All patients with an ICD should be considered for pulse generator replacement when there is evidence of battery depletion, since late shocks occurring many years after primary implantation appear to define a continuing need for this therapy in many patients.[50] At the time of elective pulse generator replacement, the pace-sense characteristics of the ICD system are reassessed, and VF is induced in order to confirm satisfactory sensing and ability to defibrillate VF with a safety margin of 10 J or more. Occasionally, a patient's defibrillation energy requirements may be unexpectedly elevated at the time of generator replacement, and appropriate revision of the system or implantation of a new integrated lead is required.

Psychosocial Issues

The ICD is generally well tolerated in the vast majority of patients for whom it is recommended. Quality of life declines in the first 6 months postimplantation but by 12 months has returned to preimplant levels.[51] Depression, anxiety, and reduced sexual function may occur after device implantation. Factors that adversely affect quality of life include frequent or inappropriate shocks, device malfunction, or product recall.[52,53] Since shock delivery has a major impact on quality of life, it is appropriate to consider measures such as concomitant drug therapy, empiric programming of ATP for VT, and use of detection enhancement algorithms to minimize the risk of both appropriate and inappropriate shock delivery during long-term follow-up.[13,14,26] In a prospective, multicenter trial of ICD patients randomized to receive either sotalol or placebo, sotalol significantly reduced the mean annual number of shocks (1.4 shocks) compared to placebo (3.9 shocks) and significantly prolonged the time interval to first shock.[54]

Automobile Driving

A major concern among ICD patients is driving restrictions. Because of the risk of an arrhythmia recurrence or the delivery of high-energy shocks, restrictions on driving should be considered and discussed with all patients prior to device implantation. The period for greatest risk of ICD discharge is within the first 6 months after implantation. Patients receiving implantable defibrillators comprise a heterogeneous population. At one end of the spectrum is the patient with drug-refractory recurrent sustained ventricular tachyarrhythmias causing syncope or cardiac arrest

who is likely to receive more frequent device discharges. At the other end of the spectrum is the asymptomatic high-risk patient who has never experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia. A more restrictive approach to the issue of driving seems appropriate for the former group of patients but is inappropriate for the latter and may make such patients unwilling to accept ICD therapy. Published guidelines from the American Heart Association and the North American Society of Pacing and Electrophysiology recommend that patients who receive an ICD because of a previously documented episode of VT or VF should be prohibited from all driving for the first 6 months after ICD implantation.[55] After 6 months, if an ICD discharge has not occurred, patients may resume driving. Patients who have a prophylactic ICD implant and who have never had a documented episode of spontaneous ventricular tachyarrhythmia should not be prohibited from noncommercial driving. The recommendations make no distinction between patients whose primary treatment is antiarrhythmic drug therapy rather than ICD therapy.

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

COMPLICATIONS AND TROUBLESHOOTING

Morbidity and Mortality

ICD therapy is associated with well-known risks (Table 30-1) that must be weighed against the potential benefits of automatic ventricular tachyarrhythmia therapy. The last 10 years have seen a simplification of device implantation from nonthoracotomy transvenous abdominal implantation to single-lead pectoral implantation. A multicenter study of 473 patients implanted with a pectoral unipolar device reported successful device implantation in 98 percent of patients; in 7 percent of patients, implant criteria either were not met or were not fully assessed. No patient died within 24 h of the procedure, and the 1-month (perioperative) mortality rate was 0.9 percent.[57] Patients were followed for a mean of 6 months. Twenty-nine patients (6 percent) has serious procedure- or device-related complications requiring surgical intervention. A study of over 3000 patients who had nonthoracotomy ICD systems implanted in either an abdominal, a prepectoral, or a subpectoral position found that the 1-year cumulative complication-free survival rate was 88 percent and did not differ significantly among the three groups.[58] However, the complication rate depends on the definitions used and the duration of follow-up. If one includes mild device-related complications (e.g., inappropriate therapy delivery), approximately 50 percent of patients experience an adverse event within the first year of ICD implantation.[59] This needs to be considered when recommending device implantation in high-risk asymptomatic patients.

Table 30-1: Complications Associated with Pectoral ICD Implantation

PROCEDURE-RELATED
Short-Term
DFT testing (inability to defibrillate, worsening sys-tolic function, electromechanical dissociation)
Subclavian stick complications (pneumothorax, hemo-thorax, air embolism, subclavian artery puncture)
Venous thromboembolism
Phrenic nerve stimulation
Right ventricular perforation
Pericardial effusion or tamponade
Hematoma (pulse-generator pocket)
Seroma (pulse-generator pocket)
Hypotension
Myocardial infarction
Cerebrovascular accident
Proarrhythmia (atrial fibrillation, increased fre-quency of ventricular tachyarrhythmia: 'electricalstorm')
Long-Term
Infection

Erosion
Migration
Venous thromboembolism
Endocarditis
Shoulder-related problems
SYSTEM-RELATED
Lead dislodgment (Gross-, microdislodgment, Twiddler's syndrome)
Lead conductor fracture
Lead insulation defect
Lead perforation (+/- diaphragmatic pacing)
Loose set screw
Exit block (high pacing threshold)
Inappropriate shock delivery
Premature battery depletion
Device recall

SOURCE: Modified from O'Callaghan and Ruskin,[56] with permission.

Lead-related problems, such as dislodgment, insulation defects, or conductor fracture, which can result in failure to sense, failure to pace, and either inappropriate defibrillation shocks or inability to defibrillate VF, remain a significant problem despite the enormous advances in lead technology. A comparison of abdominal versus pectoral implants followed for a mean of 4 months postimplantation found that pectoral devices were associated with significantly fewer severe lead-related events, the majority of which were dislodgments (5 versus 11 percent).[60]

One of the most devastating complications is infection of the ICD system. Pectoral devices avoid the infection risks associated with tunneling to the abdomen or placement of a subcutaneous patch. Of 950 patients who had a transvenous system implanted, the infection rate was 0.6 percent, compared to 1.9 percent in patients who had a transvenous system plus a subcutaneous patch.[61] Infection resembles that observed with permanent pacemaker implantation. Direct intraoperative contamination is the source of most infections. However, due to the low virulence of some organisms (e.g., *Staphylococcus epidermis*), infections may not become obvious for some considerable time after implantation. In general, explantation of the entire ICD system is required. After a regimen of intense antibiotic therapy and if all clinical evidence of infection is resolved, reimplantation at a different site may be performed, but the risk of reinfection is higher than following a primary implant.

Troubleshooting

The differentiation of appropriate from inappropriate device function in a patient who has received an ICD discharge is a challenging problem. The initial step toward management is device interrogation to determine whether the ICD therapy was appropriate or inappropriate. ICDs have advanced from devices providing basic diagnostic data, such as event counts or RR intervals only, to sophisticated electrocardiographic monitoring units. Analysis of stored intracardiac electrograms recorded during the time interval preceding and following ICD therapy, in addition to marker channels that annotate each sensed event, results in a confident diagnosis of the causes of most ICD therapies (Fig. 30-6). In

general, changes in electrogram morphology compared to sinus rhythm are consistent with ventricular tachyarrhythmias, while an identical electrogram morphology is consistent with supraventricular arrhythmias. Atrial activity can often be identified with far-field electrograms. A distinct change in electrogram morphology can be demonstrated in either the near-field or the far-field electrogram in virtually 100 percent of VTs.[62] In dual-chamber devices, the differentiation of appropriate from inappropriate device function is greatly facilitated by the analysis and retrieval of simultaneously recorded atrial and ventricular electrograms.

In addition to careful analysis of stored electrogram data, real-time measurements (sensing, pacing, and impedance measurements) can be obtained, the ICD system can be x-rayed, and VF may be induced under intravenous sedation to determine the cause of inappropriate device function. Occasionally, problems such as loose connections only become obvious by device manipulation or a patient's movement during real-time telemetry. Accurate diagnosis is essential in order to institute the appropriate action, which may include device reprogramming, activation of VT detection enhancement algorithms, alteration of antiarrhythmic drug therapy, or surgical revision of the ICD system.

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

THE EVIDENCE BASE FOR ICD THERAPY

Background

As a therapeutic modality, the ICD is unsurpassed in its ability to prevent SCD (Fig. 30-2). Nevertheless, despite a marked reduction in SCD rates, overall mortality rates in ICD recipients remain high, with nearly a 20 percent 2-year mortality rate in most series.[63] The degree of survival benefit conferred by the defibrillator in a given patient population is dependent on the sudden arrhythmic death rate relative to the nonarrhythmic death rate, a ratio that is largely unknown. Patients with heart failure constitute a large proportion of ICD recipients. There was concern that implantable defibrillators may have little effect on overall survival rates in this population of patients for several reasons. First, as New York Heart Association (NYHA) functional class deteriorates, the proportion of deaths that are sudden and unexpected decreases. Second, successfully terminating an episode of VT or VF will have little effect on overall survival if the patient dies shortly thereafter of progressive pump failure. Because of these concerns, prospective randomized trials were conducted to test the hypothesis that implantable defibrillators significantly improve total survival rates.

Secondary Prevention of Sudden Cardiac Death

The results of three large prospective ICD trials comparing implantable defibrillators to antiarrhythmic drug therapy (mainly amiodarone) in patients with life-threatening ventricular tachyarrhythmias have consistently shown that the implantable defibrillator improves overall survival (Table 30-2). In the Antiarrhythmic Versus Implantable Defibrillator (AVID) trial of over 1000 patients, implantable defibrillators resulted in a 31 percent reduction in total mortality rate at 3 years compared to the antiarrhythmic drug therapy group (25 versus 36 percent; $p < .02$; Fig. 30-7).[64] The Canadian Implantable Defibrillator Study (CIDS) randomized over 600 patients presenting with sustained ventricular tachyarrhythmias to treatment with either the implantable defibrillator or amiodarone.[65] After 3 years' follow-up, patients randomized to receive the implantable defibrillator had a 20 percent reduction in total mortality rate compared to amiodarone-treated patients (25 versus 30 percent; $p = .07$). The Cardiac Arrest Study-Hamburg (CASH) randomized 346 cardiac arrest survivors to one of four treatment groups: amiodarone, metoprolol, propafenone, or the implantable defibrillator.[66] The propafenone arm was stopped in 1993 because of excessive mortality rates with this class I agent. During follow-up, patients randomized to receive the implantable defibrillator had a 37 percent reduction in total mortality rate compared to amiodarone- or metoprolol-treated patients (12 versus 20 percent; $p = .047$).

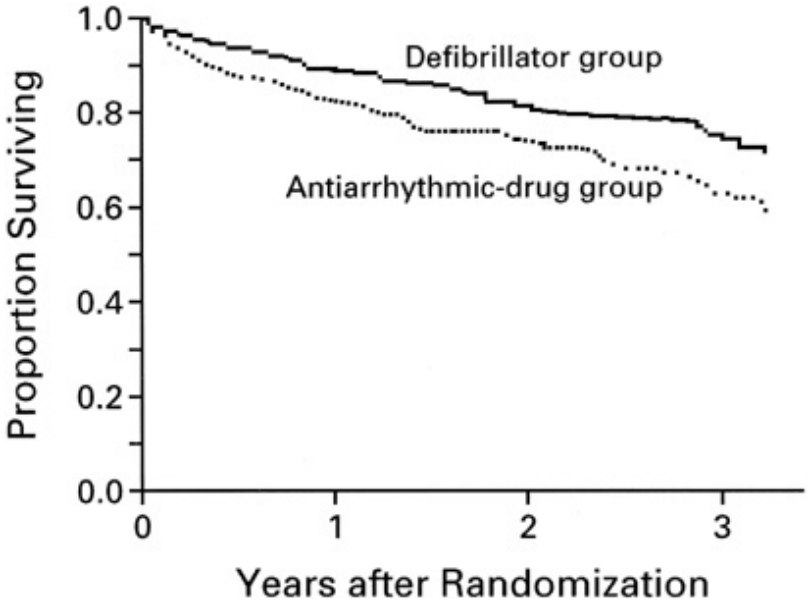

Figure 30-7: The Antiarrhythmic Versus Implantable Defibrillator (AVID) Trial. Overall survival in the defibrillator group and the antiarrhythmic drug group up to 3 years after randomization in the AVID trial. Survival was better among patients treated with the implantable defibrillator ($p < .02$). (From the AVID Investigators,[64] with permission.)

Although each of these three studies found lower total mortality rates in ICD recipients, only the AVID trial reached clear statistical significance. A meta-analysis of these three trials was presented at the North American Society of Pacing and Electrophysiology Annual Scientific Sessions in 1999 (unpublished). In total, there were 200 deaths among patients treated with implantable defibrillators and 255 deaths among patients treated with amiodarone. Compared to amiodarone, the ICD reduced the total mortality rate by 27 percent ($p < .05$). As a result of evidence from these clinical trials, the implantable defibrillator is now accepted as the therapy of first choice in survivors of symptomatic sustained ventricular tachyarrhythmias.

Primary Prevention of Sudden Cardiac Death

The majority of patients at risk of SCD have not previously experienced a sustained ventricular tachyarrhythmia. Primary (prophylactic) ICD implantation involves placing the device in a patient who is considered at high risk but has never had a spontaneous episode of sustained VT or VF, with the aim of effectively treating the first episode and thereby preventing sudden death. Defining populations of patients who are at sufficiently high risk that primary ICD implantation is justified is the focus of several prospective clinical trials (Table 30-3). Included are select patients with left ventricular dysfunction and nonsustained ventricular tachycardia (NSVT), high-risk coronary artery disease patients postsurgical revascularization, and patients with either ischemic or nonischemic dilated cardiomyopathy.

Table 30-3: Multicenter Primary Prevention ICD Trials

Trial	Study Population	Treatment Groups	Sample Size	Primary End Point	Study Period	Outcome
MADIT[67] (Multicenter Automatic Defibrillator Implantation Trial)	Prior MI with LVEF <35%, NSVT, and inducible nonsuppressible VT or VF	ICD vs conventional medical therapy	196 patients	Total mortality rate	1990-1996	Total mortality rate in ICD group significantly less than in conventional group (16 vs 39%, $p < .01$)

MUSTT[68] (Multicenter Unsustained Tachycardia Trial)	CAD with LVEF <40%, NSVT and inducible VT or VF	Antiarrhythmic therapy (ICD or EP-guided antiarrhythmic drug) vs no antiarrhythmic therapy	704 patients	Cardiac arrest or death from arrhythmia	1990-1998	5-year incidence of cardiac arrest or death from arrhythmia significantly less among 'antiarrhythmic therapy' than among 'no antiarrhythmic therapy' patients (25 vs 32% *p* = .04)
CABG-Patch[69] (Coronary Artery Bypass Graft Patch Trial)	CABG with LVEF <36% and positive SAECG	ICD + CABG vs CABG only	900 patients	Total mortality rate	1990-1997	At 4-year follow-up, total actuarial mortality rate in ICD group no different than for control group (27 vs 24%, *p* = .7)
CAT[70] (Cardiomyopathy Trial)	Dilated cardiomyopathy with LVEF <30% and no symptomatic ventricular arrhythmias	ICD vs control group	~720 patients	Total mortality rate	1991-present	No possible benefit from ICD determined at interim analysis (1997)
SCD-HeFT[71] (Sudden Cardiac Death in Heart Failure Trial)	Ischemic or dilated cardiomyopathy with congestive heart failure (NYHA II-III) and LVEF <35%	ICD vs amiodarone vs conventional group	~2500 patients	Total mortality rate	1996-present	Ongoing
MADIT-II[71] (Second Multicenter Automatic Defibrillator Implantation Trial)	Prior myocardial infarction with LVEF <30%	ICD vs conventional group	~1200	Total mortality rate	1998-present	Ongoing

ABBREVIATIONS: CABG = coronary artery bypass graft; CAD = coronary artery disease; EP = electrophysiologic; MI = myocardial infarction; Rx = treatment; SAECG = signal-averaged electrocardiogram.

NSVT in the setting of a previous myocardial infarction and left ventricular dysfunction is associated with a 2-year mortality rate of approximately 20 to 30 percent.[72-74] The Multicenter Automatic Defibrillator Implantation Trial (MADIT) was designed to determine whether prophylactic ICD implantation in patients with prior myocardial infarction, left ventricular ejection fraction (LVEF) less than or equal to 35 percent, NSVT, and inducible, nonsuppressible VT or VF would improve survival rates compared to conventional medical therapy.[67] Amiodarone was used in 74 percent of the conventional therapy group 1 month after

randomization, but by the end of the study only 45 percent of the conventional group were still taking amiodarone. Total mortality rates in the ICD group were significantly less than in the conventional treatment group. The Multicenter UnSustained Tachycardia Trial (MUSTT) was designed to determine whether electrophysiologically guided antiarrhythmic therapy would reduce the risk of sudden death among patients with coronary artery disease, LVEF less than or equal to 40 percent, NSVT, and inducible VT or VF compared to no antiarrhythmic therapy.[68] Patients randomized to antiarrhythmic therapy (ICD or electrophysiologically guided drug therapy) had a significantly reduced arrhythmic mortality rate compared to the conservative treatment group. It is noteworthy that the improvement in outcome was entirely due to the ICD patients; electrophysiologically guided drug therapy (mostly class I agents) did not improve and may have worsened outcome. Although not a primary end point of the trial, Kaplan-Meier estimates of overall mortality rate show significantly fewer deaths in ICD patients than in either of the other two groups (Fig. 30-8). Therefore, the results of the MADIT and MUSTT trials confirm that, in patients with coronary artery disease, depressed LVEF, NSVT, and inducible sustained ventricular tachyarrhythmias who have never had a spontaneous episode of sustained VT or VF, the ICD is effective in significantly reducing the risk of SCD and prolonging overall survival.

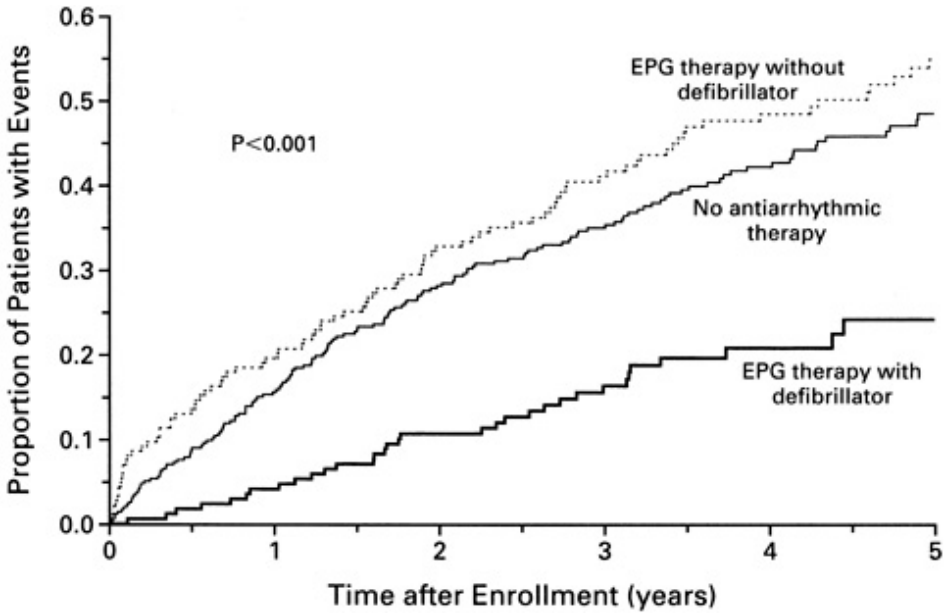

Figure 30-8: The Multicenter Unsustained Tachycardia Trial (MUSTT). Kaplan-Meier estimates of overall mortality rate according to whether the patients received treatment with electrophysiologically guided (EPG) therapy without defibrillator (i.e., antiarrhythmic drug therapy), no antiarrhythmic therapy, or electrophysiologically guided therapy with a defibrillator. Mortality rates were significantly less in the ICD-treated patients than in the other two groups. (From Buxton et al.,[68] with permission.)

The Coronary Artery Bypass Graft (CABG) Patch trial randomized patients with LVEF less than 36 percent and a positive signal-averaged electrocardiogram who were undergoing coronary artery bypass surgery to a prophylactic ICD or no specific antiarrhythmic therapy.[69] There was no survival benefit from prophylactic ICD implantation in this population. This observation reflects the fact that many of the patients enrolled in the CABG-Patch trial would not have demonstrated inducible sustained VT had electrophysiologic testing been performed and therefore were at relatively low risk of arrhythmic death compared with the MADIT or MUSTT populations. The study also underscores the survival benefit of coronary artery revascularization in patients with coronary artery disease and left ventricular dysfunction.

Despite conventional medical therapy, the mortality rate associated with congestive heart failure and left ventricular systolic dysfunction remains unacceptably high, in the range of 5 to 15 percent annually in mild heart failure and increasing to 20 to 50 percent annually in patients with severe heart failure.[75] SCD is responsible for approximately half of all cardiac deaths in patients with heart failure. The Cardiomyopathy

Trial (CAT), the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), and the second Multicenter Automatic Defibrillator Implantation Trial (MADIT-II) will address the issue of whether the ICD improves survival in a population of cardiomyopathy patients irregardless of the presence or absence of arrhythmia markers (inducibility, NSVT, etc.).[70,71] Preliminary results from the CAT trial suggest that the ICD does not improve overall survival, however our future approach to the management of heart failure patients awaits the results of SCD-HeFT and MADIT-II.

The results of negative ICD trials (CABG-Patch and CAT) emphasize the fact that ICDs prolong survival in a population of patients only if that population has a sufficiently high incidence of life-threatening ventricular tachyarrhythmias and a sufficiently low incidence of death from all other causes. The real challenge over the next few years will be developing means of accurately identifying patients at sufficiently high risk of life-threatening ventricular tachyarrhythmias and sufficiently low risk of death from all other causes in whom ICD therapy is both efficacious and cost effective.[76]

Cost-Effectiveness

The cost of ICD therapy compared to alternative therapies will be the focus of much study and discussion in the next few years. In addition to hardware costs (approximately $20,000 to $25,000), there are implantation costs, hospital admission charges, and the cost of routine follow-up and pulse generator replacement. Treatment strategy is central to the issue of overall costs. In the early 1990s, management of patients with life-threatening ventricular tachyarrhythmia consisted of serial antiarrhythmic drug testing, with ICD therapy reserved for those patients whose arrhythmias were not adequately suppressed. This strategy was characterized by long hospitalizations and frequent progression to late ICD implantation, resulting in substantial costs. In recent years, the strategy of ICD implantation as first-line therapy and the progression from thoracotomy and abdominal implantation to transvenous pectoral implantation has significantly reduced the length of hospital stay and substantially lowered the initial cost of ICD therapy.[77,78]

Long-term costs need to be compared with outcome measures, including total mortality rate and quality of life, in order to assess cost effectiveness. In the AVID trial, the average length of additional life associated with ICD therapy was 2.7 months. The estimated cost per life-year saved was $127,000.[79] In the MADIT trial, the average length of additional life associated with ICD therapy was 10.3 months, and the estimated cost per life-year saved was $27,000.[80] The cost analysis of MADIT, in contrast to AVID, compares favorably with other cardiac interventions. The difference is most likely due to differences in patients' selection. The MADIT patients, all of whom had inducible nonsuppressible ventricular tachyarrhythmias (NSVTs) on electrophysiologic testing, were at higher risk of death than were the AVID patients, as evidenced by the poorer prognosis in the conventional arm of MADIT compared to that in the antiarrhythmic-drug arm of AVID. These results emphasize the fact that the patients' selection largely determines the cost effectiveness of ICD therapy. The most cost-effective use of the ICD is in patients at high risk of death due to ventricular tachyarrhythmia and at low risk of death from all other causes. More accurate risk stratification is necessary to ensure that ICD therapy is applied in an optimally efficient and cost-effective manner.

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

ICD THERAPY IN SPECIFIC CLINICAL SETTINGS

The American College of Cardiology (ACC) and the American Heart Association (AHA) advise ICD therapy in cardiac arrest survivors, in patients with spontaneous sustained ventricular tachycardia, in select patients with syncope of undetermined origin, and in select patients with coronary artery disease, left ventricular dysfunction, and NSVT (Table 30-4).[81] In these clinical circumstances, the implantable defibrillator is now regarded as the treatment of first choice. The role of antiarrhythmic therapy in these patients is mainly limited to adjunctive therapy in ICD recipients who have other tachyarrhythmias (e.g., atrial fibrillation) or who are receiving frequent shocks and require suppressive drug therapy. Future drug trials in patients with ICDs may result in the development of new, safer antiarrhythmic drugs.

Cardiac Arrest Survivors

Aborted SCD is, in the majority of cases, caused by life-threatening ventricular tachyarrhythmias (VF and hypotensive VT). Structural heart disease is almost invariably present, which in adult populations is most frequently coronary artery disease.[82] Survivors of cardiac arrest, in the absence of an acute myocardial infarction (first 48 h), are at high risk of future recurrence. Data from the 1970s, which today reflect the natural history of this condition, show a 36 percent 1-year mortality rate in patients who were successfully resuscitated, hospitalized, and discharged home following an out-of-hospital VF arrest.[83]

The role of ischemia in the pathogenesis of SCD is not clearly defined. Only a small proportion of cardiac arrest survivors have clinical evidence of an acute myocardial infarction. Nonetheless, since the majority of cardiac arrest survivors have evidence of significant chronic coronary atherosclerosis, transient ischemia is suspected as the major trigger factor for life-threatening ventricular tachyarrhythmias. Cardiac catheterization identifies those survivors of SCD who have critical obstructive coronary artery disease. It is our practice to revascularize these patients whenever feasible. Cardiac arrest occurring in the setting of acute clinical ischemia or within 48 h of an acute myocardial infarction is, with rare exception, treated in the conventional manner without electrophysiologic workup or ICD implantation. In addition, select patients with significant multivessel coronary artery disease, reversible ischemia on functional assessment, and no obvious arrhythmic substrate (no prior Q-wave infarction, preserved left ventricular function, and negative signal-averaged ECG) usually require revascularization rather than ICD implantation. In this group, we perform an electrophysiologic study following revascularization, and those with no inducible arrhythmias are considered to be a low-risk group, whose treatment usually consists of beta blockade.[84] These two groups (patients with acute clinical ischemia and patients with significant multivessel coronary artery disease, reversible ischemia, and no obvious arrhythmic substrate) account for only a minority of cardiac arrest survivors. The majority of cardiac arrest survivors have an obvious arrhythmic substrate [prior Q-wave infarction, depressed LVEF, positive signal-averaged ECG, or inducible sustained monomorphic VT (SMVT)], and, in addition to revascularization, we advise ICD implantation.

Until now, it has been assumed that ventricular tachyarrhythmias due to a transient or reversible disorder are adequately treated by correcting the underlying cause; this is supported by the current ACC-AHA guidelines. Recent analysis of the AVID trial registry of screened nonrandomized

patients has reported that the overall mortality rate in these patients is as great as in patients with prior cardiac arrest.[85] Determining whether this high mortality rate is due to sudden arrhythmic death or progressive pump failure requires further study and may significantly affect our management of these patients.

Sustained Monomorphic Ventricular Tachycardia

In patients with SMVT that has resulted in a cardiac arrest or syncope, the ICD is usually employed as first-line therapy. In patients with SMVT that is tolerated hemodynamically, other potential therapeutic options include empiric amiodarone therapy, electrophysiologically guided antiarrhythmic drug therapy, transcatheter radiofrequency ablation, and arrhythmia surgery. Empiric amiodarone therapy is associated with high rates of drug discontinuation due to adverse side effects. "Guided" drug therapy using either invasive electrophysiologic study or noninvasive Holter monitoring has failed to adequately protect against arrhythmia recurrence and has largely been abandoned. Catheter ablation, the treatment of choice in patients with VT and structurally normal hearts, is usually only employed as adjunctive therapy in patients with underlying structural heart disease, typically in patients with implanted devices. Catheter ablation is suitable in only about 10 percent of patients with spontaneous sustained ventricular tachycardia.[86] Arrhythmia surgery is the only therapy with SCD rates similar to those for ICD therapy.[87,88] Although this approach can be curative, perioperative mortality rates are much higher than those associated with ICD implantation, ranging from 9 to 15 percent. Combined aneurysmectomy and intraoperative map-guided subendocardial resection yields a low rate of arrhythmia recurrence and is only indicated in highly selected patients who have a discrete left ventricular aneurysm.

In summary, compared to the other available treatments, ICD therapy is widely applicable, well tolerated, and associated with good short-term and long-term results. Today it is the preferred mode of therapy in the vast majority of patients with structural heart disease and SMVT. The various therapeutic options available should be considered as complementary rather than competing therapies. In managing individual patients, more than one therapy or even all therapies may be employed over a period of time.

Syncope of Undetermined Origin

Syncope is a common, usually benign condition. However, when associated with structural heart disease and inducible VT at electrophysiologic study, it carries a high risk of SCD. One representative study reported a sudden death rate of 48 percent at 3 years in patients with syncope of undetermined origin and inducible sustained VT, compared to 9 percent in patients with negative electrophysiologic study results.[89] The risk of death in patients presenting with syncope plus inducible ventricular tachyarrhythmia on electrophysiologic study is similar to that in patients presenting with documented spontaneous VT or VF.[90] The ACC-AHA guidelines recommend ICD therapy in patients with syncope of undetermined origin, structural heart disease, and inducible hypotensive ventricular tachycardia.[81] However, follow-up of small series of such patients have reported a high total mortality rate despite ICD therapy.[91] Whether ICD therapy truly reduces the total mortality rate in this group can only be answered by a prospective, randomized trial. The CIDS trial randomized patients with syncope of undetermined origin and documented or induced sustained VT.[65] Analysis of this subgroup should help resolve this issue.

Patients with idiopathic dilated cardiomyopathy who present with syncope have a high mortality rate, and, in contrast to coronary artery disease patients, the role of electrophysiologic study is ill defined. According to the ACC-AHA guidelines, ICD therapy is contraindicated in patients with syncope of undetermined origin and no inducible ventricular tachyarrhythmia. Knight et al. reported on 14 consecutive patients with nonischemic cardiomyopathy, unexplained syncope, and

a negative electrophysiologic test result who underwent defibrillator implantation.[92] Fifty percent of patients received appropriate shocks during 2 years' follow-up, supporting the use of ICD therapy in these patients. Prospective studies are needed to identify which patients with dilated cardiomyopathy and undetermined syncope may benefit from ICD implantation. Meanwhile, these patients need careful clinical assessment, and select patients may benefit from implantable event loop-recording devices.

Symptomatic Patients with Severe LeftVentricular Dysfunction

Patients with poor left ventricular function who have experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia are a high risk of both SCD and death due to progressive pump failure. Successfully terminating an episode of VT or VF will have little effect on overall survival if the patient dies shortly thereafter of pump failure. In the past, this observation raised the concern that implantable defibrillators may have little effect on overall survival in this patient population. It is somewhat surprising that subgroup analysis of both the AVID and CIDS trials has found that patients with a LVEF less than or equal to 35 percent derive the greatest survival benefit from defibrillator therapy.[93,94] Patients with an LVEF greater than 35 percent had similar survival benefit up to 3 years postrandomization with either empiric amiodarone or device therapy, probably due to a lower arrhythmia recurrence rate. Bocker et al. also assessed the potential benefit of ICD therapy in 603 patients with and without heart failure and concluded that patients with NYHA functional class I to III heart failure benefited in terms of overall survival from ICD implantation.[95] ICD therapy is contraindicated in patients with NYHA class IV heart failure unless they have experienced an episode of life-threatening ventricular tachyarrhythmia and are awaiting cardiac transplantation.

Patients awaiting heart transplantation who have experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia deserve special consideration. Not only are they at risk of sudden tachyarrhythmic death, but they also are at high risk of sudden death due to bradyarrhythmias or electromechanical dissociation and of death due to progressive pump failure.[96] Nevertheless, it has been reported that cardiac transplant candidates who have experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia can be effectively protected against sudden arrhythmic death despite having a high incidence of appropriate shocks early after implantation.[97]

Asymptomatic High-Risk Patients

Since the prognosis associated with a first cardiac arrest is very poor, an effective primary prevention strategy is required to identify and effectively treat patients at high risk of sudden death who have not yet experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia (hypotensive VT or VF). The results of the MADIT and MUSTT trials confirm that, in a clearly defined high-risk group of patients with coronary artery disease, depressed left ventricular function, NSVT, and inducible sustained ventricular tachyarrhythmias, the ICD is effective in significantly reducing the risk of SCD and prolonging overall survival. In clinical practice, however, patients with coronary artery disease, depressed left ventricular function, and NSVT are common, and there is at present no consensus as to which patients should proceed to invasive electrophysiologic study and possible ICD implantation. In addition, the cost effectiveness of screening large numbers of these patients has not been assessed. We do not recommend routine screening of patients with left ventricular dysfunction to detect the presence of NSVT. However, in selected patients with severe left ventricular dysfunction due to who are brought to our attention because of recurrent NSVT, we recommend electrophysiologic testing and, if MADIT or MUSTT criteria are met, ICD implantation.

Primary prevention in many patients with cardiomyopathy is limited by our inability to accurately identify those at risk of SCD. The issue of whether the ICD improves survival in cardiomyopathy patients irregardless of the presence or absence of arrhythmia markers (e.g., inducibility, NSVT, etc.) is at present being addressed by SCD-HeFT and MADIT-II trials (Table 30-3). The ability of noninvasive markers to predict overall mortality rates and arrhythmic events in over 200 patients with idiopathic dilated cardiomyopathy over a 5-year follow-up period is currently being undertaken and should help identify patients who may benefit most from ICD therapy.[98]

Patients awaiting heart transplantation who have never experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia deserve special consideration. Although ICD therapy is contraindicated in patients with NYHA class IV heart failure, due to a high incidence of nontachyarrhythmic deaths, it has been argued that ICD should be implanted in all NYHA class III patients as a "bridge" to transplantation. To date, no prospective randomized trial has been conducted to assess the benefit of such a strategy.

Summary

The ICD is now accepted as first-line therapy in the management of most patients who have experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia. Much work needs to be done to accurately identify those patients at high risk of arrhythmic death who are at relatively low risk of death from all other causes and who would benefit from prophylactic ICD therapy. Prospective randomized trials have identified specific subgroups of patients who benefit from ICD therapy (MADIT and MUSTT patients), but a clear strategy regarding the screening and the investigation of such patients is required.

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

FUTURE DIRECTIONS

Implantable cardioverter-defibrillator technology is evolving rapidly. Nonetheless, ICD devices are far from ideal, and many advances can be anticipated in the years ahead.[99] Advances in battery and capacitor technology, improved lead systems, and more efficient defibrillation waveforms will hopefully enable the ICD of the future to more closely approach the size of today's permanent pacemakers. Increased battery longevity is required to reduce the morbidity associated with pulse-generator replacements and to improve the cost-effectiveness of ICD therapy. Integrated arrhythmia management systems incorporating sophisticated dual-chamber pacing, dual-chamber cardioversion, and dual-chamber defibrillation will be employed in patients with paroxysmal supraventricular and ventricular tachyarrhythmias. The incorporation of a reliable hemodynamic sensor to differentiate hemodynamically stable from hypotensive tachyarrhythmias would help identify the most appropriate therapy for each arrhythmia.

More important than technological advances in the next few years will be a clearer understanding of the role of ICD therapy in the primary prevention of SCD. Careful selection of patients to reduce overall mortality rates as well as SCD will ensure that both patients and society benefit.

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

List of Figures

Figure 30-4: Posteroanterior chest x-ray of pectoral ICD device. A single integrated lead is inserted via the cephalic vein and positioned at the right ventricular apex. This is attached to a pulse generator implanted in the left pectoral region. ICDs are implanted using techniques similar to permanent pacemaker implantation. The integrated lead consists of right ventricular and superior vena cava defibrillation coils (*arrows*) and a tip electrode. In addition to the defibrillation coils, the titanium case of the pulse generator acts as a large-surface-area defibrillation electrode (active can). The defibrillation pathway in this patient is right ventricular coil to both superior vena cava coil and active can.

Figure 30-5: Percent probability for successful defibrillation versus shock energy. The measured ICD energy margin is the energy difference between the lowest conversion success [defibrillation threshold (DFT)] and the programmed ICD energy: energy margin = E_{ICD} - DFT. The ICD safety margin is the energy difference between the lowest energy required for consistent defibrillation success (E_{99}) and the programmed ICD energy: safety margin = E_{ICD} - E_{99}. (Adapted from Singer and Lang,[40] with permission.)

Figure 30-6: Stored electrogram of inappropriate shock delivery due to atrial fibrillation. The recording is a continuous 32-s strip consisting of a waveform channel and a status channel. Atrial fibrillation is seen throughout the recording. In the first panel, the ICD classifies the shorter intervals as fibrillation (F). In the second panel, before the 12-s mark the detection criterion for VF is met. Device charging (*) and reconfirmation (R) of the arrhythmia begin as recorded in the status channel. In the third panel, a high-voltage shock is delivered inappropriately at the 21-s mark, denoted by a full-scale positive rectangular marker in both the waveform and status channels. Atrial fibrillation persists, and the detection criterion for VF is met a second time, in panel 4 before the 27-s mark. During device charging, the ventricular rate slows, and redetection of "sinus rhythm" (normal rate zone) aborts shock therapy. Sinus redetection is denoted by an arrow in the status channel and a negative deflection in the marker channel. Information regarding the device, date and time of the episode, screen sweep speed, the electrogram number and duration, and the reason the event was stored is located in the oblong box at the top of the page. (Courtesy of Mary Guy RN, ICD Clinic, Massachusetts General Hospital. From O'Callaghan and Ruskin,[56] with permission.)

Figure 30-7: The Antiarrhythmic Versus Implantable Defibrillator (AVID) Trial. Overall survival in the defibrillator group and the antiarrhythmic drug group up to 3 years after randomization in the AVID trial. Survival was better among patients treated with the implantable defibrillator ($p < .02$). (From the AVID Investigators,[64] with permission.)

Figure 30-8: The Multicenter Unsustained Tachycardia Trial (MUSTT). Kaplan-Meier estimates of overall mortality rate according to whether the patients received treatment with electrophysiologically guided (EPG) therapy without defibrillator (i.e., antiarrhythmic drug therapy), no antiarrhythmic therapy, or electrophysiologically guided therapy with a defibrillator. Mortality rates were significantly less in the ICD-treated patients than in the other two groups. (From Buxton et al.,[68] with permission.)

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 31:

CARDIAC PACEMAKERS

Authors: Raul D. Mitrani, Robert J. Myerburg, Agustin Castellanos

The concept for bradycardia pacemakers originated in the 1950s. Over the past 4 decades, cardiac pacing has undergone tremendous growth, while the pacer units themselves have been downsized. Current units are capable of fully programmable dual-chamber pacing, rate response to activity and metabolic changes, have telemetry of pacer function, incorporate algorithms to respond to changes in intrinsic rhythms, and can store a history of patients' arrhythmic events. Besides providing bradycardia support, pacers are an integral part of patients' comprehensive arrhythmia and hemodynamic management strategies. A number of current and comprehensive reviews are available,[1-3] and the reader is referred to these for more detailed discussion of selected topics.

The basic pacemaker system consists of a pulse generator connected to one or two leads attached to the heart. Almost all pacemakers use a lithium-iodide battery. Pacing is accomplished by sending current pulses through the lead to a distal electrode (cathode), which initiates depolarization of the myocardium. Current returning through the anode completes the electrical circuit.

CODES FOR CARDIAC PACING

Pacemakers are coded by a specific abbreviation according to the type of pacemaker and mode of pacing. In common usage, the first three or four letters are used, but a total of five letters have been defined by the North American Society of Pacing and Electrophysiology (NASPE) and the British Pacing and Electrophysiology Group (BPEG) (Table 31-1).[4]

Table 31-1: The NASPE/BPEG Pacemaker Code

Chamber Paced	Chamber Sensed	Response to Sensed Event	Programmability/Rate Response
O (none)	O	O	O
A (atrium)	A	I (inhibit)	R (rate responsive)
V (ventricle)	V	T (triggered)	P (simple programmable)
D (dual)	D	D (I + T)	M (multiprogrammable)
S (single chamber, A or V)	S		C (communicating)

NOTE: In current terminology, only rate responsiveness (*R*) is indicated by the fourth position. All current pacers have full programmability; therefore, the letters *P*, *M*, and *C* are no longer used.

The first three letters refer to the type of pacemaker or pacing mode that is being employed. The first letter refers to the chamber(s) being paced and the second letter refers to the chamber(s) being sensed. The letter A indicates atrial pacing or sensing, and V refers to ventricular pacing or sensing. If A and V are both being paced and/or sensed, the designation D, dual-chamber pacing or sensing, is used. The third letter refers to the response to a sensed event. The pacemaker can either inhibit (I) pacing output from one or both of its leads, or it can trigger (T) pacing at a programmable interval after the sensed event. The detailed

description and indications for different pacing modes will be described.

The fourth letter designation represents either the type of programmability or whether the pacemaker is capable of providing rate-responsive pacing. Lastly, the fifth letter represents cardiac devices that are capable of treating atrial or ventricular tachyarrhythmias. In common usage, only the rate responsiveness of the pacemaker is noted in the fourth letter designation, and the fifth letter designation is only used for atrial pacers with antitachycardia function.

Chapter 31: CARDIAC PACEMAKERS

TEMPORARY PACING

Temporary pacing is a modality required to provide patients with heart rate support when they experience intermittent or persistent hemodynamically relevant bradyarrhythmias or to provide standby pacing for patients at increased risk for sudden and complete heart block. Occasionally, temporary pacing is used to control sustained atrial or ventricular tachyarrhythmias. The end point for temporary pacing is either resolution of a temporary indication for pacing or implantation of a permanent pacemaker for a continuing indication. The clinician must decide whether to insert a temporary transvenous pacemaker versus relying on a noninvasive external unit.[5]

Indications

Indications for pacer implant can be divided according to whether there is consensus opinion as to the appropriateness of the indication (Table 31-2). The indications for temporary pacing are listed in Table 31-3. In general, indications for temporary pacing may include patients who are at high risk for developing complete heart block, such as is the case in patients with acute myocardial infarctions and alternating bundle branch blocks. Other indications for temporary pacing include those indications for permanent pacing when patients are symptomatic and cannot wait for the permanent pacemaker. In general, it would be advisable to place the permanent pacemaker as soon as possible to avoid the risks of temporary pacemaker placement.

Table 31-2: Consensus for Appropriateness of Pacer Implant Indication

Class I	Conditions for which there is general agreement that permanent pacemakers should be implanted.
Class IIa	Conditions for which permanent pacemakers are frequently used but there is divergence of opinion with respect to the necessity of their insertion. Weight of evidence/opinion is in favor of pacemaker use.
Class IIb	Conditions for which permanent pacemakers are frequently used but there is divergence of opinion with respect to the necessity of their insertion. Weight of evidence/opinion is in favor of pacemaker use.
Class III	Conditions for which there is general agreement that devices are unnecessary.

Temporary pacing is also indicated when a patient has bradycardia causing symptomatic or hemodynamic compromise. Temporary pacing at rates of 80 to 100 beats per minute can be used to prevent bradycardia-dependent ventricular arrhythmias or those associated with a long QT interval and torsade de pointes. Temporary atrial pacing is occasionally used in patients to restore atrioventricular (AV) synchrony in patients with temporary sinus arrest who have intact AV conduction. Toxic drug effects, such as digitalis toxicity, or metabolic abnormalities, such as hyperkalemia, may produce a temporary symptomatic bradycardia requiring temporary pacing.[6]

Lyme disease is a specific cause of carditis that has been associated with various degrees of AV

block in some patients.[6,7] In the presence of high-degree or complete AV block (see Chap. 23), the escape rhythm consists of a slow wide QRS or there may be a systole. Temporary cardiac pacing is necessary in the more advanced cases, but implantation of a permanent pacemaker is generally not necessary for patients with Lyme disease since the AV block almost always resolves.

Occasionally, temporary pacing is used for management of tachyarrhythmias for overdrive pacing of atrial or ventricular arrhythmias. The most common clinical setting is generally in the postoperative period after major cardiac surgery, when atrial flutter may be pace terminated into sinus rhythm.[8]

Temporary Pacing in Acute Myocardial Infarction

The use of temporary pacing in acute myocardial infarction can be accomplished by transcutaneous systems in those patients without active need for pacing and in those patients at low to moderate risk for developing complete heart block. Because transcutaneous systems are uncomfortable during active pacing for prolonged periods of time, transvenous pacing may be placed in patients requiring active pacing or in those patients at increased risk for developing complete heart block (Table 31-3).[9]

In patients with inferior infarction, any conduction disturbance is likely to be proximal to the His bundle. Therefore, patients with inferior infarction require temporary cardiac pacing only if there are symptoms (angina, hypotension, etc.) associated with the bradycardia or for persistent rates less than 40 beats per minute.

Although patients with inferior myocardial infarction are less likely to require temporary pacing compared with patients with anterior infarction, the recent guidelines on the use of temporary pacing in patients with acute infarction do not differentiate between anterior and inferior infarction.[9] Temporary pacing is indicated in the presence of high-degree (Mobitz type II second-degree AV block) or complete AV block because of the likelihood that these patients will be hemodynamically unstable with their bradyarrhythmia. Any symptomatic bradycardia with hypotension is also an indication for temporary pacing. Additionally, the presence of new bifascicular block generally places patients at increased risk for complete AV block, especially with associated first-degree AV block; therefore, temporary pacing would be reasonable. It is unclear whether patients with new left bundle branch block with normal PR interval or new right bundle branch block (with normal axis) require temporary pacing.

Selected patients with right ventricular infarction or other patients who require AV synchrony may require dual-chamber AV pacing. However, most patients who need temporary transvenous pacing receive a single ventricular lead because of its ease of use.

Techniques for Temporary Pacing

Techniques and clinical competence required to implant temporary pacemakers have been described elsewhere.[1,10,11] Catheters are generally placed into the right heart by percutaneous sheaths placed into the internal jugular, subclavian, brachial, or femoral vein. For temporary VVI pacing, the catheter is advanced under fluoroscopic guidance into the right ventricle. If fluoroscopy is not available, the pacing catheter can be advanced into the right ventricle by using intracardiac electrograms to position the lead.

Alternatively, transcutaneous pacing is a common method for noninvasively pacing patients who require a prophylactic temporary backup pacer or require emergent pacing.[5,12] It can be activated quickly in situations in which emergency ventricular pacing is required. The unit incorporates two

large pads placed in an anterior and posterior position. The main drawback is the high energy requirements (50 to 100 mA at 20 to 40 ms), which cause skeletal muscle stimulation and pain; therefore, this should not be used for extended periods in awake patients.

Chapter 31: CARDIAC PACEMAKERS

INDICATIONS FOR PERMANENT PACING

The indications for permanent pacemakers can be divided into three classifications (Table 31-2) and are listed in Table 31-4 according to the most recent indications published by a joint task force by the American College of Cardiology and American Heart Association in 1998.[13] These recommendations serve as guidelines, and there are other clinical factors that may affect the decision to implant a pacer. Many indications for pacemaker implantation are predicated by the presence of symptoms. However, many symptoms such as fatigue or subtle symptoms of congestive heart failure may be recognized only in retrospect, after placement of a permanent pacemaker.

Table 31-4: Indications for Permanent Pacemaker

	Class I	Class II	Class III
Acquired AV block	Third-degree AV block with:	*Class IIa*	Asymptomatic first-degree AV block
	Bradycardia and symptoms due to AV block	Asymptomatic complete AV block with average awake ventricular rate >40 bpm	Asymptomatic type I second-degree AV block above the level of the bundle of His
	Requirement of drugs that result in symptomatic bradycardia	Asymptomatic type II second-degree AV block (permanent or intermittent)	AV block expected to resolve
	After catheter ablation of the AV junction or after postoperative AV block not expected to resolve	Asymptomatic type I second-degree AV block at or below the bundle of His (documented by electrophysiologic studies)	
	Neuromuscular diseases with AV block	First degree AV block with symptoms suggestive of pacemaker syndrome and documented alleviation of symptoms with temporary pacing	
	Escape rhythm <40 bpm or asystole >3 s in awake symptom-free patients		
	Second-degree AV block, permanent or intermittent, with symptomatic bradycardia	*Class IIb*	
		Marked first-degree AV block in patients with congestive heart failure	

After myocardial infarction	Persistent second- or third-degree AV block in the His-Purkinje system or Transient advanced infranodal AV block and associated BBB Symptomatic second- or third-degree AV block at any level	*Class IIb* Persistent advanced AV block at the AV node level	Transient AV conduction disturbances without intraventricular conduction defects or with isolated left anterior fascicular block Acquired left anterior fascicular block Persistent first-degree AV block in the presence of old or age-indeterminate BBB
Bifascicular or trifasicular block	Intermittent complete heart block associated with symptoms Type II second-degree AV block	*Class IIa* Bifascicular or trifascicular block with syncope not proven to be due to AV block but other causes of syncope not identifiable HV interval >100 ms or pacing-induced infra-His block	Fascicular block without AV block or symptoms Fascicular block with first-degree AV block without symptoms
Sinus node dysfunction	Sinus node dysfunction with documented symptomatic bradycardia (in some patients, this will occur as a result of long-term essential drug therapy of a type and dose for which there is no acceptable alternative) Symptomatic chronotropic incompetence	*Class IIa* Sinus node dysfunction, occurring spontaneously or as a result of necessary drug therapy, with heart rates <40 bpm without clear association between significant symptoms and bradycardia *Class IIb* In minimally symptomatic patients, chronic heart rate <30 bpm while awake	Sinus node dysfunction in asymptomatic patients, including those in whom substantial sinus bradycardia is a consequence of long-term drug treatment Sinus node dysfunction in patients in whom symptoms suggestive of bradycardia are clearly documented not to be associated with a slow heart rate Sinus node dysfunction with symptomatic bradycardia due to nonessential drug therapy

Hypersensitive carotid sinus and neurocardiac syndromes	Recurrent syncope associated with clear, spontaneous events provoked by carotid sinus stimulation; minimal carotid sinus pressure induces asystole of >3 s duration in the absence of any medication that depresses the sinus node or AV conduction	*Class IIa* Recurrent syncope without clear, provocative events and with a hypersensitive cardioinhibitory response *Class IIb* Syncope with associated bradycardia reproduced by head-up tilt (with or without provocative maneuvers or isoproterenol)	A hyperactive cardioinhibitory response to carotid sinus stimulation in the absence of symptoms Vague symptoms (dizziness or light-headedness) with a hyperactive cardioinhibitory response to carotid sinus stimulation Recurrent syncope, light-headedness or dizziness in the absence of a cardioinhibitory response

SOURCE: Adapted from Gregoratos et al., 13 with permission.
See Table 31-2 for definition of classes I, II, and III indications.
ABBREVIATIONS: AV = atrioventricular; BBB = bundle branch blocks; bpm = beats per minute.

Pacing in Acquired Atrioventricular Block

It is generally agreed that complete heart block, permanent or intermittent, at any anatomic level associated with symptoms such as dizziness, lightheadedness, syncope, congestive heart failure, or confusion is an indication for a permanent pacemaker. In the absence of symptoms, pacing is indicated for patients with third-degree AV block, especially with awake heart rates of less than 40 beats per minute or pauses of longer than 3 s.

In the presence of bifascicular or trifascicular block, intermittent third-degree or type II second-degree AV block usually indicates the need for a permanent pacemaker. When patients with these conduction patterns present with syncope, a pacemaker is usually required. However, an electrophysiology study may be useful to rule out other causes of syncope (e.g., ventricular tachycardia) particularly if structural heart disease is present. Additionally, during electrophysiology study, permanent pacing may be indicated if there is a markedly prolonged HV interval (>100 ms)[14] or nonphysiologic pacing or drug-induced infra-His block.[15]

Second-degree AV block associated with symptomatic bradycardia is an indication for pacing. In asymptomatic patients with second-degree AV block, type II, cardiac pacing may be required if the level of block is infranodal, because the progression to complete heart block is common.[16] Although type I second-degree AV block is usually located at the AV nodal level, there are patients with bundle branch block or intraventricular conduction delays in whom type I second-degree AV block is located at an infranodal level. These patients should be approached similar to patients with second-degree type II AV block, since the risk of progression to complete heart block remains high. Lastly, with 2:1 AV block, the level of block may be difficult to determine. In the presence of a bundle branch block or intraventricular conduction delay and 2:1 AV block, the level of block is usually infranodal and therefore may be an indication for pacing.

In asymptomatic and otherwise healthy patients, the presence of intermittent second-degree, type I AV block may be due to enhanced vagal tone.[17,18] In asymptomatic elderly patients with daytime type I second-degree AV block and structural heart disease, however, there is some divergence of opinion as to whether permanent pacing should[19-21] or should not[13,18] be considered. Many patients may become symptomatic during clinical follow-up.[18,19]

Due to the benign prognosis first-degree AV block is not considered an indication for permanent pacing.[13,22] However, with marked first-degree AV block (PR > 0.30 s), inappropriately timed atrial systole that occurs after ventricular systole can lead to symptoms similar to having retrograde ventriculoatrial conduction. This may be of hemodynamic consequence in some patients, particularly with left ventricular systolic or diastolic dysfunction.[23,24] Additionally, because there is not an appropriately timed ventricular systole occurring at the end of atrial systole, end-diastolic mitral regurgitation develops, which may be of clinical significance in patients with left ventricular systolic dysfunction.[25] Therefore, dual-chamber pacing may be indicated in select patients with marked first-degree AV block in whom hemodynamic improvement can be demonstrated by temporary pacing to resynchronize the atrium and ventricles.[13]

Of note, patients with neuromuscular diseases with AV block should be considered for DDD pacing, since progression of conduction system disease is not uncommon.[26-28]

Pacing in Congenital Atrioventricular Block

Congenital heart block is usually due to AV nodal block. Patients tend to be asymptomatic and typically have narrow QRS complex rhythms. However, congenital AV block is associated with serious and possible fatal complications, including syncope and sudden death.[29-32] In one study,[30] a mean daytime heart rate less than 50 beats per minute was associated with sudden death or need for pacemaker. Exercise testing is useful to assess heart rate response at rest and exercise.[30] Other indicators of poor outcome include prolonged QT interval (corrected for heart rate), cardiomegaly, atrial enlargement, decreased left ventricular systolic function, mean ventricular rates lower than median for age, periods of junctional exit block, and mitral regurgitation.[30-32]

Therefore, cardiac pacing is indicated in all symptomatic patients with congenital AV block. Furthermore, cardiac pacing is now recommended even for symptom-free adults. In the largest series published to date, there was reported a 5 percent mortality risk in adults older than 15 years with congenital AV block in the absence of heart disease. Eight of 102 patients whose cases were followed for 7 to 30 years had fatal Stokes-Adams attacks.[31] Syncope, mitral regurgitation, and/or heart failure occurred in 30 percent of this cohort.[31,32]

Pacing in Sinus Nodal Dysfunction

Sinus nodal dysfunction has become the most common indication for pacing in the United States. Pacing therapy has been demonstrated to be superior to medical therapy with theophylline for patients with sinus nodal dysfunction.[33] The guidelines (Table 31-4) stress the importance of correlating symptoms with bradyarrhythmias. Often, it is difficult to correlate ECG findings with symptoms. Furthermore, symptoms may be nebulous. For instance, the presence of fatigue and dyspnea may be due to a bradyarrhythmia but may also be due to lack of conditioning or other cardiac dysfunction.

The presence of the tachycardia/bradycardia syndrome is especially common in patients with paroxysmal atrial arrhythmias (Fig. 31-1). The bradyarrhythmia often occurs at the termination of tachycardia and can lead to pauses of several seconds. Drugs used to suppress tachyarrhythmias may lead to symptomatic bradycardia, in which case a bradycardia pacemaker would be required.

Patients with asymptomatic bradyarrhythmias should be evaluated carefully prior to placing a pacemaker. In general, an absolute heart rate of less than 30 beats per minute is an indication for pacer placement, even in the absence of symptoms. An exercise test can demonstrate intact sinus nodal function in patients with otherwise asymptomatic bradyarrhythmias who do not require pacing therapy. Athletes commonly have physiologic bradycardia, even with heart rates of less than 40 beats per minute, due to enhanced vagal tone. Finally, it should be noted that sleep apnea may cause asymptomatic, nocturnal bradyarrhythmias,[34] in which case pacing therapy is not indicated.

Pacing in Carotid Sinus Syndrome

The diagnosis for carotid sinus syndrome (CSS) is typically made by demonstrating asystolic pauses of longer than 3 s with carotid sinus massage or a vasodepressor response of greater than 50 mmHg associated with clear symptoms provoked by carotid sinus stimulation, such as wearing a tight shirt or turning one's head. Vague symptoms such as dizziness associated with a hyperactive cardioinhibitory response to carotid sinus stimulation do not represent an indication for permanent pacing.

Improvement of symptoms and suppression of syncope have been demonstrated by treating patients with cardiac pacing,[35-38] particularly dual-chamber pacing.[36-38] Single-chamber atrial pacing is contraindicated because of the increased risk of transient AV block. Some studies suggest that hemodynamic evaluation of patients may enable them to be stratified into groups among whom VVI pacing would be sufficient. However, DDD pacing is probably better in most patients with CSS, because of the presence of vasodepressor and cardioinhibitory reflexes.

Cardiac Pacing in Neurocardiogenic Syncope

The role of pacing for neurocardiogenic syncope is controversial. Because these are younger patients who generally respond to medication, pacing is not required in most patients.[39] Cardiac pacing has been shown to prevent the bradycardia and AV block associated with neurocardiogenic syncope, but patients still typically experience hypotension, vasodilatation, and other associated symptoms.[39-41] The Vasovagal Pacemaker Study demonstrated a role for pacing in patients with vasovagal syncope refractory to standard medical therapy.[42] Therefore, patients with refractory neurocardiogenic syncope may benefit from pacing, especially if they have a predominant cardioinhibitory component.[43]

Pacing in Hypertrophic Cardiomyopathy

In patients with hypertrophic cardiomyopathy (HCM) and left ventricular outflow tract (LVOT) gradients, DDD pacing with a programmed short AV interval has been proposed as therapy to reduce LVOT gradient and improve symptoms.[44-47] This concept is based on early studies where it was shown that DDD pacing with short AV interval decreased the LVOT gradient by a mean of 35 mmHg,[44] and there was improvement of symptoms associated with HCM. An observational study involving 84 patients whose cases were followed for a mean of 2.3 years showed improvement of symptoms in nearly all patients, and there was reduction in the left ventricular wall thickness by more than 4 mm in a subgroup of patients.[47] However, 15 percent of the patients required AV junction ablation to allow ventricular preexcitation by the pacer.

The mechanism by which DDD pacing reduces LVOT gradient remains controversial. With ventricular pacing at short AV interval, the right ventricular apex is preexcited by the pacemaker, causing alteration of the left ventricular activation sequence and paradoxical septal motion. This causes the septum to move away from the posterior left ventricular wall in early systole, thereby widening the LVOT during systole. It is also possible that ventricular pacing alters myocardial perfusion, decreases mitral valve systolic anterior motion, and/or decreases inotropy, which may also contribute to the beneficial effects of pacing in this disorder.

Therefore, if DDD pacing is used as therapy for obstructive hypertrophic cardiomyopathy, placement of pacing lead and programming of the AV interval are crucial for a beneficial effect. The AV interval should be programmed to the longest interval that still allows for left ventricular preexcitation, which would decrease but not eliminate the deleterious effects of pacing with very short AV intervals.[46] Echocardiography may help select the optimal pacing AV interval.

The long-term clinical effectiveness of DDD pacing in patients with obstructive HCM remains controversial. Some recent and randomized studies cast some doubt as to the clinical effectiveness of pacing for objectively improving functional capacity, quality of life, and LVOT gradient.[46,48,49] One small randomized study failed to demonstrate improvement in exercise response to DDD pacing.[48] Another study in patients with symptomatic obstructive HCM showed that when patients were randomized to backup AAI pacing versus DDD pacing with short AV interval, there was no difference in subjective improvement.[49] LVOT gradient was reduced by 40 percent in 57 percent of patients and remained unchanged in the other

43 percent of patients. Only 12 percent of patients (all older than age 65) showed improvement in functional capacity after 12 months in the study. Therefore, based on this randomized double-blind study, pacing could not be routinely recommended for drug-refractory patients with obstructive HCM but, rather, may be considered for select patients with medically refractory obstructive HCM as an alternative to surgical myectomy.[50]

Patients with hypertensive cardiac hypertrophy with cavity obliteration may also show clinical improvement with DDD pacing.[51] In contrast to obstructive HCM, patients with nonobstructive symptomatic HCM experience limited symptomatic improvement and no objective evidence of hemodynamic benefit with DDD pacing and short AV interval.[52]

Pacing in Dilated Cardiomyopathy and Congestive Heart Failure

Initial reports suggested that patients with congestive heart failure and dilated cardiomyopathy may benefit from dual-chamber pacing by altering and optimizing timing of left atrial to left ventricular activation or improving left ventricular contractile function. There was initial enthusiasm that pacing with a short AV interval may improve hemodynamic function[24,25] and that the patients with first-degree AV block derived the most benefit.[25] An acute hemodynamic study demonstrated that pacing with a short AV interval could eliminate presystolic mitral regurgitation in patients with first-degree AV block, restore normal AV relationships, and improve hemodynamic function.[25] Subsequent studies showed that standard DDD pacing does not improve hemodynamic function in patients with physiologic PR intervals.[53,54] On this basis, DDD pacing is possibly indicated in patients with dilated cardiomyopathy or marked first-degree AV block and where acute hemodynamic studies demonstrate improvement by dual-chamber pacing.[13]

Whereas pacing the ventricles with short AV interval may have limited benefit, the ability to pace the ventricles in a more synchronous manner to improve mechanical efficiency has also been studied. Ventricular pacing typically is achieved by pacing through a lead placed in the right ventricular apex, which may not produce the most efficient ventricular mechanical function. Pacing through the His-Purkinje system in theory may provide more physiologic ventricular activation patterns but is currently not readily available.[54a] Pacing from the right ventricular septum or outflow track may enable earlier left ventricular activation and, hence, more simultaneous contraction. However the results of hemodynamic improvement using right ventricular outflow tract pacing has shown a trend for improvement in some studies,[55,56] whereas other studies[57-59] show no benefit at all compared with right ventricular apical (RVA) pacing.

It has been proposed that left ventricular or biventricular pacing may optimize hemodynamic function in patients with dilated congestive cardiomyopathy, particularly those patients with intraventricular conduction delay. Left ventricular pacing can be accomplished by either an epicardial lead or a transvenous lead through the coronary sinus venous system. An acute hemodynamic study[58] was performed on patients with severe heart failure, intraventricular conduction delay (usually left bundle branch block), and increased capillary wedge pressure. These patients had measurement of hemodynamic parameters during either right ventricular pacing or biventricular pacing, which was compared with AAI pacing (control values). These results showed improvement of cardiac index and decrease in capillary wedge pressure with either right ventricular pacing or biventricular pacing compared with AAI pacing. Furthermore, biventricular pacing showed more hemodynamic benefit compared with right ventricular pacing. Another study on patients with congestive heart failure and wide QRS duration showed that epicardial left ventricular pacing, with or without concurrent right ventricular pacing, improved hemodynamic function at optimized AV intervals compared with control values.[60] Therefore, left ventricular pacing may evolve as a therapeutic pacing technique in patients with congestive dilated cardiomyopathy and intraventricular conduction delay.

Chapter 31: CARDIAC PACEMAKERS

PACEMAKER HARDWARE

Implant and Explant

Nearly all pacemakers are implanted through a transvenous approach by either cardiologists or surgeons. The choice of using an operating room or a catheterization laboratory for the implant procedure probably plays little role in procedural-related complications, but a cardiac catheterization laboratory involves lower hospital costs.[61,62]

A full description of the surgical procedure has been reviewed elsewhere.[1,63] Venous access for lead placement generally is through a subclavian venipuncture or a cephalic vein cutdown. The use of subclavian venipuncture is technically easier, and this vein can almost always accommodate two leads. With the subclavian venipuncture, there exists the risk of subclavian artery puncture, pneumothorax, or air embolus. Furthermore, pacing leads placed medially incur an additional long-term risk of being "crushed" by the clavicle and first rib leading to lead insulation breaks or fractures (Fig. 31-2). Lateral puncture of the subclavian or axillary vein using intravenous contrast may allow for safe lateral subclavian venous puncture.[64] A cephalic vein cutdown[65] may also avoid some of the risks associated with subclavian vein puncture; however, this vein is not always accessible and cannot always accommodate two pacing leads.

Explanations of pacemaker generators are routinely performed during pacemaker generator changes. However, removal of pacemaker leads can be difficult due to fibrosis between chronically implanted leads and surrounding cardiac, valvular, and vascular structures. Traditional methods for extraction of chronically implanted leads involve specialized extraction sheaths that are glided over implanted leads to tear and peel away the encapsulating tissue.[66] Recently, a technique using ultraviolet excimer laser light has been introduced to facilitate lead extraction by allowing advancement of sheaths over pacer leads without excessive mechanical tearing of fibrotic tissues.[67,68] Compared with mechanical extraction, laser-assisted extraction demonstrated a greater success rate in lead removal (94 percent versus 64 percent) and less time to remove leads,[67] with no difference in complications.

Hardware

The pacemaker system consists of a pulse generator and the pacing lead(s). Pacemaker system selection should be primarily based on the medical and surgical requirements of the patient. It is unusual that one pacemaker system would be most optimal and cost effective for all patients. An algorithm for choosing a pacemaker system and pacing mode is presented in Fig. 31-3.

Pacemaker leads can be unipolar or bipolar (Figs. 31-4 and 31-5). Unipolar leads use a distal electrode in the catheter as the cathode and the shell of the pacemaker generator as the anode. Therefore, the myocardium and adjacent tissue complete the circuit. A bipolar lead consist of two separate conductors and electrodes within the lead. Since the electrodes for sensing in a bipolar lead are much closer together, bipolar signals are sharper with less extraneous noise (Fig. 31-6).

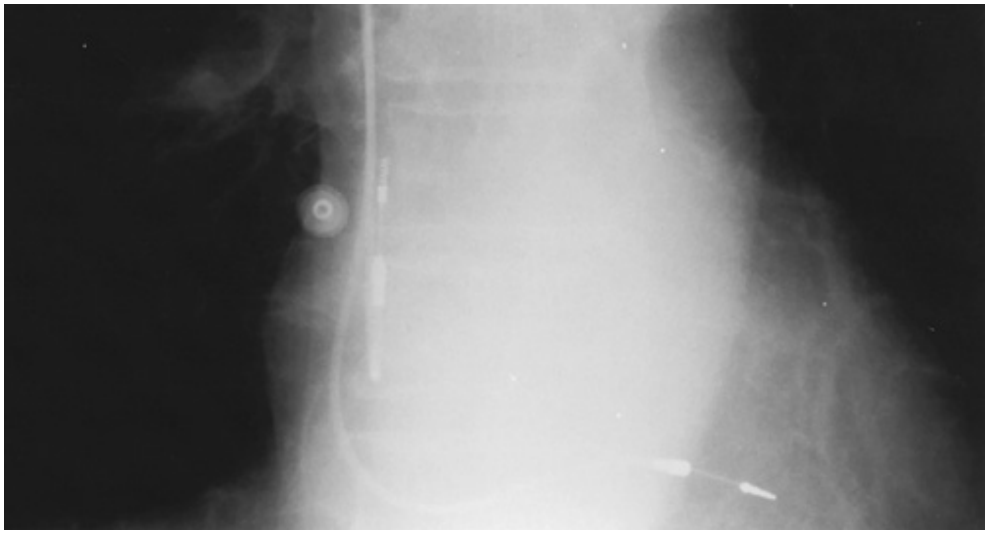

Figure 31-5: Chest x-ray from a patient with a bipolar dual-chamber pacing system. The atrial lead is attached to the right atrial appendage by active fixation (screw-in lead), and the screw is visible on the chest x-ray. The ventricular lead is attached to the ventricle by passive fixation.

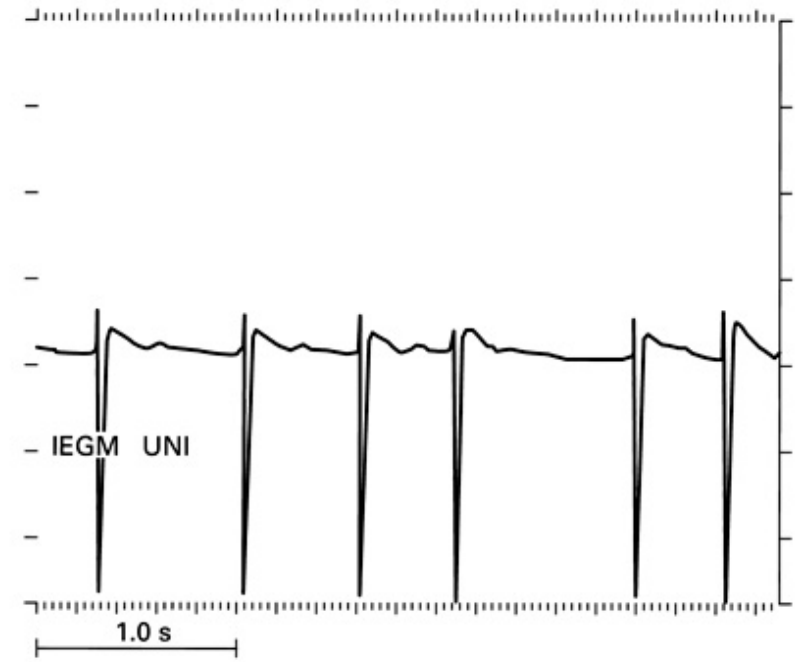

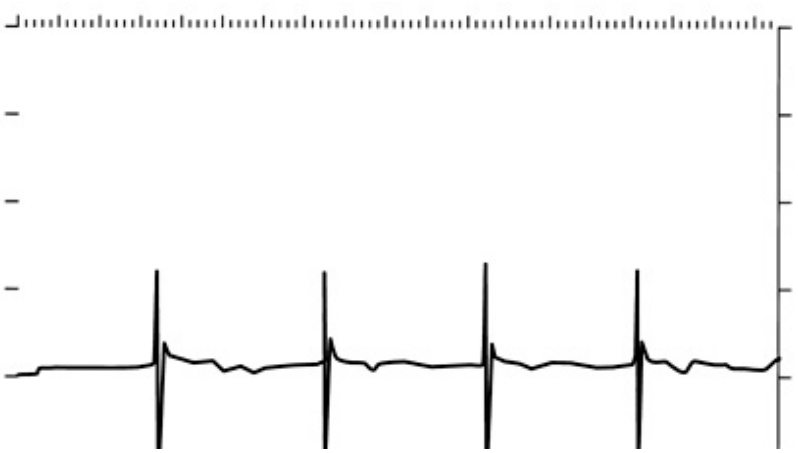

Figure 31-6: Unipolar (*top*) and bipolar (*bottom*) intracardiac electrograms (IEGMs) from a patient with a ventricular pacemaker whose underlying rhythm is atrial fibrillation. Note that the bipolar signal is sharper, with less sensing of far-field ventricular electrical activity or T waves. With either unipolar or bipolar electrograms, direct measurement of the electrogram amplitude is possible. Each division on the left represents 1 mV. Therefore, the unipolar intracardiac electrogram is 2 to 3 mV from baseline to peak. The bipolar electrogram would be expected to be approximately 2 mV.

Unipolar leads are simpler to design, smaller in diameter and, because of their simplicity, probably less likely to fail.[69] Because of their small size, it is easier to pass two unipolar leads through a cephalic venous approach. However, there are several disadvantages to unipolar lead systems. Because the unipolar lead uses body tissue to complete the circuit, there is the possibility of causing muscle stimulation. Most pacemakers avoid this by placing the stimulating surface of the pacemaker anterior such that it interfaces with subcutaneous tissue and not the pectoralis muscle. Unipolar sensing is far more likely to pick up extracardiac signals, including myopotentials (Fig. 31-6), far-field sensing of remote cardiac potentials, and electromagnetic interference. Finally, unipolar pacing is generally contraindicated in patients with a concomitant implantable defibrillator. Therefore, most leads implanted today are bipolar.

Leads are attached to the heart by active or passive fixation. Active fixation involves the use of some type of exposed or retractable screw within the lead system that fixes the lead to the heart (Fig. 31-5). Passive fixation involves the use of tines, which are short protuberances that extend proximal to the distal electrode and interact with myocardial tissue to hold the lead in place. Active fixation leads are used more in the atrium and allow fixation of the leads almost anywhere within the right atrium or ventricle. The use of either type of lead probably has little effect on complication rate or lead dislodgment rate when used by experienced operators.

Lead Placement and Acute Threshold Testing

Atrial and ventricular leads are placed into the appropriate chambers after ensuring adequate pacing and sensing thresholds (Table 31-5). The basic premise in obtaining acute pacing and sensing thresholds during implant is that these thresholds may degenerate over time, and adequate safety margins need to be obtained to ensure safe long-term pacing and sensing. Furthermore, one should be aware of the type of unit implanted, its capabilities for pacing outputs, programmed sensitivities, and pacing modality (bipolar versus unipolar). The indication for pacing may also affect decisions about acceptable pacing thresholds, because of the inverse relationship between current drain and battery life. In patients who only require occasional backup pacing, higher pacing thresholds may be acceptable. Therefore, pacing thresholds should be optimized at the time of implant as influenced by the patient's pacing requirements and pacing capabilities of the pacemaker.

Table 31-5: Acceptable Pacing and Sensing Thresholds During Implant

	Atrial	Ventricular
Pacing threshold at 0.5 ms	<1.2 V	<1.0 V
Sensing threshold (bipolar)	>1.5-2 mV	>5 mV
Sensing threshold (unipolar)	>2-2.5 mV	>5 mV
Impedance*	300-1400 ohm	300-1400 ohm

*New high-impedance leads result in less current drain and improved longevity.

For sensing functions, ventricular electrograms should measure at least 5 mV and frequently measure in excess of 10 to 20 mV. Ventricular sensitivity is generally programmed between 2 to 3 mV so that adequate safety margin exists for sensing intrinsic ventricular depolarization without the risk of oversensing T waves or other artifacts. Atrial electrograms are lower in amplitude than ventricular electrograms; however, a minimum atrial electrogram of 1 to 2 mV should be obtained. In unipolar systems, a larger atrial electrogram is important because of the increased risk of oversensing myopotentials or other artifactual signals if the atrial sensitivity is programmed to less than 1 mV. In patients with paroxysmal atrial fibrillation or flutter, the atrial electrogram during tachycardia might be smaller than during sinus rhythm. Conversely, in patients with marked sinus bradycardia where it is expected that there will be nearly 100 percent atrial pacing, atrial sensing thresholds may not be as important. Finally, the minimum programmed sensitivity available by the pacer (0.15 to 0.5 mV) may influence acceptable sensing thresholds at implant.

Many factors may affect atrial or ventricular pacing and sensing thresholds. There is variation to these thresholds depending on the autonomic tone or the electrolyte status. There is an expected rise in acute thresholds within 1 to 4 weeks following implant due to acute inflammation, which appears to be more exaggerated with active fixation lead systems. Many drugs, particularly antiarrhythmic medications, may affect pacing thresholds. The presence of new myocardial infarction around the leads would be expected to lead to deterioration of pacing and/or sensing thresholds. Leads that are steroid eluting generally limit the acute rise in pacing threshold. Long-term thresholds appear to stabilize sometime after 3 to 6 months.[70]

Chapter 31: CARDIAC PACEMAKERS

PACEMAKER FOLLOW-UP

The goal for pacemaker follow-up should be to perform a systematic evaluation of the pacemaker as it relates to and functions with the patient and his or her individual needs. These goals are outlined in Table 31-6. Complete guidelines for pacemaker follow-up have been described.[71]

Table 31-6: Goals of Pacemaker Follow-up

TTM or Direct	Direct or indirect measurement of battery voltage and anticipate need for replacement
TTM	Evaluation of pacing and sensing during normal pacer function and during application of magnet
Direct	Lead function: sensing, pacing thresholds, and impedance measurement; telemetry of lead during various arm/chest positions to expose any subtle lead insulation defects
Direct	Optimization of pacing outputs and parameters based on results of pacing tests, patient clinical condition, and medications
Direct	Evaluation of diagnostic information stored in pacemakers and integrate information with overall patient management strategy
Direct	Patient education

ABBREVIATIONS: TTM = transtelephonic monitoring; Direct = direct evaluation of pacemaker using specific programmer.

In the first several months after pacer implant, several evaluations of pacer function may be required in order to optimize pacing outputs, rate responsiveness, and other features. There is a stable period of pacer function starting 6 to 12 months following implant until the expected time for battery depletion. Therefore, direct evaluations of pacer function may be performed once or twice per year during this time, depending on whether the patient is pacer dependent and depending on the pacer type and whether any of the pacer components are under any advisory warnings.

Transtelephonic Monitoring

Technology is available for simple devices used by patients to transmit their ECG by telephone to a receiving station so that their ECG rhythm may be analyzed to detect normal or abnormal pacemaker function.[71,72] In this way, a spontaneous pacing rhythm can be assessed for normal or abnormal pacing function. More importantly, by applying a magnet to the pacemaker and observing the *magnet rate* during the transtelephonic monitoring (TTM), the battery status can be assessed. During TTM, changes in pacing rate or loss of output could always be detected. Ventricular oversensing or atrial pace/sense problems can sometimes be detected during TTM.[72]

Follow-up using TTM should be used to supplement and not replace direct evaluation of pacer function. The frequency of follow-up should be individualized according to the type of pacemaker, whether the patient is pacemaker dependent, age of pulse generator and expected longevity, presence of any pacemaker component under advisory or warning, and patient clinical factors. As depletion of pacer battery occurs, TTM may be used as often as every month to appropriately determine the timing for pacer replacement.

Components for Direct Evaluation of Pacemaker Systems

CHECKING PACING THRESHOLDS AND PROGRAMMING PACING OUTPUTS

Pacemakers should always be programmed for maximal safety particularly in patients who are pacemaker dependent. To understand how to program pacemakers safely and efficiently, some basic principles are reviewed.

Current Drain

Ultimately, the longevity of the battery will be a function of the current drain versus battery capacity. There is nominal current drain for operating pacemaker circuitry, which varies according to the pacer type; however, most current drain results from pacing output. The current delivered per pacing pulse is a function of the voltage divided by the lead impedance ($I = V/R$)-Ohm's law. Therefore, it is desirable to be able to implant leads with low pacing voltage thresholds. Additionally, leads designed to have high impedance appear to decrease long-term current drain.[73]

Strength-Duration Curve

The strength-duration curve (Fig. 31-7) relates voltage and pulse width. This curve is dynamic during the first 2 to 3 months following implant. With an acute rise in threshold, the curve is expected to shift upward two to four times and then subsequently shift back downward at a level greater than the initially obtained values. At pulse widths less than 0.2 ms, the curve is steep; at pulse widths exceeding 1.0 ms, the curve is flat. With this kind of relationship, programming pulse widths greater than 1 ms generally does not add safety margin to the pacing output but does substantially increase battery current drain. Similarly, programming pacing pulse widths less than 0.2 to 0.3 ms may not allow sufficient safety margin at even high voltage amplitudes.

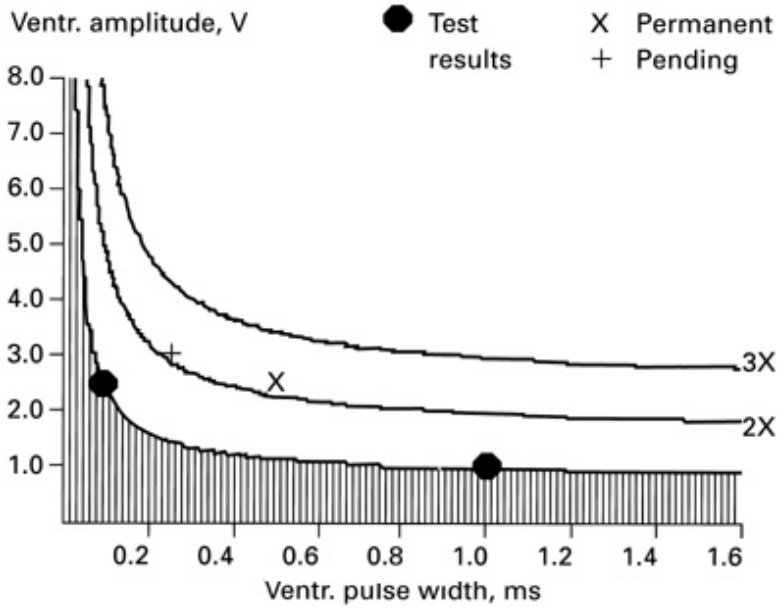

Figure 31-7: A sample of a strength-duration curve. The voltage threshold at 2.5 V was 0.1 ms, and the pulse-width threshold at 1.0 ms was 1.0 V. Sample curves are shown providing for two and three times the safety margin for programming voltage and pulse width. Ventr. = ventricular.

Total Energy Expenditure of the Pacemaker

This is defined as energy = $(\text{voltage})^2$ multiplied by pulse width divided by impedance. According to this

relationship, the energy expenditure has an exponential relationship to voltage output but has a linear relationship to pulse width. Therefore, it is preferable to reduce voltage output rather than pulse width to conserve battery life.

Calculating Pacing Threshold

At implant, it is standard to fix the pulse width at 0.5 ms and reduce the voltage until the lowest voltage that maintains consistent pacing-which is the pacing threshold (Fig. 31-8). One can fix the pulse width at any value, however (usually between 0.3 and 1.0 ms), and calculate a voltage threshold. Similarly, one can fix the voltage at a certain value and reduce the pulse width to the lowest value that maintains consistent pacing, which would also define the pacing threshold. Either method is acceptable to define a pacing threshold.

Safety Margin

The safety margin for pacing outputs can be calculated by multiples of either the pulse width or the voltage threshold. For example, if the voltage threshold at 0.5 ms is 1.5 V, then a pacing output of 0.5 ms and 3.0 V would yield an energy safety margin of fourfold, given the relationship between energy and voltage. Similarly, if the pulse width threshold at 3.0 V is 0.15 ms, then a pacing output of 3.0 V and 0.6 ms would provide an energy safety margin of fourfold.

Acute Pacing Outputs

Because the extent of the acute rise in pacing thresholds may be difficult to predict, it is better to program high pacing outputs at implant and during the first 6 to 24 weeks after implant. A greater safety margin may be desired in patients who are pacemaker dependent. Typically, greater safety margins are also desired in ventricular leads rather than atrial leads. Steroid-eluting leads generally result in blunting of the acute rise in threshold,[74] which may allow for lower pacing outputs early after implant.

Chronic Pacing Outputs

In the time frame of 2 to 6 months, the pacing thresholds stabilize. Therefore, chronic pacing outputs may be programmed (Table 31-7). Almost all pacing batteries consist of lithium-iodide systems, which generate 2.8 V. It is most efficient to pace at the voltage of the battery (2.5 to 2.8 V). Therefore, longevity of pacemakers can be improved if pacing outputs are reduced to 2.5 V with pulse widths programmed 2 to 4 times pulse-width thresholds.

Table 31-7: Recommendations for Pacing Outputs

	Atrial Leads	Ventricular Leads
Pacemaker dependent	2-3 × PW threshold	4 × PW threshold
	1.5-1.8 × V threshold	2 × V threshold
Not pacemaker dependent	2 × PW threshold	2-3 × PW threshold
	1.5 × V threshold	1.5-1.8 × V threshold

ABBREVIATIONS: PW = pulse width; V = voltage.

Finally, some newer pacemakers have the ability to confirm capture on a beat-by-beat basis.[75] Using algorithms to automatically check pacing capture thresholds, these pacers adjust pacing voltages just above the pacing threshold in order to reduce current drain and prolong battery longevity.

OTHER FEATURES

Sensing

Sensing of atrial and ventricular intracardiac electrograms can be evaluated by different algorithms. To test atrial sensing, the pacemaker needs to be programmed temporarily at a programmed atrial rate less than the intrinsic sinus rate. To test ventricular sensing, the pacer can be temporarily reprogrammed to the VVI mode if the programmed rate is less than the intrinsic heart rate. Alternatively, with intact AV conduction, the AV delay can be increased to allow AV conduction and thereby allow for ventricular sensing in the DDD mode. Increasing the programmed sensitivity until the intrinsic P or R wave is no longer sensed (Fig. 31-9) is another method to test sensing threshold. Telemetry of atrial or ventricular electrograms allows for direct measurement of the electrogram amplitude (Fig. 31-6). Lastly, some pacemakers have algorithms whereby the pacemaker automatically measures atrial and ventricular electrograms.

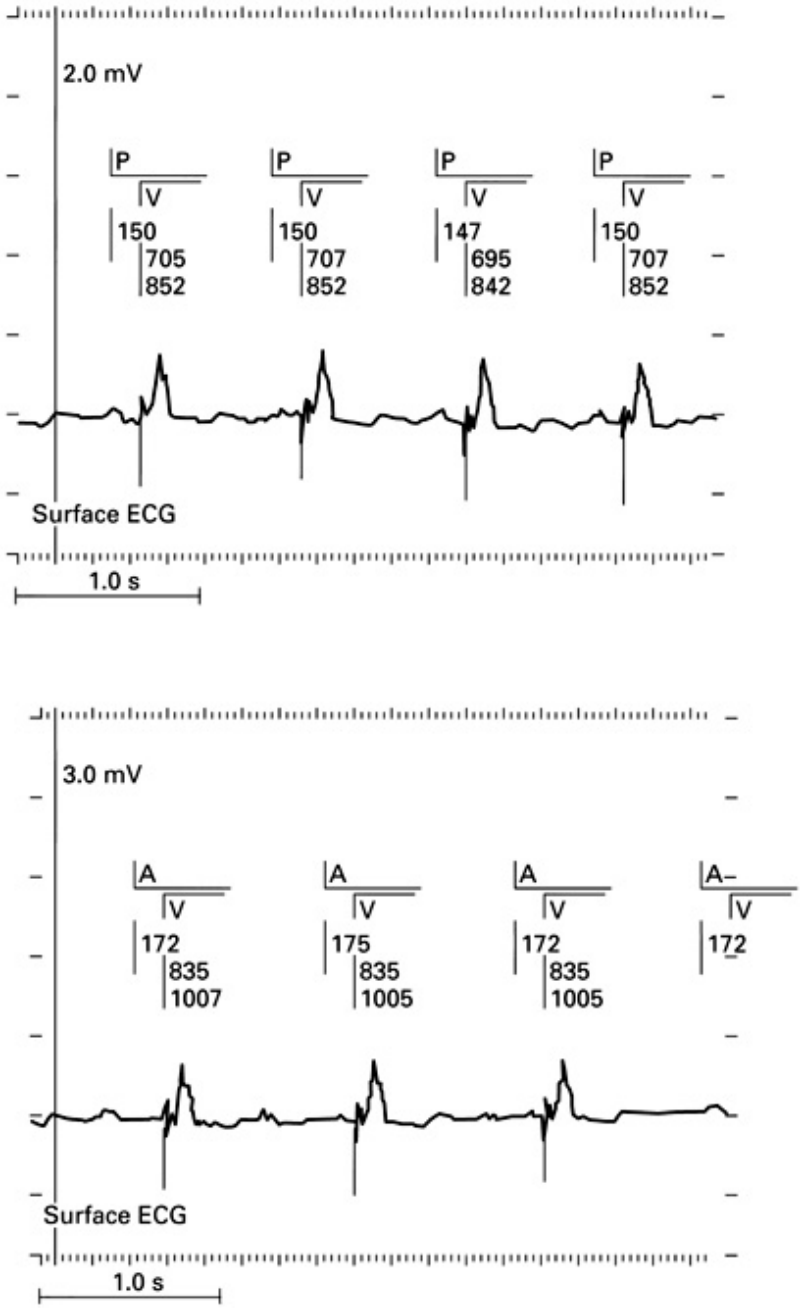

Figure 31-9: *Top*. P-wave synchronous ventricular pacing, with marker channels "P" indicating sensed P

waves and "V" indicating paced ventricular complex. At 2 mV, there was appropriate P-wave sensing. *Bottom*. "A" indicates that the pacemaker is pacing the atrium. At the programmed sensitivity of 3 mV, there was undersensing of the P wave and therefore atrial pacing occurred. Hence, the sensed P-wave amplitude is between 2 and 3 mV.

Lead Function

Lead function is assessed by checking pacing and sensing function and by measuring impedance. Although there is a wide variability of normal lead impedances, chronic lead impedances should not widely vary between outpatient follow-up visits. A fractured lead exhibits a markedly elevated lead impedance. Insulation breaks manifest by reduced lead impedances. Lead fractures or insulation breaks often are intermittent problems. Therefore, normal lead impedances and pacing and sensing thresholds do not rule out these problems. The leads can be stressed by having the patient change position and do various provocative arm movements to facilitate diagnosis of lead-related problems that are not otherwise observed.

Battery Function

Almost all pacemakers use lithium-iodide batteries, which have an initial battery voltage of 2.8 V. Battery voltages can be directly measured and, at a certain level (elective replacement index [ERI]), the pacemaker unit requires elective generator change. At a lower battery voltage (end of life [EOL]), there is potential loss of pacemaker function; therefore, immediate generator change is mandated.

Battery function can also be assessed without formal interrogation. Many pacemakers reset to a VVI mode at a preset pacing rate, or the pacing rate decreases to less than the programmed lower rate of the pacemaker when battery function reaches the ERI or EOL stage. Additionally, the magnet mode causes asynchronous pacing at a preset *magnet* rate for each particular pacemaker model. This magnet rate varies according to whether the battery status is adequate or not.

Rate Responsiveness

Rate-responsive pacemakers require periodic adjustments of the rate-responsive features to optimize clinical responsiveness. The programmable variables include a rate-responsive upper pacing rate, which may be a separate programmable variable than the upper tracking rate. A rate-response slope may be programmed to determine the pacing rate at a certain activity level. Some pacemakers store data with respect to the use of rate responsiveness over a certain period. Otherwise, one can simply have the patient walk briskly for 2 to 3 min and assess the heart rate to determine whether it is appropriate given the patient's age and clinical status. Some pacemakers offer algorithms whereby the physician chooses the appropriate heart rate for "brisk walking," and the pacemaker automatically calculates the optimal rate-responsive programming.

Pacer Diagnostic Function

Modern pacemakers have increased memory capabilities to store diagnostic information. The basic diagnostic feature displays counts or percentages of pacing versus sensing in the atrial and ventricular chambers. If a patient has complete heart block but has intact sinus nodal function, it would be expected that there be 100 percent ventricular pacing with predominant atrial sensing. The breakdown of pacing and sensing in each chamber can be stratified according to the heart rate that can give the clinician some clues as to the presence of chronotropic incompetence or appropriateness of rate responsiveness.

With respect to arrhythmia monitoring, the presence and quantity of premature ventricular and atrial complexes are presented. For patients with mode-switching pacemakers, the number of mode switches probably represents a marker for the number of atrial arrhythmias.[76] However, these data do not provide information with respect to duration and timing of these atrial arrhythmias. One study showed that most of these atrial arrhythmias are very brief, lasting only a few seconds in many cases.[77] More information about the occurrence, timing, and duration of arrhythmias, including stored intracardiac electrograms, is available in some pacers. This type of information may facilitate diagnosis of arrhythmias without the need for ancillary testing (Fig. 31-10). Furthermore, when patients complain of symptoms such as palpitations, these diagnostic features may enablediagnosis of, or rule out, atrial or ventricular tachyarrhythmias.

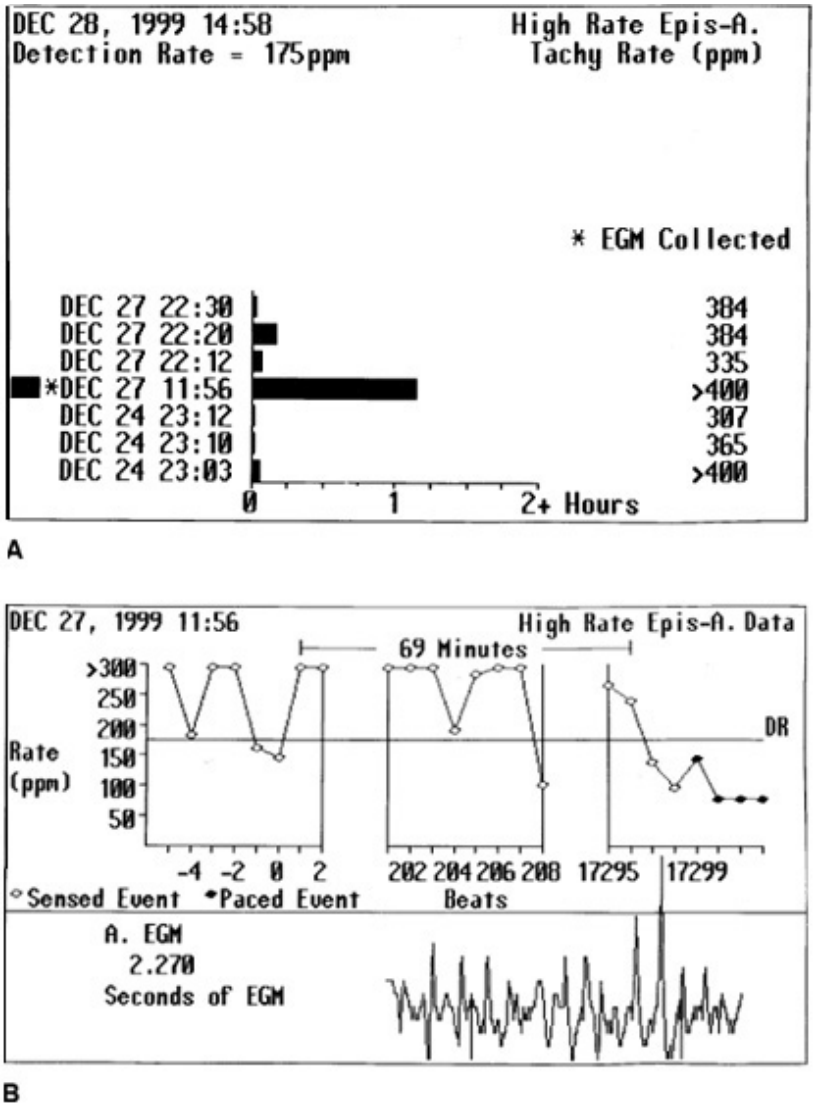

Figure 31-10: *A.* Shown are rate histograms demonstrating seven episodes of atrial fibrillation lasting from a few minutes to an episode lasting over an hour. *B.* This graphic demonstrates the beat-to-beat rate just before onset of the atrial tachyarrhythmia, after 200 beats, and just after termination of the arrhythmia, 69 min later. A snapshot of the stored intraatrial electrograms (A-EGMs) confirms atrial fibrillation as the mechanism. DEC, December; Tachy, tachycardia.

Chest Radiograph (Posteroanterior and Lateral)

A standard chest x-ray (Figs. 34-4 and 34-5) is recommended as part of the predischarge evaluation to ensure appropriate placement of leads, rule out lead migration, and serve as a baseline.

