demonstrated equal protection against an adverse neurologic event when aspirin (325 mg daily) was compared to warfarin. In SPAF III,[8] the aspirin was less protective if atrial fibrillation occurred in association with LV dysfunction or uncontrolled hypertension, if the patient was a woman over age 75, and most importantly, if the patient had had a previous thromboembolic event. Warfarin is indicated in these patients if they are reasonable candidates for the drug, with particular emphasis on its role in those who have had a previous embolic event, as secondary prevention;[6,8] the International Normalized Ratio (INR) should be in the 2.0 to 3.0 range (see also Chap. 44).

The exclusion of mitral stenosis in these prospective trials implies that the risks of emboli and the benefits of warfarin in these patients with associated atrial fibrillation are well understood; however, these are not thoroughly documented or proven. Retrospective assessment, however, suggests that such patients may have an embolic rate >5 percent per year. Until the role of warfarin is better defined, the authors recommend its use in patients with mitral stenosis and one or more risk factors.

LEFT VENTRICULAR DYSFUNCTION

Systemic or pulmonary thromboemboli occur at a rate of over 5 percent per year in patients with LV dysfunction. The type and degree of dysfunction indicating risk are not well defined, but LV systolic abnormalities have been related to emboli most often. However, antithrombotic therapy is of unproven value in preventing or reducing the embolic rate.[9,10] Still, the risk is sufficient that, with or without valve disease, consideration should be given to treatment. One approach (including the authors') is to use warfarin if the LV ejection fraction (EF) $\leq$0.30 and the patient is a reasonable candidate for this treatment.

PREVIOUS THROMBOEMBOLI

In other clinical situations (e.g., in patients with atrial fibrillation[6,8] or with a prosthetic valve[11-13]), a thromboembolic event defines patients at high risk for having an embolic event-i.e., a recurrent event. It is unclear whether this is true in patients with native valve disease, but we recommend lifelong warfarin

therapy.

HYPERCOAGULABLE CONDITIONS

Reasons to consider anticoagulant therapy are the presence of protein C, protein S, or antithrombin III deficiencies; the anticardiolipin antibody syndrome; resistance to activated protein C; or an associated malignancy. This is also true in patients with native valve disease (see also Chap. 44).

Screening for Patients at High Risk for Thromboemboli

The risk factors described above define patients requiring antithrombotic therapy. Transthoracic (TTE) and transesophageal echocardiography (TEE) are often performed in patients with valvular heart disease and in those who have had a systemic embolic episode. The use of these procedures in determining which patients are at risk of thromboemboli is not yet well defined; left atrial (LA) thrombi, a patent foramen ovale, an atrial septal aneurysm, or spontaneous echo contrast are occasional findings of concern, but the value of treatment is unproven. Until more is known, it may not be appropriate to screen patients with native valve disease who do not have one of the obvious clinical risk factors listed above.

Antithrombotic Treatment for Native Valve Disease

Antithrombotic therapy is not required in patients with native valve disease (Table 61-2) unless there is an associated risk factor.[2-14] Theoretically, the risk of thrombosis is greater with mitral valve disease as compared to aortic valve disease: there is more blood stasis, the LA may be larger, and the frequency of atrial fibrillation is greater. Still, the presence of mitral valve stenosis or regurgitation by itself is not a reason to initiate antithrombotic therapy. If there is a risk factor, antithrombotic therapy should be considered as defined in Table 61-2. If the patient is a reasonable candidate for warfarin therapy, the use of warfarin (maintaining an INR of 2 to 3) is appropriate if a patient with valve disease has atrial fibrillation (constant or paroxysmal) in combination with reduced LV function (heart failure or LV EF ≤0.30) or with associated severe hypertension or if there is a history of thromboemboli. There is a suggestion that women over the age of 75 with atrial fibrillation might be better protected by warfarin than aspirin,[8] but the bleeding rate on warfarin is significant in this patient population; treatment should be individualized and the INR more closely monitored. If a patient with atrial fibrillation has reasonable LV function, has not had a previous thromboembolism, and does not have other risk factors, aspirin (325 mg/day) is just as likely as warfarin to be protective against thromboemboli, without the associated expense and risk of warfarin therapy.[7-15] Unrelated to atrial fibrillation, warfarin therapy is recommended if a patient has had a previous thromboembolism or has LV dysfunction (heart failure and an ejection fraction ≤0.30).

Table 61-2: Antithrombotic Therapy-Native Valve Disease

I. *No therapy* if no thrombosis risk factor
II. *Therapy* if thrombosis risk factor present
    A. *Atrial fibrillation*
        1. Warfarin (INR 2-3) if congestive heart failure, hypertension, or previous thromboembolism
        2. Warfarin (INR 2-3) if valve lesion is mitral stenosis
        3. Aspirin (325 mg/day) or warfarin (INR 2-3) if valve lesion other than mitral stenosis
    B. *Previous thromboembolism*-warfarin (INR 2-3)
    C. *LV dysfunction* (ejection fraction ≤0.30-warfarin (INR 2-3)
    D. *Hypercoagulable state*-warfarin (INR 2-3)

Abbreviation: INR = International Normalized Ratio.

Chapter 61: ANTITHROMBOTIC THERAPY FOR VALVULAR HEART DISEASE

PROSTHETIC HEART VALVES

All patients with mechanical valves require warfarin therapy. Even with the use of warfarin, the risk of thromboemboli in these patients is 1 to 2 percent per year;[16-19] the risk is *considerably higher* without treatment with warfarin.[11] The risk of an embolus in patients with biological valves in sinus rhythm has been approximately 0.6 to 0.7 percent per year, and most of those patients were not on warfarin therapy.[16,17,19-21] Almost all studies have shown that the risk of embolism is greater with a valve in the mitral position (mechanical or biological) as compared to a valve in the aortic position;[11,16] however, this was not found in one study.[17] With either type of prosthesis or valve location, the risk of emboli is probably higher in the first few days and months after valve insertion,[20] before the valve is fully endothelialized.

Antithrombotic Treatment for Prosthetic Valves (Table 61-3)

MECHANICAL VALVES

All patients with mechanical valves require warfarin, and the INR should be maintained between 2.0 and 3.5.[16,17,22-24] In patients with an aortic prosthesis without risk factors for emboli the INR should be between 2.0 and 3.0; in those with risk factors and in those with a mitral prosthesis the INR should be between 2.5 and 3.5.[2] Some valves are thought to be more thrombogenic than others (particularly the tilting-disk valves), and a case could be made for increasing the INR to between 3 and 4.5, but this would be associated with an increased risk of bleeding.[22,25,26] The addition of low-dose aspirin (50 to 100 mg/day) to warfarin therapy may further decrease the risk of thromboembolism.[27,28] The authors recommend the addition of aspirin (50 to 100 mg/day) to warfarin unless there is a contraindication to the use of aspirin (i.e., bleeding or aspirin intolerance). This combination is particularly appropriate in patients who have had an embolus while on warfarin therapy and/or who are known to be particularly hypercoagulable; for example, it is recommended by a committee addressing antithrombotic therapy in women during pregnancy.[29] It is important to note that the thromboembolic risk increases early after the insertion of the prosthetic valve; this is a reason to initiate heparin therapy within the first 24 to 48 h of surgery, with maintenance of the *activated partial thromboplastin time* (aPTT) at a "therapeutic effect" level (Table 61-4) until warfarin therapy has achieved the recommended INR level.

Table 61-4: 'Therapeutic Effect' of Heparin

Unfractionated heparin	An aPTT at 8 h after a dose that has been calibrated[a] to reflect a heparin level of 0.35 to 0.70 anti-Xa units
Low-molecular-weight heparin	An aPTT at 8 h after a dose that has been calibrated[a] reflect a heparin level of 0.7 to 1.1 anti-Xa units
During pregnancy	A heparin level of 0.6 to 0.7 anti-Xa units with unfractionated heparin or 0.10 to 0.11 anti-Xa units with low-molecular-weight heparin[b] (aPTT measurements do not accurately reflect heparin levels during pregnancy)

[a]Calibration of aPTT to heparin levels is performed in each clinical laboratory; thus the time (number of seconds) of the aPTT reflecting the 'therapeutic effect' levels will vary.
[b]*Important Note:* Although low-molecular-weight heparin is increasingly being utilized in many disorders, it is reemphasized here (see text) that its value in protecting against thromboemboli in patients with valve disease has *not* been proven. Therefore its use in patients with valve disease *cannot* be recommended at the present time.

BIOLOGICAL (TISSUE) VALVES

Because of an increased risk of thromboemboli during the first 3 months after implantation of a biological prosthetic valve, anticoagulation with warfarin is indicated.[20] The risk is particularly high in the first few days after surgery, and heparin therapy should be started within 24 to 48 h, with maintenance of the aPTT at a "therapeutic effect" level (Table 61-4) until an INR of 2.0 to 3.0 is achieved with warfarin. After 3 months, the tissue valve can be treated like native valve disease (see Table 61-2), and warfarin can be discontinued in approximately two-thirds of patients with biological valves.[16,17,20,30] Associated atrial fibrillation or an LV EF ≤0.30 are reasons for lifelong warfarin therapy.

Chapter 61: ANTITHROMBOTIC THERAPY FOR VALVULAR HEART DISEASE

SPECIAL CLINICAL SITUATIONS

Altered Native Valves

Valve disease is increasingly being treated by interventional catheter techniques or surgical valve repair. It is difficult to give firm recommendations about antithrombotic therapy in these patients, but the recommendations given for treatment of native valve disease would seem most applicable in patients who have had surgical valve repair or catheter valve procedures (see Table 61-2).

Pregnancy

Pregnancy makes decisions regarding antithrombotic therapy for valve disease more difficult. Warfarin should be avoided in the first trimester of pregnancy, particularly in weeks 6 through 12.[29,31-32] It crosses the placental barrier and is associated with, and is the clear cause of, an embryopathy manifest in the live born as mental impairment, ocular atrophy, and facial and digital abnormalities. Therefore, warfarin should be discontinued immediately when pregnancy is recognized and heparin therapy should be initiated. The value of switching from warfarin to heparin *before* conception is uncertain. We suggest this when pregnancies are planned, since little is known about the consequences of warfarin taken in the first 6 weeks of pregnancy; however, this is often not clinically practical or feasible. Currently, the estimated risk of an embryopathy in well-managed warfarin therapy is ≤5 percent. While a return to warfarin during the second and third trimesters is recommended, there is concern that this drug may continue to endanger the fetus.

Heparin does not cross the placenta. While not devoid of problems (maternal bleeding, heparin-initiated thrombocytopenia, an increased risk of osteoporosis when used for longer than 1 month), successful pregnancies have occurred when adequate doses of the drug are administered subcutaneously at home throughout gestation.[33] Thromboembolic complications have occurred with heparin use during pregnancy in women with a mechanical prosthesis.[34,35] To minimize this, it is important to give a dose that will result in high "therapeutic effect" heparin levels (Table 61-4) prior to the next dose (this usually requires 15,000 to 30,000 units every 12 h).[29,36] Activated PTT measurements do not accurately reflect heparin levels during pregnancy.

Low-molecular-weight heparin (LMWH) is currently approved *only* for treatment of venous thrombosis. Still, there is no reason to suspect that it will not result in effective anticoagulation in patients with valve disease. It has been used safely in pregnancy,[37,38] does not cross the placenta, can be given once or twice daily, does not require regular blood test monitoring, and is associated with less thrombocytopenia and osteoporosis. More studies are needed.[39] Since there are *no* data about use of LMWH in patients with native valve disease or with prosthetic heart valves, LMWH cannot be recommended in such patients at this time.

Aspirin crosses the placenta and has been implicated as a cause of abortion and fetal growth retardation,[40] but it has been used so frequently without problems and has even been considered for use in all pregnant women as prophylaxis against preclampsia[41] that, when required for valve disease (see Table 61-2), it should be continued.

The concern about the use of antithrombotic therapy during pregnancy makes the decision about management of valve disease more difficult in women of childbearing age. If valve surgery is required, commissurotomy or valve repair is preferable because subsequent antithrombotic therapy is not required unless the woman has one of the risk factors for thrombosis (see Fig. 61-1). If a prosthetic valve is required in a woman of childbearing age, the advantage of a mechanical prosthesis is its durability. On the other hand, it obligates the woman of childbearing age to anticoagulation with warfarin because aspirin

therapy itself does not offer adequate protection against thromboembolism. The theoretical advantage of a biological prosthesis is that, except for the first 3 months after valve replacement, warfarin therapy is not required. However, as many as one-third of patients with biological valves have associated atrial fibrillation and require warfarin antithrombotic therapy. In addition, the rate of degeneration of biological valves accelerates dramatically in young patients and thus also in women of childbearing age.[42] Furthermore, some data suggest that the rate of structural valve degeneration is increased in pregnant women. The choice of a prosthesis should be individualized. A young woman capable of safely using warfarin when not pregnant and warfarin/heparin during pregnancy is best treated with a mechanical valve. If a woman's social situation or attention to her health is questionable in regard to the safe use of anticoagulation therapy, a biological valve may be considered. In young women needing aortic valve replacement, the Ross procedure should be considered (see also Chap. 60).

Surgery and Dental Care (Table 61-5)

The risk of increased bleeding during a procedure performed with a patient on antithrombotic therapy has to be weighed against the increased risk of a thromboembolism caused by stopping the therapy.

Table 61-5: Antithrombotic Therapy at the Time of Surgery

I. Usual approach
   A. If patient on warfarin
      Stop 72 h before procedure
      Restart on day of procedure or after control of active bleeding
   B. If patient on aspirin
      Stop 1 week before procedure
      Restart the day after procedure or after control of active bleeding
II. Unusual circumstances
   A. Very high risk of thrombosis if off warfarin[a]
      Stop warfarin 72 h before procedure
      Start heparin 48 h before procedure[b]
      Stop heparin 6 h before procedure
      Restart heparin within 24 h of procedure and continue until warfarin can be restarted and the INR is 2-3
   B. Surgery complicated by postoperative bleeding
      Start heparin as soon after surgery as deemed safe and maintain aPTT of 60-80 s until warfarin restarted and the INR is 2-3
   C. Very low risk from bleeding[c]
      Continue antithrombotic therapy

[a]Clinical judgment: consider this approach if recent thromboembolus or if three risk factors are present.[b]Heparin can be given in outpatient setting before and after surgery.[c]For example, local skin surgery, dental prophylaxis, and treatment for caries.
Abbreviation: aPTT = activated partial thromboplastin time.

The risk of stopping warfarin can be estimated and is relatively low if the drug is withheld for only a few days. As an example, and using a *worst case* scenario (e.g., a patient with a mechanical prosthesis with previous thromboemboli), the risk of a thromboembolus off warfarin could be as high as 10 to 20 percent per year. Thus, if the therapy were stopped for 3 days, the risk of an embolus would be 3/365 times 0.10 to 0.20, which equals 0.08 to 0.16 percent. There are theoretical concerns that stopping the drug and then reinstituting it might result in hypercoagulability-with a thrombotic "rebound." An increase in markers for activation of thrombosis with abrupt discontinuation of warfarin therapy has been observed,[43] but it is not clear that these increase the clinical risk of thromboembolism.[44] In addition, when reinstituting warfarin therapy, there are theoretical concerns of a hypercoagulable state caused by suppression of proteins C and S before the drug affects the thrombotic factors. Although the risks are only hypothetical, this is a reason to treat individuals at very high risk with heparin therapy until the INR returns to the desired range.

Although antithrombotic therapy must be individualized, some generalizations apply (see Table 61-6). For procedures where bleeding is unlikely or would be inconsequential if it occurred, antithrombotic therapy should not be stopped. This can apply to surgery on the skin, dental prophylaxis, or simple treatment for dental caries. Eye surgery, in particular surgery for cataracts or glaucoma, is usually associated with very little bleeding; when bleeding is likely or its potential consequences are severe, antithrombotic treatment should be altered. If a patient is on aspirin, it should be discontinued 1 week before the procedure and restarted as soon as it is considered safe by the surgeon or dentist.

Table 61-6: Antithrombotic Therapy at the Time of a Thromboembolic Event

I. Acute management
   A. *No* antithrombotic treatment for 72 h
   B. CT scan at 72 h
      1. *No (or little) hemorrhage* on CT:
         a. Heparin: aPTT in low 'therapeutic effect' (Table 61-4)
         b. Warfarin: continue heparin until INR in desired range[a]
      2. *Hemorrhage* on CT:
         a. No treatment until bleed stabilized or treated (7-14 days), then heparin and warfarin as above

II. Chronic management
   A. If embolus occurred *off* antithrombotic therapy:
      1. Treat with warfarin[a]
   B. If embolus occurred *on* antithrombotic therapy:
      1. If patient was on aspirin, switch to warfarin[a]
      2. If patient was on warfarin but INR was low, increase dose until INR in high desired range[a]
      3. If patient was on warfarin and INR was in desired range, add aspirin 80-325 mg/day
      4. If recurrent embolus or bleed on warfarin plus aspirin, assess valve for possible surgery

[a]See Tables 61-2 and 61-3.
Abbreviation: CT = computed tomography.

For most patients on warfarin, the drug should be stopped 48 to 72 h before the procedure to ensure the INR is ≤1.5 and restarted within 24 h after a procedure; admission to the hospital or a delay in discharge to give heparin is usually unnecessary.[2,27,44-47] Deciding who is at very high risk of thrombosis and thus should require heparin until warfarin can be reinstated may be difficult; clinical judgment is required. Heparin can usually be reserved for those who have had a recent thrombosis or embolus (arbitrarily within 1 year), those with demonstrated thrombotic problems when previously off therapy, and those with three or more risk factors. When used, unfractionated heparin should be started 24 h after warfarin is stopped (i.e., 48 h before surgery) and stopped 4 to 6 h before the procedure. The heparin should be restarted as early after surgery as bleeding stability allows and the aPPT maintained at a "therapeutic level" (Table 61-4) until warfarin is restarted and the desired INR can be achieved. Home administration and management of heparin (and warfarin) can be arranged to minimize time in the hospital. LMWH is even more easily utilized outside of the hospital (see also Chap. 48); however, there are no data with its use in patients with valve disease.

Cardiac Catheterization and Angiography

Antiplatelet therapy or heparin need not be stopped for these procedures. Protamine can be given to the patient on heparin if bleeding occurs. In an emergent or semiemergent situation, cardiac catheterization can be performed with a patient on warfarin, but, preferably, the drug should be stopped 72 h before the procedure and restarted the day of the procedure. This is also true for most patients with prosthetic heart valves (mechanical as well as biological). If a patient is at very high risk of thromboembolism, heparin should be started 48 h before the procedure and continued until warfarin is restarted and the desired INR is

achieved. If the catheterization procedure is to include a transseptal puncture (especially in a patient who has not had previous opening of the pericardium), patients should be off all antithrombotic therapy and the INR should be <1.2-the same is also true if an LV puncture is to be performed.[48]

Therapy at the Time of an Active Thromboembolic Event

VALVE THROMBOSIS

Thrombosis of a valve, usually a prosthetic valve, can result in severe hemodynamic compromise. If recognized (TEE can be diagnostic[49]), this complication may be treated with thrombolytic therapy, although the risk of bleeding and of emboli at the time of treatment is high.[50,51] Thrombolytic therapy is most effective for a "young thrombus." Many valves, however, have pannus formation and tissue ingrowth on the valve, which is not amenable to thrombolytic therapy. Therefore, we recommend emergency surgery rather than thrombolytic therapy in the patient with severe hemodynamic compromise. If a patient is not a surgical candidate, thrombolysis should be attempted.[2,52] Streptokinase or urokinase should be initiated but stopped at 24 h if there is no improvement by Doppler echocardiography and at 72 h even if hemodynamic recovery is incomplete.[2] This should be followed by heparin until high INR levels are achieved with concomitant warfarin therapy (INR 3 to 4 for aortic prostheses or 3.5 to 4.5 with mitral prostheses).

THROMBOEMBOLIC EVENT

An embolic event often indicates inadequate therapy for that patient's circumstances. Data and opinions about optimal timing for initiating or continuing anticoagulants in patients in whom an embolus is the presumed cause of a stroke are conflicting.[2,53-55] Ideally, treatment would be started early to prevent recurrent emboli, but the early use of heparin (within 72 h) is associated with a 15 to 25 percent chance of converting a nonhemorrhagic into a hemorrhagic stroke.[54] While a case can still be made for immediate use of heparin,[53,54] the early recurrence of an embolus in patients with valve disease while off anticoagulants has not been clearly documented. Data are insufficient to provide definitive treatment outlines, but the authors' practice is listed in Table 61-6.

ACUTE MANAGEMENT OF AN EMBOLIC EVENT

Antithrombotic therapy should be withheld or stopped for 72 h. If a computed tomography (CT) scan at that time reveals little or no hemorrhage, heparin should be administered to maintain an aPPT at the lower end of the therapeutic level (Table 61-4) until warfarin, started at the same time, results in the desired INR (see Tables 61-2 and 61-3). If the CT scan demonstrates significant hemorrhage, antithrombotic therapy should be withheld until the bleed is treated or has stabilized (7 to 14 days). Anticoagulation can then be started as just described.

LONG-TERM MANAGEMENT

If the embolic event occurs when a patient is *off* antithrombotic therapy, long-term warfarin therapy is required (see Tables 61-2 and 61-3). An exception may be those with mitral valve prolapse; aspirin (325 mg/day) is recommended for those who are judged to have had a minor event. If the embolic event occurs while the patient is *on* antithrombotic treatment, therapy should be individualized. Those who are on warfarin but in whom the INR was low at the time of the embolus should have the dose increased into the high end of the desired range (see Tables 61-2 and 61-3). If the embolus occurs in a patient despite an INR in the desirable range, aspirin (50 to 100 mg/day) should be added to the warfarin. Embolism recurring with this combination should lead to consideration of possible valve surgery if the valve is the likely source of the thrombus.

Therapy at the Time of a Bleed

With significant bleeding, antithrombotic therapy should be stopped and, if the patient is at risk, drug effects should be reversed. If possible, the site of bleeding should be corrected and antithrombotic therapy restarted as soon as possible. If this is not possible, treatment decisions are difficult. In patients with a

mechanical prosthesis or multiple risk factors for thromboemboli, acceptance of intermittent bleeding with acute management for the bleeds may be necessary. In valve patients who are at lower risk of emboli or in whom the role of antithrombotic treatment is less clear (e.g., LV dysfunction), it may be optimal to withhold chronic therapy or, if a patient is on warfarin, to switch to aspirin. In some patients with mechanical valves, consideration should be given to replacing the mechanical valve with a biological valve, for example, in those who have had multiple, large life- or organ-threatening bleeds.

Antithrombotic Therapy in the Patient with Endocarditis

If a patient with valve disease develops endocarditis, antithrombotic therapy should be continued.[2,56] If the patient presents with or develops an embolic event involving the central nervous system, therapy should be as described above for acute embolic events. Additionally, the issue of whether or not the embolus is due to thrombus or infected vegetation should be addressed. If thrombus is likely, the chronic anticoagulation program will also require alteration.

Part 10: CONGENITAL HEART DISEASE
Chapter 62:

CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

Authors: Jeffrey A. Towbin, Robert Roberts

Genetic factors play a significant role in the pathogenesis of many if not all cardiovascular disorders. Malformations of the heart and blood vessels account for the largest number of human birth defects, occurring in about 1 percent of all live births; among stillbirths, the prevalence is estimated to be tenfold higher.[1,2] In conjunction with cytogenetics (the study of chromosomes and their abnormalities), molecular genetics provides an opportunity to decipher the genetic basis of cardiovascular diseases. Genetic diagnosis and screening for genetic disorders will soon be incorporated into standard practice.[3] The goal of the Human Genome Project[4] is to identify all of the genes by the year 2001 (see Chap. 7).[5] The challenge for the clinical and investigative cardiologist is to link these genes to their specific physiologic or pathologic function.[6] It is thus imperative that the cardiologist understand the basis for genetic disorders so as to have a better appreciation of the medical, ethical, and moral implications.[7]

BASIS FOR GENETIC TRANSMISSION

All hereditary information is transmitted through DNA, a linear polymer composed of purine (adenine, guanine) and pyrimidine (cytosine, thymine) bases (see Chap. 4). The basic hereditary unit is the gene, which consists of a distinct fragment of DNA that encodes for a specific polypeptide (protein). It is estimated there are only about 100,000 genes, although there is enough DNA to code for several hundred thousand genes. However, less than 5 percent of the DNA is used to code for genes. Each individual has two copies of each gene-called alleles. The genes are localized in linear sequence along 23 pairs of chromosomes, the rod-shaped bodies derived from the parents of each individual. Each parent contributes one member of each chromosome pair (the pair is referred to as *homologous chromosomes*) and thus one copy of each gene. The site at which a gene is located on a particular chromosome is called the *genetic locus*. A given gene always resides at the same specific locus on a particular chromosome, so the loci on homologous chromosomes are identical but the alleles residing at these loci may be the same or different. When the same loci on two homologous chromosomes have identical alleles, the individual is homozygous. When the two genes differ (i.e., two different alleles present at the locus), the individual is heterozygous at that locus. Each individual is homozygous at some loci and heterozygous at others, and, based on present knowledge, at least one-third of human genes have polymorphic forms. The gene, transmitted to each offspring during the union of sperm and ova, passes on the genetic information to the offspring (genotype), which, through the synthesis of their corresponding proteins, determines the observable characteristics of an individual (phenotype). The genetic information carried in the gene's DNA is coded by the sequence of the four bases. Translation of this information into protein is through a translational code passed on through messenger ribonucleic acid (mRNA), whereby each specific amino acid is encoded by three bases referred to as a *codon* (Chap. 4). The mRNA transcribed from the gene serves as the template that determines which amino acids are included and their sequence in the resulting polypeptide. Although it is true each gene encodes for a unique protein, it is preferable to use polypeptide, since many proteins are single polypeptides and other proteins consist of several polypeptides which may be from a single gene or multiple genes. The 23 pairs of chromosomes include 22 pairs of autosomes (chromosomes 1 to 22) and one pair of sex chromosomes, X and Y. Females have two X chromosomes, while males carry one X and one Y chromosome. Both autosomal alleles are

potentially active in specifying RNA copies of their DNA sequences, but the expression of each gene depends on the cell type, developmental stage, and regulatory molecules that interact with promoter sequences, and enhancer sequences that control gene transcription. In cells that carry two X chromosomes, whether these are derived from normal females or XXY individuals with Klinefelter syndrome, only one X is active after early embryogenesis.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

ORIGIN OF GENETIC DISEASE

The three broad categories of inherited diseases are chromosomal abnormalities, single gene disorders, and polygene disorders (Table 62-1). Thus, hereditary and congenital diseases may be due to chromosomal abnormalities or mutations within a single gene or multiple genes. A mutation is a stable, heritable alteration in DNA caused by a number of factors, including environmental agents such as radiation, chemicals, and viruses as well as baseline changes in the fidelity of transfer of sequences. Since offspring typically resemble their parents, it is assumed that the DNA nucleotide sequences remain stable. Base sequence changes do occur, however, albeit at a slow rate compared to the overall life span of humans, and these changes occur by a number of different mechanisms. Mutations can involve a visible alteration at the level of the chromosome, such as deletion or translocation of a portion of the chromosome, whereby often several genes are eliminated or altered. Chromosome alterations (discussed later), especially those involving too many or too few chromosomes (called an euploidy), are quite common in human development. The sequence of each codon determines the amino acid, and the linear sequence of the codons in the mRNA is collinear with the linear sequence of the amino acids in the protein. A change in even one amino acid, if critical to the function of the protein, will result in altered function or lack of function, with a concomitant change in the phenotype. Since proteins are the working molecules derived from genes, mutations in genes exert their deleterious effects via structural alteration of the proteins, whether they be enzymes, regulatory proteins, or structural proteins. On the average, a mutation occurs every 106 cell divisions, and, obviously, only mutations occurring in the gametes are transmitted. On the average, a gene undergoes one mutation per 200,000 years.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

GENETICS OF SINGLE-GENE DISORDERS

Inherited disorders due to a single abnormal gene are transmitted to offspring in a predictable fashion termed *mendelian transmission*. These inheritance patterns produce phenotypes that are inherited according to Mendel's laws of inheritance. As previously noted, in each individual there exists two copies of each gene, referred to as alleles, one obtained from the mother and one from the father. Mendel's first law states that each of the two alleles located on separate chromosomes segregates independently and is passed unchanged into different gametes at the formation of the next generation. Thus, the odds of getting the mother's allele versus the father's are by chance alone, namely, 50 percent. Mendel's second law states that genes on the same chromosome also assert themselves independently through the process of crossover between chromosomes (discussed below). The greater the distance between two loci, the more likely they are to be separated during genetic transmission. As a result of gene mutations, abnormal genes located on any of the 22 autosomal pairs or the two sex chromosomes may produce phenotypes inherited by simple patterns classified as autosomal (dominant or recessive) or X-linked, respectively. When different genes induce the same phenotype, it is referred to as *genetic heterogeneity*, and most diseases in humans exhibit genetic heterogeneity. The same disease may be due to multiple mutations in the same gene (*allele heterogeneity*) or it may be due to a single or multiple mutations in two or more genes (*locus heterogeneity*). Within any one family, however, the gene and the mutation responsible for the disease are the same and only rarely would two genes be transmitted for the same disease. A good example is familial hypertrophic cardiac myopathy (HCM), in which eight different genes have been recognized with multiple mutations in each. Genetic heterogeneity is to be distinguished from polygenic disorders, such as atherosclerosis, which are due to the interaction of several genes. As noted above, mutations can involve a microscopically visible alteration, such as deletion or translocation of a portion of the chromosome, or they can involve a minute change in one purine or pyrimidine base in the DNA sequence of a single codon. Mutations involving only a single nucleotide are known as point mutations and are responsible for 70 percent or more of all adult single gene disorders (Table 62-2). A point mutation may be a substitution of one nucleotide for another, resulting in a different amino acid being encoded (missense mutation); or it may change the codon from encoding for an amino acid to that of a stop codon, which will truncate the protein (truncated mutant); or it may eliminate a stop codon so the protein is elongated (elongated mutant). Finally, a nucleotide may be deleted or added, which results in a frame shift, and the gene is read entirely differently (nonsense mutation), resulting in a nonfunctioning protein. If a purine nucleotide is substituted for a pyrimidine, the mutation is referred to as a *transversion*, while if purine or pyrimidine substitutes for another purine or pyrimidine, respectively, it is called a *transition*. Other mutations may result from deletion or addition of several nucleotides. An example of the latter is the defect responsible for myotonic dystrophy, where a triplet repeat of several thousand nucleotides in length is inserted into the 3′ end of the gene. Another type of mutation is known as *gene conversion*, where two genes interact and part of the nucleotide sequence of one gene becomes incorporated into the other. Mutations in genes exert their deleterious effects via structural alteration of enzymes, regulatory proteins, or structural proteins. The terms *dominant inheritance* and *recessive inheritance* refer to characteristics of the phenotype and are not characteristics of the gene per se. Dominant inheritance implies that a person with one copy of a mutant allele and one copy of the normal allele develops a phenotype of the mutant allele. Recessive traits, on the other hand, require both alleles to be mutant to develop a phenotype. This situation usually occurs when the patients are consanguineous, with each carrying mutant alleles, or when the mutant allele is common in the population, as is seen in sickle cell anemia.