Chapter 31: CARDIAC PACEMAKERS

PACEMAKER FUNCTION AND MODES

Magnet Mode

Virtually all pacemakers pace in an asynchronous mode when they come into contact with a magnetic field. The response to a magnet varies according to manufacturer, pacemaker model, and sometimes even the mode in which a pacer is programmed. Single-chamber pacers respond to magnets by asynchronous pacing at either the programmed rate or a special magnet rate (Fig. 31-11). This allows a simple noninvasive method to assess pacing at the bedside, office, or by TTM. In patients who are pacemaker dependent and experiencing oversensing thereby inhibiting pacemaker output, a magnet is a convenient short-term method to ensure pacing. Furthermore, pacemakers usually have one magnet rate for a battery that is intact and another one for a battery that is at ERI or at EOL. If these rates are known, applying a magnet to a pacemaker is an easy noninvasive method to assess battery status.

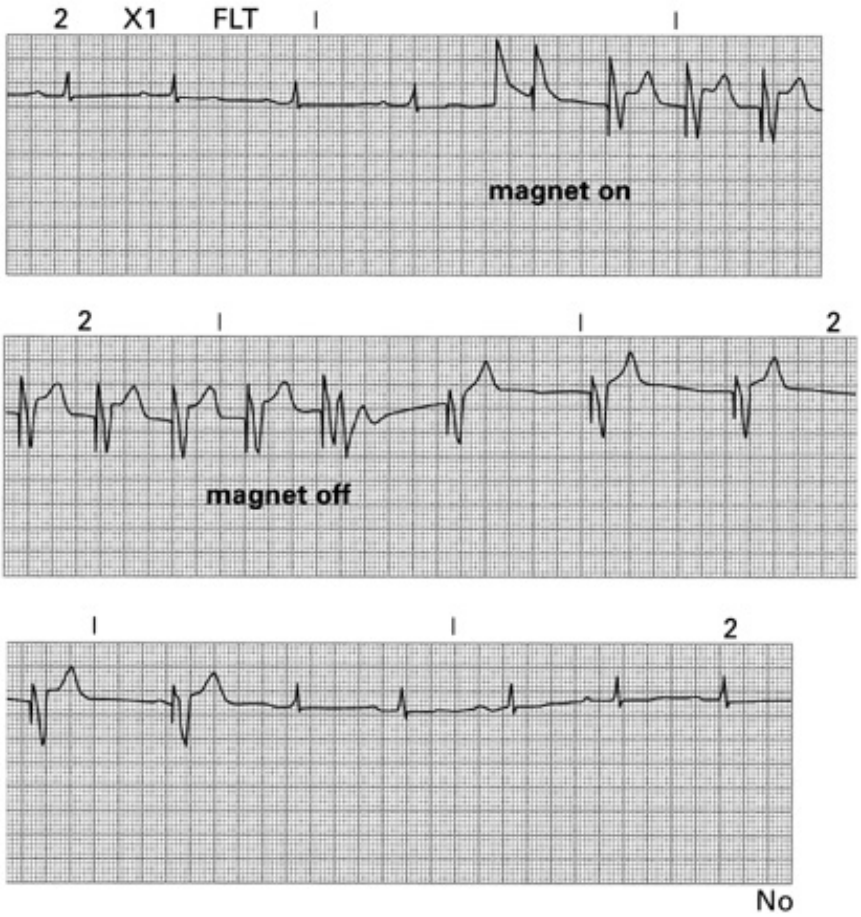

Figure 31-11: An electrocardiogram of a patient with sinus nodal dysfunction and first-degree atrioventricular block who has an implanted VVI pacemaker. Note that application of a magnet causes VVI pacing in the asynchronous mode at a rate of approximately 95 beats per minute. After the magnet is removed, the pacemaker reverts to VVI at 50 beats per minute until the

patient's sinus rhythm inhibits pacemaker function.

VVI Mode

In the VVI mode, a pacemaker operates as shown in Fig. 31-12. The lower rate is converted to an interval (milliseconds). After a paced or sensed ventricular event, a programmable refractory period prevents inappropriate sensing of T waves. After the pacemaker ventricular refractory period, there is an interval extending to the escape interval during which time the pacemaker senses a ventricular event, if one occurs before the end of the interval; otherwise, there is ventricular pacing output.

Hysteresis is a programmable function in which the ventricular escape interval is longer after a sensed ventricular event than after a paced ventricular event. This feature can be used in patients with sinus rhythm so that VVI pacing would not initiate until the sinus rate drops below the hysteresis rate, which is lower than the pacemaker rate (Fig. 31-13).

AAI Pacing

AAIR is an excellent mode of pacing in patients with sinus node dysfunction and normal AV nodal and His-Purkinje function.[78,79] The timing sequences are the same for AAI as for VVI pacing. Atrial sensitivities are programmed at lower values (increased sensitivity) to sense intrinsic P waves safely. This frequently leads to oversensing of far-field ventricular electrograms, which can be avoided by programming a longer refractory period.

Patients with sinus nodal dysfunction may develop AV block, which may be a source of concern when using AAI pacing. However, with careful selection of patients, [78,79] including normal PR intervals, absence of bundle branch block, and AV Wenckebach occurring at atrial pacing rates of more than 120 beats per minute, the risk of development of second- or third-degree AV block is less than 0.6 percent per year.

DDD Pacing

DDD pacing is the most common pacing mode for dual-chamber pacemakers. The timing sequences for DDD pacing are described in Fig. 31-14. This mode is used for patients with AV node and/or sinus node dysfunction.

DDD PACING IN PATIENTS WITH SINUS NODE DYSFUNCTION

Patients with sinus node dysfunction may have intermittent or chronic sinus bradycardia requiring intermittent or continuous atrial pacing. If patients have intact AV conduction, the pacemaker functions as an AAI pacer. Due to medications that slow AV conduction and/or intrinsic AV nodal or His-Purkinje disease, however, patients with DDD pacemakers frequently demonstrate fused ventricular complexes originating from ventricular stimulation and through the AV conduction system. The degree of fusion of the ventricular complex between pacing from a right ventricular lead and conduction down the AV nodal-His-Purkinje system depends in large part on the difference between the programmed AV interval and the intrinsic AV conduction time.

For ventricular output to be inhibited in patients with DDD pacemakers, the pacemaker AV interval must be longer than the conduction time between the sensed or paced atrial complex to the right ventricular lead. A very long AV interval (more than 0.25 s) may decrease the benefit of AV synchrony when AV pacing does occur. It is not uncommon that pacemakers sense the ventricular electrogram late during ventricular depolarization especially with right ventricular

conduction delay or right bundle branch block. Pacemaker *pseudofusion* occurs when there is ventricular pacing within the QRS complex (Fig. 31-15).

PATIENTS WITH ATRIOVENTRICULAR BLOCK AND NORMAL SINUS NODE FUNCTION

In the DDD mode, if the lower rate of the pacer is programmed at a sufficiently low value to permit atrial tracking, the pacemaker stimulates the ventricle synchronous with intrinsic P waves. If a patient does not require atrial pacing, it may be reasonable to implant a dual-chamber pacer with a single tripolar or quadripolar lead that allows atrial sensing and ventricular pacing and sensing (Fig. 31-16). These VDD pacing systems allow for ease of implant and for bipolar atrial sensing. Atrial sensing may not be as reliable compared to a fixed atrial lead, which may lead to occasional atrial undersensing.[80,81] In a recent prospective comparison between single-lead VDD systems to DDD leads, however, there were lower P-wave amplitudes in the group with VDD systems, but no significant clinical differences with respect to atrial undersensing.[82]

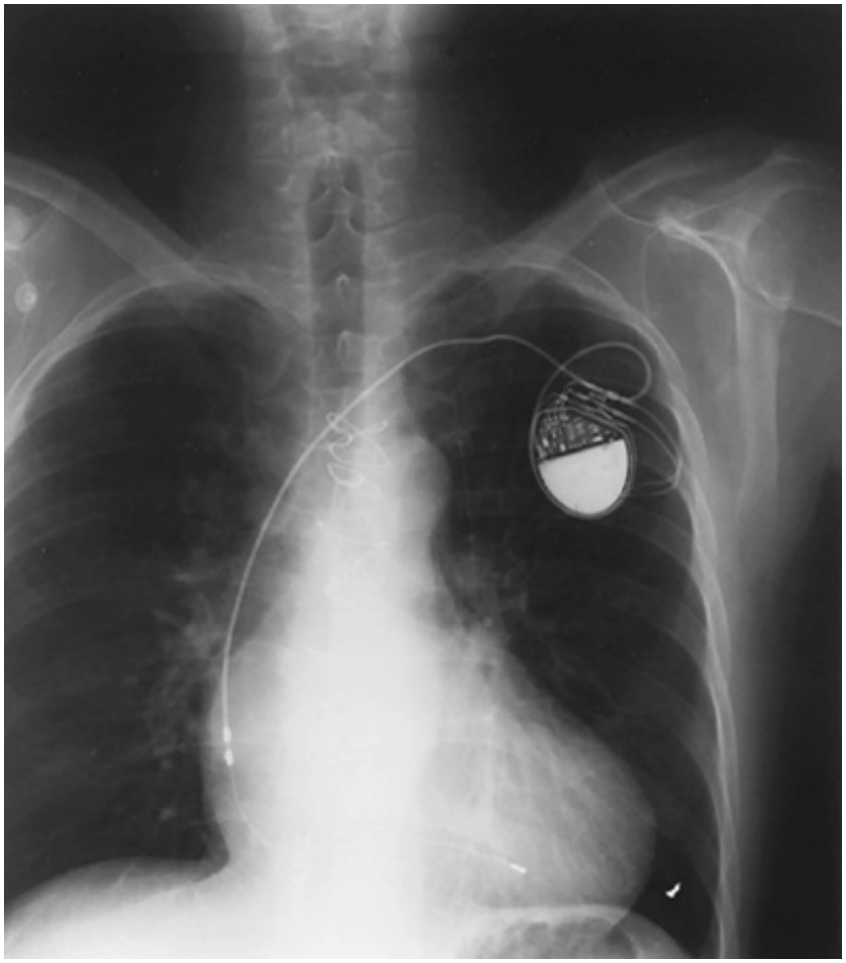

Figure 31-16: Chest x-ray showing a single lead in the heart. Note the bipolar electrodes in the atrium and the single electrode in the ventricle. This pacemaker system is capable of VDD pacing. Therefore, it senses atrial depolarizations and can pace or sense in the ventricle.

DDD versus VVI Pacing

Multiple retrospective and observational studies[83-91] and a few prospective studies[92-94] demonstrate hemodynamic, clinical, and quality-of-life benefits of dual-chamber or atrial-based

pacing versus ventricular pacing. Therefore, it appears prudent to implant DDD pacers in most patients with intact atrial function but not all patients.

In patients with congestive heart failure due to left ventricular systolic dysfunction, the dependence of cardiac output to AV synchrony appears to decrease secondarily to the already increased left ventricular filling pressures. Patients with fixed stroke volume (i.e., left ventricular systolic dysfunction) may depend almost exclusively on heart rate for cardiac output[83] and, therefore, may have limited benefit from AV synchrony. However, any improvement in cardiac output with restoration of AV synchrony may be clinically significant. Additionally, clinical conditions such as left ventricular hypertrophy or diastolic dysfunction generally are dependent on adequate preload to maintain cardiac output. Restoration of AV synchrony appears to be particularly significant for these patients.

Patients with Sick Sinus Syndrome

In patients with sick sinus syndrome, dual-chamber pacing has been shown to be superior to VVI pacing.[9293,95-97] Many studies have demonstrated that atrial-based pacing (DDD) is associated with decreased clinical events, including atrial fibrillation, congestive heart failure, stroke, and death,[88-98] mainly but not exclusively in patients with sick sinus syndrome. Several mechanisms by which atrial-based pacing is beneficial in patients with sick sinus syndrome may not apply to the subset of patients with AV block. Patients with sick sinus syndrome are more likely to have intact VA conduction compared with patients with high-degree or complete AV block. VVI pacing in patients with retrograde VA conduction causes atrial contractions against closed AV valves, leading to atrial distension and transient increases in pulmonary capillary wedge and jugular venous pressures. Increased atrial distension may predispose individuals to atrial fibrillation. This is apt to be more evident in the patients with sick sinus syndrome who already have paroxysmal atrial fibrillation or are at risk for such arrhythmias. Sympathetic activity is elevated during VVI versus dual-chamber pacing, which contributes to increased morbidity and possible mortality.[99] Even in the absence of retrograde conduction, VVI pacing with VA dissociation leads to atrial systoles throughout the cardiac cycle, which can also lead to a similar deleterious effect on atrial size and function. Therefore, dual-chamber pacing appears to reduce the incidence of atrial fibrillation and embolic complications.[88,90,93]

Andersen and colleagues published short- and long-term reports on a randomized study comparing single- and dual-chamber pacing in patients with sick sinus syndrome.[92,93] In their long-term study, they reported a reduction of embolic events, atrial fibrillation, and mortality with use of atrial-based pacing. Additionally, they found progressive benefit from atrial pacing compared with ventricular pacing, which resulted in overall improvement of survival based on total mortality and death from cardiovascular causes. Additionally, many studies have shown that maintenance of AV synchrony improves quality of life particularly at rest.[86,87] In fact, many patients who have VVI pacers may not recognize the extent of their symptoms until they have an upgrade to a DDD system.

Atrioventricular Block

In patients with AV block, the advantage of dual-chamber pacing has been demonstrated by some authors[98,100] but not by others.[91,94] In a retrospective study from the Mayo Clinic[91] on an elderly population, long-term survival was not affected by the mode of pacing. Lamas et al.[94] published a series on 407 elderly patients (older than age 65) who were randomized to have a dual-chamber pacer programmed to either VVI[R] or DDD[R] modes. These authors concluded that the main quality-of-life benefits associated with DDDR pacing were noted in the group of patients with sick sinus syndrome, and there were no quality-of-life benefits noted in the patients with pacers implanted for AV block.[94]

Therefore, there now appear to be adequate data supporting the use of atrial-based pacing (AAI, DDI, and DDD) in patients with sick sinus syndrome. The benefit of dual-chamber versus ventricular pacing in patients with advanced or complete AV block appears to be controversial. In patients with intact sinus node function and AV block, however, it is prudent to at least implant a single-lead VDD system, if not a complete dual-chamber pacing system, to restore AV synchrony in order to restore physiologic pacing.

Chapter 31: CARDIAC PACEMAKERS

PACING TIMING INTERVALS AND UPPER RATE BEHAVIOR

Atrioventricular Interval

The AV interval is divided into three zones. The first 20 to 40 ms of this interval is the atrial blanking period. The ventricular channel is blanked during this period to prevent inappropriate sensing of atrial output (crosstalk). Crosstalk is a greater problem in unipolar than in bipolar systems. The next part of the AV interval occurs from the end of the blanking period to approximately 100 to 120 ms after the atrial pacing output. If a ventricular sensed event occurred at this point, it would be nonphysiologic because of the short elapsed AV interval. The pacemaker responds with a ventricular output at a short AV interval (100 to 120 ms), which is a safety feature [ventricular safety pacing (Fig. 31-17)]. Ventricular safety pacing is a feature that ensures ventricular pacing in case the sensed event was not a ventricular depolarization; instead, pacing occurs at a short interval so that the pacing output falls before the T wave.

Finally, if there is a sensed event in the latter part of the AV interval, the pacemaker response is to inhibit ventricular pacing output.

Upper Rate Behavior

The total atrial refractory period (TARP) consists of the AV interval and the postventricular atrial refractory period (PVARP). The TARP is a programmable value that can be calculated in milliseconds. Ventricular tracking of atrial events cannot exceed a frequency shorter than the TARP. By dividing 60,000 by the TARP, a rate can be calculated that is the upper rate at which a pacemaker can track atrial events at a 1:1 ratio. At atrial rates exceeding this value, every other atrial event will fall within the pacemaker refractory period (PVARP) and there will be 2:1 pacemaker AV block. Therefore, the rate corresponding to the TARP corresponds to the pacemaker 2:1 rate.

The upper tracking rate is a separate programmable value. The upper tracking rate is generally programmed at a rate less than that corresponding to the TARP. This leads to pacemaker Wenckebach behavior when the patient's atrial rate exceeds the programmed upper rate (Fig. 31-18). The Wenckebach interval is defined as the difference between the programmed upper rate and the rate corresponding to the TARP.

Therefore, when a patient has a sinus or other atrial tachycardia, the pacemaker can track the P waves in a 1:1 fashion up to either the upper programmed rate of the pacer or to the pacemaker 2:1 rate, which ever is lower. If the 2:1 pacemaker rate is lower, there may be deleterious hemodynamic consequences for an exercising patient in whom the ventricular response would abruptly drop by nearly half. For this reason, a Wenckebach interval is preferred by programming the TARP to a sufficiently short interval or the upper rate of the pacemaker to a rate that is less than the 2:1 AV block rate.

Various strategies are available for active patients with DDD pacemakers who require physiologic upper rates. Many pacemakers offer autoadjusting AV intervals that shorten with increasing rates.

By shortening the AV interval, the TARP decreases, which allows greater upper tracking rates before reaching the rate of 2:1 AV block. Another strategy involves sensor-driven rate smoothing.[101] The rate-responsive features are activated, and, in fact, a separate upper sensor-driven rate, different than the upper atrial tracking rate, may be programmed. This enables maintenance of increased ventricular pacing rates driven by the sensor when the pacer would otherwise respond with AV Wenckebach or 2:1 AV block.

Chapter 31: CARDIAC PACEMAKERS

USE OF PACEMAKERS IN DIFFERENT CLINICAL SITUATIONS

Paroxysmal Atrial Fibrillation, Flutter, and Other Tachyarrhythmias

DDD pacing is problematic in the presence of atrial tachyarrhythmias. During atrial fibrillation, there are so many sensed atrial events occurring at rapid rates that a DDD pacemaker responds with an attempt to track these electrograms up to but not exceeding the upper rate (Figs. 31-19 and 31-20). The ECG hallmark is an irregularly irregular ventricular paced rhythm at a mean rate just below the upper rate. Of course, if the patient has intrinsic AV conduction, the patient's ventricular rate is not controlled by the pacemaker but rather by the intrinsic AV nodal conduction.

There are various strategies for preventing inappropriate upper tracking behavior during atrial tachyarrhythmias. In a patient with intact AV conduction and paroxysmal atrial tachyarrhythmias, DDI or DDIR modes would be appropriate (Fig. 31-19). In this mode of pacing, there is no tracking of atrial events. If there is a sinus or other atrial sensed electrogram, the pacer will inhibit atrial pacing output. Ventricular pacing occurs only at the lower rate interval. For patients with sick sinus syndrome, the clinical problem necessitating a pacemaker is the bradycardia resulting from intrinsic sinus node dysfunction or the bradyarrhythmias resulting from therapy to suppress the tachyarrhythmias. Therefore, DDIR is a very effective pacing mode for patients with sick sinus syndrome who have intrinsic AV conduction.

At the initiation of atrial fibrillation or other atrial tachyarrhythmia, many pacers can automatically switch pacer modes from DDD[R] to VVI[R] or DDI[R] (Fig. 31-20). The automatic mode switch may occur at the upper rate of the pacemaker or at a separate programmable mode switch rate. It may occur with single or multiple sequential premature atrial complexes, depending on the pacemaker model. Mode switching appears to be a clinically effective method of pacing in patients with AV block and paroxysmal atrial arrhythmias.[102-104]

Mode switching reduces symptoms associated with atrial fibrillation only if patients have adequate control of intrinsic AV conduction during atrial fibrillation. For this reason, a strategy of AV junction ablation with implantation of a mode-switching dual-chamber pacemaker can provide symptomatic relief for those patients with medically refractory paroxysmal atrial fibrillation with rapid ventricular response.[103,104]

Prevention of Atrial Fibrillation by Pacing

The initiation and maintenance of atrial fibrillation involve several pathophysiologic mechanisms, the most dominant of which is multiple reentrant pathways (see Chaps. 23 and 24). Pacing therapy may reduce dispersion of refractoriness in the atrium, a feature in reentry, or eliminate pause-dependent initiation of arrhythmias. As discussed above atrial-based pacing (AAI or DDD) reduces the incidence of atrial fibrillation compared with VVI pacing in those patients who require pacing; it is unknown, however, whether atrial pacing in itself may reduce the occurrence of atrial fibrillation. In patients with sick sinus syndrome who require bradycardia pacing support, it has been suggested[105-107] that standard atrial pacing reduces the frequency of atrial fibrillation. These studies examined the arrhythmia-free interval before and after atrial pacing. In another study of

patients who had atrial fibrillation without sinus nodal dysfunction, however, DDD pacers were implanted 3 months prior to planned AV junction ablation, and these pacers were programmed to DDD pacing at 70 beats per minute or to backup DDI pacing at 30 beats per minute.[108] The patients who were actively paced did not have fewer episodes of atrial fibrillation. Therefore, pacing in itself may not reduce the occurrence of atrial fibrillation but may be helpful in the management of those patients who have sinus nodal dysfunction.

It has been reported that dual-site atrial pacing may reduce the occurrence of episodes of atrial fibrillation.[106,107] One lead is placed in the right atrium and a second lead is placed in the coronary sinus ostium or inside the coronary sinus to advance left atrial depolarization. In theory, synchronization of the atria may reduce dispersion of refractoriness and thereby reduce the occurrence of atrial fibrillation.

Pacing in Chronic Atrial Fibrillation or Other Atrial Tachyarrhythmia

Patients with persistent atrial tachyarrhythmias and high-degree or complete AV block generally require a VVIR pacemaker unless their functional status is limited, in which case a VVI pacemaker would suffice. DDD[R] may be implanted in select patients with persistent atrial fibrillation in whom cardioversion to sinus rhythm is expected.

Pacing in Complete or Intermittent Third-Degree Atrioventricular Block

Patients with complete or intermittent third-degree AV block generally receive a DDD pacemaker (Fig. 31-3). If their sinus nodal function is intact, the ventricles are paced synchronous with the P wave after a programmed AV delay. Because some of these patients would not require atrial pacing, some manufacturers offer a single tripolar or quadripolar lead that utilizes a bipole in the atrial cavity for atrial sensing, and the distal electrode(s) are attached to the right ventricle for ventricular pacing and sensing (Fig. 31-16). This mode of pacing, VDD, facilitates implant, since only one lead is required.

Pacing in Carotid Sinus Syndrome and Vasovagal Syncope

Patients with one of the neurally mediated syncope syndromes generally have intact sinus and AV nodal function. Because of combined vasodepressor and cardioinhibitory responses, patients usually require dual-chamber pacing when a pacer is implanted. Additionally, these patients benefit from an interventional pacing rate (80 to 100 pulses per minute) during their vasovagal episodes and only require backup pacing at rates of 40 to 50 pulses per minute during other times. Therefore, one algorithm is to use dual-chamber hysteresis so that when a patient's heart rate drops to the lower rate, pacing is initiated at the interventional rate. This algorithm has limitations, since a patient's heart rate needs to exceed the interventional pacing before inhibiting the pacer. Some pacemakers now offer *rate-drop response* pacing, which involves interventional pacing (80 to 110 pulses per minute with gradual decline in paced rate at 1 to 5 minutes) that is triggered by a steep drop in a patient's intrinsic heart rate. Based on the North American Vasovagal Pacing Study, there was a reduction in syncope from 70 percent in the control group to 22 percent in patients who had pacers implanted with the rate-drop response feature.[42]

Pacing in Cardiac Transplant Patients

After orthotopic cardiac transplant, there is a high incidence of chronotropic incompetence resulting in slow junctional rhythm, sinus arrest, or sinus bradycardia. Bradycardia tends to resolve spontaneously in most patients, but 6 to 21 percent of patients may require permanent pacing.[109] Although symptomatic bradycardia is generally an early finding after transplantation, up to 5 percent of patients following transplant may have symptomatic bradycardia as a late

finding.[110] During the implant, the atrial lead is positioned in the donor atrium. A DDDR or AAIR pacer is placed, depending on whether AV conduction is intact.[111]

Chapter 31: CARDIAC PACEMAKERS

HEMODYNAMICS OF CARDIAC PACING

In theory, a pacemaker optimizes and maintains AV synchrony and optimizes ventricular activation and heart rate to enable cardiac output to meet the metabolic needs of the patient, whether he or she is resting, sleeping, or exercising. There are many variables involved in determining cardiac output through an effect on stroke volume, such as the autonomic tone, physical condition of the patient, left ventricular diastolic and systolic function, and peripheral vascular resistance. As seen in Table 31-8, many variables in pacing systems can affect cardiac hemodynamic function.

Table 31-8: Effects of Cardiac Pacing Variables on Hemodynamic Function

Feature	Effects
AV synchrony	Improves hemodynamic function in patients with diastolic dysfunction
	Required for most patients with one of the neurally mediated syncope syndromes
	Prevents AV valve regurgitation that is observed with ventricular contraction against open AV valves
	Prevents increase in pulmonary venous or central venous pressure seen when atria contract against closed AV valves
AV interval	Short AV interval in patients with hypertrophic cardiomyopathy
	Shorter AV interval after sensed P wave than during AV sequential pacing to have equivalent PR intervals
	In patients with dilated cardiomyopathy, physiologic AV interval may be preferable to markedly prolonged PR interval
Rate responsiveness	Useful in patients with chronotropic incompetence
	Useful as a rate-smoothing feature during upper tracking rate behavior in DDD patients to prevent deleterious effects of pacemaker AV Wenckebach or 2:1 AV block
Pacing site	Right ventricular apex is preferred in patients with hypertrophic cardiomyopathy to have left ventricular apical preexcitation preceding septal activation
	Multisite ventricular pacing is under study in patients with congestive heart failure, dilated cardiomyopathy, and intraventricular conduction delay

ABBREVIATIONS: AV = atrioventricular.

Atrioventricular Interval

The role of the AV interval and the optimal AV interval for improving hemodynamic function has been studied.[112-114] For most patients, the optimal AV interval corresponds to the physiologic range (i.e., an AV interval of approximately 150 ± 50 ms). In clinical practice, however, most patients' quality of life is not significantly different between AV intervals that are *optimized by noninvasive assessment* versus AV

intervals that are *suboptimal*.[114]

There are other considerations when programming AV intervals. With AV sequential pacing, the start of the P wave corresponds to the start of the AV interval while, with P-wave synchronous ventricular pacing, the start of the P wave begins approximately 20 to 70 ms prior to the start of the AV interval, depending on the conduction time from the sinus node to the atrial electrodes. The optimal AV interval for P-wave synchronous ventricular pacing would be shorter than the optimal AV interval for AV sequential pacing.[112] Therefore, to achieve similar hemodynamic effects from ventricular pacing following a sensed or paced P wave, the sensed AV interval should be programmed approximately 40 to 50 ms shorter than the paced AV interval. Additionally, left ventricular cardiac function is more dependent on left atrial to left ventricular relationships rather than right atrial to right ventricular AV interval. For this reason, there is much variability between patients with respect to programming AV intervals.

Pacemaker Syndrome

The pacemaker syndrome is a constellation of signs and symptoms representing adverse reaction to VVI pacing.[115-117] Most of the symptoms relate to loss of AV synchrony and also to retrograde conduction. These include orthostatic hypotension, near syncope, fatigue, exercise intolerance, malaise, weakness, cough, awareness of heartbeat, chest fullness, neck fullness, headache, chest pain, and other symptoms that may be nonspecific. On exam, these patients may have intermittent or persistent cannon A waves and possible liver pulsation. ECG demonstrates VVI pacing present at the time of the symptoms.

The basis for pacemaker syndrome is not only loss of AV synchrony but also the presence of ventricular-atrial conduction. Atrial contraction against closed AV valves leads to increases in jugular and pulmonary venous pressure causing cough and malaise in patients with intact cardiac function and congestive heart failure in other patients with structural heart disease. Distended atria can lead to reflex vasodepressor effects mediated by the autonomic nervous system and diuresis mediated by elevated levels of atrial natriuretic peptide.[118,119] Therefore, if patients have decreased cardiac output and arterial pressure secondary to VVI pacing, autonomic and humoral reflexes can lead to further hypotension and hemodynamic deterioration.

DDI pacing may produce pacemaker syndrome if the sinus rate exceeds the lower rate. DDD pacing can lead to pacemaker syndrome in select patients with severe intraatrial conduction delay who experience inappropriate timing between left atrial systole and left ventricular contraction.[120] This may necessitate the addition of a coronary sinus pacing lead to advance left atrial systole.[121]

The management of pacemaker syndrome usually requires restoration of AV synchrony. In many patients, an upgrade to a dual-chamber pacer is indicated. In some patients with intact sinus and AV conduction, lowering the pacing rate in VVI mode and using the hysteresis mode may promote sinus rhythm, lessening the symptoms associated with pacemaker syndrome. Using the VVIR mode by itself will not prevent or reduce symptoms from the pacemaker syndrome. Many patients may experience mild symptoms of the pacemaker syndrome and not recognize the symptoms until after an upgrade to a dual-chamber pacemaker.[122] Most patients prefer DDD pacing to VVI pacing[117,122,123] in various clinical and hemodynamic studies.

Chapter 31: CARDIAC PACEMAKERS

RATE-RESPONSIVE PACEMAKERS

The ability of a pacemaker to increase the lower rate in response to a physical or physiologic stimulus is termed *rate-responsive*, *rate-adaptive*, or *sensor-driven* pacing. The letter R in the fourth position of the NASPE/BPEG pacing code indicates rateresponsive pacing. Sensor systems that respond to parameters or activities that correlate with physiologic need for increased cardiac pacing rate provide input to the pacer, which increases the pacer lower rate. Numerous sensors have been developed with the goal of providing sensor input into the pacemaker, which can be then used to provide rate-adaptive pacing.[124-133]

Hemodynamic Evaluation of Rate-Adaptive Pacing

Cardiac output is a function of ventricular rate and stroke volume, modified by variables such as AV synchrony, ventricular preload, ventricular afterload, and autonomic state. In normal individuals at rest, pacing-induced increase in ventricular rate usually results in a transient increase in cardiac output followed by decrease in stroke volume, returning cardiac output toward normal. When there is a physiologic need for increased cardiac output, however, such as during exercise, stroke volume is maintained during increased ventricular pacing rate.

The role of the atrium and the need for AV synchrony remain less certain during faster rates compared with heart rates under 100 beats per minute. In patients with AV and ventricular-atrial block, pacing in the VDD mode compared with VVI pacing matched to the atrial rate (without AV synchrony) appears to provide similar cardiac output.[134,135] Multiple studies have shown that the change in work capacity correlates with ventricular rate during exercise whether the ventricular rate is triggered by spontaneous atrial activity or by a pacemaker sensor. Therefore, AV synchrony may be less important in patients during exercise who achieve or require heart rates in excess of 120 beats per minute. Nevertheless, VVIR pacing is not a substitute for DDD pacing.

If a patient has a VVI pacemaker and ventriculoatrial conduction, or a DDD pacing programmed with long AV intervals such that the P wave is closer to the preceding R wave, deleterious hemodynamic consequences may result. In this circumstance, there would be a decrease in cardiac output, since the atrium would consistently pace against closed AV valves, producing increases in the pulmonary and jugular venous pressures. This would also produce symptoms of the pacemaker syndrome. Dual-chamber pacemakers currently available often have options of rate-adaptive AV intervals. This provides the advantage of maintaining normal AV relationships during exercise and prevent retrograde atrial contraction.

RATE-ADAPTIVE SENSORS

Multiple rate adaptive sensors are available or under development.[124-133] Actively based sensors are used most commonly. These are piezoelectric crystal systems that are very sensitive to detection of vibration induced by up-down motion (activity) or acceleration, particularly (forward-backward motion).

The drawback of activity-based pacers is that they do not provide feedback that is proportional to physiologic need. For instance, climbing up stairs requires more work than going down stairs;

however, going down stairs is usually faster and would activate the sensor more than climbing up stairs. This leads to faster-paced rates while going down stairs. Similarly, other activity with little body vibrations may produce ineffective rate adaptation from the pacemaker. Therefore, true physiologic sensors are desirable for rate-responsive pacing. The role of physiologic sensors is to provide some measurable index of activity, exercise, or catecholamine state that can provide a more accurate input to the pacemaker for rate-adaptive pacing. The QT interval is affected by heart rate but also independently by catecholamines. Therefore, pacers can measure the interval from the ventricular stimulus to the end of the sensed T wave and modulate heart rate based on this measurement. The drawback of this technique is that the patient has to be ventricular paced in order to measure the QT, or stimulus-T, interval.

Since there exists a close relationship between respiratory rate or minute ventilation and heart rate, various sensors incorporate measurements of respiratory effort. These systems are based on measurement of transthoracic impedance between the pacemaker lead and the pulse generator. The impedance increases with inspirations and decreases with expiration; the amplitude of the impedance change is proportional to the tidal volume. Minute ventilation is the product of the tidal volume and respiratory rate. Thus, minute ventilation can provide an accurate physiologic estimate of metabolic needs. One of the disadvantages of this system is that energy is required to measure impedance, which increases current drain from the pacemaker.

A number of other sensor systems are available or under development. Many use physiologic parameters, such as pH, oxygen saturation, stroke volume, or temperature. The premise behind all of these are that the measured parameters can provide an accurate measure of a patient's metabolic needs, which can be used to guide rate responsiveness. There are various benefits and drawbacks to the different methods.

DUAL SENSORS

Some sensors systems provide the advantage of more physiologic pacing during steady state but have a slow response time during initiation of exercise. Other sensors, particularly activity sensors, have fast response times at initiation of activity but may not produce physiologic responses during peak or steady-state activity. Pacers with dual sensors can provide patients with rapid responses during the start of exercise to augment the heart rate and a more physiologic sensor (QT, minute ventilation) to provide more proportional heart rate response during steady state.[136,137] The benefit of dual sensors has not been conclusively demonstrated in long-term randomized studies, and, in fact, one acute exercise study demonstrated no clinical advantage of dual sensor over single-sensor rate-responsive pacing.[138]

Programming Rate-Adaptive Parameters

The parameters for programming rate responsiveness include the lower and upper activity rates, which may be separate from the upper tracking rate. A treadmill test may be required to optimize pacemaker programming. In practice, it is often sufficient to have the patient walk for a few minutes and program the rate-responsive features to achieve what would be expected to be a physiologic pacing rate for that patient. Different pacers have different algorithms that can automate the adjustments of the rate responsiveness. In most patients, it is difficult to demonstrate clinical effectiveness of automatic rate-response optimization versus fixed rate-responsive programming in the office or clinic.[139]

Chapter 31: CARDIAC PACEMAKERS

PACEMAKER COMPLICATIONS

Pacemaker complications can occur at the time of implantation[66,140] or, less likely, can occur late after implantation (Table 31-9). Overall, early complications have been reported in the range of 3 to 11 percent,[1,66,140,141] depending on the definition of complication, duration, and intensity of follow-up.

Table 31-9: Complications Related to Pacemakers

Early complications, related to implant	
Pneumothorax	0.5-1.9%
Large hematoma	0.5-1.7%
Cardiac perforation	0.2-1.2%
Lead dislodgment, atrial	1.6-3.8%
Lead dislodgment, ventricular	0.5-1.4%
Venous thrombosis	2-5%
Other complications	
Wound dehiscence	
Infection	
Pain	
High thresholds	
Loose setscrew	
Lead failure	
Pacemaker failure	
Diaphragmatic stimulation	
Skin erosion	
Pacemaker syndrome	

Complications of Pacemaker Implant

Cardiac perforation is a potentially serious and often unrecognized complication of pacemaker

lead insertion. This may be recognized at the time of lead insertion by fluoroscopic position of the lead, a paced QRS complex having right bundle branch block pattern, diaphragmatic stimulation, or hypotension resulting from cardiac tamponade. In the absence of anticoagulation, perforation usually does not lead to tamponade if the lead is withdrawn and repositioned. After implantation, cardiac perforation may be recognized by pericardial pain, friction rub, increasing ventricular pacing threshold, diaphragmatic stimulation, or pericardial effusion. The presence of these signs is not diagnostic of cardiac perforation, and echocardiograms should be performed to examine the lead position. If perforation is suspected, and the patient is hemodynamically stable, clinical observation is often the prudent course.

Other implant-related complications include subclavian arterial puncture, pneumothorax, hemothorax, and air embolus. Rarely, a lead may be introduced into the left ventricle through an inadvertent subclavian arterial puncture or through an unrecognized atrial or ventricular septal defect.[142,143]

Complications of venous leads include venous occlusion with resulting superior vena cava syndrome or thrombosis of the subclavian vein with ipsilateral arm edema.[144-147] Acute thrombosis may be treated with heparin and warfarin and managed conservatively if the patient responds to anticoagulation. Invasive and surgical interventions, including venoplasty and stent placement, have been described.[144,147] Most occlusions, partial or complete, may occur over time and tend to be asymptomatic because of the formation of venous collaterals.[148]

Infections related to pacemaker implantation are rare. The use of prophylactic antibiotics and irrigation of the pacemaker pocket with antibiotic solution may help prevent infection, especially from local flora.[149,150] Early infections may be caused by *Staphylococcus aureus* and can be aggressive. Late infections are commonly related to *Staphylococcus epidermidis* and may have a more indolent course. Occasionally, pacemaker infections are misdiagnosed as pacemaker allergy. Other signs of infection include local inflammation and abscess formation, erosion of the pacer, and fever with positive blood culture without an identifiable focus of infection. Transesophageal echocardiography may help determine whether vegetations are present on the pacemaker lead.[151,152] If the pacemaker is infected, removal of the pacemaker leads and generator is usually required.[153]

Mechanical Complications

During implant, the leads are connected to the pulse generator by a setscrew mechanism. If the setscrew is loose (Fig. 31-4), then pacemaker malfunction may occur, manifested by increased impedance and intermittent or complete failure to capture.

The pacemaker leads are subject to long-term complications. The insulation of the leads may break, leading to problems with oversensing (due to electrical noise), undersensing, and failure to capture (due to current leak). This problem often manifests intermittently and may be difficult to detect during a routine pacer check. The patient may complain of pectoral muscle stimulation due to current leak around an insulation break.[154] An abnormally low impedance with demonstrable lead malfunction is diagnostic for insulation break. Subtle insulation breaks may be detected by having the patient perform provocative maneuvers while monitoring an ECG (and marker channels) and or measuring impedances.

Leads may also fracture over time (Fig. 31-2). Early lead fractures lead to increased impedances associated with failure to capture, oversensing, and undersensing. Some leads use retention wires to preform an atrial lead so that it is more likely to attach and remain within the atrial appendage. Fracture of a retention wire does not cause any pacemaker malfunction, but it can lead to serious complications, including cardiac perforation and death, when it penetrates

through the insulation into the atrial cavity.[155]

Twiddler's syndrome is a term applied to patients who intentionally or unintentionally manipulate their pulse generator, causing twisting of the entire pacemaker system. This leads to lead dislodgment or fracture. This may also result from an excessively large pacemaker pocket allowing rotation of the pacemaker.

Electromagnetic Interference of Pacemaker Function

In general, electromagnetic interference (EMI) can originate from a variety of sources that have the potential to affect pacemaker function adversely. In Table 31-10 are listed some of the more common sources of EMI with potential pacemaker effects.

Unipolar pacemakers are usually more susceptible to EMI interference than are bipolar pacemakers because the sensing circuit encompasses a larger area compared with bipolar sensing. Factors that affect EMI interference have to do with the source of the interference and the proximity to the pacemaker generator. Many of these sources are located in a hospital environment or specialized places such as construction sites. Magnetic resonance imaging scans are contraindicated in patients with pacemakers, although there are case reports of patients with pacers undergoing MRI scans without adverse events.[156] Sources of EMI at home and the office usually do not pose a problem for patients. There is concern, however, that electronic article surveillance devices, found commonly in retail establishments, can interfere with pacemaker function,[157,158] if patients linger by these devices.

The effects of EMI vary according to its source and the type of pacemaker. Inhibition of pacing output can potentially be life threatening for patients who are pacemaker dependent. If the EMI is interpreted as atrial events by the pacemaker, then inappropriate ventricular pacing may occur in patients with DDD pacemakers, since these pacemakers attempt to *track* these events, which are interpreted as atrial. EMI often causes electrical noise that causes the pacemaker to function in a *noise reversion mode*. The actual function of this mode differs among the different pacemakers, but this mode involves switching to an asynchronous pacing mode. After elimination of this interference, pacers generally revert to the previously programmed mode; however, it is possible for EMI to cause pacemakers to revert to a backup pacing mode. Backup pacing in some models is unipolar VVI pacing at a preset rate.

Occasionally, EMI causes permanent damage to the pulse generator. Therapeutic radiation can damage the complementary metal oxide semiconductors (CMOS) that are part of most modern pacemakers. Generally, doses in excess of 5000 rad, but as little as 1000 rad, may induce pacemaker circuitry damage, which in turn can cause pacemaker failure or even induce a runaway pacemaker. If the pacemaker cannot be shielded from the field of radiation, then consideration should be given to reimplanting the pacemaker at a distant site.

In studies[159,160] examining interactions between pacemakers and cellular telephones, it was noted that digital telephones may cause intermittent pacemaker dysfunction. These adverse effects observed included pacemaker inhibition, inappropriate ventricular tracking (in VDD or DDD pacemakers), or resetting the pacemaker to a backup asynchronous mode. Factors associated with interference include unipolar pacing systems, digital cellular phones, increased output by the cellular phone, and close proximity of the cellular phone to the pacer. Because of the diversity of cellular phones and pacemakers that have different shielding capabilities against electromagnetic interference, it is difficult to draw firm conclusions on the use of digital cellular telephones.[159] No consistent problems have been detected with analog telephones. It is advisable that patients use cellular telephones that are analog or to keep digital cellular (with power outputs greater than 3 W) phones 20 cm away from their pacemaker generator.

Chapter 31: CARDIAC PACEMAKERS

PACEMAKER MALFUNCTION

Pacemaker malfunction can be categorized as loss of capture, abnormal pacing rate, undersensing, oversensing, or other erratic behavior. The approach to diagnosing pacemaker malfunction is to inspect the ECG carefully, interrogate the pacemaker; check pacing and sensing thresholds, lead impedances, and battery voltage/magnet rate; and perform a chest x-ray. Many instances of pacemaker malfunction actually represent normal function of the pacemaker (Table 31-11). Usually, causes of pacer malfunction may be diagnosed noninvasively, but, occasionally, surgery is required to diagnose problems.

Table 31-11: Suspected Malfunction Occurring During Normal Pacer Function

Observation	Suspected Problem	Possible Normal Pacer Function
Pacing artifacts delivered in the middle of normal QRS complexes	Pacemaker undersensing	Pseudofusion
Unexplained pauses after sensed but not paced complexes	Pacemaker oversensing	Hysteresis
Pacer rate less than lower rate, which occurs at night	Pacemaker oversensing at night	Different sleep rate/lower rate
Rapid pacing rates	Pacemaker oversensing of EMI in atrial channel or other atrial events causing upper rate tracking	Scanning hysteresis/rate drop response causing an increased 'intervention' pacing rate for vasovagal episodes
	Pacemaker-mediated tachycardia	Activation of rate-response sensors
		Upper rate tracking of unsuspected atrial tachyarrhythmia or sinus tachycardia
DDD pacer operating in VVI mode	Malfunction of pacer	Pacer reset due to EMI or low battery
		Pacer that mode switched due to atrial tachyarrhythmia

ABBREVIATION: EMI = electromagnetic interference.

Abnormal Pacing Rates

Abnormal pacing rates can be due to normal or abnormal pacing function (Table 31-11). Failure of the pacemaker to output is usually due to oversensing. Occasionally, there is pacemaker output that is not visible because of bipolar pacing producing very low amplitude pacing artifacts (artifacts from digital ECG recording are commonly difficult to visualize). Conversely, absence of pacing stimuli may be due to

interruption of current flow from a lead fracture, insulation break, or a loose setscrew.

Abnormally fast pacing rates usually are due to normal pacing function. They may be in response to rate-adaptive sensors. In DDD pacemakers, upper rate pacing may be due to sinus tachycardia, atrial tachyarrhythmias, or pacemaker-mediated tachycardia (Table 31-12). In either case, the pacemaker function is normal and is responding either to a rapid atrial rate or to retrograde atrial activity. Rarely, very rapid ventricular pacing ("runaway pacemakers") can cause life-threatening problems requiring disconnection of the pacemaker. Occasionally, abnormal pacing rates can be due to an unstable lead position where the lead is swinging between heart chambers.

Table 31-12: Causes of Upper Rate Behavior in DDD Pacemakers (and Atrioventricular Block)

	ECG Characteristics	Response to Magnet
Sinus tachycardia	1:1 Atrioventricular pacing, pacemaker Wenckebach or 2:1 block depending on the PVARP, upper rate, and sinus rate	No change in paced rhythm after magnet removed
Atrial fibrillation	Irregularly irregular paced ventricular rhythm up to but not exceeding the upper rate	No change in paced rhythm after magnet removed
Pacemaker-mediated tachycardia	Regular paced ventricular rhythm equal to or less than upper rate	Termination of tachycardia

ABBREVIATION: PVARP = postventricular atrial refractory period.

Loss of Capture

The loss of pacemaker capture occurs when there is a visible pacing stimulus and no atrial or ventricular depolarization. This may be intermittent or persistent. Most problems occur at the pacemaker lead/tissue interface. For instance, lead dislodgment can cause obvious failure to capture. An increase in the pacing threshold above the pacing output can occur as part of the rise above initial threshold within a few weeks following lead placement (Fig. 31-21) or because of drug therapy, electrolytes, myocardial infarction, or ischemia. Fracture of the lead, insulation breaks, and loose setscrews are mechanical problems that can cause failure to capture. Lastly, battery depletion may cause the pacing output to decline sufficiently such that pacing failure occurs.

Loss of capture requires a check of pacing threshold and of pacing lead impedance and a chest x-ray. For instance, if the problem is an elevated pacing threshold, pacing outputs must be increased. Abnormal lead impedances may confirm a lead failure and the need for lead replacement.

Oversensing

This problem leads to abnormal pacing rates with pacemaker pauses. Generally, unipolar lead systems are more susceptible to oversensing. The sources for oversensing can be intracardiac, extracardiac, or due to EMI. Analysis of ECG, especially with pacemaker interrogation and pacemaker marker channels, may help to determine the cause. If the oversensing is regular, analysis of the pauses may suggest T-wave or P-wave oversensing. T-wave oversensing usually can be eliminated by decreasing the sensitivity (increasing the millivoltage required to sense electrical activity) or increasing the ventricular refractory period.

Oversensing due to lead fracture, insulation break, or other electrode problems will usually be random and erratic (Fig. 31-22). With early lead problems, the malfunction is intermittent and may be

exacerbated by certain body positions or motions. In later stages, the combination of oversensing, undersensing, and failure to capture is almost always diagnostic of a lead-related problem. Programming to an asynchronous mode may temporarily control this problem while awaiting a lead replacement, which should be carried out as promptly as possible.

Crosstalk inhibition is a phenomena usually seen in unipolar pacers. It is due to ventricular sensing of atrial output. This is currently a rare problem because of blanking periods and ventricular safety pacing.

Myopotential oversensing is usually a problem in unipolar but not bipolar systems. These skeletal myopotentials generate interference, which tends to correspond to certain activity. The optimal solution is reprogramming the sensitivity to a level high enough to avoid myopotential sensing while preserving adequate safety margin to sense intrinsic cardiac depolarizations.

Undersensing

An inadequate intracardiac signal can lead to undersensing ( Fig. 31-17). The intracardiac electrograms can deteriorate due to inflammation or scar formation at the tissue lead interface. Additionally, certain drugs, electrolyte abnormalities, infarction, ischemia, lead fracture, or insulation breaks can lead to undersensing. Cardioversion or defibrillation can also cause attenuation of intracardiac electrograms. Usually, undersensing is a greater problem in the atrium than in the ventricle. The optimal solution is to program an enhanced sensitivity (decrease sensing level). With bipolar systems, the programmed sensitivity can usually be reduced to 0.18 mV in the atrium, without oversensing of myopotentials or other extraneous signals.

Other etiologies for undersensing occur when intrinsic atrial or ventricular complexes fall within one of the programmed refractory periods. Undersensing can also result from a pacer that was inadvertently programmed to an asynchronous mode (occasionally occurring with battery depletion or pacemaker generator reset).

Chapter 31: CARDIAC PACEMAKERS

List of Figures

Figure 31-10: *A.* Shown are rate histograms demonstrating seven episodes of atrial fibrillation lasting from a few minutes to an episode lasting over an hour. *B.* This graphic demonstrates the beat-to-beat rate just before onset of the atrial tachyarrhythmia, after 200 beats, and just after termination of the arrhythmia, 69 min later. A snapshot of the stored intraatrial electrograms (A-EGMs) confirms atrial fibrillation as the mechanism. DEC, December; Tachy, tachycardia.

Figure 31-11: An electrocardiogram of a patient with sinus nodal dysfunction and first-degree atrioventricular block who has an implanted VVI pacemaker. Note that application of a magnet causes VVI pacing in the asynchronous mode at a rate of approximately 95 beats per minute. After the magnet is removed, the pacemaker reverts to VVI at 50 beats per minute until the patient's sinus rhythm inhibits pacemaker function.

Figure 31-12: Schematic diagram of the pacemaker timing cycles during VVI pacing. After a ventricular paced or ventricular sensed event, the pacemaker begins a ventricular refractory period (VRP). This is a programmable value usually between 250 and 400 ms. During this time, a sensed ventricular event will not initiate a new timing interval and will not reset the pacemaker. The lower rate interval (LRI) of the pacemaker corresponds to the programmed lower rate. If this interval expires and there is no sensed ventricular event following the end of the ventricular refractory period, the pacemaker stimulates the ventricle (second and fourth complex) and the VRP and LRI begin anew. If there is an intrinsic ventricular depolarization between the end of the VRP and during the LRI, then ventricular output is inhibited and the VRP and LRI begin anew.

Figure 31-13: A patient with atrial fibrillation and the VVI pacemaker with lower rate of 70 pulses per minute (857 ms) and hysteresis rate of 50 beats per minute (1200 ms). The square pulses in the bottom line represent pacing output. This tracing (two leads recorded simultaneously) represents normal hysteresis function. See the text for discussion.

Figure 31-14: Schematic diagram of DDD pacing with selected timing cycles and refractory periods. After a paced atrial complex, the paced atrioventricular interval (PAV) begins. If there is no ventricular depolarization before this interval expires, the pacemaker response is to output a ventricular impulse. After a paced ventricular output, several refractory periods and timing cycles are initiated. The ventricular refractory period (VRP) is the time during which a ventricular event will not reset the timing intervals. The postventricular refractory period (PVARP) represents the time during which an atrial event will not be sensed or will not reset the timing intervals. The upper rate interval represents the shortest interval (maximum rate) that a pacemaker will ventricular pace corresponding to the programmed upper tracking rate. The ventricular-atrial escape interval (VA) represents the time during which, if there is no sensed atrial electrogram, atrial pacing occurs. The programmed lower rate corresponds to the AV interval and the VA interval. During the first two complexes, there were no sensed atrial complexes; therefore, the VA interval expired and atrial pacing occurred. During the third and fourth complexes, there were sensed atrial electrograms following the PVARP and before the VA interval expired (shaded area in the VA bar). Note that atrial sensing usually occurs after the start of the P wave, representing the atrial conduction time to the atrial electrodes. The programmed AV interval following a sensed atrial complex (SAV) may be programmed at a value lower than the PAV to obtain equivalent PR intervals.

Figure 31-15: Surface electrocardiogram with marker channels of a patient with a dual-chamber pacemaker in the DDD mode. Note atrial pacing of all complexes. The first, second, and last complexes have paced ventricular outputs in the middle of the QRS complex. Compared to the third, fourth, and fifth complexes, which do not have these ventricular pacing spikes, there is no change in the QRS complex. This is consistent with "pseudofusion" of the QRS complex. This is due to the fact that the ventricular depolarization is not sensed by the pacemaker until the middle or end of the QRS complex in this particular patient. Subtle variations in the conducted PR interval account for the fact that some of the complexes have a paced ventricular complex and some do not.

Figure 31-16: Chest x-ray showing a single lead in the heart. Note the bipolar electrodes in the atrium and the single electrode in the ventricle. This pacemaker system is capable of VDD pacing. Therefore, it senses atrial depolarizations and can pace or sense in the ventricle.

Figure 31-17: Surface leads I, II, and III are shown at paper speed of 50 mm/s. Note that there is complete undersensing of the P wave. The pacemaker therefore tends to pace at the lower rate interval, which corresponds with an intrinsic QRS complex. This QRS complex is sensed within the ventricular safety period, triggering ventricular safety pacing. For this particular pacemaker, ventricular safety pacing occurs at 110 ms after atrial pacing in order to avoid ventricular pacing during the T wave.

Figure 31-18: *Top*. Sinus tachycardia in a patient with atrioventricular block and a DDD pacemaker with a programmed upper rate of 100 beats per minute, which is less than the intrinsic sinus rate. Note that the interval between the sensed P wave and the paced ventricular complex lengthens progressively, until there is a P wave (within the T wave) following the first, fourth, and seventh paced ventricular complexes without subsequent ventricular pacing, consistent with pacemaker Wenckebach. *Bottom*. The pacemaker is programmed in the DDDR mode with upper rate of 100 beats per minute. The presence of rate response, during activity, acts to smooth the upper rate, preventing the longer pauses during pacemaker Wenckebach.

Figure 31-19: Tracings of a patient with a dual-chamber pacemaker who has underlying atrial fibrillation. Electrocardiograms and corresponding marker channels are shown for pacing modes DDD, DDI, and DVI, respectively. Note that during DDD the pacemaker rhythm is an irregularly irregular paced ventricular rhythm at, but not exceeding, the upper rate of the pacemaker. In the DDI mode, there is no tracking of the atrial fibrillation; therefore, it functions effectively as a VVI pacemaker so long as the patient is in atrial fibrillation. In the last tracing, the mode is DVI; therefore, there is no sensing of atrial electrograms, which accounts for the AV sequential pacing pattern. This mode is generally not used when the DDI mode is available. AR = sensed atrial electrogram in the pacemaker refractory period; AS = sensed atrial electrogram; VP = ventricular paced complex.

Figure 31-20: Electrocardiogram, marker channels, and intracardiac atrial electrograms (IEGMs) are shown for a patient with atrial fibrillation. At the left-hand part of the tracing, there is upper track pacing at an irregular rate due to the atrial fibrillation. Automatic mode switch was programmed on (indicated by the triangles), and the pacemaker automatically mode switched (MS) to the DDIR mode. Note the prolonging of ventricular cycle lengths after mode switch was activated.

Figure 31-21: Electrocardiogram marker channels of a patient with a dual-chamber pacemaker. Note that the atrial pacing outputs (APs) are capturing the atrium, and there is appropriate P-wave sensing (AS or AR). However, none of the ventricular outputs are capturing the ventricle. This is a tracing of a patient who had a pacemaker placed 3 weeks prior to acquisition of this ECG, and the pacing threshold had exceeded the tracing output.

Figure 31-22: Electrocardiogram and marker channels are shown for a patient with a ventricular lead impedance break. Note that based on the ECG there is failure to sense, as manifested by the second and fourth pacing outputs coming very shortly after the QRS complex. There is failure to capture, demonstrated by the second and third pacing outputs, which should capture the ventricle. There is also evidence of oversensing, as demonstrated by the long pause between the fourth and fifth pacing outputs during a diastolic period that exceeds the interval between the previous two pacing outputs. In general, when there is evidence of oversensing, undersensing, and failure to capture, then the likely etiology is either a lead insulation break, lead fracture, or other mechanical problem. The marker channels confirm the above ECG findings. There are sensed ventricular events (S or SR) that do not correspond to surface QRS complexes, consistent with oversensing. Additionally, the erratic pattern of sensed ventricular events is consistent with electrical noise. There are also lack-of-sense markers corresponding to QRS complexes; finally, there are ventricular pace markers (P) that fail to capture the ventricle.

Part 5: SYNCOPE, SUDDEN DEATH, AND CARDIOPULMONARY RESUSCITATION
Chapter 32:

DIAGNOSIS AND MANAGEMENT OF SYNCOPE

Authors: Harisios Boudoulas, Steven D. Nelson, Stephen F. Schaal, Richard P. Lewis

Syncope is a sudden and transient loss of consciousness. The occurrence of syncope in the general population, as reflected in the 26-year surveillance of the Framingham Study, is 3.0 percent in men and 3.5 percent in women in the general population. As a general rule, the incidence of syncope increases with age.[1]

As an initial presentation, syncope denotes a diversity of disorders ranging from a benign episode to sudden death. Studies in recent years have documented the multiple causes and the widely divergent mortality risks associated with an episode of syncope. On the basis of these studies, patients with a transient episode of altered consciousness (presyncope) and those with complete loss of consciousness (syncope) can be classified into three broad categories[2] (Table 32-1): *cardiac syncope, noncardiac syncope,* and *syncope of undetermined cause.* The relative incidence of these categories varies with the clinical site from which the patients are selected. In the emergency room, noncardiac syncope is most common. For patients admitted to the hospital, cardiac syncope is the most common diagnosis.[3]

Table 32-1: Classification of Syncope

I. Noncardiac
II. Cardiac
III. Undetermined cause

Clearly, the highest mortality occurs among those with cardiac syncope. Among all patients with syncope associated with cardiac disease, sudden death is extremely high.

NONCARDIAC SYNCOPE (Table 32-2)

Sudden transient loss or impairment of consciousness occurs under a wide variety of circumstances. The pathophysiologic mechanisms, diagnostic features, and therapy for these disorders are discussed below.

Table 32-2: Classification of Noncardiac Syncope

Neurocardiogenic Syncope

The syndrome of neurocardiogenic syncope, the common faint (also referred to as neurally mediated hypotension, vasovagal syncope, and vasodepressor syncope), is one of the most common causes of syncope. This disorder is considered to be an abnormality in the complex neurocardiovascular interactions responsible for maintaining systemic and cerebral perfusion (Fig. 32-1).[4-10]

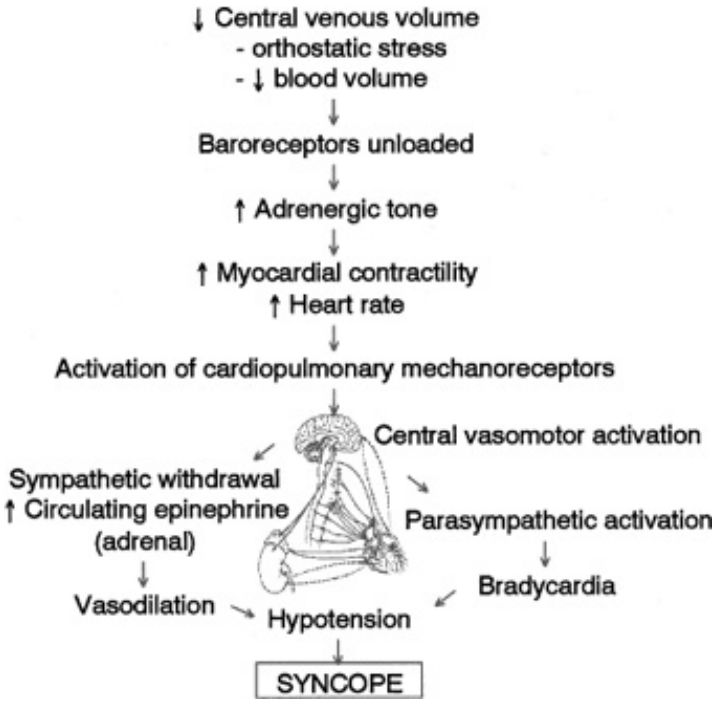

Figure 32-1: Presumed mechanisms of neurocardiogenic syncope. Schematic presentation. ↑ = increase; ↓ = decrease.

PATHOPHYSIOLOGY

The pathophysiology of neurocardiogenic syncope is quite complex and incompletely understood. Under normal circumstances, upright posture causes venous pooling and a transient decrease in arterial pressure, resulting in an unloading of baroreceptors. Reflex augmentation of sympathetic activity and parasympathetic withdrawal result in peripheral arterial vasoconstriction, venoconstriction, and an increase in heart rate and contractility. These adaptive mechanisms serve to maintain normal systemic and cerebral perfusion. Neuroendocrine systems (e.g., renin-angiotensin and vasopressin) may be important modulators of homeostasis during prolonged periods of orthostatic stress.[11]

Individuals susceptible to neurocardiogenic syncope are unable to maintain the adaptive neurocardiovascular responses to upright posture for prolonged periods. These patients tend to have a modest reduction in central blood volume, which is aggravated by upright posture. Increases in circulating catecholamines and cardiac adrenergic tone in response to orthostatic stress result in increased myocardial contractility.[12] Studies in animal models suggest that, under these conditions, cardiopulmonary mechanoreceptors are activated, resulting in increased neural traffic across afferent C fibers leading to the central nervous system vasomotor center; this in turn results in reflex paradoxical vasodilation (vasodepressor response) and bradycardia (cardioinhibitory response).[13] The final result is hypotension, cerebral hypoperfusion, cerebral hypoxia, and syncope. This paradoxical reflex is believed to be a variant of the Bezold-Jarisch reflex and has also been documented during nitrate therapy for acute myocardial ischemia, and during acute hemorrhagic syndromes.[14,15] In addition, vasomotor center activation is believed to cause several of the prodromal symptoms of diaphoresis, nausea, vomiting, and dyspnea that frequently accompany neurocardiogenic syncope. Recent evidence from patients with denervated hearts (i.e., cardiac transplantation patients) and those with neurocardiogenic syncope raises the possibility that other neurohumoral mechanisms, primarily involving the peripheral circulation, may play an important role.[16]

The mechanism of paradoxical vasodilation observed during neurocardiogenic syncope is

incompletely understood. Clinical studies have shown that serum epinephrine concentrations surge prior to the syncopal event with resultant intense β_2 activation, which may cause inappropriate vasodilation and syncope. Withdrawal of peripheral sympathetic neural activity at the time of neurocardiogenic syncope has also been demonstrated by direct recordings of sympathetic neural activity.[17]

The paradoxical bradycardia (cardioinhibitory response) during neurocardiogenic syncope is due to a surge in cardiac parasympathetic tone and usually lags vasodilation by several seconds.[18] The cardioinhibitory response is highly variable, ranging from a relative bradycardia with heart rates in the 40 to 60 beats per minute range to profound periods of asystole. Variable degrees of atrioventricular (AV) block and junctional escape rhythms are observed as well. *Bradycardia aggravates but is not the principal cause of hypotension during neurocardiogenic syncope.* Maintaining heart rate with atropine or cardiac pacing will often reduce, but not prevent, symptomatic hypotension during neurocardiogenic syncope. Elderly patients with neurocardiogenic syncope are likely to have a predominant vasodepressor response without a significant cardioinhibitory component.

CLINICAL CHARACTERISTICS

Predisposition to neurocardiogenic syncope occurs under a wide variety of clinical circumstances. Indeed, the neurocardiogenic reaction per se may be the ultimate cause of most types of syncope. Neurocardiogenic syncope is often noted in individuals receiving sympathetic blocking agents and vasodilator drugs for hypertension, in elderly individuals receiving tranquilizers, in patients with acute or chronic anemia, and in those with transient reductions in blood volume, such as occur following a brisk diuresis or blood donation. Neurocardiogenic syncope complicates acute febrile infections and occurs with prolonged recumbency in chronic illness. Normal individuals at prolonged bed rest have a propensity for fainting, particularly when they arise abruptly from a sitting or recumbent position. Neurocardiogenic syncope is probably the most frequent cause of cardiovascular collapse during dental manipulations (dental syncope).[19] Neurocardiogenic syncope has been noted to follow strenuous exercise and may also occur during rapid acceleration in air flight, particularly when centrifugal force is applied in the head-to-foot position. Neurocardiogenic syncope of an unusual type may occur in pregnancy, being precipitated when the patient is supine and reversed when the patient assumes a lateral decubitus or upright posture (see Chap. 82).

The identification of aggravating factors (*triggers*) is important not only for the diagnosis but also for the prevention of syncope. Situations that decrease central venous volume or increase cardiovascular adrenergic tone are particularly important in the aggravation of neurocardiogenic syncope. The postprandial state, exertion in warm environments, prolonged upright posture, sodium restriction or diuretic use, and emotional or stressful situations are but a few important triggers to consider. Evidence suggests a relationship between chronic fatigue syndrome and neurocardiogenic syncope.[20]

The classic syncopal spell is often preceded by a constellation of prodromal symptoms occurring several seconds prior to the syncopal event. The prodrome may include symptoms of nausea, headache, diaphoresis, dizziness, chest pain, palpitations, dyspnea, and paresthesia. These symptoms may also persist for several minutes to several hours after the syncopal episode has resolved. Patients with sudden loss of consciousness may not report prodromal symptoms. Usually the spell occurs when the patient is upright and is less likely while seated. *Syncope while supine should prompt the search for etiologies other than neurocardiogenic syncope.*

During the syncopal episode, patients typically appear pale and diaphoretic, with a slow, diminished pulse. Occasionally, seizure-like activity may occur during asystolic periods. The syncopal spell classically resolves spontaneously once the patient is in the supine position but may

recur if the patient stands or sits upright soon after the initial spell. The observations of a bystander are particularly helpful. *If the patient experiences a prolonged period of confusion after the syncopal event or is incontinent, etiologies other than neurocardiogenic syncope should be considered.*

Natural History

The frequency and clinical significance of neurocardiogenic syncope are highly variable. Neurocardiogenic syncope may occur as a single isolated event or as a cluster of spells over weeks to months, or it may be a recurrent lifetime problem. The overall prognosis in patients with neurocardiogenic syncope is quite favorable compared with arrhythmic or left ventricular outflow obstructive forms of cardiac syncope. A very small subset of patients has been described as having *malignant* neurocardiogenic syncope.[21,22] This form of syncope is characterized by profound periods of asystole with sudden loss of consciousness, potentially leading to severe trauma and a theoretically increased risk of ischemia-mediated ventricular tachyarrhythmias. This risk is greatest in patients with underlying structural heart disease.

DIAGNOSTIC EVALUATION

Head-up tilt (HUT) testing has become a useful diagnostic study for the identification of patients with neurocardiogenic syncope.[23-25] The sensitivity, specificity, and reproducibility of HUT testing depend on the patient population studied and the HUT protocol employed.[23-30] HUT at an angle of 60° to 90° for a time period of 20 to 60 min has been found to yield a sensitivity ranging from 20 to 74 percent. Longer durations of HUT (45 to 60 min) lead to improved sensitivity without a significant increase in false-positive responses. Recent studies suggest that the optimal HUT angle should be between 60° and 80°. Tilt angles less than 45° sacrifice sensitivity, whereas angles greater than 80° can result in more false-positive results.[24] An average of 63 percent of patients studied with HUT after a negative electrophysiologic study were found to have a positive HUT response, suggesting that a significant proportion of patients with unexplained syncope have neurocardiogenic syncope. Isoproterenol infusion during HUT testing has been shown to improve sensitivity.[23] Low-dose isoproterenol infusion (<2 μg/min) has been shown to nearly double the number of positive responses compared with baseline (short-duration HUT), with an acceptable specificity of 93 percent and reproducibility of 83 percent.[28] High doses of isoproterenol, especially at HUT angles of greater than 80°, markedly increase the incidence of false-positive responses.[29] High-dose intravenous isoproterenol, intravenous adenosine, and sublingual nitroglycerin during HUT have all been shown to increase sensitivity with some reduction in specificity and significant reduction in the time required to perform the test.[31-33]

MANAGEMENT

The management of recurrent neurocardiogenic syncope is challenging and sometimes unsatisfactory. The choice of therapy should be based on an understanding of the neurocardiovascular cascade that eventually culminates in neurocardiogenic syncope. First-line therapy includes counseling the patient to avoid dehydration, prolonged periods of standing motionless, and situations known to trigger syncope. Increased salt intake may be beneficial, if not contraindicated. Patients should be educated to recognize premonitory symptoms and, if they are present, to assume a recumbent position and cough in order to maintain cerebral perfusion. Data suggest that tilt training may improve outcome.[34]

The severity and frequency of recurrence of neurocardiogenic syncope are highly variable. As a result, its pharmacologic management must be highly individualized. Patients with infrequent, near-syncopal spells may respond to general measures alone. Frequent syncopal spells, especially if trauma occurs, usually necessitate pharmacologic interventions.

Therapeutic options include volume expansion, beta-adrenergic receptor blockade, anticholinergic agents, serotonin reuptake inhibitors, methylxanthines, alpha-agonists, and dualchamber cardiac pacing. A stepped approach to pharmacologic therapy is advisable, starting with low initial doses, as these patients seem to be more prone to adverse reactions than the general population. The dose can be gradually titrated until the frequency and severity of spells are diminished. If one class of drug is ineffective, a combination of drugs, each acting on different limbs responsible for the neurocardiogenic syncope, may be beneficial. Several centers report the use of HUT testing to predict the clinical outcome of therapy. This approach has been questioned by two placebo-controlled trials that showed no significant difference in HUT response during treatment with active drug versus placebo.[35,36]

Volume Expansion

A significant proportion of patients with neurocardiogenic syncope have evidence of mild reduction in central plasma volume, and plasma volume expansion can prevent recurrence. Simple measures such as liberalizing salt and fluid intake may suffice.[37] Custom-fitted, counterpressure support garments that extend from the ankle to the waist may be of benefit in highly motivated individuals. In some instances, fludrocortisone acetate may be helpful in augmenting salt retention and volume expansion. The initial dose is 0.1 mg daily; this may be increased by increments of 0.1 mg every 5 to 7 days. The maintenance dose varies from 0.1 to 1.0 mg daily.[38] Potential side effects include recumbent hypertension, marked fluid retention, congestive heart failure, and hypokalemia.

Beta Blockers

Increased adrenergic stimulation with resultant activation of cardiac mechanoreceptors is believed to be an important mechanism in the pathophysiologic cascade that culminates in neurocardiogenic syncope. The negative inotropic effect of beta blockers may theoretically prevent activation of the ventricular mechanoreceptors or block the peripheral vasodilator effects of beta-adrenergic receptor stimulation. Oral metoprolol has been shown to prevent symptom recurrence in patients with neurocardiogenic syncope. In addition, intravenous metoprolol can blunt the hypotension and bradycardia during HUT testing. Recent studies suggest that patients who require isoproterenol infusion during tilt to elicit neurocardiogenic syncope are more likely to respond to beta blockers than are patients who are tilt positive without isoproterenol provocation.

Anticholinergic Agents

During neurocardiogenic syncope, certain subsets of patients experience profound bradycardia that can aggravate the hypotension associated with vasodilation. This subset is believed to have a sudden surge in vagal activity because the bradyarrhythmia, but not the vasodilation, can be prevented by intravenous atropine. The profound bradyarrhythmias are primarily observed in the young and presumably healthy age group. Despite the unimpressive response of neurocardiogenic syncope to atropine, certain other anticholinergic drugs may be of benefit, if tolerated. The anticholenergic activity of propantheline bromide may be an effective treatment.[39]

Transdermal scopolamine has been shown to be a useful preventive agent in certain subsets of patients with recurrent neurocardiogenic syncope. Its mechanism of action is poorly understood but is probably related to its peripheral anticholinergic actions, as well as a depressant effect on the central nervous system transmission to the autonomic nervous system. These central actions of scopolamine are believed to be important for the prevention of the nausea of motion sickness, which may incidentally involve neuropathways common to the vasovagal pathways.[40]

The class 1A antiarrhythmic drug, disopyramide, has known anticholinergic and negative inotropic properties. These properties, which are considered undesirable effects of disopyramide in the therapy of tachyarrhythmias, may prevent the activation of cardiopulmonary mechanoreceptors and the neurogenic reflex observed in neurocardiogenic syncope. Disopyramide has been shown to prevent tilt-induced syncope and to prevent spontaneous syncopal spells. Disopyramide, however, must be used with caution because of its potential for proarrhythmia. In addition, the noncardiovascular anticholinergic side effects of disopyramide may be intolerable for some patients.

Serotonin Reuptake Inhibitors

Serotonin may be an important mediator of inappropriate vasodilation and bradycardia in animal models of hemorrhagic shock. Blockade of serotonin receptors with methysergide can block this event. Nonrandomized studies suggest that the serotonin reuptake inhibitors fluoxetine hydrochloride (Prozac) and sertraline hydrochloride (Zoloft) may both be beneficial in the prevention of neurocardiogenic syncope after 4 to 6 weeks of therapy in approximately 55 percent of patients with severe, recurrent neurocardiogenic syncope.[41] A randomized, double-blinded, placebo-controlled trial showed that paroxetine hydrochloride-treated patients had an 18 percent incidence of recurrence versus a 53 percent recurrence rate in the placebo group.[42]

Methylxanthines

Theophylline appears to reduce the frequency of neurocardiogenic syncope in patients who can tolerate this durg. Two separate clinical studies have shown that theophylline can prevent recurrences in greater than 70 percent of patients.[43] Even low doses of theophylline (6 to 12 mg/kg per day) appear to have benefit in those patients who cannot tolerate higher doses. Unfortunately, side effects such as nervousness, anxiety, and gastrointestinal abnormalities limit the usefulness of theophylline in this setting. Methylxanthines, such as theophylline, appear to have three different pharmacologic effects that may be beneficial therapeutically. In low concentrations, methylxanthines are potent adenosine receptor antagonists. At *therapeutic* serum concentrations, theophylline acts as a phosphodiesterase inhibitor and as a calcium transport inhibitor, both of which may be important in maintaining peripheral vascular tone.

Alpha-Agonists

Nonrandomized studies in a small number of patients have suggested that alpha-agonists may prevent neurocardiogenic syncope due to a patent vasoconstrictor effect that may reduce venous pooling and concomitant reflex arteriolar vasodilation. However, two double-blinded, randomized placebo-controlled trials have yielded mixed results. Etilefrine was no better than placebo in the prevention of syncope. In contrast, the alpha-agonist medodrine reduced the incidence of HUT-induced syncope and improved quality of life compared with placebo control.[44,45]

Cardiac Pacing

Similar to the use of anticholinergics, pacing is valuable in preventing the component of hypotension that is due to bradycardia; however, peripheral vasodilation may still occur despite heart rate control as noted. *Cardiac pacing should be reserved for those patients who have documented episodes of prolonged bradycardia associated with the syncopal spell.* Pacing may be especially beneficial in those rare patients with malignant neurocardiogenic syncope due to cardiac asystole.[46,47] These patients typically require pharmacologic therapy in addition to cardiac pacing to prevent the vasodepressor component. Dual-chamber pacing with rate-drop response is the preferred mode of pacing. The North American Vasovagal Pacemaker Study was the first randomized trial to confirm the effectiveness of pacing in patients with frequent syncope, positive head-up tilt, and relative bradycardia.[48]

Orthostatic Syncope (Orthostatic Hypotension)

Orthostatic hypotension is a disorder in which assumption of the upright posture is associated with a fall in arterial pressure associated with light-headedness, blurring of vision, and a sense of weakness and unsteadiness.[2,49-55] Hypotension is progressive over a period of seconds to minutes, depending on the degree of loss in reflex adaptation. If the fall in perfusion pressure to the brain is profound, syncope occurs. If the individual assumes the recumbent posture, arterial pressure rapidly normalizes and consciousness is restored.

From the diagnostic viewpoint, orthostatic hypotension is conveniently classified under three major causes:[2] *venous pooling and/or blood volume depletion, pharmacologic agents,* and *neurogenic causes* (Table 32-3). In certain cases, circulating endogenous vasodilators may result in orthostatic hypotension and syncope.

Table 32-3: Causes of Orthostatic Syncope

Venous pooling or volume depletion
❍ Prolonged bed rest ❍ Prolonged standing ❍ Pregnancy ❍ Venous varicosities ❍ Blood loss ❍ Dehydration
Pharmacologic agents
❍ Antihypertensive ❍ Sympathetic blocking agents ❍ Calcium channel blockers ❍ Converting enzyme inhibitors ❍ Nitrates ❍ Diuretics ❍ Antidepressants, antipsychotic ❍ Phenothiazides ❍ Tranquilizers ❍ Antiparkinsonian ❍ Central nervous system depressants
Neurogenic

- Diabetes mellitus
- Alcoholic neuropathy
- Spinal cord disease
- Amyloidosis
- Multiple sclerosis
- Multiple cerebral infarcts
- Parkinsonism
- Tabes dorsalis
- Syringomyelia
- Idiopathic orthostatic hypotension
- Shy-Drager syndrome (multiple system atrophy)

Circulating endogenous vasodilators

- Hyperbradykinism
- Mastocytosis
- Carcinoid syndrome

VENOUS POOLING AND/OR BLOOD VOLUME DEPLETION

Excessive venous pooling accounts for the postural hypotension accompanying sustained bed rest, prolonged standing, pregnancy, and marked venous varicosities. Tall, asthenic individuals with poorly developed musculature are particularly prone to this form of postural hypotension. Deconditioning of normal autonomic reflex vasoconstriction may contribute to the orthostatic hypotension associated with prolonged bed rest and following extended periods of weightlessness in astronauts.[2] Blood volume depletion accounts for the orthostatic hypotension associated with dehydration, excessive diuresis, anemia, hemorrhage, excessive gastrointestinal fluid loss, third-space sequestration, prolonged fever, renal dialysis, excessive perspiration, adrenal insufficiency, pheochromocytoma, and diabetes insipidus.[56-60]

PHARMACOLOGIC AGENTS

Pharmacologically induced postural hypotension is a side effect in the administration of several classes of drugs, including antihypertensives, sympathetic blocking agents, diuretics, nitrates, calcium channel blockers, converting enzyme inhibitors, antidepressants, phenothiazines, tranquilizers, antipsychotic drugs, antiparkinsonian drugs, and central nervous system depressants.

NEUROGENIC CAUSES

Neurogenic postural hypotension has been observed in a wide variety of diseases affecting the autonomic nervous system. Specific entities include diabetes mellitus, alcoholic neuropathy, spinal cord injury, idiopathic orthostatic hypotension, and Shy-Drager syndrome (Table 32-3).[57-62] Administration of adrenergic blocking drugs and vasodilators may accentuate the predisposition to orthostatic hypotension in patients with primary neurogenic postural hypotension.

In the idiopathic form of orthostatic hypotension, postural hypotension is accompanied by relatively fixed heart rate, heat intolerance, anhidrosis, nocturnal polyuria, urinary and anal sphincter dysfunction, and impotency.[59,60] In the Shy-Drager syndrome, orthostatic hypotension is accompanied by multiple central nervous system manifestations and is referred to as *multiple*

system atrophy.[57,61]

The central nervous system manifestations in multiple system atrophy may be indistinguishable from those of idiopathic Parkinson's disease and may precede or follow the onset of orthostatic hypotension. The prognosis appears to be worse in patients with multiple system atrophy than in those with idiopathic orthostatic hypotension, with death often resulting from general debilitation and its complications. Severe supine hypertension may complicate the presence of orthostatic hypotension.

When the total or central blood volume is depleted in the presence of an intact autonomic nervous system, pallor, coldness of the extremities, tachycardia, and sweating are evident. Relative bradycardia may occur at the time of syncope, and the clinical presentation may be identical to that of neurocardiogenic syncope. When orthostatic hypotension is due to loss or severe impairment of autonomic reflexes, the syncope is associated with little or no change in heart rate, and there is an absence of the pallor, sweating, and other manifestations observed in patients with intact autonomic reflexes.

THERAPY

Effective therapy in postural hypotension is closely linked to an accurate diagnosis. Primary emphasis must be based on treatable causes, in particular, pharmacologically induced postural hypotension, blood volume loss, venous pooling, and reversible disease entities. A summary of treatment modalities currently applied among patients with chronic orthostatic hypotension is presented in Table 32-4.[2] The wide variety of recommended approaches reflects the frequently disappointing therapeutic response to each of these modalities. Commonly, multiple maneuvers are necessary to achieve optimum control of postural hypotension. Of singular importance is the need to have the patient avoid experiences, such as dehydration, that accentuate postural hypotension and to restrict the use of pharmacologic agents that induce blood volume depletion, vasodilation, and sympathetic blockade. *Patients should be instructed about simple adaptive maneuvers, including slow rising from a recumbent or sitting position, flexing of the calf muscles during assumption of the upright posture, and avoidance of prolonged immobility during standing*.[63,64] Erythropoietin administration to expand red blood cell mass and blood volume has been used to maintain pressure in the upright posture in certain cases of orthostatic hypotension.[65]

Table 32-4: Treatment of Chronic Orthostatic Hypotension

- Evaluation for reversible and accentuating disease entities
- Specific modalities for irreversible orthostatic hypotension
  - Mechanical measures
    - Head-up position of bed
    - Lower body compression garment
    - Slow motion and calf muscle flexing on arising
  - Volume expansion
    - High-salt diet
    - Fludrocortisone acetate
  - Pharmacologic agents
    - Sympathomimetics
    - Vasoconstrictors

Cerebrovascular Syncope

In patients with extensive occlusive disease of the origins of the brachiocephalic vessels, such as pulseless disease (e.g., aortic arch syndrome and Takayasu's arteritis), syncope is not uncommon.[2,66] With lesser degrees of cerebral occlusive disease, as with atherosclerotic narrowing, transient lowering of arterial pressure such as that immediately following assumption of the upright posture may be followed by vague symptoms suggesting impaired cerebral blood flow. In patients with cerebrovascular occlusive disease, a transient decrease in cardiac output and arterial pressure may provoke syncope at levels of arterial pressure that would otherwise be tolerated (see below, "Multifactorial Syncope").

Impairment or loss of consciousness in relation to changing positions of the head, particularly hyperextension and lateral rotation, has been attributed to mechanical narrowing of the vertebral arteries by skeletal deformities of the cervical spine. Such symptoms have been observed in patients with Klippel-Feil deformity, cervical spondylosis, and severe cervical osteoarthritis. Altered consciousness is often preceded by vestibular symptoms. When vertigo is a predominant symptom, the syndrome of benign postural vertigo must be considered.

Among patients with major occlusive disease of the carotid-vertebrobasilar arterial system, manual compression of the carotid artery as a test for carotid sinus hypersensitivity may induce syncope, at times associated with focal neurologic signs. The occurrence of syncope under such circumstances may be misdiagnosed as carotid sinus syndrome. The occurrence of a cerebrovascular accident following manual compression of the carotid sinus has been reported in patients with carotid disease, and *carotid sinus massage should be avoided in patients with symptomatic or suspected occlusive carotid vascular disease.*

Syncope in the *subclavian steal syndrome* is caused by major occlusive disease of the subclavian artery proximal to the origin of the vertebral artery. During upper extremity exercise, blood flow is shunted retrograde, by the circle of Willis, to the distal subclavian artery. The consequent decrease in cerebral circulation induces cerebral ischemia.[2,66] This syndrome is suggested by the findings of diminished brachial arterial pressure on the affected side, a bruit that is maximal over the supraclavicular area adjacent to the origin of the vertebral artery, and the induction of symptoms by exercise of the involved extremity.

Although focal neurologic symptoms and signs are the usual neurologic manifestations of cerebral emboli, transient loss of consciousness can be a primary presenting symptom. *Syncopal episodes are more likely to occur when atherosclerotic occlusive disease involves the vertebrobasilar system, with compromised perfusion to the medullary arousal center.* In vertebrobasilar vascular insufficiency, syncope or presyncope is nearly always preceded by symptoms of vertigo, diplopia, dysarthria, and ataxia. The episodes are generally attributed to microemboli arising from an atherosclerotic plaque, although vasospasm or postural hypotension may contribute (see Chap. 89).

THERAPY

The treatment of recurrent syncope in cerebrovascular disease is predicated on an accurate diagnosis. In this regard, it is essential to segregate the potential contribution of cardiac and vascular factors and their interplay. Anticoagulants and/or platelet antiaggregant agents are recommended for the prevention of embolic disease from the heart or central vessels (see Chap. 44). Surgical endarterectomy should be considered in carotid arterial occlusive disease.

Seizure Disorders

The various forms of syncope from the loss of consciousness during a generalized convulsive seizure are often differentiated on the basis of history alone.[67,68] Grand mal epilepsy as a cause of

sudden loss of consciousness is suggested by the dramatic nature of the onset of the attack, which is often preceded by an aura. Other observations that aid in distinguishing epilepsy are the absence of hypotension and cardiac arrhythmia (other than sinus tachycardia); the presence of sustained tonic-clonic convulsive movements with upturning of the eyes; prolonged unconsciousness; urinary incontinence; and postictal drowsiness, headache, and confusion. While any of these findings occasionally occur in episodes of syncope, the frequent association of these several events generally allows differentiation of epilepsy as its cause. In fact, it is common for patients with true syncope to be incorrectly diagnosed as having a seizure disorder. Akinetic seizures and absence (petite mal) seizures may be difficult to differentiate from syncope. The occurrence in childhood, a past history of recurrent episodes, and the absence of pallor in witnessed episodes are helpful diagnostic findings. *Temporal lobe seizures are the most likely form of epilepsy to masquerade as syncope.*

An abnormal electroencephalogram (EEG) between episodes of altered consciousness can aid in distinguishing a seizure disorder when clinical observations are not definitive, and in some instances continuous EEG and electrocardiogram (ECG) monitoring are required.

Carotid Sinus Hypersensitivity

Compression of the carotid sinus in normal persons is often associated with transient slowing of the heart rate and mild hypotension. In some patients, such stimulation is followed by a profound slowing of heart rate and/or a marked diminution of arterial pressure. This disorder is referred to as *carotid sinus hypersensitivity.*

There are three forms of carotid sinus syncope, as originally described by Weiss and Baker:[69] cardioinhibitory, vasodepressor, and mixed type.

CARDIOINHIBITORY TYPE

The cardioinhibitory type of carotid sinus syncope which is the most common, is associated with slowing of the heart rate secondary to marked sinus bradycardia, sinoatrial block, and/or high-degree AV block. Syncope in this instance is related to the prolonged asystole rather than to a fall in peripheral vascular resistance.

VASODEPRESSOR TYPE

The vasodepressor type of carotid sinus syncope is that form of the syndrome in which syncope occurs as a result of a primary decrease in arterial pressure in the absence of profound bradycardia. Presyncopal signs, such as nausea, sweating, and pallor, are usually not observed, and the fall in arterial pressure may be precipitous.

MIXED FORM

In the mixed form of carotid sinus syncope with bradycardia and hypotension, the vasodepressor component may not be evident until after atropine blockade or during cardiac pacing. Under such circumstances, carotid sinus massage uncovers the hypotension in the absence of bradycardia.

Carotid sinus syncope and presyncope are commonly found in elderly patients in whom symptoms of light-headedness and impaired consciousness may be initiated by relatively minor stimulation of the carotid sinus.[2] Carotid sinus hypersensitivity in the elderly is often associated with generalized atherosclerosis.

Manual carotid sinus compression in elderly persons enjoins caution whenever this maneuver is

attempted. Digital carotid massage should first be attempted with a very gentle and brief (2 to 4 s) compression, always when the patient is supine and with monitoring of the heart rate and blood pressure.[70-73] *The presence of carotid artery bruits is a relative contraindication to carotid massage.*

Carotid sinus syncope has been observed in patients with neoplasms, inflammatory masses, and lymph nodes in the neck adjacent to the carotid sinus.[74] Carotid sinus syncope is well established as a complication of carotid body and parotid tumors. In certain patients, carotid sinus hypersensitivity may be documented only when carotid sinus massage is performed in the upright position or during HUT studies with careful attention to the blood pressure response.

THERAPY

Thorough patient education concerning avoidance of carotid sinus pressure may be effective in preventing syncopal episodes. Anticholinergic and sympathomimetic agents may be tried, but inadequacy of drug therapy and the occurrence of side effects usually necessitate pacemaker therapy. AV sequential pacing appears to minimize the hypotensive effect of cardiac pacing and, hence, is the preferred form of pacemaker therapy in the mixed form of carotid sinus syncope. It is important that pacemaker effectiveness be verified objectively through observation of the effect of carotid sinus stimulation on cardiac rhythm and arterial pressure following pacemaker insertion.

Situational Syncope

The term *situational syncope* has been applied to a group of syndromes that is defined by the circumstances that precipitate the event. In the past, the syncope in these disorders has been attributed mainly to mechanical factors. Recent observations suggest that, at least in part, neurocardiogenic factors contribute to the syncope.[75]

COUGH SYNCOPE

Also called laryngeal vertigo, tussive syncope, and posttussive syncope, cough syncope is associated with loss of consciousness following a paroxysm of vigorous coughing. It is often seen in robust men and children but rarely in women. Cerebral blood flow is impaired by the marked increase in cerebrospinal fluid pressure during coughing, which increases cerebrovascular resistance. There is also a *concussive effect* transmitted via the cerebrospinal fluid. Reflex-induced sinus bradycardia, sinus arrest, and AV block have been observed in patients with cough syncope.[76]

In the treatment of cough syncope, the patient should be informed of the deleterious effects of vigorous coughing. Cessation of smoking and initiation of bronchodilator and anti-inflammatory therapy for associated bronchitis are mandatory for the prevention of cough-induced syncope.

SWALLOWING, OR DEGLUTITION, SYNCOPE

Deglutition syncope has been reported in association with tumor, diverticulum, achalasia, stricture, and spasm of the esophagus. In some patients, no abnormality can be identified radiologically or endoscopically. Syncope is usually associated with sinus bradycardia, sinus arrest, or high-degree AV block.[77]

Similar mechanisms have been implicated in syncope following distension of the viscera, glossopharyngeal neuralgia, fainting associated with irritation of the pleura or peritoneum, and cardiac asystole associated with esophagoscopy or bronchoscopy.[78]

VALSALVA SYNCOPE

Valsalva syncope is related to prolonged increases in intrathoracic pressure that may be observed during a sustained Valsalva maneuver. With prolonged exhalation against a closed glottis, there is a progressive fall in venous return, arterial pressure, and cardiac output.[2] These hemodynamic changes may be sufficient to impair cerebral circulation. An episode of Valsalva syncope may be the first indication of the presence of a disorder predisposing an individual to syncope (e.g., cerebrovascular occlusive disease or sick sinus syndrome). Instruction to the patient regarding avoidance of sustained Valsalva maneuvers is essential in preventing recurring episodes.

MICTURITION SYNCOPE

Micturition syncope is often seen in adult men with nocturia. During or immediately following voiding, there is a loss of consciousness, often without premonitory symptoms. The ingestion of large quantities of alcoholic beverages before retiring is common.[2,79] A similar type of syncope may be observed following drainage of the distended bladder or after removal of large quantities of ascitic fluid. The loss of consciousness in these circumstances may be related to bradycardia and a sudden reflex decrease in peripheral arterial resistance induced by the precipitous fall of intraabdominal volume. The loss of consciousness of typical micturition syncope is precipitated by such factors as the Valsalva maneuver in the upright posture and the peripheral vasodilation associated with a warm bed and recent alcohol consumption.

DEFECATION SYNCOPE

Defecation syncope occurs most commonly in the elderly, usually after arising from bed at night or during manual disimpaction of the rectum.[2,80] It has been attributed to sudden decompression of the rectum. Valsalva-related syncope could also explain some instances of this form of syncope. Many patients with defecation syncope have underlying gastrointestinal or cardiovascular disease.

DIVER'S SYNCOPE

Diver's syncope is an unusual and poorly understood form of loss of consciousness or even sudden death that may occur in underwater diving. In some instances diver's syncope may represent a form of neurocardiogenic syncope. Hypoxia and bradycardia of the diving reflex may be contributing factors.

POSTPRANDIAL SYNCOPE

Hypotension postprandially may result in presyncope and/or syncope and is most common in the elderly. The mechanisms of postprandial hypotension and syncope are not fully understood. Possible contributing factors include inadequate sympathetic nervous system compensation for meal-induced splanchnic blood pooling, impairments in baroreflex function, inadequate postprandial increase in cardiac output, impairment of peripheral vasoconstriction, and release of gastrointestinal peptides.[81,82]

TREATMENT

Therapy of situational syncope should be individualized and should be addressed to the specific circumstance associated with it. Episodes of syncope may be prevented by anticholinergic drugs such as atropine if they are administered prior to a procedure. Other measures include avoidance of vasodilators before meals and/or resting in a supine position after meals for patients with postprandial hypotension and sitting while urinating for men with micturition syncope. Octreotide, a somatostatin analog, has been shown to be effective in patients with postprandial hypotension,

but it is expensive and must be given parenterally.[81,82]

Metabolic Syncope

HYPOXIA-RELATED SYNCOPE

Hypoxia may induce syncope that is related directly to a lack of oxygen or to an episode of neurocardiogenic syncope initiated during a period of oxygen lack. In the presence of cardiovascular disease, pulmonary insufficiency, and anemia, symptoms of hypoxia occur at lesser levels of oxygen deprivation. The impairment of consciousness due to hypoxia is accompanied by sinus tachycardia, while arterial pressure is usually normal. Short-term exposure to moderate altitude may be related to otherwise unexplained syncope in healthy, young adults. The environmental setting in which impaired consciousness due to hypoxia occurs usually leaves little difficulty in its differentiation from other forms of syncope.

HYPOGLYCEMIA-RELATED SYNCOPE

This form of syncope may be associated with weakness, sweating, a sensation of hunger, confusion, and altered consciousness. The symptoms are unrelated to posture and usually respond promptly to food ingestion or intravenous glucose administration. Impaired consciousness is usually associated with sinus tachycardia and is rarely accompanied by hypotension. In contrast to syncope of circulatory origin, it is gradual in onset. Hypoglycemia has been implicated as a possible factor that may trigger neurocardiogenic syncope.

HYPERVENTILATION, PANIC ATTACKS, AND SYNCOPE

In normal persons, anxiety is accompanied by varying degrees of hyperventilation. In the hyperventilation syndrome or in a panic episode, anxiety is associated with an inordinate degree of hyperventilation. Symptoms of hypocapnia and alkalosis may dominate the clinical picture. During the episode, the patient may complain of a tightness in the chest and a feeling of suffocation. These symptoms may be followed by confusion, a sense of unreality, bewilderment, light-headedness, and a feeling of panic. Symptoms of palpitation, precordial oppression, and dyspnea may suggest an acute cardiac or pulmonary catastrophe. Digital and circumoral paresthesias may develop and, in severe cases, may be accompanied by carpopedal spasm, which is probably related to alkalosis-induced decreases in serum ionized calcium. The symptoms may be protracted and persist while the subject is sitting or recumbent. During hyperventilation, there is slight hypotension but no profound fall in arterial pressure, while the heart rate is rapid. Although mentation is impaired, complete loss of consciousness rarely occurs. Typical neurocardiogenic syncope may be superimposed, making identification of the syndrome more difficult. *The induction of a typical episode by voluntary hyperventilation is helpful in distinguishing this syndrome and aids in educating the patient regarding the prevention and control of attacks.*

Other Forms of Syncope or Conditions Mimicking Syncope

MIGRAINE-RELATED SYNCOPE

Symptoms suggesting syncope are unusual in ordinary types of migraine. In rare instances in which the basilar arterial system is involved (as opposed to the more usually affected carotid system), the premonitory aura of migraine terminates in a period of unconsciousness of several minutes' duration. The unconsciousness is slow in onset and may be preceded by a dreamlike state. When the patient awakens, there is severe headache, typically in the occipital area. This form of migraine usually afflicts young women and has a strong menstrual association. The symptoms in syncopal migraine may suggest hyperventilation and/or hysterical syncope.