Genetic Penetrance and Expressivity

The percentage of individuals with a disease-related gene who have one or more features of the disease is referred to as *penetrance*. Penetrance is an all-or-none phenomenon, and any manifestation, however minute, indicates that the gene has full penetrance in that individual. Nonpenetrance refers to lack of any observable phenotype. This feature is to be distinguished from *expressivity*, which refers to the variable nature of the clinical features. Thus, by definition, to have expressivity, the trait must be penetrant. Numerous genetic and environmental factors can affect expression of a gene, making it nearly impossible to determine which factor is most important in a specific individual or specific disease. These factors include (1) genetic background, (2) age-dependency, (3) sex influence and sex limitation, (4) exogenous factors, (5) maternal factors, (6) modifying loci, and (7) gene alterations.

Patterns of Inheritance

AUTOSOMAL DOMINANT INHERITANCE

Dominant disorders are those that have phenotypic manifestations (disease) in heterozygous individuals-persons carrying only one abnormal allele, with the other allele on the homologous chromosome being normal. In autosomal dominant disorders, both males and females can be affected, and since alleles segregate independently at meiosis, there is a 50-50 chance that the offspring of an affected heterozygote will inherit the mutant allele. Not all affected individuals, however, must have an affected parent because, in all autosomal dominant diseases, a certain proportion of cases occur due to a new mutation (i.e., they are sporadic). The parent whose germ cells contain the new mutation will be clinically normal, since the mutation affects only a single germ cell, but will transmit the disease-causing allele to half of his or her offspring. Autosomal dominant inheritance can be misdiagnosed as sporadic if there is low expressivity in the phenotypically normal parent carrying the mutant allele or if extramarital paternity has occurred. The following features are characteristic of autosomal dominant inheritance (Fig. 62-1): (1) each affected individual has an affected parent unless the disease occurred due to a new mutation or the heterozygous parent has low expressivity; (2) equal proportions (i.e., 50-50) of normal and affected offspring are likely statistically to be born to an affected individual; (3) normal children of an affected individual bear only normal offspring; (4) equal proportions of males and females are affected; (5) both sexes are equally likely to transmit the abnormal allele to male and female offspring, and male-to-male transmission occurs; and (6) vertical transmission through successive

generations occurs. Two other features are characteristically seen in autosomal dominant diseases that help to differentiate this type of inheritance from autosomal recessive disorders: delayed age of onset and variable clinical expression. The former is commonly seen in such disorders as familial HCM, while the latter may occur in Holt-Oram syndrome, in which the patient may present with an atrial septal defect (ASD) and skeletal abnormality of the upper extremity in combination or with either of these abnormalities individually. Examples of autosomal dominant primary heart disease include HCM and Romano-Ward long-QT syndrome.

AUTOSOMAL RECESSIVE INHERITANCE

Autosomal recessive phenotypes are clinically apparent when the patient carries two mutant alleles (i.e., is homozygous) at the locus responsible for the disease state. The disease-causing gene is found on one of the 22 autosomes, and thus both males and females will be equally affected. Clinical uniformity is typical, and disease onset generally occurs early in life. Recessive disorders are more commonly diagnosed in childhood than are dominant diseases. Only one in four children (25 percent) on average, will be affected. The following are characteristics of autosomal recessive disorders (Fig. 62-1): (1) parents are clinically normal heterozygotes; (2) alternate generations are affected, with no vertical transmission; (3) both sexes are affected with equal frequency; and (4) each offspring of heterozygous carriers has a 25 percent chance of being affected, a 50 percent chance of being an unaffected carrier, and a 25 percent chance of inheriting only normal alleles. Examples of autosomal recessive disorders affecting the heart include Jervell and Lange-Nielsen long-QT/deafness syndrome and Pompe's (type II glycogen storage) disease.

X-LINKED INHERITANCE

X-linked inherited disorders are caused by genes located on the X chromosome; therefore the clinical risk and severity of disease differ between the sexes. Since a female has two X chromosomes, she may carry either one mutant allele (heterozygote) or two mutant alleles (homozygote); the trait may therefore display dominant or recessive expression. Males have a single X chromosome (and one Y chromosome); therefore they are expected to display the full syndrome whenever they inherit the abnormal gene from their mother. This development of the trait occurs regardless of whether the mother carrying the mutant allele exhibits a recessive (i.e., clinically silent) or dominant (i.e., clinically apparent) trait. Hence, the terms *X-linked dominant* and *X-linked recessive* apply only to the expression of the gene in females. Since males must pass on their Y chromosome to all male offspring, they cannot pass on mutant X alleles to their sons; therefore no male-to-male transmission of X-linked disorders can occur. On the other hand, males must contribute their one X chromosome to all daughters. All females receiving a mutant X chromosome are known as *carriers*, and those who become affected clinically with the disease are known as *manifesting female carriers*. The characteristic features of X-linked inheritance (Fig. 62-1) include (1) no male-to-male transmission; (2) all daughters of affected males are carriers; (3) sons of carrier females have a 50 percent risk of being affected, and daughters have a 50 percent chance of being carriers; (4) affected homozygous females occur only when an affected male and carrier female have children; and (5) the pedigree pattern in X-linked recessive traits tends to be oblique because of the occurrence of the trait in the sons of normal carriers sisters of affected males (i.e., uncles and nephews affected). Examples of X-linked disorders of the heart include X-linked cardiomyopathy, X-linked cardioskeletal myopathy (Barth's syndrome) and those X-linked diseases in which the heart is affected, such as muscular dystrophy (MD) (e.g., Duchenne/Becker and Emery-Dreifuss MD).

MITOCHONDRIAL INHERITANCE

Another inheritance pattern described in patients with cardiovascular anomalies occurs because of abnormalities of the mitochondrial genome. Generation of energy is dependent on the oxidative

phosphorylation process within the mitochondria. Within many mitochondria is a single chromosome that encodes for a number of the enzymes of oxidative phosphorylation (i.e., encodes for 13 of the 69 proteins required for oxidative metabolism) and the transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs) required for their translation. The remaining enzymes of the oxidative-phosphorylation pathway are encoded by genes on the nuclear chromosomes, and the resultant proteins are transported into the mitochondrion. Genetic defects of oxidative phosphorylation, therefore, can be due either to gene mutations within the X chromosome or autosomes (i.e., nuclear chromosomes), resulting in diseases that behave as Mendelian recessive traits, or to mitochondrial genome defects that cause diseases with nonmendelian traits. These differences may be explained by events of conception, since the spermatocyte contributes few or no mitochondria to the zygote (Fig. 62-2). The entire mitochondrial complement present in a fetus must therefore be derived from the mitochondria already present in the cytoplasm of the oocyte. Thus, phenotypes due to mitochondrial DNA mutations demonstrate maternal inheritance only. The characteristic features of mitochondrial inheritance of disease (Fig. 62-1) include (1) equal frequency and severity of disease for each sex; (2) transmission through females only, with offspring of affected males being unaffected; (3) all offspring of affected females may be affected; (4) extreme variability of expression of disease within a family (may include apparent nonpenetrance); (5) phenotypes may be age-dependent; (6) organ mosaicism is common. An example of mitochondrial inherited cardiac disease is the cardiomyopathy of Kearns-Sayre syndrome.

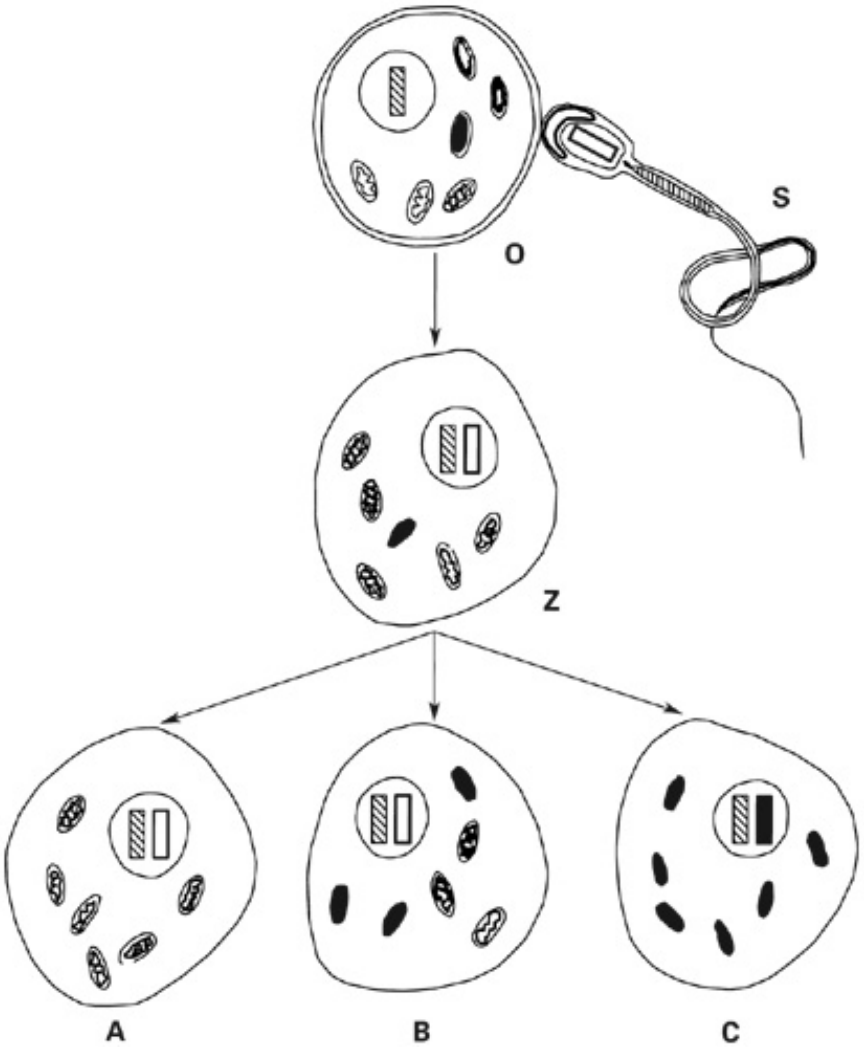

Figure 62-2: Cartoon (not to scale) illustrating maternal inheritance of mtDNA, compared with

biparental inheritance of nuclear genes, and the random distribution of normal and mutant mitochondrial genomes in daughter cells of the zygote. It is assumed for simplicity that individual mitochondria contain either normal (open mitochondria) or mutant (filled mitochondria) mtDNA, not both. O = oocyte; S = sperm; Z = zygote; A, B, C = daughter cells of zygote, representing stem cells of different tissues. (Reprinted with permission from DiMauro S et al. Mitochondrial encephalomyopathies. *Neurol Clin* 1990; 8:494.)

POLYGENIC INHERITANCE OF CARDIAC DISEASE

Disorders such as hypertension or ischemic heart disease are believed to require concomitant mutations in several genes-i.e., they are polygenic hereditary disorders (discussed in Chap. 7). The genes responsible for polygenic hereditary disorders are difficult to map, since computational methods to describe their mode of inheritance are only now being explored.[8] Over the past two decades, this type of inheritance has been invoked for a large number of disorders, including coronary artery disease and congenital heart disease. In multifactorial, or polygenic, genetic diseases, multiple genes interact in a cumulative fashion to induce the disease or provide an increased risk of developing the disease. This multifaceted process is illustrated by coronary artery disease, in which one common phenotype is myocardial infarction due to thrombosis superimposed on atherosclerosis. There are many single-gene disorders that alter plasma lipoproteins and contribute to atherosclerosis (see Chaps. 7, 35, and 38). Several other genetic risk factors have been identified that predispose to atherosclerosis, such as the paraoxonase gene or homocysteine gene.[9] The phenotype of acute myocardial infarction is more likely if the individual, in addition to atherosclerosis, has a mutant form of fibrinogen[10] or mutant forms of other clotting factors, discussed in detail in Chap. 7.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

OVERVIEW OF CHROMOSOMAL MAPPING AND IDENTIFICATION OF A DISEASE-RELATED GENE

Identification of a disease-causing gene, in the setting where the protein is unknown, was until the 1980s nearly impossible. Familial hypercholesterolemia and some of the thalassemias are disorders in which genes were isolated and cloned, knowing the protein. For the majority of diseases, however, neither the defect nor the protein is known. Technical advances[11] aiding chromosomal mapping include (1) computerized linkage analysis, (2) development of highly informative DNA markers, and (3) detection of markers by polymerase chain reaction (PCR).[11] The 46 chromosomes of the human genome contain 3 billion base pairs (bp). To locate a particular gene, one must first map the chromosomal location and its relative position. This process requires certain chromosomal landmarks. Identification of a particular locus is made possible by showing that the disease-related gene of interest is on the same chromosome and in close proximity to one of these landmarks, a method referred to as *genetic linkage analysis*. This technique requires a family with a disease that is transmitted over at least two generations (and preferably three) with at least 10 affected individuals, although even 6 or 7 affected individuals may be adequate, depending on the structure of the family. A landmark, referred to as a DNA or chromosomal *marker*, is a polymorphic sequence of DNA, the chromosomal position of which is known and can be detected by analyzing an individual's DNA (discussed in detail below). A major limitation until recently was the lack of markers evenly distributed across each of the chromosomes. Today there is a marker available at least every 1 million base pairs on all chromosomes.[12,13] Genetic distance is measured in terms of centimorgans (cM), named after the geneticist T. H. Morgan, and 1 cM approximates 1 million bp. Markers, like genes, have two alleles and are transmitted to offspring according to Mendel's law, with the individual being heterozygous or homozygous for that marker. If a marker is homozygous, it is not informative for genetic linkage. Hence, several markers in the same region may have to be analyzed to find one that is heterozygous in that individual. When all of the markers are placed together on each chromosome and the genetic distance between them is estimated, a *genetic map* is produced. A map of over 5000 highly informative markers has been developed, which has significantly accelerated the mapping of disease-related genes-an achievement that provides the foundation for genetic linkage analysis.[13] Each gene, allele, or marker is transmitted independently; thus, the odds of any two genes (or a marker and a gene) being coinherited are by chance alone (50 percent), even though they are on the same chromosome. The homologous pairs of chromosomes are assorted, and one from each parent is transmitted to the offspring by chance. Genetic diversity from homologous chromosomes segregating independently would produce 223 types of gametes; in other words, the probability of an offspring inheriting a set of chromosomes identical to those of a parent is one in 8,388,608.[14] If this were the only mechanism for diversity, all of the genes on a particular chromosome would be coinherited in the next progeny. This does not happen. Genes on the same chromosome are transmitted independently unless they are in close physical proximity to each other. Genes on the same chromosome are transmitted independently by the mechanism of crossover between homologous chromosomes (Fig. 62-3), which provides continual mixing of the genes during every meiosis and is the predominant reason why no two individuals have the same genotype unless they are identical twins. Prior to meiosis, the two homologous chromosomes come together and form bridges (*chiasmata*) such that segments of equal proportion are exchanged between them, giving rise to crossover of various genes. There is no net loss of chromosomal material or genes, but crossover leads to a constant intermixing of the chromosomes such that no two offspring will ever be identical. Crossovers occur only between homologous chromosomes. The loci occupy the same chromosomal position on the homologous chromosome

on which they are combined as they had on their original homologous chromosome. On average there are 33 crossovers between homologous chromosome pairs per meiosis.[14] In genetic parlance, crossing over is referred to as recombination.

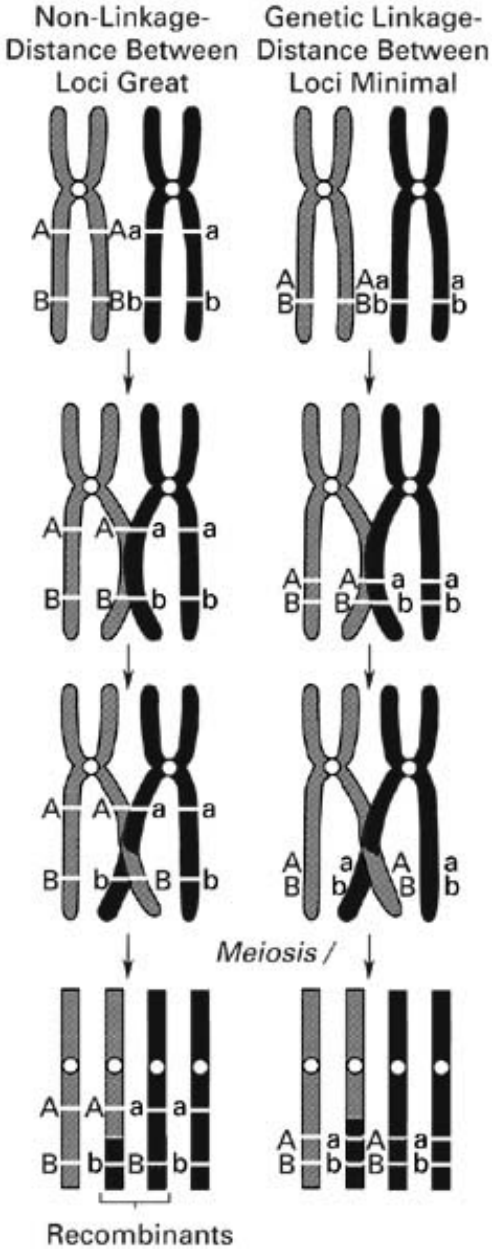

Figure 62-3: Comparison of nonlinked genes (*left*) and linked genes (*right*). In nonlinkage, the distance between loci is large, allowing crossing over to occur and resulting in recombinants after meiosis. The distance between linked genes is comparatively small, thereby minimizing the chance for recombinants.

Concept of Genetic Linkage Analysis

Despite the independent assortment of chromosomes and genes, the genes (alleles) on two or more loci are often coinherited because they are so close together that the chance of a chiasmatic bridge forming between them is less likely. Thus, breakage and recombination of the chromosomes does not occur and they tend to be coinherited more often than by chance alone; by definition this means the two loci are in genetic linkage. Any two loci coinherited more than 50 percent of the

time are said to be genetically linked.[15] To map the chromosomal locus responsible for a disease-related gene, one selects DNA markers that are evenly distributed across the chromosomes. DNA is collected from all the members of a family (normal and affected) and analyzed for these markers. If one or more DNA markers is coinherited in more than 50 percent of the affected individuals, the locus where the marker resides is on the same chromosome and in close physical proximity to the locus of the gene responsible for the disease. This is referred to as *genetic linkage* between the disease (gene) and the marker. Once a disease is linked to a marker of known chromosomal locus, it follows that the disease locus is on the same chromosome and in close proximity. The concept of linkage analysis is illustrated in Fig. 62-3. Shown in the panel at the right is an illustration of genetic linkage between a locus for a DNA marker and that of a disease that is inherited in a mendelian dominant fashion. The locus, designated with an "A," carries the allele responsible for the disease. The corresponding locus, "a," on the homologous chromosome has the allele that codes for the same protein but has not undergone a mutation and is thus the normal allele. The loci designated "B" and "b" represent alleles of a DNA marker of known location that has nothing to do with the disease. In the panel on the right, the disease and the marker loci are so close that they tend to be coinherited within the family, whereas in the panel on the left, the DNA marker of known location is so far from the locus carrying the disease allele it is not coinherited but separate by chance. The calculation necessary to prove definitively that genetic linkage exists between a marker and a disease-related locus is sophisticated and requires advanced computer programs. The odds for and against linkage are calculated, and linkage exists if the odds in favor of linkage are at least 1000:1. To avoid the cumbersome ratio (1000:1), the logarithm to base 10 is derived, which is 3 (i.e., 10^3), and is referred to as the LOD score (log of the odds). If the LOD score is -2 (i.e., 10^{-2} or 100:1 odds against linkage), it excludes linkage. The likelihood of two genes being separated by recombination increases in proportion to the distance between them. The distance between a marker and a disease-causing gene when genetically linked is quite variable and may be anywhere from 1000 kilobase pairs (kbp) to 50,000 kbp but is usually within 1000 to 10,000 kbp.[16] The inherent resolution of genetic linkage analysis is never better than 1000 kbp. It is possible on the basis of linkage analysis alone to construct a chromosomal map of all the markers, with the distance between the various markers estimated in centimorgans. This is a complex calculation derived from the number of recombinations between the markers during meioses. The recombination frequency between two markers, two genes, or a gene and a marker is the ratio of the number of crossover events to the total number of meioses. The lower the recombination frequency between the locus of a marker and that of a disease-related gene, the closer those two must be in physical distance on the chromosome. Even though the locus of the marker and that of the disease-related gene are in close enough proximity to be genetically linked, recombination may occur, and the extent to which recombination does occur reflects roughly the physical distance between the two loci. The recombination fraction (or *theta*) is used to develop a means of estimating the genetic distance (in centimorgans) between genetically linked loci. A recombination frequency or crossover of 1 percent between two loci, whether occupied by two genes or one gene and a marker, reflects a physical distance between them of approximately 1 million bp (1 cM).[16] For a marker and a gene separated by 1 cM, this means the chance of a crossover between them during meiosis is only 1 percent; thus, the chance of being coinherited is 99 percent. This is a statistically derived genetic map, however, and the distances are only approximate. The correlation between the percent crossover and the physical distance in base pairs varies somewhat from chromosome to chromosome and from region to region even on the same chromosome. For example, recombination is more frequent in the telomeric than in the centromeric portion of the chromosome and is also more frequent in females. If the marker locus and the disease-related locus are close, such as 5 to 10 cM, then a single crossover may be uncommon and a double crossover rare. Two loci may be 20 to 40 cM apart, however, and a double crossover occurs, which recombines the locus with the original chromosome and leads to coinheritance of the two (linkage of the two loci). When this occurs, the genetic distance is misleading and represents a gross underestimation of the true physical distance between the two loci.

Chromosomal Markers and Their Identification

A chromosomal marker (as defined above) is any DNA sequence of known chromosomal location that is polymorphic for the population (two or more alleles). The greater the number of alleles, the more informative the marker. When compared between individuals in the population, the DNA of the human genome shows a difference in the nucleotide sequence (polymorphism) every 300 to 500 bp. Polymorphisms occur more frequently in the sequence of the unexpressed DNA (intron) than in DNA coding for proteins (exon). Until recently, the most common chromosomal marker was that of restriction fragment length polymorphism (RFLP)[17] identified by Southern blotting. These markers have been replaced by what are referred to as short tandem repeat polymorphisms (STRP),[18] which occur more frequently, are more informative, and are more conveniently and rapidly detected than are RFLPs[19] (Fig. 62-4). Distributed throughout the human genome are repeats of dinucleotides, trinucleotides, or tetranucleotides that are repeated in tandem (microsatellites) and may vary anywhere from 60 to 300 repeats. The number of tandem repeats of STRPs, which provide for marked polymorphism, occur about every 500 bp throughout the human genome. The dinucleotide repeats of cytosine-adenosine are more common than trinucleotide or tetranucleotide repeats. A major advantage of STRPs is rapid and convenient detection by PCR rather than requiring Southern blotting, as is necessary for RFLPs. PCR requires only a nanogram of DNA as opposed to a milligram for RFLPs, and results are available in only 1 to 24 h as opposed to 9 to 10 days for Southern blotting. The resolution of STRPs detected by PCR is much better than by Southern blotting and, since STRPs have multiple alleles (as opposed to RFLPs, which have only two alleles), they are much more informative for genetic linkage. A more recent marker is that of single nucleotide polymorphism, which may represent the markers of the future.[17-19]

Identification of the Gene

Once the chromosomal location of a gene has been mapped, the first technique in attempting to identify the gene is referred to as the *candidate gene approach*. Over 5000 loci have now been mapped for human genes and over 1000 genes recorded in a gene bank. In addition, there are over 50,000 expressed sequenced tags (ESTs) mapped. The ESTs are unique DNA sequences of 100 to 200 bp, each of which is believed to represent a unique gene.[20] These genes and ESTs are entered through a worldwide network of databases[21] in the United States, Europe, and Japan that is updated on a daily basis. Once a locus is identified on a chromosome, genes previously known to be localized to that region become candidate genes for the newly mapped locus. These genes are amplified, usually by PCR, to determine if there is a mutation that segregates with the disease. If none of the candidate genes in the region is shown to have a mutation that cosegregates with the disease, it may be necessary to clone the region. This approach is referred to as *positional cloning*, so named because a region is cloned knowing only its position relative to the genetically linked marker. Positional cloning is usually not attempted unless the region (containing the gene) between the flanking markers is 1 cM or less. To reduce the region for cloning, it is necessary to expand the family with the hope of finding crossovers such that markers common to all affected would span only a short distance (<1 cM). This collection of markers in a region would represent the haplotype being inherited by the affected individual and contains the responsible gene. To prove that the gene causes the disease, the mutation must be identified and shown to cosegregate with the disease and not with the unaffected members in the family. The remaining task would be to determine the gene product (protein) and the pathophysiology of how the mutation induces the disease. In attempting to decipher the pathophysiology, one may transfect cells in culture with normal and mutant forms of the gene and compare the resulting phenotype. The other definitive approaches for determining causality are to overexpress the gene as a transgene in animals such as mice or to do homologous knockout, replacing the normal with the mutant gene to determine whether the disease phenotype is induced as have been done for familial hypertrophic cardiomyopathy (FHCM).[22-24] Chromosomal mapping of hereditary diseases by linkage analysis

and subsequent isolation of the gene[25] are summarized in Table 62-3.

Table 62-3: Chromosomal Mapping and Identification of a Gene

1. Identification of a family with a familial disease
2. Collection of clinical data from the family
3. Clinical assessment to provide an accurate diagnosis of the disease using a consistent and objective criterion to separate normal individuals from those affected and from those that are indeterminate or unknown
4. Collection of blood samples for immediate DNA analysis and development of lymphoblastoid cell lines for a renewable source of DNA
5. Development of a family pedigree
6. DNA analysis for markers of known chromosomal loci that span the human genome in an attempt to find a marker locus linked to the disease
7. Identification of the gene
8. Identification of mutation(s) causing the disease
9. Demonstration of a causal relationship between the mutant gene and the disease
10. Development of a convenient test to screen for the mutations

---

Family History and Evaluation

The most important part of an evaluation for genetic disease is the family history. First, the family history may give clues to the diagnosis of a particular disorder, information about possible inheritance patterns within an individual family, and information about conditions for which family members may be at an increased risk. An individual's ethnic background may, for instance, suggest the need for specific types of genetic screening such as for hemoglobinopathies in individuals of African or Mediterranean ancestry or for Tay-Sachs disease in individuals of eastern European (Ashkenazi) Jewish ancestry. The individual with the medical problem who brought the family to the attention of the physician is referred to as the *proband*, or *propositus* (proposita for females). Information generally should be collected on all individuals who are first-, second-, or third-degree relatives of the proband. First-degree relatives of the proband are the parents and children. Second-degree relatives are aunts and uncles, grandparents, and grandchildren of the proband. Third-degree relatives are first cousins, great aunts and uncles, great-grandparents, and great-grandchildren. A pedigree chart (as shown in Fig. 62-1) is useful in this task. This information should include medical problems and pregnancies. If relatives are deceased, the age at death and the cause of death should be recorded. With a pedigree chart and specific family information, more general questions are asked, including whether other family members have the same or similar problems. Information about various types of birth defects, mental retardation, early infant deaths, miscarriages, stillbirths, or other diseases or handicaps in the family is sought. With some disorders, there may be a variability of a particular condition (i.e., clinical heterogeneity), even within a family. For example, with a possible diagnosis of FHCM, one should ask about premature death or syncope. A pregnancy history may provide information to support a possible teratogenic exposure. The date of the last menstrual period, whether the pregnancy was planned, whether contraception was used immediately prior to pregnancy, the time when the pregnancy was recognized, and when the mother sought prenatal care should be noted. Problems during the pregnancy, such as bleeding, spotting, cramping, fevers, rashes, or illnesses; drug exposures (both prescribed and nonprescribed), alcohol intake, or "recreational" drug use; and exposures to potent chemicals in the workplace or while involved in various hobbies should be explored. Pregnancy and family histories can then be used in conjunction with the findings on physical examination to derive a potential etiologic diagnosis and to plan for further diagnostic studies. The term *etiologic diagnosis* should suggest whether a specific cardiac defect is familial

(by family history), genetic but not familial (sporadic), teratogenic (by pregnancy history), or multifactorial. Prognosis and recurrence risk are linked strongly to an accurate diagnosis and its probable etiology.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

GENETIC COUNSELING PRINCIPLES

Genetic counseling should provide information about the diagnosis, its possible etiology, and its prognosis. In addition, psychosocial issues, reproductive options, and the availability of prenatal diagnosis should be discussed. Genetic counseling should be nondirective, providing information in a nonjudgmental, unbiased manner. The family should then be able to make decisions based on medical information in the context of their religious, moral, cultural, and social backgrounds and their financial situation. Although a genetic counselor may occasionally feel frustrated with a specific couple's decision, an effective counselor does not let personal biases interfere with the counseling role. Conflicts leading to major ethical issues and disputes may arise, however, and may be particularly apparent regarding issues of nonpaternity, sex selection, pregnancy termination, and selective nontreatment of malformed infants. Couples have many reproductive options, but not all may be acceptable religiously or culturally. Nevertheless, potential options should be mentioned in a sensitive manner. A common misunderstanding among families in genetic counseling is the issue of prenatal diagnosis and its relationship to abortion. Prenatal diagnosis does not imply that a parent should or would terminate the pregnancy. In many circumstances, the information from prenatal diagnosis may help to reassure a couple that their risk of having another handicapped child is in fact much lower than expected. Conversely, if defects are found, the subspecialist may use more diagnostic approaches to make rational decisions about medical management of the infant prior to or immediately after delivery.

Genetic Diagnosis and Health Insurance

The accelerated pace of gene discovery, molecular medicine, and molecular diagnostics has begun to allow for improved genetic counseling and portends the possibility of future genetic therapy. As knowledge about the genetic basis of disease grows, however, so does the potential for health insurance coverage discrimination to be used to exclude individuals at risk or to change prohibitively high rates on the basis of predetermined illness. For this reason, planners of the Human Genome Project recognized the need to protect individuals who volunteered for genetic study as well as those diagnosed by molecular methods in the future. Also for this reason, the National Institutes of Health-Department of Energy (NIH-DOE) Working Group on Ethical, Legal, and Social Implications (ELSI) of the Human Genome Project was developed. The Congress has passed a bill prohibiting companies from using DNA analysis to assess genetic risk as a basis for hiring. Only 11 states, however, prohibit the use of DNA analysis to determine who should get medical insurance or whether they qualify for high- or low-risk premiums.[7]

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

CARDIOVASCULAR DISEASE DUE TO SINGLE-GENE MUTATIONS

Compensatory Response of the Heart Is Limited to Hypertrophy, Dilatation, or a Combination

The heart responds to stimuli, physiologic or pathologic, which may be inherited or acquired, with hypertrophy, dilation, or a combination of the two.[26] The same mechanisms mediate the growth response to pressure overload, volume overload, or loss of contractile mass (myocardial infarction). In FHCM, hypertrophy occurs without altered workload. In familial dilated cardiomyopathy (DCM), the heart responds predominantly by dilatation, generally in association with diffuse loss of myocytes and fibrosis. Most inherited defects are associated with hypertrophy. Several mutations in the mitochondrial genome have been associated with cardiac hypertrophy or dilatation.[27,28] In mitochondrial DNA mutations, HCM or DCM is usually part of a general phenotypic expression of a systemic disease that is characterized by metabolic disorders and involving the central nervous and the skeletal muscle systems. Three clinical categories of primary cardiomyopathies exist: (1) hypertrophic, (2) dilated, and (3) restrictive forms. Most of the cardiomyopathies other than those caused by infection have a genetic basis, although many of the mutations may occur de novo and are not necessarily familial. Only when a genetic defect is present in the germline and transmitted to one or more generations is it familial. For a detailed discussion of the clinical features, diagnosis, and treatment of the cardiomyopathies refer to Chaps. 64 to 69.