HYSTERICAL SYNCOPE

Altered consciousness of circulatory origin may be mimicked by hysteria. Hysterical episodes occur most frequently in young adults, often with severe emotional illness, and generally in the presence of an audience.[83] The individual slumps gently, even gracefully, to the floor or in a convenient chair or sofa, typically without injury or awkwardness. The patient may be motionless or may exhibit symbolic restrictive movements. Episodes are of varying duration and may last an hour or more. Although the patient is unresponsive to verbal stimulation, there is evidence, such as eyelid movement, that consciousness is well preserved, and no abnormalities in pulse, arterial pressure, or skin color are evident.

Chapter 32: DIAGNOSIS AND MANAGEMENT OF SYNCOPE

CARDIAC SYNCOPE

Either severe obstruction of cardiac output or disturbances of cardiac rhythm can produce syncope of cardiac origin.[2,84-95] Obstructive lesions and arrhythmias frequently coexist; indeed, one abnormality may accentuate the other. Common disorders associated with cardiac syncope are listed in Table 32-5.

Table 32-5: Common Disorders Associated with Cardiac Syncope

○ Left-sided heart
○ Aortic stenosis
○ Hypertrophic cardiomyopathy
○ Prosthetic valve malfunction
○ Mitral stenosis
○ Left atrial myxoma (rare)
○ Right-sided heart
○ Eisenmenger syndrome
○ Tetralogy of Fallot
○ Pulmonary embolism
○ Pulmonary stenosis
○ Primary pulmonary hypertension
○ Cardiac tamponade
○ Cardiac arrhythmia
○ Sinoatrial disease
○ Atrioventricular block
○ Supraventricular tachycardia
○ Ventricular tachycardia/fibrillation
Pacemaker related

Syncope Related to Obstruction of Cardiac Output

Obstruction to cardiac output sufficient to cause syncope may occur on the left or right side of the heart. Syncope, particularly that occurring with effort, is a major symptom of aortic stenosis and is often the initial presentation. The mechanisms are unclear, but studies suggest a reflex fall in peripheral vascular resistance as the usual cause. Failure of cardiac output to increase adequately during exercise, while peripheral resistance decreases, may play a role (see also Chap. 56). Transient arrhythmias can also induce syncope in aortic stenosis. Syncope associated with effort (often occurring immediately after effort) is observed in patients with hypertrophic

cardiomyopathy as well. Nonexertional syncope related to acute decreases in preload or afterload, to inotropic stimulation, or to transient arrhythmias may also occur in hypertrophic cardiomyopathy (see also Chap. 67). Left-sided heart prosthetic valve malfunction can produce transient and at times profound obstruction to blood flow with syncope (see Chap. 60). A left atrial myxoma may obstruct left ventricular filling, leading to low cardiac output and syncope. The obstruction of left ventricular inflow in atrial myxoma may be posturally induced (see also Chap. 77). Mitral stenosis can produce cardiac syncope but usually does so only when tachycardia or other arrhythmias supervene (see also Chap. 57).

Primary pulmonary hypertension and pulmonary hypertension secondary to congenital heart disease may both be complicated by syncope, particularly effort-related syncope. In these conditions, limitation of right ventricular outflow markedly inhibits the cardiac output during increased peripheral demand. The fall in peripheral resistance in the presence of an inability to increase cardiac output may result in profound hypotension. A reflex fall in peripheral resistance similar to that which occurs with aortic stenosis may play a role. In a young patient without a cardiac murmur who presents with syncope during or shortly after exertion, primary pulmonary hypertension should be considered (see also Chap. 52). In pulmonary stenosis and pulmonary embolism, similar mechanisms may account for syncope. Pulmonary embolism as a cause of syncope should also be suspected in paraplegic patients.[96] In tetralogy of Fallot, the magnitude of flow through the right-to-left shunt increases when systemic resistance falls with effort, since the right ventricular outflow obstruction is usually fixed. This shunting results in marked arterial hypoxia, which may precipitate a syncopal episode (see also Chap. 63).

Cardiac tamponade, which affects both the right side and the left side of the heart, can produce syncope, but this is extremely rare. The likelihood of syncope is increased by concomitant arrhythmias.

Syncope Related to Cardiac Arrhythmia

Arrhythmias are a common cause of syncope and must be considered in any patient, particularly when cardiac disease is present. Either extreme of ventricular rate-bradycardia or tachycardia-can depress cardiac output to the point of critical hypotension with cerebral hypoperfusion and syncope. As noted earlier for other forms of syncope, a neurocardiogenic reaction may be precipitated by the hemodynamic effects of arrhythmias (see also Chaps. 23 and 24). The most common arrhythmias producing syncope or presyncope are profound sinus bradycardia, sinoatrial exit block or sinus pause, high-grade AV block, supraventricular tachycardia and ventricular tachycardia/fibrillation. Although arrhythmias occur in the absence of demonstrable underlying cardiac disease, they are usually secondary to such disorders as ischemic heart disease, cardiomyopathy, valvular heart disease (including mitral valve prolapse), and primary conduction system disease.

Primary degenerative disease of the sinus node and the specialized conduction tissue is the most common cause of sinoatrial disease (*sick sinus syndrome;* see Chap. 24). The sick sinus syndrome may be manifested by persistent or episodic sinus bradycardia or sinoatrial exit block, often with impaired junctional escape rhythm. The presence of alternating sinus bradycardia or sinoatrial block with paroxysmal supraventricular tachycardia of diverse types is quite common and is referred to as the *bradycardia-tachycardia syndrome. Syncope often occurs with asystole or bradycardia at the termination of tachycardia, when overdrive suppression of the sinoatrial or junctional pacemakers is present.*[2] A high incidence of associated AV and intraventricular conduction defects occurs in the sick sinus syndrome. AV block, impaired junctional escape rhythm, or ventricular arrhythmias may actually be responsible for syncope in the setting of sick sinus syndrome.

High-grade AV block may be due to disease of either the AV node or the His-Purkinje system. Block of the AV node is usually associated with a functional junctional pacemaker and a normal QRS complex, whereas AV block due to disease of the His-Purkinje system is usually associated with a wide complex idioventricular escape rhythm, which may be quite slow. Bifascicular block associated with a prolonged PR interval is associated with a substantial risk of developing high-grade AV block and syncope. Progression to high-grade AV block in patients with bifascicular block and a normal PR interval is less common. Ventricular tachycardia can cause syncope in patients with AV block or other bradycardic rhythms (see Chap. 24).

Sinus bradycardia, AV block, or cardiac asystole may be mediated by reflex vagal mechanisms and have been observed in a variety of disease states or during diagnostic procedures. Ventricular asystole (usually sinus arrest, although AV block can occasionally be noted) is most commonly due to neurocardiogenic syncope. Transient sinus bradycardia or AV block can also occur in apparently healthy young individuals; certain of these patients may have mitral valve prolapse.[93] Paroxysmal supraventricular tachycardias usually do not produce syncope in young individuals. Syncope, however, may occur in individuals who have accessory AV pathways due to the Wolff-Parkinson-White (WPW) syndrome, wherein supraventricular tachycardia is associated with a very rapid ventricular response. Studies have shown, though, that syncope during supraventricular tachycardia may be related to vasomotor factors and not be due solely to heart rate (Fig. 32-2).[97,98] AV node reentry, atrial fibrillation, or atrial flutter may be associated with a rapid ventricular rate in the setting of baseline short PR interval, or tachycardia occurring during or after exercise may cause syncope. Patients with cardiac disease, particularly obstructive outflow disorders, and older individuals may more commonly have hypotension significant enough to cause cerebral hypoperfusion and syncope.

Paroxysmal ventricular tachycardia may produce syncope at any age. The tachycardia is usually a manifestation of cardiac disease in which there are structural abnormalities and/or ischemia. Ventricular tachycardia is the most common arrhythmic cause of syncope in most series. In some patients, ventricular and supraventricular tachycardia may coexist (see Chap. 24).

Syncope may occur with ventricular tachycardia in the setting of the long QT syndrome. The long QT interval syndrome may be congenital or acquired (see Chaps. 11 and 24). The recognition of the long QT syndromes depends on demonstration of QT prolongation and of recurrent syncope, which is almost always due to ventricular arrhythmia. The ventricular arrhythmia is usually torsades de pointes. Ventricular tachycardia in the long QT syndromes is often triggered by exercise or stress reaction. A pause preceding the onset of tachycardia is common since the early after-depolarizations thought responsible for torsades are bradycardia dependent.[94,99]

It is particularly important to recognize the polymorphic ventricular tachycardia associated with acquired long QT syndromes, because it is a potentially life-threatening side effect of many drugs and metabolic abnormalities. The most frequent causes of acquired long QT syndromes are antiarrhythmic drugs and electrolyte disorders (hypokalemia and hypomagnesemia).

A variety of other drugs may produce arrhythmias or arrhythmia aggravation, resulting in syncope or presyncope. Beta-blocking drugs, calcium-channel-blocking agents, sotalol, and amiodarone are some of the more common agents that may cause significant sinus bradycardia or AV block. Digitalis may occasionally cause sinoatrial exit block or AV block, particularly in patients with sinoatrial or AV node disease. Supraventricular and ventricular tachycardias can be a result of digitalis therapy, particularly in patients with organic heart disease and hypokalemia. Theophylline and beta agonists, used for therapy of chronic obstructive pulmonary disease, may precipitate ventricular or supraventricular arrhythmias. Therapy with diuretics often causes hypokalemia and hypomagnesemia, which predispose individuals to supraventricular and ventricular arrhythmias. Both caffeine and alcohol may precipitate either atrial or ventricular

tachycardia.

In patients with an artificial ventricular pacemaker, syncope may be secondary to pacemaker malfunction or to the pacemaker syndrome (see Chap. 31). Dual-chamber pacemakers can produce pacemaker-mediated tachycardias when there is retrograde conduction of the ventricular impulse to the atria. Improvements in technology have reduced the incidence of this complication.[100,101]

DIAGNOSTIC EVALUATION OF SYNCOPE ASSOCIATED WITH CARDIAC DISEASE

While the history and physical examination often establish the diagnosis of obstructive cardiac syncope, laboratory studies are usually required for the determination of the severity of the disorder. Cardiac catheterization is required when corrective cardiac surgery is contemplated.

By far, the most challenging diagnostic evaluation occurs when arrhythmic cardiac syncope is suspected. Such patients often have evidence of underlying cardiovascular disease, which, when present, portends a poor prognosis. Thus, diagnostic studies directed to the nature and severity of the underlying cardiac disease must be pursued in addition to the arrhythmia evaluation.[102]

The various diagnostic tests used for the evaluation of arrhythmic syncope are listed in Fig. 32-3. Because of the transient nature of most arrhythmias, the routine ECG is generally of limited value. It is, however, very useful in identifying patients with abnormalities that may predispose individuals to syncope, such as prior infarction, WPW pattern, and AV or bundle branch block.

The technique of signal-averaged ECG for detecting late potentials can be used as a noninvasive screening test for detecting a high-risk subset of patients prone to lethal ventricular arrhythmias. The accuracy of the signal-averaged ECG in predicting the induction of sustained monomorphic ventricular tachycardia in high-risk patients with coronary artery disease who undergo electrophysiologic studies is good. The signal-averaged ECG may be helpful in some instances of other myocardial disease such as right ventricular dysplasia.[103-107]

Exercise testing can directly provoke arrhythmias in patients with a history suggesting exercise-induced arrhythmias. It should be performed when exertional arrhythmias are suspected but not documented by ambulatory monitoring or when ischemia is suspected (see also Chap. 14).[108,109] Continuous ECG monitoring is a widely used screening test for suspected arrhythmic syncope. It has low yield in unselected patients. *It is important to recognize that one 24-h monitoring period may not be sufficient for detecting transient rhythm disturbances. The diagnostic yield, moreover, increases only slightly with more prolonged monitoring* (see also Chap. 25).[108-110]

When ambulatory monitoring does not document an arrhythmia, a patient-activated electrocardiographic device (event recorder) may prove efficacious. This type of monitoring is effective in documenting infrequent arrhythmia. It should not be used in patients with suspected life-threatening arrhythmias.[111-113] Extended monitoring with an implantable loop recorder has been demonstrated to provide diagnostic ability in approximately two-thirds of patients with syncope of undetermined cause.[114,115]

When noninvasive testing is inconclusive for the diagnosis of suspected arrhythmic syncope, an electrophysiologic study should be performed on high-risk patients (i.e., those with underlying heart disease, suspicious arrhythmia by ECG monitoring, or recurrent syncope). Patients without identifiable heart disease are less likely to have the cause of syncope identified by electrophysiologic study. The cause of syncope most commonly identified by electrophysiologic study is ventricular tachycardia.

Electrophysiologic studies are useful in stratifying risk among symptomatic patients with bundle branch block or patients with bifascicular block. Patients with normal electrophysiologic study results have a favorable prognosis even without treatment. Patients undergoing permanent pacing on the basis of electrophysiologic testing also have a favorable prognosis, with a low rate of symptom recurrence.[116-121]

The prognosis in patients with syncope due to supraventricular tachycardia is usually good, since therapeutic approaches are available (i.e., drugs and radiofrequency ablation). The prognosis in patients with inducible ventricular tachycardia is less favorable but is improved when specific therapy can be demonstrated to inhibit the inducibility of ventricular tachycardia or with the use of an implantable cardioverter-defibrillator.

TREATMENT OF CARDIAC SYNCOPE

Obstructive Heart Disease

For patients with syncope caused by obstructive heart disease, cardiac surgery is often the treatment of choice.[2] Patients with hypertrophic cardiomyopathy and syncope may respond well to pharmacologic therapy. Recent studies have suggested that an AV sequential pacemaker might control symptoms in certain patients with hypertrophic cardiomyopathy.[122-130] In rare cases with severe obstruction and persistent symptoms, surgery must be considered (see Chap. 67). Among all patients with obstructive heart disease and recurrent syncope, the diagnosis of fixed pulmonary hypertension is most difficult to treat because effective therapeutic options are limited (see Chap. 52).

Arrhythmic Syncope

A detailed discussion of therapy for cardiac arrhythmias is presented in Chap. 24. Some general principles of arrhythmia management as they apply to patients with syncope are summarized here. Treatment of arrhythmic syncope requires accurate definition of the arrhythmia associated with syncope or presyncope.

The bradycardic rhythm disturbances responsible for syncope, primarily AV and sinoatrial pauses or exit block, usually require the implantation of a pacemaker. Patients receiving drugs that cause or contribute to the bradyarrhythmia, however, may benefit from withdrawal or substitution of the offending agent. Patients with bradycardia-tachycardia syndrome usually require pacemaker therapy, because the antiarrhythmic agents required for control of the tachycardia will often further suppress sinoatrial function.

Implicit in the approach to the tachycardias causing syncope is the accurate diagnosis of a specific tachycardia. The definition of the tachycardia and the response to antiarrhythmic therapy are often best achieved in the electrophysiologic laboratory. Patients with syncope due to supraventricular tachycardia associated with an accessory pathway are most often approached with catheter ablation of the accessory pathway.[131,132] Catheter ablation is also a successful mode of therapy in patients with AV nodal reentry supraventricular tachycardia or other supraventricular tachycardias associated with a rapid heart rate (see Chap. 28).

Therapy of paroxysmal ventricular tachycardia responsible for syncope is best guided by pharmacologic testing in the electrophysiologic laboratory.[133-139] Predictive accuracy of therapeutic effectiveness due to antiarrhythmic agents is higher with electrophysiologic testing than with ambulatory monitoring or exercise testing. Empiric drug therapy, except for amiodarone, for ventricular tachycardia causing syncope appears to offer no benefit. Other

modalities of therapy for ventricular tachyarrhythmias include surgical ablative techniques guided by catheter mapping, antitachycardia pacing, automatic internal cardioverter-defibrillator (see Chap. 30), and catheter ablation (see Chap. 28). The operative risk is quite high with surgical ablation of tachycardia, although the success rate is also high. Antitachycardia pacing with defibrillation capability is an effective approach to tachycardia termination and prevention of sudden death.

Polymorphic ventricular tachycardia in the setting of a long QT interval (torsades de pointes) is often secondary to drug therapy, particularly antiarrhythmic drug use. The potential offending drug should be stopped. Acute therapy includes intravenous magnesium and measures to increase the heart rate and shorten electrical diastole (intravenous isoproterenol or cardiac pacing). Treatment of polymorphic ventricular tachycardia associated with a congenitally prolonged QT interval is discussed in Chap. 24.

Pacemaker-induced hypotension and syncope are rectified by changing from ventricular pacing to AV sequential pacing when hypotension due to loss of atrial transport or neurocardiogenic response is responsible for symptoms. Identification of pacemaker-mediated tachycardia usually requires only pacemaker programming changes. Pacemaker malfunction or myopotential inhibition requires a change in programming or replacement of the defective part of the system.

Chapter 32: DIAGNOSIS AND MANAGEMENT OF SYNCOPE

SYNCOPE OF UNDETERMINED CAUSE

Despite careful diagnostic evaluation, the cause of syncope often cannot be defined. Unexplained syncope probably has a broad spectrum of etiologies. The varying mortality rate among patients with syncope of undetermined cause probably reflects the varying incidence of undetected cardiac syncope. A certain number of these patients probably have experienced syncope of multiple causes.

Chapter 32: DIAGNOSIS AND MANAGEMENT OF SYNCOPE

SPECIAL PROBLEMS IN SYNCOPE

Syncope in the Elderly

Elderly persons are particularly prone to develop syncope or presyncope. The aging process can result in diminished cerebral oxygen delivery by a variety of physiologic mechanisms, including decreased cerebral blood flow from low cardiac output, cerebral vascular disease, decreased hemoglobin, and lower arterial P_{O_2} . In addition, cerebral arteriolar sclerosis may be present and may necessitate a normal arterial perfusion pressure. Thus, many older patients have only marginal cerebral oxygen delivery at rest.[140-143] Physiologic defenses against a fall in blood pressure may also be impaired as discussed previously.

The aged may also suffer from multiple sensory deficits (e.g., in vision, vestibular function, and peripheral sensory nerve function), variable degrees of dementia, bradykinesis, arthritis, and muscle weakness, all of which enhance the likelihood of a fall when cerebral perfusion is marginal. *Drop* attacks, in which muscle tone in the lower extremities is lost, are frequent in the elderly and must be distinguished from syncope. Carotid sinus hypersensitivity also is relatively common in the elderly, as is postprandial syncope; these entities should be evaluated as discussed previously. *The elderly frequently have multisystem disease and are likely to be taking several medications, sometimes in excessive amounts, that may aggravate the tendency to syncope* (*e.g., antihypertensive drugs, diuretics, vasodilators, antiarrhythmic drugs, or psychoactive drugs*).

Arrhythmias are common in elderly individuals, especially in those presenting with syncope. Syncope is a significant contributor to unexplained automobile accidents among the elderly and should be suspected when external causes are not apparent.[144-146]

In the elderly, syncope may be the presenting complaint for common disorders such as pneumonia, viral illness, acute myocardial infarction, or occult hemorrhage. Thus, the management of syncope in the aged often requires initial management of underlying diseases, with subsequent evaluation to determine whether such therapy controls syncope.

Multifactorial Syncope

In many instances, syncope requires that a constellation of events occur, either simultaneously or in sequence. Without the full complex, the patient may note only light-headedness or perhaps no definable symptoms. A carefully recorded history is required to elucidate such complex presentations.

Transient abnormalities such as fever, fatigue, hypoglycemia, or drug ingestion may increase the likelihood of syncope. Coexisting diseases may decrease the patient's physiologic defenses for maintaining adequate cerebral perfusion to sustain consciousness. A cardiac arrhythmia that ordinarily would not produce syncope may become a contributory factor when other predisposing factors are present (Fig. 32-4). With respect to combined causes of syncope, it is notable that, in the original description of Adams-Stokes syncope, the patients exhibited a permanently slow pulse rate accompanied by aortic stenosis.

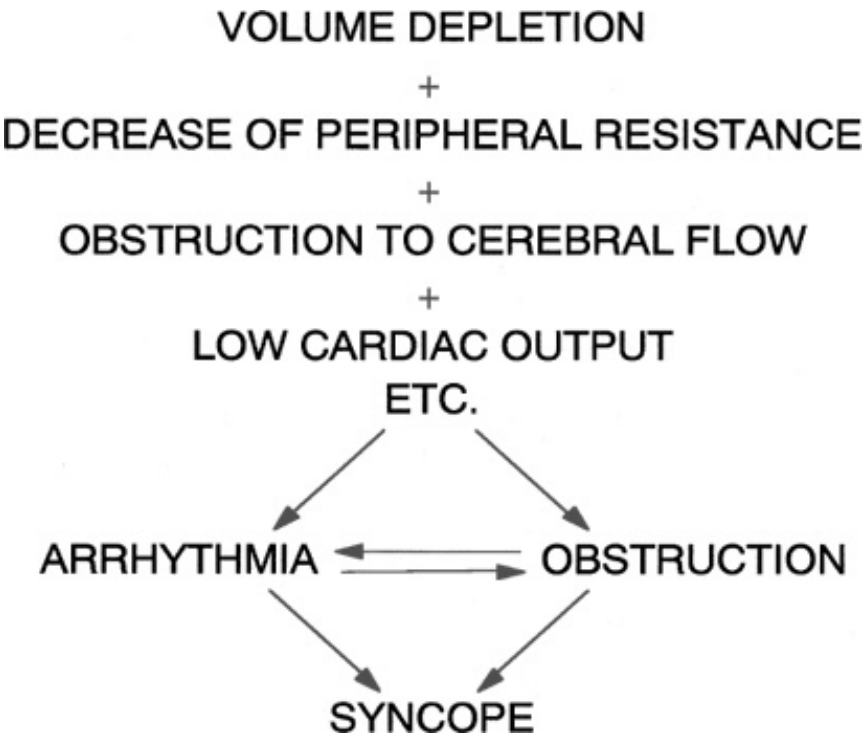

Figure 32-4: Frequently, multiple factors must be present simultaneously or in sequence for syncope to occur as a result of an arrhythmia or obstruction to cardiac output. (From Boudoulas H and Lewis RP.[159] Reproduced with permission from the publisher and authors.)

The development of the neurocardiogenic reaction may determine whether a given stimulus initiates syncope. This relationship has been shown in such diverse causes of syncope as aortic stenosis, vasodilator drug therapy, volume loss, pulmonary embolism, tachyarrhythmias, pacemaker syndrome, postprandial state in the elderly, and after exercise. A common pathophysiologic mechanism that may trigger neurocardiogenic syncope is diminished venous return to the right side of the heart.

Syncope and Sudden Death

Sudden death is common among those with known cardiac syncope (both obstructive and arrhythmic), but occasionally sudden death may also occur in presumptive noncardiac syncope and syncope of unknown cause. It would appear therefore that, in some patients, syncope is a harbinger of sudden death. Patients with advanced heart failure and syncope are at especially high risk for sudden death regardless of the etiology.[147-149] Syncope is also associated with a high mortality rate in patients with hypertrophic cardiomyopathy. It is not always clear to what extent the occurrence of syncope per se is a risk factor for sudden death or whether the risk is more related to the underlying disease.

Recurrent Syncope

In up to one-third of all patients with syncope, it is a recurring event. For most patients, the persistence of syncope increases morbidity from trauma but does not increase mortality. Such recurrences most often reflect a lack of effective therapy and/or a failure to establish the correct diagnosis.

Unexplained syncope in patients with negative initial diagnostic studies has a broad spectrum of etiologies, the most common of which is bradycardia. An implantable long-term monitoring device is useful for establishing a diagnosis when symptoms are recurrent but too infrequent for

conventional monitoring techniques.[114,115,150] Recurrent syncope is particularly common in a subset of patients with mitral valve prolapse in whom dysautonomia, arrhythmia, and hypovolemia all play a role.[93] In certain patients with unexplained recurrent syncope, especially in individuals with multiple physical symptoms, screening for psychiatric disorder may be necessary. In patients with recurrent syncope, advice regarding the avoidance of certain activities, such as working with dangerous equipment, is needed and, in some cases in which public safety is involved, a change in jobs is required (e.g., pilots or bus drivers).

Exercise and Syncope

Individuals with a history of syncope associated with activity and who participate in physical activities or competitive athletics constitute a special problem. Since exercise syncope may be a manifestation of serious underlying cardiac disease, complete evaluation is indicated to define the cause of syncope prior to recommendation for participation in sports. *Identification of myocardial abnormalities by physical examination and echocardiogram is paramount to the prevention of potential sudden cardiac death.*[151-158]

Syncope may occur during or immediately after exercise. The most common causes of exercise-induced syncope are shown in Fig. 32-5. Neurocardiogenic syncope is not uncommon in highly trained individuals with high resting vagal tone, but caution should be used in making this diagnosis without first excluding underlying structural myocardial abnormality. HUT studies can be used to assess patients at risk for neurocardiogenic syncope, but this test may lack sensitivity and specificity in highly trained individuals. Exercise testing is useful, especially if the syncope is exercise induced. Exercise-induced ventricular ectopy, sustained ventricular tachycardia, or rapid supraventricular tachycardia requires electrophysiologic evaluation and general cardiologic evaluation.

Final recommendation and advice to participate in sports with high, moderate, or low intensity should be individualized. Recommendations should be balanced between restricting activity unduly and reducing chance of death or injury from the participation in sports.

Chapter 32: DIAGNOSIS AND MANAGEMENT OF SYNCOPE

DIAGNOSTIC EVALUATION OF SYNCOPE: AN OVERVIEW

In the initial approach to the diagnosis of syncope, it is essential to distinguish the underlying cause in terms of the three basic categories outlined in Table 32-1. This differentiation is accomplished in a majority of patients by a history (Fig. 32-6), physical examination (Fig. 32-7), and ECG (Fig. 32-8) and is supplemented by routine laboratory studies, including echocardiography (Fig. 32-9). Further, Figs. 32-5 and 32-10 provide a useful framework for initiating a diagnostic evaluation of syncope based on age and in situations when syncope is induced with physical activities.[159-164]

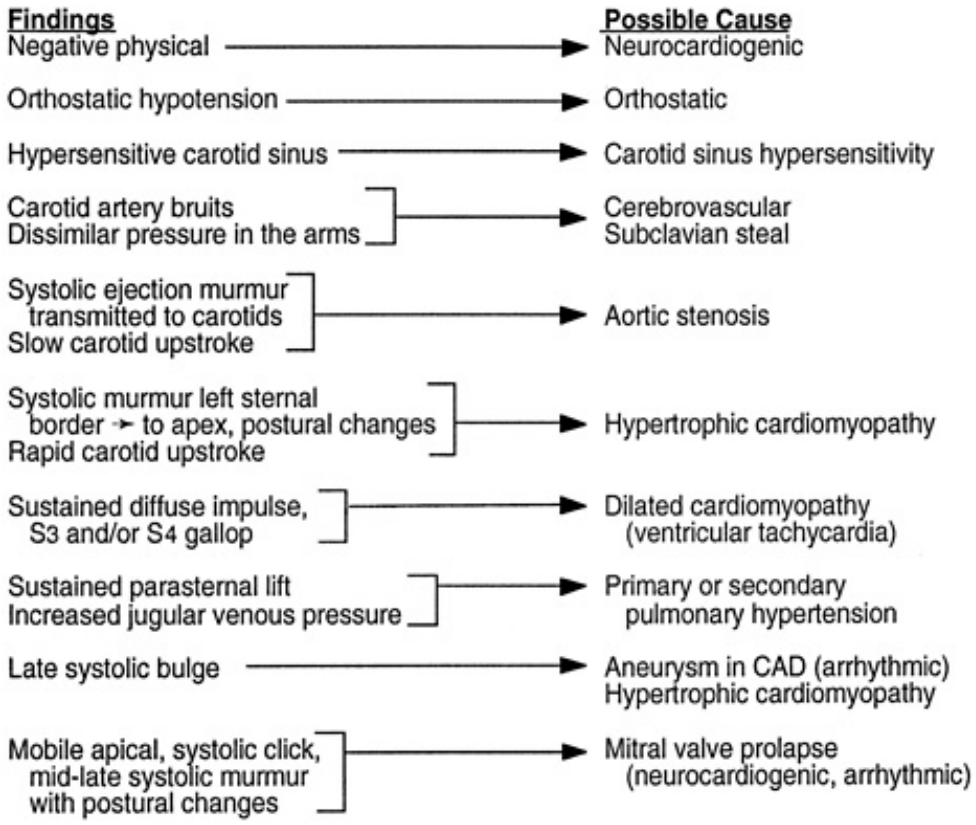

Figure 32-7: Differential diagnosis of syncope based on physical examination. CAD = coronary artery disease.

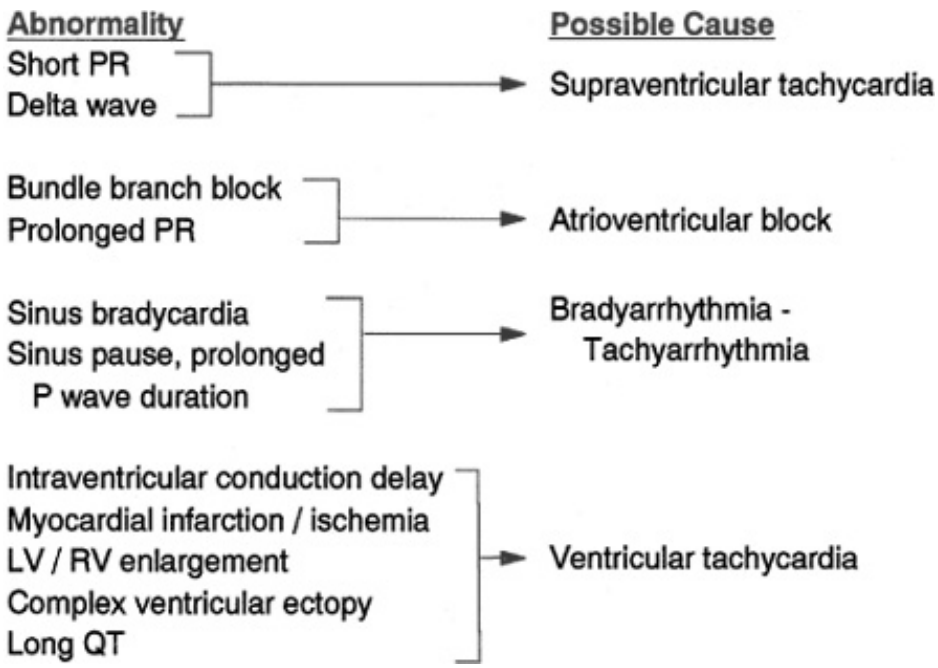

Figure 32-8: Differential diagnosis of syncope based on the electrocardiogram. LV/RV = left ventricular/right ventricular.

The extent of evaluation should initially be predicated on the estimation of mortality and morbidity risk, which is high in cardiac syncope or syncope associated with cardiac disease and low in syncope without structural heart disease. Although cost effectiveness in diagnostic testing should be practiced, the need for an assiduous search should not be dismissed when lethal disease is suspected.

Complete evaluation of syncope is required for the elderly and for patients with suspected arrhythmic syncope (Fig. 32-11). When patients in such a selected group undergo a thorough evaluation, including an electrophysiologic study, an arrhythmic basis for syncope can be found in the majority of patients. *Negative results are often as important as actual identification of an arrhythmia, since the negative evaluation usually denotes a favorable long-term prognosis.* Long-term follow-up suggests that both morbidity and mortality risks can be reduced by therapy guided by electrophysiologic study results. Unfortunately, no controlled studies exist (or are likely to be done) to establish these benefits conclusively.

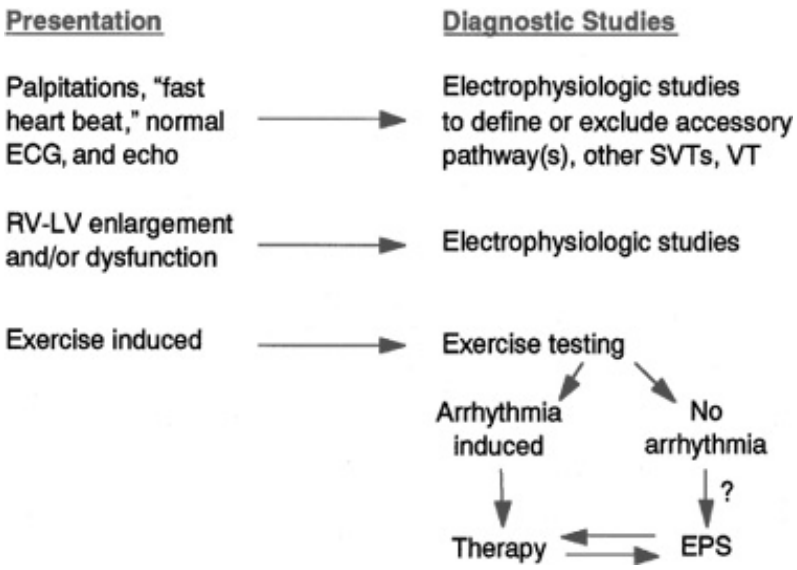

Figure 32-11: Diagnostic evaluation of patients with suspected arrhythmic syncope. RV-LV = right ventricular/left ventricular; SVT = supraventricular tachycardia; VT = ventricular tachycardia; ECG = electrocardiogram; ECHO = echocardiography; EPS = electrophysiologic studies.

The diagnostic evaluation of patients with syncope of unknown cause presents a perplexing problem, particularly when syncope occurs repeatedly and because it may be a harbinger of sudden death. As the understanding of the mechanisms and the breadth of causes of syncope improves (particularly the role of multiple causes), it is reasonable to suspect that the incidence of patients with syncope of unknown cause will be further diminished in the future. In certain cases, devices with extended monitoring capabilities can be used.

Chapter 33:

SUDDEN CARDIAC DEATH

Authors: Duane S. Pinto, Mark E. Josephson

DEFINITION OF SUDDEN CARDIAC DEATH

Sudden cardiac death describes the unexpected natural death due to a cardiac cause within a short time period from the onset of symptoms in a person without any prior condition that would appear fatal. It is most often due to a sustained ventricular tachyarrhythmia. Disparities in definitions have led to differences in the classification of deaths and have influenced the outcomes of studies looking at the incidence of sudden cardiac death.[1-11] The definition of sudden cardiac death should include the time interval from onset of the symptoms leading to collapse and then to death, the unexpected nature of the event, and the specific cause of death. Although many cardiovascular disorders increase the risk of sudden cardiac death, the presence or absence of preexisting cardiovascular disease is not necessary. More recent definitions have focused on time intervals of 1 h or less, which normally identify sudden cardiac death populations having a high proportion (up to 91 percent) of arrhythmic death.[12,13] The information necessary to establish a diagnosis of sudden cardiac death is often not available. For instance, up to 40 percent of sudden deaths are not witnessed, making a determination of the time of onset of symptoms to loss of consciousness impossible.[14-16] Prodromal symptoms such as palpitations, chest pain, and dyspnea may suggest a cardiovascular etiology such as arrhythmia, ischemia, or congestive heart failure but are not specific.[11,17]

Advances in emergency medical services, technological advances such as automatic external defibrillators, and community-based interventions have resulted in a contradiction in terms. Biologic death is an absolute and irreversible event, while patients can survive a cardiac arrest that would lead to sudden cardiac death if left untreated. Processes such as malignant arrhythmias, pump failure, and coronary ischemia that initiate the cascade of events leading to cardiovascular collapse can be modified, and the episode of sudden cardiac death can be averted. Ultimately, though, the distinction between sudden cardiac death, nonsudden cardiac death, and noncardiac death is relevant more from a historical perspective, and total mortality rate is a more definitive end point in assessing the efficacy of an intervention aimed at improving survival.

Chapter 33: SUDDEN CARDIAC DEATH

EPIDEMIOLOGY

Incidence

Sudden cardiac death accounts for approximately 300,000 to 400,000 deaths yearly in the United States, depending on the definition used (Table 33-1).[1-11] When its definition is restricted to death less than 2 h from onset of symptoms, 12 percent of all natural deaths were sudden, and 88 percent of those were due to cardiac disease. In autopsy-based studies, a cardiac etiology of sudden death has been reported in 60 to 70 percent of sudden death victims.[15,16] Sudden cardiac death is the most common and often the first manifestation of coronary heart disease (CHD) and is responsible for half the deaths from cardiovascular disease, which remains the main cause of death in this country. In the Framingham Study,[1-3] a 26-year survey of 5128 subjects (age 30 to 62) without evidence of cardiac disease at entry, 13 percent of all natural deaths were sudden, accounting for 50 percent of the deaths from CHD. Fifty percent of sudden cardiac deaths in men and 64 percent in women occurred in people without known CHD. The proportion of sudden cardiac death was lower (20 to 34 percent) in patients with known CHD. Sudden cardiac death was the first symptom of CHD in 10 percent of all coronary events in men and 8 percent of those in women.

Table 33-1: Incidence of Sudden Cardiac Death in Selected Regional Population Studies

Study	Patient Population	Definition of Sudden Cardiac Death	SCD (CHD Deaths)	Annual Incidence of SCD (per 1000 population)	Known CHD, %	Proportion of CHD Deaths, %	Comments
Framingham,[1-3] 1948–1974	5128 M + F 30–62 years; no prior CHD	<1 h	M: 160 (350) F: 73 (196)	*Age:* *45–54* *55–64* *65–74* M: 1.1 2.7 2.6 F: 0.3 0.4 1.2	M: 50 F: 36	M: 46 F: 35	18% M (24% F) had SCD as first symptom of CHD

[a]Acute myocardial infarction only.
[b]White population only.
ABBREVIATIONS: CHD = coronary heart disease; ER = emergency room; F = female; M = male; OOH = out-of-hospital; SCD = sudden cardiac death.

The overall annual incidence of sudden cardiac death in the United States is probably best estimated with data derived from the National Center for Health Statistics.[10] This data base from 40 states represents 71 percent of the U.S. population. Based on a combination of the place of death (out of hospital or emergency room) and diagnosis of CHD as an estimate of sudden cardiac death, the sudden cardiac death incidence in 1985 was 1.9 in men and 0.6 in women, resulting in 223,864 deaths of a total of 399,324 deaths from ischemic heart disease. Sudden cardiac death rates in developed countries outside the United States are comparable to those inside the United States. Using methods similar to those of the National Center for Health Statistics study,[10] the World Health Organization reported an annual incidence of sudden cardiac death of 1.9 in men and 0.6 in women, again accounting for nearly half the deaths from CHD in a surveillance study of 3.5 million men and women aged 20 to 64 years.[17] Sudden cardiac death rates in developing countries are considerably lower, paralleling the rates of ischemic heart disease as a whole (Fig. 33-1). In the United States, several populations-based studies have documented a decline (15 to 19 percent) in the incidence of sudden cardiac deaths caused by CHD since the early 1980s.[7,18]

Influence of Age, Race, and Gender

AGE

The incidence of sudden cardiac death increases with age in men and women as well as whites and nonwhites because of the higher prevalence of ischemic heart disease at older ages (Fig. 33-2).[3] Among sudden natural deaths, the proportion of cardiac causes increases with advancing age. Among patients with CHD, however, the proportion of coronary deaths that are sudden decreases with age.[1,3]

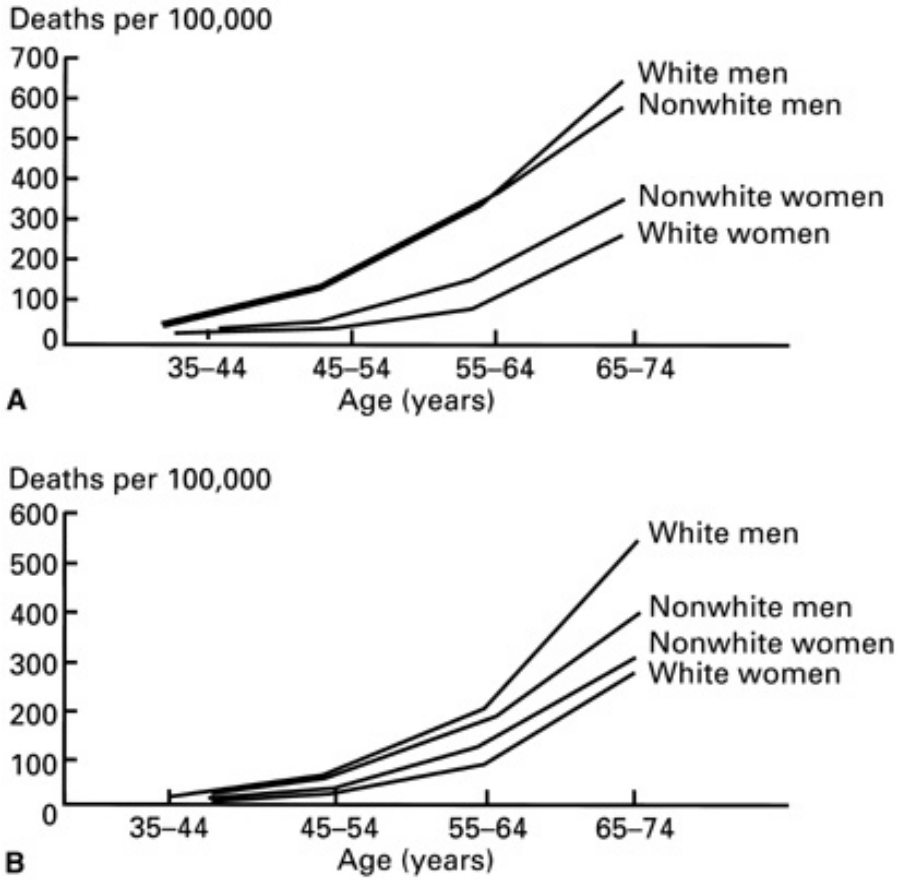

Figure 33-2: Plots of mortality rates (deaths per 100,000) for ischemic heart disease occurring (*A*) out of hospital or in emergency room (an estimate for sudden cardiac death rate) and (*B*) in the hospital, by age, gender, and race in 40 states during 1985. (From the National Center for Health Statistics. Reproduced from Gillum,[10] with permission.)

RACIAL DIFFERENCES

An analysis of cardiac death rates from 40 U.S. states between 1980 and 1985 showed that the rate of sudden coronary death is higher in blacks than in whites (men, 66 versus 61 percent; women, 56 versus 50 percent).[10] The annual age-adjusted incidence of sudden cardiac death in a cohort of 860 white and 117 black cardiac arrest victims in Seattle between 1984 and 1986 was also higher in blacks than in whites: 3.4 percent versus 1.6 percent per 1000 population (p <.001).[19] A similar difference was reported in an analysis of 6451 cardiac arrest victims in Chicago.[20] Not only was the sudden cardiac death rate higher, but the overall survival was also lower in blacks than in whites (10.2 percent versus 16.7 percent, p <.07, in Seattle, and 0.8 percent versus 2.6 percent, p <.001, in Chicago). In both studies, blacks were less likely to receive bystander cardiopulmonary resuscitation (CPR); however, differences in outcome could not be accounted for by differences in emergency medical team response time or administration of advanced cardiac life support. Possible explanations for these findings include limitations in access to preventive care, prehospital delays in patient activation of emergency medical services, and denial or self-treatment of prodromal symptoms. Blacks are also prescribed diuretics more often than whites, leading to an increased risk of hypokalemia and possibly sudden cardiac death.[2] These issues warrant further investigation.

GENDER

Sudden cardiac death has a much higher incidence in men than in women, reflecting gender differences in the incidence of CHD.[1-3] Between 70 and 89 percent of sudden cardiac deaths occur in men, and the annual incidence of sudden cardiac death in men is overall three to four times higher than in women. As is the case with coronary disease, however, this disparity decreases with advancing age, with a male-female ratio for sudden cardiac death of 7:1 in 45- to 64-year-olds and 2:1 in 65- to 74-year-olds.

A higher percentage (64 percent) of sudden cardiac death in women than in men (50 percent) occurs in patients without prior evidence of coronary heart disease.[3] Among survivors of cardiac arrest, women are more likely than men to have other forms of structural heart disease (valvular heart disease, 13 percent versus 5 percent; idiopathic dilated cardiomyopathy, 19 percent versus 10 percent) or a "normal" heart (10 percent versus 3 percent).[21]

SUDDEN CARDIAC DEATH IN THE YOUNG

Sudden cardiac death accounts for 19 percent of sudden deaths in children between 1 and 13 years of age and 30 percent between 14 and 21 years.[22] The overall incidence is low, 600 cases per year, compared with approximately 300,000 per year in the adult population. Structural cardiac abnormalities can be identified in over 90 percent of young victims of sudden cardiac death (Table 33-2).[22-34] About 40 percent of sudden cardiac deaths in the pediatric population occur in patients with surgically treated congenital cardiac abnormalities; in the majority of young victims, however, sudden cardiac death is often the first manifestation of underlying cardiac disease in otherwise healthy-appearing individuals.[35] The most common underlying pathologic conditions in people who die of sudden cardiac death in the first three decades of life are myocarditis, hypertrophic cardiomyopathy, congenital coronary artery anomalies, atherosclerotic coronary heart disease, conduction system abnormalities, congenital arrhythmogenic disorders, arrhythmias associated with mitral valve prolapse, and aortic dissection.

Among young people with sudden death and known congenital disease, aortic stenosis and primary or secondary pulmonary vascular obstruction were most common in patients without prior cardiac surgery, while tetralogy of Fallot and transposition of the great vessels were more common in postoperative patients.[35,36] Both ventricular arrhythmias and supraventricular tachyarrhythmias play important roles, the former being more important in tetralogy of Fallot and the latter, especially atrial flutter, in transposition of the great vessels[37-39] (see below).

Risk Factors for Sudden Cardiac Death

Only a fraction of patients survive an episode of sudden death, and there has been considerable interest in identifying the population at risk for sustained ventricular arrhythmias. More than 80 percent of sudden cardiac deaths occur in patients with underlying coronary disease, and the risk factors for sudden cardiac death largely reflect those for CHD (see Chap. 35). Left ventricular dysfunction and CHD confer the highest risk for sudden cardiac death.[40] In the Framingham Study, a multivariate model based on risk factors such as age, systolic blood pressure, left ventricular hypertrophy, intraventricular block or nonspecific abnormalities on the electrocardiogram (ECG), elevated serum cholesterol level, glucose intolerance, decreased vital capacity, smoking, relative weight, and heart rate found that 53 percent of men and 42 percent of women who were at risk for sudden death were in the upper decile of this analysis (Fig. 33-3).[1-3]

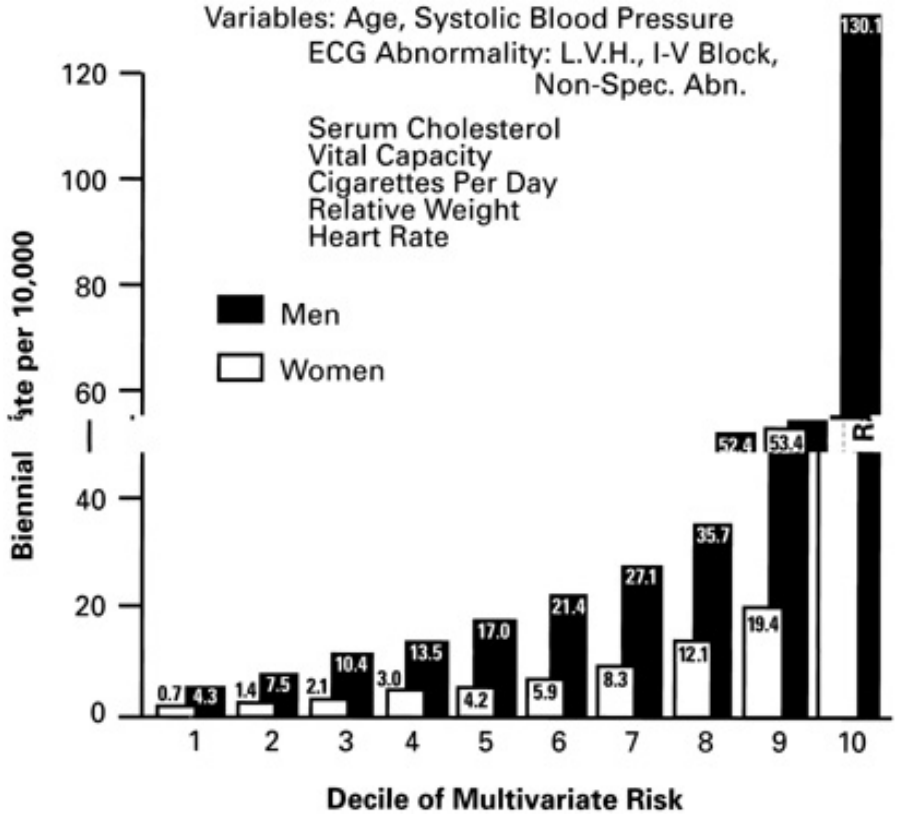

Figure 33-3: Risk of sudden cardiac death by decile of multivariate risk: 26-year follow-up, the Framingham Study. ECG, electrocardiographic; I-V, intraventricular; LVH, left ventricular hypertrophy; Non-Spec. Abn., nonspecific abnormality. (Reproduced from Kannel and Schatzkin,[2] with permission.)

Despite the fact that numerous population-based studies have shown a strong relationship between risk factors for CHD and sudden cardiac death, none of them has identified a single set of risk factors that are specific for sudden cardiac death (Table 33-3).[1,2,40-43] The inability to determine a profile based on coronary risk factors that is specific for sudden cardiac death reflects the fact that these factors are manifestations of chronic disease processes that create the structural basis for sustained arrhythmia. These structural abnormalities may be necessary but are not sufficient to cause an episode of sudden cardiac death. Triggers such as acute ischemia, alterations in hemodynamic status, electrolyte abnormalities, transient drug or toxin effects, or circadian variations in vasoconstriction, plaque stability, and thrombosis may precipitate an event.[44-46] A challenge for the future will be to identify these triggers so that patients at risk for malignant arrhythmias can be targeted for intervention.

LIFESTYLE FACTORS

Observations suggest that changes in lifestyle factors can be of potential importance in protecting patients with CHD from

dying suddenly.[1,2,47-57]

Alcohol

Individuals who consume high amounts of alcohol (more than 5 drinks per day) have increased risks of ventricular arrhythmia and sudden cardiac death. The relationship is less clear for drinkers of light to moderate amounts. A recent prospective analysis of 21,537 males in the Physicians Health Study demonstrated a decreased risk of sudden cardiac death. Men who consumed light to moderate amounts of alcohol (2 to 6 drinks per week) had a significantly reduced risk of sudden cardiac death compared with those who rarely or never consumed alcohol.[47,48]

Cigarette Smoking

Smoking is one of the few coronary risk factors that has been associated with a disproportionate number of sudden deaths as compared to coronary deaths. Smoking has been shown to induce physiologic changes that predispose to sudden cardiac death, such as increases in platelet adhesiveness, decreases in ventricular fibrillation threshold, acceleration of heart rate, increases in blood pressure, induction of coronary spasm, decreases in oxygen-carrying capacity of the circulation by accumulation of carboxyhemoglobin and impairment of myoglobin utilization, and short-term nicotine-induced catecholamine release.[49] A postmortem study linked smoking and the presence of acute coronary thrombus. Fresh thrombus was found in 59 of 113 men who died suddenly, and cigarette smoking was a risk factor in 75 percent of these men, compared with 41 percent of the men with stable plaques ($p < .001$).[50] In the Framingham Study, the annual incidence of sudden cardiac deaths increased from 13 per 1000 in nonsmokers to 31 per 1000 in those smoking more than 20 cigarettes per day.[1,2,49] People who stopped smoking had a prompt reduction in CHD mortality rate compared with those who continued to smoke, irrespective of the duration of previous smoking habits.[51]

Stress and Socioeconomic Status

There are many reports linking stress, particularly emotional stress, to sudden cardiac death.[52-54] For instance, in the hours following the Northridge earthquake in California in 1994, there was a more than fourfold increase in sudden cardiac death in patients with known or unknown CHD, illustrating the role of emotional stress as trigger for sudden cardiac death in this population.[55] Based on the difference of average and actual daily sudden cardiac death rates in that period, it was estimated that as many as 40 percent of sudden cardiac deaths are precipitated by emotional stress.

Socioeconomic factors, presumably associated with higher levels of stress, can also contribute to sudden cardiac death. For instance, a more than threefold increase of sudden cardiac death following myocardial infarction was reported in men with low levels of education and complex ventricular ectopy compared with better-educated men with the same arrhythmias.[56] In a study of sudden cardiac death in women, those who died suddenly were less often married, had fewer children, and had greater educational discrepancies with their spouses than did age-matched controls in the same neighborhood.[57]

Physical Activity

There is increasing evidence that regular physical activity may help prevent CHD and its complications.[2,58-62] On the other hand, the value of vigorous exercise in patients with known CHD is controversial, and several clinical and autopsy-based studies have reported triggering of sudden cardiac death and acute myocardial infarction by vigorous exercise.[63-66] Emergency medical records show that in adults, 11 to 17 percent of cardiac arrest victims collapsed during or immediately after exertion, although the amount of exertion is rarely quantified.[59] The increased risk of cardiac arrest due to ventricular fibrillation during or after exercise is also evident from cardiac rehabilitation programs and exercise stress testing in patients with heart disease. These studies are of selected patients with known heart disease who are already at risk for sudden death, but in these situations, cardiac arrests rates of 1 in 12,000 to 15,000 (rehabilitation) and 1 per 2000 (stress testing) have been reported. This rate is at least six times higher than the general incidence of sudden cardiac death for patients known to have heart disease.[59] Because of immediate and successful defibrillation in most cases, these reported cases of cardiac arrest have rarely been fatal. These observations, however, do support the concept that vigorous physical activity can trigger cardiac arrest due to ventricular fibrillation. On the other hand, there is increasing experimental evidence that regular exercise may prevent ischemia-induced ventricular fibrillation and death.[60,65] Thus, it appears that regular participation in moderate-intensity activities is associated with reduced rates of cardiovascular morbidity and mortality, while the risks of sudden cardiac death and myocardial infarction are transiently increased during acute bouts of high-intensity activity.

Sudden Cardiac Death in Competitive Athletes

Sudden cardiac death in competitive athletes is an extremely rare event. Between 10 and 25 sports-related sudden deaths from cardiac causes occur annually in the United States.[23] The annual incidence of sudden cardiac death during exercise is 1 per 200,000 in competitive high school athletes[29] and 1 per 250,000 among unscreened young runners.[67] Collapse usually occurs during or shortly after exercise, either in training or during competition. Although, unfortunately, sudden cardiac death is often the first manifestation of their disease, the majority of sudden cardiac deaths in athletes occur in persons with underlying cardiac disease.[24,68-70] Age has been shown to be the most useful variable in predicting the underlying cardiac disease (Fig. 33-4). In athletes below 35 years of age, the vast majority of sudden cardiac deaths arise from a variety of congenital cardiovascular diseases, most commonly hypertrophic cardiomyopathy (36 percent) and congenital coronary artery anomalies (19 percent).[69] Arrhythmogenic right ventricular dysplasia, myocarditis, arrhythmias associated with mitral valve prolapse, the Wolff-Parkinson-White syndrome, and aortic dissection are much less common. Coronary artery disease was present in 10 percent, compared with 80 percent in those older than 35 years.[68] Arrhythmogenic right ventricular dysplasia was the most common finding in a cohort from northern Italy, accounting for 22 percent.[71] Hypertrophic cardiomyopathy accounted for only 2 percent of sudden cardiac deaths in this population.[72]

Screening programs for identifying relatively rare cardiac abnormalities in a large population of asymptomatic athletes are often costly and inefficient.[73] Guidelines for such screening have therefore been published. They are based mainly on detailed personal and family history, physical examination, and ECG, with echocardiography and other noninvasive tests reserved for those with any positive finding during the initial evaluation.[74] Guidelines have also been published outlining which athletes with cardiac arrhythmias can participate in competitive athletics[74] (see also Chap. 85).

Chapter 33: SUDDEN CARDIAC DEATH

MECHANISM OF SUDDEN CARDIAC DEATH

Relationship between Structure and Function in Sudden Cardiac Death

A vast majority of patients who have experienced sudden cardiac death have cardiac structural abnormalities. In the adult population, these consist predominantly of coronary heart disease, cardiomyopathies, valvular heart disease, and abnormalities of the conduction system. These structural changes provide the substrate for ventricular tachyarrhythmias that are the cause of sudden cardiac death in most cases. It is important to recognize the role of triggering factors, such as fluctuations in the autonomic nervous system, electrolyte abnormalities, and proarrhythmic effects of drugs in the initiation of ventricular arrhythmias resulting in sudden cardiac death (Fig. 33-5).[75,76] Strategies aimed at eliminating or reducing the triggers of arrhythmias may prove to be efficient short- and midterm solutions, since many of the structural abnormalities cannot be cured or require long-term risk-factor modification to prevent their development.

Tachyarrhythmias versus Bradyarrhythmias in Sudden Cardiac Death

Ventricular fibrillation is the first recorded rhythm in approximately 70 percent of patients who have cardiac arrest.[77,78] Sustained ventricular tachycardia is only rarely (less than 2 percent) documented as the initial rhythm, but it is unknown how often it precedes and precipitates ventricular fibrillation. In a series of 157 ambulatory patients who were wearing an ECG monitor at the time of their cardiac arrest, primary ventricular fibrillation was documented in 8 percent, ventricular tachycardia degenerating into ventricular fibrillation in 62 percent, and torsades de pointes in 13 percent.[79]

Electromechanical dissociation and asystole are found in about 30 percent of patients experiencing cardiac arrest, and this finding is usually related to the time interval from collapse to first monitoring of the rhythm, suggesting that it is a later manifestation of cardiac arrest.[77,78] The incidence of bradycardia as the first documented rhythm varies according to the population studied. In patients who have died suddenly while wearing an ambulatory ECG monitor, bradyarrhythmias as the initial rhythm were documented in 17 percent (26 of 231), but even in patients with preexisting atrioventricular or intraventricular conduction defects, ventricular tachyarrhythmias are most often the mode of recurrent cardiac arrest.[79,80] In a group of 21 patients with severe congestive heart failure awaiting cardiac transplantation, bradycardia or electromechanical dissociation was associated with 62 percent of sudden cardiac deaths.[81]

We believe that bradycardias reflect the failing heart and are not a significant cause of sudden death unless the bradyarrhythmia allows for the development of a tachyarrhythmia. Therefore, treatment of bradycardia may prevent the onset of tachyarrhythmias and is an important consideration in the prevention of sudden cardiac death. Since ventricular fibrillation is the most frequent cause of sudden cardiac death, understanding the mechanisms responsible for this arrhythmia is essential in its prevention and treatment. A complete discussion is beyond the scope of this chapter (see Chaps. 23 and 24).

Electrophysiologic Effects of Ischemia

The electrophysiologic effects of acute ischemia lead to a loss of membrane integrity, with efflux of potassium, influx of calcium, decrease in amplitude and upstroke velocity of the cardiac action potential, depolarization of the resting membrane potential, and shortening of action potential duration.[82] Within minutes of the onset of ischemia, the resting membrane depolarizes. This depolarization is inhomogenuous and is largely caused by local abnormalities in extracellular potassium levels and acidosis. Refractory periods in the ischemic zone and action potential duration shorten. Despite shortening of the action potential duration, fast sodium and slow calcium channels in partially depolarized fibers may remain inactive, thereby prolonging refractoriness, even after completion of repolarization. This postrepolarization refractoriness may further contribute to inhomogeneities in the electrophysiologic properties within and around the ischemic zone, causing significant conduction delays, unidirectional block, and reentrant arrhythmias. Subsequently, cellular uncoupling occurs after 20 to 25 min of ischemia, causing conduction to become slow and discontinuous.[83]

Ventricular arrhythmias during experimental acute ischemia occur in two peaks, one between 2 and 10 min following coronary occlusion and the second at 15 to 20 min. Rapid polymorphic ventricular tachycardias and ventricular fibrillation are the characteristic arrhythmias during the early stages of ischemia and are the cause of sudden cardiac death.[84] Activation mapping during ventricular fibrillation has demonstrated that the initial arrhythmias are due to reentry, which is facilitated by the inhomogeneous conduction velocities and refractory periods in and around the ischemic zone. The second peak of ventricular arrhythmias coincides with a peak in catecholamine release. Automatic and triggered rhythms have also been implicated in these arrhythmias. Ventricular arrhythmias can be a sign of reperfusion after thrombolysis, percutaneous revascularization, or spontaneous reperfusion. In addition, it appears that the rate, time, and degree of reperfusion influence the incidence, rate, and duration of these arrhythmias. More work is needed to further define these relationships.[85]

In the subacute phase of myocardial infarction (within the first 3 days), sudden cardiac death may occur due to ventricular fibrillation initiated by early, frequent premature ventricular complexes (PVCs). Such PVCs have been shown, in experimental models, to be predominantly due to abnormal impulse initiation consistent with abnormal automaticity. Other manifestations of abnormal automaticity are accelerated idioventricular rhythm and idioventricular tachycardia. These arrhythmias appear to arise, for the most part, from surviving Purkinje fibers in the subendocardial border zone of a transmural infarction. They have no prognostic significance for development of late arrhythmias and usually subside after 2 to 3 days at about the same time that the resting membrane potential and action potential duration of Purkinje fibers normalize.[82]

In the late phases following myocardial infarction, when the infarction is healed, reentrant excitation appears to be the principal mechanism of ventricular arrhythmias. Critical areas of the reentrant circuit are formed by surviving myocardial cells in the epicardial and endocardial border zone of a healed infarction as well as surviving intramural fibers within the infarct zone[84] (see also Chap. 23).

Mechanoelectrical Feedback

Left ventricular dysfunction has been identified as the strongest independent predictor of sudden cardiac death. Despite the clinical recognition that acute heart failure can precipitate ventricular tachyarrhythmias, the mechanism by which this occurs is incompletely understood. Besides mechanisms related to acute and chronic ischemia, it has been shown that acute changes in the mechanical state of the heart related to altered preload and contractility can have direct electrophysiologic effects that may precipitate arrhythmias; this relationship is usually referred to as mechanoelectrical feedback.[86] An increase in both left ventricular preload and contractility has been shown to shorten action potential duration in the canine ventricle.[86] An increase in right ventricular pressure has been shown to shorten action potential duration in humans.[87] The cellular

mechanism by which this occurs is unknown, but there is some evidence that these changes might be mediated by fluctuation of intracellular calcium levels.[86]

Role of the Autonomic Nervous System in the Genesis of Arrhythmias

There is increasing evidence that cardiac abnormalities associated with a high risk of sudden cardiac death are accompanied by changes in autonomic innervation of the heart. Myocardial infarction, for instance, has been shown to cause regional cardiac sympathetic and parasympathetic denervation.[88] The denervated areas show supersensitivity to catecholamine infusion, with disproportionate shortening of action potential duration and refractoriness.[89] This autonomic heterogeneity may predispose to arrhythmia development by creating dispersion of refractoriness and/or conduction.

Sensitivity to sympathetic activation favors the onset of life-threatening cardiac arrhythmias, while vagal activation has been shown to have a protective effect in the presence of tonic sympathetic stimulation.[90] This is thought to be due, at least in part, to the antiadrenergic effects of vagal stimulation via reduction of norepinephrine release and inhibition of adenylate cyclase via inhibitory G proteins. Because it is difficult to study the effects of vagal activity on ventricular electrophysiologic properties directly, the behavior of the sinus node has been used as a surrogate by measuring indices of heart rate variability (reflecting primarily tonic vagal activity) and evaluating baroreflex sensitivity (a measure of reflex vagal activity). In dogs, decreased baroreflex sensitivity is associated with an increased susceptibility to ventricular fibrillation and sudden cardiac death provoked by ischemia in a chronic (4-week) infarct model.[65] Myocardial infarction reduced baroreflex sensitivity 4 weeks after myocardial infarction in 73 percent of animals studied compared to control animals. A transient (less than 3 months) decrease in baroreflex sensitivity following myocardial infarction has also been demonstrated in humans.[91] The prognostic value of baroreflex sensitivity in humans has been suggested in several studies.[92,93]

Chapter 33: SUDDEN CARDIAC DEATH

CARDIAC DISEASES ASSOCIATED WITH SUDDEN CARDIAC DEATH

Table 33-4 summarizes cardiac abnormalities associated with sudden death.

Ischemic Heart Disease

CORONARY ATHEROSCLEROSIS

In survivors of cardiac arrest, CHD is present in 40 to 86 percent of patients, depending on age and gender of the population.[94] There is ample evidence to support the concept that the electrical instability caused by acute ischemia is more important than infarction in the pathogenesis of sudden cardiac death. Although the majority of patients who suffer sudden cardiac death have severe multivessel coronary disease, fewer than half of the patients resuscitated from ventricular fibrillation evolve evidence of myocardial infarction by elevated cardiac enzymes, and less than 20 percent have Q-wave myocardial infarction.[77] Holter monitoring at the time of arrest has infrequently shown evidence of ischemic ECG changes before the event.[95-97] In postmortem examinations and in catheterization studies, there was a significant (75 to 85 percent) stenosis in at least two major coronary arteries in as many as 76 percent of patients. Detailed pathologic studies have confirmed the presence of acute coronary arterial lesions (plaque fissure, plaque hemorrhage, and thrombosis) in up to 95 percent of patients dying suddenly, but only a fraction had total occlusion.[50,66,98-100] Thus, the important observation is that sudden cardiac death can occur in the absence of infarction but is usually in the presence of diffuse coronary disease.[101]

Coronary collateralization may play an important role in the presentation of coronary artery disease as sudden cardiac death. Studies looking at occluded arteries demonstrated that minimally stenosed coronary arteries were a weaker stimulus for development of collaterals than were high-grade lesions.[102] This mitigating effect of coronary collateralization is further supported by a study of exercise testing in 894 healthy men followed for a mean of 12.7 years. In this study, the initial coronary event was acute myocardial infarction or sudden cardiac death in 73 percent of those with a normal stress test result, as opposed to 20 percent of those with an abnormal stress test result.[103] It has been hypothesized that chronic ischemia may be a stimulus for development of coronary collaterals, which in turn could have a protective effect during acute coronary occlusion. It should be noted that patients with silent ischemia during exercise testing have the same likelihood of developing an acute myocardial infarction or sudden cardiac death as do symptomatic patients.[104]

Since coronary artery disease is the major substrate of sudden cardiac death, risk stratification following myocardial infarction is an important step in the prevention of sudden cardiac death. Few variables, mainly, frequent PVCs (more than 10 per hour), nonsustained ventricular tachycardia, reduced left ventricular ejection fraction (less than 40 percent), and use of digitalis are independent risk factors for sudden versus nonsudden cardiac death following myocardial infarction.[105-109] The incidence of sudden cardiac death in the first 2 years after myocardial infarction ranged from 11 to 18 percent in these studies. Patients with both nonsustained ventricular tachycardia and left ventricular dysfunction have the worst prognosis.[109]

The variables identified to predict sudden cardiac death following myocardial infarction in these

studies are better in selecting a low-risk population for sudden cardiac death than in predicting who will go on to die suddenly. In the absence of frequent PVCs and with a normal left ventricular ejection fraction following myocardial infarction, the risk of sudden cardiac death is low (less than 2 percent in the first year).[110] Even when all clinical risk factors for sudden cardiac death are present following myocardial infarction, the reported risk varies between 10 and 40 percent and generally does not warrant prophylactic antiarrhythmic therapy. It is hoped that risk-stratification models incorporating other methods (e.g., heart rate variability, baroreflex sensitivity, nonlinear dynamics, T-wave alternans, and imaging of the cardiac autonomic innervation) of assessing such triggers of sudden cardiac death as autonomic fluctuations and electrical instability will enhance their positive predictive value (see also Chap. 42).

NONATHEROSCLEROTIC DISEASE OF THE CORONARY ARTERIES

Several nonatherosclerotic diseases of the coronary arteries are associated with increased risk of sudden cardiac death precipitated by cardiac ischemia. Congenital coronary artery anomalies, found in approximately 1 percent of all patients undergoing angiography and in 0.3 percent of patients undergoing autopsy, have been complicated by sudden cardiac death, often exercise-related, in up to about 30 percent of patients.[111] Origin of the left main coronary artery from the right aortic sinus or origin of the right coronary artery from the left coronary sinus were most frequently the cause. It has been postulated that acute ischemia is due to compression of the anomalous coronary artery between the pulmonary artery and aorta during exercise-induced expansion of these vessels and to diminished coronary flow reserve due to the slitlike orifice and acute takeoff angle of the anomalous vessel.[111]

Life-threatening ventricular arrhythmias and sudden cardiac death have been described in patients with coronary artery spasm (Prinzmetal's angina or variant angina). In a series of 81 patients with coronary artery spasm, 13 patients (16 percent) had at least one episode of cardiac arrest due to ventricular fibrillation.[112,113] Significant arrhythmias during attacks of variant angina were documented in 41 percent of these patients and appeared to be associated with a higher risk of sudden cardiac death. Calcium channel blockers are effective in many patients in preventing coronary spasm and appear also to protect from malignant ventricular arrhythmias if the attacks can be completely abolished.[112,113]

Sudden cardiac death has been described as a rare complication of coronary artery dissection in Marfan's syndrome, after labor and delivery, secondary to trauma or coronary catheterization, as a consequence of syphilitic aortitis, or as an extension of aortic dissection. Myocardial bridges have been reported in association with sudden cardiac death during exercise, but they are also an incidental finding at autopsy in up to 25 percent of patients dying of other causes.[114] Coronary arteritis and subsequent infarction have been reported in Kawasaki's disease, giant-cell arteritis, Beçhet's disease, systemic lupus erythematosus, and Churg-Strauss syndrome.[115-120]

Cardiomyopathies

IDIOPATHIC DILATED CARDIOMYOPATHY

Idiopathic dilated cardiomyopathy is the substrate for approximately 10 percent of sudden cardiac deaths in the adult population. The mortality rate for idiopathic dilated cardiomyopathy is high, reaching 10 to 50 percent annually, and seems most closely tied to the severity of pump dysfunction.[121] Mortality rates are higher among patients with advanced heart failure, but the proportion of sudden cardiac deaths is not increased.[122] In an overview of 14 studies including 1432 patients with idiopathic dilated cardiomyopathy, the mean mortality rate after a follow-up of 4 years was 42 percent, with 28 percent of deaths classified as sudden.[121] Sudden cardiac death in idiopathic dilated cardiomyopathy is usually attributed to both polymorphic and monomorphic

ventricular tachyarrhythmias occurring in the setting of a high frequency of complex ventricular ectopy.[123] The terminal event may, however, also be asystole or electromechanical dissociation, especially in patients with advanced left ventricular dysfunction.[81] Factors potentially contributing to the generation of arrhythmias in idiopathic dilated cardiomyopathy are mechanoelectrical feedback, electrolyte depletion due to chronic diuretic therapy, excessive activation of the sympathetic nervous and renin-angiotensin systems, and proarrhythmic effects of antiarrhythmic drugs.[124]

Risk stratification of patients with idiopathic dilated cardiomyopathy is difficult because there are few clinical predictors specific for sudden cardiac death.[125] The only clinical variable that identifies patients with a higher risk of sudden cardiac death is unexplained syncope, and these patients should undergo further evaluation.[121,126] A recent study looked at patients with implantable defibrillators, nonischemic dilated cardiomyopathy, and unexplained syncope with negative electrophysiologic test results. Fifty percent of the patients received appropriate shocks for ventricular arrhythmias within a mean of 10 ± 14 months from implantation.[127] Patients with idiopathic dilated cardiomyopathy have a very high incidence of ventricular ectopy, with simple PVCs, complex PVCs, and nonsustained ventricular tachycardia present in 94 percent, 76 percent, and 40 percent, respectively, thus limiting their prognostic value by a low specificity.[123] The prognostic value of intraventricular conduction delays on ECG, which are associated with decreased survival rates, is, again, not specific for sudden cardiac death, and late potentials recorded by signal-averaged ECGs can be detected only in a minority of patients with idiopathic dilated cardiomyopathy.[128] It is clear that induction of polymorphic ventricular tachycardia or fibrillation during electrophysiologic testing is nonspecific and that the absence of inducible ventricular tachyarrhythmias in this population does not accurately predict a low risk for sudden cardiac death[129] (see Chap. 66). In up to 40 percent of patients with nonischemic dilated cardiomyopathy, inducible monomorphic ventricular tachycardia can be due to a macro-reentry circuit, such as bundle-branch reentry, that is readily amenable to catheter ablation.[130]

HYPERTROPHIC CARDIOMYOPATHY

The incidence of sudden cardiac death in patients with hypertrophic cardiomyopathy (HCM) is 2 to 4 percent per year in adults and 4 to 6 percent per year in children and adolescents.[131] A review of 78 patients with HCM who died suddenly or survived a cardiac arrest episode showed that 71 percent were younger than 30 years of age, 54 percent were without functional limitation, and 61 percent were performing sedentary or minimal physical activity at the time of cardiac arrest.[132] The mechanism of sudden cardiac death in HCM is not clear. Primary arrhythmias, hemodynamic events with diminished stroke volume, and/or ischemia have been implicated.[131,133] It must be emphasized that atrial arrhythmias can lead to ischemia and hemodynamic compromise leading to sudden death in these patients. Assessment of autonomic function in patients with HCM revealed abnormal responses of heart rate and blood pressure to exercise in two-thirds, which was associated with a more malignant clinical course, suggesting that autonomic imbalance may be important in the genesis of sudden cardiac death in these patients.[134]

There are few predictors of sudden cardiac death in patients with HCM. A clinical history of spontaneous, sustained monomorphic VT or sudden death in family members indicates a worse prognosis, as does onset of symptoms in childhood.[132] Hemodynamic and echocardiographic variables such as left ventricular wall thickness or the presence of outflow tract obstruction are not useful in identifying patients at high risk for sudden cardiac death. Ambulatory ECG monitoring has been reported to be of some value in identifying patients with HCM at risk for sudden cardiac death.[135] The prognostic value of electrophysiologic study in the absence of spontaneous, sustained ventricular tachycardia is limited, and in fact the study itself may be dangerous. Sustained ventricular tachyarrhythmias, predominantly rapid polymorphic ventricular tachycardia,

have been induced in 27 to 43 percent of patients with HCM at electrophysiologic study, but their prognostic significance is controversial.[135] The predictive value of asymptomatic nonsustained ventricular tachycardia is also limited.[136] Paced electrogram fractionation in hypertrophic cardiomyopathy may be helpful in determining which patients are at risk for ventricular fibrillation.[137] The absence of inducible, sustained monomorphic ventricular tachyarrhythmias, absence of nonsustained ventricular tachycardia on ambulatory ECG, and no history of "impaired consciousness" (i.e., cardiac arrest or syncope) identified a subset (22 percent) of patients with HCM with a low (less than 1 percent) risk for sudden cardiac death.[136] A large number of mutations in genes coding for the β-myosin heavy chain, cardiac troponin T, cardiac troponin I, α-tropomyosin, myosin-binding protein C, and myosin light chains 1 and 2 in patients with HCM have been identified. Genotype-phenotype correlation studies have shown that mutations carry prognostic significance. Some mutations of the β-myosin heavy chain are associated with a benign prognosis, while other mutations are associated with a high incidence of sudden cardiac death. Mutations in cardiac troponin T are associated with a mild degree of hypertrophy but a high incidence of sudden cardiac death[139,140] (see Chaps. 62 and 67). As with most genetic disorders, the phenotypic expression of the same genetic abnormality is highly variable.

HYPERTENSIVE CARDIOMYOPATHY

Left ventricular hypertrophy has been identified as one of the strongest blood pressure-independent risk factors for sudden death, acute myocardial infarction, congestive heart failure, and other cardiovascular disease and deaths.[141-143] Hypertensive patients with left ventricular hypertrophy have a significantly greater prevalence of PVCs and complex ventricular arrhythmias than do patients without left ventricular hypertrophy or normotensive patients. In the Framingham Study, ECG evidence of left ventricular hypertrophy doubled the risk of sudden cardiac death. Echocardiographic studies showed an incremental risk for cardiovascular deaths of 1.73 in men and 2.12 in women for each 50 g increment in the index of left ventricular mass.[144] A possible mechanism for the increased mortality rate in patients with left ventricular hypertrophy is ventricular tachyarrhythmia.[141] Decreased coronary blood flow, flow reserve, and endothelial dysfunction may all be factors favoring the development of transient ischemia,[142] and long-term, repeated transient ischemic episodes could lead to interstitial fibrosis, which may underlie the arrhythmias in this population.[145] Other potential contributing factors to the increased risk of sudden cardiac death in hypertensive cardiomyopathy are the electrolyte disturbances associated with diuretic therapy of hypertension.[146,147] It remains to be shown that the reduction of hypertrophy or concomitant ventricular ectopy confers a clinical benefit that exceeds the one from the reduction of arterial pressure alone[143,148] (see also Chap. 51).

ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA

Arrhythmogenic right ventricular dysplasia (ARVD) is predominantly right ventricular cardiomyopathy characterized by fatty or fibrofatty replacement of myocardium. It is a rare cause of sudden cardiac death except in a few endemic regions.[31] Recurrent ventricular tachycardia with multiple left bundle-branch block morphologies typifies this disorder. It is a familial disorder in approximately 30 percent of cases, with an autosomal dominant mode of inheritance. The gene defect has been localized to chromosomes 1, 3, and 14.[149-152] In the fibrofatty variety, patchy myocarditis, programmed cell death, and/or congenital abnormalities of development appear to lead to myocardial atrophy and repair by fibrofatty replacement, which may become the basis for reentrant ventricular arrhythmia. The left ventricle and ventricular septum can be involved in 50 to 67 percent of cases, especially later in the course of the disease, and such involvement confers a poor prognosis.[153,154]

The electrocardiographic manifestations in sinus rhythm include T-wave inversion in V_1-V_3 or

complete or incomplete right bundle-branch block. Intraventricular conduction delay may produce a terminal notch on the QRS complex called an epsilon wave in approximately 50 percent of patients. The ventricular ectopy is usually of a left bundle-branch pattern, with a QRS axis between -90° and +110°, and generally arises from one of three sites of fatty degeneration. Called the triangle of dysplasia, these sites are the right ventricular outflow and inflow tract and apex. Any patient with frequent premature beats of a left bundle-branch morphology and left-axis deviation should be evaluated for this disorder.

In patients with ARVD, particularly at early stages of the disease, ventricular tachycardia is often precipitated by exercise, and its induction is usually found to be catecholamine sensitive at electrophysiologic study.[31,155] The course and prognosis of ARVD are highly variable and difficult to predict. The annual incidence of sudden cardiac death in ARVD has been estimated to be about 2 percent despite various treatments[156,157] (see Chap. 24).

Valvular Heart Disease

The risk of sudden cardiac death in asymptomatic patients with aortic stenosis or regurgitation appears to be low.[158,159] In contrast, in the presurgical era, sudden cardiac death was one of the three most common types of death in symptomatic patients with aortic stenosis, the other two being bacterial endocarditis and congestive heart failure.[160] There appears to be an increased risk of sudden cardiac death following aortic valve replacement for aortic stenosis or regurgitation.[161,162] In 831 patients receiving a Björk-Shiley prosthesis in the aortic (341 patients), mitral (345 patients), or double-valve (145 patients) position, the incidence of sudden cardiac death in the subgroups was 1.8 percent, 3.5 percent, and 4 percent, respectively, over a follow-up period of 7 years.[162] Malignant tachyarrhythmias have been suggested as the cause of sudden cardiac death in such patients, since the presence of PVCs is more frequent in patients who die suddenly than in those who die of other causes. Transient complete heart block is relatively common following both aortic (17.6 percent) and mitral (13 percent) valve replacement, pointing to bradyarrhythmias as the potential precipitating factor for sudden cardiac death[163] (see also Chap. 56).

MITRAL VALVE PROLAPSE

Whether or not mitral valve prolapse (MVP) is a cause of sudden cardiac death is controversial. The prevalence of MVP is so high (4 to 5 percent of the general population and up to 17 percent of young women) that its presence may just be a coincidental finding in victims of sudden cardiac death and not causally related.[164,165] The overall 8-year probability of survival in a group of 237 asymptomatic or minimally symptomatic patients with echocardiographically documented MVP who were prospectively followed was not significantly different from that for a matched control population.[165] On the other hand, MVP may not always be benign. MVP is the only structural cardiac disease found in a significant number of victims of sudden cardiac death, especially in the young female population.[28,166] Of course, they may have had a primary electrical disease unrelated to mitral valve prolapse.[167] Patients with MVP associated with mitral regurgitation and left ventricular dysfunction are clearly at higher risk for such complications as infective endocarditis, cerebroembolic events, and sudden cardiac death.[168,169] Some victims of sudden cardiac death with MVP, mild mitral regurgitation, and normal left ventricular function have been treated with antiarrhythmic agents, raising the possibility of proarrhythmia as the cause of death.

Ambulatory electrocardiography in patients with mitral valve prolapse who experienced sudden cardiac death suggests that, based on the increased incidence of complex ventricular ectopy, the cause of sudden cardiac death in patients with MVP is a ventricular tachyarrhythmia.[167] A prolonged QTc interval and changes in autonomic tone have also been related to sudden cardiac

death in patients with MVP.[170] Several risk factors for sudden cardiac death have been identified in asymptomatic or mildly symptomatic MVP patients without significant mitral regurgitation, including mitral valve annular circumference, thickness of the anterior and posterior mitral valve leaflets, presence and extent of endocardial plaque, and presence or absence of redundant mitral valve leaflets on M-mode echocardiography[165,170] (see Chap. 58).

Inflammatory and Infiltrative Myocardial Disease

Any inflammatory disease can cause sudden cardiac death due to either ventricular tachyarrhythmias or complete heart block. Histologic findings suggestive of myocarditis have been reported in 10 to 44 percent of young victims of sudden cardiac death (Table 33-2).[23] In adults, the diagnosis of myocarditis is made much less frequently, perhaps because of concurrent structural heart disease or because the late manifestations of the disease are indistinguishable from idiopathic dilated cardiomyopathy (see Chap. 69). In South America, however, myocarditis due to specific pathogens, such as Chagas' disease, is the most frequent cause of cardiomyopathy and related sudden cardiac death.[171] Patients with infective endocarditis may also be at risk for sudden cardiac death due to coronary emboli from valvular vegetations. More often, sudden cardiac death is caused by acute hemodynamic deterioration due to valvular failure. Intramyocardial abscesses can also precipitate ventricular tachycardia and lead to sudden cardiac death.

Infiltrative cardiomyopathies, such as primary or secondary amyloidosis, hemochromatosis, or sarcoidosis, have been associated with predominantly cardiac conduction defects but also ventricular tachyarrhythmias and sudden cardiac death. Ventricular tachycardia is sometimes the mode of presentation of sarcoidosis, can usually be reproduced by programmed electrical stimulation, and is associated with a high rate of recurrent arrhythmia and sudden cardiac death[172] (see also Chap. 68).

Congenital Heart Disease

An increased risk of sudden cardiac death due to an arrhythmia has been found predominantly in four congenital conditions: tetralogy of Fallot, transposition of the great vessels, aortic stenosis, and pulmonary vascular obstruction.[35] Patients who have undergone reparative surgery for tetralogy of Fallot have a reported risk of sudden cardiac death of 6 percent before age 20.[37,173,174] A QRS duration of 180 ms or more was found to be the most sensitive predictor of sudden cardiac death and ventricular tachyarrhythmias in 178 adults after repair of tetralogy of Fallot and correlated with other parameters of right ventricular volume overload.[174] Transposition of the great vessels (post-Mustard-Senning) is associated with a 2 to 8 percent rate of late sudden cardiac death, which is due in some cases to sinus node dysfunction and in others to ventricular tachyarrhythmias[38,39] (see Chap. 63). Sudden cardiac death is often (45 to 60 percent) the mode of death in patients with primary or secondary pulmonary hypertension (see Chap. 52). Death is often precipitated by general anesthesia, dehydration, exertion, or pregnancy. Any process that decreases systemic vascular resistance increases right-to-left shunting and decreases pulmonary flow. The resultant peripheral desaturation may trigger lethal arrhythmias and sudden cardiac death.[175] The sudden cardiac death risk in congenital aortic stenosis is estimated to be 1 percent and occurs predominantly in symptomatic patients with severe left ventricular hypertrophy. Ebstein's anomaly is frequently (up to 25 percent) associated with the presence of accessory pathways and the Wolff-Parkinson-White syndrome, which carries a small risk of sudden cardiac death (see below). Congenital heart block without associated structural heart disease occurs in 1 of 20,000 infants, and a moderate decrease in heart rate is usually well tolerated. A maternal risk factor is systemic lupus erythematosus. As previously noted, patients with severe bradycardia, however, have a tendency to develop ventricular arrhythmias. Pacemaker therapy has virtually eliminated the risk of sudden cardiac death in this population.[175]

Primary Electrical Abnormalities

LONG-QT SYNDROME

Sudden cardiac death is one of the hallmarks of the idiopathic long-QT syndrome (LQTS), a group of genetically distinct disorders each resulting from a mutation in one of six genes encoding cardiac ion channels or auxiliary ion-channel subunits.[176-178,341] The prolonged QT interval reflects abnormal prolongation of repolarization. Other characteristics of this disorder, in addition to prolonged (greater than 460 ms) QT interval, include abnormal T-wave contours, relative sinus bradycardia, a family history of early sudden death, a propensity for recurrent syncope, and sudden cardiac death due to polymorphic ventricular tachycardia (torsades de pointes) and ventricular fibrillation. Over 90 percent of the congenital forms of LQTS have been linked to six specific chromosomal defects, resulting in a genetically based classification (LQTS 1 through 6) with important functional and prognostic implications.[178]

The six defects have been mapped to chromosome *11p15.5* (LQTS1), chromosome *7q35-36* (LQTS2), chromosome *3p21-24* (LQTS3), chromosome *4q25-27* (LQT4), and chromosome *21* (LQTS5 and LQTS6). Several mutations have been identified in each gene, and this locus heterogeneity appears to be important prognostically. Defects in outward currents (potassium) or impaired inactivation of inward currents (sodium) can cause abnormal prolongation of the action potential repolarization, enhancing the propensity to develop early afterdepolarizations that may initiate arrhythmias[178] (see Chaps. 23 and 24). Recent data suggest that reentry due to transventricular heterogeneity is responsible for sustaining the arrhythmia.[179]

Five of these genes have been identified as encoding ion-channel proteins (LQTS1, LQTS2, LQTS3, LQTS5, and LQTS6). Four of them (LQTS1, LQTS2, LQTS5, and LQTS6) encode potassium channels. The gene products of LQTS1 and LQTS5 combine to form the slow delayed-rectifier potassium current, I_{K_S}. LQTS1, also referred to as KVLQT1, encodes the alpha subunit of the channel, and LQTS5, or KCNE1, encodes the beta subunit, called minK. Similarly, the products of LQTS2, known as HERG, and LQTS6, or KCNE2, combine to form the rapid delayed-rectifier potassium current, I_{K_r}. LQTS3, or SCN5A, encodes the cardiac sodium channel. The protein encoded by LQTS4 remains unknown.[180-183] Mutations in KVLQT1 account for approximately 50 percent of all cases of the LQTS. The congenital LQTS associated with deafness, or Jervell-Lange-Nielsen syndrome, appears to be caused by homozygous mutations of the KVLQT1 gene.[184]

Carriers of the LQT gene have been reported to have a 5 percent incidence of aborted sudden cardiac death and a 63 percent incidence of recurrent syncope.[177] The mean age at presentation was 24 years, and the annual incidences of sudden cardiac death and recurrent syncope were 1.3 percent and 8.6 percent, respectively, in a series of 196 patients enrolled in an international registry.[176] Multivariate analysis in the registry population identified female gender, congenital deafness, history of syncope, and a documented episode of torsades de pointes or ventricular fibrillation as independent risk factors for postenrollment syncope or sudden cardiac death.[176] Exercise-related cardiac events dominate the clinical picture of LQTS1 patients, and auditory stimuli tend to be a trigger for arrhythmic events in LQTS2 patients.[185] Echocardiographic studies have also been reported to reveal specific wall motion abnormalities associated with an increased risk (relative risk 2.75) of syncope and sudden cardiac death.[186] Genetic typing in the future may facilitate risk stratification, providing valuable information not only about the underlying abnormality but also about the expected severity of the disease and preferred therapy.[178]

WOLFF-PARKINSON-WHITE SYNDROME

The risk of sudden cardiac death in patients with Wolff-Parkinson-White syndrome is less than 1 per 1000 patient-years of follow-up.[187] Although a rare event, it is an important one to consider, since it usually occurs in otherwise healthy individuals and, in the era of catheter ablation of accessory pathways, is a curable cause of sudden cardiac death.[188] Almost all survivors of sudden cardiac death with Wolff-Parkinson-White syndrome have had symptomatic arrhythmias prior to the event, but up to 10 percent had sudden cardiac death as their first manifestation of the disease.[189-193] The mechanism of sudden cardiac death in most patients with this syndrome is presumably the development of atrial fibrillation with rapid ventricular rates due to conduction over an accessory pathway and subsequent degeneration into ventricular fibrillation. Sudden cardiac death survivors tend to have a higher prevalence of atrial fibrillation, multiple bypass tracts, and Atrioventricular Nodal Reentrant Tachycardia (AVNRT). There are no good predictors during sinus rhythm for the development of sudden death in these patients. Spontaneous or exercise-induced intermittent loss of preexitation is helpful in identifying patients who will have a slower ventricular response in atrial fibrillation. Loss of preexitation due to enhanced conduction through the atrioventricular node or other causes of antegrade block in the accessory pathway must be excluded for this finding to be reliable. The best predictor for development of ventricular fibrillation during atrial fibrillation is the spontaneous occurrence of a rapid ventricular response over the accessory pathway, with the shortest interval between preexcited ventricular beats (i.e., those conducted over the accessory pathway) being less than 220 ms.[188-192] Although this short RR interval is a highly sensitive marker, identifying virtually 100 percent of patients at high risk for ventricular fibrillation, its specificity is low, since this finding is present in approximately 20 percent of asymptomatic patients with Wolff-Parkinson-White syndrome[189] and 50 percent of those with mild to moderate symptoms due to atrioventricular reentrant tachycardia.[190] In symptomatic patients, an electrophysiologic study offers the opportunity to assess conduction properties of the accessory pathways, the propensity to develop tachyarrhythmias, and the possibility of curing the patient with catheter ablation at minimal risk. There is no proof that refractory period measurements predict sudden death in asymptomatic or symptomatic patients.

IDIOPATHIC VENTRICULAR TACHYCARDIA

Several distinct clinical or electrophysiologic patterns in patients with idiopathic monomorphic ventricular tachycardia have been described. Sudden cardiac death rarely occurs in these populations.[194] They include a reentrant form, known as verapamil-sensitive ventricular tachycardia or idiopathic left ventricular tachycardia, typically located in the region of the left posterior fascicle, an automatic form that may originate from either ventricle and paroxysmal or repetitive forms that originate from the right ventricular outflow tract. Eighty percent of cases of idiopathic ventricular tachycardias originate from the right ventricular outflow tract and typically have a left bundle-branch block with inferior axis pattern. These arrhythmias are sensitive to vagal maneuvers, such as administration of adenosine, and can be provoked by isoproterenol.[195] Ventricular tachycardia originating from the left ventricular outflow tract is uncommon. The reentrant form generally arises from the left inferior septum posteriorly and has a right bundle-branch block pattern with left-axis deviation but can arise more apically, in which case the axis is right and superior. Calcium channel blockers are effective in suppressing this arrhythmia, and vagal maneuvers, β-blockers, and lidocaine are usually ineffective.

In contrast, several types of idiopathic polymorphic ventricular tachycardias have been described and are associated with an unfavorable prognosis. These arrhythmias include idiopathic ventricular fibrillation (see below), torsades de pointes with a short coupling interval, and catecholaminergic polymorphic ventricular tachycardia. They can occur in sporadic or familial forms and are frequently but not uniformly associated with catecholamine release during physical or emotional stress. Patients with catecholaminergic polymorphous ventricular tachycardia have a favorable response to β-blocker therapy, while those with idiopathic ventricular fibrillation and

short-coupled torsades de pointes may not.[196]

Idiopathic Ventricular Fibrillation

Although the list of potential causes of sudden cardiac death continues to grow, a definite cause of sudden cardiac death cannot be established in approximately 1 percent of patients dying suddenly or after successful resuscitation from cardiac arrest.[197] These instances of sudden cardiac death without evident cause are presumed to be due to idiopathic ventricular fibrillation. The incidence of idiopathic ventricular fibrillation is higher in selected populations, such as younger patients (up to 14 percent in patients below 40 years of age) who had sudden cardiac death[198] or female survivors of sudden cardiac death unrelated to myocardial infarction (10 percent).[21] The risk of recurrent ventricular fibrillation in this young and otherwise healthy patient population ranges between 22 and 37 percent at 2 to 4 years.[197,199,200] In survivors of cardiac arrest due to idiopathic ventricular fibrillation, the diagnosis is made by exclusion if extensive cardiac workup (including physical examination, laboratory tests for acute myocardial infarction and electrolyte abnormalities, ECG, exercise test, echocardiographic study, cardiac catheterization, and electrophysiologic study to exclude significant conduction system abnormalities or accessory pathways) reveals no abnormality that is thought to account for the ventricular fibrillation episode. In a review of 54 published cases of presumed idiopathic ventricular fibrillation, patients were younger (mean age 36 ± 16 years) than those who had sudden cardiac death associated with structural heart disease, and there was a relatively higher proportion of women.[197] Noninvasive evaluation, including exercise testing and ambulatory ECG monitoring, may help confirm the diagnosis of idiopathic ventricular fibrillation in selected patients in whom rapid, nonsustained runs of polymorphic ventricular tachycardia can be documented. Unfortunately, such markers are present in fewer than half the patients with this disorder.[197,201] The prognostic role of electrophysiologic evaluation in these patients is controversial: sustained rapid polymorphic ventricular tachycardia or ventricular fibrillation is inducible in 38 to 75 percent of patients studied[197,200-202]; however, these arrhythmias are generally considered a nonspecific finding,[203,204] and noninducibility of ventricular fibrillation in this patient population did not predict a more favorable outcome.[200]

The syndrome of sudden cardiac death associated with right bundle-branch block and persistent ST-segment elevation in ECG leads V_1-V_3 in patients without demonstrable structural heart disease is known as the Brugada syndrome.[205] Symptomatic patients and those in whom ventricular tachycardia or ventricular fibrillation are inducible at the time of electrophysiologic study have a high incidence of sudden death.[206,207] This syndrome is genetically determined, and three mutations of the gene for the sodium channel SCN5A have been found in chromosome 3. These mutations are distinct from those identified in the LQTS and in right ventricular dysplasia.[208]

A sudden unexpected nocturnal death syndrome is described in young, apparently healthy males from Southeast Asia.[209] This syndrome is known among Asian-Pacific populations and has several names. The Thai describe it as *Lai Tai* (death during sleep). In the Philippines, it is known as *Bangungut* (to rise and moan in sleep followed by death) and as *Pokkuri* (unexpected sudden death at night) by the Japanese.[210] A majority of these patients have been found to have the electrocardiographic manifestations of the Brugada syndrome.[211,212]

In any case, it should be kept in mind that the diagnosis of "idiopathic" ventricular fibrillation is made by exclusion and therefore depends on the sensitivity of the diagnostic tests used. With the development and validation of new diagnostic tools, many forms of "idiopathic" sudden cardiac death in "structurally normal" hearts may have to be reclassified.