Familial Hypertrophic Cardiomyopathy (FHCM)

GENETIC BASIS

Familial HCM is an autosomal dominant disorder characterized by myocardial hypertrophy with a wide spectrum of symptoms, including dyspnea, chest pain, and syncope. The annual mortality rate of 2 to 4 percent is primarily due to sudden death, which often occurs in asymptomatic individuals (see Chap. 67). This disorder is the leading cause of sudden death in the young and in athletes. The annual incidence of sudden death is higher in younger patients with FHCM (about 6 percent) than in the elderly (1 percent). The diagnosis is based on typical clinical features and the demonstration of unexplained left ventricular, right ventricular, or biventricular hypertrophy on two-dimensional echocardiography. The left ventricular hypertrophy is commonly asymmetrical, localized to the septum, but it may involve the entire ventricle in a concentric pattern. Isolated right ventricular hypertrophy occurs in fewer than 5 percent. Isolated apical hypertrophy is rare except in Japan, where it is claimed to account for 20 to 30 percent of the cases. Dynamic outflow tract obstruction occurs in about 30 percent.[29,30] Histologically, the myocardial hypertrophy consists of myocyte hypertrophy, cellular and myofibrillar disarray, and myocardial fibrosis. The literature suggests that the hallmark of FHCM is myocyte and myofibrillar disarray (see Chap. 66). The disorder exhibits marked variability of expressivity, even in the same family. FHCM was the first primary cardiomyopathy to yield to molecular genetics. Jarcho et al. in 1989 showed genetic linkage of the disease to the chromosomal locus of 14q1 in a large French/Canadian family.[31] The 14q1 locus subsequently was shown to be involved in FHCM in several families throughout North America.[32] The β-myosin heavy chain (βMHC) gene was identified as the responsible gene (Fig. 62-5), and over 50 mutations have been detected.[11,33,34] A total of eight genes have now been identified responsible for FHCM and a brief description of the loci and

the proteins they encode, together with their function, is summarized in Table 62-4. Mutations in the βMHC gene may account for 30 to 50 percent of the families with FHCM.[33] While it remains to be determined for certain, these eight genes probably account for 80 to 90 percent of the disease of FHCM. Two other loci have been identified, one in a family with HCM and Wolff-Parkinson-White (WPW) syndrome mapped to 7q3[35] and the other to chromosome 11q in a Japanese family.[36] Since all of the genes identified to date involve the sarcomere, it has been proposed that FHCM is a disease of the sarcomere and perhaps should be referred to as *sarcomeropathy*.[34]

The βMHC is the most common gene for FHCM and over 50 mutations have been described. Almost all of the mutations are point mutations (a single base nucleotide) that result in substitution of one amino acid for another and are located in the globular head of the myosin molecule. These mutations appear to arise independently.[37] The frequency of each particular mutation is low. Two hot spots, codons 403 and 719, have been identified for mutations in the βMHC in patients with HCM.[38,39] Mutations in the rod region of the βMHC molecule have also been described but are uncommon and appear to induce a mild phenotype.[40]

PROGNOSIS FROM GENOTYPE-PHENOTYPE CORRELATIONS

The hypertrophy of FHCM is markedly variable in its degree, distribution, and age at onset as well as in the type and severity of its associated clinical manifestations.[41-43] The natural course of FHCM in certain families is riddled with sudden cardiac death, whereas in others, sudden cardiac death is almost absent and the life span is essentially normal.[34] None of the clinical features are reliable predictors of sudden death. Hypertrophy, while present in all individuals, since it is required for the clinical diagnosis, does not correlate with the incidence of sudden death. FHCM due to mutations in the troponin T gene is associated with a high incidence of sudden death, yet there is often minimal hypertrophy.[44] The occurrence of palpitations, arrhythmias, or syncope are poor predictors of sudden death. A family history of sudden death usually indicates that the affected individuals in the family are at risk for sudden death. Several studies have now been performed correlating the genotype to the phenotype and several interesting observations have evolved pertinent to the diagnosis and treatment and future genetic screening. Results of these studies[45] have shown that the majority of families with the βMHC mutations $Arg^{403}Gln$, $Arg^{453}Cys$, and $Arg^{719}Trp$ are associated with a poor prognosis and a high incidence of sudden cardiac death[34,42,43,46] (Fig. 62-6). In contrast, the βMHC mutations $Leu^{908}Val$, $Gly^{256}Glu$, and $Val^{606}Met$ are associated with near-normal life expectancy, and mutations $Glu^{930}Lys$ and $Arg^{249}Gln$ are associated with an intermediate risk of sudden cardiac death.[47] The incidence of premature death in affected individuals with $Arg^{403}Gln$ is approximately 50 percent,[34] and the mean age of sudden cardiac death is 33 years. The life expectancy of affected individuals with the βMHC mutation $Arg^{719}Gln$ appears to be about 38 years and in those with $Arg^{453}Cys$ about 30 years. In contrast, the mutation $Leu^{908}Val$ is associated with low penetrance, a benign course, and a low incidence of sudden cardiac death.[46] The cumulative survival rate at 60 years of age was 92 percent with this mutation. Similarly, the $Gly^{256}Glu$ and $Val^{606}Met$ mutations are associated with a relatively benign course, with most individuals having a near-normal life span. In contrast, the two mutations $Glu^{930}Lys$ and $Arg^{249}Gln$[46,47] show an intermediary prognosis, with an average age of onset of cardiac failure and severe symptoms around 49 years. These correlations must be interpreted with caution, however, as the number of families studied remains too small for definitive generalizations to be made. Although most individuals affected with FHCM due to the βMHC mutation manifest the disease in the second or third decade of life, those with FHCM due to myosin-binding protein C mutations frequently do not develop any evidence of the disease until the fourth or fifth decade.[48] This is a striking example of age-dependent penetrance based on 16 families involving over 500 individuals. However, once the disease develops, the particular

mutation is highly predictive of risk for sudden death. Mutations in the essential light chain (3p) and the regulatory light chain of myosin (12q23-q24.3) of patients is associated with a peculiar form of HCM in which mid-left ventricular chamber thickening occurs due to massive hypertrophy of the papillary muscles and adjacent ventricular tissue, resulting in mid-cavitary obstruction.[49] In addition to the cardiac abnormalities described, the skeletal muscles of these patients were histologically abnormal and appeared as ragged-red fibers.

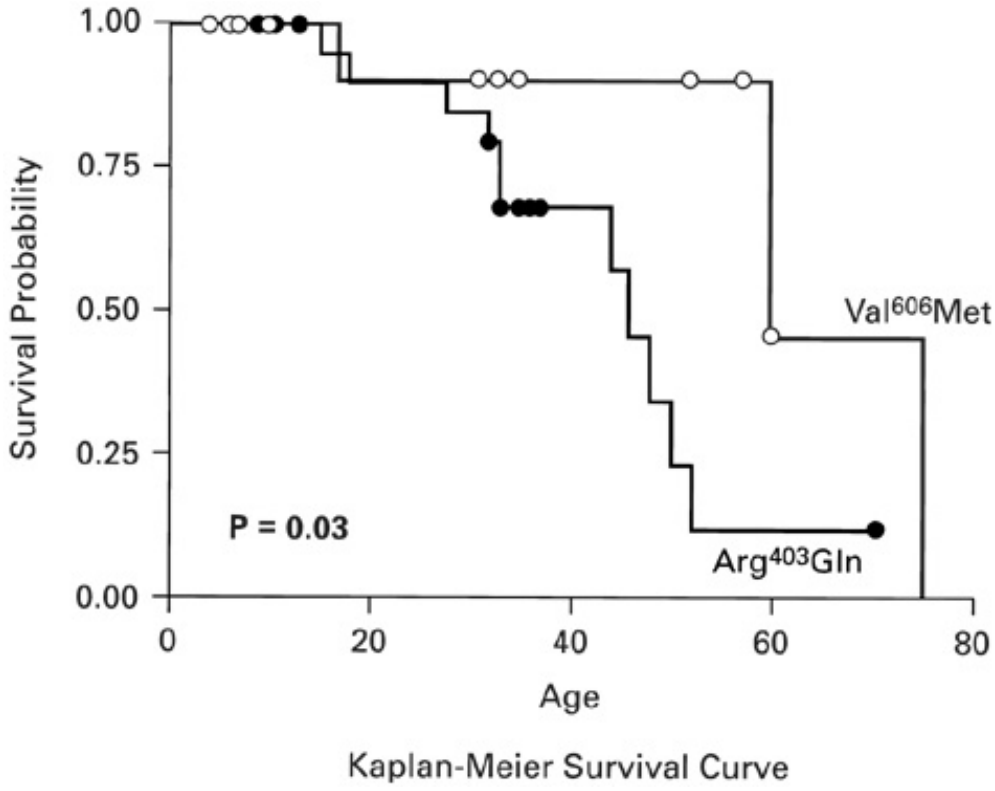

Figure 62-6: Kaplan-Meier survival curve in patients with hypertrophic cardiomyopathy depending on myosin heavy chain mutation.

INFLUENCE OF OTHER GENES AND THE ENVIRONMENT

While a single-gene mutation appears to be the primary cause of the disease, there remain significant environmental and other genetic influences that determine whether or not the phenotype develops (penetrance) and its expressivity. A striking example of the influence of environment on FHCM is the observation that hypertrophy seldom develops in the right ventricle, yet the defective genes and their mutations are present to the same extent in the right as in the left ventricles.[34] Presumably, the increased workload and pressure in the left ventricle stimulate the development of the hypertrophy and phenotypic expression. There also appears to be more hypertrophy in males than females who have FHCM. βMHC is the major myosin and contractile unit of many skeletal muscles, yet the latter do not appear to be affected by this disease, again emphasizing the influence of either the environment or other genes.[50] Another example of presumably environmental or other genetic influences is the marked variability of the extent and degree of left ventricular hypertrophy that occurs even within the same family with the same mutation. In addition, there is a significant effect from other genes that predispose to features such as hypertrophy. An example of the influence of another gene on FHCM is afforded by the angiotensin converting enzyme (ACE) DD genotype. Patients with FHCM who also have the ACE DD genotype have a much higher incidence of sudden death[51] and more extensive hypertrophy,[52]

which may be mediated through the mitogenic effect of angiotensin II. Individuals with FHCM who participate in combative reports seem to be more prone to develop hypertrophy and sudden death.[53] A similar effect is observed if they have a variance of the endothelin I gene.[54] It is not surprising that the phenotype of cardiac hypertrophy requires the coordination of probably hundreds of genes, and thus it is highly likely that other genes in addition to ACE will exert a minimal, yet significant influence on either the penetrance or expressivity of the primary genetic defect.

ELUCIDATION OF THE PATHOGENESIS FROM GENETIC MODELS

Based on in vitro and in vivo studies in genetic animal models of HCM, it now appears that the primary defect is impaired contractility. Analysis of a human heart from a patient with the $Arg^{403}Gln$ mutation showed the ratio of myosin to actin was normal,[55] indicating there is no deficiency of the βMHC protein. All of the responsible mutant genes encode for a sarcomeric protein and appear in some way to impair systolic contraction or diastolic relaxation. In feline adult cardiac myocytes, in which βMHC is the predominant myosin form, expression of human mutant βMHC gene, $Arg^{403}Gln$, was associated with sarcomere disassembly.[56] Expression of the human mutant troponin T in this model also induced sarcomere disassembly and was associated with impaired rate of cell shortening as detected by laser.[24] Furthermore, it was shown the expressed mutant protein was incorporated into the sarcomere. In a transgenic mouse, expression of troponin T gene (cTnT-Gln^{92})[57] exhibited sarcomere disarray, increased fibrous tissue, and sudden death, but only minimal hypertrophy. In this model it was also shown that increased expression of the mutant protein was associated with a more severe phenotype, confirming the mutant protein has a dominant-negative effect as expected. These results have been confirmed by several investigators.[56,58-60] Expression of the mutant myosin heavy chain gene or the troponin gene in the mouse has, in general, been associated with less hypertrophy than expected.[57] Recently, a transgenic rabbit model (rabbit has βMHC as its cardiac myosin) has been developed expressing the βMHC ($Arg^{403}Gln$) mutation, which exhibits sarcomere disarray, hypertrophy, and increased fibrous tissue virtually identical to that observed in humans.[61] Thus, the overall postulated pathogenesis of FHCM may be summarized briefly as follows: The mutant protein is incorporated into the sarcomere and acts as a poison peptide which impairs contractility of that particular cell which, in turn, provides the stimulus for the mitogenic response (probably several growth factors) of compensatory hypertrophy. The growth stimulus, as in acquired disorders, appears highly localized and mediated by autocrine or intracrine factors, given that the hypertrophy is localized in many patients, primarily to the interventricular septum. The growth factors also stimulate fibroblast proliferation and increased matrix formation. The relationship between the hypertrophy and increased fibrous tissue response to sudden death and arrhythmias remains to be determined. It is postulated that the fibrous tissue leads to delayed electrical conduction and predisposes to arrhythmias and sudden death.[62,63] The future elucidation of the molecular basis for the pathogenesis of this disease, however, must provide a rationale for three puzzling, consistent features of the pathology of FHCM: (1) predominance of hypertrophy in the septum, (2) sarcomere and myocyte disarray, and (3) the supernormal systolic function. The diastolic stiffness or decreased compliance is expected with hypertrophy, whether it is primary or compensatory, but these other features are not seen in compensatory hypertrophy associated with myocardial infarction or pressure overload.

IMPLICATIONS FOR FUTURE THERAPIES

Based on clinical studies and experimental genetic models, certain important observations have evolved. FHCM is seldom manifested before puberty and when due to certain genes may not be manifested until the fourth or fifth decade. This provides a window for future therapeutic intervention as therapies become available. The observation that the DD genotype increases the extent of hypertrophy and the risk for sudden death in individuals with FHCM is of considerable

therapeutic interest.[51] ACE inhibitors have been shown to either induce regression or prevent progression of hypertrophy due to pressure overload, in part due to a direct effect on the growth response. Therefore, it would be intriguing to know whether or not ACE inhibitors induce regression of hypertrophy in patients with FHCM and, perhaps more importantly, prevent hypertrophy in children genetically affected who are identified by genetic testing prior to the development of hypertrophy. There is no evidence to recommend such therapy for FHCM at this time. Elucidation that the hypertrophy is secondary and similar to the hypertrophy developed in response to pressure overload also has important implications; hence, therapies shown to be effective in FHCM would be expected to be effective in acquired hypertrophy. Thus, HCM, as a model, may be a paradigm for the evaluation of known therapies and the development of more specifically targeted therapies. It is evident that genotyping could provide risk stratification of therapeutic and prognostic significance. Genotyping will also have a major diagnostic impact since it is not always possible to make a diagnosis with conventional methods, particularly in the elderly. It will be essential for genetic screening of asymptomatic individuals within families with the disease. Despite the observation that not all of the genes responsible for FHCM have been identified, it must be realized that the first gene was not identified until 1990. Screening for mutations in individuals from a family affected with FHCM is feasible for known mutations but is tedious and expensive. In a family in which the disease is not due to a known mutation, chromosomal mapping and subsequent identification of the gene are required. It is expected, however, that the techniques for mass genetic screening, such as the DNA chip array, will make it possible to do routine genetic screening.[64] Ultimately, if gene therapy becomes available, genotyping will, of course, be essential. It is conceivable that regression of cardiac hypertrophy can be induced by inhibiting transcription of the mutant allele or translation of the mutant mRNA, thus abolishing synthesis of the mutant peptide. Thus, not only genetic diagnosis but also curative therapy may be possible. Since the heart, even in an adult, is renewed every 2 to 3 weeks, there is a tremendous potential for a cure with subsequent remodeling to normal.

Pompe's Disease (Type II Glycogen Storage Disease)

Genetic deficiency of acid α-1,4-glucosidase production results in a wide clinical spectrum ranging from the rapidly fatal infantile-onset of type II glycogen storage disease (GSD) to a slowly progressive adult-onset myopathy. The infantile-onset form (Pompe disease) typically manifests during the first months of life and patients usually die before their second year.[65] This rare inborn error of glycogen metabolism occurs in less than 1 per 100,000 persons. Massive glycogen accumulation occurs, leading to the clinical findings of enlarged tongue, striking hepatomegaly, hypotonia with decreased deep tendon reflexes, and hypertrophic cardiomyopathy[65] with cardiac failure (Table 62-5). The diagnosis may be predicted from the electrocardiogram (ECG), which demonstrates striking QRS complex voltage.[65] The diagnosis can also be made by analysis of α-glucosidase in blood lymphocytes or skin fibroblasts. Recently, urinary oligosaccharide identification using matrix-assisted laser desorption ionization time-of-flight mass spectrometry has been shown to allow facile and sensitive identification of the pathognomonic oligosaccharidiuria of this disorder.[66] The disease has autosomal recessive inheritance and is caused by mutations in this lysosomal gene found on chromosome 17q23-q25. Recently, the lysosomal-associated membrane protein (LAMP-1) was shown to be elevated in Pompe disease, which occurs due to altered trafficking and turnover of LAMP-1.[67]

Table 62-5: Cardiovascular Anomalies Associated with Selected Autosomal Recessive Syndromes

Syndrome	Cardiovascular Anomaly
Carpenter's syndrome	Patent ductus arteriosus
Cockayne's syndrome	Atherosclerosis
Cutis laxa	Pulmonary hypertension
Cystic fibrosis	Cor pulmonale
Ellis-van Creveld syndrome	Atrial septal defect
Friedreich's ataxia	Hypertrophic cardiomyopathy
Homocystinuria	Thromboses
MPS IH (Hurler's syndrome)	Coronary artery disease, aortic and mitral insufficiency, hypertrophic cardiomyopathy
MPS IS (Scheie's syndrome)	Aortic valve disease
MPS IV (Morquio's syndrome)	Aortic valve disease
MPS VI (Maroteaux-Lamy syndrome)	Aortic valve disease
Pompe's disease (GSD II)	Hypertrophic cardiomyopathy
Pseudoxanthoma elasticum	Coronary artery disease, mitral insufficiency
Refsum disease	Arrhythmias
Smith-Lemli-Opitz syndrome	Ventricular septal defect, patent ductus arteriosus
Thrombocytopenia-absent radii (TAR) syndrome	Atrial septal defect, tetralogy of Fallot

In an attempt to better understand this metabolic disorder, animal models have been developed using targeted disruption of the murine acid α-glucosidase gene.[68,69] This model closely mimics the human disorder, particularly the cardiac phenotype. Also, using animal models such as quail and rat, gene therapy using recombinant α-glucosidase has been shown to correct the enzyme levels and clinical phenotype, suggesting that enzyme replacement by this method is promising therapy in humans.[70-72]

Beckwith-Wiedemann Syndrome (BWS)

The combination of macroglossia, exophthalmos, and visceromegaly has been designated the BWS.[73-74] Multiple other abnormalities have also been described, including fetal adrenocortical cytomegaly, hypoglycemia due to pancreatic islet hyperplasia, transverse linear creases of the ear lobules, hemihypertrophy, and accelerated osseous maturation. Infants with this syndrome are at particularly high risk, cumulatively estimated at between 5 and 20 percent, for development of Wilms' tumor, adrenocortical carcinomas, hepatoblastomas, and rhabdomyosarcomas.[75] The cardiovascular system is also commonly affected with the development of HCM. The BWS occurs with an incidence of 1 in 13,700 live births. Cases (about 85 percent) are generally sporadic, but familial disease (15 percent) has been described. Most of these familial cases have apparent autosomal dominant inheritance,[76] albeit with reduced, sex-dependent penetrance and variable

expressivity. A variety of structural abnormalities of chromosome 11 have been shown, including partial duplication of 11p13, duplication of 11p15 only, deletion of 11p11-13, or deletion of 11p11. The extra chromosomal material is usually of paternal origin. The breakpoints found in BWS patients with balanced chromosomal translocation or inversion involving chromosome 11 lie in two regions: (1) close to the insulin/insulin-like growth factor II (INS/IGF2) genes in 11p15.5 or (2) proximal to β-hemoglobin (HBB). The recombinant chromosome was shown to be of maternal origin. Family studies showed that the gene responsible for familial BWS mapped to 11p15.5. For sporadic BWS, uniparental paternal disomy for 11p15.5 markers was found in approximately 20 percent of cases analyzed. Mutations in p57KIP2, a potent tight-binding of several G1 cyclin/cyclin-dependent kinase complexes, have been identified in cases of BWS,[77-80] and mice lacking this gene have been shown to have a phenotype similar to that seen in humans.[81] Clinical heterogeneity exists, however; potential mechanisms include a possible role for genomic imprinting (i.e., an epigenetic chromosomal modification in the gamete or zygote causing preferential expression of a specific parental allele in the somatic cells of the offspring) in 11p15, and this was later shown to occur with KVLQT1, a cardiac potassium channel gene known to cause long-QT syndrome when mutated.[82,83] This region of 11p15.5 has a cluster of imprinted genes, in fact, such as insulin-like growth factor II (IGF2),[84] HI9,[85] LIT1,[86] and p57KIP2.[77-80] Animal models have been created using these as transgenes.[84]

Leopard Syndrome

This rare autosomal dominant disorder is characterized by the cardinal features leading to the pneumonic L (lentigenes), E (ECG conduction defects), O (ocular hypertelorism), P (pulmonic valve stenosis), A (abnormalities of genitals), R (retardation of growth), and D (deafness, sensorineural). Cardiac abnormalities are common and include both anatomic as well as conduction defects. Anatomically, PS is the most frequent, followed by HCM and endocardial fibroelastosis (Table 62-6). The most common ECG defects include first-degree AV block, left anterior hemiblock, and complete heart block. No cytogenetic or molecular genetic abnormalities have been identified.

Table 62-6: Cardiovascular Anomalies Associated with Selected Autosomal Dominant Syndromes

Syndrome	Cardiovascular Anomaly
Albright's hereditary osteodystrophy	Cardiomyopathy
Ehlers-Danlos syndrome	Rupture of large vessels
Holt-Oram syndrome	Atrial and ventricular septal defects
Leopard syndrome	Pulmonic stenosis, hypertrophic cardiomyopathy, prolonged PR interval
Marfan syndrome	Aortic aneurysm, aortic insufficiency, mitral valve prolapse
Myotonic dystrophy	Dilated cardiomyopathy, conduction abnormalities
Neurofibromatosis	Coarctation of the aorta, renal artery
	Stenosis

Treacher Collins syndrome	Atrial and ventricular septal defects, patent ductus arteriosus
Tuberous sclerosis	Myocardial rhabdomyoma, Wolff-Parkinson-White syndrome
Noonan's syndrome	Pulmonic stenosis, hypertrophic cardiomyopathy, atrial septal defect, aortic stenosis

Friedreich's Ataxia (FA)

FA is the most common of the hereditary spinal cerebellar degenerations, with an incidence of 1 in 50,000 and carrier frequency of 1 in 110.[87] This autosomal recessive form of spinocerebellar degeneration is characterized by progressive limb ataxia, loss of deep tendon reflexes, sensory abnormalities, and musculoskeletal deformities. The symptoms of FA usually appear insidiously during childhood or early adolescence. Progressive weakness of the upper and lower extremities gradually becomes obvious. Gait difficulties are often the first symptom; they progress slowly, followed by unsteadiness in the arms and hands. Difficulty in writing and handling eating utensils subsequently becomes apparent.

Cardiac involvement[87] occurs in 50 to 90 percent of patients. The most common abnormality is hypertrophic cardiomyopathy (Table 62-5); dilated cardiomyopathy occurs rarely. Thus, the most common cardiac symptoms relate to cardiac failure and arrhythmias. Left ventricular outflow tract obstruction due to asymmetrical septal hypertrophy may be evident, and approximately 50 percent of patients die of cardiac disease. Patients are followed for development of arrhythmias and the signs and symptoms of cardiac failure. Treatment consists primarily of conventional drugs to relieve the symptoms and signs of heart failure.

Involvement of the heart is readily detected by electrocardiography and echocardiography. The electrocardiographic abnormalities are found in 90 percent of patients and include repolarization abnormalities manifesting as inverted or biphasic T waves in the inferior limb leads and left precordial leads, a short PR interval, left and right ventricular hypertrophy, as well as left and right axis deviation. Premature atrial contractions, atrial flutter/fibrillation, and premature ventricular contractions are common. Echocardiography detects cardiac involvement in 60 to 100 percent of patients with the most common finding of concentric hypertrophy, but asymmetrical septal hypertrophy accompanied by systolic anterior motion (SAM) of the mitral valve is also common. Left ventricular chamber diameter may be normal or decreased and fractional shortening or ejection fraction is usually normal, although dilated cardiomyopathy (left ventricular dilation and reduced contractility) is seen occasionally (see Chap. 10). There is no specific treatment for the cardiac manifestations except symptomatic treatment if cardiac failure ensues (see Chap. 23).

Friedreich's ataxia is inherited as an autosomal recessive disorder, and parental consanguinity has been noted in some cases. The gene was initially mapped to chromosome 9q13-31.1,[88] and in 1996 the gene was identified.[89] This gene is 40 kb, contains five exons, has a 1.3-kb transcript, and encodes a 210-amino acid protein called frataxin. The highest level of expression is within the heart, while intermediate levels are seen in liver, skeletal muscle, and pancreas; minimal levels are identified in other tissues, including the brain. Although a few affected patients were found to have a point mutation of frataxin, the majority (about 95 percent) are homozygous for an unstable GAA trinucleotide expansion in the first intron.[89] The remainder of patients are compound heterozygotes for the expansion. In patients homozygous for the expansion, there is a correlation between the number of GAA repeats on the smaller allele, age of onset, disease progression, and cardiomyopathy,[87,90-93] confirming that the expansion is the primary cause of disease. The

expansion results in severely reduced levels of mature frataxin mRNA.[89]

Campuzano et al.[94] demonstrated that frataxin is localized to the mitochondria associated with the mitochondrial membranes and crests using immunocytofluorescence and immunocytoelectron microscopic evaluation. They suggested that reduction in frataxin results in oxidative damage. Subsequently, Rotig and colleagues[95] suggested that frataxin regulates mitochondrial iron transport and that deficiency of iron-sulfur cluster-containing subunits of mitochondrial respiratory complexes I and II and the iron-sulfur protein aconitase occurs. Hence, it appears that Friedreich's ataxia is a mitochondrial disorder.[96,97] As these patients have HCM, diabetes, ataxia, and apparent free radical toxicity, the mitochondrial basis of this disorder clarifies the clinical features.

Dilated Cardiomyopathy

IDIOPATHIC DILATED CARDIOMYOPATHY

Idiopathic DCM (DCM) is a disease of unknown etiology characterized by increased ventricular chamber size, decreased wall thickness, and impaired systolic ventricular function. The prevalence of idiopathic DCM has been estimated to be approximately 40 cases per 100,000.[98] The diagnosis of DCM is typically made by echocardiography (see Chap. 65), and symptoms usually are those of sudden death and heart failure. Familial DCM (FDCM) is estimated to account for 30 percent of patients with idiopathic DCM. In a large family with idiopathic DCM, an autosomal dominant pattern was determined and the disease was linked to chromosome 1q32.[99] Three other chromosomal loci have been identified: 9q13,[100] 2q31,[101] and 10q21-23.[102] Three additional chromosomal loci have been mapped-to 1p1-1q1,[103] 3p22-25,[104] and 6q23[105]-in families having DCM in association with conduction defects and 6q23 also has limb girdle dystrophy. In the family mapped to 1p1-1q1, transient arrhythmias, which presented in the second or third decade, become sustained and commonplace by the third or fourth decade. The abnormal rhythms included second- or third-degree AV block, atrial fibrillation, or marked bradycardia, commonly requiring a pacemaker. DCM usually developed in the fourth or fifth decade, generally out of proportion to the severity of the rhythm disturbance. Sudden death commonly occurred in the late stages of the disease. On autopsy, marked right and left ventricular dilatation, interstitial fibrosis, myocyte degeneration characterized by cytoplasmic vacuolization, and AV nodal cell replacement by fibrous tissue were noted. The gene and its characteristics have recently been described as lamin A/C, the same gene identified for autosomal dominant Emery-Dreifuss muscular dystrophy. None of the other genes residing at these loci responsible for FDCM have yet been identified. However, two genes have now been identified responsible for FDCM-actin[106] and desmin.[107] Three missense mutations have been identified in actin. Actin, in addition to forming the thin filaments of the sarcomere, essential to the generation of force, is also an important cytoskeletal protein involved in structural integrity and the transmission of force. Mutations in actin responsible for FDCM are located in the domain which is immobilized and attached to the Z-band or intercalated disk and involved with transmitting force. In contrast, it was recently shown that mutations in the actin domain affecting the myosin cross bridges and the generation of force (sarcomere) give rise to FHCM.[108] Desmin is the specific intermediate filament for muscle and an essential cytoskeletal protein for maintaining cardiac structure and for the transmission of force and other signals to the cytoplasm and the nucleus of the cell. Desmin stretches from its attachment to the sarcomere Z-band to the nuclear membrane and other organelles.[109] Mutations in desmin have been shown to be associated with cardiac and skeletal abnormalities.[110] A missense mutation ($Ile^{451}Met$) was recently found to be responsible for DCM in a family without any skeletal or smooth muscle abnormalities. Mutations leading to combined skeletal and cardiac abnormalities have all been in the rod region of desmin. In contrast, the $Ile^{451}Met$ mutation responsible for the restricted cardiac phenotype of DCM encodes for the tail domain of human

desmin, located in codon 451 with cytosine substituting for guanine. This would suggest a possible unique cardiac function for the domain in this region. Elimination of the desmin gene in a knockout mouse was associated with a phenotype of DCM exhibiting impaired cardiac function and myocyte necrosis.[110] It is of note that DCM associated with musculoskeletal disorders such as Duchenne muscular dystrophy are due to dystrophin, α-dystroglycan, and α-sarcoglycan, all of which are cytoskeletal proteins[111] (Fig. 62-7). There is thus the strong suggestion that familial DCM may be a disease of the cytoskeletal proteins[107,112-114] analogous to HCM being a disease of the sarcomere. This has been termed by Towbin as the "final common pathway hypothesis"[113,114] (Fig. 62-8).

X-LINKED DILATED CARDIOMYOPATHY (XLCM)

Berko and Swift[2] reported a five-generation kindred with DCM and no clinical evidence of skeletal myopathy. Males presented in their teens or early twenties with clinical evidence of mitral regurgitation and an echocardiographic diagnosis of DCM. Episodes of ventricular tachycardia were noted in several patients. The males progressed rapidly (within 1 or 2 years) to death or cardiac transplantation. Manifesting female carriers developed mild cardiomyopathy in the fourth or fifth decade and progressed slowly. Right ventricular endomyocardial biopsy revealed minimal interstitial fibrosis, while postmortem evaluation showed marked dilatation, widespread patchy fibrosis (worst in the posterior wall), and normal mitochondria on electron microscopy. There were no pathognomonic findings differentiating this cardiomyopathy from other dilated forms except for the apparent X-linked inheritance and elevation of the muscle isoform of creatine kinase (CK-MM) in the serum of affected males and female carriers.

Towbin and colleagues[115] demonstrated linkage of XLCM to the dystrophin locus at Xp21 (i.e., the gene responsible for Duchenne and Becker muscular dystrophy) in the family described above as well as in a second family. Evaluation of the protein defect in XLCM showed absence (or low abundance) of the *N*-terminal and rod portion of the dystrophin protein, while skeletal muscle total protein was normal.[115] The 156-kDa dystrophin-associated glycoprotein (known as α-dystroglycan),[116,117] a membrane-bound constituent of the dystrophin-associated glycoprotein complex, was decreased in cardiac tissue as well.[116] This was later confirmed.[118] Diverse mutations leading to XLCM have been shown by Towbin and Ortiz-Lopez,[119,120] Yoshida et al.,[121] Muntoni et al.,[122] and Milasin et al.,[123] with most mutations residing in the 5′ portion of the gene. It appears that the DCM occurs due to mechanical destablization of the muscle membrane. Recently, novel mutations in the 5′ end of dystrophin, including a transposon[124] insertion and an *Alu*-rearrangement[125] were found to result in XLCM. Treatment of congestive heart failure and ventricular arrhythmias is necessary and transplantation is common (see Chap. 23).

X-LINKED CARDIOSKELETAL MYOPATHY (BARTH SYNDROME)

Neustein et al.[126] and Barth and coworkers[127] described an X-linked recessive disease characterized by the triad of DCM with endocardial fibroelastosis, neutropenia, and skeletal myopathy. All affected males died in infancy or early childhood from cardiac decompensation or septicemia. There were no affected females. Ultrastructural abnormalities were detected in mitochondria from cardiac and skeletal muscle as well as in neutrophil bone marrow cells. Furthermore, respiratory chain abnormalities were observed and isolated skeletal muscle mitochondria demonstrated diminished cytochrome concentrations. Lactic acidemia not provoked by prolonged fasting, increased plasma and muscle carnitine concentrations, growth retardation, and increased levels of urinary 3-methylglutaconic acid and 2-ethyl-hydracrylic acid have also been seen.

The locus was mapped by linkage to Xq28.[128] The gene G4.5 codes for a novel protein known as

taffazin, whose function is unclear.[129] Tafazzin belongs to a family of proteins ranging from 129 to 292 amino acids in length. Direct sequencing of genomic DNA indicated different mutations in G4.5, which interfere with translation of the putative protein. Mutations in G4.5 have also been shown to cause other infantile cardiomyopathies, including isolated left ventricular noncompaction[130-132] and dilated hypertrophic cardiomyopathy. Treatment is that for cardiac failure (see Chap. 23).

FAMILIAL ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA (ARVD)

Arrhythmogenic right ventricular dysplasia is characterized by fatty infiltration of the right ventricle, fibrosis, and ultimately thinning of the wall with chamber dilatation.[133] It is the most common cause of sudden cardiac death in the young in Italy[134] and is said to account for about 17 percent of sudden death in the young in the United States.[135] Rampazzo et al.[136] mapped this disease in two families, one to 1q42-q43, and the other on chromosome 2q32; a third locus was mapped to 14q12.[137] A large Greek family with arrhythmogenic right ventricular dysplasia and Naxos disease was recently mapped to 17q.[138] Two loci responsible for ARVD in North America were recently mapped at 3p23[139] and the other at 10p12.[140] This is a very devastating disease, since the first symptom is often sudden death. Electrocardiographic abnormalities include inverted T waves in the right precordial leads, late potentials, and right ventricular arrhythmias with left bundle-branch block (LBBB). This is compounded by the great difficulty in making the diagnosis even when the condition occurs in a family with a history of the disease. Since the disease affects only the right ventricle, it is difficult to detect.[106] There is no definitive diagnostic standard. The right ventricular biopsy is definitive when positive but often produces a false-negative result, since the disease initiates in the epicardium and spreads to the endocardium of the right ventricular free wall, making it inaccessible to biopsy. Consensus diagnostic criteria was developed that include right ventricular biopsy, magnetic resonance imaging (MRI), echocardiography, and electrocardiography.[141] Identification of the gene will have tremendous diagnostic impact and hopefully will provide an explanation as to why ARVD is restricted to the right ventricle. Is it a specific right ventricular chamber gene? Is there a stimulus that is unique or predominates in the right ventricle that precipitates the phenotype? What is the stimulus? There are data suggesting that apoptosis is the process leading to the development of fat and fibrosis in ARVD. Discovery of a gene should shed light on the apoptosis pathway.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

RESTRICTIVE CARDIOMYOPATHY

In the western countries, restrictive cardiomyopathy (RCM) is the least common of the three major categories of cardiomyopathy (see Chap. 75). The most common cause of secondary restrictive cardiomyopathy in adults is myocardial amyloid. Patients manifest exercise intolerance due to their inability to increase cardiac output by tachycardia without further compromising ventricular filling. Weakness and dyspnea are often prominent, and chest pain may also occur. At end stage, the findings are those of cardiac failure with anasarca. Mutations in the transthyretin (TTR) gene[142,143] which codes for the TTR serum protein, has been found associated with RCM. This protein contains four subunits, each with 127 amino acids, encoded by four exons within a 7-kb gene. Many TTR point mutations cause TTR to form amyloid, which occurs primarily in the heart, leading to heart failure. The diagnosis is suspected by echo and confirmed by genetic analysis. Treatment is that of cardiac failure.

Familial forms of restrictive cardiomyopathy have also been seen. One such family was found to have mutations in the desmin gene[144] and mice have been created with desmin mutations that have a similar phenotype as the clinical condition.[110]

Mucopolysaccharidoses

The mucopolysaccharidoses (MPS) are a group of diseases caused by deficiency of lysosomal enzymes involved in the degradation of glycosaminoglycans.[145] Undegraded glycosaminoglycans accumulate in lysosomes and affect tissue function. MPS have been divided into seven major types. The classification (types I to VII) is based on the deficient enzyme responsible for the disorder. These disorders carry such eponyms as *Hurler*, *Scheie*, *Hurler-Scheie*, *Hunter*, *Sanfilippo*, *Morquio*, *Maroteaux-Lamy*, and *Sly*. They share many clinical features, including multiple system involvement, organomegaly, dysostosis multiplex, facial abnormalities, loss of hearing and vision, joint involvement, cardiac involvement, and central nervous system (CNS) involvement. Cardiac disease includes myocardial hypertrophy, pulmonary and systemic hypertension, valvular disease, coronary occlusion, and myocardial infarction. Congestive heart failure and sudden death are relatively frequent. The most common mucopolysaccharidosis with cardiac involvement is MPS I (Hurler syndrome). Valvular disease is prominent in the Scheie's syndrome (late-onset form). Less commonly, heart disease has been noted in Sanfilippo A syndrome with aortic regurgitation, as well as in severe Maroteaux-Lamy syndrome with valvular heart disease (Table 62-5). The diagnosis for either of these disorders is made by assaying the enzyme activity in cultured skin fibroblasts or leukocytes.

Hurler's Syndrome

Hurler's syndrome (MPS-I) is an autosomal recessive trait found on chromosome 22 (22q11), which occurs in approximately 1 of 40,000 people. It is caused by a deficiency of α-iduronidase (IDUA), which is required for the degradation of both heparan sulfate and dermatan sulfate.[146] The result is similar to that of Hunter's syndrome, with both dermatan and heparan sulfate in high concentrations in the urine. Myocardial infarction occurs in childhood (Table 62-5). *Severe* (Hurler, MPS-IH), *intermediate* (Hurler/Scleie, MPS-IH/S), and *mild* (Scheie) clinical subtypes of MPS-I occur.[145] MPS-IH patients usually present within the first year of life and progress with a

combination of hepatosplenomegaly, skeletal deformities, corneal clouding, and severe mental retardation. Obstructive airway disease, respiratory infection, and cardiac complications usually result in death before age 10 years. Dangel[147] reported on 64 children with mucopolysasccharidoses, noting 72 percent with cardiac disease (valvular lesions, cardiomyopathy). Mitral valve thickening with regurgitation or stenosis, hypertrophic cardiomyopathy, aortic stenosis, and EFE were most common. MPS-IH/S is characterized by little neurologic involvement but most of the somatic involvement described for MPS-IH develops early in the teenage years, causing considerable loss of mobility. MPS-IS patients, those with the mildest symptoms, have little or no neurologic involvement, normal stature, and normal life span but do develop stiff joints, mild hepatosplenomegaly, aortic valve disease, and corneal clouding.[145] Diagnosis is confirmed in MPS-I by demonstration of mucopolysaccharidiuria and absence of IDUA activity in leukocytes and fibroblasts. Biochemical differentiation between subtypes is difficult. Gene identification[148] has allowed for mutation analysis; the broad range of clinical phenotypes is related to the types of mutations in the IDUA gene.[149] Allogenic bone marrow transplantation is the most effective treatment for Hurler's syndrome[150] and gene transfer is being evaluated.[151] Animal models are now available[152154] for study.

Hunter's Syndrome

Hunter's syndrome, an X-linked disorder mapped to the Xq26-Xq28 region, is found in approximately 1 of 30,000 people.[145] It is caused by a deficiency of the enzyme iduronate sulfatase and results in excessive urinary excretion of dermatan and heparan sulfate and accumulation of mucopolysaccharides, which can result in coronary obstruction and subsequent myocardial infarction in childhood. Most patients die before the third decade. Mutations in this gene are heterogeneous, ranging from small microlesions to gross deletions and inversions[155-157] and, in some cases, involves neighboring genes. Therefore, wide clinical variation is common. Gene therapy has been reported.[158-160]

Morquio's Disease

Morquio's disease (MPS-IVA), an autosomal recessive disorder caused by a genetic deficiency in *N*-acetyl-galactosamine-6sulfatase, is a prototypical chondroosteodystrophy.[145] The disorder is characterized by specific spondyloepiphyseal dysplasia, short-trunk dwarfism, coxa valga, odontoid hypoplasia, corneal opacities, normal intelligence, and excessive urinary excretion of keratan sulfate and chondroitin 6-sulfate. The deficient *N*-acetyl-galactosamine-6-sulfatase results in progressive accumulation of mucopolysaccharides in lysosomes of various tissues, leading to vertebral involvement and cardiac disease (Table 62-5) in the second decade of life. Tomatsu et al.[161] isolated and characterized the full-length cDNA of the gene and it was localized to chromosome 16q24.[162] This gene is approximately 50 kb in size and has 14 exons; mutations have been described.[163,164]

Maroteaux-Lamy Disease

The Maroteaux-Lamy syndrome is caused by the deficiency of the enzyme arylsulfatase B, which is required for degradation of the glycosaminoglycans, dermatan sulfate, and chondroitin 4-sulfate.[165] It is associated with aortic valve disease. This gene, located on 5q13-q14,[165] has been isolated and characterized.[166] Mutations have been identified, and different mutations cause different clinical phenotypes.[167] The clinical features are quite variable, occurring in infancy and consist of growth retardation, coarse facies, corneal clouding, and multiple skeletal changes, together with dilated cardiomyopathy and aortic or mitral value stenosis or insufficiency. Cardiac manifestations usually appear after the neurologic features but are usually present by adolescence. Molecular diagnosis is currently available. Bone marrow transplants are currently the treatment of

choice.[150] All of these disorders can be diagnosed prenatally by enzyme assay in at-risk pregnancies.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

MUSCULAR DYSTROPHIES WITH CARDIAC INVOLVEMENT

The muscular dystrophies are a heterogeneous group of diseases, the primary manifestations of which include progressive muscle wasting secondary to intrinsic defects of the muscle fiber. These defects have a wide spectrum of clinical expression and include Duchenne's muscular dystrophy, Becker's muscular dystrophy, Emery-Dreifuss muscular dystrophy, the limb-girdle muscular dystrophies, and myotonic dystrophy. Cardiac disease, especially DCM, is central to the morbidity and mortality associated with these disorders (Table 62-7).

Duchenne Muscular Dystrophy (DMD)

DMD is an X-linked disorder characterized by the early onset of progressive, generalized muscle weakness and "pseudohypertrophy" of certain muscle groups.[168] The incidence of DMD is estimated to be 1 in 3300 live male births with little ethnic variation, and the calculated mutation rate of 10^4 is an order of magnitude higher than for most other genetic diseases. About one-third of cases arise by spontaneous mutation, with the remaining two-thirds occurring by inheritance of the disease-causing gene from the carrier mother. Female carriers of DMD are usually asymptomatic but occasionally have a slowly progressive myopathy of moderate severity. This "manifesting female carrier" state occurs in approximately 8 percent of carriers and is thought to occur due to random X-inactivation. The disease may also be expressed in females with Turner syndrome having a single X chromosome and in females with X-autosome translocations that disrupt the DMD gene. In the latter case, the translocation not only disrupts the DMD gene but also causes the nonrandom inactivation of the normal allele on the other X chromosome, resulting in the expression of the disease phenotype.

Although evidence of skeletal muscle disease in boys with DMD is evident in the neonatal period, as seen by high serum muscle enzymes (particularly CK-MM), clinical disease is not. There may be mild developmental delay, walking later than expected, but weakness is usually not appreciated until at least 2 or 3 years of age. Early symptoms reported by parents include difficulty in running or climbing stairs, frequent falling, and enlargement of calf muscles. Pelvic-girdle weakness is more obvious than shoulder-girdle weakness in the early stages. The gait becomes lordotic and waddling, and the child usually walks with the heels raised slightly off the ground (i.e., toe walking). As pelvic girdle weakness increases, the child has increasing difficulty rising from a seated position. In order to rise from the floor to a standing position, the child must brace the arms against the front of the thigh and climb up the legs, the so-called Gowers sign. Muscle pseudohypertrophy usually appears by 5 to 6 years of age, with muscle enlargement most commonly occurring in the calf muscles; the quadriceps, infraspinatus, deltoid, and gluteal muscles may also be involved, however. The upper and lower extremities become progressively weaker with age, and joint contractures may appear due to uneven weakness of agonist and antagonist muscles. Contractures of the hip flexors, iliotibial bands, and heel cords develop in 70 percent of patients between 6 and 10 years of age. Most patients are wheelchair-bound by the end of the first decade of life. After ambulation is lost, fixed contractures occur and paraspinal muscle weakness leads to progressive kyphoscoliosis. Significant weakness of the respiratory muscles occurs early in the second decade and is a common cause of demise.

Although most cases of DMD can be recognized on the basis of the patient's history and clinical

signs alone, laboratory evaluation is important to confirm the diagnosis.[168] As previously noted, extremely high levels of CK-MM are found in the early stages of disease, as early as birth, and precede evidence of clinical involvement. Other muscle enzymes-including aldolase, SGOT, lactic dehydrogenase (LDH), and pyruvate kinase-are also grossly elevated. In the end stages of the disease, enzyme levels fall but do not reach normal values. Electromyographic examination may also be useful, demonstrating the characteristic features of a myopathy. Insertional activity is normal or increased initially but decreases in the advanced stages of the disease, when fibrosis replaces muscle fibers. Fibrillation potentials and positive sharp waves occur in the early stages of the disease due to the splitting of muscle fibers. The motor unit potentials are small and polyphasic, and an early recruitment pattern with minimal effort is present. Mild intellectual impairment is common in patients with DMD. The retardation is present at an early age, is nonprogressive, and does not correlate well with the stage of the disease. Approximately one-third of patients have IQs below 75, characterized primarily by impaired verbal ability.

The heart is commonly involved in DMD, with electrocardiographic abnormalities and dilated cardiomyopathy being most typical.[168] Cardiac symptoms, however, are unusual before the terminal stages of the disease. Congestive heart failure tends to occur. A midsystolic click and late systolic murmur associated with mitral valve prolapse are also common. In addition, an S3 or S4 gallop, sinus tachycardia, and a mitral regurgitation murmur are usually heard; cardiomegaly and increased pulmonary vascular markings appear at this stage, and bilateral diaphragmatic elevations may be seen owing to diaphragmatic dystrophy. Unlike the late-onset findings of dilated cardiomyopathy, the electrocardiogram is abnormal early in the course of DMD, with a tall R-wave and an abnormally increased R/S ratio in the right precordial chest leads and a deep, narrow Q-wave in leads I, aV_L, V_5, and V_6. These abnormalities progress over time and are attributed to the finding of that the greatest dystrophic myocardial changes in the posterobasal and contiguous lateral left ventricular myocardium. In addition, P waves with negative terminal deflections in V_1 exceeding 20 ms and 0.1 mV appear in 20 to 45 percent of patients and, in the absence of left atrial enlargement on echocardiogram, are attributed to an intrinsic disorder of left atrial or intraatrial conduction. A short PR interval may be seen in up to 50 percent of patients but is not thought to be due to a bypass tract, as seen in Wolff-Parkinson-White syndrome. Infranodal conduction abnormalities, however, may be seen in patients with DMD, and these include complete or incomplete bundle-branch block, and left anterior or posterior fascicular block. Atrial and ventricular premature beats and atrial flutter are seen in some patients.

Echocardiography reveals left ventricular dilatation and dysfunction, with significantly reduced ejection fraction, and LV hypokinesis of the posterobasal ventricular wall is identified. Doppler and color Doppler commonly demonstrate mitral regurgitation, either secondary to the dilated cardiomyopathy or to the associated mitral valve prolapse, which occurs secondary to papillary muscle dysfunction. In some patients systolic function appears normal but diastolic dysfunction is present.

Histopathologic abnormalities of the heart and skeletal muscle are universal in patients with DMD, and those of skeletal muscle are widespread even in the early stages of disease.[168] Typical findings are rounding of the muscle fibers, increased variability in fiber size, increased central nucleation, and fiber splitting. Necrotic and regenerating fibers are present along with large, round hyaline fibers. In the late stages, muscle may be virtually replaced by fat and fibrous tissue. In the heart, degenerative changes in muscle fibers and areas of fibrosis in the ventricles, atria, and conduction system occur, with most pronounced changes in the posterobasal region and adjacent lateral wall of the left ventricle. The underlying cause of cardiac disease is not currently known, but it is speculated that the gene defect in DMD leads to instability of the translated cytoskeletal protein, leading to weakening of the myocyte membrane and subsequent myocyte death due to mechanical stress.

The dystrophin gene, on the short arm of the X chromosome,[168,169] is responsible for these disorders and when dystrophin abnormalities occur due to mutations, may cause either low level production of a nonfunctional protein or complete absence of dystrophin in the heart and skeletal muscle of affected patients. It is among the largest genes discovered thus far, comprising approximately 2.5 Mbp and transcribing a 14-kb mRNA molecule. This cytoskeletal protein-encoding gene is normally expressed in striated and smooth muscle as well as in brain. In muscle tissue, the dystrophin protein has been localized to the cytoplasmic surface of the sarcolemma and is associated with several integral membrane glycoproteins.[170] This glycoprotein/dystrophin complex-which involves the sarcoglycans, dystroglycans, syntrophins, and dystrobrevins-connects dystrophin to the sarcolemma and links to the extracellular matrix; it may be involved in the regulation of intracellular calcium, which is increased in dystrophin-deficient muscle, along with increased calcium channel transport.

The diagnostic approaches to DMD have changed dramatically over the past decade. Previously, serum CK-MM level and muscle biopsy were the standard approaches. Today DMD is diagnosed primarily by molecular analysis, which is rapid and accurate and may predict clinical course. Most commonly, dystrophin mutations that cause a frameshift[171] of the nucleotide sequence result in the severe form of muscular dystrophy, DMD.

Management of the congestive heart failure associated with the DCM seen in DMD is identical to that used for patients with other causes of heart failure and arrhythmias. Pacing is not usually necessary.

Becker's Muscular Dystrophy (BMD)

BMD is an X-linked disorder that differs in both severity and time of onset from DMD,[168] despite being due to allelic mutations in dystrophin, the gene responsible for DMD. BMD appears later and progresses more slowly than DMD, so that survival to middle age is seen. The pattern of muscle weakness, however, is identical to that in DMD, with early involvement of the pelvic girdle and proximal lower extremities.[168] The initial signs of weakness usually appear during the second decade but may be seen as late as the third decade. The weakness gradually progresses, with the upper extremities becoming involved after 5 to 10 years. Patients generally remain ambulatory until their mid-thirties. As in DMD, muscle hypertrophy is common; intellectual impairment, however, is less common and less severe. As in DMD, life expectancy is also reduced in BMD, with only 50 percent of patients surviving to 40 years of age.

Cardiac involvement may be seen in adolescence and ultimately affects 80 percent of patients.[172] As in DMD, dilated cardiomyopathy and cardiac failure are the usual abnormalities encountered ( Table 62-7) and are often the ultimate cause of death. Conduction abnormalities manifesting as fascicular block or complete heart block are also seen. As in DMD, muscle enzyme activity is markedly elevated in BMD, and preclinical cases may be detected by elevated CK-MM. Electromyographic examination shows a "myopathic" pattern with small, polyphasic motor units and early recruitment of motor units. The histology of BMD is similar to that of other forms of muscular dystrophy. In contrast to DMD, hyaline fibers are rarely seen. Electrocardiographic changes are similar to those seen in DMD. Other electrocardiographic abnormalities encountered include left axis deviation, right bundle-branch block, left bundle-branch block, and complete heart block. The echocardiogram may demonstrate the features of dilated cardiomyopathy.

BMD is also due to mutations within the dystrophin gene; i.e., it is allelic with DMD. As is the case with DMD, more than 30 percent of patients with BMD have no family history of the disease, an indication that they represent spontaneous mutations. The phenotypic difference

between DMD and BMD patients has been speculated to be due to frameshift mutations leading to more severe disease (DMD) while out-of-frame mutations cause less severe (BMD) disease.[171] The frameshift hypothesis explains more than 90 percent of the cases of DMD versus BMD. The cardiac abnormalities in BMD, like those described for DMD, require further study.[173] The treatment of CHF and arrhythmias is similar to that of other patients with these signs and symptoms.

Animal models have been created during the past several years that help to characterize the roles of dystrophin and the associated complexes.[174-180] Loss-of-function mutations of dystrophin lead to a DMD or BMD phenotype, while utrophin-deficient mice have defects in the postsynaptic membrane folds at the neuromuscular junction. Mice lacking both dystrophin and utrophin display a severe muscular dystrophy with premature death.[177-180] Sarcoglycan-deficient mice also demonstrate severe muscular dystrophy but, in addition, severe hypertrophic and/or dilated cardiomyopathy has been seen.[174,175]

Various methods evaluating the possibility of gene therapy for dystrophinopathies have been reported over the past several years in mice, with varying degrees of success. Minigene and stem-cell transplantation have both been considered promising using dystrophin and utrophin.[181,182]

Emery-Dreifuss Muscular Dystrophy (EDMD)

EDMD is a relatively rare disorder[168] characterized by weakness in the humeroperoneal distribution, early joint contractures, and dilated cardiomyopathy, with X-linked (occasionally, autosomal dominant) inheritance. The onset of disease in these patients occurs between 2 and 10 years of age, with weakness initially noted in the shoulder girdles and upper extremities. Contractures of the elbows and posterior cervical muscles appear early. The disease is slowly progressive, with involvement of the distal leg musculature following that of the upper extremities; contractures of the knees and ankles follow contractures of the elbows. Unlike the case in DMD and BMD, muscle pseudohypertrophy does not occur. The disease evolves slowly and usually stabilizes in the third decade, with most patients remaining ambulatory. Dilated cardiomyopathy is a common occurrence, but the severity of disease varies from family to family. Varying degrees of atrioventricular block are common (Table 62-7) and atrial standstill may occur. These electrical abnormalities may lead to episodes of syncope, transient ischemic attacks, stroke, and sudden death. A pacemaker is commonly required. Atrial fibrillation has also been observed. As in DMD and BMD, muscle enzyme activity is elevated, albeit to a lesser extent. Skeletal muscle biopsy histopathologic findings are similar to those associated with other forms of muscular dystrophy. Type I fiber atrophy has been described in some cases (Fig. 62-9). The gene responsible for X-linked EDMD was localized to Xq28[184] before being cloned. The gene called emerin (or STA) was shown to have an open reading frame of 762 nucleotides that encodes a serine-rich 254-amino acid protein with probable mechanical/structural function.[185] Emerin mRNA shows ubiquitous tissue distribution, with the highest expression in skeletal and cardiac muscles. The cDNA sequence of emerin predicts a tail-anchor membrane protein with an amino acid sequence similar to that of the thymopoietins, a group of nuclear lamina-associated proteins.[186] Nagano et al.[187] and Manilal et al.[188] both showed that emerin is a 34-kDa nuclear membrane protein in skeletal and cardiac muscle, which is absent in EDMD.

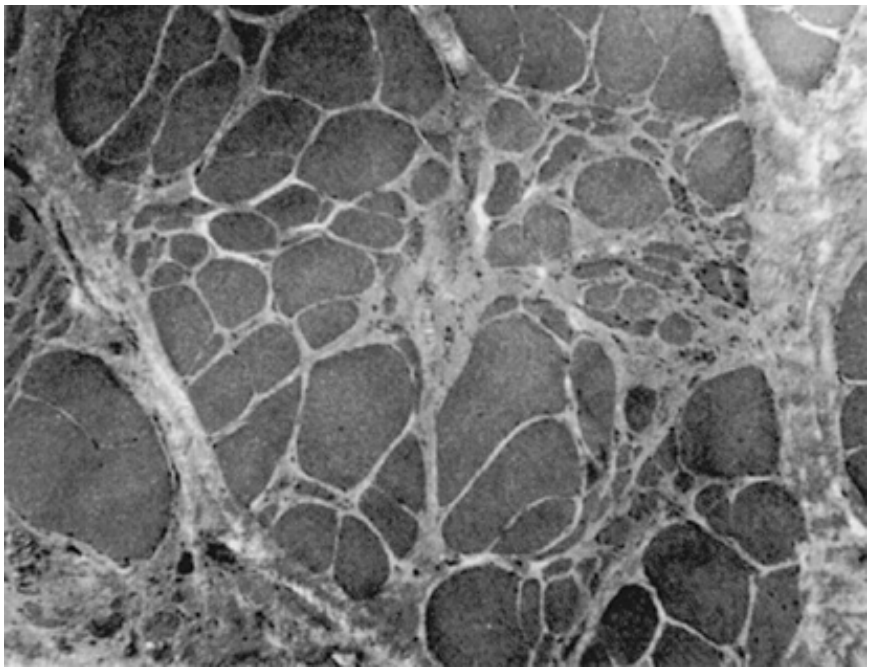

Figure 62-9: Skeletal muscle biopsy in Emery-Dreifuss muscular dystrophy. Increased endomysial and perimysial connective tissue, with marked variation in myofiber size, internal nuclei, and myofibers splitting (×153). (Reprinted with permission from Specht LA, McKee AC. MGH Case Records (case 34-1992): A 19-year-old man with progressive proximal muscle weakness, contractures, and cardiac abnormalities. *N Engl J Med* 1992; 327:558.)

The autosomal dominant form of EDMD was initially mapped to chromosome 1, and recently the gene was identified as lamin A/C.[189] The encoded protein is also thought to be a nuclear lamina-associated protein. The phenotypic spectrum of this gene appears to be broad when mutated. In some cases, only a DCM phenotype with conduction disease occurs in the absence of skeletal muscle disease clinically, similar to what is seen with dystrophin.

Myotonic Dystrophy (Steinert's Disease)

Myotonic dystrophy (DM) is the most common form of inherited muscular dystrophy in adults, with an incidence of 1 in 8000 to 10,000 persons.[168] This autosomal dominant disorder affects multiple organ systems and its name is derived from the combined myopathy, dystrophy, and myotonia of skeletal muscle. Myotonia, an abnormality in relaxation after muscle contraction, is the primary feature of this disease. DM is variably expressed, and individuals may present with signs and symptoms involving many different organ systems. Penetrance varies with age and the disease may affect different tissues at different periods of life; a severe form of DM exists with symptoms at birth.

Classically, DM presents in a young adult with new-onset weakness of the hands or mild foot drop. Asymptomatic myotonia-namely, sustained contraction and depolarization of skeletal muscle in response to a percussive or electrical impulse-may be elicited. Myotonia is usually in the hands and tongue, while weakness involves the distal extremities predominantly. A typical facies usually accompanies these findings, including loss of temporal muscle and slight weakness of the lips and mouth with a "hatchet-like" shape, frontal balding, and ptosis (Fig. 62-10). Other systems including heart, eyes, CNS, endocrine system, gastrointestinal system and respiratory system may be involved (Table 62-5). Electromyographic abnormalities are frequent and subcapsular; punctuate iridescent cataracts are common in middle-aged patients.

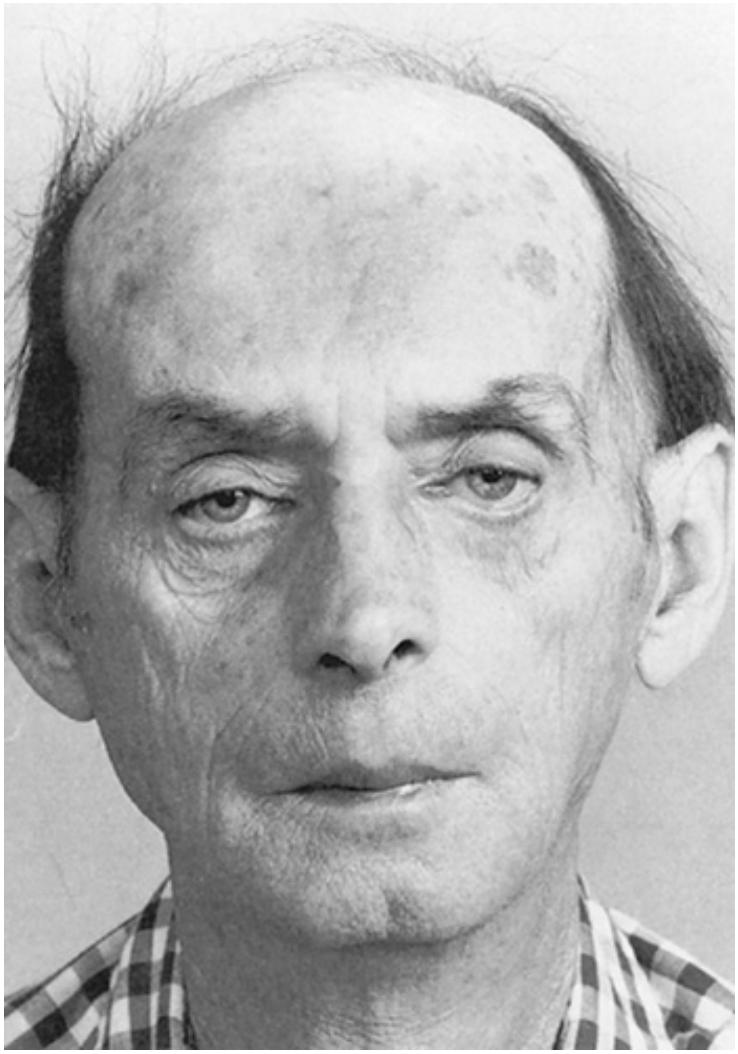

Figure 62-10: A 41-year-old man with myotonic dystrophy (DM). Muscle wasting of temporalis muscles with narrow small chin produces a "hatchet-like" facies. Baldness and ptosis (note droopy eyelids with pupils partially covered and sclerae visible) contribute to characteristic appearance. (Reprinted with permission from Roses AD, Pericak-Vance MA. In: *Molecular Basis of Neurology*. Cambridge, MA: Blackwell; 1993:147-159.)

Myotonia is best seen in the small muscles of the hand and in the tongue. There are repetitive discharges with gradual and uneven decay of amplitude on electromyography. Myotonic muscles undergo dystrophic changes, which may take years to several decades. In general, the younger the presentation, the more rapid the progression. Only a small percentage of affected individuals, probably less than 10 percent, progress to requiring a wheelchair for ambulation; many require a brace worn in the shoes to control foot drop.