Drugs and Other Toxic Agents

PROARRHYTHMIA

The apparent paradox that antiarrhythmic agents can cause arrhythmias has been recognized since the introduction of quinidine in 1918.[213] The results of the Cardiac Arrhythmia Suppression Trial (CAST) showed an increased mortality rate in postinfarction patients treated with encainide, flecainide, and moricizine compared with placebo, despite effective antiarrhythmic efficacy as documented by the suppression of PVCs.[214] Besides antiarrhythmic drugs, many other agents with diverse actions have been implicated in the induction of tachyarrhythmias.[215] Among commonly used drugs associated with the risk of producing ventricular arrhythmias leading to sudden cardiac death are erythromycin, terfenadine, hismanal, pentamidine, and certain psychotropic drugs, such as tricyclic antidepressants and chlorpromazine, which generally affect repolarization. Phosphodiesterase inhibitors and other positive inotropic agents that increase intracellular calcium loading have also been shown to be proarrhythmic and to increase the risk of sudden cardiac death, despite their beneficial effects on hemodynamic parameters.[216] Suggested proarrhythmia mechanisms of classes Ia and III antiarrhythmic drugs-as well as psychotropic drugs, erythromycin, and pentamidine-include increased prolongation of refractoriness (QT interval of the ECG) and development of early afterdepolarizations[217] (Table 33-4). The initiation of the arrhythmia is often triggered by bradycardia or a characteristic "long-short" coupling interval that initiates a pause-dependent prolongation of the QT interval. The ventricular tachycardia in this setting has commonly a typical torsades de pointes morphology. This form of proarrhythmia may be facilitated by electrolyte abnormalities such as hypokalemia or hypomagnesemia. It is usually an early event during drug therapy (within 3 days), and concomitant therapy with digitalis and diuretic agents may predispose patients to this complication.[218] Since it is not possible to predict who will develop proarrhythmic effects, initiation of antiarrhythmic therapy in a telemetry unit is recommended (see Chaps. 23, 24, and 27).

A second mechanism of proarrhythmia, observed predominantly with class IC antiarrhythmic drugs such as flecainide and propafenone, appears to be associated with acute ischemic events and occurs more frequently in patients with ischemic cardiomyopathy.[219] It is believed that the antiarrhythmic drug exacerbates ischemia-induced myocardial conduction delays in an heterogeneous fashion and promotes reentrant ventricular tachycardias.[219]

COCAINE AND ALCOHOL

The increasingly widespread use of cocaine in the United States has led to the realization that this drug can precipitate life-threatening cardiac events, including sudden cardiac death. In a series of 41 survivors of cardiac arrest due to ventricular fibrillation in patients 18 to 35 years of age, one-third had ingested alcohol or drugs (cocaine, heroin, or tricyclic agents).[220] The combination of alcohol and cocaine is especially dangerous due to the generation of a unique metabolite, cocaethylene, that has enhanced cardiotoxicity.[221] Cocaine causes coronary vasoconstriction, increases cardiac sympathetic effects, and precipitates cardiac arrhythmias irrespective of the amount ingested, prior use, or whether there is an underlying cardiac abnormality.[222] The combination of increased oxygen demand due to sympathetic stimulation and diminished coronary flow due to vasoconstriction may precipitate ischemia-induced arrhythmias and sudden cardiac death (see Chap. 71).

ELECTROLYTE ABNORMALITIES

Hypokalemia is often found in patients during and following resuscitation from a cardiac arrest. Although it is often a secondary phenomenon due to catecholamine-induced potassium shift into the cells, primary hypokalemia can also be arrhythmogenic. There is an almost linear inverse

relationship between serum potassium concentration and the probability of ventricular tachycardia in patients with acute myocardial infarction.[223] A decrease in the extracellular potassium level hypopolarizes the resting membrane potential, shortens the plateau duration, prolongs the phase of rapid repolarization in ventricular fibers, and causes an increase in pacemaker activity in Purkinje cells, triggering ventricular arrhythmias.[224] These changes in repolarization may increase the dispersion of the recovery of excitability and facilitate reentrant ventricular arrhythmias.[224] Many of the electrophysiologic effects of hypokalemia are similar to those caused by digitalis and catecholamine stimulation, explaining the high risk of ventricular arrhythmias when a combination of these factors is present.

An association between magnesium deficiency and sudden cardiac death has been reported in humans, especially as a cofactor in drug-induced torsades de pointes.[225] Hypomagnesemia in humans is generally associated with congestive heart failure, digitalis use, chronic diuretic use, hypokalemia, and hypocalcemia, making it difficult to establish whether the hypomagnesemia alone caused the sudden cardiac death. Acute administration of magnesium has been successfully used in the treatment of drug-induced torsades de pointes, although hypomagnesemia is not usually documented in this situation.

Changes in intracellular concentration of calcium may also be arrhythmogenic.[224] An increase in intracellular calcium concentration causes oscillatory release of calcium from the sarcoplasmic reticulum and gives rise to delayed afterdepolarizations, which may lead subsequently to ventricular arrhythmias due to triggered activity. Increases in intracellular calcium are believed to play a significant role in arrhythmias associated with digitalis glycosides, catecholamine-induced ventricular tachycardia, reperfusion arrhythmias, and the proarrhythmic effect seen with phosphodiesterase inhibitors and other positive inotropic agents.

Several studies in patients with hypertension who received treatment with diuretics suggested an increased risk of sudden cardiac death due to therapy with non-potassium-sparing diuretics.[226] Drug-induced potassium or magnesium depletion leading to cardiac arrhythmias has been suggested as the underlying mechanism (see also Chap. 23).

Electrolyte abnormalities are thought to be the cause of sudden cardiac death in patients with severe eating disorders, such as anorexia nervosa and bulimia, or patients who are on liquid protein diets. Sudden cardiac death due to ventricular tachycardia related to prolongation of the QT interval has been reported in a few patients with anorexia nervosa and bulimia.[227] It is thought to account partially for the high fatality rate of this eating disorder.

Chapter 33: SUDDEN CARDIAC DEATH

CLINICAL PRESENTATION AND MANAGEMENT OF THE PATIENT WITH CARDIAC ARREST

Out-of-Hospital Cardiac Arrest

Cardiac arrest is characterized by abrupt loss of consciousness that would uniformly lead to death in the absence of an acute intervention, although spontaneous reversions rarely occur. About 75 percent of cardiac arrests occur at home, and about two-thirds are witnessed.[14,228,229] Individuals who live alone and women appear more likely to have unwitnessed deaths.[230] The average age of cardiac arrest victims is around 65 years, and 70 to 80 percent are men.[229]

As discussed above, the most common mechanisms of cardiac arrest are ventricular tachyarrhythmias, followed by bradyarrhythmias, or asystole. The most important determinant of successful resuscitation is the time interval from cardiovascular collapse to initial intervention. Since most patients are found in ventricular fibrillation, the time to successful defibrillation is a key element in the acute management of the cardiac arrest victim (see also Chap. 34). The importance of early intervention is reflected in the "chain of survival" concept of emergency cardiac care systems: early access, early CPR, early defibrillation, and early advanced cardiac life support.[231] This concept has led to the development of tiered medical emergency systems in most urban areas. Following activation of the emergency call (911) system, the first response consists of the nearest emergency medical technicians or fire departments who are trained to provide basic CPR and defibrillation. The second response is by paramedics who are trained in advanced cardiac life support, including endotracheal intubation, intravenous medications, and additional defibrillation if necessary.

Initiation of bystander CPR by people trained in basic cardiac life support is another important element of early intervention and improves the chances of successful resuscitation. In an overview of 17 controlled studies of survival from out-of-hospital cardiac arrest, bystander CPR was associated with a greater than twofold odds ratio of survival (28 ± 16 percent of 5565 patients receiving bystander CPR versus 12 ± 11 percent of 8329 patients who did not).[231] The association between early CPR and improved survival appears to be related to the beneficial effects of CPR on ventricular fibrillation. The earlier CPR is performed, the greater the proportion of patients who are found in ventricular fibrillation as opposed to bradycardia or asystole.[78] Further, successful defibrillation is more likely when early CPR is performed. Community-based CPR training programs, such as those implemented in Seattle and Minneapolis, resulted in training of 20 to 25 percent of the adult population and have led to a higher likelihood of bystander CPR being administered in out-of-hospital cardiac arrest. The percentage of patients receiving bystander CPR varies in the communities studied between 8 and 54 percent, with an average around 30 percent.[229] A more efficient approach is targeted CPR training for persons who have an increased likelihood of having to perform CPR. It has been suggested that learning CPR be a mandatory course in high school, much like learning how to drive a car.[232]

In order to improve the time to initial defibrillation, early defibrillation by nonmedical personnel has been advocated. The widespread use of automatic external defibrillators has the potential to improve significantly the availability of early defibrillation.[231,233] These are relatively simple and inexpensive devices that have an automatic detection and treatment algorithm for ventricular

tachyarrhythmias, but whether widespread use of these devices will translate into improved overall mortality rates and quality of life remains to be determined. The addition of interposed abdominal compression to standard CPR techniques has been reported to improve the outcome, particularly in patients found in asystole or electromechanical dissociation.[234]

Although duration of arrest is the most important determinant of successful ventricular defibrillation, other factors should be kept in mind. It has been estimated that in humans only about 4 percent of the transthoracic current actually traverses the heart, the rest being shunted by the thoracic cage and lungs.[235] The transthoracic impedance is inversely proportional to the size of defibrillator patches and the force applied on the paddles. It also depends on the location of the paddles and the paddle-skin coupling material, and it decreases with the number of shocks applied.[236] To improve defibrillation efficacy, especially in individuals with large chests and expected high transthoracic impedance, the operator should use a gel, cream, or saline-soaked gauze between the paddles and the skin and press firmly on the largest hand-held paddles available; several successive shocks may be necessary.[237] Recent experimental evidence suggests that ischemia-triggered release of endogenous adenosine may have deleterious effects on the success of defibrillation.[238] Development of specific adenosine antagonists and their administration during CPR in patients found in ventricular fibrillation might further improve defibrillation success.

Chapter 33: SUDDEN CARDIAC DEATH

SURVIVAL AND PROGNOSIS AFTER CARDIAC ARREST

Survival to hospital discharge after cardiac arrest varies from 1.4 to 28 percent.[77,78,229,239,240] Marked differences in survival rates following out-of-hospital cardiac arrest have been reported in different communities, being lowest in large cities such as New York (1.4 percent) and Chicago (4 percent)[196] and highest (28 percent) in Seattle, an urban community where many of the early intervention concepts have been pioneered.[241] The in-hospital mortality rate following successful resuscitation outside the hospital remains high, in the range of 30 to 50 percent[77,78,242] (Fig. 33-6). The most important factors associated with increased in-hospital mortality rates after out-of-hospital cardiac arrest are cardiogenic shock after defibrillation, age 60 years or greater, requirement of four or more shocks for defibrillation, absence of an acute myocardial infarction, and coma on admission to the hospital.[77,242]

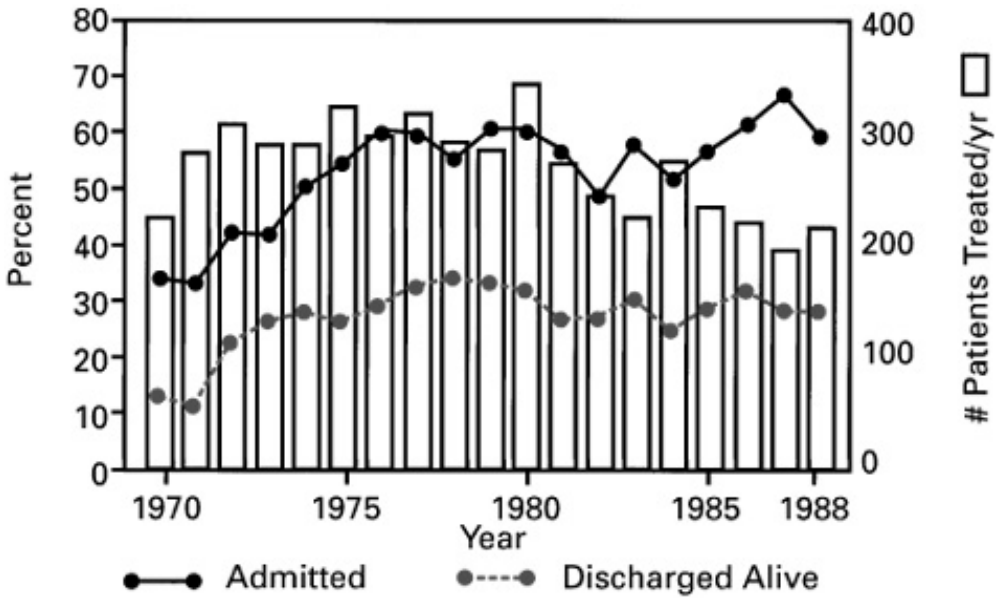

Figure 33-6: Percentage of out-of-hospital cardiac arrest victims admitted to the hospital by emergency medical service personnel and subsequently discharged alive during the period from 1970 to 1988. (From Cobb LA et al. Community-based interventions for sudden cardiac death: Impact, limitations, and changes. *Circulation* 1992; 85:I98-I102. Reproduced with permission from the publisher and authors.)

Survival depends largely on the initial recorded rhythm.[77,78,229,239,240] Some 40 to 60 percent of patients who are found in ventricular fibrillation are successfully resuscitated, but only about one-fourth of patients survive to be discharged from the hospital. The outcome is much better in the small (less than 7 percent) group of patients in whom ventricular tachycardia is the initial documented rhythm: 88 percent survive to the hospital and 76 percent are discharged alive. Bradycardias and electromechanical dissociation as the presenting rhythms are associated with the worst prognosis, and very few (less than 5 percent) of these patients survive to discharge from the hospital.[78] Other factors associated with improved survival are a low "comorbidity index,"

reflecting chronic conditions such as history of heart failure, diabetes, hypertension, and gastrointestinal disorders as well as recent symptoms prior to the event.[243]

An important consideration in the treatment of the cardiac arrest victim is the appropriateness of CPR and the use of life-sustaining therapies in patients with a low likelihood of survival, such as chronically ill people found in asystole or electromechanical dissociation. Their chances of surviving until hospital discharge are less than 1 percent. Further, many older people prefer to die suddenly rather than experience chronic suffering.[244] Advance directives, when available, and consultation with family members and personal physicians might aid in the difficult decision process of when to administer supportive care rather than aggressive management.

Chapter 33: SUDDEN CARDIAC DEATH

MANAGEMENT OF CARDIAC ARREST SURVIVORS AND RISK STRATIFICATION FOR SUDDEN CARDIAC DEATH

Establishing the Underlying Cardiac Pathology

The initial management following successful resuscitation from cardiac arrest consists of allowing a period of hemodynamic and respiratory stabilization, after which every effort should be made to establish the cause of cardiac arrest and likelihood of recurrence. For this, the underlying cardiac disease should first be determined. History and physical examination may provide the first clues. Myocardial infarction must be excluded by serial enzyme and electrocardiographic studies. Echocardiographic studies can determine left ventricular function, regional wall motion abnormalities, valvular heart disease, or cardiomyopathies. Stress-imaging studies can demonstrate inducible ischemia. Cardiac catheterization is often recommended to evaluate the coronary anatomy and right and left ventricular hemodynamic parameters. Other tests, such as radionuclide studies, magnetic resonance imaging, or cardiac biopsy, may be necessary in selected patients. As discussed above, an underlying cardiac disease can be found in nearly all patients.

PRIMARY VERSUS SECONDARY CARDIAC ARREST

One of the important questions following cardiac arrest is whether it was primarily due to acute circulatory or respiratory failure or to an arrhythmia. Although all these events are usually present during the arrest, it is important to distinguish whether the arrhythmia preceded or followed the hemodynamic collapse. While several clinical and historical clues help to answer this question (Table 33-5), the distinction sometimes cannot be made with certainty. Separating primary from secondary cardiac arrest has important prognostic and therapeutic consequences. In 142 survivors of cardiac arrest with coronary artery disease, the 1-year survival rate was 89 percent, 80 percent, and 71 percent in the patients classified as having had cardiac arrest secondary to acute myocardial infarction (44 percent of patients), secondary to an ischemic event (34 percent), or due to a primary arrhythmic event (22 percent), respectively.[96] Patients who present with cardiac arrest secondary (and within 48 h) to an acute transmural myocardial infarction have a prognosis similar to that of those who have an acute myocardial infarction without an arrhythmia.[77] Specific antiarrhythmic therapy is therefore usually not recommended if cardiac arrest occurs during or within 2 days of an acute Q-wave myocardial infarction. In contrast, if the arrhythmia is the primary event and myocardial infarction developed secondary to the acute hemodynamic deterioration during the arrhythmia, then antiarrhythmic therapy with a drug or device is recommended unless a transient or reversible cause is identified.[96]

Table 33-5: Differences in Clinical Status Immediately before Death in Patients Dying Primarily of Arrhythmia versus Circulatory Failure

Clinical Status Immediately before Death	Arrhythmic Deaths *n* = 82	Circulatory Failure Deaths *n* = 59
Comatose	0/82 (0%)	56/59 (95%)
Standing or actively moving	39/82 (48%)	0/59 (0%)
Terminal arrhythmia		
Ventricular fibrillation	15/18 (83%)	3/9 (33%)

Asystole	3/18 (17%)	6/9 (67%)
Duration of terminal illness		
<1 h	53/82 (65%)	4/59 (7%)
>24 h	17/82 (21%)	48/59 (81%)
Nature of terminal illness		
Acute cardiac events	80/82 (98%)	8/59 (14%)
Noncardiac events	1/82 (1%)	51/59 (86%)

SOURCE: Modified with permission from Hinkle et al.[13]

Every effort should be made to exclude potentially reversible causes of sudden cardiac death (Table 33-6), including transient ischemic episodes in patients who are candidates for complete revascularization and in whom the onset of the arrhythmia is clearly preceded by ischemic ECG changes or symptoms.

Table 33-6: Potentially Reversible Causes of Cardiac Arrest Due to Ventricular Fibrillation

Myocardial ischemia	Electrolyte abnormalities
Prinzmetal's angina	Hypoxia
Proarrhythmia	Acute congestive heart failure
Antiarrhythmic agents	
Other drugs	

Other reversible etiologies for cardiac arrest include transient severe electrolyte disturbances and proarrhythmic effects of antiarrhythmic drugs and other pharmacologic agents. It can be difficult to establish a causal relationship between the proarrhythmic agent and the malignant ventricular arrhythmia, as opposed to its being a coincidental finding. A pathologic prolongation of the QT_c interval preceding initiation of the arrhythmia and return of the QT_c interval to normal following discontinuation of the presumed proarrhythmic agent is strongly suggestive of a cause-effect relationship. Occasionally, especially when type IA agents are implicated in the cardiac arrest event, electrophysiologic evaluation, with programmed stimulation after washout and following reexposure to these agents, is necessary to confirm proarrhythmia as the sole cause of the episode of cardiac arrest. Another setting in which a reversible etiology for cardiac arrest is often present is in the hemodynamically unstable patient in the early postoperative period following cardiac surgery. Infusion of positive inotropic agents, electrolyte imbalances, and hypoxia are often precipitating factors.

Risk Stratification for Sudden Cardiac Death

Several clinical, noninvasive, and invasive strategies can aid in the risk stratification of patients for sudden cardiac death. The underlying cardiac disease largely determines the choice of appropriate testing.

CLINICAL HISTORY

Four independent prognostic variables for sudden cardiac death related to clinical history were identified in a study of 200 patients who suffered from ventricular fibrillation or sustained ventricular tachycardia following myocardial infarction: (1) cardiac arrest at the time of the first documented episode of arrhythmia, (2) New York Heart Association (NYHA) class III or IV, (3) ventricular fibrillation or ventricular tachycardia occurring early after myocardial infarction (3 days to 2 months), and (4) history of multiple previous myocardial infarctions.[245] Risk stratification for sudden cardiac death using these four variables can identify subgroups with a sudden cardiac death incidence ranging from 0 to 28 percent. It is noteworthy that patients with hemodynamically tolerated ventricular tachycardia occurring more than 2 months after myocardial infarction, a subgroup that constituted 40 percent of the study population, were reported to have a 0 percent incidence of sudden cardiac death at 26 months. Syncope in patients with a left ventricular ejection fraction below 30 percent is associated with increased risk of sudden cardiac death (about 50 percent at 3 years) irrespective of finding an arrhythmic cause.[246]

LEFT VENTRICULAR FUNCTION

Depressed left ventricular function is a major independent predictor of total and sudden cardiac mortality rates in patients with ischemic as well as nonischemic cardiomyopathy.[247-250] In survivors of cardiac arrest who have a left ventricular ejection fraction below 30 percent, the risk of sudden cardiac death exceeds 30 percent over 1 to 3 years if the patients do not have inducible ventricular tachycardia; it ranges between 15 and 50 percent in those who have inducible ventricular tachyarrhythmias despite therapy with drugs that suppressed the inducible arrhythmias or with empiric amiodarone.[251-253] Assessment of left ventricular function by clinical history (e.g., a history of congestive heart failure) and by other noninvasive methods (echocardiographic or radionuclide studies) or invasive means (angiography) is therefore essential in the evaluation of a patient at risk for sudden cardiac death.[248] Unfortunately, detection of severe left ventricular dysfunction serves to predict the total cardiac mortality rate but does not distinguish patients who will die suddenly from those who will die of progressive congestive heart failure.[124,248,249]

ELECTROCARDIOGRAPHIC ABNORMALITIES

In survivors of out-of-hospital cardiac arrest, the presence of atrioventricular block or intraventricular conduction defects on ambulatory ECG (72 h) is associated with a higher recurrence rate of cardiac arrest (10 of 14 patients versus 1 of 28 patients without).[78] Other ECG parameters that have been reported to be associated independently with an increased risk of sudden cardiac death are prolongation of the QT interval (in the absence of inherited or acquired long-QT syndrome),[254] increased dispersion of the QT interval,[255,256] and an increase in resting heart rate above 90, particularly in men without a history of coronary artery disease.[257]

Detection of nonsustained ventricular arrhythmias by ambulatory ECG monitoring has been reported to be of value in the risk stratification of patients for sudden cardiac death.[247,258-261] The incidence of sudden cardiac death in the 2 years following myocardial infarction in 766 patients enrolled in the Multicenter Post-Infarction Research Group increased with the frequency of PVCs detected during 24-h ECG monitoring from 3 percent for less than 1 per hour to 14 percent for more than 30 per hour; similarly, patients with nonsustained ventricular tachycardia runs had a higher (17 percent) incidence of sudden cardiac death than did those with single PVCs (6 percent).[247] The prognostic value of ambulatory ECG monitoring in patients with congestive heart failure is limited by the high incidence of these arrhythmias (up to 88 percent) in this population, resulting in a low specificity of this parameter.[262]

BAROREFLEX SENSITIVITY

Reduced baroreflex sensitivity, reflecting mainly an impairment in the vagal efferent component of the baroreceptor reflex, may help to predict cardiovascular mortality rates and arrhythmic events, particularly in patients following myocardial infarction.[91-93] In two prospective studies including a total of 200 patients following myocardial infarction, baroreflex sensitivity was significantly reduced in the 14 patients with sudden cardiac death or life-threatening arrhythmias compared to those without (less than 3 ms/mmHg

versus 8 ms/mmHg).[95,263] The prognostic significance of baroreflex sensitivity was not diminished in patients with reduced left ventricular function and carried the highest relative risk for arrhythmic events, superior to that of other prognostic variables, including left ventricular function.

HEART RATE VARIABILITY

Another noninvasive measure of sympathovagal balance is heart rate variability, beat-to-beat variations of RR intervals and their mathematically derived parameter. Several measures of heart rate variability have been reported to be associated with an increased risk of sudden and total cardiac death following myocardial infarction, underscoring the importance of the autonomic nervous system in the evolution of life-threatening arrhythmias.[261,264-266] In a study of 808 survivors of myocardial infarction, heart rate variability of less than 50 ms carried a 5.3 relative risk of death compared with the group with a heart rate variability of greater than 100 ms.[264] In a prospective study of 6693 nonselected and consecutive patients who underwent 24-h ambulatory ECG monitoring, those with a heart rate variability of less than 25 ms had a fourfold higher risk of sudden cardiac death than did patients with higher variability.[266] The sensitivity, specificity, positive predictive value, and relative risk in the prediction of arrhythmic events following myocardial infarction have been reported to be 60, 94, 55, and 10.4 for reduced heart rate variability [standard deviation of RR intervals (SDNN), less than 50 ms] and 80, 91, 44, and 23.1, respectively, for decreased baroreflex sensitivity (less than 3.0 ms/mmHg).[267] A prospective international study is in progress to assess the prognostic significance of diminished baroreflex sensitivity and heart rate variability 20 days after myocardial infarction in a large population.[268]

NONLINEAR DYNAMICS

According to the chaos theory, apparently irregular events such as ventricular ectopy are nonrandomly distributed in time, and their clustering can be quantified by fractal geometric analysis.[269] Fractal clustering of ventricular ectopy has been associated with sudden cardiac death in patients with mitral regurgitation and has also been demonstrated in other patients with life-threatening ventricular arrhythmias. The physiologic correlate for a low fractal dimension appears to be transient increases in cardiac sympathetic tone.[270]

T-WAVE ALTERNANS

Macroscopic T-wave changes with an alternating pattern have been observed in patients with long-QT syndrome prior to onset of ventricular fibrillation as well as in the setting of mechanical alternans, as is sometimes present during cardiac tamponade. Recent studies have indicated that T-wave alternans that is discernible only by computer-averaging techniques may be a more ubiquitous phenomenon that can identify patients at risk for ventricular arrhythmias.[271] Techniques for computer-assisted analysis of T-wave alternans are being developed and may provide a quantitative, noninvasive method for assessing susceptibility to ventricular fibrillation. T-wave alternans assessed by computer analysis has been shown to predict arrhythmia-free survival over 20 months, with a nearly 90 percent sensitivity and specificity in a small cohort of 66 patients[272] (see Chaps. 23 and 24). The positive predictive accuracy of this test appears to be similar to that of others with a very high negative predictive value.

LATE POTENTIALS

Late potentials, microvolt waveforms extending the duration of a filtered QRS complex detected by signal-averaging electrocardiography (SAECG), have been shown to be helpful in the risk stratification of patients following myocardial infarction. The prognostic significance of late potentials has been demonstrated in several studies, which reported a 17 to 29 percent incidence of sudden cardiac death, ventricular fibrillation, or sustained ventricular tachycardia in patients with an abnormal SAECG, in contrast to 0.8 to 3.5 percent in those without.[273] Although the negative predictive value of a normal SAECG is good, the application of SAECG in risk stratification for sudden cardiac death is limited by a low positive predictive value in patients following myocardial infarction as well as by its low sensitivity in patients with nonischemic cardiomyopathies[130,274,275] (see also Chap. 23). The sensitivity, specificity, and positive predictive value of SAECG are all improved when used in patients with known left ventricular dysfunction after myocardial infarction and/or nonsustained ventricular tachycardia.[275]

ELECTROPHYSIOLOGIC STUDIES

Electrophysiologic studies have advanced our understanding of life-threatening ventricular arrhythmias and facilitated the development of new therapies for their prevention and treatment. Induction of sustained monomorphic ventricular tachycardia is the generally accepted end point for programmed stimulation, while induction of nonsustained ventricular arrhythmias, polymorphic ventricular tachycardia, or ventricular fibrillation may be a nonspecific finding, depending on the aggressiveness of the stimulation protocol.[204,276] Information obtained during the electrophysiologic study-such as ventricular tachycardia rate, morphology, origin, mechanism, and hemodynamic stability-is crucial to determining whether the patient is a candidate for serial drug testing, catheter ablation therapy, surgical therapy, or an implantable defibrillator. In patients who present with sustained monomorphic ventricular tachycardia, ventricular tachycardia is reproducibly inducible in the vast majority, especially in those with coronary artery disease.[276] Electrophysiologic testing is also useful in patients with structural heart disease presenting with unexplained syncope. Ventricular tachycardia is the most common abnormal finding in these patients, but demonstration of His-Purkinje conduction disease or hemodynamically unstable supraventricular tachycardia can also be important. In patients with CHD, reduced left ventricular function, and documented nonsustained ventricular tachycardia, electrophysiologic studies can help select patients who would benefit from antiarrhythmic therapy. In survivors of cardiac arrest due to ventricular fibrillation, the prognostic value of electrophysiologic testing is less clear. Since sustained ventricular tachycardia or ventricular fibrillation is inducible in fewer than half the patients, suppression of induction of ventricular fibrillation by antiarrhythmic therapy is an unreliable end point, and even patients with no inducible ventricular arrhythmias remain at a high risk for recurrent cardiac arrest.[277,278] Nevertheless, in survivors of cardiac arrest, electrophysiologic study may reveal the mechanism of arrest, have prognostic significance, and help select an appropriate therapy.[279,280] The routine use of electrophysiologic testing following myocardial infarction and in patients with nonischemic cardiomyopathy is controversial, and the appropriate end points are unclear[277,281] (see Chap. 26).

Chapter 33: SUDDEN CARDIAC DEATH

TREATMENT OPTIONS FOR PATIENTS AT RISK FOR SUDDEN CARDIAC DEATH

General Considerations

There are few direct and randomized comparisons of various treatment strategies to prevent sudden cardiac death. Since reduction of sudden cardiac death rates does not necessarily parallel a reduction in total mortality rate, reduction in total mortality rate is a more appropriate end point in assessing antiarrhythmic efficacy. Patient selection affects the outcome of different treatment strategies. For example, in patients at low risk of sudden cardiac death, proarrhythmia or procedural mortality rates may outweigh the benefits achieved with an antiarrhythmic intervention. On the other hand, in patients at high risk for recurrent cardiac arrest, the risk-benefit profile of antiarrhythmic treatment strategies may be more favorable. Selection of therapy is further limited by the patient's baseline characteristics. For instance, only patients with inducible sustained ventricular arrhythmias are good candidates for electrophysiologically guided antiarrhythmic drug therapy, and radiofrequency ablation of ventricular tachycardia is an option only in patients with hemodynamically stable monomorphic ventricular tachycardia or bundle-branch reentry. In an era of limited health care resources, the cost-effectiveness of different treatment strategies is another element to be considered in choosing therapy. Last but not least, quality of life is an important aspect in the selection of the most appropriate therapy.

Pharmacologic Therapy

BETA BLOCKERS

Of all the therapies currently available for the prevention of sudden cardiac death, none is more established or more effective in patients with coronary heart disease than beta blockers.[282,283] Although beta blockers are less effective in suppressing spontaneous or induced ventricular ectopy when compared with other membrane-active antiarrhythmic agents, both nonselective beta blockers (timolol and propranolol) and cardioselective agents (e.g., metoprolol) have been shown in placebo-controlled, randomized trials to reduce total mortality rates by 20 to 36 percent, in large part because of a reduction of sudden cardiac death.[283-286] The benefits of beta blockade are additive to those of standard treatment for congestive heart failure. The Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) trial demonstrated a 34 percent decrease in the mortality rate due to all causes, a 38 percent decrease in the cardiovascular mortality rate, and a 41 percent decrease in sudden death in 3991 patients who were randomized to beta blockers or placebo while being treated with standard medical therapy, including angiotensin-converting enzyme (ACE) inhibition, digitalis, and diuretics.[287]

In a review of 19,000 post-myocardial infarction patients who were randomized to beta blockers or placebo, active treatment was associated with a decrease in total mortality rate of 20 percent, of sudden cardiac death rate of 30 percent, and of reinfarction of 35 to 40 percent.[288] Beta blockers are effective in the setting of ventricular arrhythmias provoked by a high sympathetic tone, as in patients with congenital long-QT syndrome,[176] arrhythmogenic right ventricular dysplasia,[157] or congestive heart failure.[289] It is important to note that the beneficial effects of beta blockers on cardiac mortality rate are most pronounced in patients who are at higher risk for sudden cardiac death, such as patients with congestive heart failure, atrial and ventricular arrhythmias post-myocardial infarction, and diabetes[282] (see also Chaps. 23 and 42).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Vasodilator therapy is an effective treatment in patients with congestive heart failure and has been shown to reduce mortality rates by up to 40 percent in the first year.[290-292] The effect of ACE inhibitors on sudden cardiac death in established heart failure is less clear. In studies of patients with class I through IV congestive heart failure treated with ACE inhibitors or placebo, approximately 20 percent of patients died suddenly, without a significant difference in the sudden death mortality rate.[290-292] The situation is somewhat different in patients without heart failure in the post-myocardial infarction setting. Several trials have demonstrated a significant reduction in overall deaths in post-myocardial infarction patients (ejection fraction less than 35 percent) with or without mild heart failure. These studies have demonstrated a significant or trend toward a significant decrease in sudden cardiac death.[293-296] A recent metaanalysis analyzed 15 trials that included 15,104 post-myocardial infarction patients treated with ACE inhibitors. There were 900 sudden cardiac deaths in these studies, and a significant or trend toward significant reduction in sudden cardiac death in all of the larger (*n* >500) trials.[297]

CLASS I ANTIARRHYTHMIC DRUGS

The role of antiarrhythmic drug therapy in the prevention of sudden cardiac death has changed considerably since placebo-controlled trials such as Cardiac Arrhythmia Suppression Trial (CAST) demonstrated that suppression of spontaneous nonsustained ventricular arrhythmias with certain drugs does not necessarily result in improved survival rates.[214] In CAST, type IC antiarrhythmic drugs, such as encainide, flecainide, and moricizine, were associated with excess deaths from arrhythmias in asymptomatic post-infarction patients with frequent ventricular ectopy despite effective suppression of spontaneous ventricular ectopy[214] (Table 33-7). These results were interpreted as being due to an excessive proarrhythmic effect, which outweighed the lower mortality risk of these patients. Whether the risk-benefit ratio between pro- and antiarrhythmic effect of antiarrhythmic drugs is different in other patient populations or with other antiarrhythmic drugs is not clear, since there are very few placebo-controlled, randomized trials with total mortality rate as an end point.

There is no evidence that other class I antiarrhythmic drugs can prolong survival in any patient group studied, and they may even be harmful. Results of a meta-analysis of empiric long-term antiarrhythmic therapy after myocardial infarction with mostly class I antiarrhythmic agents (mexiletine, phenytoin, tocainide, flecainide, encainide, procainamide, aprindine, imipramine, and moricizine) showed either no beneficial effects or detrimental effects on mortality rate despite effective reduction of PVCs.[298,299] A meta-analysis of lidocaine in acute myocardial infarction suggested an increase in in-hospital mortality rate despite a reduction in the prevalence of ventricular fibrillation.[300] Empiric use of these drugs in patients with sustained ventricular arrhythmias has been associated with a very high rate of sudden cardiac death, between 30 and 70 percent at 2 years.[301] In a randomized trial between electrophysiologically guided conventional (i.e., class I drugs) therapy versus empiric amiodarone in survivors of cardiac arrest (CASCADE), overall survival rates were lower in the conventional arm (78, 62, and 32 percent at 2, 4, and 6 years, respectively).[302] The propafenone arm was stopped early in the Cardiac Arrest Study-Hamburg (CASH) because of excess mortality rates in cardiac arrest survivors compared with amiodarone, beta blockers, and implantable defibrillators[303] (see also Chap. 24).

SOTALOL

Sotalol, in the currently marketed form of a racemic mixture of the *d*- and *l*-stereoisomers, is a potent class III antiarrhythmic agent with nonselective beta-blocking effects.[304] Sotalol has been reported to suppress inducible ventricular tachycardia in 30 to 40 percent of patients who present

with sustained ventricular arrhythmias. In a randomized trial of sotalol and other antiarrhythmic agents in patients with sustained ventricular tachycardia, the arrhythmia recurrence rate (21 percent at 1 year) and the arrhythmic death rate (12 percent at 4 years) was half of that achieved with class I agents.[305] However, since most patients receiving sotalol had failed other antiarrhythmic agents, the results were biased in favor of sotalol. The beta-blocking effect of sotalol seems to be essential for its benefit. The Survivor With Oral *d*-Sotalol (SWORD) trial of the *d*-isomer (class III antiarrhythmic effect only, devoid of beta-blocking effect) in patients with prior myocardial infarction was associated with increased mortality rates[306] (Table 33-7). The most serious side effect encountered with sotalol is proarrhythmia (mostly torsades de pointes), which has been reported to occur in up to 8 percent of treated patients.[303] In survivors of cardiac arrest, sotalol therapy was less effective than implantable cardioverter defibrillators.[307]

AMIODARONE

Amiodarone is widely considered the most effective antiarrhythmic agent for therapy of supraventricular and ventricular arrhythmias. It is a class III antiarrhythmic agent with additional class I, II, and IV properties and has unusual pharmacokinetics with a delayed onset of action and an elimination half-life of up to 53 days after chronic therapy[308] (see Chap. 27). In contrast to that of other antiarrhythmic agents, the long-term clinical efficacy of amiodarone is poorly predicted by the results of electrophysiologic evaluation.[252,253] Uncontrolled trials in patients with sustained ventricular tachycardia or ventricular fibrillation demonstrated a relatively low incidence of sudden cardiac death in patients treated with amiodarone, despite a high recurrence rate of ventricular arrhythmias. The sudden cardiac death rates at 1, 3, and 5 years in two series of 462 and 589 patients with mostly sustained ventricular arrhythmias were 9 percent, 15 to 16 percent, and 21 to 22 percent, respectively, whereas the arrhythmia recurrence rates were approximately 20 percent, 30 percent, and 40 percent during the same time period.[252,253] Again, the most important predictor of sudden cardiac death in patients treated with amiodarone for sustained ventricular tachycardia or ventricular fibrillation is left ventricular ejection fraction. In a series of 122 such patients with mostly coronary artery disease, the actuarial probability of sudden cardiac death at 5 years was 5 percent when the ejection fraction was greater than or equal to 40 percent and 49 percent when the ejection fraction was less than 40 percent.[309]

Amiodarone has been shown to reduce significantly sudden cardiac death rates following myocardial infarction in several placebo-controlled randomized studies, but its effects on the total mortality rate are inconsistent.[310] The Basel Antiarrhythmic Study of Infarct Survival (BASIS), a prospective randomized trial of empiric amiodarone, ambulatory ECG-guided conventional antiarrhythmic therapy, or placebo in 312 patients with complex ventricular ectopy following myocardial infarction showed that amiodarone significantly reduced the total mortality rate at 1 year from 13 percent in the placebo group to 5 percent in amiodarone-treated patients ($p < .05$).[311] On the other hand, amiodarone therapy did not reduce the total mortality rate compared with placebo in nearly 2700 post-myocardial infarction patients enrolled in the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT)[312] and the European Myocardial Infarction Amiodarone Trial (EMIAT),[313] despite a 50 percent risk reduction in the arrhythmic mortality rate (Table 33-7).

In patients with congestive heart failure who are at high risk for sudden cardiac death, prophylactic therapy with amiodarone was shown to decrease the mortality rate (by 28 percent) in the Argentinean Grupo de Estudio de la Sobrevida en la Insufficiencia Cardiaca en Argentina (GESICA) trial[314] but not in the Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure (STAT-CHF).[315] Comparison of the two patient populations and subgroup analysis suggested that prophylactic amiodarone may be more beneficial in patients with nonischemic cardiomyopathy, found in greater number in the GESICA study (Table 33-7). The consequence of these amiodarone trials is that this drug can be used safely in patients with left

ventricular dysfunction, and, in contrast to some class I agents, it does not increase mortality rates. Therefore, amiodarone is the drug of choice when antiarrhythmic drug treatment is indicated in patients with left ventricular dysfunction.

In patients who survived cardiac arrest not associated with myocardial infarction, empiric amiodarone therapy has been shown to be superior to electrophysiologically guided conventional therapy.[302] Rates for survival free of cardiac death, resuscitated cardiac arrest, and defibrillator shocks associated with syncope at 1, 3, and 5 years was 91 percent, 76 percent, and 63 percent, respectively, in the amiodarone-treated patients, compared with 77 percent, 56 percent, and 46 percent in the conventionally treated patients. The efficacy of amiodarone in reducing total mortality rates in patients with ventricular fibrillation or hemodynamically unstable ventricular tachycardia compared to implantable cardioverter-defibrillator (ICD) treatment has been evaluated prospectively in the randomized Amiodarone versus Implantable Defibrillator (AVID) study, which reported a survival benefit in the patients randomized to ICD therapy.[307] Prospective, randomized trials addressed a similar question in cardiac arrest survivors in the Canadian Implantable Defibrillator Study (CIDS)[316,317] and CASH[303,318] (see below).

Intravenous Amiodarone

Intravenous amiodarone in the United States remains a powerful parenteral drug for the acute treatment of patients with life-threatening ventricular arrhythmias.[319] The efficacy of intravenous amiodarone in patients with recurrent, hemodynamically unstable ventricular tachycardia refractory to lidocaine, procainamide, and bretylium is approximately 40 percent in prospective studies, and about 80 percent of the arrhythmias are suppressed within the first 48 h. A loading dose of 5 mg/kg over the first 30 min and a total dose of 1000 mg in the first 24 h is recommended. Additional boluses of 150 mg may be necessary for arrhythmia control.[320] Compared with bretylium, intravenous amiodarone was at least as effective and caused significantly less hypotension than did bretylium in 302 patients with recurrent or incessant ventricular arrhythmias refractory to lidocaine and procainamide[321] (see also Chaps. 24 and 27).

The use of intravenous amiodarone in out-of-hospital cardiac arrest was recently studied. Intravenous amiodarone was compared to placebo in 504 patients suffering out-of-hospital cardiac arrest that was refractory to three or more precordial shocks. Patients receiving 300 mg of intravenous amiodarone had an improved rate of survival to admission to the hospital as compared to placebo. Whether use of intravenous amiodarone confers a survival benefit remains to be determined.[322]

Device Therapy

AUTOMATIC IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

The ICD was initially developed to recognize ventricular fibrillation or rapid ventricular tachycardia and terminate it automatically by delivering one or more high-energy shocks.[323] Newer-generation defibrillators have the additional ability to deliver low-energy cardioversion, antitachycardia pacing for ventricular tachycardia, and antibradycardia pacing. In addition, the extended storage capabilities of new defibrillator systems permit retrospective analysis of the stored electrograms during arrhythmia detection, allowing more accurate conclusions about the type of arrhythmia recognized by the device (supraventricular or ventricular), their mode of initiation, and effects of additional antiarrhythmic therapy.

The first generation of epicardial defibrillators required a thoracotomy to place the sensing and defibrillator leads epicardially, and the generator size mandated implantation of the device in an abdominal pocket. The development of biphasic waveforms, "active cans" (the generator case

itself serves as a defibrillator electrode), and more efficient capacitors has made it possible to reduce the size of the defibrillators, which can now be implanted subpectorally with a transvenous endocardial lead system that integrates both pace-sense and high-voltage defibrillation abilities. Endocardial placement has reduced the perioperative mortality rate associated with defibrillator implants from 4 to 5 to less than 1.0 percent.[324]

ICDs are very effective in terminating ventricular tachyarrhythmias. In a large data base of 2834 epicardial and endocardial defibrillators implanted in 2807 patients between 1989 and 1993, 98.8 percent of 7470 ventricular fibrillation episodes were detected, and 97.9 percent of 42,132 ventricular tachycardia episodes were successfully terminated by the device.[324] The long-term outcome of patients with implantable defibrillators is also favorable, considering that virtually all patients receiving such devices are at high risk for sudden cardiac death, since they had either cardiac arrest or recurrent ventricular tachycardia refractory to medical therapy prior to implantation of the device. Defibrillator therapy has been shown to effectively reduce the annual incidence of sudden cardiac death in patients with severe underlying cardiac disease (less than 5 percent)[325,326] as well as in patients without significant structural heart disease (0 percent).[327] Despite effective reduction of the mortality rate from sudden cardiac death, however, long-term survival in patients with severely depressed left ventricular function is still poor despite defibrillatory therapy, and the overall cardiac mortality rate does not appear to be reduced in direct proportion to the reduction in sudden cardiac death.[328]

To investigate the potential benefit of ICD therapy compared with antiarrhythmic drug treatment in secondary prevention, the AVID, CASH, and CIDS studies randomized patients with documented sustained ventricular arrhythmia to one of these two treatment strategies. AVID and CIDS enrolled patients with ventricular fibrillation or poorly tolerated ventricular tachycardia and left ventricular dysfunction. In the AVID trial, which enrolled 1016 such patients, the ICD group had 38 and 25 percent reductions in the overall mortality rate at 1 and 3 years, respectively, compared to the group of patients taking amiodarone or sotalol.[307] CIDS enrolled 659 patients. Preliminary results after 1 year of follow-up were recently reported, and a 20 percent reduction in mortality rate with ICD was demonstrated.[317] CASH enrolled patients with cardiac arrest secondary to a ventricular arrhythmia regardless of the underlying disease or ventricular function. The final results have not yet been published, although a 2-year 39 percent reduction of the mortality rate due to all causes in the ICD arm compared with the drug arm (metoprolol or amiodarone) has been reported by the investigators.[318] These studies show that, compared to the best currently available antiarrhythmic drug therapy, ICDs improve survival rates in patients with a history of ventricular fibrillation or ventricular tachycardia (Table 33-7).

Several studies looking at the primary prevention or prophylactic use of defibrillators in high-risk populations have been completed (Table 33-7). The Multicenter Automatic Defibrillator Implantation Trial (MADIT)[329] demonstrated a survival benefit of defibrillator therapy compared with conventional therapy in patients who are post-myocardial infarction with nonsustained ventricular tachycardia, left ventricular dysfunction, and inducible sustained ventricular tachycardia that was not suppressed by procainamide. It has led to the approval of prophylactic implantation of defibrillators in this narrowly defined patient population. The Multicenter Unsustained Tachycardia Trial (MUSTT) was a randomized, controlled trial to test the hypothesis that electrophysiologically guided antiarrhythmic therapy would reduce the risk of sudden death among patients with coronary artery disease, a left ventricular ejection fraction of 40 percent or less, and asymptomatic, nonsustained ventricular tachycardia. Patients in whom sustained ventricular tachyarrhythmias were induced by programmed stimulation were assigned to receive either antiarrhythmic therapy, including drugs and implantable defibrillators, as indicated by the results of electrophysiologic testing, or no antiarrhythmic therapy. Electrophysiologically guided antiarrhythmic therapy with implantable defibrillators, but not with antiarrhythmic drugs, reduced the risk of sudden death in high-risk patients with coronary disease[330] (Fig. 33-7). The

Coronary Artery Bypass Graft (CABG) Patch trial enrolled patients with coronary artery disease scheduled for elective coronary artery bypass grafting (CABG) who also had a left ventricular ejection fraction of less than 30 percent and an abnormal SAECG. Nine hundred patients were randomized to receive either an ICD at the time of CABG or usual care and followed for a mean of 32 months. This study found no significant difference in the primary end point of total mortality at 30 days and a mean of 32 months.[331] The findings were not surprising in view of the known benefit of revascularization in preventing sudden cardiac death (see below) and the poor positive predictive value of the SAECG (Table 33-7).

The number of patients who could benefit from an ICD implant is increasingly larger due to the lower mortality and morbidity rates associated with the implantation of newer endocardial devices, which can be implanted with techniques similar to those of bradycardia pacemaker insertion. ICDs can effectively protect against both tachycardic and bradycardic sudden cardiac death regardless of the underlying heart disease or various triggers of arrhythmias. Since their mode of action is therapeutic rather than preventive, ICD therapy might effectively be combined with other antiarrhythmic strategies, such as drugs or catheter ablation, to prevent frequent recurrences of tachyarrhythmias. Despite the undisputed efficacy of implantable defibrillators in preventing sudden cardiac death, there are several major questions that remain to be answered: (1) Which patients will benefit most from defibrillator therapy?, (2) Do ICDs improve quality of life?, (3) Are ICDs cost-effective compared with antiarrhythmic drug therapy?, and (4) Will adjunctive antiarrhythmic drug therapy add to the efficacy of ICDs? (see also Chap. 30).

PERMANENT PACEMAKER

Permanent pacing appears to have a beneficial effect on survival in patients with congenital long-QT syndrome.[332,333] The beneficial effects of permanent pacing may be related to prevention of bradycardia and pauses, potentially contributing to a more homogeneous repolarization, as well as rate-dependent shortening of the QT_c interval in patients with mutation in the sodium channel gene (*SCN5A*)[178] (see Chap. 24). This is an unreliable approach and is unlikely to be used in the future due to the development of small, dual-chambered ICDs.

Patients with obstructive hypertrophic cardiomyopathy are at increased risk for sudden cardiac death may also benefit from pacemaker implantation. In a series of 84 patients with this condition who had severe, drug-refractory symptoms and a history of syncope in half the patients, only two sudden cardiac deaths occurred during the 2.5-year follow-up period after pacemaker implantation.[334] This approximately 1 percent annual mortality rate compares favorably with the annual incidence of sudden cardiac death in hypertrophic cardiomyopathy of 2 to 4 percent per year in adults and 4 to 6 percent per year in children and adolescents[134] demonstrated in previous studies. Most studies have shown a decrease in left ventricular outflow tract gradient, however, pacing may have deleterious effects on other hemodynamic parameters, and there are no controlled trials demonstrating improved survival[334,335] (see Chap. 67).

Role of Surgery

REVASCULARIZATION

There is a reduced prevalence of sudden cardiac death after CABG.[336,337] Among the 13,476 patients in the Coronary Artery Surgical Study (CASS) registry, all of whom had significant coronary artery disease, operable vessels, and no significant valvular disease, the mean incidence of sudden cardiac death during the 4.6-year average follow-up was 5.2 percent in patients treated medically and 1.8 percent in those treated surgically.[336] The beneficial effect of CABG was even more pronounced in the subgroup of patients with reduced left ventricular ejection fraction and

multivessel disease, where the survival rate free from sudden cardiac death at 5 years was 91 percent for the surgical group versus 69 percent in the medical group. CABG also seems to be beneficial in patients with cardiac arrest prior to hospitalization. In an uncontrolled study of 265 survivors of cardiac arrest, 32 percent underwent CABG and 68 percent were treated medically.[338] After adjusting for differences in baseline variables between the two treatment groups, the use of CABG was associated with a significant risk reduction in recurrent cardiac arrest (risk ratio 0.48, confidence interval 0.24 to 0.97). The protective effect of CABG against recurrent cardiac arrest appears to be best in patients with reversible ischemia as the major pathophysiologic factor in sudden cardiac death. These patients are characterized by critical coronary artery disease, significant regions of myocardium at risk for ischemia, and no inducible monomorphic ventricular arrhythmias at electrophysiologic study.[251,338] Despite the encouraging results of CABG in survivors of cardiac arrest, it should be noted that only a minority of these patients are candidates for operative revascularization and that monomorphic ventricular tachycardia, which is often associated with ventricular scars from healed myocardial infarctions, is usually not controlled by myocardial revascularization alone.[339]

ANTIARRHYTHMIA SURGERY

Electrophysiologically guided subendocardial resection and cryoablation are potentially curative surgical options in patients with recurrent monomorphic ventricular tachycardia in whom areas of slow conduction around myocardial scars are critical for sustaining ventricular tachycardia. Long-term follow-up of this operative technique has yielded a clinical success rate of nearly 90 percent in eliminating the presenting ventricular tachycardia in patients who survive surgery. The technique is limited, however, by the high surgical mortality rate of 10 to 15 percent.[340] These data, gathered in the 1980s, may exaggerate the operative risk, since current myocardial preservation is improved. We believe that the use of this therapy should be revisited. The best candidates for electrophysiologically guided subendocardial resection are patients who require coronary revascularization and have a well-defined left ventricular aneurysm.

Another surgical technique aimed at reducing sudden cardiac death rates in high-risk patients is left cardiac sympathetic denervation in the therapy of congenital long-QT syndrome.[341] The goal of this surgery is selective partial sympathetic denervation of the heart. In a review of 85 long-QT patients who continued to have recurrent syncope and cardiac arrest despite beta-blocker therapy and subsequently underwent left sympathectomy, the cardiac event rate was reduced from 22 ± 32 to 1 ± 3 per patient, and the number of patients with cardiac events decreased from 99 to 45 percent.[341] The rate of sudden cardiac death over a follow-up period of nearly 6 years was 8 percent (see also Chap. 24). This therapy, which, when successful, is almost always associated with development of Horner's syndrome, has fallen out of favor as a result of the evolution of ICD therapy.

CATHETER ABLATION THERAPY

Catheter ablation of arrhythmias has emerged as a curative approach for many supraventricular arrhythmias and a few specific forms of ventricular tachycardias.[188] The role of catheter ablation in the prevention of sudden cardiac death is less well established, but this therapy form has been successfully employed in selected cases. Rarely, supraventricular tachycardias with a rapid ventricular response may degenerate into fatal ventricular tachyarrhythmias and cardiac arrest.[342] Radiofrequency catheter ablation can eliminate the risk of a rapid ventricular response by abolishing conduction over an accessory pathway in patients with Wolff-Parkinson-White syndrome, or it can slow or completely block conduction over the atrioventricular node in patients with atrial arrhythmias and rapid, medically uncontrolled atrioventricular conduction.

Radiofrequency catheter ablation can potentially prevent sudden cardiac death in patients with

documented and inducible bundle-branch reentrant ventricular tachycardia as the only mechanism of cardiac arrest.[343] The role of catheter ablation in other forms of ventricular tachycardia is less well established. Catheter ablation of ventricular tachycardia in patients with structural heart disease is currently feasible in only a small subset of patients who present with a hemodynamically relatively well-tolerated monomorphic ventricular tachycardia.[344] Although the acute success rate in eliminating the index arrhythmia in a few specialized centers is near 60 percent, these patients often have extensive coronary heart disease, and other ventricular tachycardia morphologies recur frequently during follow-up, necessitating additional therapies.[345] Improved mapping techniques of the ventricular tachycardia circuit, better catheters, and perhaps other energy sources may help improve the efficacy of catheter ablation for ventricular tachycardia and potentially expand its role in the prevention of sudden cardiac death (see also Chap. 28).

Chapter 33: SUDDEN CARDIAC DEATH

SUMMARY

Sudden cardiac death affects more than 300,000 individuals in the United States annually and accounts for half the mortality rate due to coronary heart disease. The vast majority of people who have experienced sudden cardiac death have underlying structural heart disease, which in the adult population is most frequently coronary heart disease, but a variety of other cardiac disorders can cause sudden cardiac death as well. Ventricular tachycardia and fibrillation and, less often, bradycardia and asystole are responsible for sudden cardiac death. Enhanced sympathetic tone appears to be important in triggering or predisposing to sudden cardiac death. Long-term survival following a cardiac arrest episode is still poor (less than 30 percent). The time delay to defibrillation and/or bystander administration of CPR directly influences survival. ICDs appear to be the most effective therapeutic option for treating survivors of cardiac arrest. Beta blockers and ACE inhibitors are helpful in the prevention of sudden cardiac death, in part through a reduction in the incidence of myocardial infarction. Proof for the use of other prophylactic medications, including antiarrhythmics, to prevent sudden cardiac death is inadequate. The most important factor limiting our ability to alter the incidence of sudden cardiac death is our inability to identify with acceptable sensitivity and specificity a large percentage of the individuals who experience sudden cardiac death. Short-term efforts to improve the survival of sudden cardiac death victims should be directed toward delivering CPR and electrical therapy as soon as possible after the onset of an arrest.[232] Long-term goals should be focused on the prevention of sudden cardiac death and encompass basically four interrelated, stepwise objectives:[232] (1) more accurate and specific identification of the patients at risk, (2) identification and characterization of mechanisms responsible for ventricular tachycardia-ventricular fibrillation, and bradycardia-asystole, (3) identification of interventions that prevent these arrhythmias, and (4) testing of these interventions in the individuals at risk.

Part 5: SYNCOPE, SUDDEN DEATH, AND CARDIOPULMONARY RESUSCITATION
Chapter 34:

CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

Authors: Nisha Chandra-Strobos, Myron L. Weisfeldt

INTRODUCTION: HISTORICAL ISSUES

Since biblical times, humans have attempted to restore life to the dead or nearly dead individual. The modern era of resuscitation began in the 1930s, when Wiggers pioneered the study of the mechanisms and treatment of ventricular fibrillation.[1] Major developments occurred in 1954, when Elam and colleagues showed that mouth-to-mouth or mouth-to-nose resuscitation was superior to the Schafer prone method of resuscitation in terms of efficacy of ventilation.[2,3] The importance of the circulation of blood was also recognized, and direct or internal cardiac massage became an accepted technique as early as 1916. Largely due to its complication rates and limited practical usefulness, it was replaced by noninvasive techniques of resuscitation.[4,5] In 1960, Kouwenhoven and coworkers developed the present technique of external chest compression in the supine position and coupled this with artificial respiration.[6] This technique of cardiopulmonary resuscitation (CPR) gained rapid popularity and was shown to be effective.[7] Only recently has the importance of prompt defibrillation taken a primary position in resuscitation efforts. Studies in large populations have confirmed that survival from prehospital cardiac arrest is dependent upon both prompt CPR and prompt defibrillation.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

MECHANISMS OF MOVEMENT OF BLOOD DURING CARDIOPULMONARY RESUSCITATION

The original hypothesis suggested that blood flow to the periphery during external chest compression resulted from direct compression of the heart between the sternum and the vertebral column.[6] According to this concept, chest compression ("systole"), similar to internal cardiac massage, resulted in blood being squeezed from both ventricles into the great arteries as the pulmonary and aortic valves opened.

Retrograde flow of blood was prevented by closure of the mitral and tricuspid valves. During the release phase of chest compression ("diastole"), the ventricles recoiled to their original shape and filled by a suction effect, while elevated arterial pressure was thought to close both the pulmonic and aortic valves.

This widely held concept is not, however, consistent with a number of observations in animal models[8] and humans[9]; these suggest a correlation between the rise in intrathoracic pressure during chest compression and the apparent magnitude of carotid flow and pressure. The importance of fluctuations in intrathoracic pressure as a means for generating blood flow is further supported by the observations of Criley et al. that, by the continuous and early initiation of coughing, patients in ventricular fibrillation can maintain consciousness as long as cough is continued.[10] The critical ingredient of the cough is clearly a rise in intrathoracic pressure, probably with no cardiac compression. Criley's observations strongly suggest that following cardiac arrest, a rise in intrathoracic pressure is a potent mechanism for the movement of blood to the brain in humans.[10]

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

EXPERIMENTAL OBSERVATIONS

For brain blood flow to occur during CPR, a carotid arterial-to-jugular pressure gradient must be present during chest compression. In large animals, chest compression during CPR results in an essentially equal rise in central venous, right atrial, pulmonary artery, aortic, esophageal, and lateral pleural space pressures with no transcardiac gradient being developed (Fig. 34-1).[11]

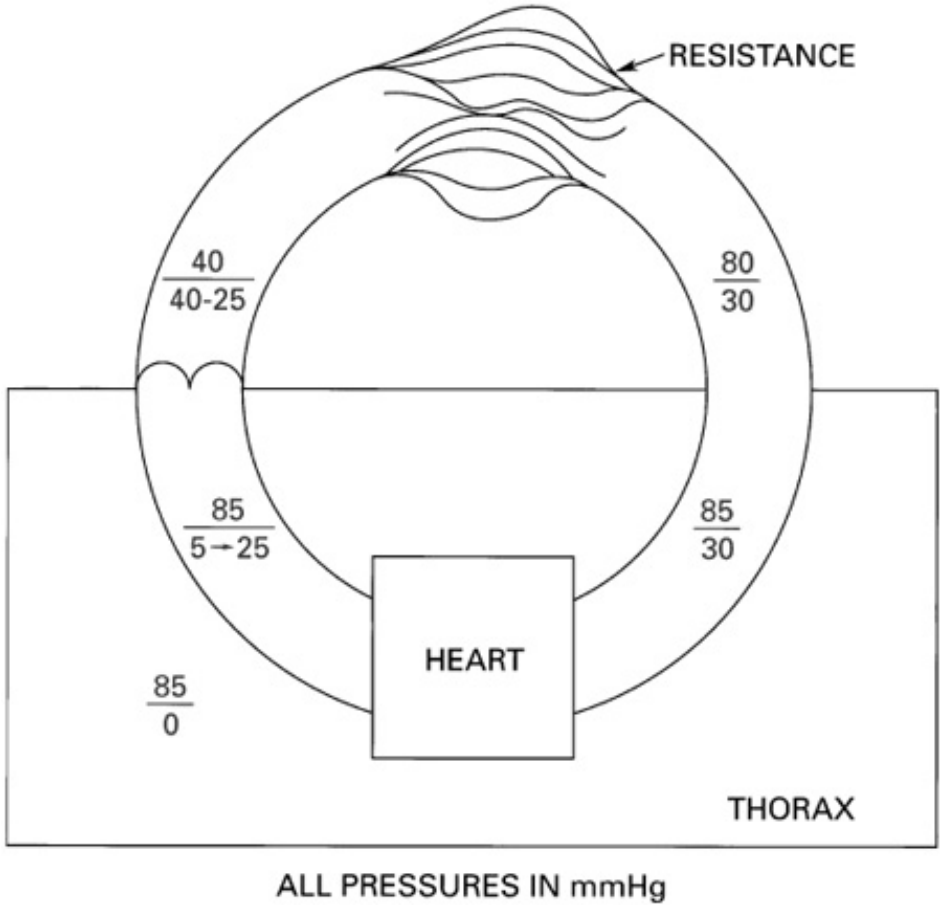

Figure 34-1: Representative pressures recorded during conventional cardiopulmonary resuscitation with forward carotid flow. Pressures are those recorded during compression. Intrathoracic pressures were indexed from esophageal pressures. There is no significant pressure gradient across the heart. The extrathoracic arterial pressure is similar to the intrathoracic aortic pressure. The extrathoracic venous pressure is markedly lower than the intrathoracic venous (right atrial) pressure. There is an extrathoracic arteriovenous pressure gradient that results in forward flow.

In large animals, aortic pressure is transmitted directly to the carotid arteries, but retrograde transmission of intrathoracic venous pressure into the jugular veins is prevented by valves at the thoracic inlet. Thus, during chest compression ("systole"), a peripheral arteriovenous pressure

gradient appears, and blood flow occurs consequent to this gradient. During compression, there is no pressure gradient across the heart; therefore, the heart cannot be the pump responsible for generating blood flow during CPR. In fact, the heart functions merely as a passive conduit. When chest compression is released ("diastole"), intrathoracic pressures fall toward zero, and venous flow into the right side of the heart and lungs occurs.

During diastole, a modest gradient also develops between the intrathoracic aorta and the right atrium and determines myocardial flow. Limited retrograde flow occurs into the aorta from extrathoracic arteries, raising aortic diastolic pressure and increasing coronary flow. The rise in intrathoracic pressure during chest compression is likely a consequence of airway collapse, which occurs at the level of the small bronchioles and results in air trapping. With the release of chest compression, this airway collapse is relieved.[12]

Unlike the hemodynamic pattern described above, in some animals intrathoracic vascular pressures during vigorous chest compression are much higher than pleural pressure.[13] In such animals, the rise in vascular pressures probably results from compression of the heart during chest compression, and the classic mechanism of direct cardiac compression is probably operating in these animals. Even during cardiac compression, however, venous valves at the thoracic inlet remain essential for establishing a peripheral arteriovenous pressure gradient, which facilitates peripheral flow. It is likely that flow produced by the two mechanisms operating simultaneously can occur, and in such situations the resultant flow is additive.

The position of the mitral valve during chest compression came to be regarded as a marker for the mechanism of blood flow during CPR, with mitral valve closure suggesting direct cardiac compression.[14] Some investigators, using transesophageal echocardiography, have demonstrated mitral valve closure during CPR in humans.[15] Others have reported that the mitral valve remains open during chest compression.[16] Animal studies have demonstrated that mitral valve closure or position cannot be used to identify the primary mechanism for blood flow during CPR.[17]

Studies of the perfusion of vital organs indicate that during CPR (irrespective of the primary mechanism for blood flow), cerebral flow is dependent on the gradient between the carotid artery and the intracranial pressure during systole, with myocardial flow being dependent on the gradient between the aorta and right atrium during diastole.[18]

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

OBSERVATIONS IN HUMANS

Unfortunately, at this point we can draw no final conclusion as to the frequency or importance of the two mechanisms (cardiac compression or generalized increase in intrathoracic pressure) during conventional cardiopulmonary resuscitation in humans. Published studies, however, suggest that manipulation of intrathoracic pressure is probably the dominant mechanism.[19] In a number of patients, comparable arterial and right atrial pressures have been observed as well as the presence of a pressure gradient at the thoracic inlet upon withdrawing an intravascular catheter from the superior vena cava to the extrathoracic internal jugular vein.[11,20,21] This hemodynamic pattern favors the concept of forward flow of blood through manipulation of intrathoracic pressure. This concept is further strengthened by the observation that maneuvers designed to increase intrathoracic pressure during chest compression-such as prolonged compression or vest CPR-are rewarded by a significant increase in peripheral arterial pressure. Recent studies have also shown increased peripheral arterial pressures in man during CPR with the use of an inspiratory airflow resistance valve. Inspiratory resistance is designed to reduce "diastolic" intrathoracic pressure (during the release phase of chest compression) and thereby increase net intrathoracic pressure fluctuations.[23] Perhaps the strongest evidence supporting the theory of manipulation of intrathoracic pressure as a mechanism for blood flow in humans is found in the documented efficacy of "cough CPR."[10] In some patients, who are usually thin-chested, with cardiomegaly, extremely high arterial pressures are generated with conventional CPR. In a few of these patients, central venous pressure was found to be lower than arterial pressure. This hemodynamic picture suggests cardiac compression. In other patients, however, this higher arterial pressure may reflect higher generalized intrathoracic pressure during chest compression. This may be a result of functional airway obstruction due to airway collapse, pulmonary congestion, and/or bronchospasm.[12] In the majority of the patients in whom radial artery pressure has been measured during CPR, the arterial pressure has been relatively low and similar to that seen in the dog during conventional CPR.[19,20]

In human beings (and also in animals), it is not essential to think about the mechanisms of blood flow during CPR in an exclusive fashion. As the force of chest compression changes or as chest wall anatomy and chest compliance change during prolonged resuscitation, the dominant mechanism for blood flow (during resuscitation) may also change.

Building on these concepts, several experimental maneuvers and techniques have been developed to increase arterial pressure during chest compression. Following clinical evaluation, some are now being considered for limited clinical use. Some of these techniques require special equipment, whereas others can be performed by unequipped health care providers.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

EXPERIMENTAL AND ALTERNATIVE TECHNIQUES OF CARDIOPULMONARY RESUSCITATION

"High-impulse CPR" requires no special equipment and has been shown to improve vascular pressures.[13] It incorporates high-force, rapid down-thrust chest compression. However, clinical experience with this technique is limited.

Interposed abdominal compression (IAC) CPR can be performed by three unequipped health care providers. In this technique, the upper abdomen is compressed when the chest is released. The mechanism of benefit with IAC CPR in humans is unclear but may relate to improved venous return, decreased arterial runoff, or greater rise in intrathoracic pressure (with the diaphragm pushed up before chest compression). This technique increases carotid flow and improves survival in animals. Human clinical trials during in-hospital IAC CPR have also shown improved survival as compared with conventional CPR.[24] Based on these results, the 2000 American Heart Association (AHA) Guidelines for CPR suggest that IAC CPR be considered an alternative to conventional in-hospital CPR (class 2A recommendation).[25] The clinical value of this technique in the prehospital arrest patient, however, remains unproven.

Recently, the technique of phased chest and abdominal compression-decompression has also undergone animal and clinical testing. This technique is a mechanized IAC CPR in which the rescuer uses a special chest-abdomen manual compression device (the Lifestick Resuscitator); the chest and abdomen are thus compressed alternately. Its originators suggest that this technique, although similar to IAC CPR, is safer and more effective. Clinical studies are presently ongoing.[26]

The technique of perithoracic high-pressure vest inflation without airway manipulation (vest CPR) requires special equipment and allows cyclic increments in intrathoracic pressure to 100 to 150 mmHg during external chest compression. It has been shown to significantly increase cerebral and myocardial blood flow during CPR in animals. This technique employs a special computer-controlled pneumatic vest device positioned around the chest. Initial human data confirm higher vascular pressures during vest CPR as compared with conventional resuscitation.[22] Survival studies are lacking. A multicenter randomized survival trial was terminated prior to target patient enrollment. Data suggests that this technique may be of value as an alternative to standard CPR for short-term hemodynamic support.[26]

Active compression-decompression CPR (ACD CPR) requires a special suction-cup plunger-type device that can be readily deployed by first responders. It incorporates a negative pressure "pull" on the thorax during the release phase of chest compression and slightly improves vascular pressures and air exchange during CPR.[27] The mechanism of benefit from this technique of resuscitation may relate to improved venous return and/or increased intrathoracic pressure during chest compression as a consequence of changes in the bony thorax. Except for one 500-patient French study, all other recent, large, in-hospital and out-of-hospital studies in cardiac arrest patients have shown no survival benefit of ACD CPR.[28,29] It may, however, be of some value in improving short-term resuscitation outcomes. Lurie et al. have reported on the hemodynamic benefits of an inspiratory impedance valve attached to the endotracheal tube during resuscitation.

Preliminary human data suggests that this device, coupled with ACD CPR, increases coronary perfusion pressures and improves end-tidal CO_2.[23] Larger clinical studies are necessary before the clinical usefulness of this technique is assessed.

In cardiac arrest in animals, aortic infusion during CPR (via catheters placed retrograde) has been shown to improve coronary flow and survival. However, human experience with this technique is limited. Emergency cardiopulmonary bypass and hypothermia during cardiac arrest is also undergoing clinical evaluation following promising animal studies. The initial clinical experience is favorable and a multicenter trial is ongoing. In summary, recent data suggest that several experimental CPR techniques may offer short-term survival benefit-i.e., survival to hospital admission-but the data on long-term improved outcome as compared to conventional CPR is less compelling for all strategies studied.

Although such experimental techniques lend themselves to limited clinical use, their study has resulted in a better understanding of physiology, which, in turn, allows several aspects of conventional external chest compression to be manipulated in order to optimize vital-organ perfusion pressures.[30] First, greater sternal force augments myocardial and cerebral perfusion but can also result in greater tissue injury. Second, adequate duration of compression during each chest compression-release cycle is critical for maintaining maximal myocardial and cerebral blood flow during resuscitation. At higher rates of chest compression, more time per minute is spent in chest compression. Based on these data, changes in the AHA recommendations regarding chest compression rate have evolved. The 2000 standards recommend that chest compressions be performed at a rate of approximately 100/min.[25]

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

DIAGNOSIS AND IDENTIFICATION OF CARDIAC ARREST

Cardiac arrest is defined as the sudden cessation of effective cardiac pumping function as a result of either ventricular asystole (electrical or mechanical) or ventricular fibrillation. Rapid diagnosis and treatment are essential because (1) more than a few minutes of total cardiac arrest result in permanent cerebral anoxic damage and (2) the success of resuscitative measures is related to the rapidity with which they are instituted following arrest. Based on these and other observations, the concept of early activation of emergency medical systems (EMS) has evolved for victims of out-of-hospital cardiac arrest[25] (see also Chap. 36).

Preliminary Patient Evaluation and Triage

Cardiac arrest should be considered in the differential diagnosis of sudden collapse in any patient. It can be clinically confirmed by pulseless major vessels and absent heart sounds.

Although respirations (agonal respirations) may continue for a minute or two, the patient with cardiac arrest rapidly becomes cyanotic and unconscious.

Once the diagnosis of cardiac arrest is made and no trauma is suspected, the unconscious patient should be positioned supine on a firm surface and the airway opened using the head tilt-chin lift technique or alternative strategies, as described below (in the discussion of ventilation during CPR). The patient should immediately receive rescue breathing either with a bag-valve mask device or with mouth-to-mouth breathing. Simple airway barrier devices, which are easily deployed, can be used to minimize direct patient contact and are preceived as being more hygienic during mouth-to-mouth resuscitation. Following airway opening and rescue breathing, chest compressions should be promptly initiated at approximately 100/min. Recent animal data suggests that ventilation can be deferred for several minutes in witnessed cardiac arrest without changing survival if chest compressions are initiated promptly. In addition, a recent study that randomized patients receiving dispatcher-assisted CPR to ventilation or no ventilation failed to demonstrate any benefit of early ventilation.[31] These and other data have raised several questions regarding the need and benefit for early ventilation in patients in cardiac arrest. Nevertheless, the AHA continues to recommend early ventilation for all patients.[25]

If available, an electrocardiogram (ECG) can confirm the diagnosis and identify asystole, ventricular fibrillation, or electromechanical dissociation as the mechanism of arrest. However, cardiopulmonary resuscitation (CPR) should be initiated immediately, as described above, once the clinical diagnosis is made without delaying to obtain this information. If a defibrillator but not an ECG is immediately available, a 200-J countershock should be administered without delay. Prehospital CPR studies in several patients have confirmed that, early in cardiac arrest, the mechanism of arrest is usually ventricular fibrillation and that survival is critically dependent on the time to defibrillation.[32] Most hospitals and paramedics are now equipped with defibrillators with "quick look" paddles that simultaneously allow the ECG rhythm to be analyzed. On the basis of the rhythm, an etiology for the arrest can then be explored in a more focused way and appropriate therapy initiated. A recent debate has emerged prompted by animal data from Niemann et al. showing that animals receiving CPR prior to early defibrillation did better than

those in whom no CPR preceded defibrillation.[33] This observation is further supported by recent data from Cobb et al. showing that 90 s of "high-quality" CPR prior to defibrillation improved outcome in patients receiving bystander CPR.[34] The current recommendation is that if defibrillation is delayed, CPR should be performed immediately. However, if a defibrillator is available, the value of "predefibrillation CPR" is unclear. Clearly, if defibrillation fails to restore circulation, CPR should be performed immediately. Also, if collapse time without CPR is known to be more than 2 to 4 min, 90 s of initial CPR will likely be of value.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

AUTOMATIC EXTERNAL DEFIBRILLATORS

Given the value of early defibrillation, automatic external defibrillators (AEDs) were developed for use by first (minimally trained) professional responders, and were shown to dramatically improve survival after prehospital arrest.[35,36] AEDs have an approximately 90 percent sensitivity and specificity for successfully recognized ventricular fibrillation. They are designed for use by first responders or persons with little medical training (e.g., fire fighters, EMS technicians). These devices have varying degrees of automation and can deliver several successive defibrillatory shocks via two self-adhesive electrodes placed by the user directly on the left anterior and left lateral chest. Most manual physician- or paramedic-operated waveform defibrillators deliver monophasic shocks. In recent years commercially available AEDs deliver a biphasic waveform shock. Recent research has focused on the relative efficacy of these two waveforms. Data suggests that biphasic-waveform defibrillation using shocks <200 J are safe and as effective as (if not more so) higher-energy monophasic shocks. Also, animal data suggests less postshock myocardial dysfunction following biphasic-waveform defibrillation. Various modifications of the biphasic waveform (sawtooth pattern, etc.) are being evaluated. Current recommendations do not clearly rank one defibrillatory waveform over the other; both are acceptable.

AEDs have been successfully used by nontraditional health care professionals (airline crews, police, and security guards) with dramatic improvement in patient survival. This program has been termed *public-access defibrillation.* All such AED defibrillation programs have been under strict physician-guided training and supervision. Perhaps the most compelling results of this strategy of emergency care were reported recently by White et al. in Rochester, Minnesota, where police-initiated AED defibrillation and resuscitation resulted in a survival to hospital discharge of approximately 50 percent (Fig. 34-2).[31] The value of training the on-site nontraditional health care provider was further tested and ratified when Valenzuela et al. trained casino security guards and demonstrated significant increases in resuscitation rates. They have demonstrated the compelling benefit of early defibrillation (Fig. 34-3).[37] Some authors have questioned the cost effectiveness of deploying first responder AEDs. A treatment should be considered economically attractive if it is associated with an incremental cost effectiveness ratio of less than twice the average annual income per life year (i.e., approximately $50,000 per life year). Modeling studies and clinical trials have demonstrated that the cost effectiveness of first responder AED programs is well within the cost of programs deemed to be clinically appropriate, if achieved by a low intensity intervention such as police or lay responder defibrillation (estimated cost $29,000 to $46,700 per year). Available data suggests that time to defibrillation is not cost-effectively reduced by adding to existing EMS systems.[38] In a dramatic move to test the value of early AED deployment, several AEDs have been prominently positioned at O'Hare Airport and have been successfully used by airport patrons. Recent state and federal legislation that endorses early AED deployment by trained supervised persons and indemnifies users, trainers, and other owners of AEDs has paved the way to evaluate public-access defibrillation.

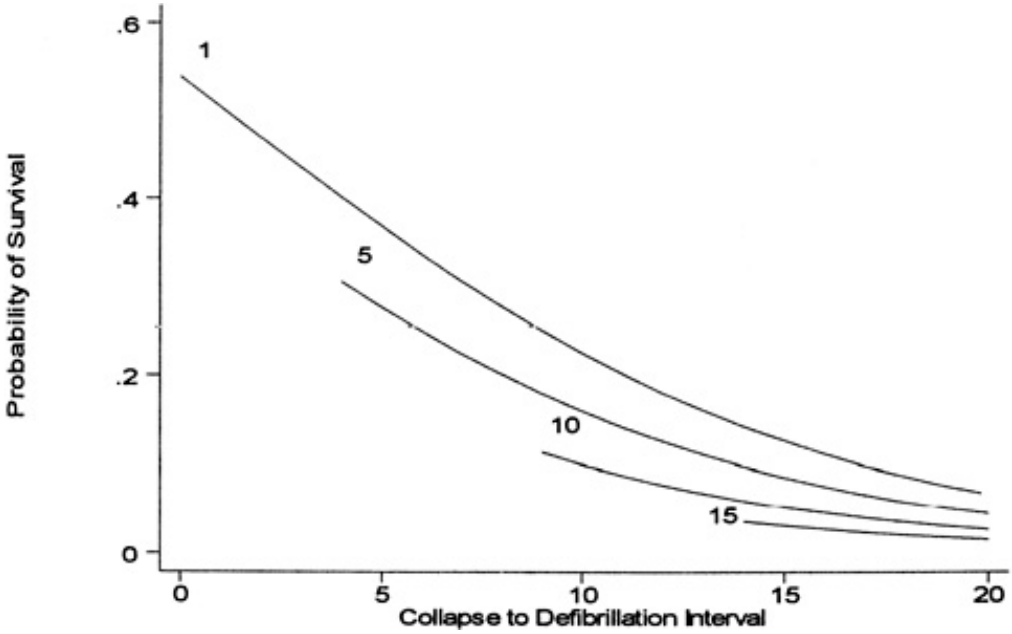

Figure 34-3: Relationship of collapse to CPR and defibrillation to survival: simplified model. Graphical representation of simplified (includes collapse to CPR and collapse to defibrillation only) predictive model of survival after witnessed out-of-hospital cardiac arrest due to VF. Each curve represents change in probability of survival as delay (minutes) to defibrillation increases for a given collapse-to-CPR interval (minutes). (From Valenzuela et al.,[37] with permission.)

The use of AEDs by nontraditional health care professionals and possibly by trained lay persons is currently the focus of intense research. It is highly recommended that all first-responder EMS units be equipped with AEDs. Several agencies have developed training programs that incorporate AEDs and basic CPR training. However, the duration of training needed to correctly teach the use of an AED is likely much less than that currently used by most training agencies (i.e., only 3 or less hours appear to be needed).

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

RESPIRATORY ARREST

Respiratory arrest is the cessation of effective respiratory effort. It can result from airway obstruction (due to a foreign body or other causes), drowning, smoke inhalation, drug overdose, head trauma, cerebrovascular accident, or suffocation. When respiratory arrest occurs suddenly (as with foreign-body obstruction), the patient rapidly becomes cyanotic, though a palpable pulse with blood pressure, consciousness, and ineffective respiratory efforts may be maintained for several minutes. Opening the airway and/or rescue breathing may be all that is necessary to resuscitate such a patient.

The Heimlich maneuver is recommended for relieving foreign-body airway obstruction. It is implemented by standing behind the victim and delivering a series of sharp thrusts to the upper abdomen with a closed fist.[39] Abdominal thrusts can also be used directly in the unconscious, supine patient by the trained health care provider to help dislodge a foreign body mechanically. The Heimlich maneuver can also be self-administered by placing the fist between the navel and the xiphoid process and delivering a series of quick upward thrusts. If incorrectly administered, this maneuver can lead to visceral damage.[40] When properly used, however, the technique is both safe and effective.

Manual removal of a foreign body in the unconscious victim should be done only by trained health care providers. This can be achieved by opening the victim's mouth and attempting to dislodge any obvious foreign body with a finger. As a single method, back blows may not be as effective as the Heimlich maneuver in adults.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

VENTILATION AND CHEST COMPRESSION DURING CARDIOPULMONARY RESUSCITATION

The 1980s defined the physiology of circulation during CPR. In the last 5 years, several investigators have focused on understanding the physiology of ventilation during CPR (see below). Although several questions remain unanswered, recent research has served to challenge several "dogmas," as discussed below.

Clearing the airway is of the utmost importance. Foreign bodies, loose dentures, or any other oral obstruction should be removed. Next, the head tilt-chin lift technique, which causes the tongue to move anteriorly, is used to open the airway. The chin is lifted forward, with the fingers of one hand supporting the jaw, and the head is tilted back by the other hand, which rests on the patient's forehead.[35] The head tilt-neck lift method of opening the airway is also commonly employed and is an acceptable technique for use by the skilled rescuer. Here, the rescuer tilts the head back with one hand on the patient's forehead; the other hand is placed behind the patient's neck, lifting it upward to open the airway. If no spontaneous respirations are present, mouth-to-mouth (or mouth-to-nose) ventilation is immediately initiated, with adequacy being judged by the rise and fall of the patient's chest with each breath. To minimize gastric distention, it is necessary to deliver slow (2-s) ventilatory breaths.

Equipped rescuers will use a barrier device or a bag-valve mask technique of ventilation together with a small plastic oral "airway," which moves the tongue anteriorly. Adequate ventilation is difficult with the bag-valve mask technique, since a single rescuer often has difficulty maintaining an adequate seal on the face, and rapid bag deflation commonly results in gastric distention and aspiration. Slow (2-s) ventilation must be employed if the bag-mask technique is used.

Several invasive airway adjuncts have also been developed for use by nonphysician health care providers in prehospital situations, and several newer devices have been shown to be superior to the bag-valve mask technique of ventilation.[41] The esophageal obturator airway (EOA), esophageal gastric tube airway (EGTA), the Combitube, the laryngeal tracheal mask airway (LMA), and the pharyngotracheal lumen airway are among those that have been used in the prehospital setting. Considerable training and skill are needed in placing and using these devices properly. Serious, life-threatening complications have been reported following the use of the EOA or EGTA. As a consequence, their use has generally been abandoned in favor of other more safe and effective devices. Recent data suggest that the Combitube and LMA are attractive alternatives to endotracheal intubation with proven field success and ease of training.[42] Although endotracheal intubation remains a class I recommendation by the AHA (to achieve ventilation and secure the airway), these other devices do have a clinical role and are considered to be class IIA alternatives when compared to bag-valve mask ventilation.

Endotracheal intubation is considered the ideal technique for ensuring adequate ventilation during CPR. Whenever possible, a nasogastric tube should be inserted following intubation to drain the stomach and thus decrease the chances of aspiration. Intubation can be rapidly implemented, but much valuable time can be wasted by repeated unskilled attempts at intubation. If this technique is used, CPR should be discontinued for no more than 20 to 30 s while the tube is being passed into the airway. If more than 20 to 30 s elapse without successful intubation, the laryngoscope should

be withdrawn and CPR reinstituted. The concern of delaying resuscitation during intubation was supported by a recent study in a pediatric population that compared bag-valve mask ventilation to endotracheal intubation and failed to demonstrate any benefit of endotracheal intubation, likely due to the delay in intubating patients.

The optimal requirements for ventilation during CPR in human beings remain unknown. No study has clearly identified the optimal timing, sequence in relation to chest compression, or tidal volume needed during CPR. During the first few minutes of cardiac arrest without prior hypoxia, as noted above, animal studies suggest that ventilation is less important relative to chest compression and defibrillation. Airflow from chest compression alone and air in the lungs at the time of arrest may be initially sufficient to sustain ventilation.[43,44] Recent human data from Seattle tend to support this observation, since dispatcher-assisted CPR with or without ventilation resulted in similar outcomes.[31] The value of expired air ventilation has further been called into question based on animal studies that show that expired air, when used for ventilation, actually worsens outcome in a ventricular fibrillation cardiac arrest model. The value of immediate expired air ventilation for victims of witnessed cardiac arrest has thus clearly been called into question. There are few data on the value (or lack thereof) of ventilation in the victim of an unwitnessed arrest. Based on these data, the new AHA guidelines for resuscitation recommend 100 chest compressions per minute with a 15:2 compression-ventilation ratio (for both single and two rescuer CPR) and ventilation with two breaths slowly delivered over 2 s with a tidal volume sufficient to achieve obvious chest rise (10 to 12 mL/kg) or if a bag-valve mask is used, 400 to 600 mL per breath.

In addition to these recommendations, it is critical, in performing chest compression, to use sufficient force to depress the sternum by approximately 2 in. (5 to 6 cm). As this is usually difficult to gauge, sufficient chest compression force should be used to generate a palpable femoral or carotid arterial pulse.

Airway, breathing, chest compression (ABC) is the specific sequence used to initiate CPR in the United States, with survival rates as high as 35 percent in cities with advanced EMS systems[32,36] (see Chap. 36). ABC is also used in many other countries. However, in the Netherlands, CAB (chest compression first followed by airway opening and breathing) is the common technique for CPR implementation, with resuscitation outcomes similar to those reported for ABC in the United States. Despite its proven efficacy, the recently perceived risk of infectious disease transmission during CPR has reduced the willingness of both lay and medical personnel to initiate mouth-to-mouth ventilation and CPR in unknown victims of cardiac arrest. In an effort to respond to these concerns and encourage the lay administration of CPR, some cities have mandated the public availability and use of barrier devices during mouth-to-mouth ventilation. The effectiveness of such barrier devices is, however, unknown. To overcome this limitation, potential rescuers who are reluctant to initiate CPR because of the perceived risk of infection should be encouraged to activate the EMS system immediately, open the victim's airway, and then initiate and continue chest compressions only until paramedics arrive (i.e., C-A). The paramedics can then initiate ventilation with the necessary protective equipment. It is important to note that a randomized comparison with CAB (chest compression, airway, breathing) or CAD (chest compression, airway opening, defibrillation) has never been done.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

DEFINITIVE THERAPY

The AHA's *2000 Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiac Care* adopted a new classification for therapeutic recommendations.[25] This classification allows a relative therapeutic value to be assigned to a given strategy of treatment based on scientific data. It is as follows:

1. Class I: Definitely helpful
2. Class IIA: Acceptable, probably helpful
3. Class IIB: Acceptable, possibly helpful, probably not harmful
4. Class III: Not indicated, may be harmful
5. Indeterminate: clinical data too preliminary or insufficient to allow classification into the other four categories

During cardiac arrest, the ECG will usually show rapid ventricular tachycardia or fibrillation, asystole, or heart block-or it may be near normal.

Ventricular Tachycardia or Fibrillation

With ventricular fibrillation, an attempt at electrical defibrillation should be made as quickly as possible. Successful defibrillation is accomplished by the passage of adequate electrical current (amperes) through the heart (see also Chap. 32). Current flow is dependent on the energy chosen (joules) and the transthoracic impedance (ohms), or resistance to current flow. Factors that affect transthoracic impedance include the energy selected, electrode size, skin-paddle coupling material, the number and time interval of previous shocks, the distance between the electrodes (size of the chest), phase of ventilation, and paddle electrode pressure.[45] Human transthoracic impedance ranges from 15 to 150 ohms, with the average adult impedance being 70 to 80 ohms. If transthoracic impedance is high, low-energy shocks are ineffective in generating enough current to achieve successful defibrillation. Transthoracic impedance can be reduced by firm pressure on hand-held electrode paddles and a gel/cream or saline-soaked gauze pads between the electrode and the skin.[45] In addition, proper electrode/paddle placement is essential; one electrode should be placed to the right of the upper sternum below the clavicle and the other to the left of the nipple, with the center of the electrode in the midaxillary line. An acceptable alternative is one electrode anteriorly over the left precordium and the other posteriorly behind the heart in the right infrascapular location. The latter positioning is best achieved by using preadhesive rather than hand-held electrodes. In female patients with large breasts, the electrodes are best placed to the right of the upper sternum and either under or lateral to the left breast. Direct current is employed during defibrillation. The paddles, coated with low-resistance gel, are applied firmly to the chest and then for monophasic defibrillations discharged with 200 J, which is repeated at 200 to 300 J if the first shock is unsuccessful. The current AHA standards suggest that a third 360-J shock should be delivered if ventricular fibrillation persists.[25] These three shocks should be delivered in rapid succession. Prospective studies by Adgey and others have shown 85 to 90 percent successful defibrillation using only 200 J in patients weighing up to 90 kg.[46,47] Some advocate higher-energy defibrillation, but few currently use more than 400 J.[48] High-energy defibrillation likely causes more cardiac injury, and increases postshock myocardial dysfunction; there is no clear evidence that it increases the frequency of successful resuscitation.[49] As mentioned above, several

defibrillators have biphasic defibrillatory shock-wave forms. Most conventional manual defibrillators use the monophasic exponential wave form, whereas several AEDs deliver a biphasic defibrillatory shock wave at lower energy levels with equal if not greater success.

When the ECG shows fine fibrillation waves, defibrillation efforts are often unsuccessful. Although commonly practiced, the early use of epinephrine in such situations is not supported by improved survival in clinical trials. Nevertheless, it is suggested that the administration of epinephrine (5 to 10 mL of 1:10,000) intravenously (IV) may result in a more vigorous and coarse fibrillation that is more responsive to defibrillation. This effect is possibly due to improved coronary flow following epinephrine administration (see below), although recent data raise the question of epinephrine-induced deleterious myocardial effects, especially at higher doses.[50] If defibrillation fails, it is likely that marked acidosis or hypoxemia is present. Emphasis should be on modest hyperventilation with supplemental oxygen to correct both hypoxemia and metabolic acidosis.[51] Sodium bicarbonate might then be administered (1 meq/kg) to aid in the management of acidosis, and defibrillation should be repeated with 360 J. By using instantaneous Fourier transformation analysis, Brown et al. have demonstrated that the coarseness of the waveform of ventricular fibrillation may be highly predictive of subsequent survival and appears to correlate with coronary flow.[52] Preliminary human data to confirm these observations are limited.

In a recent study, the value of intravenous amiodarone in shock-refractory ventricular fibrillation/ventricular tachycardia (VF/VT) was tested in patients who had experienced prehospital cardiac arrest. Athough it improved survival to hospital admission, there was no difference in survival to hospital discharge between those who did and did not receive amiodarone.[53] Although often given, there are few data to support the use of lidocaine, bretylium, procainamide, or magnesium in such patients-i.e., those with shock refractory VF/FT (class of recommendation indeterminate).[54-56] Based on these data, it appears that amiodarone may be of some short-term benefit in patients with recurrent VT/VF. Amiodarone is usually dosed as a bolus of 150 to 300 mg over 10 min, 1.0 to 2.0 mg/min for 6 h, then 0.5 to 1.0 mg/min for 6 to 24 h. For recurrent VF in the setting of ischemia, intravenous propranolol or other intravenous beta blockers or amiodarone may be effective.[54] Beta blockers seem particularly helpful in the setting of primary ventricular fibrillation complicating acute myocardial infarction.[54] In fact, the early benefit of amiodarone has been ascribed by some to its beta blocking properties.

Hyperkalemia is a readily treated condition that can cause atrioventricular (AV) block, impaired intraatrial and intraventricular conduction, and occasionally ventricular fibrillation or, less commonly, asystole. It can be recognized by the development of tall, peaked T waves with a normal QT interval and sine wave-like ventricular tachycardia. Life-threatening hyperkalemia responds most readily to calcium infusion; 10 to 30 mL of 10% calcium gluconate is infused intravenously over 1 to 5 min under constant ECG monitoring. Calcium counteracts the adverse effects of potassium on the neuromuscular membranes but does not alter plasma potassium. Its effect, though immediate, is transient. Hyperkalemia should subsequently be treated by glucose-insulin or ion-exchange resins (Chap. 31). Sodium bicarbonate is also used as an agent to lower potassium.

With VT in an alert and responsive patient, cough may reverse the arrhythmia without defibrillation, and repeated cough may maintain the conscious state as a result of the rise in intrathoracic pressure.[10,57] It is an appropriate strategy for immediate use pending more definitive drug or electrical intervention. It is commonly used in the cath lab. The efficacy of the precordial thump (precordial chest blows) has been variably reported in patients with VT. A thump is generally ineffective for terminating prehospital VF. Hence, it should never be used in the patient with VT and a pulse unless a defibrillator is immediately available.

Asystole or Heart Block

For patients with prehospital cardiac arrest, asystole has been shown to be an ominous rhythm with a very low likelihood of successful resuscitation.[32] On the other hand, asystole due to vagal stimulation is the commonest cause of cardiac arrest associated with anesthesia induction and surgical procedures. Asystole also occurs as a result of heart block or sinus node disease (see Chap. 34). Atropine (0.5 mg) given intravenously and repeated in 5 min can be used acutely to prevent or reverse severe bradycardia in many of these settings.

If asystole is witnessed or of short duration, vigorous blows to the precordium may sometimes restart the heart. Rhythmic chest blows may maintain limited perfusion and can be continued if needed while palpating the femoral or carotid pulse until other treatment is available. If the chest blow fails, CPR should be initiated and intravenous epinephrine (5 to 10 mL of 1:10,000) administered. Possible treatable causes of asystole-such as acidosis, hypoxemia, hyper- or hypokalemia, and hypothermia-should be considered and treated appropriately if suspected. If an overdose of calcium channel blocker is suspected, calcium chloride, 1 g given as an intravenous bolus, may be very effective (class IIA recommendation). Resuscitation measures may result in the return of a slow ventricular rhythm, which can subsequently be supported with atropine (1 to 2 mg IV) until a temporary pacemaker is placed. Temporary pacing is the optimal treatment for true asystole or profound bradycardia. Obviously, considerable skill and training are required for temporary transvenous pacemaker placement (see Chap. 31). Transcutaneous pacing has been developed as a noninvasive and simple technique that can be implemented rapidly. It uses external surface electrodes with a high-voltage pacing source. Higher voltages are required to overcome transthoracic resistance, but they are painful and are therefore used mainly on unconscious patients. The energy delivered to the heart by this technique is variable, as is its efficacy. Recently, pacing sources with longer pacing stimulus duration have been developed and may offer less painful and more effective pacing. Prehospital studies of transcutaneous pacing for asystole have not confirmed an improvement in survival.[58] It may, however, be of some benefit for patients early in asystole (class IIB intervention). Clinical evidence does not support its routine use in all patients with asystole.

In rare instances, very fine VF may result in an almost straight line on a single-lead ECG and thus be mistaken for asystole. In such cases, where the diagnosis of asystole is in question, it is suggested that a perpendicular ECG lead be viewed. Rotation of "quick look" ECG paddles by 90 degrees easily achieves this. If ventricular fibrillation is present, the perpendicular ECG lead will demonstrate a typical fibrillation pattern; whereas in true asystole, a straight line will be seen in all ECG leads. If VF is diagnosed, the initial treatment should be according to the outline above-i.e, three successive countershocks. There is little value in defibrillating true asystole.

Electromechanical Dissociation

In *electromechanical dissociation* (EMD), there is evidence of organized electrical activity on the ECG at a reasonable rate, but failure of effective perfusion (no pulse or blood pressure). The most treatable causes of this condition are hypovolemia due to severe hemorrhage, pericardial tamponade, tension pneumothorax, hypoxia, hypothermia, acidosis, hyperkalemia, and massive pulmonary embolism. Signs of these problems should be sought and definitive therapy undertaken with fluids and/or blood replacement, pericardiocentesis, placement of a pleural needle or tube, endotracheal intubation, and other maneuvers as deemed necessary. These conditions should also be strongly considered if CPR results in no palpable pulse or evidence of perfusion. Unfortunately, many patients with electromechanical dissociation have primary myocardial failure. Following diagnosis, ventilation should be optimized and epinephrine administered. Calcium chloride has been used for EMD, but prospective studies have not shown it to improve survival.[59] In acute myocardial infarction, sudden electromechanical dissociation is a sign of myocardial rupture. In such cases, pericardiocentesis and surgical repair can rarely result in survival.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

ESTABLISHMENT OF AN INTRAVENOUS ROUTE

While external chest compression and artificial ventilation are continued, a plastic catheter should be inserted into a large peripheral vein. Drug administration during CPR should be preferentially accomplished only from a source above the diaphragm, since there is little cephalad flow from veins below the diaphragm. If a peripheral vein cannot be cannulated, a cutdown should be attempted or a central venous line placed by a percutaneous route. If CPR is properly performed, drugs administered through a peripheral line will often reach the arterial circulation within 15 to 30 s.[51] Recent data suggest that a 20-mL fluid bolus significantly improves peripheral drug delivery to the central compartment. Larger amounts of fluids should be used if drugs are given via a femoral line. Intracardiac injections are unnecessary except when there is no intravenous access. If an intravenous route is unavailable, epinephrine (1 to 2 mg in 10 mL of sterile distilled water) and lidocaine (50 to 100 mg in 10 mL of sterile distilled water) can be administered by way of the endotracheal tube into the bronchial tree. The drug should be injected through a long catheter passed beyond the tip of the endotracheal tube. Cardiac compression should be withheld, and several insufflations with an Ambu bag should immediately follow drug administration to aid drug absorption through aerosolization.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

MAJOR DRUGS USED DURING CARDIOPULMONARY RESUSCITATION

Drugs that are used for the treatment of various arrhythmias are mentioned above. Catecholamines are used in cardiac arrest to (1) increase arterial and coronary perfusion during and following CPR, (2) stimulate spontaneous contraction during asystole, (3) make fine VF more responsive to defibrillation, and (4) act as an inotropic agent.

Epinephrine was among the earliest pressors evaluated during resuscitation. It is effective in achieving several of these goals, although recent data have highlighted its possible deleterious effects on postresuscitation left ventricular function. Both animal and clinical studies have extensively evaluated the hemodynamic effects of epinephrine during resuscitation. Animal studies show that during conventional CPR, cerebral and myocardial perfusion pressures are low. Epinephrine increases brain and heart flow by two mechanisms: (1) It prevents carotid artery collapse and raises arterial pressure during both chest compression and the release phase of chest compression (i.e., "systole" and "diastole," respectively). This results in higher carotid arterial systolic and aortic diastolic pressures, which, in turn, are reflected in higher cerebral perfusion and myocardial perfusion pressures and flow. (2) It preferentially reduces blood flow to the external carotid, renal, and splanchnic beds, thereby redirecting flow toward the brain and heart.[60,61]

Arterial collapse at the thoracic inlet has been shown to be the critical limiting factor for cerebral perfusion pressure and flow during prolonged CPR. Arterial collapse results from high extravascular intrathoracic pressures, low intravascular volumes, and loss of arterial tone. Collapse results in a precipitous fall in carotid arterial and hence cerebral perfusion pressure. Epinephrine during CPR can not only reverse arterial collapse but also prevent it from developing. With the administration of epinephrine during conventional manual CPR in the dog, cerebral blood flow can be maintained at approximately 15 percent and myocardial flow at approximately 5 percent of prearrest values for 20 min.

These data strongly support the early and frequent use of epinephrine during CPR in an effort to optimize the perfusion of vital organs. The recommended dose of epinephrine (1 mg IV every 3 to 5 min) is comparable to a 0.007 to 0.014 mg/kg dose in a 70-kg person. This dose has been questioned, since animal studies using higher doses of epinephrine have shown improved blood flow to vital organs and improved survival.[61] Other studies of higher doses of epinephrine, however, have shown increased myocardial oxygen demand despite this improved blood flow.[62] Higher than recommended doses of epinephrine have been reported to increase arterial pressure and coronary perfusion pressure in a small number of human studies. These studies spawned an intense interest in the use of higher doses of epinephrine during CPR. Results from several prospective randomized out-of-hospital clinical trials of more than 2400 adult cardiac arrest victims, however, have shown no statistically significant improvement in survival to hospital admission or discharge or improved neurologic survival when higher doses of epinephrine (0.1 to 0.2 mg/kg) were compared with standard doses.[63,64] On the other hand, these trials did not demonstrate any obvious deleterious effect of the higher doses of epinephrine.

Recent retrospective studies suggest that higher cumulative doses of epinephrine are associated with worse hemodynamic and neurologic outcome event when duration of cardiac arrest are

accounted for. Hence, most experts would use 1 mg IV uniformly. Higher doses worsen postresuscitation myocardial dysfunction, hence its use is not routinely recommended.[25] The recommended dose is 0.5 to 1 mg IV, and this dose should be repeated at approximately 3- to 5-min intervals unless effective cardiac activity is restored. If an intravenous route is not available, epinephrine can be administered down the endotracheal tube; 10 mL of a 1:10,000 solution should be used, and this can also be repeated every 3 to 5 min.

The benefits of epinephrine are principally due to the alpha vasoconstriction induced by this agent. The inotropic effects of the drug may not be helpful, since these effects increase myocardial oxygen demand, even during ventricular fibrillation, when supply or blood flow is limited.[62] Consequently, there is some interest in using a pure vasoconstrictor during CPR rather than epinephrine. Animal studies of vital organ perfusion and human survival studies comparing epinephrine and phenylepinephrine (a pure alpha vasoconstrictor) have yielded similar results. Vasopressin has recently been evaluated as an alternative pressor agent, with promising results.[64a] Animal studies have demonstrated it to be as effective as pressor but with less resultant myocardial dysfunction as compared to epinephrine. Initial human data has been encouraging. However, a large prospective randomized out-of-hospital study of vasopressin versus epinephrine failed to confirm any survival benefit of this agent.[64b] It may be considered an alternative pressor to epinephrine for patients in shock-refractory VF (class IIB).

Norepinephrine is a potent vasoconstrictor and generally produces a rise in blood pressure; it is also an inotropic agent. Its disadvantage is renal and mesenteric vasoconstriction, and it should not be used in the initial phase of resuscitation. This agent is most useful where severe hypotension is present but where the chronotropic effects of epinephrine are not desirable (as in acute myocardial infarction or severe ischemia). This agent should be administered cautiously, since severe tissue injury results from extravasation around an intravenous site. A large prehospital trial failed to identify any differences in survival following treatments with norepinephrine, high-dose epinephrine, or standard epinephrine.[63]

Similarly, dopamine (a chemical precursor of norepinephrine) and dobutamine (a synthetic catecholamine) are preferred for use as inotropic agents because of their lesser chronotropic effect. Recent animal data suggests that dobutamine may be particularly effective in reducing postresuscitation left ventricular dysfunction. Isoproterenol (a synthetic catecholamine) is a pure adrenergic agonist and effective vasodilator. Therefore, its use during CPR is contraindicated since it can significantly decrease vital organ perfusion pressures. In patients with a palpable pulse, however, it is useful for treatment of bradycardia due to heart block or asystole until a temporary pacemaker is placed (see also Chap. 31).

Sodium Bicarbonate

The recent AHA recommendations deemphasize the role of sodium bicarbonate and suggest that much less sodium bicarbonate should be used than previously advocated for acid-base control during cardiac arrest. As with other types of metabolic acidosis, if adequate alveolar ventilation is achieved, the metabolic acidosis of arrest is partially corrected through P_{CO_2} excretion.[51] Recent clinical trials failed to demonstrate improved outcome from cardiac arrest with buffer therapy.[65] Rather, several deleterious effects of bicarbonate administration including respiratory acidosis, hypernatremia, and hyperosmolality have been reported. Ideally, sodium bicarbonate should be given according to the results of measurement of arterial blood pH, P_{CO_2} determination, and calculation of the base deficit. Bicarbonate should be used, if at all, only after more established interventions such as defibrillation, ventilation with endotracheal intubation, and pharmacologic therapies (epinephrine and antiarrhythmic drugs) have been tried.[25] If needed, 1 meq/kg of sodium bicarbonate should be administered; then no more than half this dose may be repeated every 15 min. Excessive use of sodium bicarbonate can result in metabolic alkalosis, hypernatremia, and

hyperosmolality. Some benefit of the usual bicarbonate solution (7.2 percent) may occur as a result of the hyperosmolality of the solution temporarily drawing fluid into the intravascular compartment.

On the other hand, bicarbonate may be most useful during the immediate postresuscitation period, when a profound metabolic acidosis occurs. In most instances during CPR, its use should be considered as a class IIB recommendation.[30]

Calcium Chloride

Calcium chloride (5 to 7 mg/kg) enhances the contractile state of the heart and is indicated in treating severe hypotension due to an overdose of calcium channel blocker or hyperkalemia. It is no longer recommended for use in asystole or electromechanical dissociation.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

TERMINATION OF CARDIOPULMONARY RESUSCITATION

Despite resuscitative efforts, the patient in cardiac arrest may not regain spontaneous circulation. The decision to end (or even initiate) CPR should be based on a physician's assessment of the patient's prior advance directives (if known) and the cerebral, cardiovascular, and general status of the patient.[66,67] Recent prospective and retrospective data confirm that survival is unlikely in patients who have no return of spontaneous circulation after 30 min of ACLS care.[68] Recent studies have demonstrated that continued in-hospital CPR efforts (in patients failing prehospital advanced cardiac life support) are not only expensive but also unsuccessful.[69] Persistent deep unconsciousness and absence of respiration, reflex response, or pupillary reaction suggest cerebral death, and resuscitative efforts are usually unproductive. These guidelines, however, should be altered in patients with hypothermia, barbiturate overdose, and perhaps following electrocution, where recovery has been seen even after hours of resuscitation.[70]

Page: 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

POSTARREST CARE

Patients who have been successfully resuscitated usually require monitoring in an intensive care setting. These patients are prone to develop cardiac arrhythmias, hemodynamic and ventilatory instability, and ischemic encephalopathy. Ventilatory support with a respirator may well be necessary initially. Serial arterial blood-gas determinations should be made to identify hypoxemia and assess the rapidly changing acid-base status. Commonly, hyperventilation was employed postresuscitation to not only treat acidosis but also help reduce CNS edema. Recent studies raise the possibility of worsening cerebral ischemia with low P_{CO_2} levels after brain ischemia. Based on these observations, normal ventilation is preferred in the comatose postresuscitation patient.

Several therapeutic strategies have been employed in animal models to help reduce hypoxic encephalopathy after cardiac arrest. None (including emergency cardiopulmonary bypass, which is currently undergoing clinical testing) have clearly been shown to be beneficial in humans.

The treatment of encephalopathy after cardiac arrest involves the prevention of further hypoxia and hypotension. For cerebral edema after cardiac arrest, methylprednisolone (60 to 100 mg) or dexamethasone sodium phosphate (12 to 20 mg IV every 6 h) has been recommended, but there is no conclusive evidence that these agents are beneficial. High-dose barbiturates or lidoflazine have also been shown to reduce postarrest brain injury in animal studies; the value of this therapy in human beings is negligible. In animals, mild to moderate hypothermia appears to be neuroprotective following an ischemic event. Clinical data are limited but suggestive of benefit. Trials are ongoing. The prognosis of the patient with anoxic encephalopathy is related to the depth and continued duration of cerebral dysfunction (see also Chap. 89). Failure to exhibit neurologic improvement 24-72 h following resuscitation is usually an ominous sign. Clinical and laboratory evaluations (electroencephalography, sensory evoked potentials) are often employed to help define prognosis and thus guide further care in such individuals.

Other potential life-threatening problems in the postarrest period include acute renal failure, bowel infarction, infection, adult respiratory distress syndrome, and sepsis. Patients regaining consciousness may have postarrest amnesia or may develop psychotic behavior.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

OUTCOME OF RESUSCITATION

In their initial study, Kouwenhoven and colleagues reported a 24 percent successful resuscitation and discharge rate from the hospital. Recent studies have shown that with a paramedical response system, a near 40 percent successful out-of-hospital resuscitation rate can be achieved.[32,71] Many of these patients die in hospital, however, with the dominant cause of death being anoxic encephalopathy. Recent data suggest that somatosensory evoked potentials may be useful and highly predictive in identifying patients who are likely to have irreversible brain injury.[72] The critical factors for successful out-of-hospital resuscitation include approximately 7 min total duration of CPR, approximately 4 min from collapse to the initiation of CPR, and approximately 10 min to successful delivery of the first countershock.

It is important to point out, however, that the quality of life for patients surviving to hospital discharge is often quite good, with most discharged patients being able to return to gainful employment.

Chapter 34: CARDIOPULMONARY RESUSCITATION AND THE SUBSEQUENT MANAGEMENT OF THE PATIENT

CHAIN OF SURVIVAL

The concept of a "chain of survival" has been adopted by several agencies and underscores the importance of an integrated public education and health care system if outcome from prehospital cardiac arrest is to be optimized.[25] Early access (to EMS systems), early CPR (to include bystander CPR), early defibrillation (to include the use of AEDs), and early *advanced cardiac life support* (ACLS) care are the major links in the chain, and any one weak link weakens the whole chain of survival.

This is best exemplified in two recent publications that reported on prehospital cardiac arrest outcomes in New York and Chicago, where survival rates were only 1 to 2 percent. Despite a mature EMS system and considerable public training in CPR, delayed defibrillation-due to traffic, elevators, and other factors-contributed significantly to the poor outcome in these studies.[73,74] Other cities, where prompt defibrillation has been possible, have reported a 20 to 30 percent survival rate.[75] To overcome this tragic limitation, AEDs were developed and have been shown to facilitate prompt defibrillation and thereby improve survival (Fig. 34-3). Hence, the American Heart Association and American College of Cardiology have jointly recommended that all professional first-responder units (especially in rural areas where long transport times are common) be equipped with AEDs.

If mortality from out-of-hospital arrest is to be reduced, public education programs to increase awareness of the warning signs of a heart attack and teach CPR are critical (Fig. 34-3). Despite many years of public education, the incidence of bystander CPR nationwide remains low.[73,74] This may have several explanations, including a lack of training in high-risk populations, poor performance or lack of retention despite training, unnecessarily complex training programs, or a fear of communicable disease during mouth-to-mouth resuscitation. This last issue has become particularly significant in the 1990s. Individuals should be reassured that the likelihood of disease transmission is minimal, 70 percent of arrest victims collapse at home, and if an individual is still unwilling to do mouth-to-mouth CPR, he or she should be taught to at least activate EMS ("call") and start chest compressions ("pump"). Ventilation ("blow") could then be started by suitably equipped trained EMS rescuers. Present data indicate that a refocusing of basic life support (BLS) training programs is essential, with efforts being targeted at simplification of training, with specific education and training penetration into high-risk patient groups (older patients and minority groups). The CPR message must be kept simple (for example, "call-pump-blow"). These goals must be achieved if the first two links in the chain of survival (early access and early CPR) are to be strengthened. Universal 911 would facilitate early and easy access and should be encouraged in all communities. Minimal standards of performance and excellence for EMS systems should be established and monitored. Dispatcher-assisted CPR teaches CPR on the telephone to the person who is calling to report the arrest (while professional help is in transit) and has been shown to be effective. The Seattle-King County EMS system is proof that such efforts directly improve outcome (Fig. 34-3).[75] On the other hand, the Chicago-New York experience is a chilling reminder of the consequence of one weak link in the chain of survival. The outcome from prehospital arrest can be improved only if each community strives to optimize its own chain of survival.

Part 6: CORONARY HEART DISEASE
Chapter 35:

ATHEROGENESIS AND ITS DETERMINANTS

Authors: Erling Falk, Valentin Fuster

INTRODUCTION

Despite steady progress in treatment of cardiovascular diseases, people are still dying of these diseases, although at later ages.[1] In the United States as well as in many other countries, cardiovascular diseases remain by far the number 1 cause of death for both men and women of all ethnic backgrounds and, no less important, cause the greatest disability. By the year 2020, coronary heart disease (CHD) and stroke will hold first and fourth places, respectively, in the World Health Organization's list of leading causes of disability.[2] A worldwide epidemic of cardiovascular diseases is evolving, and atherosclerosis, often with thrombosis superimposed, is by far the most frequent underlying cause.

It has been known for decades that the earliest lesions of atherosclerosis, fatty streaks, are present in the aorta from early childhood, but today we know that atherosclerosis begins already during fetal development, particularly in fetuses of hypercholesterolemic mothers.[3] Therefore, literally, a life-long effort is needed to prevent this disease and its dreadful consequences. Although a genetic predisposition to atherosclerosis may be present, the vast majority of atherosclerosis-related diseases, including CHD, are acquired; that is, the clinical manifestations of atherosclerosis, which usually appear in later life, are largely preventable. This fact is the major challenge to the world of cardiology at the turn of the millennium.

Definition

Atherosclerosis is a complex inflammatory-fibroproliferative response to retention of plasma-derived atherogenic lipoproteins in the arterial intima.[4,5] Literally, both softening (*athére* is Greek for gruel or porridge) and hardening (*skleros* is Greek for hard) need to be present to qualify for the diagnosis atherosclerosis; that is, *atherosclerosis* is not synonymous with *arteriosclerosis*. The latter term is broader, covering all diseases leading to arterial hardening, including native atherosclerosis, restenosis after angioplasty, and transplant vascular disease. These conditions all share some pathologic processes, but the mix of lipid accumulation, smooth muscle proliferation, and immune activation differs markedly.[6] It is important to recognize this distinction between atherosclerosis and arteriosclerosis, particularly when dealing with animal models of arterial diseases, because it is the lipid-related atheromatous component that is dangerous in human atherosclerosis, not the smooth muscle cell-related sclerotic component. The lipid-related component destabilizes plaques and thus is responsible for the great majority of all the life-threatening complications of human atherosclerosis: plaque disruption with superimposed thrombosis.[7]

Susceptibility to Atherosclerosis

Some individuals are more susceptible to atherosclerosis than others (e.g., males compared with females), and the same applies to different arterial segments within an individual. Atherosclerosis is a focal intimal disease of large and medium-sized systemic arteries, including the aorta,

iliofemoral, coronary, carotid (bifurcation) and, to a lesser extent, intracranial arteries. Secondary changes may occur in the underlying media and adventitia, particularly in the more advanced stages of the disease. For unknown reasons, some arteries (such as the internal mammary arteries) are highly resistant to atherosclerosis. Although the epicardial coronary arteries appear to be the most susceptible arteries in the body, intramyocardial arteries are highly resistant to atherosclerosis.

NEXT

Chapter 35: ATHEROGENESIS AND ITS DETERMINANTS

ATHEROGENESIS IN SUSCEPTIBLE MICE

To reproduce in animals a vascular disease resembling human atherosclerosis, atherogenic lipoprotein concentrations need to be above a certain level. Normal wild-type mice do not develop hypercholesterolemia and are thus fundamentally resistant to atherosclerosis, even when fed a high-fat high-cholesterol diet that induces the disease in other species, such as rabbits, pigs, birds, and nonhuman primates. By inactivating and/or overexpressing selected genes, however, hypercholesterolemic atherosclerosis-prone mice have been created, for example, mice deficient in apolipoprotein E (apoE $^{-/-}$)[8,9] or low-density lipoprotein receptor (LDLR $^{-/-}$),[10] or both,[11] double knockouts deficient in both the LDLR and apobec-1 protein,[12] and LDLR $^{-/-}$ mice expressing human apolipoprotein B 100 (apoB100).[13] Among mammals, research using the mouse has several unique advantages, including the extensive knowledge of, and the ability to manipulate, the murine genome. Over the past decade, remarkable progress has been made in our knowledge of vascular biology through the use of genetically engineered mice, and mice are being increasingly used as a model for the study of atherosclerosis and its risk factors.[14-16]

The most commonly used genetically altered murine models for studies of atherosclerosis are mice deficient in apoE and/or LDLR. ApoE is a ligand for receptors that clear chylomicron and very low-density lipoprotein remnant particles. Consequently, apoE $^{-/-}$ mice develop severe hypercholesterolemia and atherosclerosis spontaneously on a normal chow diet, in contrast to LDLR $^{-/-}$ mice, which only do so when fed a high-fat high-cholesterol diet.[17] The atherosclerotic lesions that develop in these atherosclerosis-prone mice are morphologically quite similar to those in humans, which is why the mouse has become the most common experimental animal model for atherosclerosis research. Therefore, a more detailed description of atherogenesis in these mice is appropriate.

Endothelial Dysfunction

Endothelial function is generally similar in blood vessels from normal mice compared with blood vessels from other species.[18] For example, acetylcholine (the classic endothelium-dependent agonist) relaxes the mouse aorta as well as the carotid, coronary, mesenteric, and pulmonary arteries.[18] The relaxation observed in response to acetylcholine in murine blood vessels is endothelium dependent and, thus, similar to that observed in many other species, including humans.[18] In hypercholesterolemic atherosclerosis-prone mice, endothelium-dependent relaxation is impaired, i.e., endothelial dysfunction is present,[19-22] consistent with studies of atherosclerosis in other experimental animals and in humans.[18]

Transfer of the human apolipoprotein A1 (apoA1) gene tends to normalize the impaired endothelial function in these mice,[22] apparently without preventing subendothelial lipid deposition, endothelial activation [vascular cell adhesion molecule 1 (VCAM-1 expression)] or monocyte adherence to the activated endothelium.[23] Nevertheless, lesion formation is dramatically reduced.[24,25] The atheroprotective effect of the mouse's own native apoA1 has been more difficult to prove,[26-28] but clear protective effect has been documented.[29]

Lesion-Prone Areas

In aortas of normocholesterolemic mice, VCAM-1 and intercellular adhesion molecule 1 (ICAM-1), but not E-selection, are expressed by endothelial cells in regions predisposed to atherosclerotic lesion formation.[30] The complex hemodynamics in these lesion-prone areas may also increase the local transendothelial passage of lipoproteins and promote their retention and modification in the subendothelial space.[31] Oxidative modified LDL (oxLDL) has many proinflammatory properties which may explain the local upregulation of these inducible endothelial cell adhesion molecules, even before lesion formation, in hypercholesterolemic atherosclerosis-prone animals.[30]

Injuring Lipoprotein Retention

The first event in the birth of a plaque is the transendothelial passage of atherogenic lipoproteins into the subendothelial space, where they are retained and modified.[4,5,32] In normal mice, the subendothelial space contains an acellular matrix of branching filaments (presumed to be mainly proteoglycans) and numerous collagen fibrils without any visible lipid deposition[4]-normal mice do not spontaneously form an arterial intima.[33] The retention of lipoproteins in the subendothelial space provides a microenvironment where lipoprotein modification and aggregation can occur.[4] Modification, e.g., oxidation, of the retained lipoprotein makes it more atherogenic.[34,35] OxLDL is proinflammatory, cytotoxic, and recognized by the macrophage scavenger receptor promoting intracellular lipid accumulation and foam cell formation. In vitro studies suggest that lipoprotein retention involves interactions between apoB and matrix proteoglycans[36,37] and appears to be an important if not the key step in lesion development.

The concentration of a particular macromolecule within the subendothelial matrix depends on its plasma concentration, molecular size, permeability (the arterial endothelium is permeable to all plasma proteins), degree of retention (trapping) and rate of degradation within intima, and efflux from intima as well as on the location along the arterial tree.[38,39]

Inflammatory/Immune Response

One of the earliest detectable cellular responses in atherogenesis is the focal recruitment of circulating monocytes and, to a lesser extent, T cells into the arterial intima is.[40] The persistence of this cellular response seems to underlie disease progression (Fig. 35-1).[41] A few B cells may also be present,[42] but granulocytes are rare in atherosclerosis. Atherosclerotic lesions develop initially beneath an intact but activated endothelium at lesion-prone sites, preferentially affecting the outer walls of bifurcations and the inner wall of curvatures. The local factors responsible for the focal development of lesions are not well understood, but hemodynamic shear stress, the frictional force acting on the endothelial cell surface as a result of blood flow, is weaker in the susceptible lesion-prone areas.[31,43] Hemodynamic shear stress is an important determinant of endothelial function and phenotype. High shear stress (>15 dyne/cm^2) induces endothelial quies cence and an atheroprotective gene expression profile, whereas low shear stress (<4 dyne/cm^2), which is prevalent at atherosclerosis-prone sites, stimulates an atherogenic phenotype.[31,43] The endothelium mediates the transendothelial trafficking of leukocytes into the intima by expressing specific and inducible adhesion molecules such as VCAM-1 and ICAM-1. These adhesion molecules are upregulated at lesion-prone sites in apoE $^{-/-}$ mice prior to lesion formation and thus probably play an important role in the recruitment of mononuclear cells during atherogenesis.[40] Sites of predilection for lesion development include the aortic root, the lesser curvature of the aortic arch, the principal branches of the aorta (in particular, the coronary arteries and the brachiocephalic trunk), the carotid bifurcations, the aortic bifurcation, the iliac arteries, and the pulmonary arteries. Adhesion of monocytes to the endothelial surface was seen already at 6 weeks, macrophage foam cell lesions (fatty streaks) developed as early as 8 weeks, and, as lesions continued to progress, smooth muscle cells appeared and advanced atherosclerotic plaques were present after 15 weeks. The latter consisted of a fibrous cap containing smooth muscle cells

surrounded by connective tissue matrix that covered a necrotic core with numerous foamy macrophages. Thus, the apoE $^{-/-}$ mouse contains the entire spectrum of lesions observed during atherogenesis and was the first mouse model to develop lesions similar to those in humans.[44]

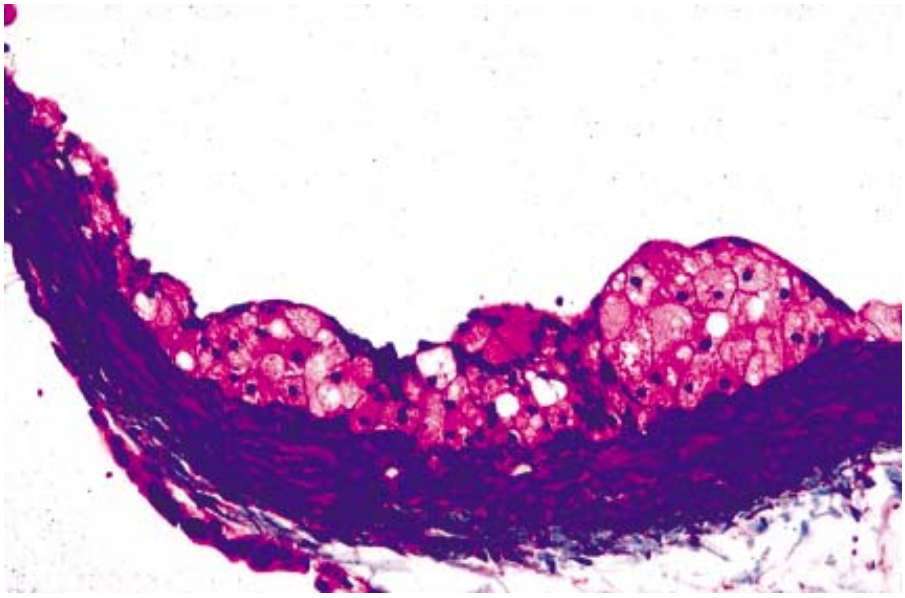

Figure 35-1: (Plate 77) An early atherosclerotic lesion (fatty streak) in the aortic root of a 3-month-old apolipoprotein E-/- mouse fed a high-fat Western-type diet for 6 weeks. The lesion consists of lipid-laden monocyte-derived macrophage foam cells and a few lymphocytes (T cells) beneath an intact endothelium. Elastin trichrome stain.

Leukocyte adhesion to the endothelium alone however, is, not enough to get monocytes and T cells into the intima. They have to pass through the endothelium and, for that, one or more chemokines (chemotactic cytokines) are needed.[45,46] The proinflammatory chemokine monocyte chemoattractant protein 1 (MCP-1) attracts potently both monocytes and T cells, but not neutrophils, eosinophils, and B cells, and plays a fundamental role in the recruitment of these cells.[47] Endothelial cells, smooth muscle cells, and macrophages all contribute to overexpression of MCP-1 in atherosclerosis. Thus, once within the intima, monocytes recruit themselves by secreting MCP-1.[45,48-50] MCP-1 appears to be uniquely essential for monocyte recruitment in several inflammatory diseases,[51] including atherosclerosis.[49,50] Additionally, MCP-1 may induce tissue factor expression in plaque cells and thus increase the risk of atherosclerosis-mediated luminal thrombosis.[52] A prime candidate for upregulation of MCP-1 in the vessel wall is minimally oxidized LDL, linking hypercholesterolemia to fatty-streak formation, plaque progression, and tissue factor expression.[53]

Once within intima and activated, macrophages may secrete a variety of potent cytokines that profoundly influence local cellular accumulation and function. Macrophages can both initiate the oxidation of LDL and take up oxLDL by specific scavenger receptors. Lesion size is reduced in atherosclerosis-prone mice lacking the macrophage-expressed oxygenating enzyme 12/15-lipoxygenase[54] and scavenger receptors, suggesting that lipoprotein oxidation and uptake are key events in atherogenesis.[35]

The humoral and cellular immune system modulates the development of atherosclerosis.[35,55] Plaque T cells and their products [e.g., interferon-γ (IFN-γ)] appear to promote atherosclerosis, whereas nonplaque B cells and their products (e.g., antibodies) are atheroprotective.[56,57]

Hyperimmunization with oxLDL, resulting in high antibody titers, and polyclonal immunoglobulin therapy protect against atherosclerosis, whereas splenectomy (removal of a B cell-enriched immune organ) promotes atherosclerosis in apoE $^{-/-}$ mice.[57] In contrast, all proatherogenic activities of the immune system discovered until now have been associated with inflammatory responses elicited by macrophages and T cells within plaques.[57] Neither B nor T cells, however, are required for the development and growth of plaques, documented in apoE $^{-/-}$ × RAG mice lacking lymphocytes.[58,59] A variety of antigens are formed in developing plaques with immune activation and subsequent modulation, mediated by both cellular and humoral events, of the ongoing atherosclerotic process.[55] Further evidence of immune activation is the upregulated expression of the immune mediator CD40 and its ligand CD154 by all cell types present in advanced atherosclerotic lesions.[60] The interaction of CD40 with CD154 mediates both humoral and cellular immune responses, and blocking this interaction reduces lesion formation in atherosclerosis-prone mice.[61,62]

There are a number of candidate antigens in the lesion that could be responsible for immune activation, including modified LDL,[35] heat-shock proteins,[63-65] β_2-glycoprotein I,[66] and microbial antigens. Of these, the most extensive data support an important role for oxLDL, which is abundantly present in atherosclerotic plaques, where it is recognized by plaque T cells and gives rise to nonplaque B-cell stimulation.[55,57]

Inflammation, but not infection, plays a critical role in atherogenesis.[67] LDL$^{-/-}$ mice fed normal chow do not develop atherosclerosis, even when infected with *Chlamydia pneumoniae* (Cp), but if cholesterol is added to the diet, hypercholesterolemia-induced atherosclerosis develops and Cp infection appears to accelerate its development.[68] Cp infection appears to accelerate atherosclerosis also in the hypercholesterolemic apoE $^{-/-}$ mice;[69] that is, Cp alone is not atherogenic, although it may be causally related to the development of atherosclerosis. Marek's disease in chickens (avian herpesvirus) is the only disease in which an infection alone causes an arterial disease with some morphologic similarities to human atherosclerosis, but full-blown human-like atherosclerosis develops only if the chickens concomitantly are fed a cholesterol-rich diet.[70] This infectious arterial disease in birds is preventable by vaccination.[71]

Fibroproliferative Response

Only endothelial cells, monocyte-derived macrophages, and a few T cells participate in the early inflammatory/immune response, giving rise to early atherosclerotic lesions (fatty streaks) (Fig. 35-1, Plate 77). In disease progression, this pure inflammatory/immune response is accompanied by a fibroproliferative response in which the vascular smooth muscle cell plays a dominant role.[72] Smooth muscle cells are not normally present in the mouse intima, but they are, of course, present in the adjacent tunica media, from which they migrate into intima to become the matrix-synthesizing cell in the developing atherosclerotic plaque.[72] Macrophages and T cells continue to be present throughout plaque development and probably promote rather than retard progression.

Lipids begin to accumulate extracellularly, partly due to di-rect retention of atherogenic lipoproteins in the extracellular matrix and partly due to foam cell necrosis and apoptosis followed by the release of intracellular lipids to the extracellular space.[44] In such a way, a *necrotic* lipid-rich core with foamy macrophages and cholesterol crystals may form, covered by a fibrous cap containing both smooth muscle cells and inflammatory cells[44] (Fig. 35-2, Plate 78).

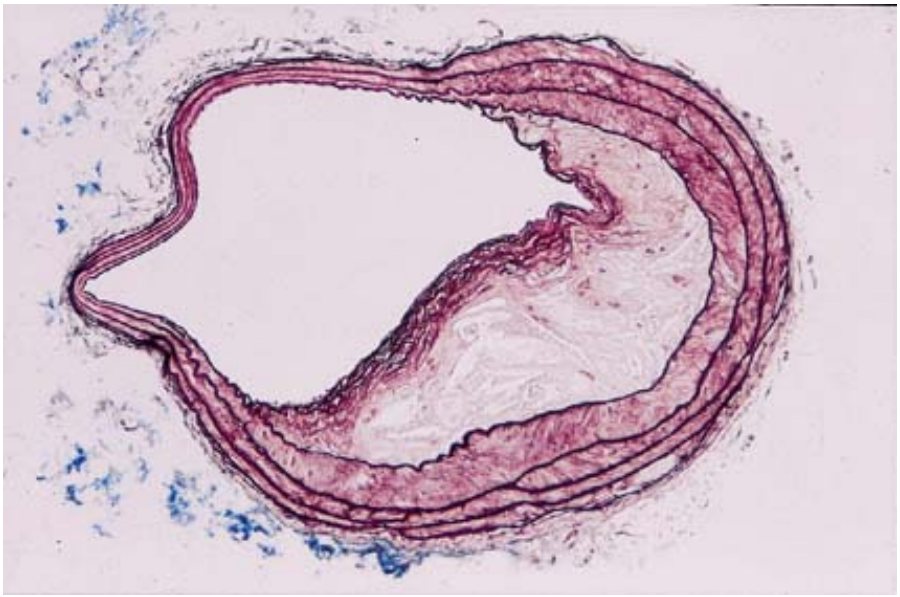

Figure 35-2: (Plate 78) An advanced atherosclerotic plaque in the brachiocephalic trunk of a 6-month-old apolipoprotein E-/- mouse fed normal chow. The plaque appears vulnerable morphologically, consisting of a lipid-rich core with cholesterol crystals covered by a thin fibrous cap. Orcein, staining elastic tissue black.

It has proved much easier to prevent and regress the early inflammatory/immune response than the subsequent fibroproliferative response,[58,59,72-76] and, consequently, much more is known about the molecular mechanisms controlling the former than the latter. All plaque cells, including smooth muscle cells, are capable of forming a large number of growth factors and cytokines, and T cell-derived IFN-γ and responses mediated by CD40 ligation could play important roles in lesion progression.[56,60-62] The smooth muscle cell is the principal connective-tissue cell responsible for healing and repair of the arterial wall. It can elaborate all of the proteins of the matrix, including several forms of collagen (e.g., types I, III, and IV), elastic fiber proteins, and proteoglycans, which together create a complex, heterogeneous extracellular matrix.[72] Cartilaginous metaplasia[77] and calcification are frequently seen in advanced lesions, and both intimal calcification[78] and medial[79] calcification have been studied in atherosclerosis-prone mice.

In normal arteries and in arteries with early atherosclerosis, vasa vasorum are confined to adventitia, but neovascularization of plaques may occur with disease progression. In apoE $^{-/-}$ mice, the incidence of neovascularization is generally low but appears to increase in more advanced and thicker lesions. Thus, thin-walled capillary-like vessels (i.e., neovascularization) have been identified in 15 (13 percent) of 114 advanced aortic lesions from cholesterol-fed apoE $^{-/-}$ mice aged 36 to 60 weeks.[80]

Fibrinogen is not required for, and does not appear to influence, the development and progression of advanced lesions in mice, documented in double gene knockout mice lacking both apoE and fibrinogen.[75] On the other hand, the loss of a key fibrinolytic factor - plasminogen - greatly accelerates lesion formation in apoE $^{-/-}$ mice.[81] Plasminogen deficiency may accelerate atherosclerosis by influencing processes in the vessel wall unrelated to fibrin(ogen) and impaired fibrinolysis.

PLATELET-VESSEL WALL INTERACTION

Before the creation of gene-manipulated atherosclerosis-prone mice, Paigen and colleagues evaluated the potential contribution of platelets to the development of atherosclerosis by

comparing the severity of atherosclerosis in susceptible C57BL/6 mice carrying either a normal or a variant phenotype for platelet function.[82] Five genetically distinct mutants with increased bleeding times and abnormal dense granules were studied, and three of these mutants (light ear, maroon, and ruby eye) developed less atherosclerosis than the controls on the atherogenic diet.[82] The result indicates that some particular component of platelet function affects atherosclerosis. Other defects than those in platelets are, however, present in these mice, which precludes any firm conclusion regarding the significance of the platelet-vessel wall interaction in atherogenesis in these mice.

Platelets may contribute to atherogenesis in at least two different ways: mural thrombi may form on denuded plaques and subsequently be incorporated into developing lesions, and/or they may serve as a source of platelet-derived growth factors and stimulate smooth muscle cell proliferation. Although the endothelium is intact, but activated, early during atherogenesis in both humans and atherosclerosis-prone mice, endothelial denudation or frank plaque rupture with subsequent thrombus formation contribute significantly to plaque development in humans. Spontaneous endothelial denudation with subsequent platelet adhesion (monolayer) or thrombus formation (aggregation) have not been described in mice.

Plaque Disruption and Thrombosis

Although we have learned a lot about atherogenesis by studying the initiation and development of lesions in atherosclerosis-prone mice, nothing has been learned about atherosclerosis-mediated thrombogenesis-the final pathogenetic chain of events precipitating life-threatening heart attacks in humans. Plaque rupture with superimposed thrombosis, which is a rather common feature of human atherosclerosis, is extremely rare in mice and all other animal models of atherosclerosis.[83] This shortcoming is probably the most significant distinction between human atherosclerosis and human-like atherosclerosis in mice.[75]

A variety of proteinases, mostly released by infiltrating mac rophages, have been implicated in plaque rupture in humans, but the actual enzymatic culprits have not yet been conclusively identified.[84] Of the many proteinases present in plaques, members of the matrix metalloproteinase (MMP) family, cysteine proteinases (e.g., elastolytic cathepsins S and K), and serine proteinases [mostly plasminogen and its activators: urokinase-type plasminogen activator (u-PA) and tissue-type plasminogen activator (t-PA)] have received much attention.[84] Atherosclerotic plaques in apoE $^{-/-}$ mice contain a lot of macrophages, both superficially in plaque and at their base, many of which express MMPs, including MMP-3, MMP-9, MMP-12, and MMP-13.[85,86] However, although macrophages at the base of plaques often infiltrate and destroy the internal elastic membrane, media, and adjacent adventitia, which may give rise to aneurysm formation, the plaque surface almost always remains intact without disruption and/or thrombosis. Not a single case of plaque disruption with superimposed thrombosis in mice has been reported. We have performed a meticulous search for ruptured and thrombosed plaques in middle-aged apoE $^{-/-}$ mice (age, >1 year), some of which had died spontaneously of natural causes. Although we have studied several hundred mice, each of which contained many rupture-prone plaques, only two ruptured plaques were identified, one with superimposed thrombosis (Fig. 35-3, Plate 79).

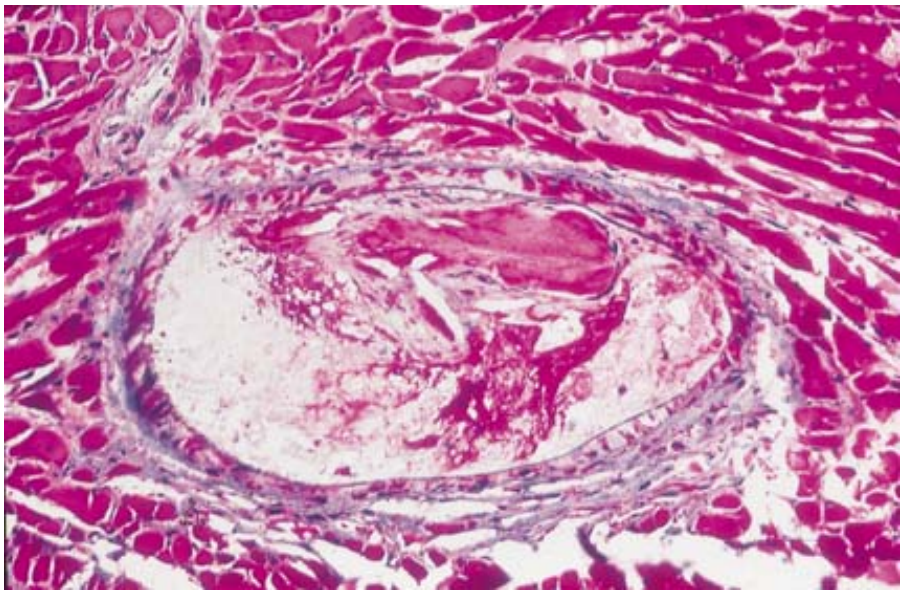

Figure 35-3: (Plate 79) Ruptured coronary plaque with occlusive thrombosis superimposed (natural death of a 21-month-old apolipoprotein E-/- mouse). Spontaneous plaque rupture and/or luminal thrombosis are extremely rare in animal models of atherosclerosis. Elastin trichrome stain.

Remodeling

Consistent with what is observed in human atherosclerosis, arteries in apoE $^{-/-}$ mice remodel in response to plaque growth with no correlation between lesion mass and lumen loss.[87] In the ascending aorta, a normal lumen is preserved due to compensatory vascular enlargement during plaque growth, in contrast to the external carotid arteries, where stenotic lesions tend to develop associated with adventitial inflammation and medial atrophy.[87] Vascular remodeling with preservation of the aortic lumen despite marked intimal thickening has also been described in apoE $^{-/-}$ × LDLR $^{-/-}$ mice.[88]

Vascular Protection

Preventing or retarding atherosclerosis is more than just controlling lipid and other major risk factors. Atherosclerosis is a lipid-driven disease, but not all mice or all arteries within the same mouse are equally susceptible to atherosclerosis;[83] that is, hypercholesterolemia does not necessarily lead to advanced atherosclerosis. The final result depends critically on the participation of many processes not directly related to lipid, and the inhibition of just one necessary step in the pathogenetic chain of events is enough to prevent or retard plaque development. To date, most interventions have targeted the initial step in atherogenesis-hypercholesterolemia-but it may prove to be as, or even more, effective to target subsequent but necessary steps for lesion development in the vessel wall.

TARGETING MONOCYTE/MACROPHAGE FUNCTIONS

Some monocyte/macrophage functions are crucial in the initiation and progression of lesions, documented by reduced lesion development in hypercholesterolemic atherosclerosis-prone mice lacking ICAM-1,[89] macrophage-colony stimulating factor,[90-92] MCP-1,[49,50] MCP-1 receptor CCR2 on monocytes,[53,93] macrophage-expressed 12/15-lipoxygenase,[54] or macrophage scavenger receptors,[94-96] or mice treated with an antibody against the M-CSF receptor c-fms.[73] In contrast, macrophage overexpression of MCP-1 accelerates atherosclerosis.[48]

TARGETING OTHER EVENTS NOT MEDIATED BY LOW-DENSITY LIPOPROTEIN

Interventions, in addition to the monocyte/macrophage-related just described, that have proved to *slow the development of lesions* in atherosclerosis-prone mice, and not mediated by LDL lowering, include apoA1 overexpression;[24,25,29,76,97] apoA1 Milano injection;[98] inactivation IFN-γ receptor;[56] immunization with oxLDL[99,100] or native LDL;[100] antioxidant treatment with high-dose vitamin E[101] (compared with lower dosing),[102] (co)antioxidants H212/43,[103] DPPD,[104] or licorice;[105] treatment with estrogen,[106] L-arginine,[107] the angiotensin-converting enzyme inhibitor captopril,[108] the angiotensin-II receptor antagonist losartan,[109] (cf. Makaritsis et al.[110]), or normal human polyspecific immunoglobulins;[111] inhibition or blocking of endothelin ET_A receptor[20] or interleukin-1 receptor;[112] CD40 ligation;[61,62] angiogenesis (advanced lesions only);[113] and cellular receptor for advanced glycation end products (in diabetic mice);[114] dietary soy protein;[115] and iron-deficient diet.[116]

Interventions that have proved to *accelerate the development of atherosclerosis* independently of LDL cholesterol include probucol (paradoxically and in contrast to other antioxidants such as vitamin E),[117-119] Cp infection,[68,69] cytomegalovirus infection,[120] interleukin 12 administration,[121] immunization with β_2-glycoprotein I,[122,123] absence of the tumor-suppressor protein p53,[124] plasminogen deficiency,[81] and angiotensin II injection.[125]

Chapter 35: ATHEROGENESIS AND ITS DETERMINANTS

HUMAN ATHEROSCLEROSIS

The Committee on Vascular Lesions of the Council on Arteriosclerosis, American Heart Association, has defined the normal arterial intima and its atherosclerosis-prone regions,[126] asymptomatic early lesions,[127] and advanced and potentially symptomatic lesions.[128] Based on these definitions, a practical histologic classification of human atherosclerotic lesions was published in 1995 (Fig. 35-4),[129] which is summarized by M. J. Davies in Chap. 36. The following description is based on these excellent publications but differs to some extent from the 1995 AHA classification.

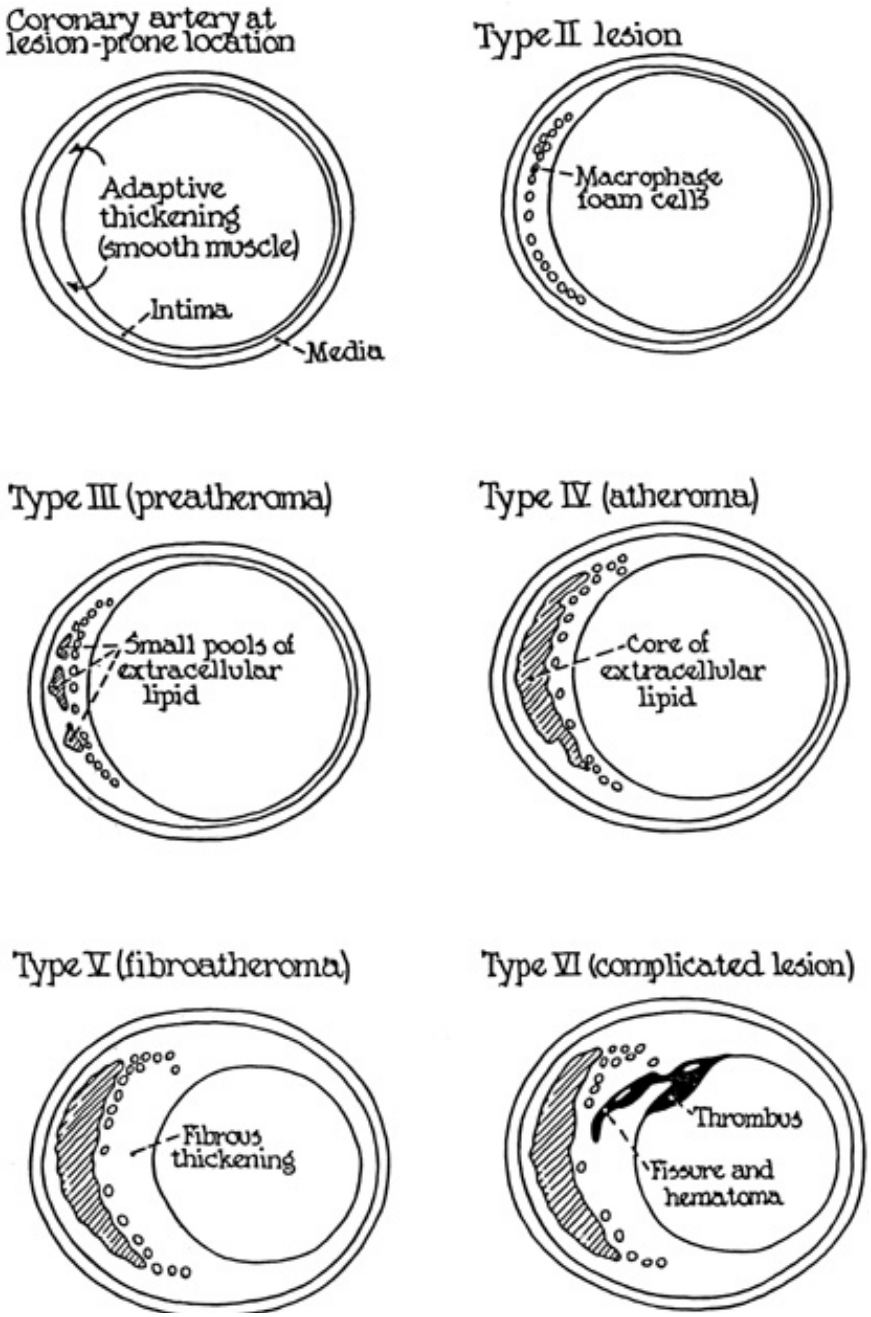

Figure 35-4: The 1995 American Heart Association classification of atherosclerotic lesions. The type I (initial) lesion, which consists of small, isolated groups of macrophages containing lipid droplets, is not shown in this figure. (Adapted from Stary et al.[128] Reproduced with permission from the publisher and authors.)

Endothelial Dysfunction

Atherogenic stimuli may give rise to nonadaptive changes in endothelial structure and function, such as enhanced permeability to plasma lipoproteins, hyperadhesiveness for blood leukocytes, and functional imbalances in local pro- and antithrombotic factors, growth stimulators and inhibitors, and vasoactive substances.[129] These manifestations, collectively termed *endothelial dysfunction*, play an important role in the initiation, progression, and clinical complications of atherosclerosis.[129] It is generally assumed, but not proved, that endothelial dysfunction as just defined equates with endothelial dysfunction as identified clinically as an impairment in endothelium-dependent vasodilation, largely mediated by the endogenous vasodilator nitric oxide and usually reversible. The mere presence of risk factors for ischemic heart disease, such as hypercholesterolemia, hypertension, cigarette smoking, diabetes mellitus, hyperhomocyst(e)inemia, and aging, is associated with endothelial dysfunction as defined clinically, even in the microcirculation and in arteries, such as the brachial artery, that are resistant to atherosclerosis.[130,131] Thus, clinically defined endothelial dysfunction is related to atherosclerosis but not necessarily causally.

Atherosclerosis-Prone Areas

The normal human intima is covered by endothelial cells and contains, in contrast to intima of many laboratory animals (including mice), smooth muscle cells, isolated macrophages, occasional mast cells, and extracellular matrix.[127] The latter constitutes up to 60 percent of the volume and contains proteoglycans (predominantly chondroitin and dermatan sulfates), collagens (predominantly types I and III), elastin, and other components such as fibronectin, laminin, and plasma proteins.[127] Apparently, all plasma proteins are present in lesion-free intima in concentrations related directly to the protein's plasma concentration and inversely to its molecular weight. In the normal artery, LDL is present in intima but is usually not detectable in media.[126]

Regardless of atherogenic stimuli, nonobstructive intimal thickenings are present at constant locations in everyone from birth, particularly at bifurcations, and progress with time. Such adaptive intimal thickenings develop in response to mechanical forces such as pressure, circumferential stretch or tension, and shear stress.[126] Low shear stress and, probably more importantly, oscillatory flow and flow reversal may promote both adaptive intimal thickening and subsequent influx and accumulation of atherogenic lipoproteins.[31] Reduced wall shear stress (dilatation) and increased wall tensile stress (hypertension) promote adaptive intimal thickening, which tends to normalize shear and tension.[126] Eccentric intimal thickening is frequently seen near bifurcations and branch points where shear and tensile stresses are not uniformly distributed, and diffuse thickening may develop in relatively straight arterial segments with evenly distributed stresses.[126] Evidence suggests that the shape of a vessel, rather than the flow patterns, may determine the degree of adaptive intimal thickening and ultimately constitute a risk factor for development of symptomatic lesions.[132]

In human arteries, there is no need for migration of smooth muscle cells into the intima from the media to initiate plaque formation, in contrast to many laboratory animals, where the intima does not normally contain smooth muscle cells. Under the influence of atherogenic stimuli, adaptive intimal thickenings appear to be good soil for the development of atherosclerosis.[133] The smooth

muscle cells present early in preexisting intimal thickenings and later show "clonality" in superimposed atherosclerotic lesions, suggesting clonal expansion during lesion development.[134] Although advanced lesions are not confined to regions with adaptive intimal thickenings, particularly not in hyperlipidemia-induced atherosclerosis in animals, lesions form earlier and more rapidly in these atherosclerosis-prone areas than elsewhere.[33] In humans, the topographic distribution of eccentric intimal thickening and of advanced atherosclerotic lesions is similar in the coronary arteries, the carotid bifurcation, the parasellar carotid artery, and the aorta.[126,132,135]

Fatty Streaks

The early lesions of atherosclerosis develop under an intact but activated and dysfunctioning endothelium, particularly in atherosclerosis-prone areas with preexisting intimal thickening. Inflammation and immune responses play an important role in atherogenesis from its very beginning.[67,136,137] Hypercholesterolemia is associated with increased endothelial permeability, increased transcytosis and intimal retention of lipoproteins, and endothelial activation with focal expression of VCAM-1 leading to monocyte and T-lymphocyte recruitment. Within intima, the monocyte-derived macrophages engulf the blood-derived LDLs, probably via their scavenger receptors after oxidative modification, and become lipid-filled foam cells. These inflammatory cells constitute by far the major part of the early fatty-streak lesion, with a ratio of approximately 1:10 to 1:50 between T cells and macrophages, and they probably play a significant role in the progression of fatty streaks to mature atherosclerotic plaques.[137] The presence of activated macrophages and T cells strongly suggests that an immunologic reaction has taken place in the atherosclerotic plaque. The antigens that elicit this response are not yet known, and both autoantigens (e.g., against oxidized LDL) and microorganisms (e.g., Cp) have been proposed to play a role.[137]

Although immunoglobulins are found in abundance in lesions, B cells are noticeably absent from human plaque. Similarly, although plasma cells have been noted in inflammatory infiltrates in the adventitia surrounding atherosclerotic arteries, few if any such cells have been seen in the plaque itself.[35]

Accumulations of lipid-filled foam cells within intima may be visible to the naked eye as yellow dots or streaks-fatty streaks. Microscopically, fatty streaks are highly cellular inflammatory lesions consisting of macrophage foam cells (intracellular lipid) and T lymphocytes (immune reaction). Extracellular lipid is hardly identifiable microscopically and B lymphocytes and polymorphonuclear neutrophil (PMN) are not seen. Fatty streaks do not protrude into the lumen, and they are therefore asymptomatic.

The fate of fatty streaks remains controversial. It has been known for decades that aortic fatty streaks are present in infants all over the world, irrespective of ethnicity or prevalence of ischemic heart disease in the population.[138] Recently, it was shown that fatty streaks are present already in arteries of human fetuses,[139,140] but, associated with the low blood cholesterol in late pregnancy and early childhood, fetal aortic fatty streaks may regress, just to progress again later during childhood.[3] In laboratory animals, fatty streaks are the most readily produced lesions and regress completely when serum cholesterol is reduced. It is generally assumed that fatty streaks can progress to more advanced lesions because they occur at the same anatomic sites and because transitional stages have been observed.[127] A smaller subgroup of fatty streaks, those superimposed on preexisting intimal thickenings, appear to be particularly prone to progress to advanced symptomatic lesions, but the mode of progression and the factors controlling it are not clear.[127] For example, aortic fatty streaks are universally present in all populations around the world early in life, even in populations at low risk for symptomatic atherosclerosis later in life, such as the South African Bantu.[138] Females have more aortic fatty streaks than males early in life even though males develop more advanced lesions than females later in life.[138,141] Blacks have

more aortic fatty streaks than whites early in life, but the latter have more advanced lesions than the former later in life.[138,141] The thoracic aorta has more fatty streaks than the abdominal aorta early in life, but the opposite applies for advanced lesions later in life.[138] These contrasting relations seen in the human aorta between asymptomatic fatty streaks in young persons and advanced and potentially symptomatic lesions in adults may put into question the relevance of results obtained in short-term animal experiments in which only the development of foam cell lesions (fatty streaks) in aorta are studied.

Advanced Plaques

Advanced lesions may cause luminal narrowing and produce symptoms. In contrast to mice and many other laboratory animals, smooth muscle cells are already present within the human intima early during atherogenesis, beneath developing fatty streaks.[127] When lipids begin to accumulate extracellulary, then atherogenesis has passed beyond the fatty-streak stage. Oxidatively modified LDL is present in atherosclerotic plaques but not in the normal intima.[35,67] Two different processes are responsible for the extracellular accumulation of lipids: blood-derived atherogenic lipoprotein particles may be trapped and retained directly within the proteoglycan-rich extracelluar matrix, and/or lipid may be released from macrophage foam cells following their death. Macrophages both proliferate and die within atherosclerotic plaques, and the balance probably depends on whether the lesion is progressing, quiescent, or regressing.

Progression beyond the fatty-streak stage is not only associated with lipid accumulation; also, connective tissue, produced by smooth muscle cells, accumulates, giving rise to very heterogeneous atherosclerotic lesions. Some plaques are lipid rich, whereas others are lipid poor, and morphologically dissimilar plaques may evolve next to each other.[6] The endothelium is intact early during atherogenesis, but denuded areas, often related to superficial foam cell infiltration (inflammation), with adherent platelets are later seen over mature plaques.[142,143] Then, growth factors released from adherent platelets and microthrombi may stimulate the smooth muscle cells within the plaques to produce more connective tissue matrix.[72] Because of a leaky endothelium, not only lipoproteins but also many other blood-derived components, including albumin and fibrinogen, are present in evolving lesions.[144]

Neovascularization, often expressing leukocyte adhesion molecules such as VCAM-1 and ICAM-1 and associated with inflammatory cell infiltration, is frequently present at the base of advanced plaques, and it has been suggested that these "new" vessels could play an active role in the recruitment of leukocytes into plaques and thus contribute to the progression of the disease.[145] Extravasated erythrocytes are also frequently seen in these neovascularized areas.

VULNERABLE PLAQUES

A subset of the advanced lesions is particularly dangerous-the vulnerable plaques-because they are at high risk of becoming complicated by luminal thrombosis (Fig. 35-5, Plate 80). Disruption of vulnerable plaques with superimposed thrombosis is the most frequent cause of the acute coronary syndromes of unstable angina, myocardial infarction, and sudden coronary death.[7,146,147]

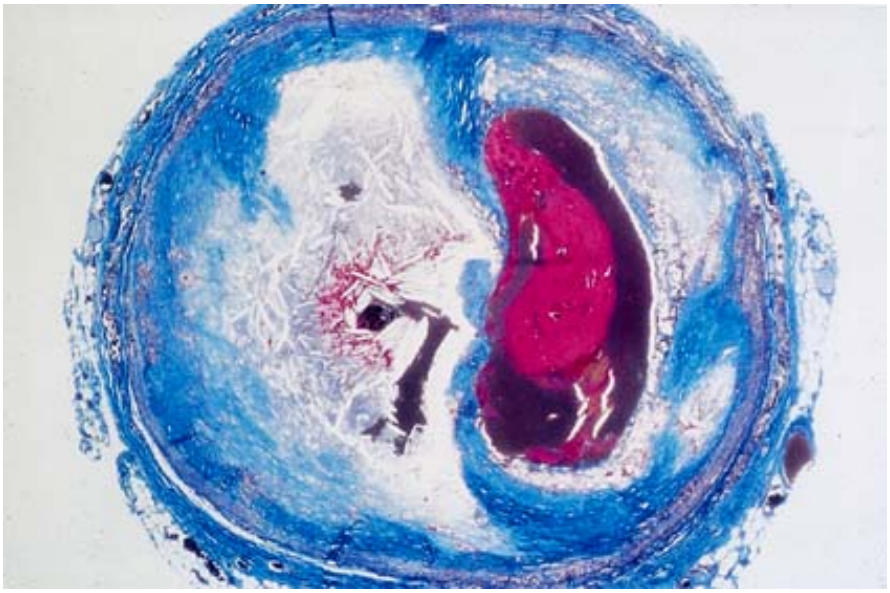

Figure 35-5: (Plate 80) Cross-sectioned coronary artery, containing a vulnerable plaque (large lipid-rich core covered by a thin fibrous cap) with ruptured surface and a nonocclusive luminal thrombosis superimposed. Trichrome stain.

The risk of plaque disruption depends more on plaque type than on plaque size: lipid-rich and soft plaques are more vulnerable and prone to rupture than are collagen-rich and hard plaques.[7] Furthermore, plaques are highly thrombogenic after disruption, because of a high content of tissue factor.[148] Pathoanatomic studies have identified three major determinants of a plaque's vulnerability to rupture (Fig. 35-6): (1) the size of the lipid-rich core, (2) inflammation with plaque degradation, and (3) lack of smooth muscle cells with impaired healing.

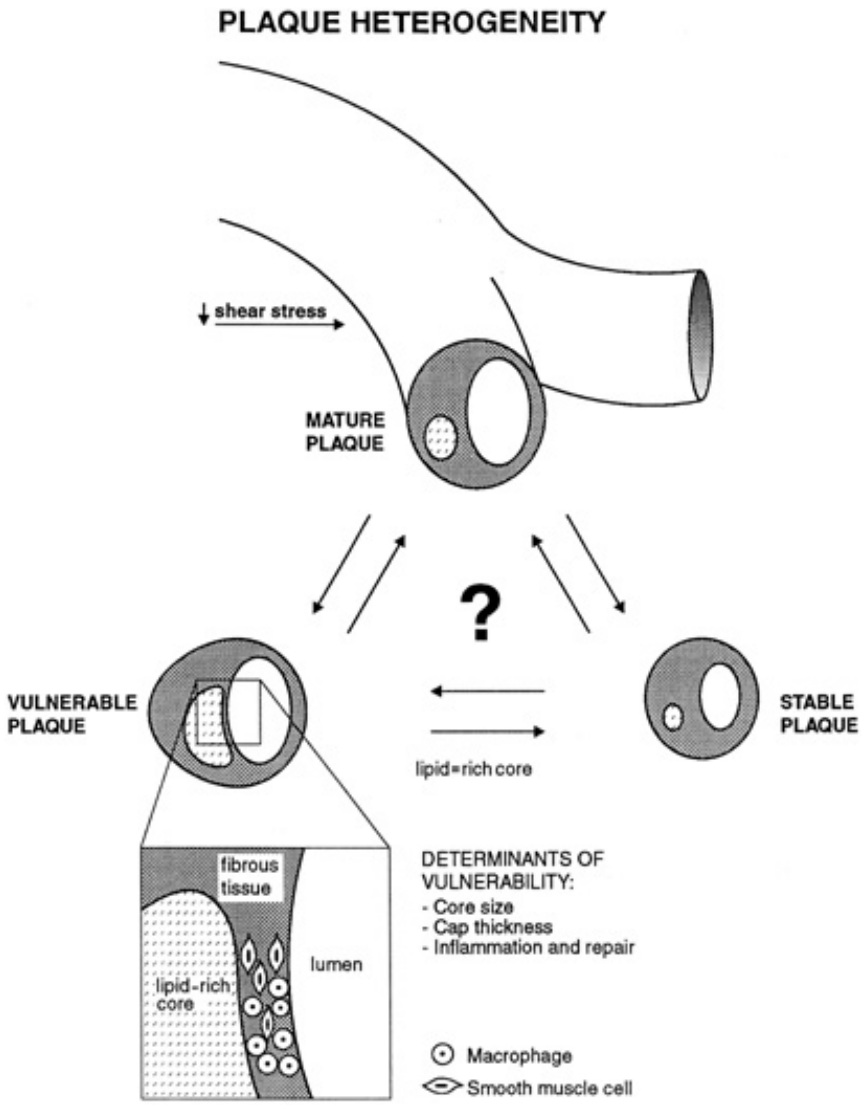

Figure 35-6: Advanced atherosclerotic plaques are extremely heterogeneous in composition. A subset of the advanced plaques are vulnerable (i.e., rupture-prone) with high risk of becoming complicated by luminal thrombosis. The relation between vulnerable and stable plaques is not well defined. (Adapted from Ravn and Falk.[412] Reproduced with permission from the publisher and authors.)

Lipid accumulation, macrophage infiltration, and lack of smooth muscle cells destabilize plaques, making them vulnerable to rupture. In contrast, smooth muscle cell-mediated healing and repair processes stabilize plaques, protecting them against disruption.[136] Plaque size or stenosis severity tell nothing about a plaque's vulnerability.[149] Many vulnerable plaques are invisible angiographically due to their small size and compensatory vascular remodeling.

Lipid Accumulation

The atheromatous core of a plaque is avascular, hypocellular, lipid rich, soft like gruel, and totally devoid of supporting collagen.[7] The size of such a soft core is, of course, critical for the stability of a plaque. At autopsy, Gertz and Roberts found much larger atheromatous cores in coronary plaques with disrupted (compared with intact) surface,[150] and Davies and coworkers found a strong relation between core size and plaque rupture in aorta.[151] Recent studies using immunohistochemical and tunnel staining techniques have identified macrophage-specific antigens and apoptotic nuclear fragments within the gruel, indicating that lipid and other cell constituents released from dead macrophage foam cells could contribute significantly to the

formation and growth of the atheromatous core, which is why it also has been referred to as the "graveyard of dead macrophages," emphasizing the inflammatory origin of this destabilizing core.[152-154]

Plaque Degradation

Disrupted fibrous caps are usually heavily infiltrated by macrophage foam cells,[7,155] and recent observations have revealed that such rupture-related macrophages are activated, indicating ongoing inflammation at the site of plaque disruption.[156] Van der Wal and colleagues identified superficial macrophage infiltration in plaques beneath all 20 coronary thrombi examined, whether or not the underlying plaque was disrupted or just eroded,[156] although a more recent study of coronary thrombi responsible for sudden coronary death could not confirm that observation.[157] Evaluated by immunohistochemical technique, van der Wal and coworkers found that macrophages and adjacent T lymphocytes (smooth muscle cells were usually lacking at rupture sites) were activated, indicating ongoing disease activity.[156] Further evidence of immune activation is the upregulated expression of CD40 receptor and its ligand by all cell types present in advanced atherosclerotic lesions.[60] Comparable results were obtained by the same group in a study of atherectomy specimens showing an inverse relation between the extent of inflammatory activity in plaque tissues of culprit lesions and the clinical stability of the ischemic syndrome.[158] There was considerable overlap between groups, however, indicating that not all patients with clinically stable angina have histologically stable plaques.[158] These observations confirmed the findings of a previous study of atherectomy specimens from culprit lesions responsible for stable angina, unstable rest angina, or non-Q-wave infarction.[159] Culprit lesions responsible for the acute coronary syndromes contained significantly more macrophages than did lesions responsible for stable angina pectoris (14 versus 3 percent of plaque tissue occupied by macrophages).[159]

Macrophages are capable of degrading extracellular matrix by phagocytosis or by secreting proteolytic enzymes such as members of the MMP family (collagenases, gelatinases, and stromeolysins), cysteine proteinases (e.g., elastolytic cathepsins S and K), and serine proteinases (mostly plasminogen and its activators, u-PA and t-PA), which may weaken the fibrous cap, predisposing it to rupture.[83,160] All these proteinases have been identified in human plaques and have been implicated in plaque rupture, but the actual enzymatic culprits have not yet been conclusively identified.[83] The MMPs are secreted in a latent zymogen form requiring extracellular activation, after which they are capable of degrading virtually all components of the extracellular matrix. The MMPs and their cosecreted tissue inhibitors or metalloproteinases TIMP-1 and TIMP-2, are critical for cell migration, tumor invasion and metastasis, and vascular remodeling. Collagen confers stability to plaques, and human monocyte-derived macrophages grown in culture are indeed capable of degrading the old and mature collagen present in advanced aortic plaques.[161] Simultaneously, they express MMP-1 (interstitial collagenase) and induce MMP-2 (gelatinolytic) activity in the culture medium.[161] Besides macrophages, a wide variety of cells may produce MMPs. Activated mast cells may secrete powerful proteolytic enzymes such as tryptase and chymase that can activate pro-MMPs secreted by other cells (e.g., macrophages), and mast cells are actually present in shoulder regions of mature plaques and at sites of disruption, although at very low density.[162] Neutrophils are also capable of destroying tissue by secreting proteolytic enzymes but are rare in intact plaques.[137,156]

Several infectious agents have been suggested to play an active role in the development of cardiovascular diseases, particularly Cp but also herpesviruses (including cytomegalovirus) and *Helicobacter pylori*.[163-165] *Chlamydia* has been identified in atherosclerotic plaques;[166] it contains lipopolysaccharide and heat-shock protein 60, which are well-known strong inducers of many enzymes including MMPs.[167] Nonspecific but sensitive blood markers of inflammation (acute-phase reactants such as C-reactive protein and serum amyloid A) have been identified as

strong risk factors for future cardiovascular events in apparently healthy men[168] and women,[169] in patients with stable[170] and unstable angina,[171-173] and after myocardial infarction.[174]

Impaired Healing

Obviously, the thickness and collagen content of the fibrous cap is very important for its strength and stability: the thinner the cap is, the weaker it is and the more vulnerable is the plaque to rupture.[175] Ruptured aortic caps contain fewer smooth muscle cells and less collagen than intact caps,[151,176] and smooth muscle cells are usually missing at the actual site of disruption.[156,162]

Collagen is responsible for the mechanical strength of the fibrous cap and is synthesized by intimal smooth muscle cells. It is important to realize that smooth muscle cell proliferation and matrix synthesis may, in fact, be good in protecting plaques against disruption, whereas local loss of smooth muscle cells or impaired smooth muscle cell function may be bad, leading to gradual plaque destabilization due to impaired healing and repair.[136] It is unknown why smooth muscle cells are lacking at sites of disruption, but apoptotic cell death could play an important role.[153,154]

Complicated Plaques

We use the term *complicated plaques* when referring to advanced lesions complicated by luminal thrombosis and/or plaque hemorrhage. Such an acute plaque event causes rapid progression of the lesion[177] and is probably the most important mechanism responsible for the unpredictable, sudden, and rapid progression of coronary lesions observed by serial angiographic examination. As just described, plaque disruption with superimposed thrombosis is the most frequent cause of a life-threatening acute myocardial infarction.

PLAQUE DISRUPTION

Vulnerable plaques rupture frequently. Autopsy data indicate that 9 percent of healthy persons harbor disrupted plaques (without superimposed thrombosis) in their coronary arteries, increasing to 22 percent in persons with diabetes or hypertension.[178] In fatal coronary artery disease, more than one disrupted plaque, with or without superimposed thrombosis, is usually present in the coronary arteries.[155,179]

The plaque surface is disrupted most often where the cap is thinnest and most heavily infiltrated by macrophages and therefore weakest, namely, at the cap's shoulders.[7,180] The weak shoulder regions, however, are also points where biomechanical and hemodynamic forces acting on plaques appear to be concentrated.[180,181] Thus, plaque disruption is probably the result of a dynamic interaction between *intrinsic* plaque changes (vulnerability) and *extrinsic* forces imposed on the plaque (triggers); the former predispose a plaque to rupture, whereas the latter may precipitate it. As the presence of a vulnerable plaque is a prerequisite for plaque disruption, plaque vulnerability is probably more important than rupture triggers in determining the risk of a future heart attack. If no vulnerable plaques are present in the coronary arteries, there is no rupture-prone substrate for a potential trigger to function on. Furthermore, the fact that exercise stress testing in individuals with advanced coronary artery disease rarely triggers an acute coronary event suggests that plaque vulnerability ultimately plays a more important role in plaque rupture than does physiologic stress or other potential triggers.

LUMINAL THROMBOSIS

The most feared consequence of coronary plaque disruption is thrombotic occlusion of the artery. About 75 percent of thrombi responsible for acute coronary syndromes are precipitated by plaque disruption whereby the highly thrombogenic gruel is exposed to the flowing blood.[155,182,183] In

the remaining 25 percent, superficial plaque erosion without frank disruption (i.e., no deep injury) is usually present.[2] Most disrupted plaques are resealed by a small mural thrombus, and only sometimes does a major luminal thrombus evolve. There are three major determinants of the thrombotic response to plaque disruption/erosion: (1) the local thrombogenic substrate, (2) the local flow disturbances, and (3) the systemic thrombotic propensity.

Inflammatory cells might also play an important role in the thrombotic response to plaque disruption/erosion via tissue factor expressed locally in plaque macrophages and systemically in blood monocytes.[148,184-186] The thrombotic response to plaque disruption is dynamic; thrombosis and thrombolysis occur simultaneously in many patients with acute coronary syndromes, with or without concomitant vasospasm, causing intermittent flow obstruction. The initial flow obstruction is usually due to platelet aggregation, but fibrin is important for the subsequent stabilization of the early and fragile platelet thrombus. Therefore, both platelets and fibrin are involved in the evolution of a persisting coronary thrombus.[187]

Clinical Manifestations

Plaque disruption itself is asymptomatic, and the associated rapid plaque growth is usually clinically silent. However, rupture-related hemorrhage into the plaque, luminal thrombosis, and/or vasospasm may cause sudden flow obstruction, giving rise to an acute coronary syndrome. The culprit lesion is frequently *dynamic*, causing intermittent flow obstruction, and the clinical presentation and the outcome depend on the severity and duration of myocardial ischemia.[146,147,187] A nonocclusive or transiently occlusive thrombus most frequently underlies primary unstable angina with pain at rest and myocardial infarction without ST-segment elevation, whereas a more stable and occlusive thrombus is most frequently seen in infarction with ST-segment elevation-overall modified by vascular tone and collateral flow. The coronary lesion responsible for out-of-hospital cardiac arrest or sudden coronary death is often similar to that of unstable angina: a disrupted plaque with superimposed nonocclusive thrombosis.[179]

Chapter 35: ATHEROGENESIS AND ITS DETERMINANTS

ATHEROSCLEROSIS-RELATED FEATURES

Patients with CHD generally have many atherosclerotic plaques in their coronary arteries, which vary considerably in their composition. Although coronary angiography may show only one or a few stenotic lesions, many more plaques are observed on intravascular ultrasound examination in living patients and at autopsy in deceased patients.[188,189] Only a minority of plaques protrude into and compromise the lumen because of compensatory abluminal vascular enlargement (remodeling) during plaque growth.[190] Thus, the lumen may remain normal despite buildup of large volumes of atherosclerotic plaque in the vessel wall. For all practical purposes, diagnostically as well as therapeutically, coronary atherosclerosis is a diffuse disease with superimposed focal luminal narrowing.

Arterial Remodeling and Luminal Narrowing

Vascular remodeling is the ability of the vessel wall to reorganize its cellular and extracellular components in response to a chronic stimulus.[191] In human atherosclerosis, there is ample evidence for active remodeling during the early stages of disease prior to significant lumenal stenosis. It was originally assumed that atherogenesis was always associated with more or less compensatory enlargement of coronary arteries during plaque growth,[190] but recent studies suggest that remodeling is bidirectional.[192] Plaques responsible for acute coronary syndromes are usually relatively large and associated with compensatory enlargement, which tends to preserve a normal lumen despite the presence of significant, and potentially dangerous, vessel wall disease. In contrast, plaques responsible for stable angina are usually smaller but, nevertheless, may cause more severe luminal narrowing because of concomitant local shrinkage of the artery.[193] The reason for these different modes of remodeling is unknown, but processes in adventitia could play a critical role.

Stenosis as Predictor

The vulnerability and thrombogenicity of atherosclerotic plaques rather than their obstructive capability (stenosis severity), together with the status of the collateral circulation, have emerged as the most important determinants for the occurrence, type, and outcome of acute coronary events.[7,146,147] Thus, coronary angiography is not a good method to identify high-risk thrombosis-prone lesions, partly because the size of a plaque and its vulnerability correlate poorly, if at all,[149] and partly because vascular remodeling tends to preserve the lumen better with the larger but vulnerable plaques (compensatory enlargement) than with the smaller and stable plaques (shrinkage).[193]

The great majority of heart attacks and ischemic strokes originate from atherosclerotic lesions that, prior to the acute events, only were mild-to-moderately stenotic; i.e., they were hemodynamically insignificant and probably asymptomatic (Fig. 35-7). Although the risk for occlusion, or myocardial infarction or stroke, increases with stenosis severity, the great majority of coronary occlusions (71 percent) in the Coronary Artery Surgery Study and myocardial infarctions (86 percent) in pooled studies originated from lesions that caused less than 70 to 80 percent angiographic stenosis prior to the acute events.[7] The reason is that stenotic lesions are markers of plaque burden, and lower-risk nonstenotic lesions will always by far outnumber the higher-risk stenotic ones and altogether increase the risk for an acute event much more than the

few stenotic lesions at higher individual risk. And the same holds for ischemic stroke. Asymptomatic plaques at the carotid bifurcation, contralateral to symptomatic lesions, were evaluated and followed in the European Carotid Surgery Trial (n = 2240).[194] Only 13 (19 percent) of 67 new strokes were judged to have originated from initially asymptomatic lesions that at baseline caused more than 70 percent angiographic stenosis (Fig. 35-7). The reason: lower-risk nonstenotic carotid plaques (n = 2113) outnumbered by far the stenotic ones (n = 127) at higher risk.

Coronary stenosis: progression to occlusion

Figure 35-7: Most coronary occlusions (*top*, 51/72 = 71 percent), myocardial infarctions (*middle*, 29/39 = 74 percent), and ischemic strokes of carotid origin (*bottom*, 54/67 = 81 percent) are caused by acute thrombosis superimposed on atherosclerotic lesions that, prior to the acute events, were asymptomatic and only mildly to moderately stenotic. Overall, nonstenotic atherosclerotic lesions by far outnumber the stenotic ones at higher individual risk, which is why most acute clinical events originate from nonstenotic lesions at relative low individual risk. MI = myocardial infarction.

Vasoconstriction

Plaque disruption and vasospasm often coexist, and the former most likely gives rise to the latter.[7] Abnormal coronary vasoreactivity is common in acute coronary syndromes but *spasm* is usually confined to the culprit lesion, suggesting that it is caused by locally released vasoactive substances.[195] The plaque, particularly macrophages in disrupted plaques responsible for unstable angina, may contain potent vasoconstrictors such as endothelin 1,[196,197] and superimposed thrombosis may also contain or generate vasoconstrictors such as thrombin and platelet-derived serotonin and thromboxane A_2.[147]

Coronary Calcification

Focal calcification in atherosclerotic plaques is very common and increases with age, both in men and women. Both lipid-rich and collagen-rich components may calcify, and the process may be active and controlled, resembling calcification in bone, rather than being passive and *dystrophic*.[198,199] Coronary calcification in adults is almost always atherosclerosis related and intimal.[200] Medical calcification (Mönckeberg's calcinosis) is rare in coronary arteries, even in diabetic persons where it frequently occurs in other arteries, particularly the muscular arteries of the legs.[201] Both autopsy and clinical data indicate that coronary calcification is a marker for, and correlates closely with, the overall atherosclerotic plaque burden,[202-204] but calcification of a plaque does not correlate with its flow-limiting capacity (degree of stenosis) [202,203] or its risk of sudden occlusion (vulnerability). If anything, heavily calcified plaques appear to be more stable than noncalcified plaques.[203,205-207] The vascular remodeling phenomenon is the likely explanation for the poor correlation of plaque calcification with lumen narrowing and/or stenosis severity.[202]

It is possible to detect and quantify coronary artery calcification noninvasively by electron-beam [or *ultrafast*] computed tomography (EBCT). Plaque calcification detected by EBCT is not necessarily an end-stage irreversible phenomenon; recent data suggest that it may regress with lipid-lowering therapy.[208] Taking age, sex, and clinical presentation into account, coronary calcification may noninvasively identify patients, rather than plaques, at increased risk, because the overall plaque burden, of which coronary calcification is a marker, rather than the severity of individual plaques/stenoses, predicts future coronary events in both symptomatic and asymptomatic adults. The more plaques there are, the greater is the likelihood of one of them

being vulnerable and prone to thrombose.

Chapter 35: ATHEROGENESIS AND ITS DETERMINANTS

FACTORS INFLUENCING ATHEROGENESIS

Atherosclerosis is the result of multiple and complex gene-environment interactions. Genetic factors alone may cause symptomatic atherosclerosis (e.g., homozygous LDLR deficiency), but it is rare. Most frequently, the genetic background determines an individual's response to proatherogenic factors and the susceptibility of the vessel wall to atherogenic stimuli, but environmental factors may markedly influence the speed of disease progression (plaque development) and, thus, determine whether CHD develops. In high-risk societies, epidemiologic studies with autopsy follow-up have revealed a large individual variation in the extent of atherosclerosis (plaque burden) in apparently homogeneous subgroups.[209] The three factors that most consistently have been shown to correlate with the extent of atherosclerotic lesions per se at autopsy in men (high total cholesterol, low HDL cholesterol, and high blood pressure) explain together only about 25 percent of the individual variation.[209] Thus, a large part of the individual variation in the development of atherosclerosis remains unexplained. Only sparse and inconclusive data are available for women.

Several major and independent risk factors for the clinical manifestations of atherosclerosis have been identified, including elevated serum total (and LDL) cholesterol, low serum HDL cholesterol, cigarette smoking, elevated blood pressure, diabetes mellitus, and advancing age.[210] If left untreated, any of these major risk factors has the potential to produce clinical disease. Nevertheless, in principle, only a single absolutely necessary and truly independent etiologic agent for atherosclerosis exists, and it is a high level of serum LDL cholesterol (or its surrogate, serum total cholesterol).[210-212] A strongly positive relation exists between serum cholesterol levels and CHD worldwide, and atherosclerotic events are rare in populations with total cholesterol less than 4 mmol/L (150 mg/dL), even in the presence of other major risk factors.[212-214] At higher cholesterol levels, smoking, hypertension, low HDL cholesterol, and diabetes mellitus promote development of coronary atherosclerosis and predispose individuals to CHD, but these statistically independent risk factors can not by themselves cause atherosclerosis.[211] In affluent societies, however, many patients with CHD have serum cholesterol levels within or below the average range for these high-risk populations, and there is considerable overlap (about 80 percent) in the distribution of cholesterol values among men with and without CHD.[215] Known risk factors for CHD, of which serum cholesterol concentration is just one, explain only half of the variance in the occurrence of the disease.[216] Although it is said that as many as 50 percent of CHD patients lack major cardiovascular risk factors,[217] recently published data indicate that very few, less than 5 to 10 percent, of young adult and middle-aged men and women in the United States lack major risk factors, defined as serum cholesterol level less than 5.17 mmol/L (<200 mg/dL), blood pressure less than or equal to 120/80 mmHg, no smoking, and no diabetes. In this small low-risk subgroup, long-term mortality is much lower and longevity is much greater.[218] Both human and experimental studies strongly indicate that a certain serum cholesterol level (~4 mmol/L; 150 mg/dL) needs to be present to initiate and drive the disease in the vessel wall: atherosclerosis.[210,216] Below that level, CHD is rare, regardless of other risk factors.

Except for LDL cholesterol, very little is known about the specific relation of cardiovascular risk factors to atherosclerosis. The matter is complicated by the fact that symptomatic human plaques develop over decades and are extremely heterogeneous. Even plaques developed next to each other in the same coronary artery and thus exposed to the same systemic risk factors may look

very dissimilar. If a particular risk factor plays a pathogenetic role in arterial occlusive disease, it could, in principle, do so by (1) accelerating the atherosclerotic process itself (plaque burden), (2) destabilizing established plaques (vulnerability, erosin, and rupture), and/or (3) promoting thrombosis on plaques via local (plaque thrombogenicity) and/or systemic factors. With these different pathways in mind, the role of the major risk factors in atherogenesis will be discussed.

Lipoproteins

Elevated serum total (and LDL) cholesterol and low serum HDL cholesterol are major independent risk factors for CHD.[210] Epidemiologic observations, angiographic studies, and lipid-lowering trials, as well as experimental studies, confirm the importance of LDL as a cause of atherosclerosis in both men and women with or without symptoms of CHD.[211,214] An elevated LDL-cholesterol level appears to be the primary CHD risk factor, and the higher the total and LDL cholesterol levels are, the greater is the risk of an atherosclerotic event.[210,211] A strongly positive relation exists between serum cholesterol levels and CHD worldwide,[212-214] and no threshold has been identified below which a lower blood cholesterol is not associated with a lower risk of CHD; the lower the cholesterol, the lower the risk of CHD, even in Chinese populations who, by Western standards, have a low cholesterol concentration.[219] Normal laboratory animals with low cholesterol levels do not develop atherosclerosis.

A low level of HDL cholesterol is a potent individual predictor for CHD in populations in which average cholesterol levels are relatively high, but it may not hold as a predictor in populations in which mean levels of serum total (and LDL) cholesterol are low.[211] In this regard, low HDL cholesterol resembles the other independent major risk factors (smoking, hypertension, and diabetes): it appears to promote coronary atherosclerosis when a high LDL level is present, but not when it is absent.[211] Thus, low HDL cholesterol and nonlipid risk factors aggravate the effect of LDL cholesterol, especially when total and LDL cholesterol are only moderately elevated; 5 to 6.5 mmol/L (190 to 250 mg/dL) and 3 to 4.5 mmol/L (115 to 175 mg/dL), respectively.[214]

Atherosclerosis is due to influx, retention, and modification of atherogenic lipoproteins in the intima, including LDL, intermediate-density lipoproteins (IDLs), and small species of very low density lipoproteins (VLDLs). The degree to which lipoproteins cause atherosclerosis depends in part on their size, explaining why large VLDLs and chylomicrons, which are too large to enter the artery wall, are not atherogenic.[214] The smallest lipoproteins, HDLs, enter the artery wall quite easily but also leave the artery wall easily and do not cause atherosclerosis. In fact, HDL probably affords protection by facilitating the removal of cholesterol from the vessel wall (reverse cholesterol transport).[214] Cholesterol and triglycerides are lipid components of all these various lipoproteins, and measurements of cholesterol or triglycerides therefore do not accurately reflect the particular lipoproteins that cause atherosclerosis. ApoB is a protein common to LDLs, IDLs, VLDLs, and chylomicrons. Since the latter are not present in plasma in the fasting state, almost all apoB is in atherogenic lipoproteins, which is why a fasting plasma apoB level is a good marker of cardiovascular risk.[214]

The relationship of triglycerides to atherosclerosis has been a source of confusion, partly because not all triglyceride-rich lipoproteins are atherogenic (smaller VLDLs versus larger VLDLs and chylomicrons) and partly because VLDLs and HDLs are metabolically closely linked (HDL-cholesterol concentrations are usually low when triglyceride concentrations are high).[214] Severe hypertriglyceridemia due to chylomicrons and large forms of VLDL is not atherogenic (but may cause pancreatitis), in contrast to less severe hypertriglyceridemia due to small VLDLs and IDLs (VLDLs normally carry most of the plasma triglyceride). Recent data have more clearly identified hypertriglyceridemia as a risk factor for CHD.[214] The strong inverse association between plasma

HDL cholesterol and CHD is a consistent observation, but exactly how this relationship comes about is not entirely understood. HDL cholesterol may, as already described, be a reciprocal measure of atherogenic lipoproteins such as small VLDLs, it may protect the vessel wall by inhibiting LDL oxidation, and/or it may promote the removal of cholesterol from the vessel wall (reverse cholesterol transport).[214] Experimental studies suggest that HDL and its major protein component, apoA1, indeed have an innate atheroprotective effect.[76,220-222]

Prospective epidemiologic studies with autopsy follow-up have shown that serum total cholesterol measured during life correlates with the amount of atherosclerosis (plaque burden) in all arterial segments studied (aorta and coronary and cerebral arteries) in men (only one small study included females).[209] In the only study in which HDL cholesterol was measured, it correlated inversely with coronary atherosclerosis.[209] Recent data from the Bogalusa Heart Study, a long-term epidemiologic study of cardiovascular risk factors in children and young adults, revealed that antemortem risk factors relate strongly to atherosclerosis in autopsied children and young adults.[223,224] LDL cholesterol, triglycerides, body mass index, and elevated blood pressure correlated positively with both fatty streaks and more advanced lesions in coronary arteries; no significant correlation was found with HDL cholesterol.[223]

In the multicenter Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study, HDL cholesterol and non-HDL cholesterol in blood obtained postmortem correlated negatively and positively, respectively, with the extent of atherosclerosis in autopsied persons (n = 715).[225] Neither apoA1 nor apoB measures were as strongly or consistently correlated with extent of lesions as the corresponding lipid measure (HDL cholesterol and non-HDL cholesterol, respectively).[225] Including all available risk factors (sex, age, race, smoking status, hypertension, and the lipid measures) in a predictive model, only up to 25 percent of the variation in raised lesions were explained, and HDL cholesterol and non-HDL cholesterol alone increased the explanatory capability by only 2.5 percent. Thus, the larger part of the individual variation in the development of atherosclerosis remains unexplained.

High plasma concentrations of lipoprotein-a- (Lp-a-) identifies persons at increased risk of ischemic heart disease (IHD), but whether Lp(a) is causally related to occlusive arterial disease is unknown. Lp(a) predominantly localizes in atherosclerotic plaques,[39,226] but neither Lp(a) concentration nor its size correlated strongly or consistently with the extent of atherosclerosis in autopsied persons in the PDAY study.[225] It was therefore concluded that Lp(a), which contains apo(a) (which bears significant homology to plasminogen), probably acts by interfering with the thrombotic complications to atherosclerosis rather than promoting atherosclerosis itself.