Serious complications of DM involve the heart.[189] Cardiac conduction abnormalities are common (Tables 62-7 and 62-8) and may be progressive, particularly in younger patients. These are identified by periodic ECG monitoring and usually occur without obvious cardiac complaints. Sudden cardiac death in athletically inclined adolescents is relatively frequent. In studies of families with DM, cardiac findings may be the initial clinical manifestation of the disease, with bradycardia and first-degree heart block being common. Progression to complete heart block may occur over time and is not well tolerated, potentially ending in death and frequently requiring pacing. In some cases, ventricular tachycardia or dilated cardiomyopathy may also occur (Table 62-8). Typically, however, systolic function is preserved but diastolic dysfunction occurs.

Table 62-8: Systemic Involvement in Myotonic Dystrophy

Organ or System	Clinical	Diagnostic Signs
Muscle	Myotonia, weakness, dystrophy	*EMG:* decreased resting membrane potential, repetitive depolarization ('dive bomber' sound) *Pathology:* sarcoplasmic masses, ringed fibers, internal nuclei frequent; nuclei often in chains; large variation in fiber size
Cardiac	Bradycardia common, complete heart block frequent, prolonged PR interval, dilated cardiomyopathy	First-degree heart block, bradycardia on ECG; abnormal vectorcardiogram; SA node, right and left bundle branch dysfunction; increased His-Purkinje conduction (His bundle studies) with progressive conduction system abnormalities; dilated cardiomyopathy
Lens	Posterior subcapsular, iridescent, or scintillating cataracts	Dust-like cataracts may be visible only on slit lamp examination
Eye	Decreased vision (independent of cataracts and diabetic retinopathy); diplopia	Pigmentary disorders of macula keratosis sicca; decreased intraocular pressure; frequent ptosis and ultraocular muscle weakness
CNS	Mental retardation (especially congenital DM); hypersomnia	Possible neuronal heterotopias; suspicious, reticent personality characteristics
Gastrointestinal	Dysphagia, abdominal pain	Disordered esophageal and gastric peristalsis; dilation of bowel
Skeletal	Cranial and facial abnormalities, malocclusion of dentition	Cranial bony abnormalities, hyperostosis of skull (localized or diffuse), small sella turcica, large sinuses, micrognathia
Respiratory	Hypoventilation, postanesthesia respiratory failure	Diaphragmatic and intercostal muscle weakness
Smooth muscle	Dilation of hollow-viscus organs and ureters, abnormal bowel motility	Thinned or interrupted smooth muscle

DM patients may have a particular psychological profile that includes indifference, reticence, and hostility. Mild mental retardation may be seen, particularly in patients with congenital DM. Young and middle-aged patients may be hypersomnolent and indolent, sometimes sleeping up to 20 h daily. Testicular atrophy is common in males and amenorrhea and ovarian cysts may occur in females (Table 62-8). Increasing debilitation, handicap, and disability may occur in subsequent generations of a family; this increasing disease severity is known as *anticipation*.

The gene for myotonic dystrophy was localized to 19q13.3[190] and encodes for myotonin protein kinase (DMPK), a serine-threonine protein kinase.[191] The genetic basis for myotonic dystrophy

consists of long stretches of three bases repeated in tandem. The triplet repeat present in the DMPK gene is CTG, which in the mRNA is CUG and is located in the 3′ end of the gene beyond the protein coding region. The severity of disease (neuromuscular, cardiac, and CNS) relates to the length of the repeats. Less than 50 triplet repeats is usually associated with no disease. Usually 100 to 250 repeats are required to cause disease and, if more than 250 repeats are present, the disease is usually seen at birth and reflects genetic anticipation (increasingly severe expression and earlier onset of disease through generations as a result of the increase in the number of CTG repeats with subsequent generations). Clinical cardiac symptoms (i.e., syncope) and ECG abnormalities (i.e., left bundle-branch block) correlate directly with CTG expansion size.[189] In addition, the incidence of malignant ventricular arrhythmias also correlate directly with the size of CTG expansion.

Myotonic dystrophy is one of the many familial neuromuscular diseases due to the genetic defect of multiple triplet repeats.[189] However, the mechanisms whereby the triplet repeats induce the disease remains an enigma. Myotonic dystrophy is somewhat unique since the triplet repeats are in the 3′ end of the gene beyond the protein coding region. DMPK levels are reduced in patients with myotonic dystrophy; when the gene for DMPK is eliminated in knockout mice, muscle weakness results, but none of the other organs are involved, such as the eyes or testes, as observed in myotonic dystrophy. This has led to an extensive search for other explanations, including adjacent genes. One by-product of this research was identification of a novel group of proteins that bind specifically to triplet repeats in DNA and RNA[192]; binding is determined by the sequence of the triplet repeat. A specific protein was identified that binds only to the CUG sequence in the mRNA of DMPK. The CUG-BP protein has a molecular weight of 52 kDa and three binding sites for CUG repeats.[192] The protein has several serine and threonine phosphorylation sites, which appear to be regulated by DMPK. Further studies indicated that this protein is identical to another protein (NB50) that is known to be responsible for mRNA transport from the nucleus to the cytoplasm.[193] This has given rise to the hypothesis that the CUG-BP is sequestered by the multiple CUG repeats and not available to other mRNAs for processing or transport from the nucleus. The involvement of several mRNAs would explain the multiple organs involved. This would also explain why, in the mouse with the DMPK gene knocked out, one observes only muscle weakness because in the absence of the multiple triplet repeats, the other mRNAs are properly transported by the CUG-BP protein and function normally.[194,195] This hypothesis is now actively pursued by many investigators. Preliminary findings show an accumulation of the CUG-BP in the nuclei of cells from DM.[196,197] Another possible mechanism is variations in gene levels in the immediate vicinity, such as the homeobox gene DMPHP.

Relative to therapy, conduction disturbances typically require permanent pacemaker implantation and dilated cardiomyopathy requires treatment for heart failure.

Fascioscapulohumeral Dystrophy

Fascioscapulohumeral,[198] or Landouzy-Dejerine, muscular dystrophy exists as two clinical types. One type has autosomal dominant inheritance with onset at the end of the first or the beginning of the second decade. The weakness of the facial, shoulder, and upper arm muscles is slowly progressive, but wide variability is seen. The second clinical type of fascioscapulohumeral dystrophy is the infantile form. Onset is within the first 2 years of life, and many patients are wheelchair-bound by 1 year of age. Clinical manifestations of muscular dystrophy generally are absent in the parents.

The cardiac involvement involves progressive atrial dysfunction resulting in permanent paralysis of the atria, beginning with sinus bradycardia, junctional escape rhythm, and AV block (Table 62-7). Criteria for diagnosis of permanent paralysis of the atria include absence of P waves on surface ECG, esophageal electrogram, and intracardiac electrocardiogram, unresponsiveness of

the atrium to electrical stimulation, and immobility of the atria on fluoroscopy and echocardiography. Focal abnormalities of the atria precede these events. Nonparalytic regions of the atrium may demonstrate enhanced activity, apparent clinically as atrial tachycardia or flutter. Therapy depends on the clinical features. The chromosomal locus has been identified on chromosome 4q35,[199] but the responsible gene(s) are unknown.

Nemaline Myopathy

Nemaline myopathy is named for the small rod-like particles found in striated muscle. Inheritance is probably autosomal dominant, although autosomal recessive inheritance may occur.[200] Clinical features include hypotonia with truncal and extremity weakness from an early age and a narrow arched palate. Conduction abnormalities and cardiac dilatation have been described[200,201] but are unusual (Table 62-7). Nemaline rods are demonstrable in the myocardium and conduction tissues. The genetic cause of this disease was recently discovered by Nowak et al.,[202] who identified mutations in the human skeletal muscle α-actin gene (ACTA1), all missense mutations. Interestingly, the clinical phenotype varied significantly, from mild disease to severe, infantile-onset disease. In addition, a different clinical disorder, actin myopathy (i.e., congenital myopathy with excessive thin filaments), was also found to carry mutations in ACTA1.[202,203]

Two other forms of nemaline myopathy have also been identified. Mutations in TPM3, encoding α-tropomyosin slow, has been found mutated in both dominant and recessive nemaline myopathy.[204] In addition, mutations in NEB, encoding nebulin, has been seen in slowly progressive congenital nemaline myopathy.[205] Therefore, the underlying cause for this phenotype are mutations in skeletal muscle sarcomeric genes, similar to that seen in HCM and cardiac sarcomeric genes. Therapy is required when the conduction abnormalities or cardiac dilatation causes clinical symptoms.

Endocardial Fibroelastosis (EFE)

This disorder is characterized by endocardial thickening, which leads to decreased compliance and impaired diastolic function. Primary forms are typically unassociated with other cardiac anomalies. Most commonly, this disease presents in infancy and early childhood with signs and symptoms of congestive heart failure.[206] The diagnosis is usually made by biopsy. The incidence of primary EFE in the United States in the past was relatively high-approximately one case in 5000 live births.[207] During the past decade, however, this incidence has decreased markedly, for unknown reasons. Treatment of children with primary EFE with anticongestive and inotropic measures has been ineffective, and the clinical course usually results in either death or transplantation. Postmortem examination typically demonstrates enlargement of the left ventricle. Histopathology commonly reveals extensive deposition of extracellular matrix, primarily collagen and elastic fibers, in the endocardium. Three inherited forms of EFE have been described: autosomal recessive, autosomal dominant, and an X-linked recessive disorder. The majority of cases, however, occur sporadically. The X-linked form shows mitochondrial abnormalities similar to Barth syndrome[127,128] with the exception that EFE patients have endocardial scarring. It is likely, however, that this form is caused by mutations in the G4.5 gene found in Barth syndrome and LV noncompaction.[129] It was hypothesized in the 1950s and 1960s that EFE is secondary to intrauterine myocarditis in sporadic cases, particularly as a result of mumps or Coxsackievirus. Ni et al.[208] recently identified mumps viral genome in the majority of autopsy specimens retrieved from infants dying between the 1950s and 1980s. This disease essentially disappeared after the program of vaccination (mumps-measles-rubella or MMR) began in the United States.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

DEFECTS OF METABOLISM CAUSING CARDIOMYOPATHY

Carnitine Deficiency

L-Carnitine is a small, water-soluble molecule containing seven carbon atoms and is important in the shuttling of long-chain fatty acids and activated acetate across the inner mitochondrial membrane. A specific translocase facilitates the exchange of long-chain acylcarnitine and acetylcarnitine. Carnitine also serves as the shuttle for the end products of peroxisomal fatty acid oxidation and for α-ketoacids derived from branched chain amino acids. These metabolites are transferred into the mitochondrial matrix for terminal oxidation.

Primary carnitine deficiency syndrome is characterized by a profound decrease in carnitine in affected tissues. The mechanism underlying the primary disorder is defective transport of carnitine from the serum into the affected cells.[209] End-stage disease of many different organs, including the heart, may induce depletion of carnitine stores and must be differentiated from the chronic inherited type. Based on carnitine levels, carnitine defiency is usually divided into two forms: a myopathic form and a systemic form. In the myopathic form, carnitine levels are decreased only in muscle tissue; in the systemic form, multiple tissues are affected, including muscle, liver, and plasma.[209] The systemic form presents in infancy or early childhood with episodes of hypoglycemia, ammonemia, acidemia, hepatomegaly, and EFE. A gene for primary systemic "carnitine" deficiency was recently mapped to chromosome 5q31.1-5q32,[210] the SCD locus. A murine model with juvenile visceral steatosis (*jvs*) has been identified[211] in which homozygotes have low serum total and free carnitine levels but no reduction in urinary excretion of carnitines.[212] This gene was mapped to the *jvs* locus on chromosome 11 of the mouse, which is syntenic to human 5q.[213] The human gene was recently found to be a novel sodium ion-dependent carnitine transporter, OCTN2.[214]

Therapy includes oral carnitine, occasionally reversing the cardiomyopathy. Additional therapy includes bicarbonate to reverse the acidemia, intravenous glucose, and anticongestive measures. Intercurrent illness commonly causes acute decompensation and death.

Medium Chain Acyl-CoA Dehydrogenase (MCAD) Deficiency

This disorder appears to be the most common inborn error of fatty acid oxidation, estimated to occur in one per 6000 to 10,000 live Caucasian births. It is characterized by recurrent episodes of illness, provoked by fasting more than 12 h, with the first episode generally occurring between 6 and 24 months of life. The most common symptoms include vomiting and severe lethargy that can progress to coma, as well as the less striking symptoms of muscle weakness and exercise intolerance. Hypoglycemia is often present between episodes, when patients appear normal. Hepatomegaly and DCM (rarely) are also seen. Liver biopsy can show marked fatty infiltrate ranging from predominantly microvesicular to a macrovesicular pattern. This autosomal recessive disorder was localized to chromosome 1p31 and human and rat MCAD cDNAs were cloned and sequenced.[215] The coding region is 1263 bp and encodes a precursor protein containing 421 amino acids. A variety of mutations have been reported. An A-to-G nucleotide replacement at position 985 of MCAD cDNA appears to be the most prevalent mutation responsible for MCAD deficiency (greater than 90 percent).[216] This deletion is predicted to result in a truncated protein of

385 amino acids instead of the normal 421-amino acid product. The common A-to-G 985 mutation appears to be due to a founder effect. Poor genotype-phenotype correlation exists.[217]

The therapy for these patients includes treatment of the acidosis and, when present, treatment of heart failure. Glucose therapy is indicated for hypoglycemia while intravenous fluids are needed during episodes of vomiting.

Long-Chain Acyl-CoA Dehydrogenase (LCAD) Deficiency/Very Long Chain Acyl-CoA Dehydrogenase (VLCAD) Deficiency

First described in 1985, LCAD manifests itself as recurrent episodes of coma, vomiting, and hypoglycemia triggered by fasting. Some patients have much more severe illness with notable involvement of cardiac and skeletal muscle.[28] Both DCM and HCM have been seen. Like MCAD, LCAD patients have secondary carnitine deficiency, and their fasting urine organic acid profile is abnormal, with low ketones and increased levels of dicarboxylic acids. The LCAD gene was identified[218] in 1991. In addition to the well-known β-oxidation enzymes in the mitochondrial matrix, there are two additional membrane-bound enzymes of β-oxidation.[219,220] One of these has been called "very long chain acyl-CoA dehydrogenase" (VLCAD), while the other is known as the "trifunctional protein." VLCAD is a membrane-bound homodimer with monomers of larger size than the other enzymes of the complex. It catalyzes the initial rate limiting step in mitochondrial fatty acid β-oxidation. The human VLCAD cDNA[221222] and genomic sequence[210] were identified over the past several years, with multiple mutations subsequently identified.[224] Andresen et al.[225] recently showed that clear correlation of genotype with disease phenotype exists. Patients with severe childhood phenotype, which has a high incidence of cardiomyopathy and mortality, have mutations that result in no residual enzyme activity. Those with milder childhood and adult phenotypes have mutations that may result in residual enzyme activity. This clear genotype-phenotype correlation sharply contrasts that seen in MCAD deficiency, in which no correlation has been established. This new understanding of the mitochondrial β-oxidation pathway has led to new insights of the disorder once thought to be due to LCAD deficiency but now thought to be VLCAD deficiency.

Therapy for these patients includes aggressive treatment with glucose and hemodynamic support. When cardiac disease persists, chronic therapy for the dilated or hypertrophic heart disease should be instituted.

Fabry's Disease

An X-linked recessive disorder with complete penetrance and variable clinical expressivity, this entity is due to a deficiency of the enzyme α-galactosidase A, a lysosomal enzyme that participates in the catabolism of neutral glycosphingolipids, and is found in one in 40,000 live births. The disease frequently has its onset in adolescence and typically manifests with sensations of burning pain in the hands and feet. These sensations tend to be associated with fever, heat, cold, and exercise. Multiple angiokeratomas are noticeable with increasing age, with the umbilical area and genitalia the sites most commonly affected. Progressive renal failure develops with age, and CNS manifestations commonly include seizures, headaches, hemiplegia, and stroke. Corneal opacities are also frequently seen.

The cardiac manifestations of Fabry's disease generally appear in young adulthood. Aortic root dilation, dilated or hypertrophic cardiomyopathy,[226] valve dysfunction (especially mitral valve),[227] and myocardial infarction occur in these patients. Recently, association with tetralogy of Fallot was reported,[228] as was restrictive cardiomyopathy.[229] Electrocardiographic abnormalities commonly include atrial fibrillation, intraventricular conduction delay, right bundle-

branch block, ST-T wave changes, short PR interval, and left ventricular hypertrophy. The short PR interval can progressively shorten over time probably secondary to lipid deposition in the atrioventricular node. Chamber thickness and mitral valve prolapse are evident on echocardiographic examination. Light microscopy shows lipid accumulation in nearly all cardiac tissue. Concentric lamellae are seen within cells and contain the neutral glycophospholipid. Therapy for these cardiac abnormalities does not differ from that typically used for HCM, myocardial ischemia or infarction, or mitral insufficiency found in patients without Fabry's disease. Recently, cardiac transplantation has been reported.[230]

The disease-causing gene, lysosomal-galactosidase A (GLA), is localized to Xq12.1-Xq12.2. The full-length cDNA has 1393 bp with a 60-nucleotide 5′ untranslated region, encoding for a precursor peptide of 429 amino acids.[231] The gene was found to contain seven exons. Mutations have been described[232,233] and genotype-phenotypic correlation performed. Mouse models have been developed which closely mimic the human disorder.[234] Antenatal and postnatal diagnosis is available. Therapy is symptomatic at present, but enzyme replacement therapy is likely in the future. Recently, gene transfer studies have been reported that correct the enzymatic and lysosomal storage defects in Fabry-like mice.[235]

Homocystinuria

Homocystinuria, inherited as an autosomal recessive defect, occurs with a frequency of 1 in 75,000. There is a deficiency of cystathionine β-synthase (CBS), which leads to elevated methionine in the blood and homocystine and methionine in the urine[236] (see Chaps. 39 and 41). In the homozygous individuals, major clinical features include a marfanoid habitus with a thin, tall body build and arachnodactyly, pectus excavatum, kyphoscoliosis, and osteoporosis. Subluxation of the lens, usually in a downward position, is frequently seen by 10 years of age, and myopia is common. Approximately 60 percent of affected individuals are mentally retarded to some degree. Schizophrenic behavior has also been noted in some patients. Cardiovascular abnormalities consist primarily of arterial and venous thrombosis (Table 62-5), with medial degeneration of the aorta and large arteries and intimal hyperplasia and fibrosis. It is estimated that about one-third of patients with familial homocystinuria will experience arterial or venous thrombosis. It is interesting that even within the same family with the same mutation there is marked variability among affected siblings.[237] The thrombotic episodes usually occur before the age of 30 years and include deep vein thrombosis, pulmonary embolism, and arterial thrombosis in the cerebral, peripheral, and coronary arteries.[237] However, when this disease occurs in individuals with other thrombogenic risk factors such as factor V Leiden,[238] the incidence of thrombosis, both arterial and venous, is significantly increased. An increased risk of cardiovascular disease has also been observed in carriers of the gene for homocystinuria. The gene was initially assigned to the subtelomeric region of band 21q22.3 by in situ hybridization studies.[239] Three types of cDNAs differing in both their translated and untranslated regions were isolated, with the resultant differences due to alternative splicing. The human gene was cloned and complete-sequence, alternatively spliced forms, and mutations described.[240] Numerous mutations have now been identified and correlated with the phenotype. The gene is 28 kb in size, contains 23 exons, and contains many *alu* repeat sequences which predisposes the gene to rearrangements.[241] The defect can be treated in some cases by pyridoxine supplementation. The percentage of pyridoxine responders ranges between 13 and 47 percent. Betaine, lowmethionine diet, and aspirin treatments have also been tried with varying success. Prenatal diagnosis is available by an enzyme assay and gene analysis. Recently, tandem spectrometry has been used in the diagnosis.[241]

Homocystinuria, while a rare disease, has received increased attention recently because of several studies indicating that homocysteine is an important and independent risk factor for atherosclerosis and thrombosis.[242,243] In one such study performed recently, of 269 patients with the first episode of deep vein thrombosis, 10 percent had elevated plasma homocysteine levels,

compared with 4 percent in 269 matched controls.[243] Homocystinuria results from impaired enzyme activity in the metabolism of cobalamin, but may also occur from a deficiency of vitamin B_6, folate, or vitamin B_{12}. The mechanism whereby homocysteine induces atherosclerosis is postulated to be through induction of the cyclin A gene which induces vascular smooth muscle proliferation, a major component of atherosclerosis.[244] The mechanism whereby homocysteine induces thrombosis is probably through its known effect on activation of factor V in endothelial cells, inhibition of protein C, and decreased antithrombin III activity. It remains somewhat controversial as to how common hyperhomocysteinemia is as a risk factor for atherosclerosis and/or thrombosis. It is, however, very important to exclude hyperhomocysteinemia in patients with vascular disease such as myocardial infarction, strokes, or systemic thrombosis, particularly if these are occurring prematurely or there are no other risk factors, since, in the acquired form, the condition is relatively easy to treat by the administration of vitamins.

Mitochondrial Cardiomyopathies

The human mitochondrial genome[245] is a small, circular DNA molecule (Fig. 62-11) that is maternally inherited. Mitochondrial DNA (mtDNA) encodes 13 of the 69 proteins required for oxidative metabolism, 22 transfer RNAs (tRNAs), and 2 ribosomal RNAs (rRNAs) required for their translation. Since mtDNA has much less redundancy than the nuclear genome (in which essentially identical information is received from both parents), and tRNAs and rRNAs are present in multiple copies, the mitochondrial genome is an excellent target for mutations giving rise to human disease.[246,247] Mitochondria are dependent on nucleocytoplasmic mechanisms for most structural components, but do contribute vital peptides that are central to cellular respiration. The electron transport chain, which generates cellular ATP, is organized into complexes I to IV and the ATP synthase (complex V) (Fig. 62-12). The 13 mtDNA genes that encode enzymes in the respiratory chain include 7 complex I[246,248] subunits (ND1, 2, 3, 4L, 4, 5, and 6); 1 complex III subunit (cytochrome b); 3 complex IV subunits (COI, II, III); and 2 complex V subunits (ATPase 6 and 8). Each cell contains numerous mitochondria and each mitochondrion contains multiple copies of mtDNA. In most mitochondrial disorders, patients carry a mix of mutant and normal mitochondria-a condition known as *heteroplasmy*, with the proportions varying from tissue to tissue and individual to individual within a pedigree, in a manner correlating with severity of phenotype.

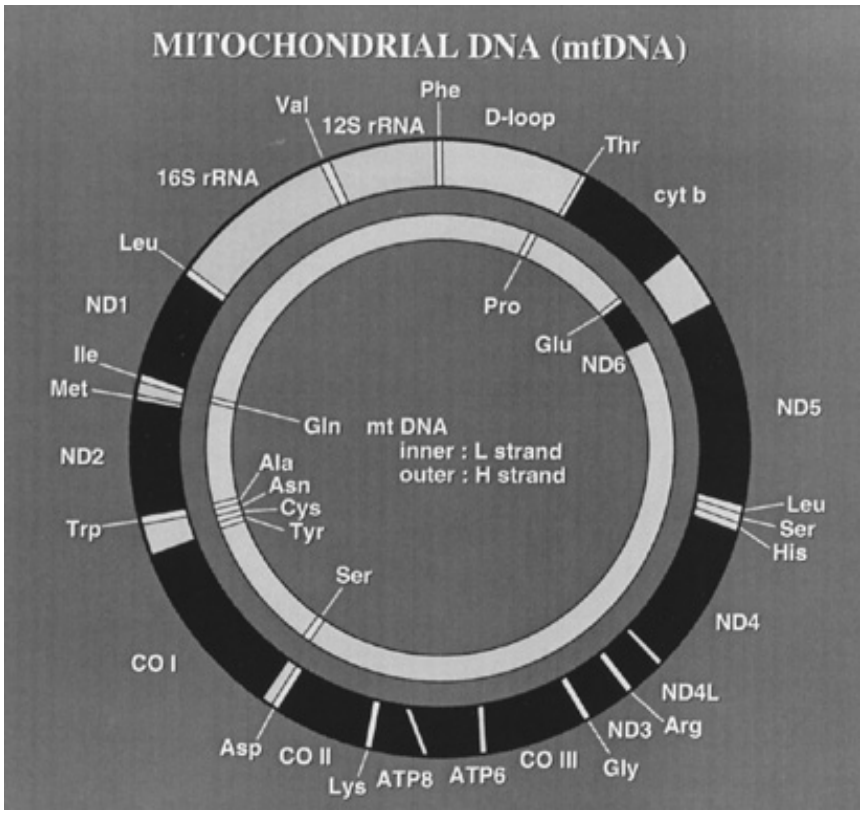

Figure 62-11: Mitochondrial genome. This small, circular DNA molecule encodes 13 enzymes of the respiratory chain, 22 tRNAs, and 2 rRNAs. When it is mutated, cardiac, neurologic, and myopathic disorders develop.

Mitochondrial diseases often produce disturbances of brain and muscle function and are usually evident during infancy or early childhood. Cardiac disease is most commonly seen with respiratory chain defects. Ragged-red fibers are present in muscle biopsy specimens almost invariably when the molecular defect involves mtDNA.[249] These defects represent the genetics of ATP production. The diverse clinical syndromes associated with various respiratory chain complexes are thought to result from involvement of tissue-specific isoforms in some cases, involvement of tissue-nonspecific (generalized) subunits in other cases, and the residual enzyme activity in affected tissues. The cardiac diseases seen associated with mitochondrial defects include both hypertrophic cardiomyopathy and dilated cardiomyopathy.[246]

Mitochondrial gene mapping, in contrast to the nuclear genome, does not require genetic linkage. One simply has to show that the disease exhibits transmission through all mothers and no fathers in a sufficiently large family. Once this is established, the mitochondrial genome can be sequenced to identify the mutation, which must be shown to segregate with the disease since there are many harmless polymorphisms.

Therapy for these disorders is generally symptom-based. Conduction disturbance generally requires placement of a permanent pacemaker, and heart failure is treated with the usual therapy. In some patients, beta-blockers may be useful. Hypertrophic heart disease is usually treated in a fashion similar to that of other forms of HCM. Mitochondrial-based therapy may include coenzyme Q10, carnitine, or vitamins, but these therapeutic approaches typically do not alter the clinical course.

COMPLEX I DEFICIENCY

Complex I, or nicotinamide adenine dinucleotide (NADH): ubiquinone oxidoreductase, is the

largest of the electron transport chain complexes[250,251] (Fig. 62-12) with at least 35 complex I nuclear gene products and 7 mitochondrially encoded proteins. It is embedded in the inner mitochondrial membrane and serves to dehydrogenate NADH and shuttle electrons to coenzyme Q. This electron transport generates a protein gradient across the inner mitochondrial membrane, helping to synthesize ATP. When complex I abnormalities occur, significant health problems arise.

Mitochondriocytopathies occur with an estimated incidence of 1 per 10,000 live births, and isolated complex I deficiency is one of those most frequently encountered.[248] The first clinical symptoms of complex I deficiency, presenting either at birth or in early childhood, result from brain dysfunction, sometimes combined with defects in other energy-consuming organs, such as skeletal muscle and the heart. For this reason, complex I deficiencies are grouped among the mitochondrial encephalomyopathies.

Robinson[248] categorized complex I-deficient patients into three major clinical groups. The most common presentation is Leigh syndrome, with cardiomyopathy occuring in about 40 percent of cases.[252] A second category often seen is fatal neonatal lactic acidosis (MELAS-see below). A third but uncommon group present with hepatopathy and tubulopathy with mild symptoms, such as exercise intolerance, or with cataracts and cardiomyopathy. The most frequently observed pathologic mtDNA mutations are found in genes for mitochondrial tRNAs for leucine (T3271C, A3243G) and lysine (A8344G, T8356C) and in the protein-encoding subunits ND1 (T4160A, G3460A), ND4 (G11778A), and ND6 (T14484C, G14459A).

Treatment of these disorders is limited. Riboflavin, succinate supplements (since the metabolite enters the respiratory chain at complex II), ubiquonone, and idebanone have been recommended for therapy in patients with MELAS. Carnitine and coenzyme Q10 have also been used.

COMPLEX III DEFECTS

This results in a myopathic or multisystem disorder. Cardiomyopathy has been found both alone or in conjunction with skeletal myopathy. Encephalomyopathy also presents with retinopathy, ataxia, spasticity, dementia, weakness, sensorineural hearing loss, and exercise intolerance.

COMPLEX IV DEFECTS

This abnormality is similar clinically to complex I defects. The mitochondrial genome encodes for three subunits of cytochrome C oxidase, which represents the terminal portion of the respiratory chain (Fig. 62-12) and catalyzes conversion of molecular oxygen to water. A benign reversible infantile myopathy which normalizes by early childhood may occur, as may a fatal infantile myopathy manifested by profound weakness, hypotonia, respiratory insufficiency, and death. This myopathy may occur alone, or in association with severe renal tubular dysfunction or cardiomyopathy with red ragged fibers.

HYPOXEMIA, mtDNA DAMAGE, AND CARDIAC DISEASE

Since cardiac tissue relies on mitochondrial oxidative phosphorylation (ox-phos) for energy production, deficiency of portions of this system or its end-product may cause cardiac abnormalities.[248] Hypoxemia can increase oxygen radical production, which results in elevated mtDNA damage and altered ox-phos gene expression. In addition, these enzymes decline with age while mtDNA deletions increase with age, especially deletion at nucleotide 4977 bp. Ischemic hearts may be more likely to have increased chances of mtDNA deletion due to the effect of hypoxemia[253] and, using PCR amplification across the deletion breakpoint of the common mtDNA4977 deletion, it was found that mtDNA damage was increased in chronically ischemic

hearts, as well as in some hearts with other forms of chronic cardiac disease (i.e., DCM, HCM), but this is probably an incidental finding and has no effect on cardiac function. Similarly, mitochondrial DNA damage increases with age independent of ischemia, but it is doubtful whether it in any way alters cardiac function.

KEARNS-SAYRE SYNDROME (KSS)

This mitochondrial myopathy is characterized by ptosis, chronic progressive external ophthalmoplegia, abnormal retinal pigmentation, and cardiac conduction defects as well as DCM.[255] Hearing loss and limb weakness are frequently associated, as are endocrinopathies such as diabetes mellitus, hypoparathyroidism, and growth hormone deficiency. Approximately 20 percent of KSS patients have cardiac involvement and of these, the majority usually have conduction defects causing progressive heart block (Table 62-7). These patients generally have large heterogeneous deletions in the mitochondrial genome, of which $tRNA^{leu(UUR)}$-3243 is most common.

Clinically, conduction abnormalities, bifascicular block, or progressive high-grade block may define the requirement for permanent pacemaker implantation. Symptomatic improvement using mitochondrial therapies may occasionally be seen with coenzyme Q10 therapy. The major function of coenzyme Q10 in mitochondria is to shuttle electrons from complexes I and II to complex III, while stabilizing the respiratory chain complexes. Vitamins such as phylloquinone (vitamin K_1), menadione (vitamin K_3), and ascorbic acid (vitamin C) have been used to donate electrons directly to cytochrome *c*. In addition, the endocrine abnormalities and heart failure should be treated in the usual way.

MERRF SYNDROME

This syndrome is characterized by *m*yoclonic *e*pilepsy with *r*agged-*r*ed muscle *f*ibers (MERRF) and is caused by a single nucleotide substitution in $tRNA^{Lys}$, which apparently interferes with mitochondrial translation.[256] The defining clinical features are myoclonus, generalized seizures, ataxia, and hypertrophic cardiomyopathy. Skeletal muscle biopsy demonstrates ragged-red fibers on microscopy. Symptoms usually begin in childhood, but adult onset has been described. Other common manifestations include impaired hearing, demential neuropathy, short stature, optic atrophy, lactic acidosis, and lipomas.

Shoffner et al.[256] showed an A-to-G transition mutation (position 8344) as the cause of the disease and associated with defects in complexes I and IV. This abnormality causes decline in ATP-generating capacity, with a resultant cardiomyopathy. Other reports have outlined various disease-causing mutations. Therapy is similar to other mitochondrial myopathies; anticonvulsant medications may also be indicated.

MELAS SYNDROME

*M*itochondrial *e*ncephalomypathy and *l*actic *a*cidosis with *s*troke-like episodes (MELAS) is clinically characterized by stroke before age 40 years; encephalopathy with seizures, dementia, or both; and lactic acidosis, ragged-red fibers, or both.[257] Recurrent headaches and recurrent vomiting are common. Other frequent manifestations include exercise intolerance, limb weakness, short stature, and elevated CSF protein. Hypertrophic cardiomyopathy or dilated cardiomyopathy may occur.

Variable respiratory chain defects have been described, but complex I abnormalities are most common. Between 80 and 90 percent of patients have an adenine-to-guanine point mutation in $tRNA^{Leu(UUR)}$ at position 3243. Therapy is similar to that described for MERRF.

THERAPY

Medical therapy for mitochondrial disorders has been disappointing and for that reason newer approaches have been sought. As most pathologic mtDNA mutations are heteroplasmic and there is a threshold whereby a certain level of mutated mtDNA is necessary before a disease becomes biochemically or clinically apparent, any approach that increases the proportion of wild-type to mutated mtDNA will reverse the phenotype and thus be a potentially useful treatment. When there is an extremely high level of the pathogenetic mutation in cells, as occurs with muscle necrosis, these necrotic cells form regenerated muscle. Clark et al.[258] took advantage of this phenomenon by inducing necrosis and regeneration in muscle by performing a muscle biopsy, which resulted in the absence of mutated mtDNA in the biopsied muscle. Due to the invasiveness of this approach, reduced utility of the therapy is anticipated unless other methods of inducing necrosis can be developed.

More recently, Taivassalo et al.[259] developed a novel therapy that they called *gene shifting*, which is similar to that described by Clark et al.[258] These authors enhanced the incorporation of new (satellite) cells through regeneration following injury or muscle hypertrophy induced by eccentric or concentric resistance exercise training. They were able to show a remarkable increase in the ratio of wild-type to mutant mtDNAs, and in the proportion of muscle fibers with normal respiratory chain activity. This work suggests that it might be possible to reverse the molecular events that led to the expression of metabolic myopathy and demonstrates that this form of "gene shifting" therapy could be effective.

Connective Tissue Disorders

The composition, structure, and function of normal and abnormal connective tissues are gradually being elucidated[260,261] (see Chap. 85). The annuli fibrosis that separate the atria and ventricles and support the two atrioventricular valves are largely type I collagen fiber bundles, while the blood vessel walls are elastin and collagen types I and III (50 percent), with lesser contributions from types IV, V, and VI collagen. Elastin in located at 7q11; collagen 1A1, at 17q21.13-17q22.05; collagen 1A2, at 7q21.3-7q22.1; collagen 2A1, at 12q13.1-12q13.3; collagen 3A1, at 2q31; and collagen 5A2, at 2q31.

MARFAN SYNDROME

Marfan syndrome is a heritable disorder of connective tissue caused by a defect in fibrillin protein encoded by the fibrillin-1 gene on chromosome 15 at 15q15-q20 (see Chap. 98). The Marfan syndrome occurs in approximately 1 in 10,000 individuals and is equally common in males and females. There is marked variation in clinical expression, and the diagnosis can be made at any age from the newborn period through adulthood.[263] Because of the variability in expression, overlap with nonpathologic features (such as tall stature) can be observed in the general population. Since fibrillin[264] is diffuse, Marfan syndrome affects skeletal, ocular, cardiovascular, skin, pulmonary, and central nervous system.[260,261] The skeletal manifestations of Marfan syndrome include tall stature, thin body build, long arms and legs (dolichostenomelia), long fingers and toes (arachnodactyly), hyperextensibility, pectus deformity, scoliosis, joint contractures, and narrow, high-arched palate. Cardiovascular abnormalities, particularly affecting the mitral apparatus and aorta, are also common. There may also be overlap with other disorders that share some of the same phenotypic features, such as the condition termed *congenital contractual arachnodactyly* (CCA).[265] Clinical manifestations of CCA include dolichostenomelia and arachnodactyly, contractures of large joints, and abnormal pinnae formation. In 1990, Marfan syndrome was mapped to the long arm of chromosome 15(15q15q-q20).[266] Subsequently, a defect in the gene for fibrillin-1 (FBN1)[267] was found to be the cause of Marfan syndrome. This large

glycoprotein has a molecular weight of 350 kDa[264] and is a component of microfibrils that are ubiquitous in the connective frequently occurs or increases during adolescence. The mRNA transcript of this gene is approximately 10 kb. Not only do defects in this gene cause Marfan syndrome, but Milewicz and Duvic[268] also showed that severe neonatal Marfan syndrome is due to a specific 3-bp insertion in the fibrillin-1 cDNA. Furthermore, fibrillin defects have been found in patients with atypical phenotypes including autosomal dominant ectopia lentis with skeletal features[269] and milder forms such as the MASS phenotype (mitral valve, aorta, skeleton, and skin)[269] or isolated ascending aortic aneurysm with dissection.[270,271] Unfortunately, each family appears to have an individual mutation in the gene, making screening difficult and requiring that each new mutation case be studied individually.[272] This high impact disorder is estimated to be responsible for 1 to 2 percent of the deaths in industrialized societies, with death usually caused by rupture of an asymptomatic, undiagnosed aneurysm. Mutations in FBN1 also have been associated with the marfanoid craniosynostosis (Shprintzen-Goldberg) syndrome.[273] Recent data suggest that CCA is a separate disorder due to a fibrillin-2 gene (FBN2) defect on chromosome 5 (5q23-q31).[274]

Another locus for Marfan syndrome has also been mapped to 3p24.2-p25.[275] Marfan syndrome has been observed in all racial and ethnic groups, and approximately 55 percent are sporadic cases with no family history. There appears to be an increased effect of paternal age, with the mean age of fathers of sporadic cases being increased.

Some of the skeletal features can be analyzed anthropometrically. For example, the increased limb length can be measured by the length of the upper and lower segments and by the upper-lower segment ratio (US/UL). The lower segment is measured from the top of the pubic ramus to the floor, and the upper segment is measured from the pubic ramus to the top of the head. US/UL is reduced for classic Marfan syndrome at all ages. The ratio of arm span to height is usually increased in Marfan syndrome, although scoliosis may complicate the calculation of both ratios. Arachnodactyly can be assessed by the ratio of the middle finger length to total hand length or by analysis of the metacarpal index on hand radiographs.

Hyperextensibility can be assessed by several simple maneuvers. The Steinberg (thumb) sign is positive when the thumb projects through the clenched hand on the ulnar side. The Walker-Murdock (wrist) sign is positive when the first and fifth digit of one hand wrap completely around the wrist of the other hand. Pectus excavatum of variable severity is fairly common. Scoliosis can occur at any age. The ocular findings of Marfan syndrome classically include subluxation of the lenses (ectopia lentis), usually but not always in an upward direction. This occurs in 50 to 60 percent of patients. Myopia is very common, and retinal detachments have also occurred, especially after surgical removal of the lenses. Corneal flattening is also described. Loss of vision occurs in a significant number of patients. Other manifestations include an increase in the occurrence of inguinal hernias, which may recur, and the development of spontaneous pneumothorax and lung abnormalities in some patients. Sacral meningoceles and dilated cisterna magna have also been reported. A severe neonatal form of the Marfan syndrome has cardiovascular, skeletal, and ocular complications present at birth,[261] and patients typically succumb within the first year of life, often from congestive heart failure.

The majority of cardiac abnormalities associated with Marfan syndrome affect the ascending aorta, the aortic valve, and the mitral valve (Table 62-6). Physical examination alone is insufficient to detect subtle changes in the heart and in the aorta. The dilation of the ascending aorta may occur gradually before physical findings occur. Echocardiograms are recommended annually and beta-blocker therapy should be considered.[276] If the diameter of the aorta corrected for body surface area exceeds the upper limits of normal by 50 percent, the frequency of evaluations should be increased to at least every 6 months. Prophylactic repair with composite graft including aortic valve should be performed when ascending aortic dilation reaches a

diameter of 6 cm[277] (see Chap. 98). Repair of a severe pectus excavatum may be indicated at an earlier stage, not only for cosmetic reasons, but to allow easier and safer aortic surgery, should it be indicated. After surgery, the use of beta blockers and anticoagulants should be maintained, and individuals should avoid contact sports and marked physical exertion. Surveillance of the aorta should continue after surgery. Some evidence suggests that beta blockers may reduce the rate of aortic dilation and the risk of serious complications.[276] Prophylactic antibiotics should be used on all patients to decrease the risk of bacterial endocarditis. In general, contact sports (e.g., football, basketball) should be avoided-along with isometric exercises, weight lifting, and extreme physical activity-and replaced with noncompetitive sports such as swimming and bicycling. Other abnormalities include mitral valve prolapse, mitral regurgitation, and aortic regurgitation. The cardiovascular abnormalities in neonatal Marfan syndrome differs somewhat from that seen in older patients, demonstrating significant mitral regurgitation as well as tricuspid and pulmonary valve regurgitation. In addition, these children have significant heart failure, as previously noted.

A special issue involves Marfan syndrome and pregnancy (see Chap. 92). In addition to the 50 percent recurrence risk in offspring, there is also a concern about the stress that pregnancy will put on the aorta. There are at least two dozen case reports of aortic dissection during pregnancy or shortly after delivery,[278] generally occurring with aortic regurgitation or other evidence of aortic dilatation. Pregnant women with Marfan syndrome should have echocardiograms every 6 to 8 weeks during pregnancy and should be followed as high-risk obstetrical patients.

The diagnosis of Marfan syndrome is currently made primarily on clinical grounds although molecular diagnosis is now feasible (although not useful).[279] Suspected patients with a positive family history should have positive clinical features in at least two organ systems. If the family history is negative for Marfan syndrome, positive findings should be present in the skeletal system and in at least two other organ systems. Suspected patients should also have a negative urine nitroprusside test to rule out homocystinuria, one of the disorders in the differential diagnosis. Management of patients with a negative family history and only suggestive skeletal features is unclear. In view of its implications, it may be unwise to inform such patients with minimal features that they have Marfan syndrome. Nonetheless, they should be followed clinically with perhaps periodic echocardiograms and ophthalmologic exams. In these individuals, strong consideration for molecular genetic evaluation is wise.

In terms of genetic counseling, families should be informed of the autosomal dominant inheritance pattern, with 50 percent recurrence in offspring. The rationale for patient follow-up and management should also be explained, along with psychosocial support and medical follow-up. Prenatal diagnosis may be possible.[263,268]

EHLERS-DANLOS SYNDROMES

There are at least 11 different forms of Ehlers-Danlos syndrome (EDS), which are generally given numerical designations.[279] The most common forms are types I through IV, as discussed here. Types II and III overlap with the features of type I, but both are progressively less severe; type III is sometimes known as *benign hypermobility syndrome*. The features of Ehlers-Danlos type I include hyperextensible and fragile skin with poor wound healing and "cigarette paper" scarring. Hyperextensibility of the joints increases susceptibility to dislocation of the hips, shoulders, elbows, knees, and clavicles. The ears tend to be hypermobile and are sometimes described as "lop ears." Scoliosis is a relatively common finding, as are clubfeet in infancy. There is an increased risk of premature birth resulting from premature rupture of membranes. Umbilical and diaphragmatic hemias tend to be relatively common.

The most common cardiac features include mitral valve prolapse, tricuspid valve prolapse, and dilation of the aortic root and/or sinus of Valsalva.[279] Atrial septal defects and other abnormalities of the aortic arch and mitral valve have also been seen. Probably the most significant

cardiovascular defect is the increased susceptibility to dissecting aortic aneurysm (Table 62-6), which can lead to death. Poor wound healing and decreased vascular integrity have been noted. Surgical procedures are freqeuntly not tolerated well, and patients should probably avoid unnecessary surgery. In addition, patients should be cautioned to avoid tauma as much as possible. Type I Ehlers-Danlos is inherited as an autosomal dominant disorder with variability in expression. The presumed defect in this disorder involves synthesis of normal collagen with mutations identified in the α2 (V) chain of type V collagen.[279,280]

Ehlers-Danlos type IV is sometimes referred to as the "malignant" form of Ehlers-Danlos syndrome,[281] since there is marked susceptibility to spontaneous rupture of large blood vessels or bowel. The hyperelasticity and hyperextensibility tend to be less obvious than in type I. Easy bruisability and susceptibility to bleeding, however, are very prominent. Spontaneous rupture of any of the major vessels has been reported. Pregnancy-related complications are particularly striking, the overall risk of death with pregnancy being 25 percent. The basic defect in this autosomal dominant disorder is in the type III collagen gene located on chromosome 2 (2q31),[282] and defects have been reported.[283] Other Ehlers-Danlos genes thus far identified include types VI (1p36.3-1p36.2; lysyl hydroxylase),[284,285] VII A1 (17q21.31-q22), and VII A2 (7q22.1),[286] with mutations of the COLIA2 gene,[281] and the progeroid variant,[287] which is caused by galactosyl-transferase mutations.

Patients with types I and IV EDS require yearly cardiac examinations. Initial evaluation with chest radiography and echocardiography will enable the cardiologist to decide the frequency of follow-up and repeat echocardiograms depending on the level of aortic dilatation and mitral valve prolapse (MVP). Annual chest x-rays are cost-effective as a minimal approach, with echocardiograms necessary every 1 to 2 years. Antibiotic prophylaxis for subacute bacterial endocarditis (SBE) is also needed in patients with MVP or aortic abnormalities.

FAMILIAL ANEURYSMS

It has been recognized for some time that certain aneurysms in peripheral and central arteries (see Marfan's syndrome above) have a familial tendency.[288] As data accumulates on genetic defects in fibrillin[261,279] (Marfan's syndrome) and in the collagen disorders,[289,290] there appears to be overlap in the genetic defects of fibrilin and procollagen, particularly type III, as causes for aneurysms. Some have a defect in type II procollagen (COL3A1) similar to defects that have been reported in Ehlers-Danlos syndrome (EDS) type IV.[283] Familial incidence of aneurysms is said to account for 7 percent of aneurysms.[291] Since EDS is relatively rare, many of the more common familial procollagen abnormalities may represent phenotypic overlap. These findings have resulted in a reassessment of the traditional teaching that most aortic aneurysms result from atherosclerosis. Family history should be carefully assessed in all patients with aortic or cerebral aneurysms, and, if it is positive, other family members should be assessed. Many should be followed with noninvasive evaluation in a fashion similar to that described for Marfan's syndrome.

PSEUDOXANTHOMA ELASTICUM (PXE)

This is a genetic disease of the elastic tissue which involves the skin, eyes, and cardiovascular system.[292] The characteristic lesion is that of the skin consisting of a highly raised, yellowish papule known as a *pseudoxanthoma,* overlying areas of flexural stress such as the neck, cubital and popliteal fossae, and groin. The eye changes are slate-gray linear bands representing tears in Bruch's membrane and subsequent fibrosis leading to loss of central vision in 70 to 80 percent of cases. Calcification of peripheral arteries occurs frequently, most commonly in the femoral artery, but also in the coronary arteries. The heart is affected by myocardial ischemia and infarction, secondary to the coronary disease, which is the major cause of morbidity and mortality (Table 62-

5). A restrictive cardiomyopathy is common due to endocardial fibrosis with mitral valve prolapse (MVP).[293294] Two genetic variants having autosomal dominant inheritance and two others with autosomal recessive inheritance occur. The only difference between the recessive and dominant forms is the presence of affected parents and offspring. Bale recently mapped a gene to 16p13.1, but the gene remains unknown.[281] Because the basic defect is unknown, no specific treatment is available.

The cardiac features should be followed closely once abnormalities are noted. In stable patients, yearly examinations are required at a minimum. Myocardial dysfunction with or without heart failure requires anticongestive and inotropic support, while SBE prophylaxis is needed for those patients with MVP. Symptoms should be used to direct therapy.

CUTIS LAXA

This designation refers not only to a specific dermatologic sign but also to a variety of mendelian and nonmendelian congenital and acquired syndromes sharing the characteristic feature of lax, nonresilient skin. Two varieties of autosomal recessive cutis laxa exist. Death from pulmonary complications may occur in the first months of life and most patients die by the third year. Signs of right-sided heart failure are often seen in infancy and are generally due to pulmonary disease, although pulmonary artery stenosis also occurs[295] (Table 62-5). Histopathologically, the pulmonary artery lesions are due to medioelastic fiber paucity. MVP has also been notable. A gene that causes this spectrum of disease has been identified as elastin (ELN), the same gene previously shown to cause supravalvular aortic stenosis (SVAS).[296-298] As increased fibroblast activity in acquired cutis laxa has also been noted,[299] there is molecular and biochemical correlation. In addition, ultrastructural alterations of skin elastic fibers has been reported.[300]

Primary Disorders of Rhythm and Conduction

Virtually all rhythm and conduction abnormalities have been reported to be familial. However, many families have been small so that the mode of inheritance (or even whether the inheritance is mendelian) is uncertain. In many cases, these conduction defects have been associated with other cardiac and systemic disorders. For a detailed clinical discussion of arrhythmia and conduction disorders, see Chap. 27.

ROMANO-WARD LONG-QT SYNDROME (LQTS)

The association of stress-induced syncope, sudden death, and ventricular arrhythmias in families has long been noted, including a distinct syndrome[301] having prolongation of the QT interval and abnormal T waves on ECG. Multiple families with this syndrome have demonstrated autosomal dominant inheritance, with torsade de pointes polymorphic ventricular tachycardia, bradycardia and T-wave alternans (see Chap. 36). The diagnosis is made when the QT interval corrected for heart rate (QTc) is greater than 480 ms using Bazzett's formula; T-wave abnormalities are usually seen. In symptomatic patients (i.e., patients with syncope or "seizures"), the diagnosis may be made with shorter QTc (i.e., 470 ms). A diagnostic algorithm has been useful.[302] Two likely hypothetical pathogenetic mechanisms for Romano-Ward LQTS was proposed by Schwartz.[303] They include (1) sympathetic nervous system abnormalities and (2) potassium channel (or other ion channel) abnormalities.

In 1991, Keating and coworkers[304] provided evidence for tight molecular genetic linkage to chromosome 11p (11p15.5). Shortly thereafter, Towbin and colleagues demonstrated genetic heterogeneity in families with Romano-Ward LQTS.[305] Linkage evidence was found for loci on chromosome 7 (LQT2)[301] and chromosome 3 (LQT3) and another gene was linked to

chromosome 4 (LQT4).[301] More recently, two other genes have been mapped for LQT5 and LQT6, both found on chromosome 21q22.[306]

The chromosome 11-linked (LQT1) gene was discovered to be KCNQ1, which encodes a potassium channel known as KVLQT1,[301] the slowly activated, delayed rectifier potassium channel I_{Ks}. Multiple mutations in KVLQT1 have been identified and this gene appears to be the most commonly mutated gene in LQTS. KVLQT1 was later shown to require a β-subunit to function normally. This β-subunit gene, KCNE1, encodes minK, which regulates the function of these combined channels, resulting in normal function of this slowly activated delayed rectifier potassium (I_{Ks}) channel. This gene, now also called LQT5, maps to chromosome 21q22. Mutations in either KVLQT1 or minK result in LQTS. The HERG gene, an I_{Kr} potassium channel, has been mapped to chromosome 7q35-q36 and mutations in a variety of domains of this channel were shown to be responsible for the disease in LQT2 families.[301] Another channel gene, the cardiac sodium channel called SCN5A, mapped to 3p21, was shown to be responsible for LQT3. Recently, LQT6 was discovered by Abbott and coworkers[306] to be the β-subunit, MiRP1 or KCNE2. This small channel protein regulates I_{Kr}, the rapidly activated delayed rectifier potassium channel, by interacting with HERG. Mutations in either MiRP1 or HERG result in the LQTS phenotype although the mutations in MiRP1 have been shown to also cause drug-induced (i.e., clarithromycin) VT or VF. The chromosome 4-linked (LQT4) gene remains undiscovered presently. The long-QT syndrome, therefore, appears to be an ion channelopathy, and multiple different ion-channel mutations could result in the long-QT syndrome (Fig. 62-13).

Phenotype-genotype studies have been reported in LQTS. Distinct ECG differences between patients have been demonstrated with mutations of different genes (LQT1-LQT3).[307] Important prognostic differences appear to occur with various mutations of the different genes.[301,308] Zareba et al.[308] recently provided genotype-phenotype correlation of mutations in LQT1, LQT2, and LQT3. In this study, mutations in LQT1 and LQT2 resulted in earlier onset of syncope than LQT3 (usually by age 15 years) and more frequent episodes of syncope. However, LQT3 patients appeared to be at higher risk of death than either LQT1 or LQT2. The mode of symptoms and death also appears to be gene-specific to some extent. LQT1 mutations have been associated with episodes of syncope, seizures, or sudden death during diving/swimming or emotional upset. LQT2 also appears to be triggered by emotions but auditory triggers (i.e., phone or alarm clock ringing) are also important. LQT3, on the other hand, has a high incidence of events during sleep. LQT3 patients appear to shorten their QT intervals with exercise, while exercise seems to trigger events in LQT1 and LQT2 patients.

Recently, Schwartz et al.[309] have provided evidence that sudden infant death syndrome (SIDS) could be due to QT prolongation. Using ECGs on the third or fourth day of life in over 34,000 infants over a >20 year period, they found 34 infants died prior to their first birthday. In 24 of these cases, SIDS was diagnosed. Retrospective ECG analysis demonstrated that one-half of these infants had QTc prolongation on the initial screening ECG. Although no molecular analysis exists, it is speculated that ion channel mutations could be at play for a group of children with SIDS.[309,310]

Gene based therapy has been reported to improve the ECG features of LQTS, including QTc shortening and T-wave normalization. Schwartz et al.[311] treated patients with LQT2 and LQT3 with the sodium channel blocker mexiletine and showed significant QTc shortenting. Compton et al.[312] used exogenous potassium to increase the serum potassium in LQT2 patients with QTc shortening noted, while Shimizu et al.[313] used potassium channel openers to achieve similar results. However, no long-term results or outcomes have been reported with any of these therapies.

JERVELL AND LANGE-NIELSEN LONG-QT SYNDROME

This syndrome, described in 1957, is characterized by congenital deafness, syncope, prolonged QT interval, sudden death, and autosomal recessive inheritance[301] (see Chap. 36). Affected individuals are usually diagnosed in childhood with congenital, severe high-tone perceptive bilateral deafness; fainting spells precipitated by exertion, rage or fright; and ECG evidence of QT interval prolongation and T-wave abnormalities. As would be expected for rare autosomal recessive traits, the parents of affected individuals are more likely than usual to be consanguineous. Homozygous mutations or compound heterozygous mutations in either KVLQT1 or *minK* (i.e., I_{Ks}) have been shown to result in Jervell and Lange-Nielsen syndrome.[314-317] In this circumstance, the deafness requires a homozygous mutation, which results in abnormal production of endolymph, a potassium-rich fluid, in the inner ear. Thus, deafness is autosomal recessive while LQTS is autosomal dominant (i.e., heterozygous mutation results in LQTS; homozygous mutation results in longer QTc and worse outcome).

BRUGADA SYNDROME (IDIOPATHIC VENTRICULAR FIBRILLATION)

First described in detail in 1992, the Brugada syndrome is characterized by ST-segment elevation in leads V_1-V_3, with or without right bundle-branch block[318,319] (Fig. 62-14). Clinical symptoms occur due to ventricular fibrillation. In many patients, spontaneous resuscitation occurs. In others, sudden death occurs, particularly during sleep. This disorder appears to be relatively common in Europe and Southeast Asia and commonly is familial, usually with autosomal dominant inheritance.[320] Some patients do not have overt ECG manifestations and provocation studies in the catheterization laboratory using procainamide, flecainide, or ajmaline may be necessary for diagnosis.

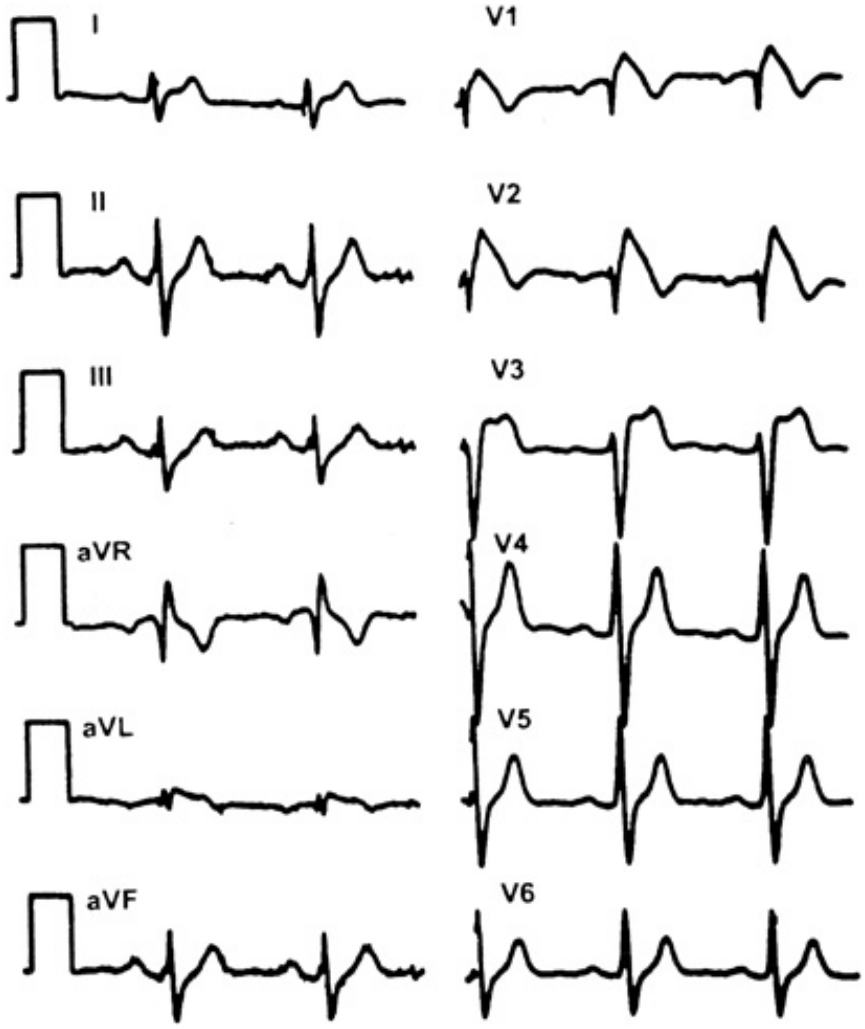

Figure 62-14: Electrocardiographic characteristics of Brugada syndrome. Note the ST-segment elevation in V_1 to V_3.

The genetics of Brugada syndrome appear to involve mutations in ion channels as well. Mutations in SCN5A, the cardiac sodium channel gene previously shown to cause LQT3, have been identified[320,321] (Fig. 62-15). Although the surface ECG and biophysical characteristics of these patients differ from LQT3, it is interesting that symptoms occur during sleep in both disorders. There also appears to be a temperature-dependent effect on the electrophysiologic properties of some of these mutations.[322] Genetic heterogeneity appears to occur, but no other genes have been reported to date.

FAMILIAL ATRIAL FIBRILLATION

Familial atrial fibrillation appears to be rare, but a moderately sized family was identified and the gene responsible for the disease mapped to 10q22.[323] This family inherited the disease as an autosomal dominant trait, with the average age of onset of atrial fibrillation being 17 years. This family has a highly penetrant form of the disease, with most affected developing atrial fibrillation very early in childhood. The signs and symptoms are those related to atrial fibrillation which include palpitations, syncope, and dyspnea. Several other families with familial atrial fibrillation have since been identified due to the same locus.

WOLFF-PARKINSON-WHITE SYNDROME (WPW)

The preexcitation syndromes, including WPW, have been considered to be congenital, but only a

small number of patients demonstrate familial occurrence; the majority of cases appear to be sporadic. ECG features of WPW include the presence of a short PR interval, and a prolonged QRS with slurred upstroke of the R wave, known as a delta wave[324] (see Chap. 26). Patients with WPW are prone to episodes of paroxysmal supraventricular tachycardia (see Chap. 27). An autosomal dominant pattern of inheritance of accessory pathways has been reported.[35] In a family with FHCM and WPW the locus was mapped to chromosome 7 (7q3) has been shown in patients with both FHCM and WPW.[35]

Autosomal Dominant Atrioventricular Block

This disorder, when familial, presents with adult onset (age 20 to 50 years) and has an autosomal dominant inheritance pattern.[301,325] Approximately 50 families have been identified with this disorder which, in each transmission, is consistent with autosomal dominant inheritance with full penetrance and variable expression. Whether all of these conditions represent a single disorder is not known. The common presentation of this disease includes one of the following: (1) right bundle-branch block (RBBB) alone; (2) left axis deviation (LAD) alone; (3) RBBB plus LAD; or (4) complete heart block. In addition, atrioventricular block has been associated with DCM and skeletal myopathy, and several genetic loci have been identified.[105,326,327] Another gene has been mapped to chromosome 19q13 in a family with AV block but without DCM.[326]

Congenital Heart Disease with or without Genetic Syndromes

FAMILIAL ATRIAL SEPTAL DEFECT (ASD)

Two mendelian forms of ASD exist as autosomal dominant traits. One form has no other associated abnormalities and was initially speculated to be on chromosome 6p, linked to the HLA complex, as yet unconfirmed by genetic linkage analysis. Further analysis identified mutations in the transcription factor Nkx2.5 in families and sporadic cases of ASD.[327] This is likely to be genetically heterogeneous and search for other disease-causing genes is being pursued. The more common form of familial secundum ASD is associated with atrioventricular conduction delay, which rarely progresses to heart block. In these patients, attention should be directed to the upper limbs, particularly the thumbs, to rule out the Holt-Oram syndrome, which will be described below. Another form of familial ASD has also been described which is thought to be mitochondrially inherited.

HOLT-ORAM SYNDROME (HOS)

The cardinal manifestations of this autosomal dominant condition include upper limb dysplasia, ASD, and marked variability within families. The abnormalities of the arm demonstrate a wide spectrum in heterozygous individuals, ranging from undetectable, to distally placed thumbs and hypoplastic thenar eminences, triphylangeal thumbs, anomalies of the carpus, and radial aplasia, to phocomelia and hypoplasia of the clavicles and shoulders. The upper extremity deformity is typically bilateral, but the left side commonly is more severe than the right. In addition to the ASD, other cardiac malformations are occasionally found, the most frequent of which is a ventricular septal defect (VSD). Cardiac conduction disturbances, usually involving the AV node in patients with septal defects and hypoplastic peripheral arteries, are also found (Table 62-6). Other noncardiac manifestations include dermatoglyphic abnormalities and pectus excavatum. Since the noncardiac abnormalities have a very wide spectrum, all patients with ASD should be evaluated closely for upper limb deformities.