Regarding plaque composition, recent studies of sudden coronary deaths indicate that elevated total cholesterol and reduced HDL cholesterol, but particularly a high total-to-HDL ratio, predispose men and postmenopausal women to the development of vulnerable rupture-prone plaques with superimposed thrombosis.[227,228]

Smoking

Cigarette smoking is a major, and the single most modifiable, risk factor for atherosclerosis-related clinical events, both in high-risk[211,229] and low-risk[230-232] populations. As many as 30 percent of all CHD deaths in the United States each year are attributable to cigarette smoking, and smoking is the predominant cause of peripheral arterial disease and abdominal aortic aneurysm, it is a major risk factor for ischemic stroke, and it increases the risk of many other chronic diseases.[229] Evaluated statistically by multivariate analysis, smoking contributes to CHD risk independently of other risk factors, but this does not mean that smoking is an independent cause of CHD. Cigarette smoking is pathogenetically a cholesterol-dependent risk factor and acts

synergistically with other risk factors, substantially increasing the risk of CHD.[211,229] Smoking is only weakly, if at all, atherogenic, and smoking alone does not cause a high incidence of CHD, exemplified by low CHD rates in populations in which cigarette smoking is heavy but total cholesterol levels are uniformly low (<4 mmol/L; 150 mg/dL).[212] A dose-related and potentially reversible impairment of endothelium-dependent vasodilation was found in healthy young adults who smoked cigarettes,[233] and smoking also contributes to coronary artery spasm.[234]

Cigarette smoking is a strong predictor of myocardial infarction but not for uncomplicated angina pectoris.[211,235,236] This could mean that smoking does not cause coronary atherosclerosis per se but rather increases the risk for thrombotic events in those who already have reached a certain level of coronary atherosclerosis. Support for this view comes from prospective epidemiologic studies with autopsy follow-up: smokers do not have significantly more extensive coronary atherosclerosis, evaluated grossly as intimal surface covered by plaques, than nonsmokers.[209,237-241] This finding is supported by the more recent PDAY study, in which the extent of coronary atherosclerosis did not correlate significantly with serum thiocyanate (a marker of exposure to smoke, measured post mortem)[141] but, evaluated microscopically, established plaques appeared to be more rapidly progressing and thus reaching an advanced stage of the disease earlier.[242] A coronary thrombus is more freqently found in smokers than in nonsmokers dying suddenly of CHD,[227,228] and preliminary data suggest that smoking may increase the thrombogenicity of plaques by upregulating tissue factor expression.[243] In contrast to coronary atherosclerosis, aortic atherosclerosis and particularly abdominal aortic aneurysm are strongly related to smoking.[141,209,237,238,240,241]

A strong synergistic interaction exists between hypercholesterolemia and smoking in the genesis of myocardial infarction: the former promotes coronary atherosclerosis and the latter, in turn, precipitates myocardial infarction.[211] The specific mechanisms by which cigarette smoking precipitates myocardial infarction are not known but are most likely related to thrombosis on coronary plaques mediated by local factors (plaque thrombogenicity) and/or systemic smoking-dependent factors.[244,245] Some of the evidence for smoking being thrombogenic rather than atherogenic are[244,245] (1) smoking is a strong risk factor for thrombus-mediated events (myocardial infarction and sudden death), but not for symptoms caused by atherosclerosis alone (angina pectoris); (2) angiographically, smoking is associated with rapid coronary occlusion (thrombosis) rather than slow nonocclusive plaque progression (atherosclerosis); (3) after thrombolysis for myocardial infarction, less residual vessel wall disease persists (atherosclerosis) in smokers than in nonsmokers;[246-248] (4) smoking is associated with a systemic hyperthrombotic state (systemic thrombin generation, activated platelets, and high fibrinogen);[249,250] (5) pathoanatomically, smoking is strongly related to coronary thrombosis and only weakly to the underlying atherosclerosis; and (6) smoking cessation rapidly and markedly reduces risk for myocardial infarction, indicating that the responsible process is rapidly reversible.[244,251] Finally, also in experimental animals is smoking more thrombogenic than atherogenic; it promotes platelet-dependent cyclic flow variation after arterial injury,[252] but forced cigarette smoking does not induce coronary atherosclerosis in nonhuman primates.[253]

In the United States, about 43 percent of nonsmoking children and 37 percent of nonsmoking adults are exposed to environmental tobacco smoke, and passive smoking appears to be associated with a small increase in the risk of CHD.[254] Thus, the public health consequences of passive smoking with regard to CHD may be important.[254]

Hypertension

Systemic arterial hypertension is a major independent risk factor for CHD, although it pathogenetically appears to be a cholesterol-dependent accelerator of atherosclerosis.[212,213] When

hypertension is defined as a systolic blood pressure of 140 mmHg or greater, a diastolic blood pressure of 90 mmHg or greater, or both, it is associated with a relative risk of 1.5 (Seven Countries Study)[255] to 2.0 (Framingham Study)[256] for death from CHD, in both high-risk (United States and Northern Europe) and low-risk populations (Japan and Mediterranean Southern Europe).[255]

It is generally assumed that hypertension accelerates atherosclerosis directly by way of increased blood pressure, but it has been suggested that associated hormonal changes, including generation of angiotensin II by systemic and/or local renin-angiotensin systems, could also play a pathogenetic role.[67] However, the original observation of an association between the insertion (I)/deletion (D) polymorphism of the angiotensin-converting enzyme (ACE) gene, which explains as much as 30 to 40 percent of the total variation in serum ACE activity,[257] and myocardial infarction was not confirmed in the two largest studies to date,[258,259] and increased serum ACE activity has never been shown to be a risk factor for CHD.[257] The recently published Heart Outcomes Prevention Evaluation trial may shed new light on that question.[260]

Hypertension and hypercholesterolemia interact strongly in promotion of coronary atherosclerosis.[211] Hypertension does not induce atherosclerosis in normal laboratory animals with low cholesterol levels; it is not in itself atherogenic. In populations where total cholesterol is less than 4 mmol/L (150 mg/dL), atherosclerotic events are rare, even in people with hypertension.[212] That the blood pressure needs to be above a certain level to accelerate atherosclerosis is best illustrated by the following examples: (1) atherosclerosis does not develop in veins unless exposed to higher-than-normal pressure (e.g., veins used as coronary bypass grafts), (2) atherosclerosis does not develop to any significant degree in pulmonary arteries unless pulmonary hypertension is present, (3) more atherosclerosis is present in high-pressure arteries proximal to congenital aortic coarctation than in downstream low-pressure arteries, and (4) much less atherosclerosis develops in coronary arteries originating anomalously from the low-pressure pulmonary trunk than from the high-pressure aorta[261,262] (Fig. 35-8, Plate 81). Furthermore, in the International Atherosclerosis Project (n > 20,000), much more coronary and aortic atherosclerosis was found at autopsy in hypertensive compared with normotensive individuals-a relation already present from a young age.[263] But much more conclusive, prospective epidemiologic studies with autopsy follow-up revealed that blood pressure measured during life was a powerful and consistent predictor for the extent of raised atherosclerotic lesions per se: the higher the pressure during life, the more severe atherosclerosis post mortem in aorta and coronary and cerebral arteries[218,237-241]-an association that is present already in children and young adults.[223] Thus, hypertension and atherosclerosis are related, probably causally. Also, the PDAY study has provided evidence for the association between hypertension and the development of atherosclerotic lesions.[264,265]

The principal components of blood pressure consist of a steady component (mean arterial pressure) and a pulsatile component (pulse pressure). As large-artery stiffness increases in middle-aged and elderly subjects, systolic pressure rises and diastolic pressure falls (isolated systolic hypertension), with a resulting increase in pulse pressure.[266] Recent data from the Framingham Heart Study indicate that pulse pressure is superior to both systolic and diastolic blood pressures in predicting CHD risk, and age-related large-artery stiffening may thus constitute an important component of CHD risk in the elderly.[266]

Diabetes

Yet another pathogenetically cholesterol-dependent, but statistically independent, major cardiovascular risk factor is non-insulin-dependent diabetes mellitus (NIDDM).[211] NIDDM and hypercholesterolemia interact strongly in the genesis of CHD.[211] In populations where total

cholesterol is less than 4 mmol/L (150 mg/dL), atherosclerotic events are rare, even in diabetics.[212] Diabetes is, however, a powerful and gender-dependent risk factor in North America and Europe, increasing the risk of CHD three- to sevenfold in women compared with two- to threefold in men.[267] In fact, as recently expressed in a Scientific Statement from the American Heart Association, "diabetes *is* a cardiovascular disease."[268] Also, the precursor to type 2 diabetes, insulin resistance with impaired glucose tolerance, carries a strongly increased risk for cardiovascular disease, but the individual roles of insulin resistance itself, hyperinsulinemia, hyperglycemia (and advanced glycation end products),[113] hemostatic abnormalities (platelets, coagulation, and fibrinolysis), and conventional risk factors such as dyslipidemia (high triglycerides, low HDL, and small dense LDL particles) and hypertension are not clear. Not only hyperglycemia but also glucose levels in the nondiabetic range are associated with an increased risk of atherosclerosis-related diseases.[269-272] Thus, the mechanisms by which diabetes promotes atherosclerosis and/or its clinical manifestations are poorly understood.

Although diabetes increases the risk of CHD much more than what can be explained by a diabetes-related elevated level of conventional risk factors (e.g., dyslipidemia and hypertension), it is unclear whether the same applies for the underlying vessel wall disease: atherosclerosis. In the largest autopsy study of diabetes and atherosclerosis, the International Atherosclerosis Project, the amount of atherosclerosis (plaque burden) was greater in coronary arteries and abdominal aortas in diabetes (compared with nondiabetes), regardless of sex, age, race, and geographic location, but it was not possible to adjust for cholesterol and blood pressure levels.[263] In the Honolulu Heart Program, a prospective epidemiologic study among Japanese-American men with autopsy follow-up, more extensive coronary atherosclerosis was found in diabetics (n = 83) than in nondiabetics (n = 159), but the difference disappeared after adjustment for other cardiovascular risk factors such as age, smoking, cholesterol, systolic blood pressure, and body mass index. There was no association with duration of diabetes or type of treatment.[273] Thus, the more adverse risk factor profile among diabetics accounted for some, but probably not all, of the observed excess of coronary atherosclerosis. In the PDAY study, however, glycohemoglobin levels exceeding 8 percent (n = 10) were associated with substantially more extensive fatty streaks and raised lesions in the right coronary artery in persons 25 to 34 years of age (n = 648).[274] It has recently been reported that coronary plaques in diabetic patients appear morphologically similar to those in nondiabetic subjects, but there is some evidence, both pathologically and angiographically, that the coronary arteries are involved more diffusely and that disease may extend more distally in diabetes.[275]

If diabetes does not accelerate atherosclerosis, it could increase the risk of atherosclerosis-mediated events by promoting thrombotic complications. Diabetes is associated with increased platelet activity and elevated plasma fibrinogen and plasminogen activator inhibitor 1 (PAI-1) levels.[276] Endothelial dysfunction occurs commonly, and endothelial erosion, rather than plaque rupture, appears to be the dominant mechanism underlying coronary thrombosis in patients with diabetes.[182]

Diabetes predisposes individuals to medial artery calcification (MAC, Mönckeberg's calcinosis), especially of the muscular arteries of the legs, but is practically never seen in the coronary arteries of adults.[202] MAC is a nonobstructive condition (apparently independent of and unrelated to atherosclerosis) leading to reduced arterial compliance. MAC is a strong independent predictor of future cardiovascular events in patients with type 2 diabetes, supporting the hypothesis that reduced arterial elasticity (arterial stiffening) could play a role in arterial occlusion in diabetes.[277-279]

There are no well-controlled studies conclusively demonstrating that intensive blood-glucose control will reduce atherosclerotic events in patients with diabetes.[275] Only a relatively small and nonsignificant reduction was seen in the U.K. Prospective Diabetes Study (type 2 diabetes),

contrasting a substantial and highly significant reduction in microvascular complications.[280] On the other hand, lipid-lowering with a statin appears to benefit all people at risk, including diabetics and those with only *impaired fasting glucose*, defined as a fasting glucose level of 6.0 to 6.9 mmol/L.[281] Intensive insulin treatment in type 2 diabetes has been shown to have survival benefits after acute myocardial infarction.[282]

Inflammation/Infection

The Roman Cornelius Celsus, living in the first century, gave us the four "cardinal signs" of inflammation: redness and swelling, with heat and pain.[283] Although the term "hot" has been used to describe plaques at high risk of rapid progression to occlusion, only recently has it been shown clinically, using a catheter-based technique, that indeed the temperature of high-risk coronary plaques responsible for unstable angina and myocardial infarction are elevated 0.7°C and 1.5°C, respectively,[284] and hot spots on the surface of carotid plaques have been shown to correlate with macrophage infiltration, i.e., local inflammation.[285]

Inflammation, but not necessarily chronic infection, plays an important role in the initiation and progression of atherosclerosis,[67] and systemic blood markers of inflammation such as C-reactive protein, serum amyloid A, and fibrinogen (acute-phase reactants) have emerged as powerful predictors of coronary events[286,287] in asymptomatic men[168] and women,[169] in patients with stable[170] and unstable angina,[171-173] and after infarction.[174] These sensitive but nonspecific markers of low-grade systemic inflammation are produced in the liver in response to cytokine stimulation (e.g., interleukins 1 and 6),[288,289] but it is unclear whether the proinflammatory cytokines originate from the vessel wall itself (macrophages?), reflecting the quantity (burden) or quality (activity) of atherosclerosis, or from nonvascular sources, reflecting inflammatory states such as chronic infections. Other novel markers of vascular inflammation include the soluble forms of leukocyte adhesion molecules, such as sICAM-1,[290,291] which may reflect ongoing atherosclerosis. Proinflammatory cytokines, regardless of their sources, and the processes they mediate may accelerate atherogenesis and/or its manifestations, but it still remains unknown whether inflammation per se represents a modifiable risk factor.[292]

The hypothesis that infection is causally related to atherosclerosis is plausible but unproven. Most evidence, particularly seroepidemiologic, has been presented for Cp, *Helicobacter pylori* (Hp), and certain herpesviruses [particularly cytomegalovirus (CMV)].[163,164,293-295] Recent observational,[296-300] interventional,[301,302] and pathoanatomic[303-306] evidence have, however, weakened the case for a possible causal role of Cp in occlusive vascular disease, and the evidence for Hp is still questionable.[307,308] CMV may play a greater role in restenosis after angioplasty and transplant vascular disease than in atherosclerosis.[164,308] If infection plays a pathogenetic role, vaccination and/or antimicrobial agents might offer protection.

It has been extremely difficult, if not impossible, to culture infectious agents from atherosclerotic lesions, but this does not preclude their involvement in lesion formation.[164] CMV genomic DNA and antigens are commonly found in the human arterial tree, both in plaque and in plaque-free vessel walls (90 versus > 50 percent, i.e., considerable overlap),[164,309] in contrast to Cp DNA and antigens that appear to be confined to diseased vessel walls (up to 73 percent of coronary plaques were defined Cp positive by immunohistochemistry).[166,167] Hp has not been detected in vessel walls.

To date, more than 20 inflammation-associated cell adhesion molecules and almost 50 proinflammatory cytokines have been described,[45] and a significant number of these have already been shown to be present in human atherosclerotic plaques.[310-318] Acute-phase reactants are also frequently present in advanced lesions, including fibrinogen,[144,319] C-reactive protein,[320,321] and

serum amyloid A (expressed in lesions).[322] The relation, if any, of local inflammation in plaques to systemic markers of inflammation such as C-reactive protein has not yet been reported. No inflammatory markers of cardiovascular risk have been related with any histopathologic changes at the plaque level, and no published evidence suggests that atherosclerotic lesions containing infectious agent-related products differ histologically from those without signs of plaque infection.[323]

Hemostatic Factors

Several systemic hemostatic factors, including fibrinogen, factor VII, PAI-1, t-PA, and platelets, have been identified as determinants of future CHD events.[324-326] Thrombin generation and platelet activation play a causal role in atherosclerosis-mediated luminal thrombosis and, most likely, also in the slow progression of atherosclerotic lesions. Platelets can adhere to denuded areas and release their granules, which contain cytokines and growth factors that, together with thrombin, may contribute to activation, migration, and proliferation of cells and thus promote plaque development.[67] Local generation of plasmin may itself, but most likely via activation of latent MMPs, digest the extracellular matrix, which is essential for cell migration. If unopposed, matrix degradation may ultimately culminate in plaque disruption.[324]

The mere presence of a positive relation between abnormal hemostasis and CHD does not indicate whether the former is a cause of, related to, or a consequence of, the latter. The most powerful and most consistent predictor of CHD among the hemostatic factors-fibrinogen-is strongly related to smoking, diabetes, and C-reactive protein (an acute-phase reactant like fibrinogen), all of which are strong, consistent, and independent predictors of CHD.[326] To answer the question about causality and, if present, its strength, studying CHD risk in persons with congenital abnormalities in coagulation, fibrinolysis and platelet function provides important information. Although conflicting results have been published,[327,328] gene polymorphisms associated with different plasma levels of fibrinogen ($G_{-455}\rightarrow A$),[329,330] prothrombin (G20210A),[331] factor V (G1691A, Leiden),[331] factor VII (e.g., G10976A, R353Q),[331-333] factor VIII,[330] t-PA (I/D),[334] and PAI-1 (4G/5G)[330,335] appear not to be, or at best weakly, causally related to atherosclerosis or arterial thrombosis, even though many of these abnormalities are causally related to venous thrombosis.[330] On the other hand, polymorphisms of the platelet fibrinogen (PIA1/A2, glycoprotein IIIa)[331,336,337] and collagen (C3550T, glycoprotein Ib; 807T/873A, glycoprotein Ia/IIa)[338] receptor genes appear, at least under certain circumstances, to be causally related to coronary thrombosis and myocardial infarction, rather than to coronary atherosclerosis, emphasizing the primary role of platelets in arterial thrombosis. Prothrombotic genetic risk factors appear to be particularly important in precipitating myocardial infarction in young persons without severe atherosclerosis, and there is a strong adverse interaction with smoking.[331] It is possible to prevent arterial occlusion and, if it occurs, accelerate reperfusion and prevent reocclusion by targeting hemostatic factors (antiplatelet agents, anticoagulants, and fibrinolytic agents), but it has never been proven that such treatments also prevent or retard the slow progression of atherosclerosis not mediated by luminal thrombosis.

Homocyst(e)ine

Numerous retrospective case-control studies have identified mild-to-moderate homocyst(e)inemia as a strong and independent risk factor for CHD, stroke, and peripheral vascular disease,[339-342] and a clear association between plasma homocyst[e]ine (Hcy) and the anatomic extent of carotid, coronary, aortic, and peripheral vascular diseases has been demonstrated in several studies,[343,344] including at least one in a low-risk population.[345] Many prospective studies, but not all,[346-348] have, however, failed to demonstrate such an association, and it has been suggested that elevated Hcy could be a marker, or a consequence, rather than a cause of cardiovascular disease.[349-351] An

argument against Hcy being causally related to CHD is the fact that the homozygous form of the thermolabile methylene-tetrahydrofolate reductase (MTHFR) gene, although leading to elevated Hcy levels in those with low folate levels, has not consistently been associated with an increased CHD risk.[351] If Hcy is a causative factor, the mechanisms by which homocysteine causes occlusive vascular disease remain to be identified.[343]

Using high nonphysiologic concentrations in vitro, potential proatherogenic effects of Hcy have been identified, such as endothelial toxicity[352,353] and promotion of smooth muscle cell growth and collagen production.[354,355] In vivo, hyperhomocyst(e)inemia is associated with endothelial dysfunction,[356] but there is no experimental evidence from animal studies indicating that mildly to moderately elevated Hcy is a cause of atherosclerosis.[343,350,357] Also in humans is elevated Hcy associated with endothelial dysfunction,[358,359] probably mediated by increased oxidant stress because antioxidant vitamin C normalizes the impaired endothelium-dependent vasodilation seen with hyperhomocyst(e)inemia and the associated metabolic changes.[360]

Elevated Hcy appears to be more closely linked to thrombus-mediated coronary events (myocardial infarction) than to coronary atherosclerosis as seen on angiography,[361] and elevated Hcy is also linked to venous thrombosis.[351,362,363] Prothrombotic effects of Hcy have been described, such as downregulation of thrombomodulin on endothelial cells[364] and upregulation of tissue factor on both endothelial cells[365] and macrophages.[366] In homocystinuria, an inborn error of Hcy metabolism associated with extremely high plasma Hcy (usually >100 μmol/L), the few published autopsy reports confirm that both arterial and venous thrombosis are frequent and occur at an early age but apparently often without concomitant atherosclerosis.[367]

Alcohol

Generally, men and women who consume one to three drinks a day live longer than nondrinkers, due to reduced risk of CHD.[368] It also holds for low-risk Chinese people.[369] The inverse association between moderate alcohol intake and CHD is documented in over 40 prospective studies in diverse populations,[368] suggesting that mild to moderate alcohol intake is associated with a 10 to 40 percent lower risk of CHD than with no alcohol intake. The five largest cohort studies, with nearly 30,000 heart disease events, showed a consistent 20 percent reduction in CHD mortality among people who drank about 1 U of alcohol a day compared with nondrinkers.[370] This reduction is generally attributed to the beneficial effects of alcohol on lipids and hemostatic factors.[368] Moderate alcohol intake is strongly and consistently associated with higher concentrations of HDL cholesterol and apoA1 and lower concentrations of fibrinogen and is weakly associated with increased triglyceride concentration.[368] It was calculated that such changes, believed to be causally related to CHD, overall may reduce the CHD risk by 25 percent. Alcohol also inhibits platelet aggregation, which may substantially reduce the risk of CHD[371] and may promote fibrinolysis.[372,373] The effect of moderate alcohol intake on blood pressure is likely to be minor, but heavy intake (more than four drinks a day) is associated with hypertension[368] and increased risk of hemorrhagic stroke.[374-376] Several large cross-sectional studies have reported strong positive associations between alcohol and increased insulin sensitivity,[368] and moderate drinking seems to be associated with extraordinary benefit in patients with late-onset diabetes, possibly due to their greater baseline risk of CHD.[377]

With regard to wine, beer, and spirits, no consistent evidence has emerged that any one beverage confers a greater health benefit than another, indicating that a substantial portion of the benefit is mediated by ethanol.[377] Some studies suggest, however, that wine offers additional benefits.[378-381] A possible special effect associated with wine drinking could be due to specific nonalcoholic compounds in wine, particularly in red wine (e.g., antioxidant polyphenols).[382-384] Alternatively,

it could be due to confounding lifestyle factors associated with wine intake.[385] Moderate wine drinking seems to be associated with a healthier lifestyle in California (less smoking and more education)[386] and Britain (less smoking and obesity),[387] a healthier diet in Denmark (higher intake of fruit, vegetables, and fish),[385] and better subjective health in Finland.[388]

The health benefit associated with regular and moderate alcohol intake may not extend to populations with irregular drinking patterns and/or substantial higher consumptions. For example, in Central and Eastern Europe and the former Soviet Union, a growing body of epidemiologic research indicates a positive rather than negative association between alcohol consumption and cardiovascular deaths, especially sudden cardiac deaths.[389] In binge drinkers, atheroprotective changes in HDL are not seen, and irregular heavy drinking appears to be associated with an increased risk of rebound thrombosis, occurring after cessation of drinking, and sudden death due to ventricular fibrillation.[389-392]

In France, the CHD mortality rate is much lower that in Britain (1:4 in men and 1:6 in women, 1992 data) and other high-risk countries, despite similar average values of major CHD risk factors (except fewer female smokers in France). Low-dose alcohol consumption, in particular wine drinking, has been suggested as the most likely explanation for this lower-than-expected CHD mortality rate in France, called the *French paradox*.[371,393,394] However, a novel *time lag* hypothesis has recently been suggested to explain this paradox.[395] Animal fat consumption and serum cholesterol concentration were lower in France than in Britain up to 1970, and only in recent years have these major determinants of CHD been similar in the two countries. For a chronic disease like atherosclerosis that evolves over decades, it seems more appropriate to compare current mortality data with levels of risk factors in the past (30 year ago) rather than recent levels. If so done, the French paradox apparently disappears.[395] The same argument holds for cigarette smoking and lung cancer where the time lag between exposure and clinical disease is well recognized; current disease correlates better with smoking habits decades ago than with recent habits.[395] Many countries with high wine consumption are also those in which saturated fat consumption used to be low but increased in recent years (France, Italy, Spain, and Switzerland, for example). The low mortality from CHD reflects the earlier low levels of saturated fat consumption, for which wine may simply be an indirect marker.[395]

Sex

The major cardiovascular risk factors are similar for both sexes, but men develop CHD 10 to 15 years earlier than women.[396] By age 60 in the United States, only 1 in 17 women has had a coronary event, as compared with 1 in 5 men. After age 60, however, CHD becomes the leading cause of death among women as well as among men, and as many women as men eventually die of the disease.[396] Diabetes mellitus is a particularly strong risk factor among women, nearly eliminating the normal protection offered by female sex. The striking influence of sex on CHD risk is cholesterol dependent, because neither men nor women develop CHD unless total cholesterol is greater than 4 mmol/L (150 mg/dL), and the higher the level is, the greater is the chance of an event, and the earlier the event occurs irrespective of sex.[212]

Estrogen may be the most obvious factor responsible for the protection against CHD conferred by the premenopausal state. With menopause, LDL levels begin to increase, whereas HDL levels stop climbing or decrease slightly.[397] This leads to a worsening of the LDL-to-HDL ratio. Although estrogen replacement therapy overall restores the deteriorated lipid profile,[397] estrogen may have beneficial effects that go beyond changes in serum lipids. In particular, estrogen may have direct atheroprotective effects on the vessel wall (estrogen receptors are present in vascular cells), suggested by the improvement of endothelial function seen with estrogen administration.[398] In nonhuman primates[399,400] and rabbits,[401] estrogen reduced diet-induced atherosclerosis, probably

via an endothelium-dependent mechanism.[402]

Premature menopause (before age 45) due to oophorectomy or occurring naturally is known to lead to an increased CHD risk.[214] However, a simple hysterectomy with the ovaries and, consequently, estrogen production left intact also appears to increase the risk, and it has been suggested that this could be due to the loss of menstruation.[403] Iron is a powerful oxidant that mediates lipid peroxidation, which may explain the positive association between total body iron stores and cardiovascular risk found in epidemiologic studies. The *iron hypothesis*, suggesting that iron stores and CHD are causally related, has recently been revived by the finding of an increased CHD risk in heterozygous carriers of a common hemochromatosis gene mutation.[404,405]

In the International Atherosclerosis Project (IAP, 1960-1964), white men were unusually susceptible to atherosclerosis as compared with other sex-race subgroups, and sex differences in extent of aortic, coronary, and cerebral atherosclerosis were striking among whites but minimal among blacks.[209,406] In contrast, in the PDAY study initiated much later (1985) and involving young adults only (15 to 34 years of age), white men were no longer the most susceptible subgroup when evaluated by the same method as that used in the IAP (intimal surface grossly covered by plaques); there were no obvious sex differences, and blacks of both sexes appeared to be at least as susceptible to atherosclerosis as were white men.[407] When evaluated microscopically, however, coronary lesions appeared to progress faster in males than in females, evidenced by the presence of much more advanced plaque in 30- to 34-year-old men compared with age-matched women.[407] Regarding rapid thrombus-mediated plaque progression, the underlying mechanism appears to be in part sex dependent: plaque erosion (versus rupture) is more frequent in females than in males.[182,183,228]

Aging

Age is a powerful risk factor for CHD. The development of atherosclerosis increases markedly with age up to an age of about 65, regardless of sex and ethnic background.[141,223] Although atherosclerosis and the incidence of stable angina (caused by atherosclerosis alone) seem to increase less markedly beyond age 65,[408] most new-onset heart attacks (atherosclerosis plus thrombosis) occur after age 65, especially among women,[409] and the CHD mortality rate increases almost exponentially with age among elderly persons.[408] The reason for this paradox (more dangerous but not more extensive atherosclerosis with aging) is unknown but could be due to age-related changes superimposed on preexisting atherosclerosis and, of course, an increase in case fatality rates among the elderly. For example, increased pulse pressure and systolic blood pressure caused by age-related arterial stiffening are powerful predictors for myocardial infarction and coronary death, [266] and treatment of systolic hypertension even in very old patients reduces risk for both stroke and CHD.[410]

Although age is a strong and independent risk factor for CHD, the independent contribution of age to CHD risk is cholesterol dependent. In populations in which average serum total cholesterol levels are less than 4 mmol/L (150 mg/dL), atherosclerotic events are rare even among older persons.[213] Atherosclerotic events are also rare among North Americans and Europeans with that low cholesterol level, but only about 5 percent of persons older than 40 years of age have a total cholesterol level less than 4 mmol/L in these populations.[212] The mean serum total cholesterol of umbilical blood of newborns is approximately 1.9 mmol/L (75 mg/dL), but within 2 weeks of life that value rises to a mean of 4 mmol/L (150 mg/dL) and remains at that level until approximately age 20 years, when it gradually starts to rise. The average serum total cholesterol level in the United States in persons 20 to 74 years of age is 5.5 mmol/L (215 mg/dL).[411] Men have higher levels earlier in life, and women have higher levels in later life.[212]

Chapter 35: ATHEROGENESIS AND ITS DETERMINANTS

CONCLUSION

Atherosclerosis is a complex and multifactorial disease, which means that many avenues for intervention can be applied. A certain blood-cholesterol level is necessary to initiate and drive the disease, but cholesterol alone is rarely enough for the development of symptomatic atherosclerotic lesions. Although many cardiovascular risk factors, such as smoking and hypertension, are not atherogenic on their own, they accelerate the development of occlusive arterial disease, and clinically it may be more rewarding to treat accelerators of the disease rather than its initiator, hypercholesterolemia. Maximum benefit, of course, is achieved by treating both. Experimental studies have clearly documented that the inhibition of just one necessary step in the atherogenetic chain of events in the vessel wall (e.g., macrophage recruitment) may markedly prevent or retard the development of mature plaques responsible for clinical disease.

Chapter 35: ATHEROGENESIS AND ITS DETERMINANTS

List of Figures

Figure 35-1: (Plate 77) An early atherosclerotic lesion (fatty streak) in the aortic root of a 3-month-old apolipoprotein E-/- mouse fed a high-fat Western-type diet for 6 weeks. The lesion consists of lipid-laden monocyte-derived macrophage foam cells and a few lymphocytes (T cells) beneath an intact endothelium. Elastin trichrome stain.

Figure 35-2: (Plate 78) An advanced atherosclerotic plaque in the brachiocephalic trunk of a 6-month-old apolipoprotein E-/- mouse fed normal chow. The plaque appears vulnerable morphologically, consisting of a lipid-rich core with cholesterol crystals covered by a thin fibrous cap. Orcein, staining elastic tissue black.

Figure 35-3: (Plate 79) Ruptured coronary plaque with occlusive thrombosis superimposed (natural death of a 21-month-old apolipoprotein E-/- mouse). Spontaneous plaque rupture and/or luminal thrombosis are extremely rare in animal models of atherosclerosis. Elastin trichrome stain.

Figure 35-4: The 1995 American Heart Association classification of atherosclerotic lesions. The type I (initial) lesion, which consists of small, isolated groups of macrophages containing lipid droplets, is not shown in this figure. (Adapted from Stary et al.[128] Reproduced with permission from the publisher and authors.)

Figure 35-5: (Plate 80) Cross-sectioned coronary artery, containing a vulnerable plaque (large lipid-rich core covered by a thin fibrous cap) with ruptured surface and a nonocclusive luminal thrombosis superimposed. Trichrome stain.

Figure 35-6: Advanced atherosclerotic plaques are extremely heterogeneous in composition. A subset of the advanced plaques are vulnerable (i.e., rupture-prone) with high risk of becoming complicated by luminal thrombosis. The relation between vulnerable and stable plaques is not well defined. (Adapted from Ravn and Falk.[412] Reproduced with permission from the publisher and authors.)

Figure 35-7: Most coronary occlusions (*top*, 51/72 = 71 percent), myocardial infarctions (*middle*, 29/39 = 74 percent), and ischemic strokes of carotid origin (*bottom*, 54/67 = 81 percent) are caused by acute thrombosis superimposed on atherosclerotic lesions that, prior to the acute events, were asymptomatic and only mildly to moderately stenotic. Overall, nonstenotic atherosclerotic lesions by far outnumber the stenotic ones at higher individual risk, which is why most acute clinical events originate from nonstenotic lesions at relative low individual risk. MI = myocardial infarction.

Figure 35-8: (Plate 81) Experiment of nature, illustrating the pathogenetic role of blood pressure in atherogenesis. The left anterior descending coronary artery (LAD) is departing normally and thus exposed to systemic blood pressure; the LAD is severely atherosclerotic, stiff, and calcified (*A*). In contrast, the right coronary artery (RC) is originating anomalously from the lower-pressure pulmonary trunk; the RC is elastic and compliant without atherosclerosis (*B*).

Part 6: CORONARY HEART DISEASE
Chapter 36:

PATHOLOGY OF CORONARY ATHEROSCLEROSIS

Author: Michael J. Davies

THE PROCESS OF ATHEROSCLEROSIS

Atherosclerosis is an intimal disease of systemic arteries that range in size from the aorta to the epicardial coronary arteries. Atherosclerosis is characterized by discrete intimal plaques, although at an advanced stage the lesions may coalesce. Each plaque has variable combinations of extracellular lipid, lipid contained within cells that have foamy cytoplasm, and connective tissue matrix proteins, such as collagen, produced by smooth muscle cells. The majority of the foam cells are macrophages derived from monocytes, which enter the plaque from the arterial lumen.

Lipid is a fundamental component of the atherosclerotic plaque, which is essentially an inflammatory/repair response in the vessel wall invoked by lipid.[1] Lesions that consist entirely of proliferating smooth muscle cells, such as the response to endothelial denudation in animal models, are a repair response to mechanical injury and are not strictly atherosclerosis. Intimal thickening that consists solely of connective tissue and smooth muscle cells is also an adaptive response of the vessel wall to flow and occurs at branching points in human coronary arteries from a young age.[2,3] While this diffuse intimal thickening without a lipid component is not atherosclerosis as such, it does occur commonly in subjects who have atherosclerotic disease and plaques. Such intimal thickening can be measured by ultrasound in the carotid arteries in vivo and has been used as a surrogate marker for the detection of risk and in evaluating lipid-lowering therapy.[4]

Morphologic Forms of Atherosclerotic Plaques

The intimal surface of an opened human coronary artery reveals several types of plaque. Some are flat yellow dots or lines (fatty streaks), and others are raised above the surface as oval humps, which range in color from white to yellow (raised fibrolipid plaques).

Observations made on human necropsies allow a developmental sequence to be proposed for plaques based on cohorts of individuals dying at different ages from noncardiac disease.[2] In children from 5 to 10 years of age, fatty streaks often are present in the coronary arteries, suggesting that they are the initial point in a sequence of plaque development.[5] Raised plaques appear later in life and, by 20 years of age, are present in areas such as the proximal left anterior descending coronary artery, where fatty streaks are most prevalent in earlier life.[5] *By middle age, most subjects will have coronary plaques of all types, suggesting that plaque initiation continues throughout life.*

Plaque Evolution

The American Heart Association has recommended a nomenclature for the types of plaques and has suggested ways in which they may evolve.[6] The initial lesion (type I) develops when monocytes adhere to the endothelial surface and migrate from the lumen of an artery to accumulate in the intima. The type II lesion is the fatty streak that consists of a focal accumulation

of lipid-filled foam cells largely of monocyte origin immediately beneath the intact endothelium. The type III lesion contains in addition small pools of extracellular lipid. While type I to type III plaques are the precursors of more advanced lesions, they do not cause clinical symptoms.

Type IV is characterized by two additional features. Smooth muscle cells appear within the lesion beneath the endothelium, and the pools of extracellular lipid coalesce to form a lipid core. Type V shows significant connective tissue deposition and the formation of a fibrous capsule containing the lipid core. The portion of this capsule separating the core from the lumen is the plaque cap.

Plaques with a lipid core and a fibrous cap are designated as type Va (Figs. 36-1 and 36-2). *Type VI plaques are those complicated by thrombosis, which predominantly develops in type Va plaques.* Some plaques have heavy calcification (type Vb). Yet another form of advanced plaque (type Vc) is almost entirely composed of collagen and smooth muscle cells.

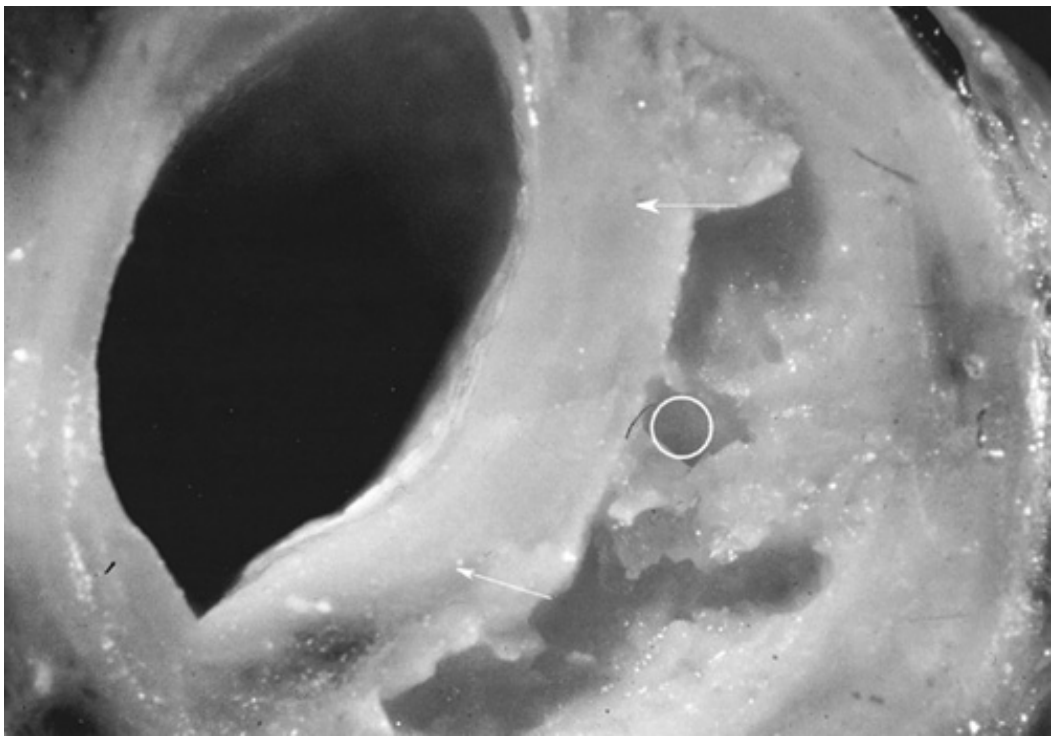

Figure 36-1: Human coronary artery in which there is a large lipid-rich plaque with a core (○) and a thick cap (*arrows*). This lesion would be designated as a type Va plaque.

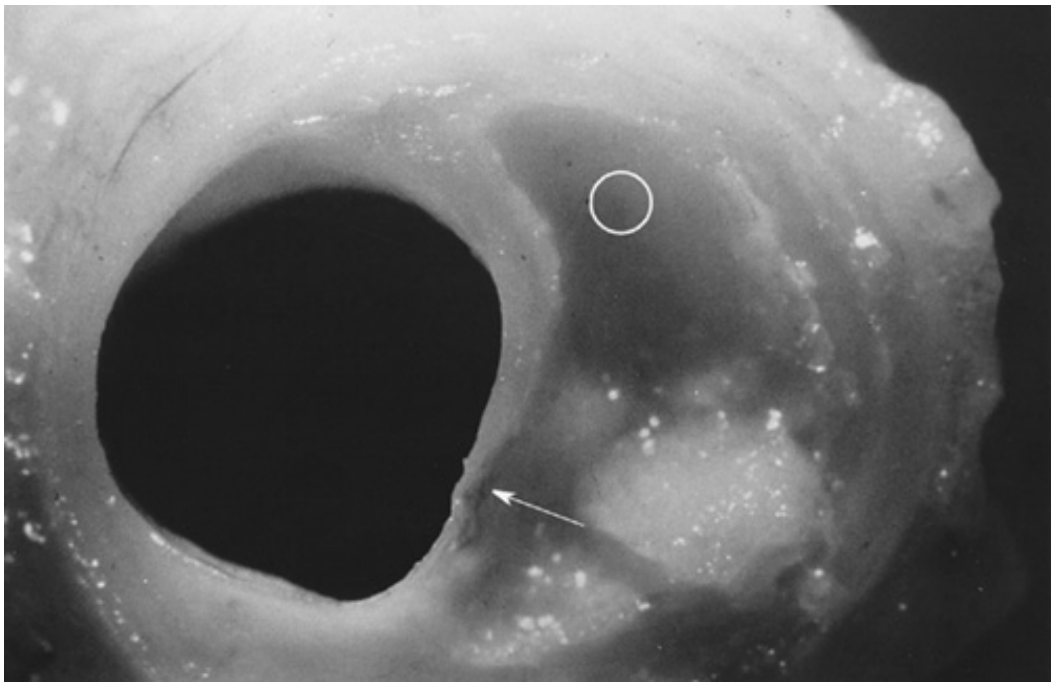

Figure 36-2: Human coronary artery in which there is a large lipid-rich plaque with a core (▫), but in contrast to Fig. 36-1, the cap (*arrow*) is thin. This lesion is also a type Va plaque.

In general, the plaques found in subjects with ischemic heart disease show the complete spectrum of possible morphologies. There are, however, individuals who show a more uniform pattern. Virtually all the plaques may contain very large amounts of extracellular lipid, or virtually all the plaques consist of connective tissue with a rich connective mucin content and a minimal lipid component. Such variations from individual to individual may depend on the profile of risk factors. Smoking and elevated homocysteine levels may produce lesions that have different characteristics than those associated with high plasma lipids.[7,8] The great majority of descriptive work on plaques is based on the hyperlipidemic white male, and there is evidence emerging that women may have a somewhat different plaque morphology. In familial hypercholesterolemia and diabetes, diffuse intimal involvement with many foam cells rather than the formation of discrete plaques occurs.

Basic Mechanisms in Plaque Formation

FOAM CELL FORMATION

In experimental models and human disease, the first morphologic phenomenon observed in plaque formation is adhesion of monocytes to an intact endothelial surface.[1,9] This adhesion is followed by monocyte migration into the intima. In the intima, monocytes are activated, converted to macrophages, and may divide. Lipid uptake by macrophages then leads to the formation of the foam cell. These observations have created a paradox in that although plasma low-density lipoprotein (LDL) freely enters the intima, it should not be taken up by macrophages, which lack the appropriate receptor. The apparent paradox can now be explained in the context of the chemical changes that LDL undergoes as it is modified by the cells in the arterial wall. The first minor modifications of the LDL molecule occur close to the endothelial surface.[10] This initial change produces a proinflammatory molecule called *minimally modified low-density lipoprotein* (MMLDL) that contributes to the endothelial expression of molecules mediating monocyte adhesion, such as *vascular cell adhesion molecule* (VCAM).[11] Other inflammatory mediators such as *intercellular adhesion molecule* (ICAM), *monocyte chemotactic protein* (MCP-1),[12] and *macrophage colony-stimulating factor* (MCSF)[13] are also induced (see also Chaps. 6 and 36). These factors act in concert to cause monocyte migration and to allow the incoming monocytes to

establish themselves and divide in the intima. Further changes in the LDL molecule lead to an oxidized form (oxidized LDL) that is recognized by the *macrophage scavenger receptor*. The scavenger receptor does not downregulate, as does the receptor for native LDL, and the cell becomes laden with lipid because of continued unregulated uptake. The macrophage foam cells that result produce a range of inflammatory cytokines including *tumor necrosis factor alpha* (TNF-α)[14] and metalloproteinases as well as the procoagulant *tissue factor*.[15] This sequence of lipid oxidation and lipid uptake by macrophages forms a credible explanation for the formation of foam cells, and oxidized LDL has been shown within macrophages in both human and rabbit atherosclerosis[16] (see also Chap. 35).

Transgenic models of atherosclerosis show the importance of these inflammatory mediators. Apoliprotein B knockout mice, for example, show a very marked susceptibility to form plaques when given lipid diets. Animals in whom in addition MCP-1 or its receptor or MCSF or VCAM or the scavenger receptors are knocked out show a profound attenuation of atherosclerotic lesions. MCP-1 is suggested by these models to be a major component of monocyte recruitment in plaques.[17,18]

LIPID CORE FORMATION

Lipid cores are potential spaces in the connective tissue matrix of the intima that are filled with cellular debris and cholesterol. Active plaques contain numerous macrophages clustered at the edge of the core, with the expression of a range of metalloproteinases that likely are engaged in the active destruction of the collagen matrix. Some extracellular lipid may be derived directly from LDL bound to proteoglycans within the intima,[19] but much of the cholesterol and esters in the lipid core is released from the cytoplasm of dying foam cells. Macrophages may be killed by lipid peroxides formed by LDL oxidation, but there is now evidence that cell death is by apoptosis.[20] Deprivation of growth factors such as MCSF-1 may induce apoptosis, particularly in association with the TNF-α present in large amounts in cellular plaques. Tissue factor (TF) expression by macrophages within the core makes this area of the plaque highly thrombogenic if it is exposed to the arterial lumen.[21]

SMOOTH MUSCLE PROLIFERATION AND CAP FORMATION

The caps of plaques with a lipid core consist of a lattice of collagen within which are lacunae containing smooth muscle cells that produce the connective tissue matrix. Intimal smooth muscle cells have the tendancy to die by apoptosis, and many caps of plaques become relatively acellular. Smooth muscle cell migration and proliferation, as well as collagen deposition, are driven by growth factors produced by virtually every cell type, including smooth muscle cells themselves.[22] Platelets, fibrin, and thrombin also can stimulate smooth muscle cell proliferation if deposited on the vessel wall, and there is increasing recognition that fibrinogen passes into the intima and can be converted to fibrin. Such fibrin is usually removed by plasminogen activation. Any residual fibrin-thrombin complexes are potent stimulators of smooth muscle cell proliferation. The plaque cap is now recognized as a dynamic structure in which there is deposition of collagen[23] balanced by degradation of the connective tissue matrix by a range of proteases. Numerous cytokines control this balance.

IMMUNE MECHANISMS IN PLAQUE FORMATION

Plaques contain T-lymphocytes,[24] the function of which may be, in part, to modify smooth muscle cell proliferation via the production of interferon-γ. CD40L-positive lymphocytes are present in plaques and react with CD40-positive macrophages to cause activation, cytokine expression, tissue factor expression, and metalloproteinase production. In experimental models, blockade of

CD40L attenuates plaque formation.[25] A significant proportion of lymphocytes within plaques are potentially cytotoxic producing perforins and granzymes and may contribute to death of smooth muscle cells and macrophages. B-lymphocytes are absent from the plaque itself but are present, often in large numbers, in the adjacent adventitia. Oxidized LDL is strongly antigenic, and the B-lymphocytes produce autoantibodies that can be measured in the plasma and may provide a marker of the activity or extent of the atherosclerotic process.[26]

A significant proportion of subjects with coronary atherosclerosis show colonization of the plaques by the intracellular bacterium *Chlamydia pneumoniae*. The frequency of such direct infection of the plaque is high, as shown by immunofluorescence studies when 40 to 50 percent of individuals with atherosclerosis have some positive plaques. Studies by polymerase chain reaction (PCR) for the detection of chlamydial DNA are less frequently positive. The current perception is that chlamydia reach the plaque by entering a monocyte in the lung or upper respiratory tract and then enter the bloodstream and migrate into the plaque. The higher frequency of immunohistochemical positivity than PCR positivity may suggest that the organism grows only for a limited time, but the capular antigens persist within macrophages. Chlamydia within macrophages in the plaque potentially would upregulate inflammatory activity and enhance plaque progression. Chlamydial heat-shock protein upregulates TNF-α production.[27,28] Antibiotic therapy may or may not turn out to be effective in slowing plaque progression.[29,30]

PLAQUE VASCULARIZATION

The normal media is avascular, but once intimal thickening occurs, new vessels grow in from the adventitia and reach the base of the plaque. Neovascularization may be visible on angiography in life.[31] The vessels that lie close to the base of the core are thin-walled, and extravasation of red cells is very common. When the core contains platelets, however, a direct continuity with the lumen is found via a cap tear (see below). Transmedial vessels strongly express adhesion molecules such as VCAM and may be another route by which monocytes enter the plaque.[32] Transgenic mouse models show that inhibition of new vessel formation will attenuate plaque formation.[33]

ENDOTHELIAL STATUS OVER PLAQUES

In early plaque formation (types I-III), the endothelial surface is intact, and there is no exposure of the subendothelial connective tissue matrix and therefore no adhesion of platelets to the vessel wall. The endothelium is structurally intact, although this does not mean that it is functionally normal. Once later plaque formation has occurred (types IV-V), however, small foci of endothelial loss do occur, and this denudation injury exposes connective tissue, allowing the formation of a monolayer of platelets adherent to the vessel wall. Associated with denudation injury is evidence of increased endothelial cell turnover. The thrombi that form are ultramicroscopic but do indicate endothelial instability in the atherosclerotic artery. Observational studies show that endothelial cell loss is associated with the proximity to macrophages.[34,35] Macrophages may induce endothelial cell apoptosis as well as producing a range of proteolytic enzymes that cut loose the endothelial cell from its attachment to the vessel wall.[36]

Chapter 36: PATHOLOGY OF CORONARY ATHEROSCLEROSIS

CLINICAL SYMPTOMS AND PLAQUE TYPES

The presence of advanced plaques of types IV and Va allows clinical symptoms to develop. Atherosclerosis is a biphasic disease; in the first stage, advanced plaques are generated, but the patient is asymptomatic; in the second stage, symptoms develop. Plaques are ubiquitous in Western populations, but not everyone develops ischemic heart disease.

Large-scale epidemiologic studies-including the International Geographic Survey,[37] the Pathological Determinants of Atherosclerosis in Youth (PDAY) study,[4] and the Bogalusa Heart Study[38]-have produced consistent information: *In all geographic populations, the mean number of coronary plaques present in a large number of autopsied patients who die from all causes predicts the incidence of ischemic heart disease in that population.* The risk factors for large numbers of subjects developing ischemic heart disease depend on how many advanced plaques are present. Smokers will, on average, have more plaques than nonsmokers. Similar data exist for hyperlipidemia, hypertension, and diabetes (see Chap. 38). Thus risk factors operate in part by increasing the number of plaques that potentially can progress to cause symptoms. Such epidemiologic studies, however, do not mean that an individual cannot die of a single, strategically placed plaque.

The majority of types IV and Va advanced plaques are clinically silent and angiographically invisible because they do not encroach on the lumen of a coronary artery. Two mechanisms are responsible for this phenomenon. First, the media behind an atherosclerotic plaque undergoes thinning and atrophy, which allows the plaque to bulge outward rather than inward. Second, *the development of an intimal plaque causes remodeling of the arterial wall, increasing the external diameter and allowing the plaque to be accommodated without altering the lumen dimensions.*[39] Intravascular ultrasound confirms that coronary angiography is very insensitive for the detection of plaques[40] (see also Chap. 47).

Plaque Heterogeneity

Common to all type Va plaques is the presence of a fibromuscular cap, but even so, there is considerable heterogeneity (see Figs. 36-1 and 36-2). The cap may be relatively thick and uniform, or it may vary in thickness with interspersed thin areas. Thick caps have high numbers of smooth muscle cells, whereas relatively thin caps often have fewer smooth muscle cells and contain appreciable numbers of macrophages. The lipid core may occupy over 70 percent of the overall volume of the plaque or as little as 10 percent. Core margins may be surrounded by macrophages, or there may be no macrophages. *Plaque heterogeneity therefore involves both the micromorphology of the lesion (core size, cap thickness) and the degree of inflammatory activity.* A plaque in inflammatory terms can be "hot" or "burnt out." There is no readily discernible relation between plaque size and any of the variables that contribute to plaque heterogeneity.

Mechanisms of Induction of Symptoms

Three major mechanisms lead to clinical symptoms (see also Chap. 35). First, thrombosis leads to acute decreases in flow in a coronary artery. Second, a plaque grows without the clinically apparent involvement of thrombosis to the point that the lumen size is reduced to a degree that causes flow limitation during exercise.

Finally, in subjects with coronary atherosclerosis, coronary vasomotor tonal responses are abnormal. This disordered control of tone, which reflects in part endothelial dysfunction (see also Chaps. 6 and 36) may take the form of local spasm at the site of an eccentric plaque in which there is a residual segment of normal vessel wall, or vasospasm may be a more generalized phenomenon.

Acute Ischemic Syndromes

The major factor initiating acute ischemia in the crescendo form of unstable angina, acute myocardial infarction, and a high proportion of sudden ischemic deaths is a thrombus of sufficient size to protrude into the arterial lumen. This assertion does not imply that thrombosis is the only factor, but necropsy studies, angiography, and angioscopy, as well as the success of fibrinolytic therapy in restoring arterial patency in infarct-related arteries, all indicate a dominant role for thrombosis.

FACTORS INDUCING PLAQUE THROMBOSIS

Postmortem study of human coronary thrombi causing death has shown the involvement of two distinct processes.[41]

Endothelial Erosion

The endothelial surface over many plaques of types IV and Va has been shown to develop small foci of endothelial cell loss[34,35] that expose the subendothelial connective tissue and lead to local ultramicroscopic areas of platelet adhesion (Fig. 36-3). The extension of this process to cause large areas of endothelial denudation over a plaque leads to much larger thrombi capable of causing symptoms. The characteristics of these thrombi are that they are adherent to the luminal surface of the plaque, which is otherwise intact, and there is no intraplaque thrombosis (Fig. 36-4).

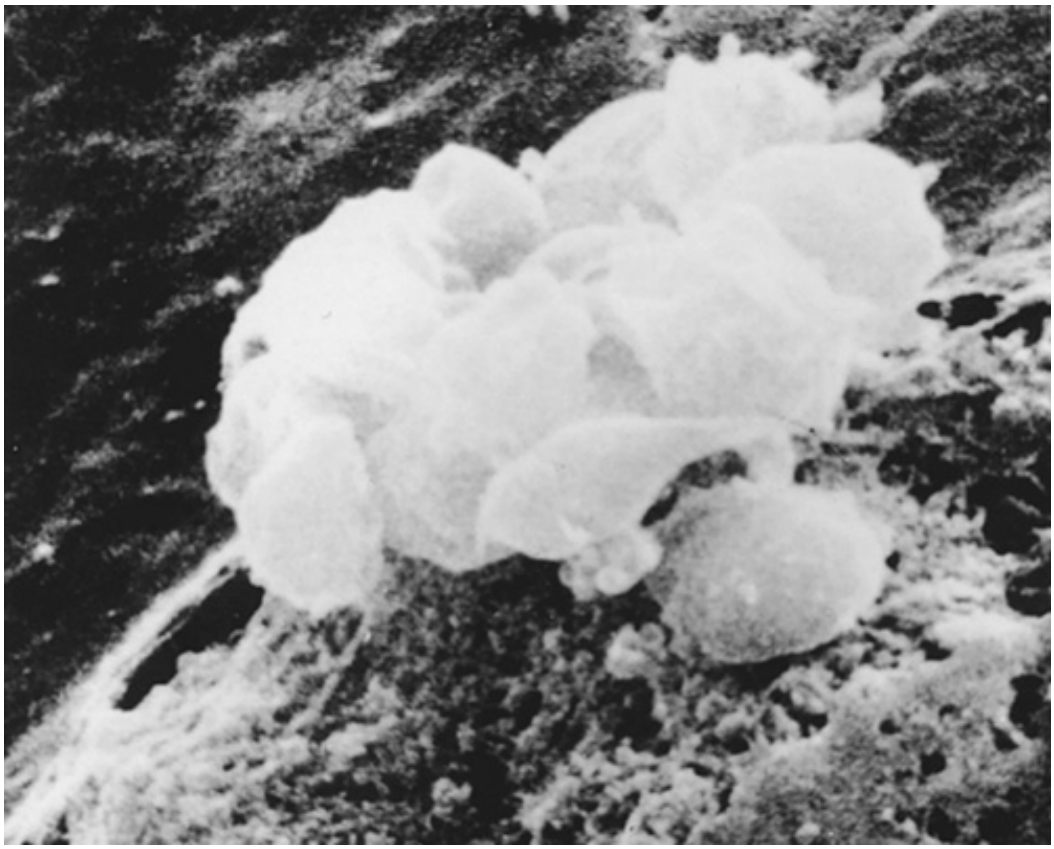

Figure 36-3: Scanning electron micrograph of human coronary artery. A single endothelial cell has undergone denudation. Over the exposed subendothelial tissue, a small clump of platelets has formed. No platelets adhere to adjacent intact endothelial cells.

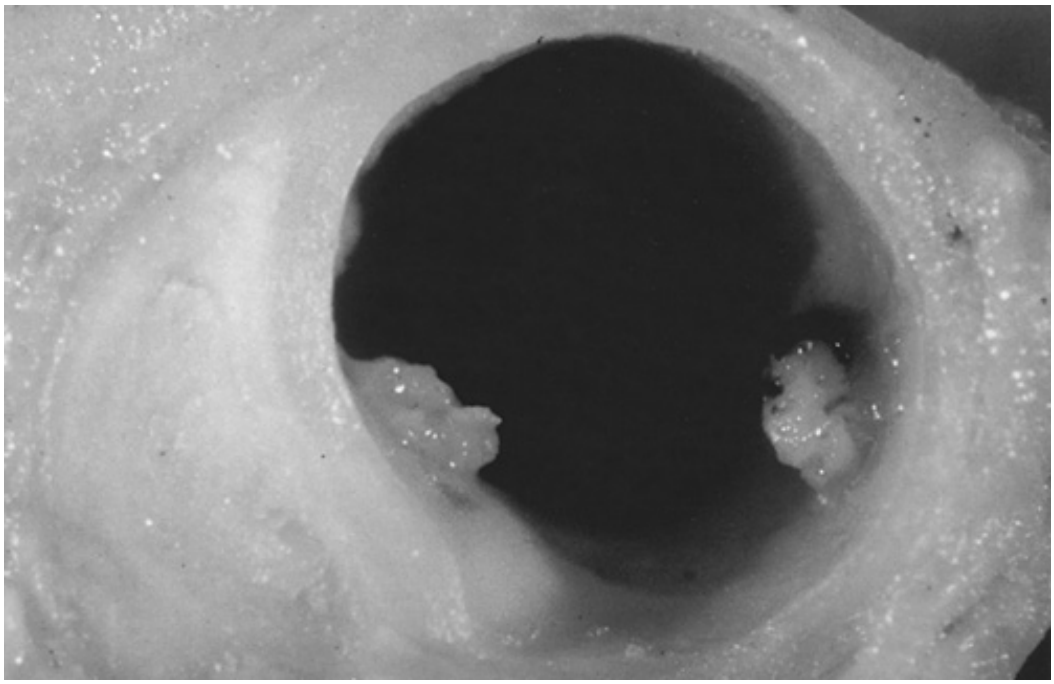

Figure 36-4: Two small thrombi due to endothelial erosion over a plaque. The thrombi are stuck onto the surface of the plaque-there is no intraplaque component of thrombus.

Plaque Disruption

Major coronary thrombi are also caused by plaque disruption (also known as *plaque cracking, fissuring, rupture,* or *ulceration*). In disruption, the cap of a plaque with a lipid-rich core will tear; blood from the lumen of the artery then enters the lipid core, where the presence of tissue factor and collagen induces platelet adhesion, aggregation, and activation.[41] Thrombus formation within the core itself expands and distorts the plaque, whereas the torn cap may project into the lumen (Fig. 36-5). Necropsy study of disrupted coronary and aortic plaques compared with intact plaques in the same individuals shows that plaques with a large lipid core occupying more than 50 percent of overall plaque volume and having a high macrophage density, a thin cap, and low smooth muscle cell density are the most vulnerable to rupture.[42] Of interest, core size and cap thickness, which are two major determinants of plaque vulnerability, are not statistically related, and neither is related to absolute plaque size or to the degree of stenosis.

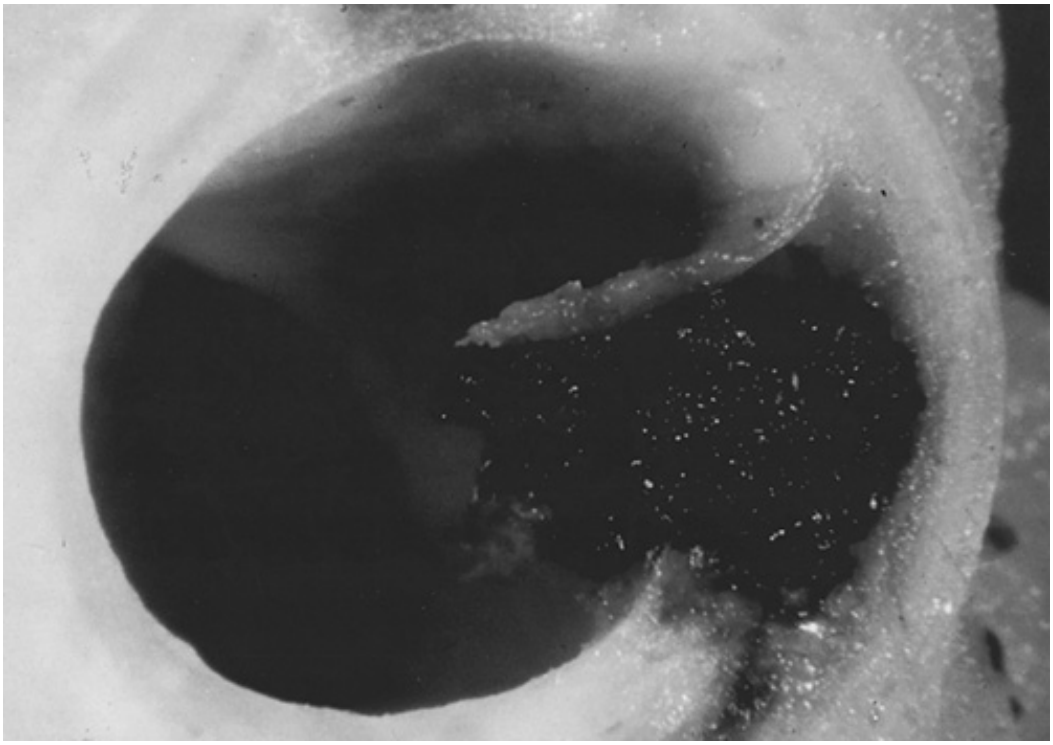

Figure 36-5: Plaque disruption in which the torn cap of a plaque projects into the lumen. The original site of the lipid core is filled with thrombus, which protrudes into but does not occlude the lumen.

Plaque disruption is responsible for at least 80 percent of major coronary thrombi causing sudden death or myocardial infarction in white males.[42] In contrast, the frequencies of disruption and erosion are almost equal in women with coronary thrombi.[43,44]

Postdisruption Events

The events that follow an episode of plaque cap disruption are dynamic and occur in stages (Fig. 36-6). Progression can be halted at any stage. The initial stage, in the past, often has been referred to as *plaque* or *intimal hemorrhage, intraplaque hematoma,* and *hemorrhagic dissection*. These names imply that the intraplaque component is predominantly composed of red blood cells. A large component of platelets and fibrin is also present, justifying the name *intraplaque thrombus.*[42] Within the area of the torn cap at the interface with the lumen, the thrombus composition is predominantly densely packed fibrin. From this transition zone, mural thrombus

may project out into the lumen without totally preventing antegrade flow. In the final stage, thrombus is predominantly made up of a loose network of fibrin-containing enmeshed red blood cells and totally occludes the arterial lumen.

Plaque disruption is a stimulus to the formation of thrombosis within the lumen. Many factors control whether or not thrombosis occurs. The magnitude of the tear varies. At one extreme it may be a narrow fissure running from the lumen to the core; at the other extreme the whole cap may be lost with extrusion of core material into the lumen. Another important factor is the local blood flow. Reduction of flow, either due to spasm or because of a large expansion of the plaque by thrombus within the core, increases the likelihood of major thrombosis within the lumen. The systemic balance of prothrombotic and natural fibrinolytic mechanisms is another factor influencing whether or not major intraluminal thrombi follow the stimulus of an episode of plaque disruption.

Plaque Healing

Plaque disruption is followed by a healing response. Natural fibrinolysis will remove a variable amount of the thrombus, which is followed by smooth muscle cell proliferation and deposition of new collagen. This healing process is analogous to that which follows angioplasty. The end stage of an episode of plaque disruption can range from a trivial increase in plaque size through more significant increases in size resulting in an increase in stenosis severity to chronic total occlusion (see Fig. 36-6).

Mechanism of Intimal Tears

Reconstruction of human atherosclerotic plaques that have undergone disruption shows that the majority have a large core of extracellular cholesterol occupying over 50 percent of the plaque by volume. Computer models of plaques using finite-element analysis have been used to show the distribution of circumferential wall stress in systole.[45,46] Normally, systolic circumferential stress is evenly distributed. Lipid cores are soft and cannot sustain stress, which has to be distributed elsewhere. The displaced stress is redistributed to the plaque cap. Focal points of maximal stress may be up to 10 times greater than that experienced by the rest of the arterial wall. Studies of coronary plaques show that the site of tearing coincides with the calculated point of maximal stress.[46] Concentration of stress on the plaque cap is also particularly enhanced in thin caps of plaques, causing minimal stenosis.[47] All these studies emphasize the concept that plaques with lipid cores and thin caps are mechanically inefficient, with stresses impinging excessively on the cap.

Another important aspect of plaque disruption is the innate mechanical strength of the cap tissue. Mechanical testing in vitro of cap tissue shows that a reduction in collagen and glycosoaminoglycans and an increase in the number of lipid-filled macrophages interact to reduce the amount of stress needed to fracture the tissue even after correction for the cross-sectional area of the test sample.[48] Collagen types and elastin content do not alter absolute tissue strength. These results lead to consideration of whether or not the cap is undergoing active destruction by proteases. Macrophages have the capacity when activated by the cytokines TNF-α and interleukin 1 (IL-1) to secrete inactive *metalloproteinases* (MMP). These connective tissue-degrading enzymes include interstitial collagenase (MMP1), gelatinase B (MMP9), stromelysins 1, 2, and 3 (MMP3, -10, and -11), and a membrane type (MTMPP). When activated by plasmin or by inactivation of intrinsic inhibitors in the tissue, these metalloproteinases can degrade the connective tissue matrix. Macrophages in plaques also produce cathepsins K and S, which will degrade elastin.[49] Both metalloproteinase mRNA and protein have been found in large amounts in the cap and core area,[30,50,51] but their activity may be neutralized by tissue inhibitors (TIMPS). Sections of plaques laid on a gelatin substrate in vitro, however, show that lysis occurs in focal areas, indicating that active degradation of collagen is occurring.[51] Evidence of enhanced collagen

destruction in lipid-rich plaques also has been shown by the presence of collagen breakdown products identified by specific immunohistochemistry.[52] *Plaque cap tears therefore can be seen as resulting from a destructive process initiated by macrophages that gains ascendancy over the repair process of collagen deposition by smooth muscle cells.*

Chapter 36: PATHOLOGY OF CORONARY ATHEROSCLEROSIS

DETAILED PATHOLOGY OF CLINICAL SYNDROMES IN ISCHEMIC HEART DISEASE

Unstable Angina

Intermittent ischemia occurring at rest is the hallmark of unstable angina and is related to "dynamic" stenosis; i.e., the obstruction to flow varies rather than being fixed (see Chap. 41). Two main mechanisms, mural thrombosis at the site of a culprit plaque and varying vasomotor tone, have been proposed. Neither process is exclusive, and both may operate contemporaneously.

Angiographic studies in unstable angina of the crescendo form, in which there is a clear risk of subsequent acute infarction, emphasize the presence of eccentric stenoses with ragged outlines, designated as type II, and of intraluminal filling defects.[53] Necropsy studies (Fig. 36-7) confirm that these angiographic appearances are due to nonocclusive thrombi developing over a disrupted plaque. *A major cause of unstable angina therefore is a culprit plaque over which thrombus is arrested at an intermediate stage in which it is neither occlusive nor resolved sufficiently to allow the plaque to reseal and heal.*

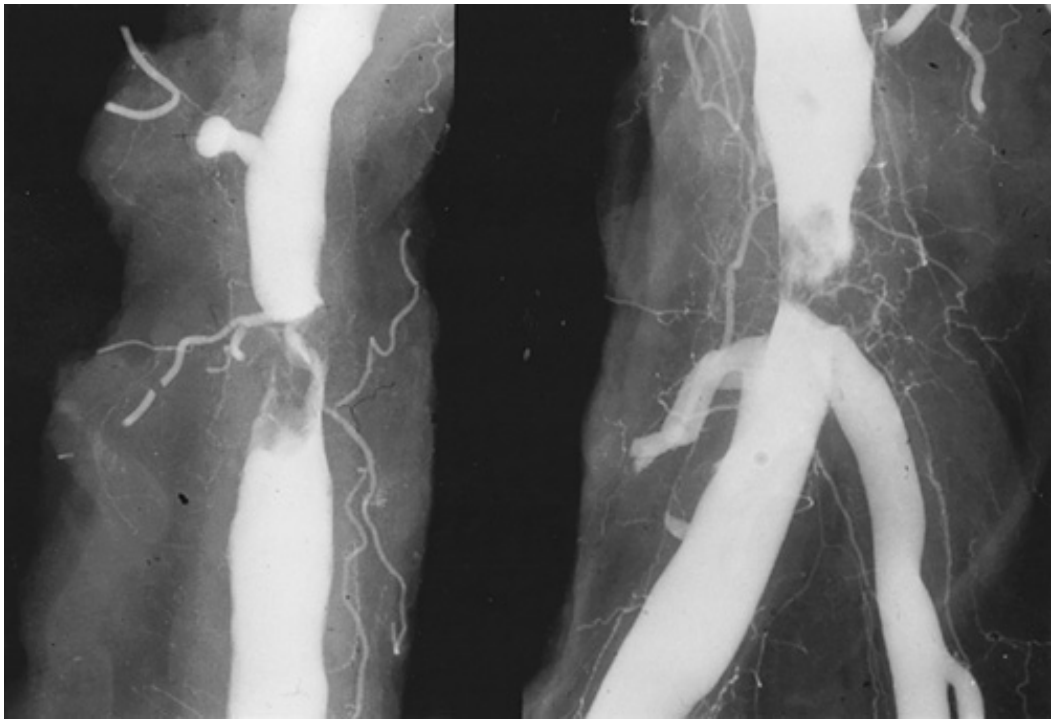

Figure 36-7: Postmortem angiograms of two patients who died suddenly after a prodrome of intermittent resting chest pain. Both had disrupted plaques. The angiograms show the typical eccentric stenoses with ragged edges. Both have related intraluminal thrombi-proximal in one (*left*) and distal in the other (*right*).

Necropsy studies of unstable angina are biased toward the worst-case scenario. To an extent, this limitation can be overcome by studies of plaque material retrieved by atherectomy of the culprit

lesion. Such studies confirm that macrophage infiltration is a feature of unstable plaques.[54] A number of atherectomy studies have shown that thrombotic material is recovered from a far higher proportion of plaques causing unstable as compared with stable angina but that this correlation is not 100 percent.[55,56] A far smaller proportion of apparently stable plaques also shows thrombotic material. Haft et al.,[57] for example, found thrombus in atherectomy material in 49 of 57 patients with unstable angina (86 percent) and in 7 of 24 patients with stable angina (29 percent). Atherectomy removes a random portion of the plaque, and this may explain the absence of thrombus in some patients with unstable angina. Timing is also important. Atherectomy samples that show accelerated growth with storiform smooth muscle cell proliferation[58] can be explained by the sample's having been taken after healing is initiated.[59] Angioscopy is probably more sensitive than angiography in identifying plaque thrombosis. A recent study[60] shows 70 of 95 (73.7 percent) patients with unstable angina had plaque thrombus. Four of 27 patients (14.8 percent) who had only exercise-related pain showed thrombus.

Pathologic studies show that platelet emboli into the distal myocardium lead to small foci of acute myocardial necrosis in subjects dying suddenly after unstable angina.[61,62] These small platelet emboli within the myocardium show intense expression of the type IIb/IIIa receptor (Fig. 36-8).

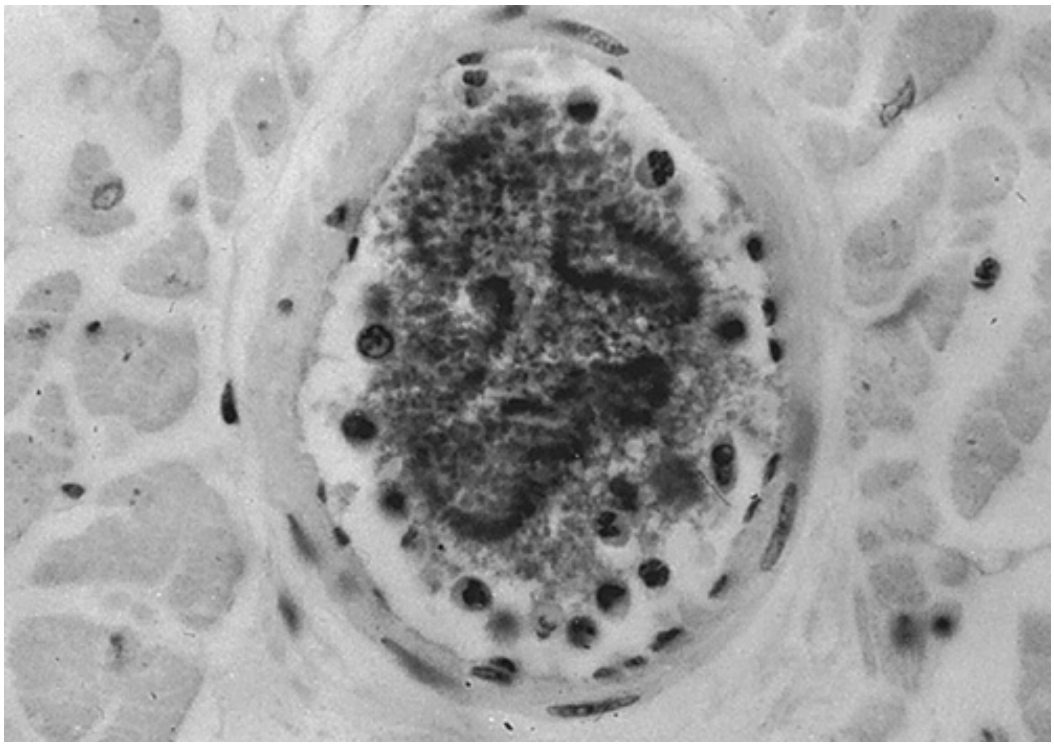

Figure 36-8: An intramyocardial artery distal to a disrupted plaque in a major epicardial artery is occluded by a mass of platelets and white blood cells. The platelets are expressing the type IIb/IIIa receptor (immunohistochemical staining with type IIb/IIIa antibody).

The arterial pathology of unstable angina differs from that of acute myocardial infarction only in that the artery remains open and some antegrade flow is retained, whereas in the latter antegrade flow ceases for at least a period of time, usually some hours. Unstable angina of the crescendo type, non-Q-wave or nontransmural infarction, and transmural infarction are different points in a continuous spectrum. It is therefore not surprising that sensitive methods of detecting myocardial necrosis, such as measuring plasma troponin-T levels, can be used to detect subjects with the clinical diagnosis of unstable angina who are at high risk of death or further infarction.[63]

The essence of the arterial pathology of unstable angina is that the process of thrombosis is arrested at the point of exposed mural thrombus. This arrest represents a balance between many active forces and does not imply that the thrombotic surface has become inert. The risk of thrombotic occlusion developing at the site remains increased for at least 6 to 12 weeks, and systemic hypercoagulative activity is also elevated for several months. Residual thrombotic material continues to be highly thrombogenic until it is completely replaced by smooth muscle cells and new connective tissue.[64]

Vasomotor Tonal Abnormalities in Unstable Angina

There is now abundant evidence in humans and in animals that atherosclerotic arteries have inappropriate vasoconstrictor responses. Vasoconstriction, which has been induced both by exercise and intracoronary infusion of acetylcholine, is caused by a failure of normal vasodilatory responses due, at least in part, to diminished nitric oxide release by the endothelium (see Chaps. 6 and 36).

Some cases of unstable angina have localized dynamic vasoconstriction, either at a site of eccentric stenosis or in a segment with minimal or no angiographic narrowing.[65,66] It is uncertain why one such lesion should acquire vasomotor excitability. Increased endothelin-1 production within plaques may be a contributing factor.[67] In one case, small amounts of thrombus, too small to be detected angiographically, were found on the endothelial surface at surgery.[68] The local release of vasoactive substances by platelets is one possible cause of spasm, and this possibility is supported by experimental models of coronary injury in pigs.[69] Another postulated cause is related to the heavy adventitial inflammation; mast cells may release pharmacologically active substances that act directly on adventitial nerve tissue.[70] The Prinzmetal variant form of angina frequently occurs in arteries that have some angiographic evidence of atherosclerosis but without an element of high-grade fixed stenosis[71] (see also Chap. 41). The greater frequency of unstable angina with either normal or mildly diseased arteries on angiography in women suggests they have a larger vasospastic component than males with acute ischemic events.[72]

Acute Myocardial Infarction

The blood supply of the mammalian myocardium is regional; each major branch of the coronary arteries supplies a specific segment of myocardium. There is considerable interspecies variation in the degree of innate cross-flow between adjacent epicardial arteries; humans and pigs share the property of having little natural collateral development.

In experimental animal models, the only way to produce regional infarction is to occlude the coronary artery supplying a given area. Clinical studies of regional myocardial infarction in humans confirm the importance of occlusion of the subtending ("infarct-related") artery. Angiography during the early hours of infarction shows the subtending artery to the region to be occluded.[73] The frequency with which occlusion is detected after a myocardial infarction diminishes with the passage of time; as antegrade flow returns (because of spontaneous lysis of thrombus), filling defects are seen within the lumen over a type II stenosis. Fibrinolytic therapy increases the speed with which the subtending artery reopens. These data suggest that a dynamic thrombotic process is occurring. Necropsy studies show a higher frequency of total thrombotic occlusion than equivalent angiographic studies of survivors of acute infarction. These findings suggest that persistent occlusion has an adverse influence on survival, probably by being linked to larger infarct size.[74]

Reconstruction of the microanatomy of occlusive coronary thrombi shows the majority to be due to plaque rupture in which there is both an intraplaque and an intraluminal component (Fig. 36-9). The thrombus found at autopsy varies in suggesting that it is formed by an intermittent process

taking place over some days. The intraplaque component of the thrombus consists predominantly of platelets; the thrombus within the fissure site is formed of densely packed fibrin. Much of the intraluminal thrombus, particularly that distal to the fissured plaque, is "venous" in type, suggesting that it has formed in a static column of blood. At least part of the intraluminal thrombus thus may be a late phenomenon. In vivo radiolabeling studies in subjects who subsequently died of acute infarction show that both fibrinogen and platelets given after the onset of the infarction can be incorporated into the coronary thrombus. Detailed studies, however, showed that the thrombus within the fissured plaque is not labeled, i.e., predates infarction, whereas a proportion of thrombus in the lumen is labeled, i.e., postdates infarction.[75]

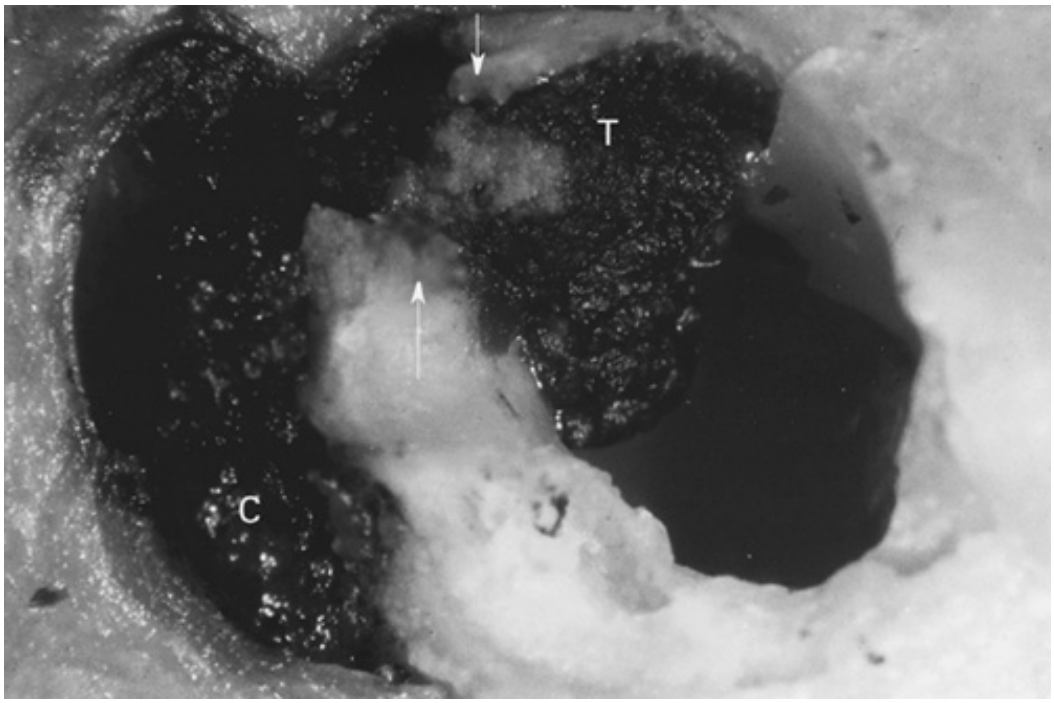

Figure 36-9: Plaque disruption related to an acute regional infarct. There is a mass of thrombus within the lipid core (*C*), which is continuous with thrombus (*T*) in the lumen via a discrete fissure (*arrows*) in the cap. The thrombus is not occlusive, presumably due to natural lysis.

INTERRELATION OF INFARCT MORPHOLOGY AND ARTERIAL THROMBI

Human regional infarcts may be formed of transmural necrosis of uniform age. Such infarcts are closely analogous to experimental infarction in the dog and represent the consequences of thrombus occurring suddenly and progressing to occlusion over a very short time in a vessel in which there was minimal or no preexisting stenosis. There may be preexisting high-grade stenosis, however, that has invoked collateral formation. In such arteries, thrombosis may occur without causing any infarction. Thrombosis may be mural and associated with distal embolization of platelet masses or intermittently occlusive prior to the final occlusive episode. Antegrade flow may or may not be restored spontaneously within a period of hours. These more complex developmental patterns of thrombosis are associated with regional infarcts that are built up by the coalescence of small, often microscopic areas of necrosis of different ages. Retention of areas of viable myocardium mixed with necrotic areas is common. Infarcts that are regional but confined to the subendocardial zone (nontransmural) are almost always of this type. In humans, nontransmural infarction, as compared with transmural infarction, has a higher frequency of previously established collateral flow and/or restoration of antegrade flow over the culprit plaque.[76,77] The sinister complications of infarct expansion, infarct rupture, and cardiogenic shock are virtually confined to transmural infarcts and are associated with persistent total occlusion of

long segments of coronary artery.

Coronary Syndromes and Markers of Inflammation

Atherosclerosis is an inflammatory response to modified lipids[78] within focal areas of the intima. All plaques at some point in their evolution have such an inflammatory response,[79] but this may burn out or progress to cause plaque disruption or endothelial erosion with resulting thrombosis and the potential to cause acute coronary syndromes.

A wide range of markers of inflammatory activity including C-reactive protein,[80] fibrinogen, neoptenin, and soluble intercellular adhesion molecule (ICAM) on a population basis give an indication of the risk of acute ischemic events in the future. These markers are not elevated to a degree that is strikingly outside the normal range, but, for example, if a population is divided into quartiles of the level of C-reactive protein, the upper quartile has a risk of myocardial infarction around three times the lowest quartile.[81] Such data can be interpreted in two ways, neither being exclusive of the other. The level of systemic inflammatory activity may be a measure of the total active plaque burden in the aorta and carotid and coronary arteries. In general, subjects with severe aortic disease have the most extensive coronary plaque formation. Alternatively, a non-lipid-dependent mechanism may be elevating overall inflammatory activity feeding back on the plaques. Such factors potentially would include *Helicobacter* and chlamydial infection, chronic peritonitis, rheumatoid arthritis, etc. Experimental evidence exists that elevation of systemic mediators will secondarily upregulate plaque inflammation.[82]

Coronary Artery Pathology in Stable Exertional Angina

Angiographic and necropsy studies[83] show that the basis of stable angina is segments of coronary artery in which the lumen is reduced in diameter by at least 50 percent (75 percent cross-sectional area) compared with the adjacent normal artery. Such stenoses are potentially flow-limiting on exertion. The number of arteries involved and the number of stenotic segments vary widely from case to case, with autopsy studies inevitably showing the more severe end of the spectrum. The morphology of lesions causing chronic high-grade stenosis can best be appreciated in coronary arteries that have been fixed after autopsy by perfusion with formalin at systolic pressures. In such preparations, the lumen is nearly circular in outline, indicating that the slitlike lumen shape shown in many pathology studies is an artifact. Segments of high-grade stenosis may be eccentric; i.e., there is an arc of vessel wall that has retained its normal media opposite the plaque[84] (see Fig. 36-2). Alterations in vascular tone in this residual segment of normal media may alter the cross-sectional area of the lumen. Stenoses may be concentric, however, surrounding the lumen and limiting variation in lumen size.

Many patients with stable angina but without a clinical history of infarction are found at autopsy to have a healed regional infarct. Arteries that supply such regions may be totally occluded by fibrous tissue, have high-grade stenosis due to complex type Vb plaques, or have many new, small vascular channels contained within the original lumen. This last appearance is pathognomonic of recanalization by organization of previous occlusive thrombus. In subjects with stable angina, such recanalized segments also may be present and unrelated to old scars, illustrating the fact that thrombotic occlusion is not inevitably followed by infarction. In one autopsy study of 54 men with stable angina who died within 6 h of the onset of symptoms, 38 patients had microscopic evidence of previous healed myocardial infarction; of these, 33 (87 percent) had one or more arterial segments in which the lumen was multichanneled. In the 16 patients who did not have microscopic evidence of an old infarction, 10 (62.5 percent) had one or more arterial segments that were multichanneled.[83]

CORONARY ANASTOMOSES (COLLATERALS)

Anastomotic flow is impossible to demonstrate in life or at necropsy without angiography. Anastomoses occur at several different levels. Local adventitial vessels open and provide very localized anastomoses at sites of short segments of high-grade or total chronic occlusion. While such periarterial vessels may show up strikingly in angiograms, the caliber of individual vessels is small, and useful flow may not be achieved. Similar-sized vessels develop within the arterial lumen, passing through an old organized thrombus. Larger anastomoses develop between adjacent arteries on the epicardial surface. These may be as much as 1000 μm in diameter and are probably preexisting smaller arteries altered by flow-induced pressure differentials between different coronary beds. These anastomoses at the epicardial surface are probably the most important functionally and develop a characteristic corkscrew configuration in angiograms. In areas of nontransmural scarring within the myocardium, a plexus of large subendocardial vessels appears that has a structure resembling that of venous sinusoids. In very diffusely scarred ventricles, these channels fill throughout the ventricle from injection into one coronary artery.

Chapter 36: PATHOLOGY OF CORONARY ATHEROSCLEROSIS

MECHANISMS OF PROGRESSION AND REGRESSION

Any morphologic explanation of disease progression must take into account a number of clinical observations.[85-89] Sequential clinical angiographic studies show that progression is phasic and unpredictable in any particular arterial segment. High-grade lesions do not necessarily appear at sites where lower-grade lesions were present previously. New lesions causing luminal stenosis over 50 percent in diameter can appear between two angiographic examinations in apparently normal segments of artery. The sites of future acute occlusions causing infarction cannot be predicted. The progression of separate lesions in an individual is unrelated, and the progression of lesions in "normal" segments is often greater than in areas recognized to have an irregular outline. Thus individual plaques can enter an accelerated growth phase that is unrelated to their degree of stenosis. Despite this unpredictable behavior, high-grade stenoses (>70 percent by diameter) do tend to progress, particularly if the segment is long. Chronic total occlusions follow such high-grade lesions three times more frequently than in the case of less severe lesions[89] but frequently do not invoke infarction because of collateral development. Sequential coronary angiograms show that increases in the overall extent of disease also predict the risk of acute ischemic events in the future.[90,91]

Episodes of plaque disruption were regarded initially as events that inevitably caused thrombosis within the arterial lumen and therefore usually were manifest as episodes of acute myocardial ischemia. Several pathology studies have altered this concept. In a significant proportion of patients who had coronary atherosclerosis but who died of noncardiac causes such as accidents, small, recent plaque disruptions were found at autopsy. Up to 16 percent of such individuals who have diabetes and/or hypertension have these lesions.[92] In three studies of patients who died of acute myocardial ischemia, many were found at necropsy to have had two or three separate areas of disruption, although one was usually larger and regarded as the culprit lesion causing death.[93-95] Such data suggest that *episodes of plaque disruption are a characteristic feature of the progression of atherosclerosis and that many are clinically silent.*

An episode of plaque disruption heals by smooth muscle proliferation, replacing residual thrombus. The repair process is identical to that which follows plaque disruption produced by angioplasty. The final outcome of an episode of plaque disruption can range from chronic total occlusion at one extreme to a mild increase in stenosis at the other extreme (see Fig. 36-6).

Generation of Chronic High-Grade Coronary Stenosis

The simplest model of the generation of significant coronary stenosis is that the plaque simply grows by the process of atherosclerosis (lipid accumulation-collagen formation) in a linear fashion until the lumen is narrowed to a degree that limits flow. Sequential angiography, however, often shows that high-grade stenotic lesions appear within a year at sites that were normal previously by angiography.

As plaques grow slowly, the artery wall remodels to accommodate the lesion, compromising lumen size. The external cross-sectional area of a coronary artery may increase by up to 80 percent of its normal size. Such compensatory dilatation is often sufficient to allow relatively large plaques not to encroach on the lumen and be angiographically invisible. At points of high-grade coronary stenosis, the degree of remodeling is often minimal (inadequate remodeling) or

even shows a reduction in the artery size (negative remodeling). Thus stenosis arises both from an increase in plaque size and from the degree of remodeling.[96,97] Failure of remodeling may reflect the rate of plaque growth. Reconstruction of segments of high-grade stenosis in pathology studies show at least 70 percent of lesions to have healed disruption that would have triggered accelerated smooth muscle proliferation and a sudden increase in the rate of plaque growth.[59]

Lipid Lowering and Atherosclerosis

Lipid-lowering trials have shown consistently that disease progression can be slowed but that the degree of reduction in narrowing of established stenoses is minimal. Trials designed to study the risk of acute events after lipid lowering by drugs, however, have demonstrated a 30 percent drop in acute ischemic events and a fall in all-cause mortality. The effect becomes apparent after 18 months of therapy (see also Chap. 38).

Acute coronary syndromes largely are due to thrombosis developing on plaques that are vulnerable, i.e., have an increased risk of causing thrombus compared with other plaques in that individual that remain inert for years. The determinants of vulnerability are a large lipid core, a thin cap, endothelial loss, and reduced smooth muscle cell content. All these characteristics reflect a high density and activity of macrophages, i.e., active inflammation. The degree of risk for any individual of developing an acute event depends on the absolute numbers of vulnerable, highly active inflammatory plaques.

Lipid lowering in experimental models of atherosclerosis shows a very consistent message in that plaque morphology is significantly altered, although the reduction in size is small.[99] The number of macrophages falls, cytokine activity falls, metalloproteinase activity falls, smooth muscle density rises, and the plaque becomes more solid due to collagen deposition.[100] [101] Such changes would reduce plaque vulnerability to thrombosis. In human subjects, while lipid lowering has systemic effects and improves endothelial function, the time course of benefit is consistent with the induction of quantitative changes in plaques reducing vulnerability. The equal benefit observed in males and females would suggest that both erosion and disruption risks are reduced.

Part 6: CORONARY HEART DISEASE
Chapter 37:

CORONARY BLOOD FLOW AND MYOCARDIAL ISCHEMIA

Authors: Attilio Maseri, Gaetano Antonio Lanza, Tommaso Sanna, Stefano Rigattieri

REGULATION OF CORONARY BLOOD FLOW

The task of the coronary circulation is to supply the myocardium with oxygen and substrates and remove metabolic waste products. Contractile cardiac function relies on aerobic metabolism and, as basal oxygen extraction is about 60 percent,[1] an adequate increase of coronary blood flow is required to meet increased myocardial oxygen consumption (M_{VO_2}).

During strenuous exercise coronary blood flow can increase about five times.[2] The maximal increase in coronary flow above resting levels is defined *coronary flow reserve* and is expressed as the ratio between the flow during maximal vasodilatation and basal flow.[3] Low M_{VO_2} at rest requires a low coronary flow; therefore it is associated with a larger coronary flow reserve than a high resting M_{VO_2}.

Vascular resistance in the coronary circulation is distributed into several functional compartments arranged in series. It is mainly determined by M_{VO_2} and modulated by neural stimuli, local vasoactive autacoids, and circulating vasoactive substances. The transmural distribution of resistance across the ventricular wall is largely determined by extravascular tissue compressive forces.

A brief description of determinants of M_{VO_2}, of the functional anatomy of the coronary circulation, and of the distribution of coronary vascular resistance is useful for a better understanding of the regulation of myocardial blood flow (see also Chap. 40).

Determinants of Myocardial Oxygen Consumption

Mechanical work performed by the myocardium is the most important determinant of M_{VO_2}, as the latter decreases to only 15 to 20 percent in the nonbeating heart. Heart rate, myocardial wall tension, and myocardial inotropic state are the major determinants of metabolic activity and therefore of M_{VO_2}.[4]

Heart rate is by far the major determinant of M_{VO_2}: when the heart rate doubles, myocardial oxygen uptake also approximately doubles. Myocardial tension developed during systole is directly proportional to aortic pressure (afterload), myocardial fiber length and ventricular volume (preload).* Myocardial oxygen uptake approximately doubles as mean aortic pressure is increased from 75 to 175 mmHg at constant heart rate and stroke volume. Finally, myocardial inotropic state determines ventricular performance independent of both preload and afterload. M_{VO_2} increases by about 30 percent when dp/dt† is doubled by extrasystolic potentiation or by norepinephrine at constant heart rate, aortic pressure, and cardiac output.

Direct measurement of M_{VO_2} requires determination of coronary blood flow and arteriovenous difference of blood oxygen content. Therefore, a number of noninvasive, indirect indices were proposed. Of these, the rate-pressure product (heart rate × systolic blood pressure) is the simplest one and is well correlated with direct measures of M_{VO_2} in a variety of physiologic and experimental conditions.

Functional Compartments of the Coronary Circulation

About 75 percent of total vascular resistance occurs in the arterial system, which can be divided into three functional compartments arranged in series: conductive vessels, prearteriolar vessels, and arteriolar vessels (Fig. 37-1).

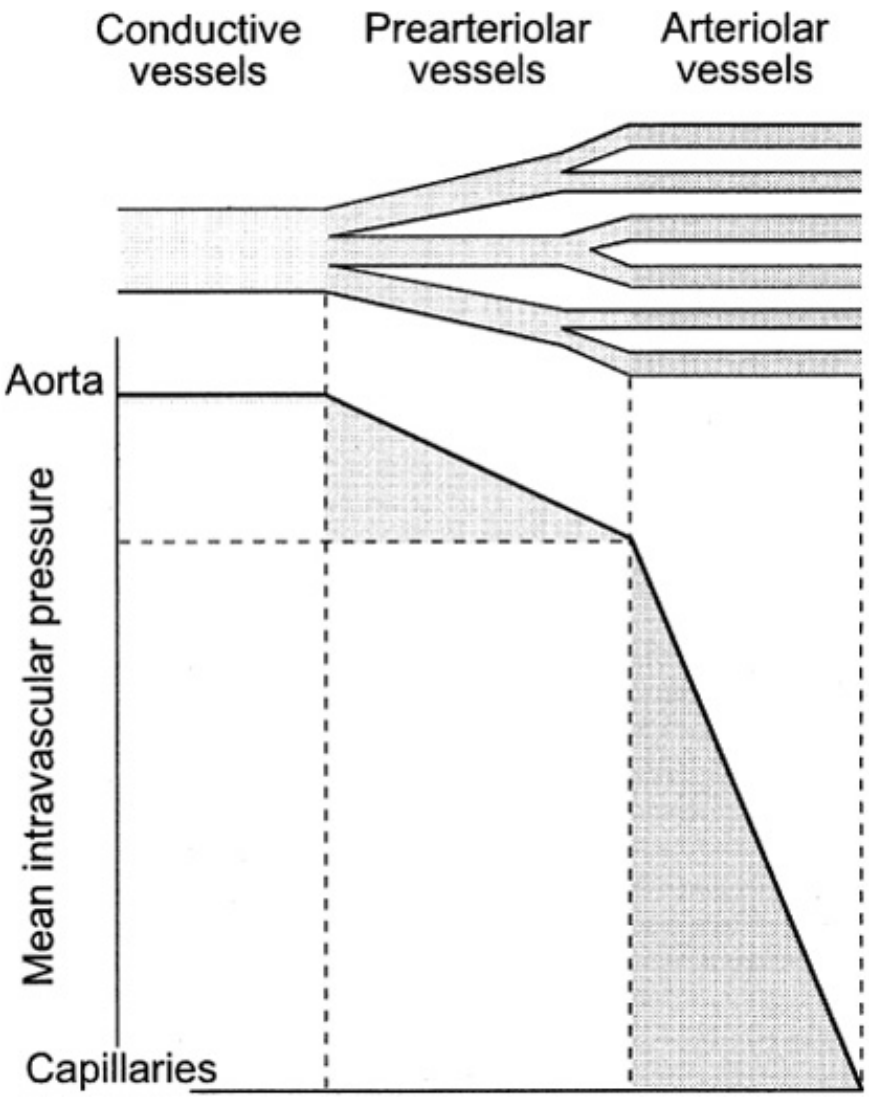

Figure 37-1: Schematic illustration of the subdivision of coronary arterial system into conductive, prearteriolar, and arteriolar vessels. Resistance to flow is negligible in conductive vessels (epicardial arteries) and maximal in arterioles, which are under the control of myocardial metabolic activity. Prearteriolar vessels offer an appreciable resistance to flow, but, unlike arterioles, are not under direct metabolic vasodilator control. Their specific function is to maintain pressure at the origin of arterioles within a narrow range when aortic pressure and coronary flow vary. The arterioles are the major site of metabolic regulation of flow. (From Maseri[46] by permission.)

1. The proximal compartment is represented by the large epicardial coronary arteries; these vessels have conductive function and do not contribute significantly to vascular resistance, as the pressure drop along their length is negligible. During systole, their blood content increases by about 25 percent as a result of anterograde flow from the aorta and retrograde flow from squeezed intramyocardial vessels. The elastic energy accumulated in the vessel wall during systole is transformed into blood kinetic energy at the beginning of diastole. About 60 percent of the wall thickness of conductive vessels is represented by the muscular media, which is responsible for myogenic autoregulation of the vascular lumen in response to changes in aortic pressure and for modulation of coronary tone in response to flow-mediated endothelium-dependent vasodilators, circulating vasoactive substances, and neural stimuli. Conversely, the caliber of large conduit arteries is totally unaffected by myocardial metabolites because of their extramural position.
2. The intermediate compartment is represented by prearterioles, which are resistive vessels connecting epicardial conduit arteries to the arterioles. The proximal and distal ends of prearterioles cannot be defined anatomically, but their diameter is in the range of 100 to 500 μm. They contribute to about 30 percent of total coronary flow resistance, but their vasomotor control mechanisms are much more like those of epicardial arteries than those of arterioles because they are largely unaffected by myocardial metabolic vasodilators. The main function of prearterioles is to maintain the driving pressure at the origin of arterioles within an optimal range. This regulatory function is mediated by myogenic autoregulation and flow-dependent vasodilatation in response to shear stress. Prearteriolar resistance is also modulated by neural stimuli and by local autacoids.
3. The distal arterial compartment is represented by the arterioles, which are the main site of metabolic regulation of coronary blood flow. They are smaller than 100 μm in diameter and are responsible for about 40 percent of coronary flow resistance. Also, their tone can be modulated by neural stimuli and local autacoids. At the arteriolar site, the effects of constrictor stimuli strong enough to induce ischemia are directly opposed by locally released myocardial vasodilator metabolites.

In an integrated response model,[5] an increase in metabolic demand of the myocardium initially causes arteriolar vasodilatation (metabolic domain) which is followed by a transient decrease in pressure at their origin, with consequent myogenic regulation (myogenic domain) as well as by an increase in flow, leading to flow-mediated, endothelium-dependent vasodilatation in proximal vessels (flow-sensitive domain). Arterioles branch into metaarteriolar and capillary vessels, which provide a regional microdistribution of flow that, under physiologic conditions, exhibits spatial and temporal heterogeneity. Such physiologic heterogeneity may have pathophysiologic consequences, as coronary hypoperfusion severe enough to cause ischemia was shown to produce a nonuniform maximal dilation of microvessels and a variable response to adenosine in adjacent myocardial regions.[6]

Diffusion of oxygen and substrates to myocardial cells takes place at the capillary level. On average, there is one capillary for each myocardial fiber, but their density is about 20 percent higher in the subendocardial layers.

The venous side of the coronary circulation has so far received little attention, although it contributes a detectable fraction of total coronary flow resistance and can influence capillary recruitment and blood volume content in the ventricular wall, increasing diastolic fiber length and therefore myocardial oxygen consumption ("garden hose" effect).

Physiologic Control Of Myocardial Perfusion

The in-series distribution of resistance as well as total vascular resistance are largely determined by changes of coronary vasomotor tone, while the transmural distribution of perfusion across the left ventricular wall is largely determined by extravascular compressive forces.

EXTRAVASCULAR MECHANICAL FORCES

At variance with all other organs, the heart generates its own perfusion pressure, and extravascular forces squeeze the vessels closed when extravascular pressure is higher than intravascular distending pressure.[7]

During systole, intramyocardial left ventricular pressure is sufficiently high to prevent systolic flow across the whole wall (perhaps with the exception of the outermost layers) and to squeeze intramyocardial blood forward out of the capillaries, venules, and veins toward the coronary sinus and backward from subendocardial and midwall layers toward epicardial arteries.[8] The extravascular compressive forces are highest in the subendocardium and decrease linearly toward the subepicardium. As intramyocardial tissue pressure is higher in subendocardial layers,[9] subendocardial vessels are squeezed more than subepicardial ones, so they take a longer time to refill and resume their caliber during diastole,[10] particularly when perfusion pressure is low (e.g., distal to flow-limiting coronary stenosis or in the presence of aortic stenosis) (Fig. 37-2). When poststenotic pressure is reduced, subendocardial perfusion is further impaired by tachycardia, which shortens the duration of diastole,[11] and by increased left ventricular diastolic pressure, which increases extravascular compressive forces in subendocardial layers. The higher extravascular resistance, together with a higher basal M_{VO_2}, determines a greater susceptibility to ischemia in subendocardial layers.

REGULATION OF CORONARY VASOMOTOR TONE

The mechanisms of contraction and relaxation of vascular smooth muscle cells are influenced by several factors and are not the same in the different compartments of the coronary circulation. Vasomotor tone is mainly determined by M_{VO_2} in arteriolar vessels (metabolic vasodilatation) and by perfusion pressure and flow-mediated vasodilatation in prearterioles and in large arteries (myogenic and endothelial control); it is also influenced by neurogenic stimuli, local autacoids, and circulating vasoactive substances in all vascular compartments.

Metabolic Regulation

Arteriolar vasomotor tone is under metabolic control, as arterioles are directly exposed to the effects of the myocardial metabolites, which diffuse into the interstitial space. When M_{VO_2} increases, vasodilator metabolites released from myocardial cells diffuse into the arteriolar wall, causing smooth muscle cell relaxation. The resulting arteriolar vasodilatation causes flow to increase, so that vasodilator metabolites are washed out and flow is reset at a higher level.

Adenosine is a major component of myocardial metabolic regulation of flow.[12] According to a "microhypoxia" model, adenosine production reflects adenosine triphosphate (ATP) degradation resulting from a local myocardial imbalance between oxygen supply and demand. ATP dephosphorylation first results in the formation of adenosine monophosphate (AMP), and then, by 5′-nucleotidase action, in adenosine production. Adenosine, diffusing into the interstitial space and arteriolar wall, can stimulate $alpha_2$-receptors of smooth muscle cells, inducing adenylate-cyclase activation, cyclic-AMP synthesis, and consequent smooth muscle cell relaxation.

However, adenosine is unlikely to be the only component of metabolic vasodilatation[13] and of reactive hyperemia following release of coronary occlusion.[14] Oxygen tension, pH, potassium, osmotic pressure[15] and ATP-sensitive potassium channels[16] also contribute to metabolic regulation of flow.

Myogenic Regulation

When metabolic requirements do not vary, the heart, like other organs, exhibits an intrinsic tendency to maintain blood flow constant despite changes in arterial perfusion pressure. Pressure-flow curves in experimental models show that flow remains nearly constant over a range of perfusion pressure from 60 to 120 mmHg, partly resulting from myogenic control. Myogenic control of vasomotor tone tends to keep the vessel wall tension constant in response to changes in vascular distending pressure: myogenic tone increases when pressure increases and decreases when pressure decreases.

The role of myogenic control of vasomotor tone cannot be easily separated from the effects of stretch-induced release of endothelium-derived relaxing factor (EDRF, see below) and of metabolic regulation. However, myogenic activity has been demonstrated in coronary vessels 40 to 200 μm in diameter[17] and the responses of vascular tone to changes in transmural pressure is not affected by endothelial denudation, confirming that myogenic activity is an intrinsic property of vascular smooth muscle cells.

Neural Regulation

Coronary vessels are innervated both by sympathetic and parasympathetic efferents of the autonomic nervous system.[18] Nerve endings are mainly located at the adventitial-medial border of vessels and their density is greater in prearterioles and arterioles than in epicardial coronary arteries. Besides acetylcholine and norepinephrine, several "nonadrenergic noncholinergic" neurotransmitters identified in axonal varicosities may play a modulatory role on adrenergic and cholinergic output.[19] These substances include purines (ATP), amines (serotonin and dopamine), and peptides [neuropeptide Y (NPY), calcitonin gene-related peptide (CGRP), substance P, and vasoactive intestinal peptide (VIP)].

Sympathetic Control

Both $alpha_1$ and $alpha_2$ and both $beta_1$ and $beta_2$ adrenergic receptors have been identified in coronary arteries. Electrical stimulation of sympathetic nerves and intracoronary infusion of norepinephrine cause an increase in coronary flow resistance mediated by alpha-receptors, whereas pharmacologic stimulation of beta-receptors results in a modest reduction (20 to 30 percent) of coronary flow resistance.[20] In humans, abolition of alpha-adrenergic tone causes an approximate 10 percent increase in resting coronary blood flow and a proportionate increase in coronary sinus oxygen saturation, indicating the presence of a tonic basal, alpha-mediated coronary vasoconstriction. Subepicardial alpha-adrenergic-mediated coronary vasoconstriction may counterbalance the greater extravascular compressive forces in subendocardial layers.[21]

Parasympathetic Control

The role of the parasympathetic nervous system in coronary blood flow regulation is still unclear. Muscarinic receptors are present on smooth muscle cells, where they trigger contraction; on sympathetic nerve varicosities, where acetylcholine inhibits norepinephrine release; and on the endothelium, where their activation induces EDRF release.[22] However, the extent to which acetylcholine released at the site of vagal nerve endings in the adventitia reaches endothelial receptors is unknown. The variable effect of cholinergic stimulation may depend on the balance among its different sites of action. VIP co-released with acetylcholine exerts a significant vasodilator effect.[23]

Purinergic Control

Two types of purinergic receptors have been identified: P_1, which is most sensitive to adenosine and mediates smooth muscle cell relaxation both directly and by endothelial release of EDRF, and P_2, which is most sensitive to ATP and mediates endothelial release of EDRF but also direct vasoconstriction. ATP was found to be released from nerve terminals together with norepinephrine. However, the role of purine release by nerve endings in the regulation of coronary blood flow and coronary vasomotion is not well defined.

Peptides

NPY is released with norepinephrine during sympathetic nerve stimulation[24] and its infusion was shown to cause severe myocardial ischemia by microvascular constriction in patients with normal coronary arteries (see below). Both CGRP and substance P are also found in cardiac nerves; their intracoronary infusion causes EDRF release and dose-dependent dilation of epicardial coronary arteries with a maximum effect similar to that produced by nitrates.

Reflex Control

Coronary vasomotor tone is also under the influence of cardiac reflexes; afferent stimuli arising outside the heart (from chemoreceptors in the carotid bodies and from mechanoreceptors in the carotid sinus, aortic arch and lungs) may produce efferent stimuli that influence coronary flow resistance. Hypotension at the level of carotid sinus baroceptors would tend to increase coronary flow resistance by alpha-adrenergic stimulation, but this effect in vivo is obscured by metabolic vasodilatation in response to the increase in heart rate and contractility consequent to enhanced cardiac sympathetic drive.

Endothelial-Mediated Regulation

Among the multiple roles of the endothelium, the production of vasoactive autacoids contributes to the regulation of coronary blood flow. (The nonvasomotor endothelial functions are presented in the following section.) Endothelial cells release several vasodilator autacoids that contribute to the physiologic regulation of coronary vasomotor tone, such as EDRF, prostacyclin (PGI_2) and endotheliumderived hyperpolarizing factor (EDHF), as well as vasoconstrictor autacoids that may have a pathologic role, such as endothelin-1 (ET-1), angiotensin II, and endothelium-derived contracting factors (EDCFs) (Fig. 37-3).

Physiologic Vasodilator Function

The maintenance of a tonic basal vasodilatation and the flow-mediated regulation of vascular tone are largely dependent on the release of EDRF, identified as nitric oxide (NO) or a NO carrier compound, e.g., L-nitrosocysteine.[25] NO exerts its vasodilator action on vascular smooth muscle cells by activating the enzyme guanylate cyclase, which leads to cyclic-GMP production. EDRF is released in response to a large number of agonists acting on endothelial receptors, including neurotransmitters (acetylcholine and norepinephrine), substances released by platelets (serotonin, adenosine diphosphate) or formed during coagulation of the blood (thrombin), and autacoids formed in the vessel wall, such as histamine, bradykinin, and endothelin. Moreover, EDRF is released also in response to pulsatile stretch and flow shear stress.

EDRF has a 5-s half-life and is continuously released, tonically reducing basal vasomotor tone as the infusion of its inhibitor NG-monomethyl-L-arginine (LNMMA) reduces forearm blood flow and coronary diameter in humans[26,27] and causes blood pressure increase in animals.

Flow-mediated vasodilatation in large arteries and in prearteriolar vessels reduces wall shear stress

when flow increases. Fluid shear stress and viscous drag, through endothelial mechanotransduction, cause EDRF release as well as transcriptional changes, with protein synthesis and vascular remodeling.[28]

Coronary vascular resistance is also modulated by PGI_2 and by EDHF. PGI_2 is synthesized from arachidonic acid, has a 10-s half-life, and is released in response to pulsatile pressure, bradykinin, thrombin, serotonin, and platelet-derived growth factor (PDGF). It contributes to resting conduit and resistance vessel tone and to flow-mediated vasodilatation.[29] EDHF is most likely a short-lived metabolite of arachidonic acid,[30] thought to open ligand-gated potassium channels, and is released in response to several stimuli, including shear stress, pulsatile flow, acetylcholine, substance P, bradykinin, and CGRP.

Pathologic Vasoconstrictor Function

Vasoconstrictor autacoids are released by endothelial cells in several pathologic conditions (hypertension, diabetes, atherosclerosis, and acute inflammation), but their physiologic role is uncertain.

ET-1, a 21-amino acid peptide released abluminally by endothelial cells, is the most powerful vasoconstrictor known.[31] Despite its short plasmatic half-life (about 5 min), it exerts a prolonged action, interacting with two major types of receptors (ET_A and ET_B) and activating the membrane phospholipase C. Its release is reduced by NO and stimulated by thrombin, angiotensin II, catecholamines, interleukin-1β, transforming growth factor beta, and by hypoxia and ischemia.[32] ET-1 was shown to exert a potent vasoconstrictor effect on small coronary vessels; in dogs, intracoronary infusion of ET-1 causes severe reduction in coronary flow without constriction of angiographically detectable arteries (see below). Under physiologic conditions, there seems to be no significant role for ET-1-mediated regulation of coronary blood flow, as myocardial perfusion is not affected by ET-1 antagonists.

Other endothelial constrictor substances include angiotensin II (produced through a local angiotensin-converting enzyme) and EDCFs, including prostaglandin H_2 and oxygen-derived free radicals.[33]

Blood/Vessel Wall Interface

In addition to its vasomotor function, the endothelium plays a major role in the homeostasis of the vessel wall and in the control of the blood/vessel wall interface. The latter is of fundamental importance, as coronary thrombosis is a major pathogenetic mechanism of acute coronary syndromes.

HOMEOSTASIS OF THE VESSEL WALL

Endothelial cells produce several constituents of the basement membrane and of the intercellular intimal matrix. They also synthesize growth factors for smooth muscle cells as well as heparan sulfates and NO, which inhibit cellular growth and migration.[34,35] The integrity of the endothelium is essential for preventing the diffusion of atherogenic components into the arterial wall. The response of smooth muscle cells to trophic stimuli produced by the endothelium depends on their phenotype:[36] cells in the proliferative phenotype respond with increased protein synthesis and proliferation to growth factors and to constrictor stimuli, whereas cells in the mature contractile phenotype respond with contraction.

CONTROL OF BLOOD/VESSEL WALL INTERFACE

The endothelium plays a key role in preserving blood fluidity and in preventing thrombosis (Fig. 37-4*A*). This overall function is performed by different mechanisms. The glycocalyx of endothelial cells, represented by proteoglycans such as heparan sulfate, forms an electronegative barrier, which prevents adhesion of platelets and circulating cells. NO production also prevents platelet adhesion, and PGI_2 opposes platelet aggregation.[37] Moreover, endothelial cells produce and bind anticoagulants such as heparan sulfate, which catalyzes the inactivation of thrombin by plasma antithrombin III, and thrombomodulin, which binds thrombin and protein C, leading, ultimately, to factor V and VIII inactivation. Finally, endothelial cells are involved in fibrinolysis by the secretion of two plasminogen activators, a urokinase type (u-PA) and a tissue type (t-PA).

ALTERATIONS OF ENDOTHELIAL FUNCTION

Chronic Endothelial Dysfunction

Patients with coronary atherosclerosis and also individuals with cardiovascular risk factors (such as hypertension, diabetes, hypercholesterolemia, hyperomocysteinemia, and smoking) show a reduced or abolished vasodilator response to acetylcholine.[33] However, acetylcholine is also a direct powerful constrictor of vascular smooth muscle cells; therefore it is impossible to establish whether an abnormal vasomotor response to acetylcholine is due to defective endothelial EDRF production or to enhanced smooth muscle vasoconstrictor response. The latter possibility is suggested by the preserved dilator effect to substance P in atherosclerotic vessels.[38] It is also unknown to what extent an abnormal response to acetylcholine implies alterations of the endothelial antithrombotic properties. As many patients with extensive coronary atherosclerosis may remain totally free from ischemic events for months and years, it would seem reasonable to consider the possibility that, in some patients and under some circumstances, coronary atherosclerosis may be associated with the development of compensatory, protective factors.

Acute Inflammatory Activation

Increasing evidence suggests that inflammatory activation of the endothelium may play a role in the pathogenesis of some acute ischemic syndromes, determining a rapid switch of its functional properties from vasodilator to vasoconstrictor and from anticoagulant to procoagulant.[39,40] Also, in the absence of detectable histologic changes such as erosion or fissure, endothelial activation by inflammatory cytokines abolishes EDRF and PGI_2 release and stimulates ET-1 release, induces the expression of tissue factor and of adhesive receptors for platelets and leukocytes on the luminal surface, causes the production of plasminogen activator inhibitors (PAI-1), and inhibits that of plasminogen activators (u-PA, t-PA) and of heparan sulfate (Fig. 37-4*B*). In addition, cytokines may also activate metalloproteases, with consequent endothelial erosions and lysis of the plaque caps.[41,42] The causes of such inflammatory processes may be multiple, acute, and chronic, infectious or noninfectious,[43] and be variably modulated by the individual inflammatory and immune responses.[44,45]

Therefore, acute activation of the endothelium and of the vascular wall is one of the possible mechanisms that set the stage for local thrombosis and vasoconstriction in presence of a very variable severity of the chronic atherosclerotic background.

* According to Laplace's law, wall tension = (pressure × radius)/2 × wall thickness.

† *dp*/*dt* indicates the rate of pressure development in the left ventricle.

Chapter 37: CORONARY BLOOD FLOW AND MYOCARDIAL ISCHEMIA

MECHANISMS OF MYOCARDIAL ISCHEMIA

Myocardial ischemia develops when coronary blood flow becomes inadequate to meet myocardial oxygen and metabolic substrate requirements for maintaining adequate cardiac function. Myocardial ischemia can result from (1) an increase of myocardial workload, and hence oxygen demand, in the presence of a flow-limiting coronary artery stenosis or (2) a reduction of coronary blood flow caused by epicardial or microvascular coronary artery constriction or by acute thrombosis. These mechanisms may act in combination in some patient as well as in different ischemic episodes in a same patient (Fig. 37-5).[46]

In clinical practice, coronary stenoses are often considered the only or main cause of myocardial ischemia, because they are the most obvious and readily plausible culprits. Indeed, acute thrombosis can be recognized until thrombi are lysed or become incorporated into the atherosclerotic plaques. The detection of coronary spasm and of dynamic stenosis is even more elusive, because they are very transient and usually require repetition of angiography following nitrates or provocative tests. Finally, microvascular constriction may only be indirectly inferred by slow distal flow dye progression at angiography or by special diagnostic studies (see also Chap. 40).

The clinical presentation of anginal syndromes can provide useful clues about the role of these distinct pathogenetic mechanisms in precipitating myocardial ischemia.

Flow-Limiting Stenosis

EFFECTS OF FLOW-LIMITING STENOSIS ON BLOOD FLOW

The presence of epicardial coronary artery stenosis, caused by atherosclerotic plaques, is by far the most frequent angiographic finding in any cardiac ischemic syndrome. However, a stenosis becomes flow-limiting only when it determines a measurable transstenotic pressure gradient at rest. The transstenotic pressure gradient increases with increase in flow, more than doubling when blood flow doubles.

A basal gradient at rest may not cause myocardial ischemia, as flow is maintained by compensatory distal arteriolar dilatation. In turn, compensatory arteriolar dilatation implies a local reduction of coronary flow reserve. The greater the basal trans-stenotic pressure gradient, the greater the reduction of coronary flow reserve and the lower the level of cardiac work at which myocardial ischemia appears during effort (*ischemic threshold*).

Experimental studies in dogs showed that the acute reduction of coronary diameter by more than 50 percent causes a measurable basal transstenotic pressure gradient.[47] Further decreases in diameter cause an exponential increase of trans-stenotic pressure gradient and reduction of maximal coronary blood flow (Fig. 37-6). A sudden 85 to 90 percent reduction of an epicardial coronary artery diameter is required to exhaust compensatory arteriolar dilatation and cause myocardial ischemia at rest. The decrease of poststenotic pressure may be reduced by the gradual development of collateral blood flow (see ahead).

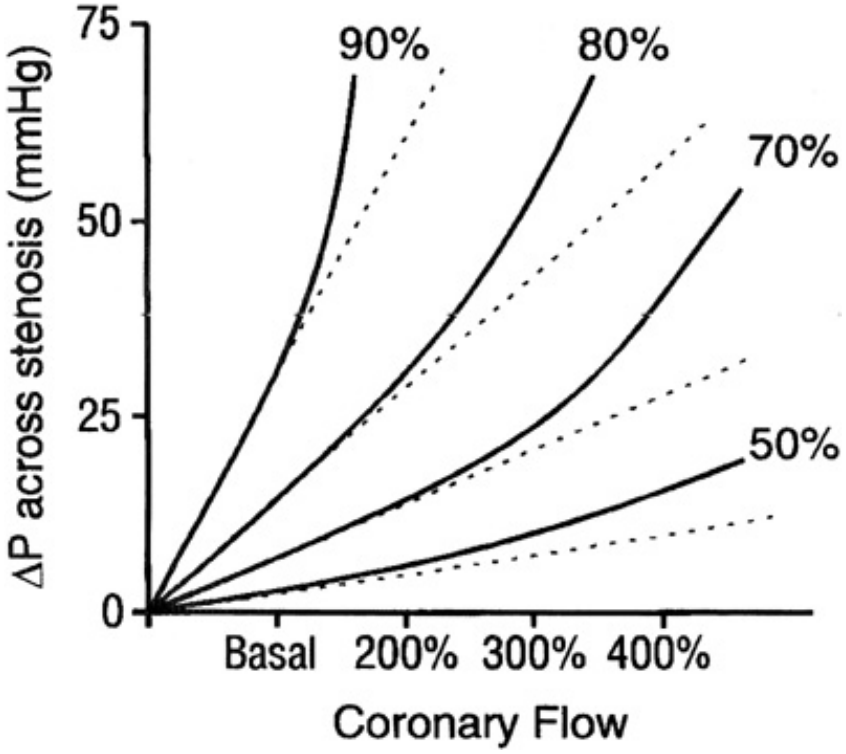

Figure 37-6: Schematic illustration of the relationship between coronary blood flow and transstenotic pressure gradient. This relationship becomes curvilinear because of energy losses caused by blood flow turbulence across the stenosis (*solid lines*). Poststenotic pressure decreases progressively with the increase of stenosis severity and, for a given stenosis, it decreases markedly with increasing flow. In the absence of collateral flow, an 80 percent diameter stenosis causes a drop in poststenotic pressure of about 12 mmHg, which would increase to about 30 mmHg when flow doubles. (From Maseri,[46] modified from Klocke,[47] by permission.)

In presence of a decreased poststenotic pressure, ischemia initially occurs in subendocardial layers, because the subendocardium is more vulnerable to ischemia than the subepicardium (see above).

The general relationship between severity of coronary stenosis as assessed on coronary angiography and impairment of coronary flow reserve has been confirmed in patients.[48,49] However, the angiographic judgment of the hemodynamic consequences of coronary stenoses is difficult because (1) quantitative angiography does not allow an accurate three-dimensional measurement of severe stenoses; (2) the lumen reduction is estimated with reference to the coronary segment proximal to the stenosis, which may be restricted by atheroma or, conversely, enlarged because of vascular remodeling; (3) the stenosis resistance is linearly related to the length of the stenosis and to the flow turbulence caused by the stenosis irregularities.

Several invasive and noninvasive methods have been proposed to assess the hemodynamic effects of coronary stenoses,[50] but the "gold standard" remains the direct measurement of basal transstenotic pressure gradient. Such measurement should be performed after intracoronary nitrates to eliminate the possible vasomotor component of the stenosis. In the absence of a measurable basal gradient, the development of ischemia, at rest or even during effort, cannot be attributed to the hemodynamic effect of the stenosis.

DYNAMIC MODULATION OF CORONARY STENOSES

Coronary flow-limiting stenoses are caused by concentric or eccentric atherosclerotic plaques,

with or without potential for local vasomotor changes. Fixed flow-limiting stenoses present smooth muscle cell atrophy and/or plaque rigidity and are associated with a predictable ischemic threshold and a stable pattern of effort-related myocardial ischemia. Dynamic stenoses are usually eccentric, with compliant segments of the wall and preserved muscular media, and are associated with a variable ischemic threshold. The vasomotor potential of coronary stenoses can also be assessed directly at angiography by intracoronary infusion of vasodilator and/or vasoconstrictor substances.[51,52]

Vasoconstriction at the site of stenoses may result from (1) neural vasoconstrictor stimuli, (2) impairment of vasodilator mechanisms, (3) increased response of dysfunctional vascular smooth muscle cells to vasoconstrictor stimuli, or (4) variable combination of these mechanisms. For example, exercise and cold pressor test cause vasodilatation in normal vessels but vasoconstriction at the site of stenoses.[53,54] Vasoconstrictor autacoids, produced locally by the endothelium (endothelin)[55,56] in the adventitia (histamine, leukotrienes) or released by activated platelets (thromboxane A_2, serotonin), are also powerful potential constrictor stimuli. Defective production and/or release of vasodilator substances (in particular, EDRF) may increase basal coronary tone and prevent flow-mediated arterial vasodilatation during increased M_{VO_2}.[57-59] In animal models, and possibly in unstable patients, the severity of stenosis may also be modulated by transient deposition of platelet aggregates.

CORONARY COLLATERAL CIRCULATION

The drop in poststenotic pressure caused by flow-limiting stenoses stimulates the development of collateral circulation from other coronary artery beds. The supply of collateral blood flow increases poststenotic pressure, thus improving coronary flow reserve and increasing ischemic threshold.

Collateral vessels develop from the progressive enlargement of preexisting intercoronary arterial anastomoses. These vary greatly in number among mammalian species, being more numerous in guinea pigs and dogs, less in pigs and rats, and practically absent in rabbits and sheep. Blood flow through these anastomoses begins as a consequence of the flow-limiting stenosis, when a pressure gradient develops between their origin and termination. In unanesthetized dogs, a pressure gradient of about 10 mmHg, caused by a lumen reduction of 70 to 80 percent, has been shown to elicit the development of collateral flow.[46]

Preexisting anastomoses progressively transform into mature collaterals over a period of 3 to 6 months by initial widening and remodeling, subsequent proliferation of endothelial and smooth muscle cells, and development of a smooth muscle coat, leading to vessels with a final diameter of 20 to 200 μm. Collateral blood flow may also develop by vessel neoformation, but in dog this mechanism contributes only by less than 5 percent of total collateral flow.[46]

Blood flow through collaterals is determined by the driving pressure and by their resistance, which is influenced by neural and humoral stimuli and by local vasoactive autacoids.[60-63]

In patients with flow-limiting stenoses, the number and size of collateral vessels is quite variable. At one extreme, some patients with an occluded coronary artery do not have signs of ischemia because collateral circulation provides adequate blood supply to the territory of the occluded coronary branch. At the other extreme, some patients with severe flow-limiting coronary stenosis do not show detectable improvement of their ischemic threshold over time and, when the vessel occludes, develop myocardial infarction. The causes of these individual differences in coronary collateral circulation are likely to be related to genetic factors.[64]

In experimental animals, no intervention was convincingly shown to improve the development of

collateral vessels. In patients, heparin[65] and fibroblastic growth factor 1 (FGF-1)[66,67] have been suggested to promote collateral growth, but the data are still uncertain.

CORONARY STEAL DISTAL TO FLOW-LIMITING STENOSIS

In the presence of flow-limiting stenoses, myocardial ischemia may develop as a result of a diversion of blood flow from a myocardial region with a very severe impairment of coronary flow reserve, determining an almost maximal arteriolar dilatation in basal conditions, toward a myocardial region with sufficiently preserved coronary flow reserve.

Such a coronary diversion may occur (1) from the subendocardium, as a result of vasodilatation of subepicardial vessels, which increases subepicardial flow but causes a further critical drop of poststenotic pressure (*transmural coronary steal*)[46,68] or (2) from collateralized territories when the parent coronary artery supplying the collaterals presents a flow-limiting stenosis proximal to their origin. In this case, arteriolar dilatation in the territory of the stenosed parent artery increases flow thus causing a further drop of perfusion pressure at the origin of collaterals, which reduces collateral flow (*lateral coronary steal*).[69] In both instances the vasodilatation responsible for the blood flow steal can be induced by vasodilator drugs or an increase in M_{VO_2}.

Coronary Artery Spasm

Epicardial coronary artery spasm is the pathogenetic mechanism of variant angina, but it can play a role in some patients who present with acute coronary syndromes (see also Chap. 40).

CORONARY SPASM IN VARIANT ANGINA

In patients who present with a variant form of angina (see below), myocardial ischemia is caused by an occlusive epicardial coronary spasm.[46] Usually, spasm develops at the site of subcritical or critical stenoses, but it may also occur in angiographically normal coronary arteries, the so-called variant of the variant form of angina. Occlusive spasm causes transmural ischemia with ST-segment elevation, but when spasm is subocclusive, it may cause subendocardial ischemia and ST-segment depression.[70]

In patients with variant angina, spasm tends to recur in the same arterial segment and can be precipitated by sympathetic and parasympathetic stimuli and by a variety of triggers, such as ergonovine, histamine, dopamine, acetylcholine, and serotonin, acting on different receptors, as well as by an increase in arterial pH to 7.65 to 7.70.[71-76] Collectively, these findings suggest a local smooth muscle hyperreactivity to a wide variety of constrictor stimuli. Such hyperreactivity may be caused by a variety of postreceptoral intracellular abnormalities.[46,60] The postmortem findings at the site of coronary spasm are not specific, but fibromuscular hyperplasia was observed in some cases. The animal model of coronary spasm developed in minipigs[77] is unlikely to adequately reflect the mechanisms of vasospastic angina occurring in patients.

CORONARY SPASM IN ACUTE CORONARY SYNDROMES

Although occlusive spasm is typically observed in patients with variant angina, it may also represent a pathogenetic component of other, more common acute coronary syndromes, including unstable angina,[78] unheralded myocardial infarction,[79,80] resuscitated sudden cardiac death,[81] and postcoronary bypass graft angina.[82] In fact, there appears to be a higher prevalence of coronary spasm in patients with acute coronary syndromes (20 to 38 percent) than in patients with stable angina (<6 percent).[46] Coronary spasm has been found to occur more frequently in Asian patients than in Caucasian patients with a recent acute myocardial infarction[80] (Fig. 37-7).

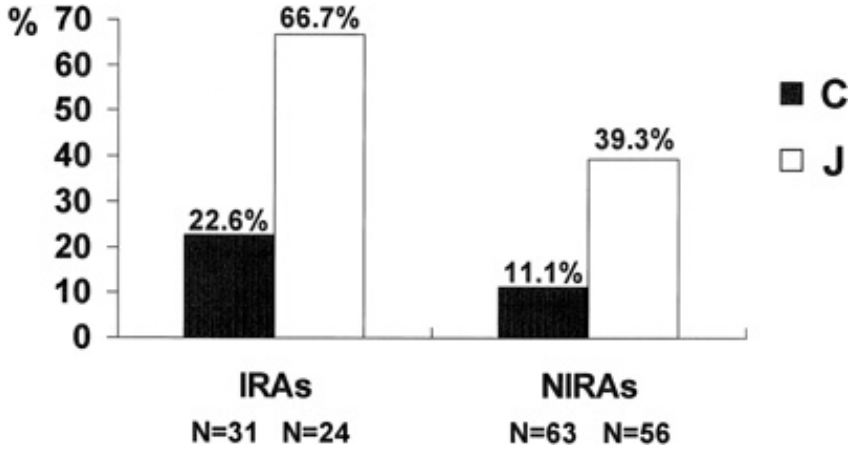

Figure 37-7: Induction of coronary spasm by intracoronary acetylcholine injection in infarct-related arteries (IRAs) and non-infarct-related arteries (NIRAs) of Japanese (J) and Italian (C) patients with a recent acute myocardial infarction. Japanese patients had about a threefold higher prevalence of spastic response in both IRAs and NIRAs. The spastic response was more frequent in IRAs than in NIRAs in Japanese, but not in Italian Caucasian, patients. (Modified from Pristipino et al.[80] by permission.)

The differences in clinical presentation between variant angina and other ischemic syndromes suggest possible different underlying pathogenetic mechanisms. In unstable plaques, the degree of constriction produced by thromboxane A_2, serotonin, and thrombin could be greatly amplified geometrically at the site of fresh mural thrombi and, in some patients, a local smooth muscle coronary hyperreactivity may contribute to the transition from a nonocclusive platelet-fibrin mural thrombus to an occlusive red thrombus.[46]

Dysfunction of Small Coronary Vessels

The possibility that an impairment of coronary blood flow could occur at the level of distal rather than proximal coronary vessels, has received little consideration until recently, as epicardial coronary artery stenoses, spasm, and thrombosis provide readily available, plausible mechanisms for ischemia. However, several animal and clinical studies indicated that ischemia can be also caused by small coronary vessel constriction.[83,84]

PHARMACOLOGIC STUDIES IN HUMANS

In patients with angiographically normal coronary arteries, the intracoronary infusion of neuropeptide Y and that of high doses of acetylcholine was found to induce myocardial ischemia without changes of large epicardial vessels but with extremely slow dye progression or diffuse constriction of distal branches, respectively, indicating microvascular constriction.[46,85] In patients with coronary stenoses, the intracoronary infusion of serotonin caused myocardial ischemia with only small changes in stenosis lumen but with diffuse constriction of distal branches and reduced filling of collateral vessels. In dogs, endothelin infusion caused marked ischemia without detectable changes of epicardial vessels, suggesting powerful microvascular constriction.[46,85]

CLINICAL CLUES TO MICROVASCULAR DYSFUNCTION

In some patients in whom myocardial ischemic episodes cannot be blamed on fixed or dynamic epicardial coronary stenoses, constriction of small coronary vessels could account for the development of myocardial ischemia (see also Chap. 40).

Patients with occlusion of a single epicardial coronary artery and no other stenoses may present very wide variations in the ischemic threshold during daily life and exercise testing, which cannot be attributed to dynamic modulation of stenoses or spasm and are most likely caused by vasomotor changes in small distal coronary vessels.[86]

Patients with single-vessel disease following successful percutaneous coronary angioplasty (*PTCA*) may continue to present with angina, ST-segment depression on exercise testing, and perfusion defects on stress myocardial scintigraphy;[87] in such patients, a dysfunction of small coronary vessels has been confirmed by intracoronary Doppler blood flow measurements and myocardial positron emission tomography (PET) following administration of vasodilator stimuli.[88,89] Microvascular dysfunction is most likely responsible for the reduced coronary dilator response of nonstenosed coronary arteries in patients with coronary disease[90,91] and also in patients with risk factors but no flow-limiting coronary stenoses.[92,93]

Patients with syndrome X who present with angina pectoris, positive exercise testing but angiographically normal coronary arteries and no evidence of epicardial spasm[94] may suffer from some form of microvascular dysfunction. Such a possibility is suggested by stress-induced myocardial perfusion defects on radionuclide studies,[95,96] transient ischemic ST-segment changes during effort test, and reproduction of typical anginal pain with or without ST-segment ischemic changes, by dipyridamole.

However, an ischemic origin of this syndrome is widely questioned because, in the vast majority of studies, no myocardial lactate production or left ventricular dysfunction can be detected during angina and transient ischemic ST-segment changes.[97,98] This apparent paradox could be explained by a patchily distributed coronary microvascular dysfunction, causing dispersed small foci of ischemia. A patchily distributed small vessel constriction may not cause detectable contractile abnormalities or lactate production but rather electrocardiographic (ECG) changes and myocardial perfusion defects when sufficiently confluent.[46,85] This possibility is suggested by observations in animal models, in which ischemia was caused by impaired coronary microcirculation by microspheres[46] or endothelin-1 infusion.[99]

Recent data showing intracardiac production of lipid peroxidation products, which are sensitive markers of ischemia-reperfusion injury,[100] during angina and ischemic ST changes following atrial pacing in syndrome-X patients strongly support the microvascular ischemic origin of the syndrome.[101,102] The occurrence of myocardial ischemia sufficiently confluent and extensive to be detected by phosphorus nuclear magnetic resonance has been reported in 20 percent of syndrome-X patients during the hand-grip stress test.[103]

SITE OF MICROVASCULAR DYSFUNCTION

Theoretically, myocardial ischemia caused by microvascular dysfunction may result from abnormal constriction or failure of adequate dilatation of arteriolar or prearteriolar vessels. Arteriolar constriction as a cause of myocardial ischemia would require constrictor stimuli sufficiently strong to overcome the dilator effect of ischemic metabolites on the arterioles themselves.[46,85] The prearteriolar vessels appear to be a more likely site of microvascular alterations responsible for myocardial ischemia. An increased, patchily distributed prearteriolar vasoconstriction was proposed as a causal mechanism of syndrome X[46,85] (Fig. 37-8).

MECHANISMS OF MICROVASCULAR DYSFUNCTION

In patients with coronary stenoses, the causes of small coronary vessel dysfunction are commonly attributed to atherosclerosis, although such dysfunction may also be related to neurohumoral

stimuli[104] or to vascular abnormalities (e.g., perivascular fibrosis, medial hypertrophy) associated with systemic diseases, such as hypertension or diabetes.[105,106] Small vessel dysfunction in these patients is also frequently attributed to EDRF deficiency on the basis of an abnormal vasomotor response to acetylcholine, but a reduced vasodilator response or a vasoconstrictor response to acetylcholine[107,108] could also be caused by an increased constrictor effect of the drug on smooth muscle cells.

In patients with syndrome X, the mechanisms responsible for microvascular dysfunction can be multiple and not necessarily the same in all patients. They may include (1) structural abnormalities, such as fibrosis and medial hypertrophy;[46] (2) impaired endothelial and nonendothelial vasodilator function;[109] (3) enhanced constrictor response of smooth muscle cells, possibly related to an increased membrane Na^+-H^+ exchanger activity;[110,111] (4) increased release of local vasoconstrictor autacoids-e.g., endothelin 1[112,113] or angiotensin;[46] and (5) abnormal neural stimuli. Evidence of abnormal cardiac sympathetic function was documented by ^{123}I-metaiodobenzylguanidine (MIBG) scintigraphy, which showed total absence of cardiac MIBG uptake in 42 percent of patients and regional defects, matching thallium perfusion defects, in another 33 percent of cases[114] (Fig. 37-9).

Each of these putative mechanisms of microvascular dysfunction may involve a very variable number of prearteriolar vessels. Therefore there may be a spectrum of vascular involvement ranging from very sparse foci of microvascular dysfunction to confluent alteration of all small coronary vessels in large vascular territories.

Acute Thrombosis

Intraluminal thrombi are the most common finding in patients with acute coronary syndromes. Most thrombi are composed of platelets and fibrin in variable proportions and often develop at the site of non-flow-limiting coronary stenoses. Thrombosis may reduce or interrupt blood flow by itself or in combination with local or distal vasoconstriction (triggered by thromboxane, serotonin, and thrombin)[115] (Fig. 37-10). Fresh thrombi may have a different fate. They may (1) grow to occlude the artery; (2) lyse completely; or (3) become organized and contribute to plaque growth.

MECHANISMS OF ACUTE THROMBOSIS

Thrombus formation is the first physiologic self-limiting step of vascular injury repair-but, under some circumstances, it may become a major mechanism of acute disease. Intracoronary thrombosis may result from strong or weak thrombogenic stimuli.[115]

Strong thrombogenic stimuli cause rapid thrombus growth with massive inclusion of red cells in the fibrin mesh (*red thrombi*), leading to persistent vessel occlusion within a few minutes, like in the copper-coil animal model. Strong thrombogenic stimuli may be represented by the mechanical rupture of a lipid-rich atherosclerotic plaque.

Weak thrombogenic stimuli cause slow, progressive deposition of platelets and formation of platelet-fibrin thrombi (*white thrombi*, as in the electrical wire animal model). Weak thrombogenic stimuli may result from the fissure of plaques with low thrombogenic potential or from a local inflammatory activation of the vascular wall caused by infectious or noninfectious stimuli.[40,116-118] Thrombus growth is mainly determined by the intensity, duration, and recurrence of the weak inflammatory stimuli.

Occlusive thrombosis may develop in the presence of strong or weak but persistent thrombogenic stimuli in spite of the continuous dilution of local prothrombotic factors and of the continuous

supply of anticoagulant and fibrinolytic factors by blood flow, as well as in spite of antiplatelet and anticoagulant drug therapy.

Occlusive thrombosis may also be caused by weak, nonpersistent thrombogenic stimuli, but only when associated with prothrombotic or deficient fibrinolytic states and when combined with blood flow stasis resulting from local spasm or from massive distal small vessel constriction.

The hypothesis that thrombosis may occur at the site of identifiable "vulnerable" coronary plaques is attractive and currently stimulates the development of new research tools for their clinical detection. However, plaques may be vulnerable for two different reasons: they may be potential sites of thrombosis because they are prone to mechanical rupture (as they have a large central lipid pool and a thin cap)[119] or because they are the site of inflammatory processes.[45] Plaque vulnerability may last days, weeks, or months.

The different mechanisms responsible for coronary thrombosis or contributing to it and acute coronary occlusion may not have the same prevalence in different geographic, ethnic, age, and sex groups; yet they may influence the individual response to antiplatelet, antithrombotic, and acute reperfusion strategies.

Chapter 37: CORONARY BLOOD FLOW AND MYOCARDIAL ISCHEMIA

CONSEQUENCES OF MYOCARDIAL ISCHEMIA

Myocardial ischemia causes myocardial cells to switch from aerobic to anaerobic metabolism with a progressive depletion of high-energy phosphate stores and impairment of mechanical and electrical function. When prolonged or repetitive, ischemia also modifies cell gene expression, which may contribute to postischemic cell dysfunction.

The most obvious clinical manifestation of myocardial ischemia is anginal pain, but most ischemic episodes are clinically silent. The consequences of myocardial ischemia vary according to its severity, extension, duration, mode of onset, and recurrence and may result in global impairment of contractile function and life-threatening arrhythmias as well as in preconditioning, stunning, hibernation, or myocardial infarction, which occurs when severe ischemia persists for longer than 30 min.

Metabolic Consequences

During ischemia, several metabolic changes occur. ATP is degraded to adenosine, which, diffusing out of cardiomyocytes, causes arteriolar dilation and anginal pain. Free fatty acids and acyl-carnitine accumulate and protein synthesis and turnover are impaired in myocardial cells. Furthermore, myocardial ischemia-reperfusion produces free radicals, which contribute to postischemic myocardial cell dysfunction by reacting with proteins, lipids, and nucleic acids. Impaired Ca^{2+} release from sarcolemma and sarcoplasmic reticulum, cross-bridge cycling inhibition,[120] and competition of H^+ accumulating during ischemia for Ca^{2+} binding sites on contractile proteins thus also contribute to systolic dysfunction. Reduced ATP availability and a decreasing Ca^{2+} reuptake rate into sarcoplasmatic reticulum also prolong the interaction of Ca^{2+} with myofilaments, causing diastolic dysfunction.

Impairment of ion pumps causes loss of intracellular K^+ and accumulation of intracellular Na^+, Ca^{2+}, and H_2O. Alterations of transsarcolemmal ion gradients may cause increased automaticity, triggered activity, and abnormalities of impulse conduction, which favor the development of reentry circuits.[121]

The consequences of ischemia and ischemia-reperfusion injury may not be limited to the myocytes but extend to endothelial cells with inflammatory changes,[122-124] resulting in vasoconstriction and a local thrombogenic tendency.

Effects on Cardiac Function

The effects of myocardial ischemia have been studied in experimental animals by producing a sudden coronary occlusion, by gradually reducing coronary flow at rest, and by increasing M_{VO_2} in the presence of a flow-limiting coronary stenosis. Such experimental models mimic, at least in part, the consequences of myocardial ischemia observed in variant angina, unstable angina, and effort angina, respectively (see ahead).

EFFECTS OF SUDDEN CORONARY OCCLUSION

Occlusion of a major coronary artery is followed within a few seconds by a typical sequence of events that includes a reduction in the velocity of ventricular relaxation and contraction, ST-segment elevation, increased end-diastolic pressure with dyssynchrony (delayed onset of contraction in ischemic myocardial segments), hypokinesis (reduced contractility), akinesis (cessation of contraction), and dyskinesis (paradoxical expansion of affected segment during systole). The sequence of hemodynamic and electrocardiographic events observed in experimental animals is similar to that observed in patients during episodes of occlusive epicardial coronary artery spasm (Fig. 37-11) or during coronary angioplasty

balloon occlusion in patients.[46] It is typically characterized by the following sequence of events: a decrease in peak relaxation -*dp*/*dt*, a decrease of peak contraction *dp*/*dt*, an increase in diastolic pressures, and a fall in systolic and in pulse pressure. In patients with variant angina and coronary occlusive spasm, pain, when present, usually appears only several seconds or minutes later.

EFFECTS OF GRADED REDUCTION OF CORONARY FLOW AT REST

In anesthetized dogs, a 25 percent reduction of basal coronary blood flow through a major coronary branch is associated with increased myocardial extraction of oxygen and with decreased oxygen consumption.[46] Further reductions of flow are followed by a decrease in the rate of left ventricular relaxation and contraction, then by ST-segment depression, elevation of end-diastolic pressure, decreased stroke volume, and, finally, by elevation of the ST segment, which develops when flow is reduced to about 70 percent and myocardial ischemia becomes transmural. Local contractile function in subendocardial layers begins to fall slightly when regional subendocardial flow is reduced by 10 to 20 percent and becomes marked as flow decreases by 50 to 80 percent. Segments with a flow reduction greater than 80 percent show paradoxical movement, with bulging of the left ventricular wall[46] (Fig. 37-12).

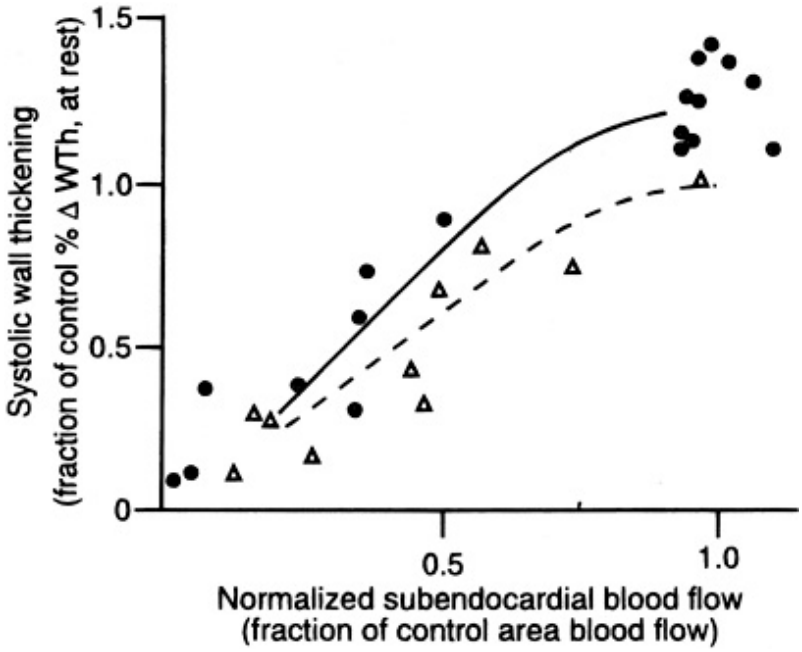

Figure 37-12: Effect of decrease of subendocardial blood flow on systolic segment shortening. In conscious dogs the percentage decrease of subendocardial segment shortening is small until blood flow is reduced by 20 percent. Systolic bulging (segment lengthening) develops only when flow is reduced by more than 80 percent. (From Maseri,[46] modified from Gallagher et al.,148 by permission.)

EFFECT OF INCREASED WORKLOAD IN THE PRESENCE OF A FLOW-LIMITING STENOSIS

When exercise reduces mean transmural blood flow by 30 percent in chronically instrumented dogs with coronary artery stenosis, a mild reduction of systolic thickening is observed, whereas in the normally perfused wall, thickening increases by 20 percent.[46] During exercise, severe regional dysfunction develops when mean flow is about 80 percent lower than in nonischemic myocardial segments. Thus a severe reduction of coronary blood flow is necessary to produce detectable effects on global ventricular contractile function.[46]

At variance with the late occurrence of pain following sudden coronary occlusion by spasm, anginal pain may precede electrocardiographic changes in about one-third of the cases during effort-induced ischemia.[46]

PRECONDITIONING

The term *preconditioning* was originally used with reference to the ability of short periods of ischemia to limit infarct size after subsequent prolonged coronary occlusion in animals. However, it is now used also to include a protective effect of transient ischemia on myocardial suffering induced by subsequent ischemic episodes. An early ischemic preconditioning after an ischemic episode was reported during the initial 2 h (early preconditioning), but a later protection was also reported beginning 24 h after the preconditioning stimulus and extending to 48 h (delayed preconditioning).[125] Findings compatible with early ischemic preconditioning were reported following balloon occlusion during coronary angioplasty, in preinfarction angina, in coronary artery bypass surgery, and in exercise-induced ischemia (warmup phenomenon).[46] In experimental settings, ischemic preconditioning was also shown to reduce ventricular tachyarrhythmias appearing in the ischemic or reperfusion phase of ischemic episodes, and a reduction of ischemia-related ventricular arrhythmias following episodes of transmural myocardial ischemia was reported in patients with vasospastic angina.[126] Preconditioning could partly explain the more favorable prognosis of patients in whom acute myocardial infarction is preceded by unstable angina.[127,128]

The bases of preconditioning are not completely understood. Extrapolation of experimental results to patients should be cautious. Early preconditioning is thought to derive from phosphorylation of a sarcolemmal protein, possibly the ATP-sensitive K^+ channel, resulting from G protein-coupled receptor activation of protein kinase C. Late preconditioning may be mediated by activation of genes encoding for protective proteins such as heat-shock proteins and growth factors (see also Table 37-1).

Table 37-1: Features of Ischemia, Stunning, and Hibernation[a]

	Coronary Blood Flow	Lactate Production	Contractile Function
Ischemia	Markedly reduced	Yes	Impaired
			Recovers after relief of ischemia
Stunning	Preserved	No	Impaired
			Transiently restored by inotropic stimulation
			Recovers spontaneously over time
Hibernation	Reduced in the presence of typical histologic changes	No	ImpairedRecovers only after revascularization

[a]Ischemia is characterized by inadequate perfusion, resulting in lactate production and impaired contractile function. Stunning develops after an ischemia-reperfusion sequence and is characterized by preserved regional blood flow and transient impairment of contractile function, which recovers spontaneously over time. Hibernation may develop after repeated episodes of ischemia-reperfusion, and is characterized by myocardial histologic changes, absence of contraction, reduced M_{VO_2}MVO2, reduced regional blood flow but no lactate production. Contractile function recovers following revascularization over a period of weeks and months.

STUNNING

The term *stunning* defines a prolonged but reversible contractile dysfunction observed after an episode of transient myocardial ischemia. It has been observed in animals following sudden coronary occlusion lasting 10 to 15 minutes or after repeated shorter periods of occlusion as well as in patients after positive exercise tests, in ischemic peri-infarction regions, and following extracorporeal circulation. The spontaneous recovery of cardiac contractile function may take hours or days, depending on the severity and duration of ischemia, but contraction can be transiently restored by inotropic stimuli such as after extrasystolic potentiation or beta-adrenergic drugs. In stunned myocardium, the delayed recovery of contractile function

is associated with a normal average myocardial perfusion in the presence of reduced myocardial oxygen consumption. It is not clear to what extent stunning represents a gradual physiologic recovery from the ischemic insult or a consequence of a reperfusion-induced injury, which could delay or reduce the benefits of reperfusion.

Several components may contribute to stunning.[129] A decreased Ca^{2+} sensitivity of myofilaments, troponin I degradation by Ca^{2+}-activated proteases, Ca^{2+} overload and the generation of free radicals,[130] slow resynthesis of adenosine nucleotides, microvascular damage with leukocyte activation, myocyte electromechanical uncoupling,[131] and extracellular matrix alterations were observed in experimental models (see also Table 37-1).

HIBERNATION

Myocardial *hibernation* was originally defined as a condition of persistent impairment of contractile function at rest, in the presence of reduced M_{VO_2} and coronary blood flow and in absence of ischemia, that partially or totally recovers when myocardial blood flow is restored. The time to functional recovery of hibernated myocardium after revascularization varies from 10 days to 6 months and is related to the severity of structural changes of cardiomyocytes and interstitium.

Hibernation is characterized[132] by progressive loss of sarcomeres, sarcoplasmatic reticulum, and T tubules in cardiomyocytes with glycogen replacement. Mitochondria appear small and scattered and nuclei distorted, with uniformly dispersed heterochromatin. Hibernated myocardial cells have normal ATP, total adenine nucleotides, and phosphocreatine content and exhibit normal glucose uptake and no lactate production. Several of these characteristics suggest that hibernation may be the result of a dedifferentiation process related to changes in gene expression, as hibernated cardiomyocytes show many features of neonatal cardiomyocytes.[132]

Hibernation is caused by a severe reduction of coronary flow reserve, as a result of which any increase in M_{VO_2} and any further reduction in coronary blood flow (e.g., by vasoconstriction or platelet aggregation) results in repeated episodes of myocardial ischemia-reperfusion (see also Table 37-1).

CLINICAL MANIFESTATIONS OF MYOCARDIAL ISCHEMIA

Chest Pain

The most obvious clinical manifestation of myocardial ischemia, irrespective of its multiple causal mechanisms, is angina pectoris. However, myocardial ischemia may occur without angina and angina may occur without detectable signs of myocardial ischemia. Typically anginal pain is retrosternal in location, with a crushing, squeezing, or burning character. It may radiate to the throat, neck, ulnar side of the left and/or right arm, interscapular region, epigastrium, and the jaw and teeth. The intensity of the discomfort can vary greatly, from a mild feeling of retrosternal fullness or tingling in only one dermatome to a diffuse, unbearable pain. These features are totally unrelated to the actual cause of ischemia and are not completely specific for ischemia, as they may also be caused by cardiac nonischemic causes and by extracardiac causes.

Myocardial ischemia, with or without angina, may occasionally present with other symptoms, including dyspnea (when ischemia is extensive with transient impairment of left ventricular function or ischemia of papillary muscles with mitral regurgitation), palpitations, syncope, or cardiac arrest (when ischemia is associated with arrhythmias).

Anginal pain originates from the stimulation of polymodal receptors (more abundant around small coronary vessels) by chemical mediators produced during ischemia.[46] The best studied of such mediators is adenosine. The algogenic effects of adenosine were studied by its intracoronary infusion and are mediated by $alpha_1$ receptors, while its vasodilator effects are mediated by $alpha_2$ receptors.[133]

Comparison of pain location during selective intracoronary infusion of adenosine in the right and left

coronary arteries has shown that, in nearly 70 percent of patients, afferent stimuli from different myocardial regions cannot be discriminated, thus suggesting that they converge on the same neurons of the dorsal roots of spinal cord.[134] In contrast, in the remaining 30 percent of patients, anginal pain during infusion of adenosine in the separate coronary beds caused a different location of pain. The possibility that a different location of pain in the same person reflects a different location of myocardial ischemia has been confirmed in patients undergoing PTCA and with a second myocardial infarction.[135,136] Moreover, convergence of afferent painful stimuli from different visceral organs and somatic dermatomes on the same ascending neurons can cause noncardiac pain to have features indistinguishable from angina. The central transmission of painful stimuli is strongly modulated at the spinal cord level by a "gating" system regulated by descending and afferent stimuli. After modulation at the spinal cord level, afferent stimuli reach thalamic centers and are finally projected to the cortex, where their processing and decoding occur.

Painless Ischemia

The total lack of pain represents one extreme of the spectrum of the possible clinical presentations of myocardial ischemia. Painless ischemia can only be diagnosed by techniques capable of detecting ischemia and depends entirely on their sensitivity and specificity. Continuous ECG recording reveals that about 70 percent of episodes of transient myocardial ischemia do not cause chest pain or any other symptom.[46] The percentage of episodes of silent ischemia is similar in chronic stable angina, unstable angina, variant angina, and microvascular angina. Thus, the presence or absence of pain is totally unrelated to the actual cause of transient ischemia. Furthermore, myocardial infarction (MI) may be totally silent in about 20 percent of the cases.

The reasons why myocardial ischemia does not elicit pain in the majority of cases are multiple.[134] Although angina is less likely to accompany myocardial ischemia when it is brief, there is no strict relationship between duration and extension of ischemia and development of chest pain also in the same patient.

The gating system at the spinal cord and possibly at the thalamic level, together with the cortical decoding of afferent stimuli, probably play a major role in determining the perception of pain. Moreover, personality, emotional status, and previous experience of pain may modulate such perception.

Arrhythmias

Arrhythmias are major potential consequences of acute ischemia, as they are responsible for most of the deaths observed during the early phases of acute MI as well as in variant angina, and thus for sudden death in the community.

During ischemia, increased automaticity, triggered activity, conduction delay and reentry may cause the development of ventricular tachycardia and ventricular fibrillation. Moreover, altered impulse formation and conduction defects may cause asystole and atrioventricular block.

The arrhythmic response to ischemic insult of individual patients is unpredictable but is influenced by the cardiac anatomic background (left ventricular hypertrophy, previous infarction), sympathetic activity (as suggested also by experimental studies on cardiac sympathetic denervation) and nervous autonomic imbalance.

Fatal ventricular arrhythmias are exceptional during mild transient ischemic episodes, but they may develop after the onset or soon after the termination of episodes of severe subendocardial ischemia and in transmural ischemia caused by occlusive spasm or by occlusive thrombosis. Reperfusion arrhythmias, although particularly common in anesthetized animals, are less frequently observed both in patients with variant angina and during myocardial reperfusion in acute MI.[46]

Effects of Persistent Myocardial Ischemia: Myocardial Infarction

In dogs, focal cell necrosis begins about 20 min following coronary flow interruption. Such foci become confluent in subendocardial layers by 40 min, reaching subepicardial layers with a progressive wavefront at about 3 to 4 h. By this time, necrosis has developed, on average, to about 90 percent of its final extension,

which is reached after 6 h.

In patients, the extension of myocardial necrosis depends not only on the area perfused by the occluded vessel, the level of myocardial oxygen consumption, and the presence of collaterals but also on the intermittence of coronary occlusion. Actually, MI is a dynamic process with intermittence of occlusion occurring in about two-thirds of the cases during the initial 6 h.[46] Therefore it is reasonable to undertake reperfusion strategies in all patients irrespective of actual delay from the onset of symptoms as long as ECG shows persistent massive ischemia without completed necrosis. The impairment of global myocardial function depends on the extension of myocardial necrosis. When infarction involves more than 15 percent of the left ventricle, ejection fraction decreases and left ventricular end-systolic volume and pressure increase. When it involves more than 25 percent of the left ventricle, signs of heart failure develop; when it involves more than 40 percent, cardiogenic shock occurs. The development of primary ventricular fibrillation is independent of infarct size but strongly influenced by high adrenergic tone.

Chapter 37: CORONARY BLOOD FLOW AND MYOCARDIAL ISCHEMIA

RELATIONSHIP BETWEEN MECHANISMS OF ISCHEMIA AND CLINICAL SYNDROMES

The mechanisms responsible for the development of ischemia do not influence the location and radiation of anginal pain but may determine specific clinical patterns of anginal episodes that, at least in typical cases, provide useful clues for personalized patient management. Therefore a carefully collected clinical history is the fundamental first step in the assessment of the pathogenetic mechanisms of MI and for the selection of the appropriate sequence of diagnostic tests.

Chronic Stable Angina

Some patients presenting with chronic stable angina report that anginal pain develops predictably only and every time they exceed a rather fixed level of exertion that they learn to recognize and avoid. The pain disappears within 1 to 2 min after the interruption of the effort or after sublingual nitrates. In these patients, the fixed anginal threshold suggests that myocardial ischemia is caused exclusively by an excessive increase in oxygen demand in the presence of a fixed coronary stenosis (*fixed-threshold effort angina*) (see Chap. 40).

On careful questioning, however, the majority of patients with chronic stable angina report that they have "good and bad days" and a variable threshold for angina, which sometimes develops unpredictably for efforts usually well tolerated and occasionally also at rest (*mixed angina*). A variable ischemic threshold, with "good days" during which patients have a good effort tolerance, is suggestive of a strong modulation of residual flow reserve by changes in vasomotor tone at the level of a potential flow-limiting stenosis or in distal vessels; therefore it represents an indication for vasodilator therapy. This indication is supported by a significant increase of effort tolerance on exercise testing following sublingual nitrates. Conversely, a low effort tolerance, persisting after sublingual nitrates, represents a mandatory indication for drugs that reduce M_{VO_2} and for coronary angiography with a view to revascularization procedures.

Syndrome X

Patients with a chronic stable pattern of mixed angina, "ischemic" ST-segment depression, and/or myocardial perfusion defects during stress test, but angiographically normal coronary arteries are classified as having syndrome X.[94] In these patients, angina also predominantly occurs on exertion, typically with a variable ischemic threshold and occasionally at rest, but very seldom at night. Although the location and radiation of pain are often indistinguishable from those of patients with flow-limiting stenosis, some distinct features raise the suspicion of syndrome X: (1) patients usually report persistence of angina for several minutes after the interruption of exertion, and many report attacks lasting over 30 min; (2) they have a poor response to sublingual nitrates, which were also shown to worsen exercise tolerance, in sharp contrast with their established beneficial effect in patients with flow-limiting stenosis (Fig. 37-13); (3) they show a variable individual response to prophylactic long-acting nitrates, calcium antagonists, and beta blockers,[137] possibly because of differences in the underlying causes of microvascular dysfunction; (4) they develop their typical pain (often with transient ischemic ECG changes) during dipyridamole test but without development of left ventricular contractile abnormalities; (5) they often have an enhanced response to painful stimuli,[138] which contributes to explain the paradox of severe angina in the absence of detectable myocardial contractile dysfunction (

Fig. 37-14); and (6) Holter monitoring demonstrates that some episodes of chest pain and ST-segment depression are not associated with tachycardia, and it may show episodes of transient ST-segment depression in patients with a negative exercise test, suggestive of possible episodic occurrence of microvascular constriction.[139]

The diagnosis of syndrome X is confirmed by (1) the evidence of a cardiac origin of pain because of its consistent association with transient ischemic ECG changes and/or myocardial perfusion defects during exercise test or by diagnostic ECG changes on Holter monitoring;[140] (2) normal coronary angiogram; and (3) the exclusion of epicardial coronary spasm on the basis of distinct clinical history, absence of transient episodes of ST-segment elevation, and failure to induce coronary spasm by provocative tests (see also Chap. 40).

Unstable Angina

The characteristic clinical feature of unstable angina is the sudden appearance and/or worsening of angina, with more frequent and prolonged attacks occurring at rest or on efforts that were previously well tolerated. In patients with a de novo angina and those with known ischemic heart disease (in the absence of anemia, fever, hyperthyroidism and tachyarrhythmias), this pattern of presentation suggests a transient, recurring impairment of myocardial perfusion by thrombosis and vasoconstriction. The crescendo, waxing, waning, and persistence of anginal attacks over a period of days and weeks suggests stimuli causing thrombosis and vasoconstriction. A sudden reduction of the ischemic threshold on exertion suggests a rapid development or increased severity of a flow-limiting stenosis by organized thrombus. Many patients continue to present recurrent instability and/or to develop MI in the initial weeks and months following hospital discharge. Unstable patients are also at an increased risk of restenosis following PTCA. The waxing and persistance of instability and restenosis following PTCA are correlated with elevated blood levels of systemic markers of inflammation-for example C-reactive protein[140] and interleukin 6[141]-consistent with the hypothesis that inflammatory cytokines may be an important component of instability.

In the first few days after onset, the presentation of unstable angina may be clinically indistinguishable from that of an acute onset of variant angina, unless repeated short episodes of transient ST-segment elevation are detected on the ECG. The absence of detectable systemic inflammatory markers is a distinctive feature of variant angina as opposed to unstable angina[142] (see also Chap. 41).

Variant Angina

The clinical diagnosis of variant angina can only be suspected when sufficient time has elapsed from the onset of symptoms to allow the emergence of a distinctive pattern of angina. The following features suggest the clinical diagnosis of variant angina: (1) a report of pain occurring predominantly at rest, without apparent cause, more often at night, in the early morning hours or at the same time of the day, usually with preserved effort tolerance (many patients with variant angina report with amazement that they have anginal attacks without apparent cause and yet can perform considerable efforts without symptoms); (2) anginal episodes are usually of short duration (2 to 5 min) and respond to sublingual nitrates within 1 to 2 min (at variance with syndrome X); (3) anginal episodes may occur in clusters of two to three in the early morning hours and then be absent throughout the day; (4) anginal episodes may be associated with syncope caused by ventricular tachycardia/ventricular fibrillation[81] or by complete atrioventricular block; (5) the exercise stress test is usually negative but in some patients it may cause ST-segment elevation during or after the test; the exercise test becomes negative after sublingual nitrate administration.

The clinical suspicion elicited by these features is supported by the demonstration of ST-segment elevation, usually a typical "lesion wave," during angina. The demonstration of ST-segment

elevation can be obtained by chance with a standard 12-lead ECG, by Holter monitoring, or soon after or during the exercise stress test. The diagnosis is confirmed by the angiographic demonstration of spasm occurring spontaneously or following provocative tests. Among these, ergonovine and hyperventilation have a 100 percent specificity but a low sensitivity, whereas acetylcholine seems to have a greater sensitivity but a lower specificity.

The occlusive spasm typically occurs at the site of coronary stenosis, but it may also occur in angiographically normal coronaries, in particular in Asian patients.[143] The diagnosis of variant angina is a mandatory indication for calcium antagonists and nitrates, as beta blockers are totally ineffective.

Myocardial Infarction

In some patients MI develops totally unheralded with the single first episode of uninterrupted anginal pain that brings them to hospital. In others, the final persistent episode of pain is preceded by a typical history of unstable angina. In an intermediate group, the final episode of persistent pain is preceded by one or two isolated anginal attacks, compatible with a hyperacute presentation of preinfarction unstable angina. During the initial 6 h from the onset of symptoms in unselected patients with acute MI, the infarct-related artery recanalizes spontaneously in 40 percent of the cases and exhibits occasional, transient reperfusion in about 70 percent. Spontaneous and early reperfusion seems to be more frequent in patients in whom MI is preceded by unstable angina[144] (see also Chap. 42).

Thus in some patients, coronary occlusion appears to develop like lightning out of a blue sky and to be persistent and uninterrupted, compatible with the fissure of a strongly thrombogenic plaque, with a persistent coronary inflammatory stimulus or with persistent spasm or distal coronary vessel constriction. In some patients with a history of preinfarction unstable angina, the coronary occlusion is transient and very occasional before the final episode; in others, the final coronary occlusion exhibits spontaneous, transient, or persistent recanalization, consistent with waxing, waning, and recurrence of weak inflammatory thrombogenic stimuli.

The presence of systemically detectable inflammatory markers in about 70 percent of patients with Braunwald class IIIB unstable angina and the much higher recurrence of instability among the 50 percent of patients in whom the elevation persists at discharge and at 3 months[145] may represent an objective marker of inflammatory thrombogenic triggers. This possibility is supported by the elevation of such markers at the time of hospital admission in nearly all patients in whom MI was preceded by unstable angina but in less than 50 percent of those in whom MI was totally unheralded.[146] The absence of inflammatory markers also allows an objective distinction of variant angina,[142] which sometimes has a clinical presentation indistinguishable from that of the more common form of unstable angina.

Different pathogenetic components of coronary occlusion are also suggested by the earlier recanalization in response to t-PA observed in patients with preinfarction angina as compared to those with a totally unheralded MI.[127]

The prodromal symptoms of MI also provide clues about its pathogenetic mechanisms. In some patients, MI occurs without any apparent cause; in others, a history of severe psychological distress[147] or of flu-like symptoms can be elicited on careful questioning. These prodromal symptoms may be associated with a different mode of presentation of acute MI and might provide clues of distinct pathogenetic mechanisms, which may not have the same prevalence in different age, sex, geographic, and ethnic groups.

Understanding the precise mechanisms of acute coronary occlusion would allow more effective

coronary reperfusion strategies to be reserved to those patients who are unlikely to respond to simpler ones. The alternative is to treat indiscriminately all patients with the newest, most efficacious, but possibly also more complex and expensive coronary reperfusion strategies. The subgroups of patients that benefit from antiplatelet drugs, anticoagulants, beta blockers, statins, and ACE inhibitors should be identified. Again, the alternative is to prescribe indiscriminately all these treatments to each patient, with the consequent burden of polytherapy, risk of low compliance, and high cost.

Part 6: CORONARY HEART DISEASE
Chapter 38:

DYSLIPIDEMIA, OTHER RISK FACTORS, AND THE PREVENTION OF CORONARY HEART DISEASE

Authors: David J. Maron, Paul M. Ridker, Thomas A. Pearson, Scott M. Grundy

Identification and management of risk factors are essential for preventing coronary heart disease (CHD) in asymptomatic individuals (*primary prevention*) and for preventing recurrent events in patients with established disease (*secondary prevention*). *Risk factor management should be conceived as prevention or treatment of the atherosclerotic disease process itself and, as such, should be included as an integral part of any management plan for the many acute or chronic manifestations of this disease.* The intensity of risk factor intervention should correspond to the patient's level of risk.[1] The presence of unmodifiable risk factors may necessitate more intense management of modifiable risk factors. The 27th Bethesda Conference proposed a classification scheme according to the strength of evidence that risk factor intervention favorably affects outcome.[1] This chapter is organized to reflect that classification scheme (Table 38-1) and reviews risk assessment for primary prevention, reviews CHD risk factors, discusses the efficacy and cost-effectiveness of managing risk factors, and provides practical recommendations for preventive cardiology practice.

RISK ASSESSMENT IN PRIMARY PREVENTION

As detailed in this chapter, the efficacy of secondary prevention of CHD using a variety of therapies has been well established. Therefore, an individual with established CHD or other atherosclerotic disease should be considered at highest risk for a CHD event and deserves the most aggressive evidence-based risk-reduction therapy. The therapeutic success achieved in secondary prevention of CHD has generated enthusiasm for extending this success to primary prevention in clinical practice. The essential issues for primary prevention are the selection of patients and selection of appropriate interventions. The first step in patient selection is to estimate a patient's risk. The key parameter for risk assessment for medical intervention is the *absolute risk*, i.e., the probability of developing CHD over a finite period.

Categories of Absolute Risk

For the sake of simplicity, absolute risk can be divided into three categories: high, intermediate, and low.[2] Patients at high risk deserve aggressive risk-reduction therapy. Those at intermediate risk also deserve medical intervention to the extent that therapy is effective, safe, and cost-effective. Finally, low-risk patients can be encouraged by their physicians to follow public health recommendations for primary prevention of CHD.

Each category of absolute risk can be examined in quantitative terms (Table 38-2). Patients at high risk are those whose absolute risk for CHD equals that of patients who already manifest clinical CHD.[2,3] Evidence from clinical trials of cholesterol-lowering therapy indicates that patients with a prior history of myocardial infarction (MI) have a 10-year risk for recurrent nonfatal or fatal MI of about 26 percent.[3-5] Patients with stable angina pectoris have a 10-year risk for acute MI of about 20 percent.[6,7] Thus, it is reasonable to say that *patients without manifest CHD who have a 10-year*

risk for MI of greater than 20 percent are at high risk. These patients also can be said to have a *CHD risk equivalent.*[3] In accord, *intermediate-risk patients have a 10-year risk for MI of 10 to 20 percent.* Assignment of risk category is first made by measurements of standard risk factors.[2] In some patients, however, estimates of absolute risk may require adjustment on the basis of other kinds of risk factors or the presence of subclinical coronary artery disease.[2] *Low-risk patients are those whose 10-year risk for MI is less than 10 percent.*

Table 38-2: Risk Categories

Risk Category	10-Year Absolute Risk for Myocardial Infarction (%) (Nonfatal + Fatal)
High	>20
Intermediate	10-20
Low	<10

Identification of High-Risk Patients (Coronary Heart Disease Risk Equivalents)

NONCORONARY FORMS OF CLINICAL ATHEROSCLEROTIC DISEASE

Patients in this group include those with peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease. The absolute risk for MI in patients with noncoronary forms of atherosclerotic disease equals that for recurrent MI in patients with established CHD.[8]

TYPE 2 DIABETES

Patients with type 2 diabetes who do not manifest CHD still appear to carry a risk for major coronary events equivalent to that of nondiabetic patients with established CHD.[9] Moreover, many patients with type 2 diabetes have had a silent MI, and many other asymptomatic patients have silent ischemia. This has led the American Diabetes Association to designate type 2 diabetes as a CHD risk equivalent.[10]

HIGH-RISK PATIENTS WITH MULTIPLERISK FACTORS

The category of CHD risk equivalents has been extended to include asymptomatic patients who have multiple risk factors (other than diabetes).[11] A modified version of the Framingham score sheet is presented in Table 38-3. Framingham scores are used to estimate the absolute risk for the development of CHD over the next decade.[12] Table 38-4 shows absolute risk for *hard CHD* (nonfatal and fatal MI) and excludes *soft CHD* (stable and unstable angina). *Hard* CHD seems a better end point for defining CHD risk equivalency because risk-reduction therapy is aimed primarily at reducing risk for MI. When absolute 10-year risk for hard CHD exceeds 20 percent, a CHD risk equivalent is identified.

Table 38-3: Scoring for Global Risk Assessment (Adjusted Framingham Scoring Points for Risk Factors)

Risk Factor	Risk Points	
	Men	Women
Age		
<34	−1	−9
35–39	0	−4
40–44	1	0
45–49	2	3
50–54	3	6
55–59	4	7
60–64	5	8
65–69	6	9

Adjusting Framingham Age Points for Coronary Calcium Scores

Percentile of Calcium Score[a]	Point Adjustment[b]
0–24th	−2
25–49th	−1
50–74th	+1
75–89th	+2
>90th	+3

[a]For percentile of calcium score, see Table 38-5.
[b]The adjustment shown should be substituted for the age score of a given patient, whether men or women.

HIGH-RISK PATIENTS IDENTIFIED BY MAJOR RISK FACTORS PLUS SUBCLINICAL ATHEROSCLEROSIS

Many patients will be found to be at intermediate risk by Framingham scoring (Tables 38-3 and 38-4), i.e., absolute 10-year risk will be 10 to 20 percent.[13] Some of these patients

undoubtedly will be at higher risk because of advanced subclinical coronary atherosclerosis. If the latter could be identified by noninvasive methods, risk could be raised to a level of CHD risk equivalent. The potential utility of noninvasive testing for this purpose has recently been reviewed in the American Heart Association's Prevention V Conference.[2] In the past, noninvasive testing in asymptomatic patients has been contentious. Many investigators are concerned that asymptomatic patients with advanced subclinical atherosclerosis will be labeled as having CHD; if so, patients receiving this label might be referred inappropriately for invasive procedures. *Only if noninvasive techniques are used for risk assessment (prognosis) and not for diagnosis can noninvasive testing be justified for asymptomatic patients.* The goal of such testing thus is to identify persons who will benefit from aggressive medical therapy for risk reduction, not for case finding for invasive intervention. Some authorities question whether the scientific evidence supporting this testing is sufficient to justify its recommendation.[14] Still others doubt that it is cost-effective. Various techniques for noninvasive testing and their utility in risk assessment are reviewed briefly below.

Exercise Treadmill Testing

Exercise treadmill testing identifies patients whose coronary atherosclerosis has advanced sufficiently to produce myocardial ischemia with exercise (see also Chap. 14). A considerable body of data exists on risk prognostication on men of ages 45 to 70 years.[15] Exercise testing has reduced predictive value when the pretest probability for CHD is low. In middle-aged men, the combination of standard risk factors and an abnormal exercise ECG denotes a high risk for developing clinical CHD. Risk for angina pectoris is 12-fold elevated above that of men with a normal test result.[15] Risk for MI is elevated fourfold. These extremely high risk ratios are sufficient to elevate an intermediate-risk category to the level of CHD risk equivalent.

Electron-Beam Computerized Tomography

Electron-beam computerized tomography (EBCT) can be used to identify coronary calcification, which is a close correlate of coronary atherosclerosis.[16-19] As shown by EBCT, coronary calcium increases progressively with advancing age in parallel with coronary atherosclerosis (Table 38-5).[20] The finding of a certain degree of coronary calcium by EBCT (Table 38-5) may provide a means to improve on the risk estimate denoted by age in the Framingham algorithm (Tables 38-3 and 38-4). Patients at apparently intermediate risk with a high calcium score may be reclassified as having a CHD risk equivalent (see also Chap. 17).

Carotid B-mode Ultrasonography

Carotid B-mode ultrasonography, which measures the intimal-medial thickness (IMT) of carotid arteries, provides an independent approximation of coronary atherosclerosis.[2] The extent of carotid atherosclerosis correlates with coronary atherosclerosis.[21-23] Recent reports indicate that carotid IMT carries independent predictive power for development of CHD.[24,25] Like coronary calcium scores, IMT scores could be used to replace age as a risk factor in the Framingham algorithm.[3,26] A high IMT score thus could elevate some apparently intermediate-risk patients to the level of CHD risk equivalent.

INFLAMMATORY MARKERS

Inflammatory markers also may improve risk prognostication in apparently intermediate-risk patients. For example, high-sensitivity C-reactive protein has been reported to carry independent predictive power.[27,28] An elevated concentration of circulating inflammatory markers might point to the presence of unstable coronary lesions. If this is confirmed, abnormalities in inflammatory markers could be used to raise a finding of intermediate risk by conventional risk factors to a

CHD risk equivalent.

UNDERLYING AND PROVISIONAL RISK FACTORS

Finally, should *underlying risk factors*-e.g., obesity, physical inactivity, diet, genetic factors, and socioeconomic status-and *provisionally atherogenic risk factors*-e.g., elevated concentrations of triglycerides, lipoprotein(a), [Lp(a)], small dense low-density lipoprotein (LDL) particles, homocysteine, and coagulation factors-be used to adjust the risk of patients found to be at intermediate risk by Framingham scoring? The best approach may be to attempt to modify these factors directly through appropriate therapy, but not to use them in risk assessment. Nevertheless, this question is contentious and its answer unresolved.

RISK ASSESSMENT IN ELDERLY PATIENTS

The predictive power of conventional risk factors declines in older patients, and age becomes the predominant risk factor. Thus, the reliability of the Framingham algorithm is suspect in people over age 65. For this reason, measures of myocardial ischemia, coronary plaque burden, or markers of inflammation could be especially useful in differentiating between high-risk and intermediate-risk elderly patients. The demonstration that aggressive medical therapy significantly reduces risk for CHD in the older population increases the need to define absolute risk in this population more accurately.

Intermediate-Risk and Low-Risk Patients

For patients found to be at intermediate risk by Framingham scoring, additional noninvasive evaluation for subclinical atherosclerotic disease may be considered to define their risk status further (see above). Patients at intermediate risk by the Framingham algorithm deserve medical intervention. Primary prevention is for the long run. Even though these patients are not at high absolute risk for the short term, their risk mounts over time. In view of the proven effectiveness of risk-reduction therapies, there is a growing debate over whom among intermediate-risk patients should receive drug therapy for risk reduction. The issue revolves around efficacy, safety, and cost-effectiveness of drug therapies. Advances in pharmacologic therapy promise to improve safety and to reduce costs; therefore, in the future, it should be possible to extend the benefits of risk-reducing drugs to more patients. In addition, advances in nondrug therapies may also make these options more attractive to many patients.

An important question is how to manage patients with a single categorical risk factor but who are otherwise at low risk. A fundamental principle of primary prevention is that *all categorical risk factors must be treated, regardless of absolute risk.*[29] For example, cigarette smoking can cause cancer and cardiovascular disease even in the absence of other risk factors. Hypertension alone can cause stroke, heart failure, and kidney failure. Therefore, patients with categorical risk factors must not be ignored even if they are found to have a low absolute risk by Framingham scoring (Tables 38-3 and 38-4).

Chapter 38: DYSLIPIDEMIA, OTHER RISK FACTORS, AND THE PREVENTION OF CORONARY HEART DISEASE

RISK FACTORS FOR WHICH INTERVENTIONS HAVE PROVED TO LOWER RISK OF CORONARY HEART DISEASE

Dyslipidemia

LOW-DENSITY LIPOPROTEIN CHOLESTEROL

Evidence of several types supports the concept that LDL is the primary atherogenic factor, and controlled clinical trials show that lowering LDL reduces the risk for CHD. Accordingly, the National Cholesterol Education Program (NCEP)[8] has identified LDL cholesterol as the primary target of lipid-lowering therapy. Five decades of research on the role of LDL in the pathogenesis of CHD represents one of the major advances in modern medicine and public health.[30] This evidence is summarized briefly.

Low-Density Lipoprotein as the Primary Atherogenic Agent

Many studies in laboratory animals indicate that raising serum levels of LDL and related lipoproteins will initiate and sustain atherogenesis.[31] Moreover, humans with genetic forms of severely elevated LDL exhibit premature atherosclerotic disease.[32] Both of these examples demonstrate that elevated LDL alone, without the need for other CHD risk factors, is independently atherogenic. For many years, it was believed that the major action of LDL was merely to deposit its cholesterol within the arterial wall. More recently, LDL has been found to be a proinflammatory agent:[33] it sets into motion the chronic inflammatory response that is the hallmark of the atherosclerotic lesion. Elevated LDL appears to be involved with all stages of atherogenesis: endothelial dysfunction, plaque formation and growth, plaque instability and disruption, and thrombosis. Elevated LDL-cholesterol levels in the plasma lead to increased retention of LDL particles in the arterial wall, their oxidation, and the secretion of various inflammatory mediators and chemoattractants[35] (see Chap. 35). One sequela of this is the disruption of endothelial cell function by oxidized LDL,[35] with subsequent loss of production of nitric oxide. Treatment of elevated LDL-cholesterol levels has been shown to reestablish normal coronary vasodilatory response to acetylcholine.[36,37] LDL is also a potent mitogen for smooth muscle cells.

The primacy of LDL as a pathogenic agent is supported by epidemiologic data of several types. In different populations, the risk for CHD is positively correlated with the serum total cholesterol level;[38] the total cholesterol level in turn is highly correlated with LDL-cholesterol levels.[8] The association between serum cholesterol levels and CHD risk is curvilinear (or long-linear).[38] Risk rises exponentially at higher cholesterol levels. In populations that have very low total (and LDL) cholesterol, risk for CHD likewise is low, even when other CHD risk factors (cigarette smoking, hypertension, and diabetes) are common.[32] This latter observation strongly suggests that an elevated LDL cholesterol is the *primary* risk factor.

Primary and Secondary Prevention

There is a long history of clinical trials of cholesterol-lowering therapy that have included dietary and drug trials.[30] One trial also induced cholesterol lowering by intestinal surgery.[39] Some trials have included patients with established CHD (secondary prevention), and others recruited patients without CHD (primary prevention). The aggregate results of early trials, both primary and secondary prevention, demonstrated that cholesterol-lowering therapy (or lipoprotein modification) reduces risk for CHD.[40] However, earlier trials failed to show that cholesterol reduction decreased total mortality.[40,41] This latter deficiency left many clinicians skeptical of the benefits of cholesterol-lowering therapy.

The introduction of HMG-CoA reductase inhibitors (statins), which are powerful LDL-lowering drugs, made possible a more effective test of the cholesterol hypothesis.[42,43] Since 1993, five major trials with statins have been published: three secondary prevention[4,5,44] and two primary prevention trials.[45,46] The results of these studies are summarized in Table 38-6. All trials showed a marked reduction in major coronary events. Three found a reduction in total mortality.[5,44,45] No increases in noncardiovascular mortality occurred in any of the trials. These trials documented convincingly that cholesterol-lowering therapy is both safe and effective for reducing CHD risk.

In this same time period, a series of angiographic trials was performed to determine whether reducing LDL-cholesterol levels would decrease progression or promote regression of coronary atherosclerotic lesions. These trials typically employed aggressive cholesterol-lowering therapy, often with combined drug regimens. Indeed, most studies revealed that marked reductions of LDL levels will slow progression, and in some cases promote regression, of coronary lesions.[47,48] Although measurable angiographic changes in lesion size were small, the incidence of major coronary events was reduced strikingly. This observation engendered the concept that LDL reduction *stabilizes* coronary lesions rather than causing them to shrink markedly. Seemingly, LDL lowering modifies lesion structure and composition more than it changes lesion size. Consequently, short-term cholesterol-lowering therapy appears to reduce the likelihood of coronary plaque rupture and thrombosis.

Practice Recommendations for Low-Density Lipoprotein Lowering

LDL lowering can be accomplished with nondrug and drug therapies. *The importance of nondrug therapies must not be minimized.* Chief among them are reducing intake of cholesterol-raising fatty acids (saturated and *trans* fatty acids) and dietary cholesterol.[8] The major sources of dietary saturated fatty acids are dairy fats (e.g., milk, butter, cream, cheese, and ice cream) and animal fats [e.g., fatty cuts of meat (especially hamburger), fatty processed meats, lard and tallow]. *Trans* fatty acids are present in shortening, hard margarine, and processed foods containing these forms of fat. Rich sources of dietary cholesterol are eggs, dairy fats, and other animal products. Current intake of cholesterol-raising fatty acids in the United States is in the range of 15 percent of total calories. For patients on cholesterol-lowering therapy, this should be reduced to less than 7 percent. Dietary cholesterol should be lowered to less than 200 mg/day. Achieving a desirable body weight will reduce LDL-cholesterol levels in most overweight patients and will decrease risk for CHD in several other ways.[49]

There is growing interest in obtaining further risk reduction by use of dietary adjuncts. A daily intake of 3 g/day of plant stanols will reduce LDL-cholesterol concentrations 10 to 15 percent beyond that which can be achieved by reducing cholesterol-raising fatty acids and cholesterol in the diet.[50] Highintakes of dietary fiber will produce another 3 to 5 percent decrease in LDL levels.[51] Unsaturated fatty acids (monounsaturated, *n*-6 polyunsaturated, and *n*-3 polyunsaturated fatty acids) will lower LDL and may reduce global risk for CHD via several other mechanisms.[52]

Statins head the list of cholesterol-lowering drugs. Table 38-7 compares the efficacy of the currently available statins in patients without hypertriglyceridemia. Most patients tolerate statins with few side effects. Occasional patients will have a mild rise in liver transaminases, but this change is currently not believed to be an indication of hepatotoxicity. Rare patients will exhibit signs and symptoms of myopathy. This side effect is more likely to occur in patients who have chronic renal failure or liver disease or who are on drugs that utilize or inhibit the cytochrome P450 3A4 pathway. For every doubling of the dose of a statin, the LDL-cholesterol level will fall by about 6 percent; a more efficacious way to enhance LDL lowering is to combine statins with bile acid sequestrants. For patients with borderline elevated triglycerides (200 to 400 mg/dL) and high LDL, niacin or a statin is an acceptable first-line drug. When triglycerides exceed 400 mg/dL, a fibrate or niacin is usually the most appropriate first-line agent.

Table 38-7: Comparative Efficacy of the Six Currently Available Statins on Lipids and Lipoproteins in PatientsWithout Hypertriglyceridemia

Statin Drug (mg)						Change in Lipid and Lipoprotein Levels (%)			
Atorvastatin	Simvastatin	Lovastatin	Pravastatin	Fluvastatin	Cerivastatin	Total	LDL	HDL	Triglycerides
-	10	20	20	40	0.2	-22	-27	+4-8	-10-15
10	20	40	40	80	0.4	-27	-34	+4-8	-10-20
20	40	80	-	-	-	-32	-41	+4-8	-15-25
40	80	-	-	-	-	-37	-48	+4-8	-20-30
80	-	-	-	-	-	-42	-55	+4-8	-25-35

Note: For the purpose of illustration, the lipid and lipoprotein responses are based on short-term clinical trials and are approximations of what might be observed in clinical practice.
Abbreviations: HDL = high-density lipoprotein; LDL = low-density lipoprotein.

Goals of Therapy Lowering Low-Density Lipoprotein

For patients with established CHD, the NCEP recommends an LDL-cholesterol goal of ≤100 mg/dL.[8] This recommendation is based on the combined data from epidemiologic studies, angiographic trials, and end-point trials. New clinical trials have been initiated to define the optimal LDL-cholesterol goal for secondary prevention. However, the NCEP contends that multiple lines of evidence already converge to support an LDL-cholesterol target of ≤100 mg/dL.[53] The American Heart Association recommends starting cholesterol-lowering drugs immediately in all CHD patients when the LDL-cholesterol level is >130 mg/dL.[54] Whether to initiate cholesterol-lowering drugs in patients whose baseline LDL-cholesterol is in the range of 100 to 129 mg/dL is unsettled. Without question, these patients should receive maximal nondrug therapy, possibly including dietary adjuncts (see above). Such therapy alone will often achieve the LDL-cholesterol goal of ≤100 mg/dL.

For patients with noncoronary forms of atherosclerotic disease, the NCEP also recommends an LDL-cholesterol goal of ≤100 mg/dL.[8] This is because other atherosclerotic disease constitutes a CHD risk equivalent. Patients with CHD risk equivalents should have the same goal for LDL cholesterol as patients with known CHD, i.e., ≤100 mg/dL.

For patients at intermediate risk (Table 38-2), a reasonable LDL-cholesterol goal is <130 mg/dL. The last NCEP report essentially made such a recommendation, although the method for establishing CHD risk was not with the Framingham algorithm (Tables 38-3 and 38-4). Rather it recommended counting categorical risk factors (Table 38-8), which is less precise for estimating absolute risk. Most men over age 65 who are not found to be at high risk can be considered to be at intermediate risk; their LDL-cholesterol goal should be <130 mg/dL. Women under age 55 generally are at lower risk than men of equivalent age and should be evaluated by Framingham scoring for risk stratification. The strategy for achieving an LDL-cholesterol level <130 mg/dL should be initiated with nondrug therapy, but some patients undoubtedly will require LDL-lowering drugs.

Table 38-8: National Cholesterol Education Program Risk Categories for Primary Prevention

Intermediate-to-high risk
Two or more major risk factors in the presence of LDL cholesterol ≥160 mg/dL[a]
▪ Cigarette smoking ▪ Hypertension (blood pressure >140/90 mmHg) or on treatment for hypertension ▪ Low HDL cholesterol (<35 mg/dL) ▪ Age (men >45 years; women >55 years or postmenopausal) ▪ Family history of premature coronary heart disease ▪ Diabetes mellitus
Low risk
Zero to one risk factor in the presence of LDL cholesterol ≥160 mg/dL

[a]Subtract one risk factor if HDL cholesterol >60 mg/dL.

ABBREVIATIONS: HDL = high-density lipoprotein; LDL = low-density lipoprotein.
SOURCE: From National Cholesterol Education Program,[8] with permission.

Finally, for patients who are at low risk (Table 38-2), the LDL-cholesterol goal is <160 mg/dL. This target can be considered to be a minimal goal, but it must be recognized that the desirable LDL in primary prevention is <130 mg/dL.[8] Most low-risk patients, however, are not candidates for cholesterol-lowering drugs unless their LDL-cholesterol levels are very high, e.g., >190 mg/dL. In low-risk patients whose baseline LDL-cholesterol concentration is in the range of 160 to 189 mg/dL, clinical judgment is required whether to start cholesterol-lowering drugs.[8] Most patients whose LDL is in this range should achieve an LDL-cholesterol level of < 160 mg/dL with maximal nondrug therapy including dietary adjuncts.

Cost-Effectiveness of Drug Therapy for Lowering Low-Density Lipoprotein

Cost-effectiveness analysis is used to consider both the effectiveness of an intervention and its cost and is commonly expressed as a ratio of cost in dollars per quality-adjusted years of life gained[1] (see also Chap. 94). The validity of the assumptions used to determine direct and indirect cost is critical to computing an accurate ratio. By convention, less than $20,000 per year of life saved is considered highly cost-effective, $20,000 to $40,000 is relatively cost-effective, and greater than $60,000 is considered expensive. Studies of the cost-effectiveness of cholesterol lowering have demonstrated the importance of effective therapies in patients at highest risk. Studies of LDL-cholesterol reduction with statins have demonstrated cost-effectiveness in CHD patients. Estimates of cost per year of life range from $22,900 in asymptomatic 55- to 64-year-old men with total cholesterol <250 mg/dL to actual cost savings in hypercholesterolemic, male CHD patients 45 to 54 years old.[55] In a direct cost analysis of the Scandinavian Simvastatin Survival Study, cost of simvastatin therapy ranged from $3800 for 70-year-old men with a cholesterol level of 309 mg/dL to $27,400 for 35-year-old women with a cholesterol level of 213 mg/dL.[56] When indirect costs were considered, the results ranged from a savings in the youngest patient to a cost of $13,300 per year of life gained in older patients. In contrast, the use of less effective agents, such as bile acid-binding resins, in low-risk, asymptomatic patients does not appear to be cost-effective.[57]

ATHEROGENIC DYSLIPIDEMIA: HYPERTRIGLYCERIDEMIA, LOW HIGH-DENSITY LIPOPROTEIN, AND SMALL DENSE LOW-DENSITY LIPOPROTEIN

Although high LDL is the primary lipid risk factor, other lipid parameters increase the risk of CHD in persons with or without an elevated LDL cholesterol. Specifically, the combination of *elevated concentrations of triglycerides, small dense LDL and low levels of high-density lipoprotein (HDL) is referred to as atherogenic dyslipidemia.*[58] This is a complex dyslipidemia that usually results from a

generalized metabolic derangement. Although an elevated LDL cholesterol deserves primary emphasis for management, atherogenic dyslipidemia is assuming increasing importance as a contributor to CHD because of the growing prevalence of obesity in the United States and worldwide.[58] Most patients with atherogenic dyslipidemia have a generalized metabolic disorder called *insulin resistance*. This syndrome is described later in this chapter.