A male with features consistent with Holt-Oram syndrome in addition to mental retardation and other anomalies was found to have a deletion of chromosome 14 in the q23-q24.2 region. Linkage

to chromosome 12 (12q213-q22) was later demonstrated in one family with Holt-Oram syndrome, while other families did not link to this region, indicative of heterogeneity.[328,329] The responsible gene for 12q21.3 was subsequently identified.[330-331] The chromosome 12-linked HOS was concomitantly reported by Basson et al.[330] and Li et al.[331] as TBX5, a member of the Brachyury (T) gene family, located at 12q24.1. This gene is a member of the T-box transcription factor family,[332-333] a group of genes that share a common DNA-binding motif (T box). Basson et al.[330] identified mutations in two families (nonsense, missense mutations) and suggested that haplo-insufficiency was the mechanism at play. Li et al.[331] identified mutations in three families and three sporadic cases, four of which encoded premature stop codons and two reading frame shift mutations. The authors pointed out that no obvious phenotype-genotype correlations existed. In fact, individuals with identical mutations had widely different skeletal and cardiac features. They also suggested that haplo-insufficiency was at play and occurred between days 26 and 52 of gestation.

SUPRAVALVULAR AORTIC STENOSIS (SVAS) AND WILLIAMS SYNDROME

SVAS occurs in three different situations, occurring with an estimated incidence of 1 in 20,000 births. The most common is associated with the Williams syndrome which is usually sporadic but may be a highly variable autosomal dominant condition. The full spectrum of Williams syndrome[334,335] includes dysmorphic facies, often called "elfin" facies, infantile hypercalcemia, mental retardation, short stature, SVAS, and multiple peripheral pulmonic stenoses.[279-334] Many of these individuals have robust (so-called cocktail party) personalities. Late-onset problems may include progressive joint contractures, gastrointestinal dysfunction, and genitourinary dysfunction.

Cardiovascular features of Williams syndrome are present in about 75 percent of patients,[279,335] the most characteristic of which is supravalvular aortic stenosis. Other findings include peripheral pulmonic arterial stenosis and pulmonic valvular stenosis. Occasionally, VSD or ASD may be present. Peripheral vascular anomalies, including renal arterial stenosis, diffuse narrowing of the aorta, and coarctation of the aorta, may be present and may be associated with systemic hypertension. Sudden death has occurred in children with Williams syndrome, especially after cardiac catheterization. Coronary arterial stenosis may occur and lead to myocardial infarction. Histopathology in these patients suggests the possibility of abnormal elastic fibers.[336]

A second setting for SVAS is the autosomal dominant entity which is distinct from that of Williams syndrome (WS). Mental retardation and abnormal facies are not found and these individuals present with SVAS and/or peripheral pulmonary artery stenoses.[279,334] In some cases, family members present with moderate pulmonic valve and branch pulmonary artery stenoses but without SVAS. Later, the valvular and branch pulmonary stenoses may disappear while SVAS becomes evident. The stenotic aortic lesion requires surgery in less than one-half of these patients. The diagnosis relies on echocardiography, but cardiac catheterization is sometimes required. Finally, SVAS may present as sporadic cases. Many investigators have long believed that the sporadic SVAS, WS, and autosomal dominant SVAS are all interrelated.

In 1993, WS was shown to result from a submicroscopic deletion involving chromosome 7q11.23 in the region of the elastin gene,[337] and subsequently confirmed.[338] Inherited or de novo deletion of one elastin allele was identified in each of the patients studied and suggested that hemizygosity at the elastin locus is responsible for the vascular pathology in WS. Concordance in monozygotic twins and occurrence in second cousins has been described and anecdotal reports of parent and child with WS have been reported. In addition, familial supravalvular aortic stenosis (SVAS) without WS, which appears to be inherited as an autosomal dominant trait, is well known. This autosomal dominant form of SVAS was found to be linked to the elastin gene at 7q11.23[334] as well, and deletions were identified. Baumer et al.[339] suggested that WS results from this deletion

at 7q11.23 that arises from recombination between misaligned repeat sequences flanking the WS region. It is currently believed that this syndrome is a contiguous gene syndrome. The first deleted gene identified in the critical region, elastin (ELN), has been shown to cause the SVAS phenotype but not any of the other features of Williams syndrome (Fig. 62-16, Plate 99). Elastin gene (ELN) deletion is seen in 90 to 95 percent of WS patients and translocations also occur. ELN rearrangements, point mutations, splice mutations, and nonsense mutations have been found in families and sporadic cases of SVAS or Williams syndrome. However, a few patients with classic features of WS, usually without cardiac defects, do not have a deletion involving elastin. This fact suggests that, while deletion of elastin is necessary for the SVAS phenotype, it may not be necessary for Williams syndrome. Elastin is an extracellular matrix protein that comprises 90 percent of the elastic matrix that restores a vessel's shape after it has been stretched. Intense efforts to identify other deleted genes that contribute to the phenotype subsequently identified deletions of LIMK1 (a protein tyrosine kinase expressed in developing brain), syntaxin IA (a component of the synaptic apparatus), WB-SCR1 (containing an RNA-binding motif), RFC2 (a subunit of the replication factor C complex involved in DNA replication), FKBP6 (a FK506-binding protein immunophilin which is thought to play a role in the calcium metabolism abnormalities and growth delay in these patients), WSTF (a putative transcription factor), WS-TRP (considered as playing a role in signal transduction), FZD3 (a gene homologous to *Drosophila* tissue polarity gene *frizzled*), and GTF21 (a multifunctional member of a widely expressed transcription factor complex that is phosphorylated by Bruton tyrosine kinase).[340-348] The roles of these genes in the Williams syndrome phenotype, however, is not known. In order to localize, isolate, and characterize the genes that contribute to the Williams syndrome phenotype, Hockenhull et al.[349] constructed a high-resolution integrated map of the critical region, established a panel of somatic cell hybrids from patients with classic clinical features, and defined deletion breakpoints and estimated the size of the deletions with classical Williams syndrome. They also identified two new genes, CPETR1 and CPETR2, which are deleted in these patients. A mouse knockout model has been created and is being studied.

NOONAN SYNDROME

In 1963, nine patients with valvular pulmonic stenosis, short stature, mild mental retardation, hypertelorism, and unusual facial features were described.[350] This disorder, sometimes confused with Turner syndrome, is distinct and females and males are equally affected. Noonan syndrome is relatively common, with an incidence of 1 in 1000 to 2500 live births. The diagnosis can sometimes be made prenatally. Postnatal growth, however, is generally delayed and tends to parallel the third percentile with normal growth velocity, although the adolescent growth spurt is usually blunted or absent. Facial features appear to change with age. The main features of the newborn period are hypertelorism with down-slanted palpebral fissures; low-set, posteriorly rotated ears with thickened helices; deeply grooved philtrum; micrognathia; and excess neck skin with low posterior hairline. As the infant ages, the head appears larger, with prominent eyes and thinning of the palpebral fissures and depression of the nasal root. The face appears more myopathic and becomes more triangular in shape. In some young adults, the eyes become less prominent. The neck length is relatively short, which exaggerates the webbing. Individuals tend to have prominent nasolabial folds, a high anterior hairline, and transparent, wrinkled skin. The hair is generally described as being curly or woolly in older children and adolescents. Approximately 60 percent of males have cryptorchidism. Sexual development is variable and may be delayed. Most females appear to be fertile. Pectus carinatum superiorly and pectus excavatum inferiorly appears to be present in about 70 percent of individuals. The chest appears to lengthen with age, giving the appearance of relatively low-set nipples. Other features include cubitus valgus, clinodactyly, vertebral anomalies, dental malocclusion, café-au-lait spots, pigmented nevi, bleeding disorders, lymphatic dysplasia, and pulmonary and intestinal lymphangiectasia. Mental retardation is present in 35 percent of cases.[351]

It appears that about two-thirds of patients with Noonan syndrome have some type of cardiac

defect. Approximately half of these patients have valvular pulmonic stenosis. Other relatively common cardiac anomalies include hypertrophic cardiomyopathy, ASDs, VSDs, and persistent patent ductus arteriosus. Pulmonic arterial branch stenosis, mitral valve prolapse, Ebstein's anomaly, and single ventricle have also been reported (Table 62-6).

The clinical features of Noonan syndrome can overlap with a number of other conditions. Chromosome studies should be done in females to rule out Turner syndrome. Phenotypic overlap with WS, primidone teratogenicity syndrome, fetal alcohol syndrome, Aarskog syndrome, Leopard syndrome, neurofibromatosis, and malignant hyperthermia (King syndrome) have been reported.

Most cases of Noonan syndrome appear to be sporadic. Thus, the percentage of inherited cases may actually be much higher than the 30 percent previously reported. The majority of inherited cases are apparently inherited from the mother, thought to be the result of decreased fertility in males. Therefore, although the recurrence risk for offspring is expected to be 50 percent, it might actually be somewhat lower. A gene causing Noonan syndrome has been mapped to chromosome 12(12q22-qter),[352] but the gene has remained elusive. Genetic heterogeneity has also been demonstrated.

TUBEROUS SCLEROSIS (TS)

Classically, tuberous sclerosis consists of the triad of mental retardation, seizures, and adenoma sebaceum. These features, however, may not be present in all patients. The term *tuberous sclerosis* primarily refers to hamartomatous lesions in the brain as well as intracranial calcifications primarily in the area of the basal ganglia. These lesions appear to be present in about 90 percent of patients. Seizures are a frequent finding, being seen in about 90 percent, and have some correlation with mental retardation. About 60 percent of tuberous sclerosis patients are mentally retarded, close to 100 percent of whom have seizures; of those without mental retardation, only 75 percent have seizures. Seizures tend to occur earlier in patients with mental retardation than those without mental retardation. Ocular lesions, particularly benign astrocytoma, occur in about 50 percent of patients. Cutaneous lesions are common; 80 percent of patients develop angiofibromas of the face, usually referred to by the misnomer adenoma sebaceum. Depigmented skin patches that are especially apparent by Wood's light examination are seen in about 80 percent of patients, frequently from birth. Pulmonary disease may occur primarily in adult females and is likely to be severe and life-threatening. The primary cardiac finding is the presence of rhabdomyomata.[353][354] Wolff-Parkinson-White (WPW) syndrome and supraventricular tachycardia have also been reported.[354-355]

Tuberous sclerosis is an autosomal dominant condition in which about 80 percent of cases are suspected as resulting from new mutations with unaffected parents. A child diagnosed with tuberous sclerosis should be evaluated by computed tomography (CT) of the brain and electroencephalography for the presence of CNS lesions and also have renal ultrasound. Parents should be examined for the presence of depigmented patches (by Wood's light), dental abnormalities, retinal findings, and abdominal ultrasound for renal cysts. It is now apparent that there are at least two genes causing tuberous sclerosis: TSC1 on chromosome 9 at 9q34 (hamartin)[356] and TSC2 (tuberin) on chromosome 16 at 16p13. These two protein products co-localize to cytoplasmic vesicles[357] and interact with each other. TSC2 spans 43 kb of genomic DNA and encodes a number of alternatively spliced transcripts of 16 kb. Constitutional inactivating mutations of the TSC2 gene, including complete deletion, have been detected in patients with TS and the associated hamartomas show loss of heterozygosity for markers in the TSC2 region, indicating that TSC2 functions as a tumor suppressor gene and that loss of function of both alleles is normally required before cellular growth becomes dysregulated. Various cancers[358] have been found to occur due to mutations in the TS complex. In addition, large deletions in TSC2 and its neighboring gene PKD1 have been seen in children with polycystic

kidney disease.[359] Genotype-phenotype correlations are not helpful.[360,361] Animal models have been developed with resultant tumors noted.[362-365]

FAMILIAL COARCTATION OF THE AORTA

Familial coarctation of the aorta (usually with autosomal dominant transmission) has been described but no locus or gene has been identified. This congenital lesion is the most common congenital anomaly of the aortic arch in humans, occurring in 5 to 8 percent of children with congenital heart defects. A recessive mutation, *gridlock*, in the zebrafish (*Danio rerio*) has been identified in which blood flow to the tail is impeded by a localized vascular defect.[366] There is some question as to whether this mutation is a model for human aortic coarctation,[367] but it may aid in learning about vascular obstruction. As coarctation of the aorta occurs in association with other left heart obstructive lesions in an individual or in members of a family with other left heart obstructive lesions, it is likely that the mechanism causing disease is complex. Other mutations, such as those of endothelin1, endothelin A receptor, Hand2, MFH-1, and retinoid receptor genes have been shown to lead to aortic arch malformations in mice (Fig. 62-16).

IVEMARK SYNDROME (ASPLENIA/POLYSPLENIA) OR HETEROTAXY SYNDROMES

Ivemark syndrome represents a group of defects that interferes with the normal establishment of laterality.[279,368] The more severe asplenia and polysplenia syndromes have an estimated incidence of 1 in 10,000 to 20,000 live births. The occurrence is usually sporadic, but familial cases have been described with autosomal recessive and X-linked transmission; chromosomal translocations (i.e., between chromosomes 12 and 13) and deletions (involving chromosomes 10 and 13) have been described, as has monozygotic twinning. Both forms tend to have similar cardiac defects, including ASDs, VSDs, endocardial cushion defects, and pulmonic stenosis as well as other defects.[369,370] Asplenia, however, tends to be more commonly associated with severe defects of the atrioventricular canal and VSDs, while polysplenia tends to be more associated with ASDs. In many cases, complex cardiac malformations occur, including single ventricle physiology. A total of 32 cases of asplenia were identified in 4059 autopsies, and all cases were sporadic with a male excess.

Rightward looping of the midline heart tube is the first overt manifestation of anatomic left-right differences, which eventually come to include the asymmetry of the lungs and most malformations associated with abnormal looping; therefore, they usually occur as one manifestation of a more global abnormality of left-right heart anomalies, abnormalities of spleen position and/or number, and some degree of malrotation of the gut. The overall left-right axis of the individual may be situs ambiguus (i.e., indeterminate sidedness) or situs inversus (complete left-right reversal), compared to normal sidedness (situs solitus).

Cardiac malformations attributable to abnormal laterality represent 3.4 percent of all heart defects.[371] Since there is familial clustering of situs, it appears that genetics contributes significantly to these abnormalities. This is supported by mutant mouse models with similar defects,[371] as well as gene defects in some humans.

The first gene locus for human situs defects was mapped to Xq26.2 in families with X-linked disease.[372] This gene was later shown to be a zinc-finger transcription factor Z1C3, and mutations were found in sporadic and familial cases.[371,372] Studies in other vertebrates yielded additional candidate genes as well. Several genes were found to be asymmetrically expressed along the left-right axis in chick prior to development of anatomic left-right asymmetry[274,368] and some of these same genes were also found to be asymmetrically expressed in the mouse (Fig. 62-16). These genes included nodal, pitx2, lefty-1 and lefty-2. Genetic studies in mice also implicated several additional genes that did not have asymmetric expression, such as HNF3, Actrllb, and

Smad.[373-375] Mutation analysis in patients have identified a small number of mutations in all of these genes.[376,377]

Other Genetic Syndromes

A variety of other genetic syndromes with associated cardiovascular disease occur primarily in childhood. These include Ellis-Van Crevald syndrome, Treacher Collins syndrome, Alagille syndrome, Smith-Lemli-Opitz syndrome, thrombocytopenia-absent radii (TAR) syndrome, Goldenhar syndrome, Cornelia de Lange syndrome, Rubinstein-Taybi syndrome, VACTERL association, and CHARGE association. Since these are primarily pediatric diseases, they are not included in this discussion. For detailed descriptions of these and other pediatric genetic syndromes with cardiovascular abnormalities, see current reviews of this topic.[378]

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

CARDIOVASCULAR DISORDERS ASSOCIATED WITH CHROMOSOME ABNORMALITIES

Chromosomal Nomenclature

Cytogenetics is the study of chromosomes and chromosomal abnormalities. Chromosomes are classified according to their size and shape. Chromosomes have two arms, one long and one short. The short arm is usually referred to as the "p" arm, and the long arm is usually referred to as the "q" arm. For instance, the long arm of chromosome 22 is designated 22q and the short arm 22p. The arms of the chromosomes meet at the centromere or primary constriction, which is responsible for division of chromosome pairs during meiosis and mitosis. There are three shapes of human chromosomes based on the position of the centromere. Metacentric chromosomes have the centromere in a central position and the long and short arms are approximately equal. Submetacentric chromosomes have an eccentric centromere, producing arms of unequal lengths. Acrocentric chromosomes have a centromere close to one end of the chromosome. Acrocentric chromosomes have small pieces of chromatin known as satellites attached to their short arms.

Since 1971, banding of chromosomes has become routine and the banding patterns of each chromosome can be distinguished separately. For this reason, chromosome abnormalities are designated by the actual chromosome number rather than the chromosome group (e.g., trisomy 18 rather than trisomy E).

Classification of Chromosomal Alterations

Chromosome alterations, especially those involving too many or too few chromosomes (called aneuploidy), are quite common in human development. Chromosome aberrations most commonly cause structural defects of the cardiovascular system, and typically these are evident at birth. Approximately 50 percent of all fetuses conceived are spontaneously aborted (usually in the first trimester), with one-half of these being aneuploid. Among live-born infants, about 1 in 200 (0.5 percent) have a chromosome abnormality. The frequency of chromosome abnormalities among live-born children with congenital heart defects is in the range of 5 to 13 percent.[378] Hence, the vast majority of chromosomal aberrations are lost in early fetal life and, in most instances, occur as new mutations. For this reason, with both parents being normal, the risk of recurrence to relatives is usually low.

1. Aneuploidy, defined as the gain or loss of chromosomes resulting in too many or too few chromosomes, occurs most commonly by nondysjunction (failure of a homologous pair of chromosomes to separate). Nondisjunction occurs during meiosis in one parent (i.e., in spermatogenesis or oogenesis) or in the first mitotic cleavage of the zygote. In meiotic nondysjunction, when a pair of chromosomes does not normally separate, both members of the pair (or neither member of the pair) pass into one gamete. When an additional copy of the chromosome is added during fertilization, three copies of the same chromosome (or only one copy) are found in the new zygote instead of the chromosome pair. Two of the most common chromosomal disorders causing heart disease, Down syndrome (trisomy 21) and Turner syndrome (XO), are due to nondisjunction. Absence of one chromosome is called *monosomy;* all autosomal monosomies, as well as those containing only a Y sex chromosome, are lethal for the embryo. The presence of three chromosomes is called *trisomy*, as seen in Down syndrome, while the presence of an entire extra set of

chromosomes is known as *triploidy*.

2. Chromosomal rearrangements occur when a chromosome breaks and rejoins within itself differently than normally occurs. This can potentially result in an inversion of genetic material. Typically there is no apparent phenotypic effect in persons carrying an inversion but their offspring may have severe abnormalities due to the disruption in chromosome pairing during melosis that can take place.
3. Chromosome deletions, or loss of chromosomal material, may be seen by light microscopy and consists of deletion of 10^6 bp or greater. If there is a large amount of DNA lost, more than one gene may be affected (disrupted or lost), a series of abnormalities in a single individual may result due to interruptions in a series of genes within the loci of a single chromosome. These contiguous gene deletion syndromes[379] may be heritable and the occurrence of the disorder in a family behaves as a dominant disorder (X-linked or autosomal dominant). Most deletions occur de novo. Two breaks in the same chromosome that reunite with the intermediate segment being inverted is referred to as an inversion. Isochromes are formed when two short or long arms join with loss of the other arm. Chromosomal translations occur when breaks occur in two chromosomes and reunite after exchange of segments. These deletions are best appreciated at the DNA level by Southern analysis or polymerase chain reaction (PCR) analysis.
4. Chromosome duplications or gains of chromosomal material may also be associated with phenotypic abnormality but most commonly cause no obvious aberration.

Cytogenetics and Techniques

High-resolution cytogenetic techniques allow unambiguous identification of each human chromosome and detection of most structural abnormalities of the chromosomes. These structural abnormalities include translocations, deletions, and duplications. High-resolution chromosome analysis involves synchronization of lymphocyte cultures in order to accumulate all cells at one point in the cell cycle. Other cells that may be used include skin, fibroblasts, and amniotic cells. Enrichment of this cell population in prophase and prometaphase rather than the middle to late stages of metaphase, which is characteristic of conventional harvesting techniques, allows improved visualization of the subbanding patterns of chromosomes. Each band seen at metaphase actually represents multiple subbands in earlier stages that have fused together as the chromosome contracts. Whereas a typical metaphase cell contains 300 to 400 bands per haploid genome, synchronized chromosome preparations make it possible to visualize 500 to 1000 bands per haploid set. With the development of banding methods, the human karyotype could be divided into 300 to 400 descrete bands or approximately 7 to 10×10^6 bp per band, and a much greater number of deletions, duplications, and translocations could be detected. High-resolution techniques allow visualization of from 500 to 2000 bands per haploid genome, and have enabled the delineation of a number of microdeletion or microduplication syndromes (also known as contiguous gene syndromes), including the DiGeorge syndrome and Beckwith-Wiedemann syndrome.

FLUORESCENCE IN SITU HYBRIDIZATION (FISH)

Fluorescence in situ hybridization or FISH provides for the detection of submicroscopic chromosomal deletions or duplications. This technique uses DNA probes conjugated with a fluorescent dye visible under a fluorescence microscope derived from chromosomal regions that hybridize to the specific chromosomes. This method makes possible direct visualization of single sequences not only on chromosomes but also within decondensed interphase nuclei, providing a high-resolution (<1 mb) approach to gene mapping and analysis of nuclear organization.

INDICATIONS FOR CHROMOSOMAL ANALYSIS

Chromosomal studies can provide valuable information to the family and the physician and should

be considered in any child who has a heart defect with (1) minor dysmorphic features, (2) growth retardation that cannot be explained by the heart defect, or (3) developmental delay. In addition, the practitioner might more strongly consider chromosome studies if there is a family history of multiple miscarriages or other infants with birth defects or mental retardation. A genetic consultant can help determine whether or not chromosome studies should be performed, and they can help to integrate the findings of the chromosome analysis with the clinical picture. The major disadvantage of doing chromosomal studies is the cost (generally between $300 to $500).

Chromosomal Disorders

Many chromosomal disorders have associated cardiovascular disease. The most common of these include Down's syndrome (trisomy 21), Patau syndrome (trisomy 13), Edwards syndrome (trisomy 18), and Turner syndrome. Since trisomy 13 and 18 usually result in death during infancy, these are not described. A significant number of other chromosomal abnormalities are also associated with cardiovascular disease and are seen primarily as pediatric disorders. These abnormalities include triploidy, aneuploidy (other than trisomy 21, trisomy 18, trisomy 13, and Turner syndrome), deletions, and duplications. The triploidy syndromes-which include 69,XXX, 69,XXY, or 69,XYY-have a greater than 50 percent incidence of congenital heart disease, the vast majority of which are atrial and ventricular septal defects (ASD, VSD). The aneuploidy syndromes, not discussed thus far, are varied and uncommon. These include mosaicism of chromosome 8 and chromosome 9, which clinically present with VSDs with or without other associated complex defects. Aortic root dilatation and MVP occur with partial monosomy of chromosome 22. Other cardiovascular abnormalities associated with partial trisomy of chromosome 7q includes VSD, pulmonic stenosis (PS), patent ductus arteriosus (PDA), coarctation of the aorta (CoA), and L-transposition of the great vessels. Partial trisomy of chromosome 7p also occurs and most commonly is associated with VSD, PS, or AV canal.

DOWN'S SYNDROME (TRISOMY 21)

Chromosome 21 is the smallest of all human chromosomes, containing less than 2 percent of the genomic DNA. Down's syndrome, however, is the most common phenotype caused by a human chromosome abnormality, occurring approximately once in every 500 to 600 births. This disorder is usually due to the presence of an extra chromosome 21 (i.e., trisomy 21), but in some cases it is caused by the presence of only the distal half of chromosome 21, band q22 (i.e., 21q22)-the "Down's syndrome critical region"-so-called due to the presence of a subset of major phenotypic features of Down's syndrome including mental retardation, congenital heart disease, characteristic facial appearance, hand and dermatoglyphic changes.[380-382] In order to produce this syndrome, the region of 21q22 must be triplicated. The gene or genes responsible for manifesting Down's syndrome are unknown, but the severity of the disease is believed to depend on the extent of the region q22 and beyond that is triplicated. Creation of a linkage map of chromosome 21 has allowed for consideration of potential candidate genes. Recently, several genes have been implicated in some of the phenotypic features, but the cardiac features currently have no known cause.

The typical trisomy 21 occurs in 95 percent of cases of Down's syndrome and results from chromosomal nondisjunction. Some 2 to 3 percent of Down's syndrome cases are mosaics, having one trisomy cell line and one normal cell line, and the remainder (1 to 4 percent) are due to an extra copy of all or part of the long arm of chromosome 21 being translocated to another chromosome. The risk of trisomy 21 is exponentially related to maternal age, with the lowest risk for young women, rising steeply after age 35 years, and reaching 4 percent for women older than 45 years.

The recurrence risk is generally quoted at 1 to 2 percent. When a child with a translocation type of Down's syndrome is discovered, parental chromosomal analysis should always be performed to

determine whether the translocation was inherited. If the translocation was not inherited and both parents have normal chromosomes, the recurrence risk is probably low, although prenatal chromosome diagnosis may be considered for future pregnancies. If the mother carries translocation of chromosome 21, the recurrence risk is approximately 10 percent. If the father is determined to be the carrier of a D;21 translocation, the recurrence risk is about 2 percent.[378] If one of the parents is determined to specifically be a 21;21 translocation carrier, the parents have a 100 percent chance of recurrence of Down's syndrome and no possibility of having normal offspring.[378] Luckily, the latter occurs in only about 1 in every 2000 cases of Down's syndrome but clearly has a significant impact on family planning.

Some 40 to 50 percent of patients with Down's syndrome have congenital heart disease (40 to 60 percent of these are atrioventricular septal defects, AVSDs) and this, along with hematologic malignant disease and duodenal atresia, are among the most common causes of morbidity and mortality.[378] Patients who escape these problems generally survive into the fifth decade and beyond. The most characteristic cardiac defect in Down's syndrome is the AVSD (also called *endocardial cushion defect* or *atrioventricular canal defect*) (Table 62-9).[378] In addition to problems of volume overload secondary to left-to-right shunting, these patients are predisposed to early pulmonary hypertension. Elevated pulmonary vascular resistance becomes a significant risk beyond 1 year of age. Once this occurs, these patients become unsuitable for surgical repair. Approximately one-third of patients with Down's syndrome and congenital heart defects have complex heart disease, increasing the morbidity and mortality further. Other clinical features of Down's syndrome include hypotonia and decreased Moro reflex with joint hyperextensibility in the newborn period, a flat facial profile with excessive, redundant skin in the posterior neck, antimongoloid slant (upward) of palpebral fissures, and small white Brushfield spots around the circumference of the irides in children with blue irides. The hands and feet may reveal a simian crease (50 percent), clinodyactyly, or incurving of the fifth finger, brachydactyly with short metacarpals and phalanges, and a wide gap between the first two toes. Individuals are mentally retarded to varying degrees, with IQs ranging from 25 to 70. Generally, males are infertile.

Table 62-9: Chromosomal Abnormalities Associated with Specific Types of Congenital Heart Defects

Endocardial cushion defect	Trisomy 21
Coarctation of the aorta	Turner syndrome
Total anomalous pulmonary venous return	Partial trisomy 22q 9,XXXXX; 49,XXXXX
Patent ductus arteriosus	Partial trisomy 8q
Tetralogy of Fallot	Monosomy 22q11
Conotruncal abnormalities	Partial trisomy 5q
Conduction defect	Turner syndrome
Hypoplastic left heart	

TURNER SYNDROME

This disorder, which is due to a single X chromosome in females (i.e., XO genotype), occurs in approximately 1 female in 2500.[378] The frequency of nonmosaic XO karotypes is significantly higher in spontaneous abortuses than in liveborns, with less than 2 percent of such conceptuses reaching term. Clinically, there is a variable and often mild phenotype, and the diagnosis may go

unsuspected until a child's short stature is evaluated or a women complains of amenorrhea. The clinical findings[378] of patients with Turner syndrome includes lymphedema of hands and feet, inguinal hernias, short stature, primary amenorrhea, facial features including a slightly traingular face with downslated palpebral fissures, epicanthal folds, and ptosis. Ears are frequently low-set and posteriorly rotated, and the mandible is commonly micrognathic. The neck is typically short with marked webbing and the posterior hairline may be low, extending to the upper shoulders. A broad thorax with widely spaced nipples is common, as is cubitus valgus and shortening of fourth and fifth metacarpals. Abnormalities of sexual development are usually associated, including hypogonadotropic hypogonadism with ovarian dysgenesis. Intelligence is normal. Many cases are mosaic for cell lines with the normal 46XX or 46XY makeup. The frequency of congenital cardiac disease varies from 20 to 50 percent, with at least one-half of these having CoA. A variety of other cardiac defects may also occur either singly or in combination with CoA. The majority of these include other left heart abnormalities including bicuspid aortic valve, aortic stenosis, dilated ascending aorta,[378] and hypoplastic left heart syndrome (HLHS). ASD and VSD as well as partial anomalous pulmonary venous return have also been reported (Table 62-9).

Coarctation of the aorta can usually be diagnosed clinically due to poor femoral pulses and differential blood pressure, with the arm blood pressure being consistently hypertensive, while the leg pressures are typically very low. Echocardiography or magnetic resonance imaging will confirm the diagnosis. Therapy may include surgical repair or, in some cases, balloon angioplasty. Infants may require prostaglandin E therapy to keep the ductus arteriosis patent; these young patients may present in heart failure or cardiac collapse if duct-dependent. Those patients with HLHS are duct-dependent and will die unless a Norwood operation or cardiac transplant is performed. Bicuspid aortic valves do not usually require therapy unless stenosis occurs. All cardiac defects require prophylaxis for subacute bacterial endocarditis (SBE). Chromosomal studies are recommended in all cases of Turner syndrome, since only about 60 percent of cases will have monosomy X. The remaining cases have mosaicism or various abnormalities of the X chromosome. Most cases of Turner syndrome are sporadic and the recurrence risk appears to be relatively low. However, parents may choose to have prenatal chromosomal diagnosis in subsequent pregnancies.

CATCH-22 Syndromes

DIGEORGE ANOMALY

First described in 1965,[383] the combination of thymic hypoplasia, parathyroid hypoplasia, and cardiac defects has been termed DiGeorge syndrome or DiGeorge anomaly. Because the disorder is of heterogeneous etiology, the term *DiGeorge anomaly* is currently preferred to *DiGeorge syndrome*. These thymic, parathyroid, and cardiac defects all result from developmental abnormalities of the third and fourth branchial arches.

Eighty percent of affected infants present with congenital heart defects within the first 48 h of life. According to the classification system of Clark,[384] the two types of defects associated with DiGeorge anomaly are conotruncal defects and branchial arch mesenchymal tissue defects. Among conotruncal defects, truncus arteriosus is the most common type. Among the branchial arch mesenchymal tissue defects, interrupted aortic arch type b and right aortic arch are the most common.[378]

The second key feature is persistent hypocalcemia, occurring either as the initial presenting feature or in combination with the cardiac defect. Parathyroid glands may be absent or reduced in size and number, and serum parathyroid hormone levels are decreased. Hypocalcemia may require continuous calcium infusions and/or frequent calcium supplementation. In cases of partial defect, the hypocalcemia may improve over time.

There are multiple etiologies for DiGeorge which include chromosome abnormalities, single-gene defects, teratogenic exposures, and association with other defects.[384] Approximately 5 to 10 percent of infants with features of DiGeorge anomaly will have an obvious abnormality of chromosome 22 with monosomy of the proximal portion of the long arm. However, approximately 70 percent of patients will have submicroscopic deletions of 22q11 detectable only by FISH.[384,385] In addition, many of these patients have features of the Sprintzen velocardiofacial (VCF) syndrome and the Takao conotruncal face syndrome.[386,387] These syndromes are currently referred to as a group by the mnemonic of CATCH-22 syndrome for the associated defects: *c*ardiac, *a*bnormal facies, *t*hymic hypoplasia, *c*left platate, *h*ypocalcemia, *22*q11 deletions). Approximately 15 percent of infants with DiGeorge anomaly can be found to have obvious chromosome abnormalities of which about two-thirds involve a monosomy 22q11.[388] This usually results from an unbalanced translocation involving chromosome 22 and another chromosome. More recent studies using fluorescence in situ hybridization (FISH) with probes from the critical region have shown that a total of about 85 percent of DiGeorge anomaly patients are deleted, with about 70 percent of patients having submicroscopic, molecular deletions, del22 (q11.21 q11.23). Although patients have different deletion endpoints, a 1.5-Mb region is deleted in most. Rarely, a syndrome of "partial" DiGeorge syndrome due to balanced translocation has been described. This translocation was cloned and a disrupted gene DNA-binding protein.[389] More recently, a variety of candidate genes have been identified, including the human homolog of the *Drosophila disheveled* segment-polarity gene,[390] the *clathrin heavy chain-like* gene (CLTCL),[391] *UFD1L* (a developmentally expressed ubiquitination gene),[392] *HIRA*,[393] *DGSI*,[394] and the *goosecoid-like* (GSCL) homeobox gene[395] (Fig. 62-16). The best of these candidate genes, fulfilling most of the criteria necessary to cause this complex, are *HIRA* and *UFD1L*. *HIRA* is a mammalian homolog of yeast proteins, which are corepressors of cell cycle-dependent histone gene transcription, expressed in neural crest and neural crest-derived tissues.[396] This gene has been shown to be required for outflow tract septation. However, mice with haploinsufficiency are normal. *UFD1L*, the homolog of a highly conserved yeast gene involved in degradation of ubiquinated proteins, results in the same craniofacial and cardiac defects seen in CATCH-22 when mutated.[397] Recently, Lindsay et al.[398] engineered a chromosomal deletion (Dfl) in mice that spanned the critical region. The heterozygous deleted animals developed heart disease identical to that seen in humans. They suggested that the cardiovascular lesions occurred due to inadequate formation, early regression, or growth failure of the fourth aortic arch arteries. It should be noted that Yamagishi et al.[397] reported a DGS and/or VCFS patient who is heterozygous for a de novo deletion spanning 20 kb of DNA, disrupting *CDC45L* and *UFD2L*, both candidate genes. The authors suggested these genes to be involved in the development of these syndromes and argued that these genes were regulated by dHAND, a basic helix-loop-helix transcription factor. They proposed a model whereby downregulation of UFD1L activity results in accumulation of certain proteins and excessive apoptosis or maldevelopment of neural crest cells. Based on their view, they suggested disruption of UFD1L function alone, or in combination with CDC45L and/or HIRA is the most likely etiology for most defects seen in DGS. This is currently being carefully studied.

Several therapies have been used to treat the profound T-cell immunodeficiency associated with the DiGeorge syndrome. These therapies have included bone-marrow transplantation. Recently, Market et al.[399] described use of cultured postnatal thymus tissue transplantation in five infants, with good results.

SHPRINTZEN VELOCARDIOFACIAL (VCF) SYNDROME

This condition was first recognized in 1978 with ascertainment primarily in children with palatal defects[386]; this is the most common syndrome associated with cleft palate and appears to be the same disorder as the Takao conotruncal anomaly face syndrome.[387] The clinical features include mild short stature, cleft palate especially of the secondary palate with submucous clefts, pharyngeal incompetence leading to speech disorders, and speech delay. Most cases are sporadic

but some autosomal cases have been reported.

Cardiac defects are prominent in this disorder, the majority being conotruncal-type defects.[400-403] Ventricular septal defect occurs in 70 to 75 percent, while right-sided aortic arch occurs in about 50 percent and tetralogy of Fallot is found in 15 to 20 percent of children. Partial DiGeorge anomaly seems to be present in some cases. About 85 percent of VCF syndrome patients have deletions of chromosome 22q11, usually submicroscopic and visible only by FISH techniques.

Takao syndrome (conotruncal face anomaly syndrome) first described in 1976, has similarities to both DiGeorge and Shprintzen syndromes clinically,[387,402] hence its incorporation in the CATCH-22 association. These Japanese children were noted to have a specific dysmorphic facial appearance in association with conotruncal malformations. Deletions within the 22q11 region in these patients have been found,[402] confirming its similarity to the DiGeorge syndrome and VCF syndrome.

Chapter 62: CARDIOVASCULAR DISEASES DUE TO GENETIC ABNORMALITIES

List of Figures

Figure 62-8: The "final common pathway hypothesis" described by Towbin, showing the pathways involved in development of hypertrophic (HCM) and dilated cardiomyopathy (DCM). In HCM, mutations in the sarcomeric protein-encoding genes result in the phenotype. In addition, the phenotype may be altered or modified by metabolic or mitochondrial derangements as well as by activation of a molecular pathway such as calcineurin. These cascade effects lead to the wide variety of clinical presentations in HCM. In DCM, direct mutations in cytoskeletal protein-encoding genes or effects on these proteins (i.e., coxsackie B3 virus cleavage of dystrophin by enteroviral protease 2A) also modify the clinical phenotype. Cascade effects via metabolism, mitochondrial abnormalities, or drug interactions are also influential in the severity of disease. HCM/DCM abbreviations: β-MHC = β-myosin heavy chain; αTM = α tropomyosin; cTnT = cardiac troponin T; MBP-c = myosin binding protein C; ELC = essential light chain; RLC = regulatory light chain; TNI = troponin I; CVB = coxsackie virus B; MLP = muscle LIM protein; DAG = dystrophin-associated glycoprotein complex; Ox-phos = oxidative phosphorylation pathway; SR = sarcoplasmic reticulum.

Figure 62-9: Skeletal muscle biopsy in Emery-Dreifuss muscular dystrophy. Increased endomysial and perimysial connective tissue, with marked variation in myofiber size, internal nuclei, and myofibers splitting (×153). (Reprinted with permission from Specht LA, McKee AC. MGH Case Records (case 34-1992): A 19-year-old man with progressive proximal muscle weakness, contractures, and cardiac abnormalities. *N Engl J Med* 1992; 327:558.)

Figure 62-10: A 41-year-old man with myotonic dystrophy (DM). Muscle wasting of temporalis muscles with narrow small chin produces a "hatchet-like" facies. Baldness and ptosis (note droopy eyelids with pupils partially covered and sclerae visible) contribute to characteristic appearance. (Reprinted with permission from Roses AD, Pericak-Vance MA. In: *Molecular Basis of Neurology*. Cambridge, MA: Blackwell; 1993:147-159.)

Figure 62-11: Mitochondrial genome. This small, circular DNA molecule encodes 13 enzymes of the respiratory chain, 22 tRNAs, and 2 rRNAs. When it is mutated, cardiac, neurologic, and myopathic disorders develop.

Figure 62-12: The electron transport chain enzyme complex (complexes I to V).

Figure 62-13: Genetic loci and ion channels encoded by the genes responsible for long-QT syndrome.

Figure 62-14: Electrocardiographic characteristics of Brugada syndrome. Note the ST-segment elevation in V_1 to V_3.

Figure 62-15: SCN5A mutations responsible for LQT3 (*black*) and Brugada syndrome (*gray*).

Figure 62-16: (Plate 99) Genetic defects causing congenital heart disease with or without genetic syndromes. Mutants from zebrafish, mouse, and human relating to primary developmental processes or maintenance of the vascular system are illustrated, including those of vasculogenesis and angiogenesis (*A*), embryonic development of the vascular system (*B*), and LV outflow tract obstruction (*C*).

Part 10: CONGENITAL HEART DISEASE
Chapter 63:

THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

Author: Michael D. Freed

INCIDENCE AND ETIOLOGY

The incidence of congenital heart disease in the United States is approximately 8 per 1000 live births.[1,2] Many infants who are born alive with cardiac defects have anomalies that do not represent a threat to life, at least during infancy. Almost one-third of those infants, or 2.6 per 1000 live births, however, have critical disease, which is defined as a malformation severe enough to result in cardiac catheterization, cardiac surgery, or death within the first year of life.[3] Today, with early detection and proper management, the majority of infants with critical disease can be expected to survive the first year of life.[3] Most who now survive infancy will join the increasingly large cohort of adults with congenital heart disease.

Estimates of the incidence of specific lesions vary, depending on whether the data are drawn from infants or older children and whether the diagnosis is based on clinical, echocardiographic, catheterization, surgical, or postmortem studies.[1-4] The incidence in other countries is remarkably similar to that reported for the United States.[5,6]

Despite these differences in case material, except for bicuspid aortic valve and mitral valve prolapse, it is apparent that ventricular septal defect (VSD) is the most common malformation, occurring in 28 percent of all patients with congenital heart disease (Table 63-1).

Among 2251 infants with critical congenital heart disease in the New England Regional Infant Cardiac Program,[3] 53.7 percent were male. Certain defects, however, are considerably more common in one sex than in the other. Aortic stenosis occurs more commonly in boys (4:1), and atrial septal defects occur more frequently in girls (2.5:1).

Although earlier theories concerning the etiology of congenital heart diseases suggested that most defects were multifactorial-that is, the malformations are caused by a combination of a hereditary predisposition (presumably caused by abnormalities in the genetic code) and an environmental trigger[7]-more recent advances in molecular biology suggest that a much higher percentage are caused by point mutations.[8]

Some abnormalities are caused by chromosomal aberrations (see Chap. 62). Trisomy 21 (Down's syndrome) is highly associated with complete atrioventricular (AV) canal, VSDs, and tetralogy of Fallot, and children with Turner's syndrome (XO) frequently have coarctation of the aorta. Other anomalies are caused by teratogens: VSD in fetal alcohol syndrome, Ebstein's anomaly in a fetus with prenatal exposure to lithium, and patent ductus arteriosus (PDA) in mothers who contracted rubella during the first trimester are examples.

Some syndromes are inherited as single-gene defects and have congenital heart disease as one of their manifestations. Holt-Oram syndrome, an association of radial limb abnormalities and atrial septal defects (ASDs), is caused by an abnormality of a T-box transcription factor Tbx5, and the

cardio-velo-facial syndrome, associated with abnormalities of the conotruncus, resulting in a high proportion of infants born with truncus arteriosus or interrupted aortic arch, is a result of a deletion on chromosome 22 (22 q 11)[9] (see Chap. 62).

It is clear now that a higher proportion of congenital heart disease than previously thought is due to single-gene defects and that the same malformation may be caused by mutant genes at different loci.[8] With increasing knowledge of molecular mechanisms, it seems inevitable that the etiology and pathogenesis of congenital heart disease will be clarified increasingly in the years ahead.

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

FETAL CIRCULATION AND THE TRANSITION TO NEONATAL AND ADULT CIRCULATION

The fetus obtains all metabolic necessities, including oxygen, from the placenta. The fetal circulation is an adaptation to allow most of the right ventricular output to bypass the lungs and go instead to the placenta to pick up oxygen. Most of the understanding of this adaptation comes from more than 40 years of research,[10-18] primarily on fetal lambs. The fetal circulation is arranged in parallel rather than in series, with mixing at the atrial (foramen ovale) and great vessel (ductus arteriosus) level (Fig. 63-1). Normally, blood returning from the body goes into the right atrium via the superior vena cava or inferior vena cava. Inferior vena cava blood is diverted by the crista dividens so that approximately 27 percent of combined ventricular output passes through the foramen ovale into the left atrium, with the remainder passing through the tricuspid valve to the right ventricle. Left atrial return is mixed with blood returning from the lungs into the left ventricle and then to the ascending aorta, where it goes to the coronary arteries, head, and upper body vessels, with a small proportion going across the arch into the descending aorta. Right ventricular blood passes out of the pulmonary artery, where approximately 90 percent (59 percent of combined ventricular output) is diverted through the ductus arteriosus into the descending aorta by the elevated pulmonary vascular resistance. Thus, approximately two-thirds of the blood passes through the right side of the heart and one-third passes through the left side of the heart.

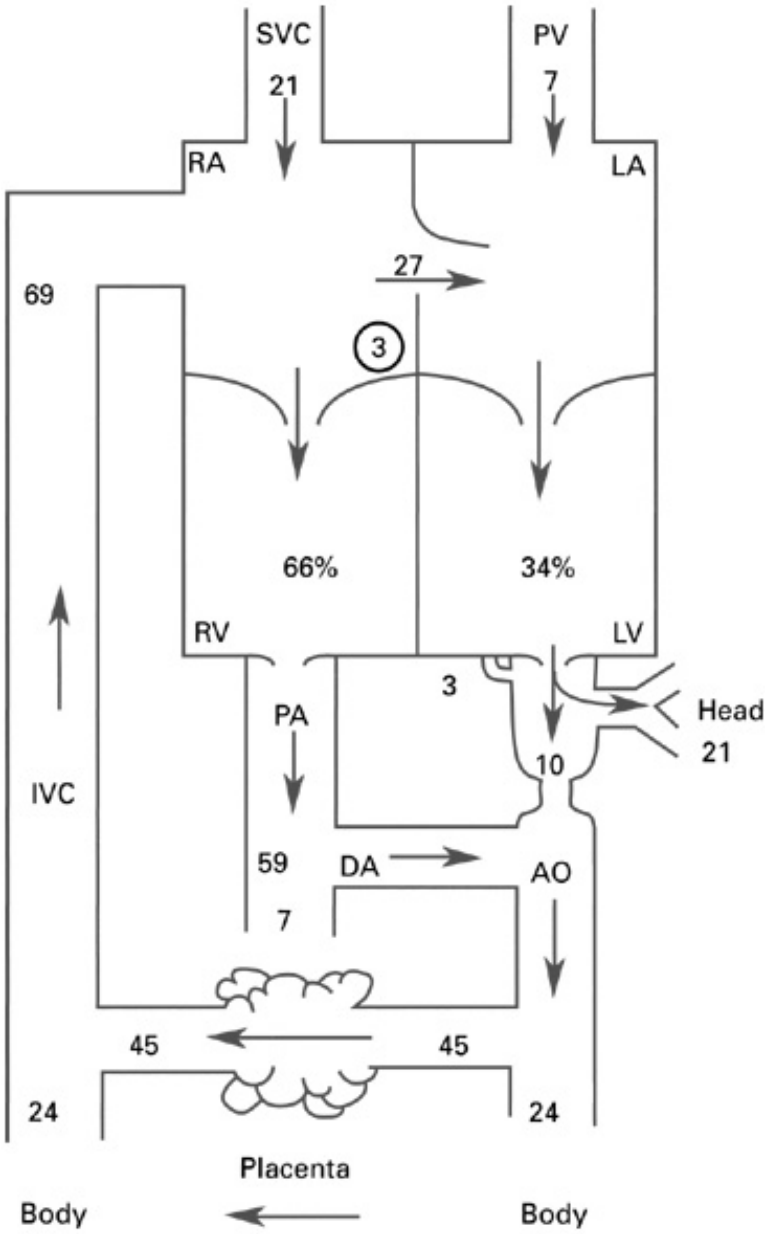

Figure 63-1: The course of the circulation in a late-gestation fetal lamb. *The numbers represent the percentage of combined ventricular output*. Some of the return from the inferior vena cava (IVC) is diverted by the crista dividens in the right atrium (RA) through the foramen ovale into the left atrium (LA), where it meets the pulmonary venous return (PV), passes into the left ventricle (LV), and is pumped into the ascending aorta. Most of the ascending aortic flow goes to the coronary, subclavian, and carotid arteries, with only 10 percent of combined ventricular output passing through the aortic arch (indicated by the narrowed point in the aorta) into the descending aorta (AO). The remainder of the inferior vena cava flow mixes with the return from the superior vena cava (SVC) and coronary veins, passes into the right atrium and right ventricle (RV), and is pumped into the pulmonary artery (PA). Because of the high pulmonary resistance, only 7 percent passes through the lungs (PV), with the rest going into the ductus arteriosus (DA) and then to the descending aorta (AO), the placenta, and the lower half of the body. (From Freed MD. Fetal and transitional circulation. In: Fyler DC, ed. *Nadas' Pediatric Cardiology*. Philadelphia: Hanley & Belfus; 1992. Reproduced with permission from the publisher and author.)

The oxygen saturation of fetal blood is considerably lower than that in a newborn or infant because of the lower efficiency of the placenta compared with the lungs for oxygen exchange (Fig. 63-2). The blood with the highest saturation (approximately 70 percent) is that returning from the placenta. Some of this higher-saturation blood is diverted across the foramen ovale so

that saturation on the left side of the heart (65 percent) is somewhat higher than it is on the right side (55 percent). This allows diversion of the lowest-saturation blood (~55 percent) through the ductus arteriosus to the placenta, increasing the efficiency of oxygen pickup. An additional fetal adaptation to oxygen transport at low oxygen saturation is the presence of high levels of fetal hemoglobin with a higher affinity for oxygen than normal hemoglobin. This leftward shift of the oxygen dissociation curve facilitates oxygen uptake at the relatively low P_{O_2} of the placenta vasculature.

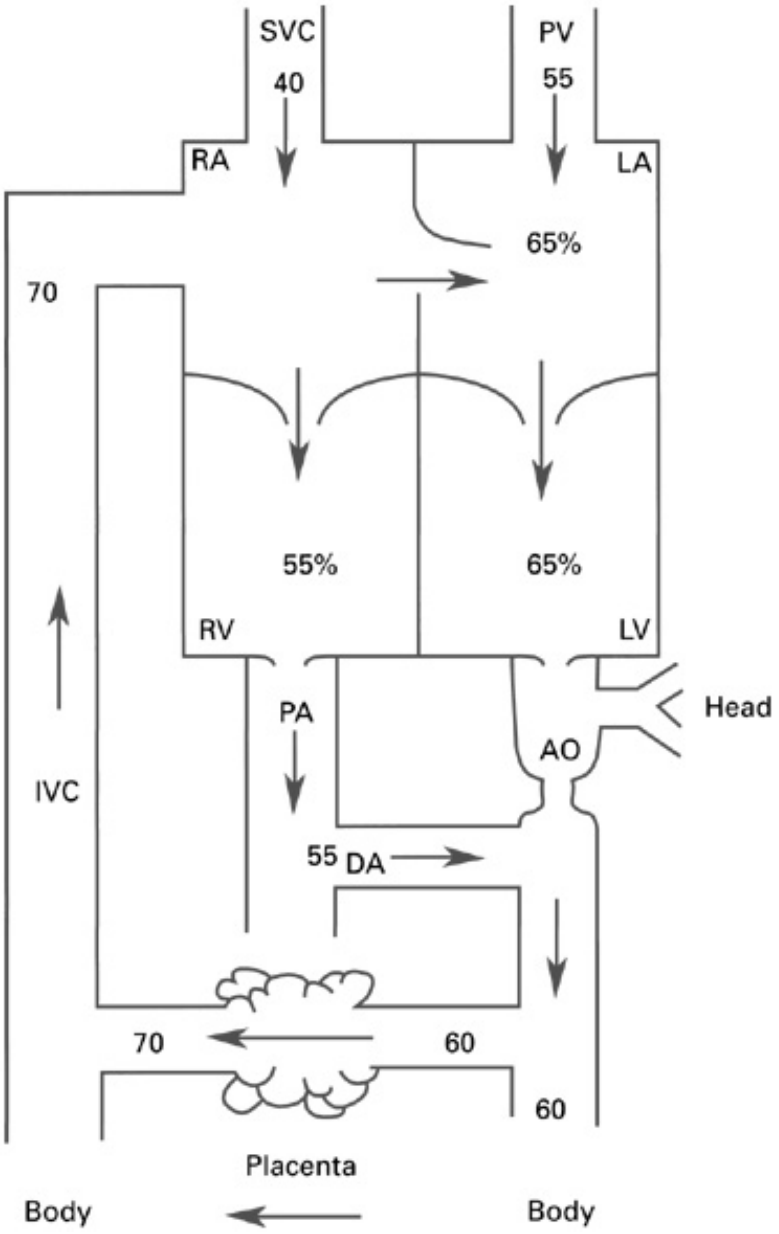

Figure 63-2: *The numbers indicate the percent of oxygen saturation in a late-gestation lamb*. The oxygen saturation is highest in the inferior vena cava, representing that primarily from the placenta. The saturation of blood in the heart is slightly higher on the left side than on the right side. The abbreviations in this diagram are the same as those in Fig. 63-1. (From Freed MD. Fetal and transitional circulation. In: Fyler DC, ed. *Nadas' Pediatric Cardiology*. Philadelphia: Hanley & Belfus; 1992. Reproduced with permission from the publisher and author.)

The wide communication at the atrial level (foramen ovale) allows for near equalization of atrial and ventricular end-diastolic pressures. The wide communication at the great vessel level (ductus

arteriosus) allows equalization of systolic pressures in the aorta and the pulmonary artery and, in the absence of aortic or pulmonic stenosis, at the ventricular level (Fig. 63-3).

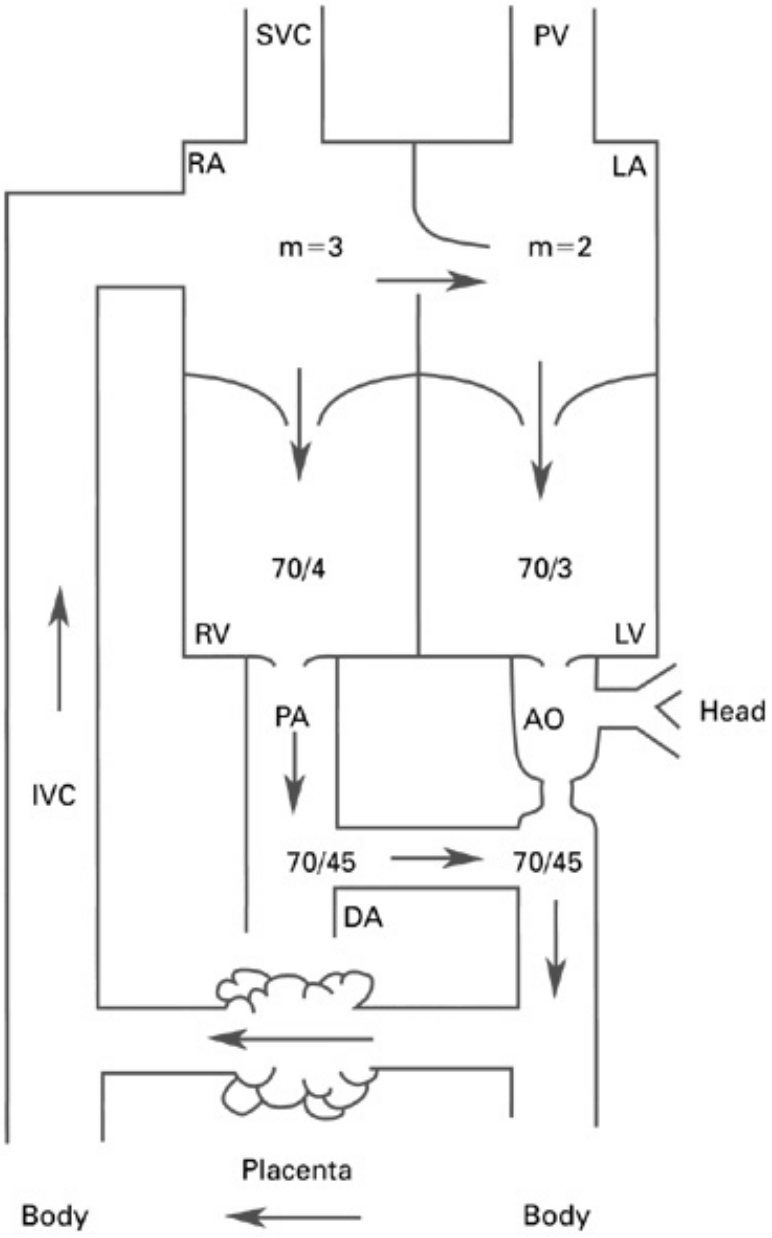

Figure 63-3: The numbers indicate the pressures observed in late-gestation lambs. Because large communications between the atrium and the great vessels are present, the pressures on both sides of the heart are virtually identical. The abbreviations are the same as those in Fig. 63-1. (From Freed MD. Fetal and transitional circulation. In: Fyler DC, ed. *Nadas' Pediatric Cardiology*. Philadelphia: Hanley & Belfus; 1992. Reproduced with permission from the publisher and author.)

Within a few moments after birth, the circulatory physiology must switch rapidly from the placenta to the lung as the organ of oxygen exchange. Failure of any one of a number of a complex series of pulmonary and cardiac events may result in cerebral and then generalized hypoxemia, with lasting damage or death. With the onset of spontaneous respiration, the lungs are expanded and the pulmonary arterioles, which probably have been actively vasoconstricted, dilate. The reduction in pulmonary vascular resistance results from both simple physical expansion of the

lung with the onset of respiration and the vasodilation of the pulmonary resistance vessels, probably partly as a result of the high level of oxygen in alveolar gas. Simultaneously, the placenta is removed from the circulation either by clamping the umbilical cord or by constriction of the umbilical arteries. This sudden increase in systemic vascular resistance and drop in pulmonary vascular resistance cause blood leaving the right ventricle to go out into the lung rather than through the ductus arteriosus. The sudden increase in left atrial return of blood now going through the lung increases left ventricular end-diastolic and left atrial pressure, shutting the flap valve of the foramen ovale against the edge of the cristae dividens, eliminating the atrial-level shunt.

With pulmonary vascular resistance lower than systemic vascular resistance, there may be some left-to-right (aorta to pulmonary artery) shunting through the ductus arteriosus. The mechanism for closure of the ductus arteriosus is not completely understood. The increased level of oxygen probably causes vasoconstriction of the ductus musculature, but there are strong suggestions that a reduction in circulating prostaglandins (PGs) of the E series plays a role. Within 3 or 4 days, the biochemical closure becomes irreversible when cellular necrosis of the endothelium leads to obliteration of the lumen. The pulmonary artery pressure drops to approximately half systemic levels within a day or so but takes another 2 to 6 weeks to drop down to adult levels.

The structure and hemodynamics of the field circulation have significant consequences in a neonate with congenital heart disease.[19] The parallel circulation with connections at the atrial and great vessel level allows a wide variety of congenital cardiac malformations to exist while still picking up oxygen at the placenta and delivering it to the tissues. For example, atresia of the tricuspid or mitral valve, while devastating after birth, does not have a significant effect in utero. Furthermore, since the right ventricle performs two-thirds of the cardiac work before birth, the left ventricle is underloaded; this may explain why congestive heart failure is seen not uncommonly with congenital defects. Because the normal flow across the aortic isthmus is relatively low (only about 10 percent of combined ventricular output), this area is especially vulnerable to small changes in flow across the foramen ovale. A somewhat small foramen may result in left-sided hypoplasia, which almost always is associated with narrowing (coarctation) or atresia (interrupted) at the distal transverse aorta just proximal to ductal insertion.

Since the pulmonary blood flow in utero is less than 10 percent of combined ventricular output and increases four to five times at birth, anomalies that obstruct pulmonary venous return may be masked in utero when the pulmonary venous return is low. Finally, the low circulating levels of oxygen before birth (P_{O_2} 26 to 38 mmHg) with the saturation at 50 to 60 percent may account for the relative level of comfort in infants with cyanotic heart disease, who may do well, at least in the short run, with a P_{O_2} of 30 mmHg and an aortic saturation of 50 percent, a level that would lead to cerebral and cardiac anoxia, acidosis, and death within a few minutes in an older child or adult.

Persistence of Fetal Circulation

Persistence of fetal circulation[20,21] or persistent pulmonary hypertension in a newborn results in right-to-left shunting through the patent foramen ovale and/or PDA. It most commonly occurs in full-term infants. Severe hypoxia usually is manifested in the first few hours of life with tachypnea and acidosis, and a chest roentgenogram shows diminished vascular flow but no evidence of pulmonary parenchymal disease. Physical examination may reveal a parasternal heave, a loud second heart sound, and a systolic murmur.

Polycythemia, transient myocardial ischemia from hypoglycemia, and cyanotic congenital cardiac defects must be excluded. A higher oxygen level in the right radial artery than in the umbilical artery confirms right-to-left shunting through the ductus arteriosus. Echocardiography and Doppler evaluation are of the utmost importance to rule out structural heart disease, especially total anomalous pulmonary venous connection.

The initial treatment[21] includes an increase in the inspired oxygen level and correction of acidosis with sodium bicarbonate. Frequently, artificial ventilation is required. Hyperventilation to diminish the partial pressure of carbon dioxide often is successful in lowering the pulmonary pressure and diminishing the right-to-left shunt. Recently, inhaled nitric oxide to reduce pulmonary vascular resistance has been found to be a useful adjunct to other therapies.[22] Treatment of severe disease with an extracorporeal membrane oxygenator is successful in a significant number of patients.[23] Similar hemodynamic alterations also may be seen in newborns with parenchymal lung disease.

Chapter 63: THE PATHOLOGY, PATHOPHYSIOLOGY, RECOGNITION, AND TREATMENT OF CONGENITAL HEART DISEASE

COMPLICATIONS OF CONGENITAL HEART DISEASE

Complications associated with congenital heart disease are listed in Table 63-2.

Table 63-2: Complications of Congenital Heart Disease in Children

Congestive heart failure	Growth retardation
Hypoxemia	Pulmonary vascular disease

Congestive Heart Failure

Congestive heart failure is a potentially lethal complication of congenital heart disease and occurs in over 80 percent of infants who have malformations severe enough to require cardiac catheterization or surgery within the first year of life.[24] Its onset is usually a phenomenon of the first 6 months of life. Onset after 1 year of age is rare without a serious intercurrent problem such as infective endocarditis, pneumonia, or anemia.

Heart failure within the first 12 to 18 h of life usually is due to malformations that involve pressure or volume overload independent of pulmonary flow, as occurs with severe valvular regurgitation or a systemic arteriovenous fistula. Rarely, myocarditis may produce failure from the time of birth, as may congenital complete heart block or supraventricular tachycardia. Other causes in this age group include primary cardiomyopathy, severe polycythemia or anemia, and depressed myocardial contractility from neonatal asphyxia, hypocalcemia, hypoglycemia, or sepsis.

A majority of full-term infants presenting with severe heart failure during the remainder of the first week have critical obstruction to systemic arterial flow, which in virtually all cases has been unmasked by narrowing or closure of the ductus arteriosus. Examples are aortic atresia, coarctation of the aorta, interruption of the aortic arch, and critical aortic stenosis. *During the second week of life, aortic atresia and coarctation remain the most common causes of heart failure, but left ventricular volume overload from VSD, transposition of the great arteries with a VSD, and truncus arteriosus make their appearance*. These malformations present as the pulmonary vascular resistance falls, increasing the left-to-right shunt. *Statistically, VSD is the primary cause of congestive failure, followed by transposition, coarctation, complete AV canal, and PDA*.

The most common symptom of congestive heart failure is difficulty in breathing, with rapid, grunting, or gasping breathing or breathlessness with feeding. Observation of an undisturbed infant reveals dyspnea, the signs of which are nasal flaring and subcostal or intercostal retractions. A respiratory rate consistently above 60 is to be expected, and rates in the range of 90 to 100 are not uncommon. Poor weight gain is the rule. Cool moist skin, a subdued and rapid arterial pulse, and hepatic enlargement are common accompanying signs. A gallop rhythm, pulmonary rales, and expiratory wheezes may be present. It may be difficult to distinguish the pulmonary findings of