Relation of Atherogenic Dyslipidemia to Coronary Heart Disease

A long-standing debate is whether the individual components of atherogenic dyslipidemia are independent risk factors. This question has been difficult to resolve because each of the three lipid components is highly correlated with the other two. Nevertheless, there is growing evidence for independent atherogenicity of each component. For triglycerides, *recent meta-analyses of multiple prospective studies strongly suggest that elevated serum triglycerides are an independent risk factor for CHD*.[59,60] *Other prospective studies show that a low HDL-cholesterol level is an independent risk factor*.[61,62] Two important mechanisms by which HDL is thought to play a protective role against atherosclerosis are reverse cholesterol transport and inhibition of LDL oxidation. *A lesser body of data also suggests that small, dense LDL particles are more atherogenic than normal-sized LDL*.[63] Atherogenic dyslipidemia is commonly accompanied by the other atherogenic risk factors of the metabolic syndrome[58] (see the section "Insulin Resistance Syndrome" below).

Primary and Secondary Prevention Among Subjects with Atherogenic Dyslipidemia

No controlled clinical trials have been conducted to address specifically whether modifying atherogenic dyslipidemia will reduce risk for CHD. Indirect evidence comes from post hoc analyses of large clinical trials and from trials using drugs that modify atherogenic dyslipidemia. The latter drugs include nicotinic acid and the fibric acids. These drugs have only small effects on LDL levels, and most changes occur in the components of atherogenic dyslipidemia. The results of clinical trials[64-69] in which nicotinic acid or a fibric acid was used are shown in Table 38-9. None of these trials except for the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT)[69] specifically targeted patients with atherogenic dyslipidemia. Nevertheless, most of the trials either showed a significant reduction in coronary events by drug therapy or a trend toward a reduction. In the Helsinki Heart Study,[65] the Stockholm Ischemic Heart Disease Study,[67] and the Bezafibrate Infarction Prevention Study,[68] the most favorable results were observed in patients with elevated triglycerides, an indicator of atherogenic dyslipidemia. These trials generally did not reveal a reduction in total mortality, nor were they statistically powered to do so. Nonetheless, taken as a whole, these trials are strongly suggestive that modification of atherogenic dyslipidemia by drug therapy will reduce the risk for CHD. This likelihood is enhanced by the findings of angiographic trials that fibrates slow progression of coronary atherosclerosis.[65,70]

It must be noted that statins also modify atherogenic dyslipidemia by reducing remnants of triglyceride-rich lipoproteins, reducing concentrations of small dense LDL, and by raising HDL-cholesterol levels modestly. Thus, some of the risk reduction from the statin trials could be related to favorable modification of the component of atherogenic dyslipidemia as well as to lowering of LDL-cholesterol levels.

Practice Recommendations for Atherogenic Dyslipidemia

First-line treatment of atherogenic dyslipidemia is weight control and physical activity. Most patients with atherogenic dyslipidemia are either overweight [body mass index (BMI), 25 to 29 kg/m^2] or obese (BMI ≥30 kg/m^2).[49] Weight reduction in these patients often will improve the lipoprotein abnormalities associated with this form of dyslipidemia.[49] Introduction of regular physical activity will further correct the lipoprotein pattern. Not only will weight control and regular exercise improve atherogenic dyslipidemia, it also will mitigate the other components of the metabolic syndrome.[71] The increasing prevalence of obesity and physical inactivity in the United States has caused a corresponding increase in the metabolic syndrome among Americans. This unfortunate trend threatens to reverse the advances made in reducing morbidity and mortality from cardiovascular disease over the past two decades. It also poses a challenge to physicians to modify their practice to place more emphasis on lifestyle changes.

Both fibric acids and nicotinic acid will improve the lipoprotein pattern in patients with atherogenic

dyslipidemia. Fibric acids have been shown to activate nuclear receptors (PPAR alpha) that favorably modify regulators of lipoprotein metabolism in the liver.[72] The mechanism of action of nicotinic acid is not known, but its effects are similar to those of fibric acids, except that nicotinic acid is more effective for raising HDL-cholesterol levels.[73] Unfortunately, nicotinic acid has several side effects that prevent its use in high doses in many patients. Nonetheless, the drug is usually well tolerated in moderate doses (1.0 to 1.5 g/day).

The primary goal of lipid therapy in patients with atherogenic dyslipidemia is to reduce LDL-cholesterol concentration to the targets recommended for primary and secondary prevention. In many patients, statin therapy will be required to achieve the LDL target. If abnormalities persist after reaching the LDL goal, renewed efforts at weight control and increased physical activity may be indicated. If these measures are not successful, a second lipid-lowering drug may be added to modify these other lipoproteins. Either a fibric acid or nicotinic acid can be employed as the second agent to achieve the secondary NCEP goals of HDL > 35 mg/dL and triglycerides < 200 mg/dL. The combination of fibrates with a high dose of a statin should be avoided because of the increased risk of myopathy.

Some investigators believe that an appropriate target of therapy in patients with atherogenic dyslipidemia is non-HDL cholesterol.[74,75] This fraction includes cholesterol in LDL and in remnants of triglyceride-rich lipoproteins. If non-HDL cholesterol is taken as a target of therapy, the goals of therapy are 30 mg/dL higher than the LDL-cholesterol goals for secondary and primary prevention. An alternate target is the serum triglyceride level. Although clinical trials are suggestive of benefit, there is no universal agreement among authorities that additional risk reduction is achieved by targeting atherogenic dyslipidemia beyond LDL cholesterol.

LIPOPROTEIN(a)

Lp(a) consists of an LDL particle linked via a disulfide bond to an apolipoprotein(a) [apo(a)] polypeptide chain. Because of homology between apo(a) and plasminogen, Lp(a) has been hypothesized to serve as a competitive inhibitor for plasminogen binding and thus may inhibit endogenous fibrinolysis.[76] Lp(a) is largely genetically determined, and distributions differ between men and women, as well as between races.

Several retrospective case-control studies support the view that Lp(a) is an independent risk factor for thromboembolic disease. However, results of the major prospective studies evaluating baseline Lp(a) concentration and future risks of MI and stroke have been inconsistent.[77-83] One possibility to explain these divergent results may relate to the fact that Lp(a) appears to be a greater marker of risk among patients with hypercholesterolemia[78,84] or among younger individuals only.[85] Another possibility is that electrophoretically detected Lp(a) may be a better marker than actual plasma level.[86,87]

Primary and Secondary Prevention

Although nicotinic acid and estrogen appear to reduce Lp(a) levels in some patients, no clinical trials have been conducted to test whether reducing plasma levels results in reduced risk.

Practice Recommendations

It is not yet clear whether Lp(a) provides information independent of the conventional lipid profile, and no recommendation for screening can be made. If elevated levels prove clearly to increase risk among hypercholesterolemic individuals, it may be prudent to lower LDL-cholesterol levels even more aggressively in such individuals than current guidelines dictate. Knowledge of Lp(a) levels may also be useful in the selection of LDL-lowering drugs (e.g., niacin) and may identify a possible treatable cause in the occasional patient with CHD and none of the major risk factors. Unfortunately, many commercial assays for plasma Lp(a) are poorly standardized.[88]

Atherogenic Diet

An atherogenic diet and a lack of physical activity are considered leading preventable causes of death,

second only to tobacco use.[89] Considerable epidemiologic data indicate that populations with diets high in cholesterol and animal fats have high rates of CHD.[90,91] Conversely, those populations consuming large amounts of calories as vegetables, cereals, and fish have lower rates of CHD.[90] Countries that increased their animal fat consumption during the 1970s and 1980s increased their CHD mortality rates, while those that decreased their annual fat consumption showed CHD mortality reductions.[92] Similarly, populations consuming larger amounts of sodium in their diet have higher average blood pressures.[93] Caloric imbalance, in part due to excess calorie consumption, is related to a rising prevalence of obesity. On an individual basis, recent clinical trials of modified diets have demonstrated reductions in angiographic progression[94] and in recurrence of clinical disease.[95]

It has been assumed that the harmful effects of the *Western* diet have been mediated by saturated fats, dietary cholesterol, and sodium, via their effects on traditional risk factors such as LDL cholesterol, body weight, diabetes, and blood pressure. A portion of the effect of a Western diet appears to be attributable to these factors. However, there is evidence for mechanisms other than the traditional risk factors. The Western Electric Study adjusted for these factors and continued to find an independent risk associated with dietary cholesterol.[96] The Lyon Diet Heart Study compared a Mediterranean-type diet high in alpha-linolenic acid with a Western diet and showed a 65 percent reduction in recurrent coronary events despite no demonstrable change in any of the traditional risk factors.[95] Mechanisms suggested as explanatory of these benefits include antioxidant, anti-inflammatory, and antiplatelet effects. This apparent independent benefit of a diet low in saturated fat, cholesterol, and sodium, and high in monounsaturated fats, fruits, vegetables, and fish provides the rationale for inclusion of *atherogenic diet* as a separate, modifiable risk factor.

PRIMARY PREVENTION

Reduction in the dietary consumption of animal fat, cholesterol, and sodium should be the mainstay of population-wide coronary disease prevention. Population-wide cholesterol reductions observed in the United States from 1979 to 1991 are attributed solely to changes in dietary consumption patterns.[97] Two older clinical trials of long-term inpatients demonstrated reductions in coronary endpoints of 34 to 50 percent among patients on low saturated fat and cholesterol diets.[98,99] Therefore, *dietary interventions should be the initial step in the treatment of dyslipidemia, hypertension, diabetes, and obesity.*

SECONDARY PREVENTION

Studies of low-fat diets, such as the STARS Trial[100] and the Lifestyle Heart Study[94] have used angiographic end points and shown a marked reduction in LDL cholesterol and a reduction in new or progressive coronary stenoses. However, these studies are too small to test for clinical end-point reduction. The Oslo Diet-Heart Study demonstrated a significant reduction in reinfarction rates with a low saturated fat diet as well as a smoking cessation program.[101] As noted, the Lyon Diet Heart Study, with a Mediterranean-type diet enriched in alpha-linolenic acid, demonstrated a 65 percent reduction in recurrent cardiac events and death over a 4-year period of follow-up.[95] *The magnitude of benefit was similar to or greater than those shown in numerous trials of lipid-lowering drugs.*

COST-EFFECTIVENESS

Dietary interventions might be targeted at the general population or at high-risk groups such as coronary disease patients. Population-wide interventions to alter eating behaviors intend to make relatively small changes in dietary habits in a large number of people. Studies from Finland[102] and the United States[103] suggest that population-wide education programs can reduce LDL-cholesterol levels 3 to 4 percent at a cost of $4 to $10 per person per year. Using a model to project benefits of such programs, Goldman et al. predicted that the Finnish program would cost $10,000 per year of life saved, whereas the U.S. program would actually be cost saving.[104] The cost-effectiveness of such a population-wide intervention was compared with a more individualized dietary intervention in a study of Norwegian men.[105] The population-wide approach cost approximately $20 per year of life saved versus $20,000 per year of life saved for the program of individual counseling. *Both approaches are considered highly cost-effective and favorable to drug treatment in that study.*

PRACTICE RECOMMENDATIONS

The current dietary recommendations emphasize a wellbalanced diet low in saturated fat, cholesterol, and sodium, while rich in fruits and vegetables.[102] Very low fat diets are poorly complied with and have little long-term safety and efficacy data to support them.[106] A diet with less than 30 percent of calories from fat is generally recommended, but with caloric content compatible with maintenance of ideal body weight. For patients with vascular disease or hyperlipidemia, less than 7 percent of calories from saturated fat and less than 200 mg of dietary cholesterol per day are suggested. Monounsaturated fats and omega-3 fatty acids from fish may be a beneficial source of calories, as compared with carbohydrates.[107] Consultation with a registered dietitian or other nutrition specialist can be recommended as part of a risk-modification program in high-risk patients.

Cigarette Smoking

Strong dose-responsive relationships between cigarette smoking and CHD have been observed in both sexes, in the young and in the elderly, and in all racial groups.[108] Cigarette smoking increases risk two- to threefold and interacts with other risk factors to multiply risk. There is no evidence that filters or other modifications of the cigarette reduce risk.[109] Pipe smoking and cigar smoking, when not inhaled, as well as oral tobacco use, whether chewing tobacco or snuff, carry rather small risks but are related to later resumption of cigarette smoking. Clearly, cigarette smoking remains a leading preventable cause of mortality, much of it due to cardiovascular disease.

Whereas active cigarette smoking has long been established as a cardiovascular risk factor, exposure to environmental tobacco smoke, or passive smoking, has increasingly been recognized as a modifiable risk factor.[110,111] In a recent meta-analysis of 18 epidemiologic studies, exposure to tobacco smoke by nonsmokers was consistently associated with a 20 to 30 percent increase in risk.[112] This is in addition to an increased risk for respiratory tract cancers and other smoking-related diseases.

Pathophysiologic studies have identified a panoply of mechanisms through which cigarette smoking may cause CHD. Smokers have increased levels of oxidation products, including oxidized LDL.[113] Cigarette smoking also lowers the cardioprotective levels of HDL. These effects, along with direct effects of carbon monoxide and nicotine, produce endothelial damage. Possibly through these mechanisms, smokers have increased vascular reactivity.[113,114] The reduced capacity of the blood to carry oxygen also lowers the threshold for myocardial ischemia and increases the risk of coronary spasm. Cigarette smoking is also related to increased levels of fibrinogen and increased platelet aggregability.[115]

PRIMARY PREVENTION

Cessation of smoking is associated with a precipitous fall in CHD events. *In a previous smoker, the relative risk declines nearly to that of a nonsmoker in a year or less.*[116] It is estimated that a 35-year-old who quits smoking extends survival by 3 to 5 years,[117] with much of the improved life expectancy caused by a reduction in CHD deaths.

SECONDARY PREVENTION

The risk of a recurrent event in a patient surviving an MI is strikingly reduced by smoking cessation. Compared with a patient who continues to smoke, the risk of recurrence can be reduced by 50 percent.[118,119] *The benefits of achieving complete abstinence from smoking for a patient with CHD compare favorably with the health benefits of any intervention in modern cardiology.*

COST-EFFECTIVENESS

Interventions to achieve smoking cessation are among the most cost-effective in either primary or secondary prevention, with or without the use of nicotine replacement therapy.[120,121] Physician counseling of middle-aged patients without vascular disease is estimated to cost only $1000 to $1400 per year in men and $1700 to $3000 per year in women.[122] The use of nicotine gum by these patients increased the cost to up to $9000 per

year in men and $13,500 per year in women.[123] In contrast, counseling to achieve smoking cessation in MI patients is exceptionally cost-effective, costing only $250 per year of life saved.[124]

PRACTICE RECOMMENDATIONS

Nothing less than complete cessation of smoking and other tobacco use should be acceptable in patients with cardiovascular disease. Moreover, the home and work environments to which patients return should be smoke free, both to encourage cessation and to reduce the risk from passive smoking. Cardiovascular specialists often have unique and time-limited opportunities to influence the behaviors of patients. After an acute event, the patient and their family members may be especially receptive to a smoking cessation intervention.

Smoking Cessation Clinical Practice Guidelines were first published by the Agency for Health Care Policy and Research in 1996 and form the basis for a successful smoking cessation program.[125] Those guidelines emphasize that tobacco use status be documented in every patient and that every smoker should be offered one or more of three effective treatment interventions. Even a brief intervention may be effective and should, at a minimum, be provided to every patient who uses tobacco (Table 38-10). Three elements of a treatment program found to be effective include social support, skills training/problem solving, and nicotine replacement. More intense efforts by the care provider to achieve complete cessation will generally result in a greater success rate. The huge reduction in risk resulting from smoking cessation in the cardiovascular disease patient provides a strong rationale for sustained and intense efforts to be expended.

Table 38-10: Strategies for Successful Cessation of Cigarette Smoking: The Four A's

Ask	Systematically identify all tobacco users at every visit (e.g., include tobacco as a vital sign).
	Determine exposure to environmental tobacco smoke at home or at work.
	Identify patients with nicotine addiction.
Advise	Provide a clear, strong, and personalized message, urging every tobacco user to quit.
	Review benefits of quitting and risk of continuing.
	Assess patient's willingness to quit.
Assist	Have the patient develop a quit plan, including setting a quit date, identifying sources of support for cessation for family and friends, removing tobacco and other cues from the home and work environment.
	Provide counseling, information materials and other behavioral interventions.
	Recommend use of pharmacotherapy including bupropion SR, nicotine gum, nicotine inhaler, nicotine nasal spray or nicotine patch.
Arrange	Provide a reminder on the quit date.
	See the patient shortly after the quit date to assess success.
	If unsuccessful, identify barriers and solutions to their removal

SOURCE: From Fiore M et al.[125] and Pearson TA.[299]

Addiction to tobacco is a major barrier to cessation, and a number of pharmacologic agents can be recommended as an adjunct to a concurrent behavioral intervention on the basis of clinical trials demonstrating significantly increased rates of smoking cessation.[126] Bupropion SR, nicotine gum, nicotine inhaler, nicotine nasal spray, and nicotine patch are all first-line drugs to prevent nicotine withdrawal; clonidine is reserved for second-line therapy. Safety of the use of these agents in coronary disease patients

was initially a concern, but several studies have now established the lack of association between the use of nicotine replacement agents and further cardiac events.[127-129]

Hypertension

(See also Chap. 51.) Several major prospective epidemiologic studies have found that both systolic and diastolic hypertension have a strong, positive, continuous, and graded relationship to CHD without evidence of a threshold risk level of blood pressure.[130-132] Among populations in different countries, the relative risk for CHD imposed by a given increase in blood pressure is similar, but the absolute risk at a given blood pressure value varies substantially.[133] This may be due to widely varying baseline risk among populations. Hypertension clusters with insulin resistance, hyperinsulinemia, glucose intolerance, dyslipidemia, left ventricular hypertrophy, and obesity, and occurs in isolation in less than 20 percent of individuals.[134] The potential mechanisms by which hypertension may cause coronary events include impaired endothelial function, increased endothelial permeability to lipoproteins, increased adherence of leukocytes, increased oxidative stress, hemodynamic stress that may trigger acute plaque rupture, and increased myocardial wall stress and oxygen demand. A widened pulse pressure, an indicator of arterial stiffness, is gaining an evidence base as another blood pressure measurement that predicts CHD.[135]

PRIMARY PREVENTION

A meta-analysis of 17 randomized trials of antihypertensive drugs in over 47,000 men and women with mild to moderate hypertension found that stroke was reduced by 38 percent and CHD was reduced by 16 percent.[131] The mean difference in diastolic blood pressure over 5 years between treatment and control groups was 5 to 6 mmHg. An important subset in whom events were reduced was elderly subjects with isolated systolic hypertension (systolic blood pressure ≥160 mmHg; diastolic blood pressure ≤90 mmHg).

For a prolonged 5- to 6-mmHg difference, observational studies predict a reduction of 35 to 40 percent in stroke risk and 20 to 25 percent in CHD risk. Although clinical trials indicate that antihypertensive therapy achieves the reduction in stroke expected from observational studies, the reduction in CHD is not as great as expected. Potential explanations for this are (1) the shortfall was due to chance, (2) the duration of observation was too short and the full benefit was not seen, (3) the treatment benefits were partially offset by metabolic side effects of medications, (4) excessive reduction in diastolic blood pressure led to excess CHD events, or (5) metabolic disturbances associated with hypertension that potentiate CHD were not corrected by the antihypertensive therapy used in the studies (see the section "Insulin Resistance Syndrome," below). Most of these trials were based on high-dose diuretic therapy, with or without beta blockers, leading some experts to propose that adverse metabolic consequences of high-dose diuretics were responsible for the less than expected benefits of antihypertensive treatment. Nevertheless, diuretics and beta blockers are the only classes of antihypertensives extensively tested to date that have been shown to reduce CHD morbidity and mortality in primary prevention. The efficacy of newer antihypertensives in reducing initial coronary events is currently being tested.[136] Blood pressure can be lowered by weight loss, exercise, salt restriction, and avoidance of alcohol,[132] but the long-term utility of these measures to prevent CHD in hypertensives has not been tested in randomized controlled studies.

SECONDARY PREVENTION

Clinical trials to test the effect of blood pressure lowering per se in CHD patients have not been performed.

COST-EFFECTIVENESS

Treatment of hypertension for primary prevention is highly cost-effective, with an estimated cost per year of life saved of about $23,000 (in 1993 dollars) for moderate to severe hypertension and twice as much for mild hypertension.[1] Estimates (in 1993 dollars) vary depending on the choice of medication, ranging from $14,000 per year of life saved for propranolol, to $20,000 for hydrochlorothiazide, and up to $90,000 for newer medications. The cost-effectiveness of blood pressure lowering for secondary prevention is unknown.

PRACTICE RECOMMENDATIONS

The Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure recommends a treatment goal of <140/90 mmHg.[132] A goal of <130/85 is appropriate for patients with diabetes, renal insufficiency, or CHF.[132,137] Please refer to Chap. 51 for a complete discussion of the treatment of hypertension.

Left Ventricular Hypertrophy

Left ventricular hypertrophy (LVH), defined either by electrocardiography or echocardiography, is a potent independent risk factor for CHD, roughly doubling the risk of cardiovascular death in both men and women.[138] LVH is the adaptive response of the heart to chronic pressure or volume overload (see Chap. 67). In addition to hypertension, LVH is associated with obesity, salt intake, advanced age, and heredity.[139] Progressive LVH may lead to decreased left ventricular compliance, decreased coronary reserve, ventricular ectopy, and impaired systolic function. The Framingham Heart Study observed that ECG evidence of LVH regression was associated with a reduction in cardiovascular disease morbidity and mortality.[140] Another observational, prospective evaluation of LVH using echocardiography indicated an improved prognosis among patients with a reduction of left ventricular mass on antihypertensive therapy.[141] Most antihypertensive drugs can reduce LVH (except direct vasodilators, e.g., hydralazine and minoxidil),[132] although not all drugs are equally effective in this regard despite their equipotent blood pressure-lowering capabilities. An analysis of several comparative studies and some meta-analyses, including only double-blind, randomized, controlled clinical studies with parallel group design, indicates that angiotensin-converting enzyme (ACE) inhibitors reduced left ventricular mass by 12 percent, calcium channel blockers by 11 percent, beta blockers by 5 percent, and diuretics by 8 percent.[142] A study of the effect of monotherapy with six antihypertensive agents on reduction of left ventricular mass revealed that captopril, hydrochlorothiazide, and atenolol reduced left ventricular mass and that diltiazem, clonidine, and prazosin did not.[143] The impact of new antihypertensive agents such as angiotensin II-receptor antagonists is still uncertain. Randomized clinical trials have not yet tested whether regression of LVH lowers CHD risk, but the observational data merit its classification as a risk factor that should be modified.[132]

Thrombogenic Factors

See the section "Antiplatelet and Anticoagulant Therapy," below.

Chapter 38: DYSLIPIDEMIA, OTHER RISK FACTORS, AND THE PREVENTION OF CORONARY HEART DISEASE

RISK FACTORS FOR WHICH INTERVENTIONS ARE LIKELY TO LOWER RISK OF CORONARY HEART DISEASE

Insulin Resistance Syndrome: The Basis of Multiple Risk Factors

Reaven[144,145] has hypothesized that *resistance to insulin-stimulated glucose uptake and compensatory hyperinsulinemia are the common metabolic bases for a cluster of coronary risk factors, particularly hypertension, diabetes, hypertriglyceridemia, low HDL, predominance of small dense LDL, and a prothrombotic state* with elevated levels of plasma fibrinogen, plasminogen activator inhibitor 1 (PAI-1), and factor VII.[146] This clustering has been called the *insulin resistance syndrome* or the *metabolic syndrome.* Interestingly, hypertensive individuals, both treated and untreated, obese and nonobese, are hyperinsulinemic compared with a matched group of normotensive individuals. Also, patients with atherogenic dyslipidemia have an increased frequency of hypertension. Hypertriglyceridemia or low HDL, major components of the syndrome, can be considered as *markers* for the presence of the metabolic syndrome. Obesity, particularly when located abdominally, exacerbates insulin resistance, and weight loss improves insulin sensitivity. Insulin sensitivity is associated with endothelial nitric oxide production in healthy persons, providing a clue as to how insulin resistance may promote CHD directly.[147] Furthermore, hyperinsulinemia has been found in a prospective study to be an independent risk factor for CHD in nondiabetic men after adjusting for body weight, blood pressure, and dyslipidemia.[148]

Some experts believe the primary mechanism for insulin resistance is lipid overload in skeletal muscle, liver, and pancreatic beta cells. This overload of tissues with lipid may derive both from an excess of adipose tissue (obesity) and physical inactivity. In skeletal muscle, lipid overload impairs glucose uptake and promotes hyperglycemia.[149] In the liver, lipid overload contributes to atherogenic dyslipidemia. And in pancreatic beta cells, excess lipid overstimulates the secretion of insulin, producing hyperinsulinemia.[150] In a significant portion of the population, the adverse consequences of an overload of tissues with lipid are accentuated by an underlying genetic susceptibility to insulin resistance.[146]

A comprehensive lifestyle approach is required to address the cluster of risk factors related to insulin resistance. Weight loss and physical activity are clear goals because they counteract insulin resistance. Although a low-fat diet is clearly beneficial for hypercholesterolemia, it might be detrimental in insulin-resistant, hypertriglyceridemic patients.[145]

Diabetes Mellitus

(See Chap. 78 for a complete discussion about diabetes and CHD.) Diabetes mellitus is an independent risk factor for CHD, increasing risk by two to four times for men and women, respectively.[9,71] CHD is the leading cause of death among diabetics, and approximately 25 percent of MI survivors have diabetes.[8,71] *Diabetic patients without a history of MI have as high a risk of coronary mortality as nondiabetic patients with a history of MI.*[9] Once patients with type 2 diabetes suffer a myocardial infarction, their prognosis for survival is much worse than that for

CHD patients without diabetes.[151,152]

Diabetes abolishes the usual protection from CHD afforded a premenopausal woman.[71] *Diabetic women have twice the risk of recurrent MI compared with diabetic men.*[153] The greater risk of CHD in diabetic women compared to diabetic men may be explained in part by the greater adverse effect of diabetes on lipoproteins in women.[154] Potential mechanisms by which diabetes may cause atherosclerosis include low HDL, high triglycerides/increased lipoprotein remnant particles, increased small dense LDL, elevated Lp(a) concentration, enhanced lipoprotein oxidation, glycation of LDL, increased fibrinogen, increased platelet aggregability, increased PAI-1, impaired fibrinolysis, increased von Willebrand factor, hyperinsulinemia, and impaired endothelial function. Most patients with type 2 diabetes have multiple risk factors. High-risk populations in the United States include whites, blacks, Hispanics, and South Asians.

PRIMARY AND SECONDARY PREVENTION

Despite overwhelming observational data that diabetes increases the risk of CHD, few data are available to determine whether glycemic control reduces risk. The University Group Diabetes Program was the first large-scale randomized clinical trial to study cardiovascular end points in patients with type 2 diabetes, and treatment with sulfonylurea therapy was associated with *increased* cardiovascular mortality.[155] The Diabetes Control and Complications Trial studied the effect of intensive insulin therapy in patients with type 1 diabetes.[156] Intensive therapy reduced microvascular end points, but the study was not of sufficient size to examine CHD end points. The United Kingdom Prospective Diabetes Study (UKPDS) examined the impact of intensive glycemic control with sulfonylureas or insulin compared with conventional therapy on the risk of complications in patients with type 2 diabetes.[157] The treatment goal in the intensive therapy group was a fasting glucose of <108 mg/dL. In the conventional treatment group, drugs were added to diet only if there were hyperglycemic symptoms or if the fasting glucose was >270 mg/dL. After a 10-year follow-up, there was a significant reduction in microvascular end points but not in macrovascular end points. There was no evidence that intensive treatment with sulfonylureas or insulin had an adverse effect on macrovascular disease.

COST-EFFECTIVENESS

The cost-effectiveness of treating diabetes for primary and secondary prevention of CHD has not been established.

PRACTICE RECOMMENDATIONS

Weight loss and exercise are key therapeutic interventions because they improve the constellation of metabolic abnormalities that accompany diabetes. Although the optimal proportion of dietary fat and carbohydrate is controversial, calorie restriction for obesity and avoidance of sugar and saturated fat are definitely recommended. *Beta blockers should not be withheld from diabetic patients following MI unless strong contraindications exist, because diabetic MI survivors have fewer deaths if treated with a beta blocker.*[158] Although there is no consistent evidence to support intensive glycemic control as a strategy to reduce macrovascular end points, aggressive lipid management in patients with diabetes lowers CHD risk. The NCEP and American Diabetes Association guidelines recommend a more aggressive LDL goal (<100 mg/dL) in primary prevention of CHD in diabetics.[8,71] The American Heart Association (AHA) recommends near-normal fasting glucose and hemoglobin A_{1c} (HgA_{1c}) ≤1 percent above normal as treatment goals for patients with diabetes.[71]

Physical Inactivity

Physical inactivity is an independent risk factor for CHD[159] *and roughly doubles the risk.* There is a dose-response relation between the amount of exercise performed weekly, from 700 to 2000 kcal of energy, and death from cardiovascular disease and all causes.[159] Data linking sedentary lifestyle with CHD derive from numerous lines of evidence, including animal studies, observational studies, and clinical trials. Moderate-intensity exercise reduces coronary atherosclerosis and widens coronary arteries in monkeys fed an atherogenic diet compared with monkeys fed the same diet but forced to be sedentary. Physical activity slows progression of angiographically defined coronary atherosclerosis in humans.[160] Over 50 observational studies, primarily of men, have established that physical fitness, on-the-job physical activity, and leisure-time physical activity reduce the risk of CHD.[161] These studies of physical activity are subject to important potential biases, including self-selection and unmeasured confounding variables. The risk of MI and sudden cardiac death is greatest during exercise, but the overall risk of MI and sudden cardiac death is reduced among those who exercise regularly.[162] The greatest potential for reduced mortality is in sedentary individuals who become moderately active.[159] Moderate-intensity activity, as opposed to high-intensity activity, produces most of the beneficial effects of physical activity on cardiovascular mortality. A recent prospective study of more than 72,000 apparently healthy female nurses indicated that brisk walking and vigorous exercise are associated with substantial and similar reductions in coronary events.[163] In addition to decreasing myocardial oxygen demand and increasing myocardial efficiency and electrical stability, other potential mechanisms of benefit include increasing HDL, lowering triglycerides, reducing blood pressure, reducing obesity, improving insulin sensitivity, decreasing platelet aggregation, and increasing fibrinolysis.[161]

PRIMARY PREVENTION

A randomized, controlled trial of physical activity for primary prevention of CHD is not likely to be conducted because of cost and compliance issues.

SECONDARY PREVENTION

(See Chap. 50 on cardiac rehabilitation.) Meta-analyses of randomized trials of cardiac rehabilitation with exercise in over 4000 MI survivors demonstrated a 20 to 25 percent reduction in cardiovascular mortality, although there were no significant differences in nonfatal reinfarction.[164,165] Most of the studies combined exercise training with other risk factor modification. The small number of trials with exercise as the only intervention does not permit definitive conclusions. The benefit of physical activity in female CHD patients is uncertain.

COST-EFFECTIVENESS

The cost-effectiveness of physical activity for primary prevention is not established. Given the low monetary cost of physical activity and its numerous favorable effects on other risk factors, exercise for primary prevention is likely to be highly cost-effective. The cost-effectiveness of cardiac rehabilitation has been estimated (in 1993 dollars) at less than $8000 per quality-adjusted year of life gained.[8]

PRACTICE RECOMMENDATIONS

The American College of Sports Medicine and the Centers for Disease Control and Prevention recommend that every adult should accumulate 30 min or more of moderate-intensity physical activity on most, preferably all, days.[166] Only about 20 percent of U.S. adults meet this goal. The AHA recommends a minimal goal of 30 min of moderate-intensity activity three to four times a

week for individuals with and without CHD.[167,168] Large-scale studies indicate that high-intensity physical activity is *not* required to achieve a mortality benefit, and that 200 calories expended daily in moderate-intensity physical activity will confer the majority of CHD risk reduction that exercise can provide. To accomplish this requires about 30 min of brisk walking; however, intermittent activity also provides substantial benefit.[167] Therefore, the minimal goal of 30 min can be accumulated in short bouts of typical daily activities like walking, climbing stairs, housework, and gardening. Exercise testing should be recommended to apparently healthy men over 40 and women over 50 who are sedentary, as well as to younger adults with coronary risk factors, before starting a *vigorous* physical activity program (intensity > 60 percent individual maximum oxygen consumption).[169] For secondary prevention, exercise testing is recommended to guide exercise prescription, and high-risk patients should exercise in a medically supervised setting.[167] Structured exercise programs, whether on site or at home, help compliance with an exercise prescription[170] (see also Chap. 50).

Obesity

Obesity is defined by the AHA as a major risk factor for CHD.[171] Obesity promotes insulin resistance, hyperinsulinemia, type 2 diabetes, hypertension, hypertriglyceridemia, low HDL cholesterol, small dense LDL, prothrombotic factors, and LVH.[132] It is associated with an increase in cardiovascular and all-cause mortality.[132,172]

Body mass index (BMI) has been adopted widely as a measure of adiposity. BMI is calculated as weight (kg)/height squared (m^2) and estimated as [weight (pounds)/height (inches)^2] × 704.5 *Overweight* is defined as a BMI of 25 to 29.9, and *obesity* is defined as BMI ≥ 30. The number of overweight and obese adults in the United States has increased since 1960. Nearly one-third of adults in the United States are overweight, and an additional one-fifth meet the definition of obese.[172] BMI correlates with total body fat content. Abdominal obesity adds to the health risks of obesity, and waist circumference correlates positively with abdominal fat content. In adults with a BMI between 25 and 35, increased relative risk is indicated in men with a waist circumference of >102 cm (>40 inches) and in women of >88 cm (>35 inches).[132]

In univariate analysis, many observational studies have found obesity strongly and positively correlated with the risk of CHD. In multivariate analysis, when controlling statistically for risk factors such as hypertension, diabetes, and dyslipidemia, obesity is usually not found to be an independent risk factor. This reflects that many of the adverse consequences of obesity are mediated through resultant metabolic risk factors acting as pathogenetic links in the causal pathway. Nevertheless, some large prospective observational studies of long duration indicate that obesity is independently related to coronary and cardiovascular mortality in men and women.[173-175] In general, the greater the degree of overweight, the higher is the risk of coronary mortality. Weight loss improves insulin sensitivity and glucose disposal, reduces HbA_{1c} in patients with type 2 diabetes, reduces blood pressure and triglycerides, produces a modest reduction in LDL, and increases HDL cholesterol.[132]

PRIMARY AND SECONDARY PREVENTION

Although weight loss leads to a number of favorable short-term changes in metabolism, it is unknown whether long-term weight loss results in reduced CHD events. No primary or secondary prevention trials of weight loss have been conducted.

COST-EFFECTIVENESS

The cost-effectiveness of weight loss is unknown. Given the favorable effect of weight loss on other risk factors, it may prove to be highly cost-effective.

PRACTICE RECOMMENDATIONS

BMI should be listed as a vital sign, used to assess overweight and obesity, and used to monitor changes in body weight. Tracking body weight alone can be used to determine the efficacy of weight-loss therapy. National Institutes of Health guidelines recommend that waist circumference be measured in patients with a BMI between 25 and 35 because of its incremental predictive power.[132] Treatment of overweight (BMI, 25 to 29.9) is recommended only when patients have two or more risk factors, increased waist circumference, or CHD or a CHD risk equivalent. Treatment should focus on diet and exercise to prevent weight gain and to produce moderate weight loss over years. The initial goal of weight-loss therapy is to reduce body weight by approximately 10 percent from baseline in 6 months. For patients with BMI in the range of 27 to 35, a decrease of 300 to 500 kcal/day will result in this degree of weight loss. Lost weight is usually regained unless a program consisting of dietary therapy, physical activity, and behavior therapy is continued indefinitely.

Smoking cessation is associated with weight gain, on average 4.5 to 7 lb. The health hazards of smoking exceed the risks of moderate obesity; therefore, cigarette smokers should be given the clear message that smoking cessation is of the highest priority even if it results in weight gain. Weight-loss drugs approved by the Food and Drug Administration for long-term use may be useful as an adjunct to diet and physical activity for patients with a BMI $\geq$ 30 and for patients with a BMI $\geq$ 27 with CHD or obesity-related risk factors. CHD end-point trials with weight-loss drugs, however, have not been conducted. Fenfluramine and dexfenfluramine have been withdrawn from the market because of associated valvular heart disease.

Postmenopausal Status

CHD is relatively uncommon in premenopausal women. There is a dramatic rise in CHD incidence in women after age 55, coinciding with increasing age and a decline in endogenous estrogen levels. Early menopause (natural or surgical) is associated with increased CHD risk.[176] These observations are consistent with the notion that estrogen deficiency permits or promotes CHD and that estrogen reduces risk. Numerous observational studies show that postmenopausal users of estrogen replacement therapy (ERT) have a 50 percent lower risk of initial CHD events compared with nonusers.[176] Because of their observational design, these studies have been subject to selection bias and uncontrolled or unknown confounding variables. In most of these studies, ERT has been unopposed by concomitant progestin therapy. Proposed mechanisms by which estrogen may confer benefit include raising HDL; lowering LDL, small dense LDL, Lp(a), and fibrinogen levels; inhibiting LDL oxidation; and enhancing endothelium-dependent and endothelium-independent coronary vasodilation.

Unopposed ERT increases the risk of endometrial carcinoma, but the addition of a progestin erases that risk.[176] Estrogen with or without progestin may increase slightly the risk of breast cancer, particularly among older women who have taken hormones for 5 or more years.[176,177] For women aged 65 to 74 years, the absolute risk of dying of CHD over the next 10 years is 15 times that of dying of endometrial cancer and 6 times that of dying of breast cancer.[178] The Postmenopausal Estrogen/Progestin Interventions Trial assessed differences between placebo, unopposed estrogen, and three estrogen/progestin combinations over 3 years on selected CHD risk factors in healthy postmenopausal women.[179] Compared with placebo, estrogen alone or in combination with a progestin raised HDL cholesterol and lowered fibrinogen levels. The best regimen for raising HDL cholesterol was unopposed estrogen, but in women with an intact uterus

this caused a high rate of atypical or adenomatous endometrial hyperplasia.

PRIMARY AND SECONDARY PREVENTION

The Heart and Estrogen/Progestin Replacement Study (HERS) investigated the impact of estrogen plus progestin on the risk of CHD in 2763 postmenopausal women with established coronary disease and an intact uterus.[180] Subjects were randomly assigned 0.625 mg of conjugated equine estrogens plus 2.5 mg of medroxyprogesterone daily or a placebo with a mean follow-up of 4 years. There was no difference in the primary end point of nonfatal MI or CHD death. The lack of an overall effect occurred despite a net 11 percent lower LDL level and 10 percent higher HDL level in the hormone treatment group. Although there was no difference overall between groups, there was a statistically significant time trend, with more CHD events in the hormone group in year 1 and fewer events in years 4 and 5. More women in the hormone group suffered venous thromboembolic events and gallbladder disease. Other large randomized trials of hormone replacement therapy for primary and secondary prevention are currently in progress.

COST-EFFECTIVENESS

The cost-effectiveness of ERT for prevention of CHD is undefined.

PRACTICE RECOMMENDATIONS

On the basis of HERS, we recommend that postmenopausal women with CHD who have not been on ERT should not be started routinely on hormone therapy for the purpose of preventing CHD events. Those with CHD who have been on ERT for at least 2 years without a CHD event should not have hormone therapy discontinued. For postmenopausal women without known CHD, clinical trial evidence is still lacking and the decision whether to treat must be individualized according to other health risks. Oral estrogen therapy is contraindicated in women with hypertriglyceridemia (e.g., serum triglycerides >400 mg/dL).

Chapter 38: DYSLIPIDEMIA, OTHER RISK FACTORS, AND THE PREVENTION OF CORONARY HEART DISEASE

RISK FACTORS FOR WHICH INTERVENTIONS MIGHT LOWER RISK OF CORONARY HEART DISEASE

Psychosocial Factors

The role of personality, environment, social support, social contact, stress and lack of control at work, and depression have all been associated with increased risk for CHD. See Chap. 80 for a discussion of these topics.

Acute emotional reactions have been implicated as triggers of acute coronary syndromes. In the absence of atherosclerosis, mental stress causes vasodilation or no change in the diameter of epicardial coronary arteries. In the presence of atherosclerosis, mental stress induces silent myocardial ischemia[181] and coronary vasoconstriction.[182] An episode of anger is capable of triggering acute MI.[183] There was a fivefold increase in the number of sudden cardiac deaths related to atherosclerosis on the day of one of the strongest earthquakes ever recorded in North America.[184] Most of these deaths did not occur in association with heavy physical exertion and were presumably related to major emotional stress. In most cases, the length of time between the earthquake and sudden death was less than 1 h. A mechanism by which acute emotional stress could trigger coronary events is release of catecholamines, leading to an increase in heart rate, blood pressure, myocardial oxygen demand, vasoconstriction, platelet aggregability, and coagulation with an inhibition of fibrinolysis. These factors could contribute to the rupture of a vulnerable plaque, with subsequent thrombosis, or to the precipitation of ventricular arrhythmias.

PRACTICE RECOMMENDATIONS

Optimal comprehensive secondary prevention should include attempts to identify and treat depression and anxiety in patients with CHD. Group support and stress management can be provided in formal cardiac rehabilitation programs.

Total Plasma Homocysteine Level

Total plasma homocysteine level reflects the sum of homocysteine and homocysteinyl moieties of oxidized disulfides, homocystine, and cysteine-homocysteine. Together, these amino acid derivatives appear to have direct toxic effects on the vascular endothelium and can result in the oxidation of LDL, both important steps in atherogenesis. Although there are genetic determinants of total homocysteine level (see Chap. 62), the most important factor affecting plasma concentration is dietary intake of folate and vitamins B_6 and B_{12}.[185] Of note, folate fortification exists in the United States, and less than 1 percent of the population has low levels of folic acid.[186]

A series of cross-sectional and case-control studies strongly supports an independent association between total plasma homocysteine level and atherosclerotic risk.[187] In addition, prospective studies have found increased risk of MI[188-193] and stroke[194] among patients with moderate hyperhomocysteinemia. However, not all large-scale studies are positive.[195-197] When pooled, these data suggest that as much as 10 percent of the population risk of CHD may be attributable to

homocysteine level.[187]

PRIMARY AND SECONDARY PREVENTION

Although folate and vitamins B_6 and B_{12} reduce homocysteine concentration,[198] no randomized trial data are yet available to indicate that reducing plasma levels reduces risk.

PRACTICE RECOMMENDATIONS

Measurement of homocysteine may be useful in patients with CHD in the absence of major risk factors or with a history of recurrent arterial thromboses.

Oxidative Stress

Oxidative modification of LDL has been hypothesized to play a major role in the initiation and progression of atherosclerosis.[34] Because naturally occurring antioxidants such as vitamins E, C, and beta-carotene may slow this process, there has been substantial interest in these compounds as agents for both primary and secondary prevention. A series of observational epidemiologic studies supports the hypothesis that increased dietary intake of antioxidants is associated with reduced cardiovascular risk, with the strongest evidence for vitamin E.[199-202] Unfortunately, it is impossible to conclude from observational studies that a given vitamin supplement is responsible for observed vascular risk reduction, since individuals who take vitamins are also likely to employ other preventive lifestyle and dietary measures. This issue can only be resolved through large-scale, randomized clinical trials.

PRIMARY PREVENTION

In the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study, which enrolled 29,133 male smokers,[203] there was no evidence that vitamin E (given as 50 mg of alpha-tocopherol daily) reduced the subsequent risk of CHD or stroke, and a small increase in rates of cerebral hemorrhage was reported. In the same trial, beta-carotene was associated with a small increase in lung cancer and deaths due to CHD. In the Carotene and Retinol Efficacy Trial conducted among 18,314 smokers, former smokers, and asbestos-exposed workers,[204] the combined use of 30 mg/day of beta-carotene plus 25,000 IU of retinol was associated with a small but statistically significant increase in lung cancer and all-cause mortality, as well as a nonsignificant increase in cardiovascular mortality. In constrast, among 22,071 men participating in the Physicians' Health Study who were randomly allocated to 50 mg of beta-carotene on alternate days for a period of 12 years, supplementation resulted in no evidence of benefit or harm in terms of the incidence of cardiovascular disease or cancer.[205]

SECONDARY PREVENTION

In the Cambridge Heart Antioxidant Study,[206] higher doses of vitamin E were found to reduce rates of nonfatal MI substantially among a group of patients with known CHD. Specifically, in this high-risk secondary prevention trial, the use of 400 to 800 IU of alpha-tocopherol daily over an average period of only 17 months was associated with a statistically significant 47 percent risk reduction in cardiovascular death and nonfatal infarction. By contrast, in the large-scale Heart Outcomes Prevention Evaluation (HOPE) trial, these effects were not confirmed, as no overall benefit was observed among those randomly allocated to vitamin E.[207]

PRACTICE RECOMMENDATIONS

Based on these randomized trial data, it is impossible to make recommendations for or against supplementation with vitamin C to prevent CHD, although beta-carotene and vitamin E appear to carry no benefit. Given observational evidence suggesting benefit for diets rich in fruits and vegetables, however, it is prudent to continue such diets that contain several hundred micronutrients that may have chemopreventive properties.

No Alcohol Consumption

Heavy alcohol intake is associated with increased risks of death from several causes and is a major public health concern. However, cross-sectional, case-control, and prospective cohort studies indicate that mild to moderate alcohol consumption is associated with reduced rates of CHD compared with abstainers.[208-210] These studies suggest a J-shaped relationship between level of alcohol consumption and total mortality such that a protective effect is apparent at low levels of consumption (one to two beverages daily), whereas there is substantial hazard among heavy consumers.[211] In large part, this dose-dependent balance reflects summation of three effects: (1) a positive association between alcohol use and cancer; (2) a U-shaped relationship between alcohol use and total cardiovascular disease due to increased risks of cardiomyopathy, sudden death, and hemorrhagic stroke among heavy drinkers; and (3) a well-established L-shaped protective effect for coronary disease.[211,212]

Several mechanisms are important in the cardioprotective effect of moderate alcohol use. Alcohol intake increases total HDL-cholesterol levels as well as HDL2 and HDL3 subfractions.[213-216] Alcohol consumption also has potentially beneficial effects on fibrinolytic function[217,218] and on platelet aggregation.[219,220]

PRIMARY AND SECONDARY PREVENTION

There have been no randomized trials of alcohol use for primary or secondary prevention.

PRACTICE RECOMMENDATIONS

How best to advise patients concerning the potential use of alcohol for cardiovascular protection is a complex process, because of this agent's potential for abuse.[221] Abstinence is advised for patients who are pregnant or who have hepatic disorders, pancreatic disease, congestive heart failure, idiopathic cardiomyopathy, or degenerative neurologic conditions. On the other hand, the recommendation to drink moderately (one drink per day for women and two drinks for men) may be safe when made on a case-by-case basis in the absence of a history of abuse or medical contraindication.[221] Whether specific beverage type matters in terms of cardiovascular protection is uncertain. Evidence indicating benefits for white wine, red wine, beer, and liquor suggest that alcohol content rather than type is the more important predictor of cardiovascular risk reduction.[209,210]

Chapter 38: DYSLIPIDEMIA, OTHER RISK FACTORS, AND THE PREVENTION OF CORONARY HEART DISEASE

UNMODIFIABLE RISK FACTORS

Age and Sex as Risk Factors for Atherosclerotic Disease

The incidence and prevalence of CHD increase sharply with age, so that age might be considered one of the most potent cardiovascular risk factors. Atherosclerotic involvement of the coronary arteries is well established in men by young adulthood, as shown in Korean War and Vietnam War casualties.[222,223] CHD incidence rates in men are similar to those in women 10 years older.[224] Approximately 52 percent of women and 46 percent of men will eventually die of atherosclerotic disease.[225] The increased risk for men and older persons should trigger more intense management of modifiable risk factors. Persons at very advanced age (e.g., 75+ years) should have the risks and benefits of preventive cardiology interventions weighed on an individual basis.

Socioeconomic Status: An Unmodifiable Coronary Risk Factor?

At any one point in time, markedly different CHD rates may be observed between socioeconomic subgroups of the population, as defined by occupation, education, income, or other measures. As a group becomes affluent, its members use their new wealth to purchase high-fat and high-salt foods, tobacco products, and automobiles. Less affluent groups lag behind this development, achieving access to these deleterious behaviors later. Affluent groups then learn about and adopt healthful lifestyles, reducing deleterious behaviors. Again, less affluent and less educated groups lag behind, eventually exceeding the rates of CHD in those educated groups whose CHD rates have begun to fall.

Currently, persons with low socioeconomic status are at high risk for CHD. A number of mechanisms may explain this.[226] First, risk factors for atherosclerosis, such as smoking, hypertension, obesity, and sedentary lifestyle, are higher in persons with low socioeconomic status. Second, some of these risk factors, as well as psychosocial responses to stressors, may increase exposure to CHD triggers in these groups. Finally, these groups may have less access to care.

Family History of Early-Onset CHD

Over 35 case-control and prospective studies have consistently identified an association between CHD and a history of first-degree relatives with early-onset CHD.[227] This risk generally persists even after adjustment for other risk factors. The family history most predictive of coronary disease is that of a first-degree relative developing CHD at an early age. Although CHD in a male relative with onset at age 55 or less or a female relative with onset at age 65 or less is defined as a positive family history, the larger the number of relatives with early-onset CHD or the younger the age of CHD onset in the relative, the stronger is the predictive value.[228,229]

Although considered a nonmodifiable risk factor, a positive family history should result in the careful screening of individual risk factors known to aggregate in families. Such familial aggregations may represent monogenic factors with known phenotypic expressions and

inheritance patterns, polygenic factors with less clear modes of expression and inheritance, or shared environments. In early-CHD families, Williams et al.[229] estimate that only 10 percent of families will not have a concordant risk factor, most of which are amenable to intervention. Thus, family members of patients with CHD at a young age represent fruitful targets for risk factor assessment. *However, risk factor screening often does not extend beyond the coronary patient. A strong recommendation that siblings and children of early-CHD patients be screened for CHD risk factors should be delivered to each patient and their family members.*

Chapter 38: DYSLIPIDEMIA, OTHER RISK FACTORS, AND THE PREVENTION OF CORONARY HEART DISEASE

OTHER PHARMACOLOGIC THERAPY

Antiplatelet and Anticoagulant Therapy

See also Chap. 44.

PRIMARY PREVENTION

Several prevention trials of aspirin have been completed in healthy men. The largest of these, the Physicians' Health Study, enrolled 22,071 apparently healthy male physicians aged 40 to 84 years of age and randomized them to 325 mg aspirin on alternate days or to placebo.[230] Among those given active aspirin, a highly statistically significant 44 percent reduction in nonfatal MI was observed. In this study, aspirin had little effect on the clinical characteristics of MI[231] or on the rate of development of angina pectoris.[232] When the Physicians' Health Study data are combined with those of a similar trial among British men,[233] an overall 32 percent reduction in risk of first nonfatal MI appears to be associated with chronic aspirin prophylaxis.[234] These trials have also demonstrated the efficacy of low-dose aspirin in the prevention of MI among patients with stable angina pectoris.[235] In the Thrombosis Prevention Trial, low-dose aspirin (75 mg daily) and low-dose warfarin (target INR = 1.5) were both effective, although combination therapy as compared with monotherapy remains controversial.[236]

SECONDARY PREVENTION

At least 25 trials have been completed in the study of antiplatelet therapy for secondary prevention.[237] Overall, among patients with known clinical manifestations of atherosclerotic disease, antiplatelet therapy is associated with a 32 percent reduction in subsequent MI, 27 percent reduction in subsequent nonfatal stroke, and 15 percent reduction in vascular mortality.[238] Although thienopyridines such as clopidogrel also appear effective, evidence that these agents are superior to aspirin alone is marginal.[239]

Few studies of anticoagulant therapy in the secondary prevention of coronary disease are available. In the Dutch Sixty Plus Study,[240] patients over 60 years of age who had been taking anticoagulants following infarction were randomly assigned to continue or discontinue warfarin. Patients continuing anticoagulant therapy had a 26 percent lower mortality rate and a 51 percent lower reinfarction rate.

The utility of warfarin initiated soon after infarction has also been demonstrated.[241] In a trial of 1214 patients with acute or subacute MI, the randomized use of warfarin with a target INR between 2.8 and 4.8 was associated with a 24 percent reduction in mortality, a 34 percent reduction in nonfatal reinfarction, and a 55 percent reduction in stroke over a mean period of 37 months. These reductions were achieved with acceptably low bleeding rates for those assigned to warfarin.

COST-EFFECTIVENESS

For primary prevention, aspirin is likely to be extremely cost-effective because of its low cost and high efficacy for preventing MI. Following MI, both aspirin and anticoagulant therapy have been shown to be cost saving.[21]

PRACTICE RECOMMENDATIONS

The United States Preventive Services Task Force has recommended that low-dose aspirin be considered in men age 40 and over who are at high risk for MI and lack contraindications.[242] Although observational data generally support the use of aspirin in women,[243] the risk-to-benefit ratio in women may differ from that of men, since the average age at first infarction is higher. For secondary prevention, 80 to 325 mg of aspirin daily is recommended, with treatment continued indefinitely. If aspirin is contraindicated, clopidogrel and then warfarin are recommended for secondary prevention, with an INR goal of 2 to 3.5.[137,167]

Fibrinogen

Plasma fibrinogen level has been shown in several studies to predict the future risk of MI and stroke.[244-248] When pooled, these studies indicate that individuals with fibrinogen concentrations in the upper third of the control distribution have a relative risk of future cardiovascular disease 2.0 to 2.5 times that of individuals with lower levels.[249] High fibrinogen levels result in increased whole blood viscosity and may play a direct role in atherogenesis and platelet aggregation. While fibrinogen levels increase with smoking, age, oral contraceptive use, and diabetes, fibrinogen is poorly correlated with dyslipidemia and therefore may provide additional risk information beyond lipid and lipoprotein measurement.

HIGH-SENSITIVITY C-REACTIVE PROTEIN

C-reactive protein (CRP) is a hepatically derived marker of low-grade systemic inflammation that largely reflects circulating cytokine function. When measured with high-sensitivity assays, CRP can be detected within the normal range and used for cardiovascular risk prediction. To date, several large-scale prospective studies have shown the inflammatory marker high-sensitivity CRP (hs-CRP) to be a potent predictor of future myocardial infarction, stroke, and peripheral vascular occlusion among apparently healthy men and women,[27,250-252] as well as among high-risk smokers[253] and the elderly[254] (see Fig. 38-1). Levels of hs-CRP are also elevated among those with acute coronary syndromes at high risk for recurrent events[255,256] and among post-MI patients at high risk for recurrent instability.[257] These effects are independent of other risk factors and appear to add to the predictive value of lipid screening in terms of risk prediction.[28] Thus, as a clinical marker reflecting the presence of an enhanced systemic inflammatory response, hs-CRP appears to have utility in the detection of high-risk patients for plaque instability.

PRIMARY AND SECONDARY PREVENTION

Exercise frequency and body mass both correlate with hs-CRP levels,[258,259] and randomized trial data indicate that lipid reduction with pravastatin lowers hs-CRP in an LDL-independent manner.[260] Further, the effectiveness of low-dose aspirin in reducing risk of first MI appears related to hs-CRP level.[250] However, no data are yet available which indicate that reducing plasma levels of hs-CRP reduces vascular risk.

PRACTICE RECOMMENDATIONS

Practice guidelines for hs-CRP screening are in development. As hs-CRP levels appear to add to

the predictive value of lipid screening[28] and pedict risk even among those with low levels of LDL cholesterol, knowledge of hs-CRP may be of use as an adjunct to lipid profiling on a population basis. A standardized commercial assay for hs-CRP has recently been approved by the Food and Drug Administration for use in cardiovascular risk assessment.[261]

Endogenous Fibrinolysis: Tissue Plasminogen Activator, PAI-1, and *D*-Dimer

The activity of the endogenous fibrinolytic system reflects a balance between plasma concentration of tissue-type plasminogen activator (tPA) and its primary inhibitor, PAI-1. Prospective studies of initially healthy individuals[262,263] as well as patients with known CHD[264] indicate that elevated antigen levels of both enzymes are associated with increased risk of future MI. Further, prospective data also indicate that tPA antigen level is a potent marker of risk for stroke.[265]

Because both tPA and PAI-1 contribute to the net fibrinolytic balance, it has been hypothesized that individuals at risk for future vascular occlusive events suffer from a net inhibition of fibrinolytic function, a finding supported in at least one prospective study.[266] Other data, however, indicate that elevations of *D*-dimer are also associated with increased risk of future MI[267] and peripheral vascular disease.[268,269] Since plasma *D*-dimer levels increase with fibrinogen turnover, these data raise the possibility that the endogenous fibrinolytic system is activated among individuals at risk.

Evidence is not available to support fibrinogen reduction as a measure to prevent CHD, although smoking cessation, physical activity, and hormone replacement therapy[179,270] all favorably affect fibrinogen levels. Other fibrinogen-reducing agents, such as bezafibrate, are also under investigation in ongoing clinical trials.[271] Many factors affect endogenous fibrinolytic activity, including obesity, estrogen status, and exercise. In addition, pharmacologic interventions may soon be available that can favorably shift fibrinolytic function in an attempt to reduce vascular risk. To date, aspirin therapy, alcohol use, and ACE inhibitors have all shown promise in this regard.[272]

Beta-Adrenergic Blocking Agents

Beta-adrenergic blocking agents reduce heart rate, systemic blood pressure, and ventricular contractility, all factors that decrease myocardial oxygen consumption (see Chap. 3). Beta blockers further have antiarrhythmic properties and appear to increase thresholds for ventricular fibrillation.[273]

PRIMARY PREVENTION

Little clinical trial data are available that directly test beta-blocking agents in the primary prevention of MI. The use of this class of agents in the treatment of hypertension, however, has been shown to be efficacious for CHD prevention,[274] and beta blockers have few long-term side effects.

SECONDARY PREVENTION

The utility of beta-blocking agents in the acute, subacute, and chronic phases following MI has been demonstrated in many clinical trials. Overview analyses indicate that therapy with beta blockers reduces mortality approximately 20 percent compared with placebo.[275,276] The mortality effect of long-term beta blockade results primarily from prevention of sudden death (pooled

relative risk = 0.68), presumably due to a reduction in the incidence and complexity of ventricular arrhythmias. Beta blockers have also proven effective in reducing rates of nonfatal reinfarction (pooled relative risk = 0.74), an effect more likely to result from chronic reductions in heart rate, contractility, and vascular stress.

COST-EFFECTIVENESS

Estimates of the cost of beta blockers after MI range from $3600 per year of life saved when used in high-risk patients to $23,400 per year of life saved when used in low-risk patients.[277] This is cost-effective as compared with other accepted CHD interventions.

PRACTICE RECOMMENDATIONS

For primary prevention, beta blockers are recommended as first-line therapy for hypertension.[132] For secondary prevention, beta blockers are recommended in post-MI patients with arrhythmias, left ventricular dysfunction, and inducible ischemia.[167] Although specific studies of beta-blocker cessation are not available, it is commonly recommended that beta-blocker therapy be continued indefinitely as long as side effects are not present.[273]

Angiotensin-Converting Enzyme Inhibitors

PRIMARY PREVENTION

Although ACE inhibitors are used widely as first-line therapy for hypertension, no data on primary prevention with this class of drugs are available. A large-scale trial is in progress.[136]

SECONDARY PREVENTION

ACE inhibitors reduce mortality in patients with congestive heart failure and reduced left ventricular ejection fraction.[278-280] More recently, this class of agents has been recognized as important adjunctive therapy following acute MI.[281] The primary rationale for using these agents in this setting is based on the experimental observation that ACE inhibition slows the process of ventricular remodeling.[282,283] This effect appears time dependent in that the use of ACE inhibition after MI requires a sufficient length of therapy to result in detectable changes in ventricular volumes and size. The observation in several trials that rates of recurrent MI may also be reduced with ACE inhibition[281,284,285] raises the possibility that these agents also result in enhanced endogenous fibrinolysis.[286] The ability of ACE inhibition with ramipril to reduce risk of MI and cardiovascular mortality among high-risk patients without heart failure further demonstrates the efficacy of these agents (HOPE trial).[207]

COST-EFFECTIVENESS

The cost-effectiveness of ACE inhibitor therapy after MI in patients with left ventricular ejection fraction < 0.40 compares favorably with other commonly accepted therapies for patients with CHD. Depending on the age of the patient and the assumptions used, estimates for the cost-effectiveness of captopril range from $3600 to $60,800 per quality-adjusted life-year.[287]

PRACTICE RECOMMENDATIONS

No data are available to recommend ACE inhibitors for primary prevention. For secondary prevention, ACE inhibitors should be prescribed to patients with congestive heart failure and

reduced left ventricular function unless contraindicated. The results of the recent HOPE trial suggest it is reasonable to prescribe ramipril for patients with CHD or CHD risk equivalent and normal left ventricular function.[207] We await the results of ongoing trials to learn whether other ACE inhibitors will confer a similar benefit for patients with normal left ventricular function.

Chapter 38: DYSLIPIDEMIA, OTHER RISK FACTORS, AND THE PREVENTION OF CORONARY HEART DISEASE

THE PRACTICE OF PREVENTIVE CARDIOLOGY

The evidence for a causal role of risk factors in the etiology of CHD and the feasibility and efficacy of risk factor modification in lowering CHD risk is some of the most convincing in all of medicine. Despite this, there are both qualitative and quantitative gaps in our treatment of coronary risk factors, even in patients at highest risk. Qualitative gaps entail the lack of any risk factor detection and management in many patients. Among patients with established coronary disease, only 40 to 60 percent receive beta blockers, only 60 percent of patients with reduced left ventricular ejection fractions receive ACE inhibitors, and only 70 to 90 percent take aspirin.[288,289] Likewise, many of those patients receiving treatment are not being treated to the goals as set by various guidelines or as documented as efficacious in randomized clinical trials. For example, in a recent study of 4888 patients receiving treatment for lipid disorders, only 17 percent of CHD patients reached their LDL-cholesterol goal of ≤100 mg/dL, and only 37 percent of high-risk (2+ risk factors), non-CHD patients reached their goal of <130 mg/dL.[290] Thus, preventive cardiology strategies backed by strong evidence for efficacy and cost-effectiveness are simply not being applied sufficiently widely, constituting a missed opportunity to reduce costs and improve prognosis.

Barriers to Implementation of PreventiveCardiology Services

A number of barriers to the implementation of preventive services can be identified at the patient, physician, health care setting, and community/society levels (Table 38-11).[291,292] The improved implementation of proven interventions therefore requires a variety of strategies targeted at patients, healthcare providers, inpatient care settings, ambulatory care settings, and health systems.

Table 38-11: Barriers to Implementation of Preventive Services

Patient

- Lack of knowledge and motivation
- Lack of access to care
- Cultural factors
- Social factors
- Physician
- Problem-based focus
- Feedback on prevention is negative or neutral
- Time constraints
- Lack of incentives, including reimbursement
- Lack of training
- Poor knowledge of benefits
- Perceived ineffectiveness
- Lack of skills
- Lack of specialist-generalist communication
- Lack of perceived legitimacy
- Health care settings (hospitals, practices, etc.)
- Acute care priority
- Lack of resources and facilities
- Lack of systems for preventive services
- Time and economic constraints
- Poor communication between specialty and primary care providers
- Lack of policies and standards
- Community/society
- Lack of policies and standards
- Lack of reimbursement

Strategies to Improve Preventive Cardiology Services

IMPROVING PATIENT COMPLIANCE

While there is a pervasive tendency to blame the patient, health care providers can take a number of actions to improve their patients' compliance with the treatment regimen.[293,294] These include (1) encouragement to engage in prevention and treatment behaviors essential to adherence with a regimen, such as acceptance and understanding of the need to control risk factors, (2) establishment of specific behavioral or physiological goals, (3) skills training of patients for adopting and maintaining the recommended behaviors, (4) recommending self-monitoring of progress toward the goals, and (5) helping patients anticipate and resolve problems that keep the goals from being realized. This will require regular communication between providers and patients about the goals and actions agreed upon.[293]

IMPROVING PERFORMANCE BY HEALTHCARE PROVIDERS

Providers must foster effective communication with both their patients and other health professionals on the preventive cardiology team.[293] Strategies to improve this communication include verbal and written instructions, negotiation of goals and a plan with the patient, and anticipation of barriers to successful attainment of goals. There also must be documentation and monitoring of progress toward goals, with assessment of patient compliance at each visit and reminder systems (e.g., listing smoking status as a vital sign) to assure that risk factors are identified and attended to. One barrier to physician action in this area is a perceived lack of legitimacy by cardiovascular specialists for involvement in risk factor management. *Professional societies counter this problem by strongly recommending that risk factor management be part of the optimal care of patients at high risk for cardiovascular disease and therefore be the responsibility of all health care providers.*[1]

IMPROVING THE INPATIENT CARE SETTING

The admission to an inpatient unit provides an enormous opportunity for risk behavior change that should not be missed, for several reasons. First, the opportunity to reduce short-term risk in patients following infarction or revascularization has not been extensively studied, but several interventions such as antiplatelet therapy, ACE inhibitors, beta blockers, and even lipid management appear to provide benefit within days or weeks. Second, the patient and family are aroused to the risk of disability and death, and their receptivity to behavior-change messages is likely highest at this time. Finally, the message communicated to the patient and their primary care provider is that behavior change is an important, integral part of their postcoronary care, along with revascularization and pharmacotherapy.

The inpatient setting can be reorganized to provide efficient risk factor assessment and management. The joint AHA/American College of Cardiology (ACC) guidelines for comprehensive risk reduction for patients with coronary and other vascular disease provide a convenient list of risk factor goals and modification strategies (Table 38-12).[167] These can be transcribed onto a simple checklist or more elaborate care protocols. The cardiovascular specialist should confirm the diagnosis of prevalent risk factors, set goals for treatment, and integrate a treatment plan into the overall regimen of care. However, the physician is often not the best person to carry out the plan, due in part to time constraints, acute care focus, and short hospital length of stay. A better model is the multidisciplinary

team approach, with nurses, nutritionists, and exercise physiologists assigned specific tasks for the patient's care. A strategy with proven effectiveness is the nurse case-manager approach, with a nurse initiating care in the hospital and following the patient to the ambulatory care setting. In one randomized trial of this approach, smoking cessation, LDL-cholesterol levels, and aerobic capacity all improved in patients assigned to a system of nurse case management, as compared with usual care.[295]

Table 38-12: American Heart Association Guide to Comprehensive Risk Reduction for Patients with Coronary and Other Vascular Disease

Risk Intervention	Recommendations
Smoking Goal complete cessation	Strongly encourage patient and family to stop smoking. Provide counseling, nicotine replacement, and formal cessation programs as appropriate.
BP control Goal <140/90 mmHg or <130/85 mmHg if heart failure, renal insufficiency or diabetes.	Initiate lifestyle modification—weight control, physical activity, alcohol moderation, and moderate sodium restriction—in all patients with blood pressure ≥130 mmHg systolic or 85 mmHg diastolic. Add blood pressure medication, individualized to other patient requirements and characteristics (i.e., age, race, need for drugs with specific benefits) if blood pressure is not less than 140 mmHg systolic or 90 mmHg diastolic or if blood pressure is not <130 mmHg systolic or 85 mmHg diastolic for individuals with heart failure, renal insufficiency, or diabetes.
Lipid management Primary goal LDL <100 mg/dL Secondary goals HDL >35 mg/dL; TG <200 mg/dL	Start AHA Step II Diet in all patients: ≤30% fat, <7% saturated fat, <200 mg/ day cholesterol and promote physical activity. Assess fasting lipid profile. In post-MI patients, lipid profile may take 4 to 6 weeks to stabilize. Add drug therapy according to the following guide:

LDL <100 mg/dL	LDL 100 to 130 mg/dL	LDL > 130 mg/dL	HDL <35 mg/dL
No drug therapy	Consider adding drug therapy to diet, as follows:	Add drug therapy to diet, as follows:	Emphasize weight management and physical activity. Advise smoking cessation. If needed to achieve LDL goals, consider niacin, statin, fibrates.

Suggested drug therapy		
TG <200 mg/dL	TG 200 to 400 mg/dL	TG >400 mg/dL
Statin Resin Niacin	Statin Niacin	Consider combined drug therapy (niacin, fibrates, statin)

	If LDL goal not achieved, consider combination drug therapy.
Physical activity Minimum goal 30 min 3 to 4 times per week	Assess risk, preferably with exercise test, to guide prescription. Encourage minimum of 30 to 60 min of activity 3 or 4 times weekly (walking, jogging, cycling, or other aerobic activity) supplemented by an increase in daily lifestyle activities (e.g., walking breaks at work, gardening, household work). Maximum benefit 5 to 6 h a week. Advise medically supervised programs for moderate- to high-risk patients.
Weight management Goal BMI 21–25 kg/m^2	Measure patient's weight and height, BMI, and waist-to-hip ratio at each visit as part of routine evaluation. Start weight management and physical activity as appropriate. Desirable BMI range: 21–25 kg/m^2. Desirable waist circumference <40 inches in men and <36 inches in women.
Diabetes	Appropriate hypoglycemic therapy to achieve near normal fasting plasma glucose as indicated by HbA_{1c}.

management	Treatment of other risks (e.g., physical activity, weight management, blood pressure) and for cholesterol manage-
Near normal fasting plasma glucose and near normal HbA_{1c}(<7)	ment see recommendations above.
Antiplatelet agents/ anticoagulants	Start aspirin 80 to 325 mg/day if not contraindicated. Consider clopidogrel as an alternative if aspirin contraindicated.
	Manage warfarin to international normalized ratio = 2 to 3.5 post-MI patients not able to take aspirin.
ACE inhibitors post-MI	Start early post-MI in stable high-risk patients [anterior MI, previous MI, Killip class II (S_3 gallop, rales, radiographic CHF)].
	Continue indefinitely for all with LV dysfunction (ejection fraction ≤40%) or symptoms of failure.
	Use as needed to manage blood pressure or symptoms in all other patients.
Beta blockers	Start in high-risk post-MI patients (arrhythmia, LV dysfunction, inducible ischemia) at 5 to 28 days. Continue 6 months minimum. Observe usual contraindications.
	Use as needed to manage angina, rhythm, or blood pressure in all other patients.
Estrogens	Estrogen replacement: individualize consistent with other health risks.

ABBREVIATIONS: ACE = angiotensin-converting enzyme; AHA = American Heart Association; BMI = body mass index; HDL = high-density lipoprotein; LDL = low-density lipoprotein; LV = left ventricular; MI = myocardial infarction; TG = triglycerides; CHF = congestive heart failure.
SOURCE: Adapted from Gibbons et al.,[137] and Smith et al.,[56] with permission.

IMPROVING THE AMBULATORY CARE SETTING

The AHA guidelines for primary prevention of cardiovascular diseases (Table 38-13) and for comprehensive risk reduction for patients with coronary and other vascular disease (Table 38-12) provide clear risk factor goals and risk-reduction strategies.[168] The office or clinic should strive to develop an environment supportive of risk factor management, including staff trained in behavior-modification skills, follow-up protocols, and tracking systems and reminders. A clear assignment of tasks and responsibilities is important, with defined roles for the physician, nurse, nutritionist, and even receptionist.

Table 38-13: American Heart Association Guide to Primary Prevention of Cardiovascular Diseases

Risk Intervention	Recommendations
Smoking Goal complete cessation	Ask about smoking status as part of routine evaluation. Reinforce nonsmoking status. Strongly encourage patient and family to stop smoking. Provide counseling, nicotine replacement, and formal cessation programs as appropriate.
Blood pressure control Goal <140/90 mmHg or <130/85 mmHg if heart failure, renal insufficiency or diabetes	Measure blood pressure in all adults at least every 2 years. Promote lifestyle modification: weight control, physical activity, moderation in alcohol intake, and moderate sodium restriction. If blood pressure ≥140/90 mmHg after 6 months of lifestyle modification or if initial blood pressure >160/100 mmHg or >130/85 mmHg with heart failure, renal insufficiency or diabetes, add blood pressure medication. Individualize therapy to patient's age, race, need for drugs with specific benefits, etc.
Cholesterol management Primary goal LDL <160 mg/dL if 0–1 risk factors or LDL <130 mg/dL if ≥2 risk factors Secondary goals HDL >35 mg/dL; TG <200 mg/dL	Ask about dietary habits as part of routine evaluation. Measure total and HDL cholesterol in all adults ≥20 years and assess positive and negative risk factors at least every 5 years. For all persons: promote AHA Step I diet (≤30% fat, <10% saturated fat, <300 mg/day cholesterol), weight control, and physical activity. Measure LDL if total cholesteral ≥240 mg/dL or ≥200 mg/dL with ≥2 risk factors or if HDL <35 mg/dL. Risk factors: age (men ≥45 years, women ≥55 years or postmenopausal), hypertension, diabetes, smoking, HDL <35 mg/dL, family history of CHD in first-degree relatives (in male relatives <55 years, female relatives <65 years). HDL ≥60 mg/dL, subtract 1 risk factor from the number of positive risk factors. If LDL ≥160 mg/dL with 0–1 risk factors; or ≥130 mg/dL on 2 occasions with ≥2 risk factors; then Start Step II diet (≤30% fat, <7% saturated fat, <200 mg/dL cholesterol) and weight control. Rule out secondary causes of high LDL (LFTs, TFTs, UA). If LDL ≥160 mg/dL plus 2 risk factors; or ≥190 mg/dL; or ≥220 mg/dL in men <35 y; or in pre-menopausal women; then consider adding drug therapy to diet therapy for LDL levels > those listed above that persist despite Step II diet. Suggested drug therapy for high LDL levels (≥160 mg/dL) (drug selection priority modified according to TG level) TG <200 mg/dL: Statin, Resin, Niacin TG 200–400 mg/dL: Statin, Niacin TG >400 mg/dL: Consider combined drug therapy (niacin, fibrates, statin) HDL <35 mg/dL: Emphasize weight management and physical activity, avoidance of cigarette smoking. Niacin raises HDL. Consider niacin if patient has ≥2 risk factors and high LDL (except patients with diabetes). If LDL goal not achieved, consider combination drug therapy.
Physical activity Goal Exercise regularly 3–4 times per week for 30–60 min	Ask about physical activity status and exercise habits as part of routine evaluation. Encourage 30 min of vigorous-intensity dynamic exercise 3 to 4 times per week as well as increased physical activity in daily life style activities (e.g., walking breaks at work, gardening, household work). Advise medically supervised programs for those with low functional capacity and/or comorbidities.
Weight management Goal BMI 21–25 kg/m^2	Measure patient's weight and height, BMI, and waist-to-hip ratio at each visit as part of routine evaluation. Start weight management and physical activity as appropriate. Desirable BMI range: 21–25 kg/m^2. Desirable waist circumference <40 inches in men and <36 inches in women.
Diabetes management:	Appropriate hypoglycemic therapy to achieve near normal fasting plasma glucose as indicated by HbA_{1c}. Treatment of other risks (e.g., physical activity, weight management, blood pressure and for cholesterol manage-

Near normal fasting plasma glucose and near normal HbA_{1c} (<7)	ment see recommendations for patients with coronary disease on other side.)
Estrogens	Consider estrogen replacement in all postmenopausal women, especially those with multiple CHD risk factors. Individualize recommendation consistent with other health risks.

ABBREVIATIONS: BMI = body mass index (704.5); CHD = coronary heart disease; HDL = high-density lipoprotein; LDL = low-density lipoprotein; LFT = liver function test; TFT = thyroid function test; TG = triglycerides; UA = uric acid.
SOURCE: Adapted from Grundy et al.,[166] with permission.

A number of specialty units might be convenient platforms for risk factor management. Cardiac rehabilitation has been documented, in meta-analyses of randomized clinical trials, to reduce coronary disease recurrence and death significantly, especially when the service includes risk factor modification.[164] The patients' extended exposure (after 12 weeks or longer) to a supportive environment provides the opportunity for behavior change, monitoring, and reinforcement. Likewise, a nurse case-manager program with extension to the ambulatory care setting provides long-term continuity and support for meaningful behavior change.[295]

IMPROVING THE HEALTH SYSTEM

Supportive of this are a large number of guidelines from professional societies, expert bodies, and governmental agencies that support preventive cardiology practices. The joint AHA/ACC guidelines in risk reduction[167] are coordinated with more extensive guidelines for individual risk factors, including hyperlipidemia,[8] hypertension,[132] smoking,[296] cardiac rehabilitation,[297] and obesity.[49] These provide clear recommendations for health care providers as to the goals and scenarios required for optimal risk reduction. Increasingly, these guidelines are being used in quality assurance programs that use provision of preventive services and attainment of risk factor goals as quality-of-care indicators. The use of preventive cardiology services as such quality indicators has motivated health care systems to implement the reorganization and reallocation of resources that have been shown to be effective in improving preventive cardiology care.

Part 6: CORONARY HEART DISEASE
Chapter 39:

NONATHEROSCLEROTIC CORONARY HEART DISEASE

Author: Bruce F. Waller

Although atherosclerotic disease of the coronary arteries is the most common cause of luminal narrowing and coronary heart disease, there are multiple nonatherosclerotic (congenital and acquired) causes of severe luminal narrowing and subsequent clinical coronary events (angina pectoris, acute myocardial infarction, and sudden death) (Table 39-1).

Table 39-1: Nonatherosclerotic Causes of Coronary Artery Disease (Coronary Heart Disease)

Congenital anomalies	Metabolic disorders
Anomalous origin from the aorta	Mucopolysaccharidoses (Hurler, Hunter)
Right-from-left sinus of Valsalva	Homocystinuria
Left-from-right sinus of Valsalva	Fabry's disease
Single coronary artery	Amyloid
Atresia of coronary ostium	Intimal proliferation
High-takeoff coronary ostium	Irradiation therapy
Ostial ridges	Cardiac transplantation
Anomalous origin from the pulmonary trunk	Fibromuscular hyperplasia (methysergide therapy)
Fistula	Ostial cannulation
Myocardial bridges (tunneled epicardial artery)	Transluminal balloon angioplasty
Embolus Natural	Idiopathic infantile arterial calcification (juvenile internal sclerosis)
Thrombus	Cocaine
Tumor	External compression
Calcium	Aortic aneurysm
Vegetation (infective, noninfective)	Tumor metastases
Iatrogenic	Muscle bridges
Cardiac surgery	Thrombosis without underlying atherosclerotic plaque
Cardiac catheterization	Polycythemia

Coronary angioplasty	Thrombocytosis
Prosthetic valves	Hypercoagulability
Paradoxical	Substance abuse
Dissection	Cocaine
Coronary artery	Amphetamines
Aortic	Myocardial oxygen demand-supply disproportion
Spasm	Aortic stenosis
Trauma	Systemic hypotension
Nonpenetrating	Carbon monoxide poisoning
Penetrating	Increased myocardial function (thyrotoxicosis)
Surgery	Intramural coronary artery disease (small vessel disease)
Catheterization	Hypertrophic cardiomyopathy
Arteritis	Amyloid
Takayasu's disease	Cardiac transplantation
Polyarteritis nodosa	Neuromuscular
Systemic lupus erythematosus	Diabetes mellitus
Kawasaki's syndrome (mucocutaneous lymph node syndrome)	Normal coronary arteries
Syphilis	
Other infections (infective endocarditis, *Salmonella*, parasites)	
Buerger's disease	
Giant-cell arteritis	

SOURCES: Adapted from Waller,[1] Alpert and Braunwald,[2] Cheitlin et al.,[4] and Baim and Harrison.[5]

Various nonatherosclerotic coronary artery diseases can reduce or interrupt coronary arterial blood flow by various mechanisms: (1) fixed luminal obstructions (internal narrowing), (2) encroachment of the lumen by disease of the arterial wall or adjacent tissues (external narrowing), or (3) both.[1] Reduction in coronary arterial blood flow also may result from dynamic changes in the walls of an otherwise normal artery (spasm) or from a disproportion of myocardial oxygen supply and demand. In view of current trends toward rapid coronary artery reperfusion to salvage jeopardized myocardium during evolving acute myocardial infarction, the various nonatherosclerotic etiologies of coronary artery disease must be kept in mind.

FREQUENCY OF NONATHEROSCLEROTIC CORONARY NARROWING PRODUCING FATAL MYOCARDIAL INFARCTION

Approximately 4 to 7 percent of all patients with acute myocardial infarction and nearly 4 times this percentage for patients under age 35 do not have atherosclerotic coronary artery disease (CAD) as

demonstrated by coronary arteriography, at necropsy, or both.[1-5] In view of the fact that coronary angiography simply represents an image of one lumen, the specificity for etiology of the coronary luminal narrowing is extremely low. Review of necropsy studies[1,3,4] suggests that approximately 95 percent of patients with fatal acute myocardial infarction have at least one major epicardial coronary artery with severe luminal narrowing or total occlusion (Fig. 39-1). The remaining 5 percent of patients apparently have normal major epicardial coronary arteries. Of the 95 percent of patients with severe coronary artery luminal narrowing, 95 percent have typical atherosclerotic plaque, with a superimposed thrombus in 85 percent of these.

The remaining 5 percent of the patients with severe coronary artery luminal narrowing have a host of etiologies (see Table 39-1), including coronary arteritis, trauma, systemic metabolic disorders, intimal fibrous proliferation, and coronary emboli. Medical centers with large populations of cardiac transplant patients will exceed the 5 percent nonatherosclerotic approximation owing to the high frequency of intimal fibrous proliferation in the coronary arteries late after transplantation. Of the 5 percent of patients seen at necropsy after fatal acute myocardial infarction with normal or nearly normal epicardial coronary arteries, perhaps 50 to 60 percent represent clinical coronary spasm, but the remaining 40 to 50 percent represent a combination of congenital coronary artery anomalies, spontaneous recanalization, and mismatches of coronary supply and myocardial demand (see also Chap. 35).

NEXT

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CONGENITAL CORONARY ARTERY ANOMALIES

Variation in the origin, course, or distribution of the epicardial coronary arteries is found in 1 to 2 percent of the population[1,6-14] (Table 39-2 and Fig. 39-2). Certain types of these anomalies-including ostial lesions, passage of a major artery between the walls of the pulmonary trunk, a major coronary artery originating from the pulmonary trunk, or perhaps myocardial bridges-may produce ischemia with subsequent myocardial infarction[8] (see also Chaps. 15 and 63).

Table 39-2: Certain Coronary Arterial Anomalies Associated with Clinical Coronary Events or Coronary Artery Narrowing

Anomalous origin of one or more coronary arteries from the aorta	High-takeoff coronary ostia	Ostial narrowing
Origin of both right (R) and left (L) from same sinus of Valsalva R + LM (left main) from right sinus	Syphilis	Takayasu's disease (pulseless disease)
R + LM (left main) from left sinus	Single coronary artery	Fibromuscular hyperplasia (drug-induced)
Arising from right sinus Arising from left sinus Arising from posterior sinus	Aortic valve surgery	Fibrous ridges Protruding masses
Anomalous origin of one or more coronary arteries from pulmonary trunk (PT)	Calcific nodules	Supravalvular aortic stenosis
Origin of R from PT Origin of LM from PT Origin of left anterior descending from PT	Aortic dissection wall	Adhesion of aortic cusp to sinus Embolism
Origin of left circumflex from PT	Fibroelastosis	
Coronary artery atresia Atresia of R Atresia of LM	Coronary artery fistula	Myocardial bridges

Origin of Both Right and Left Coronary Arteries from the Same Sinus of Valsalva

When either the right or left coronary artery arises from the left or right sinus of Valsalva, respectively, the anomalous vessel transverses the base of the heart in a course anterior to the pulmonary trunk, posterior to the aorta, or between the aorta and the pulmonary trunk (Figs. 39-3 and 39-4). At least 43 cases have been reported with necropsy where the origin of the left main coronary artery is from the right sinus with passage between the aorta and pulmonary trunk.[7] In 79 percent of these patients,[3,4] death was related to the anomaly with sudden death or an

acute myocardial infarction. At necropsy, 5 of 26 patients younger than 20 years old had myocardial infarcts.[7] When the right coronary artery originates from the left sinus of Valsalva and passes between the aorta and the pulmonary trunk, symptoms of myocardial ischemia, infarction, or sudden death may occur.[7] Of 12 patients with this anomaly,[9] 3 died suddenly, and 2 had angina or syncope. At necropsy, transmural ventricular scars (healed infarction) were seen in 2.

The mechanism of ischemia, infarction, and/or sudden death in this coronary anomaly appears related to the shape of the coronary ostium of the anomalous vessel (Fig. 39-4). Normally, the coronary ostia are round to oval in shape, but in this anomaly, the coronary artery has an acute angle of takeoff that makes the ostium slitlike in shape. With increased cardiac output, the aorta dilates with stretching of the aortic wall so that this slitlike ostium may become severely narrowed (see Figs. 39-3 and 39-4). Similar mechanisms of coronary ischemia with exercise and aortic dilatation occur in case of the presence of a very acute angle of takeoff of the left main coronary artery (see Fig. 39-5) or of valvelike ridges at the ostia (see Fig. 39-6). It is unlikely that there is "compression" of the anomalous coronary artery by the aorta and pulmonary trunk in view of the marked differences in diastolic pressures. At best, there would be an anterior shift of the anomalous vessel rather than a viselike compression.

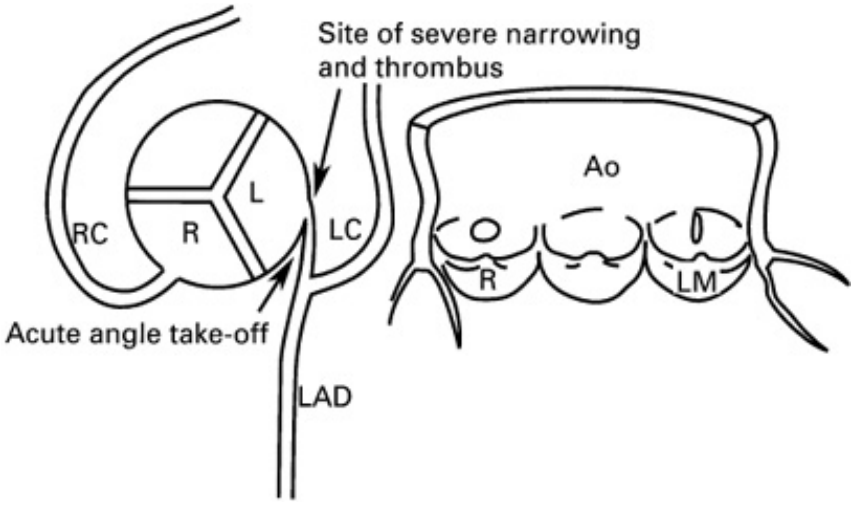

Figure 39-5: Diagram showing acute-angle takeoff of the left main coronary artery with ostial ridge and slitlike orifice. The proximal left main coronary artery is occluded by atherosclerotic plaque and thrombus, but the remaining vessels are normal. Accelerated coronary atherosclerosis may result from the acute-angle takeoff malformation. Ao, aorta; L, left cusp; LM, left main; LC, left circumflex; LAD, left anterior descending; R, right cusp; RC, right coronary. (From Menke et al.[11] Reproduced with permission from the publisher and author.)

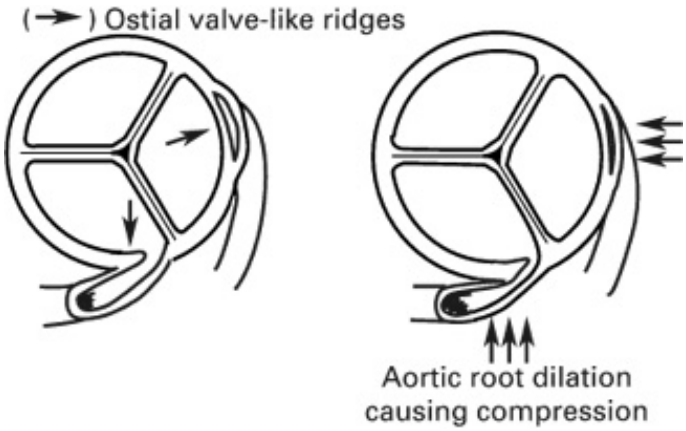

Figure 39-6: Diagram illustrating ostial valvelike ridges and the proposed mechanism of ostial compression with aortic root dilatation. (From Virmani et al.[12] Reproduced with permission from the publisher and author.)

Single Coronary Artery

Origin of the entire coronary circulation from a single aortic ostium has been termed *single coronary artery*. This anomaly is rare in the absence of other associated anomalies of the heart. One or more branches of the single artery may cross the base of the heart in a fashion described above and thus may be exposed to the risks of ischemia owing to acute angulation.[5] Angina pectoris and myocardial lactate production have been demonstrated in patients with single coronary arteries in whom coronary atherosclerosis or an anomalous coronary artery passage was absent[13] (see also Chap. 63).

Coronary Artery Atresia

Atresia of one of the two main coronary ostia may be associated with myocardial ischemia and infarction in infancy or childhood.[5] The involved vessel becomes dependent on collateral coronary blood flow from the contralateral coronary artery.

High-Takeoff Coronary Ostia

Normally, the coronary ostia are located within the sinuses of Valsalva, which optimizes coronary arterial blood flow in diastole. Location of the ostia in the tubular portion of the aorta (i.e., high-takeoff position) may be associated with decreased coronary perfusion (Figs. 39-7 and 39-8). Morphologic evidence of chronic ischemia has been reported in a patient with a high-takeoff right coronary artery who had right ventricular (RV) and left ventricular (LV) wall scarring.[14,15] High-takeoff position of the coronary ostium also has been postulated as a cause of sudden coronary death.[16] In a series of 54 major and minor coronary artery anomalies,[17] both coronary artery ostia arose above the sinotubular junction in 2, the right coronary artery ostium arose high in 5, and the left coronary artery ostium was in a high-takeoff position in 3. In 2 cases of high origin of the right coronary artery ostium, ischemia and death were attributed to the ostial lesion in 1.[18]

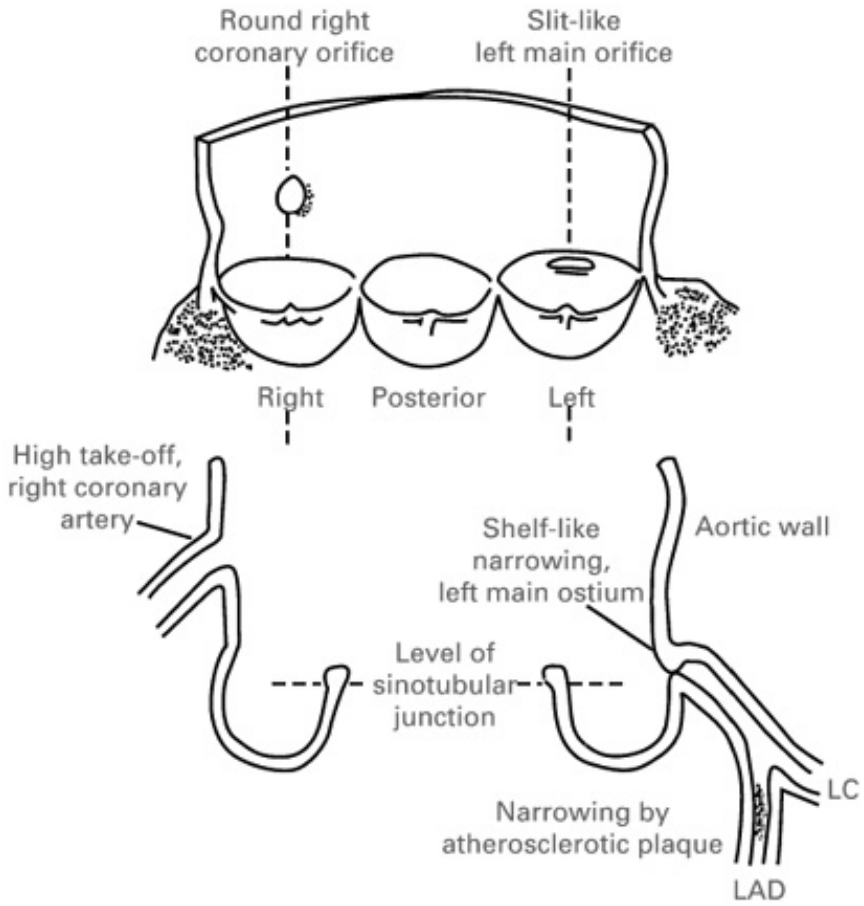

Figure 39-7: Diagram showing high-takeoff position of the right coronary artery and the nonatherosclerotic fibrous ridge occluding the left main coronary ostium. LAD, left anterior descending; LC, left circumflex. (From Foster et al.[14] Reproduced with permission from the publisher and author.)

Ostial Fibrous Ridges

Nonatherosclerotic causes of coronary ostial narrowing include syphilis,[19] Takayasu's disease (pulseless disease),[20] fibromuscular hyperplasia associated with methysergide therapy,[2122] aortic valve surgery with or without coronary artery cannulation,[14,23] and ostial valvelike ridges (see Fig. 39-7). A nonatherosclerotic fibrous shelflike ridge can project from the wall of aorta into the left main ostium.[14,15] It may have been responsible for chronic ischemia and myocardial necrosis. Other rare diseases that may narrow or occlude the coronary ostia have been summarized by Baroldi[24]: (1) a nonatheromatous, calcific protrusion from the sinotubular junction into the right or left ostium, (2) saccular aneurysm of the aorta, (3) aortic dissection extending into the coronary ostium-the right ostium involved more commonly than the left, (4) supravalvular aortic stenosis with severe intimal thickening, (5) obliteration of the ostium due to adhesion of the free edge of an aortic cusp to the aortic wall above the coronary ostium, (6) occlusion by embolus (see below), and (7) occlusive fibroelastosis.

Anomalous Origin of One or Two Coronary Arteries from the Pulmonary Trunk

Anomalous origin of a coronary artery from the pulmonary trunk (Figs. 39-9 and 39-10) may be responsible for myocardial ischemia and infarction in infants and children. In more than90 percent of cases,[5,7] the left main artery is the anomalous one; thus the anteroseptal and anterolateral LV myocardium may be at jeopardy for injury. Asymptomatic older patients with this coronary artery anomaly are usually found when they present with an abnormal

electrocardiogram (ECG), a systolic murmur, or sudden death.[7] The murmur and abnormal ECG are the result of papillary muscle and/or anteroseptal myocardial wall damage (see Chap. 42).

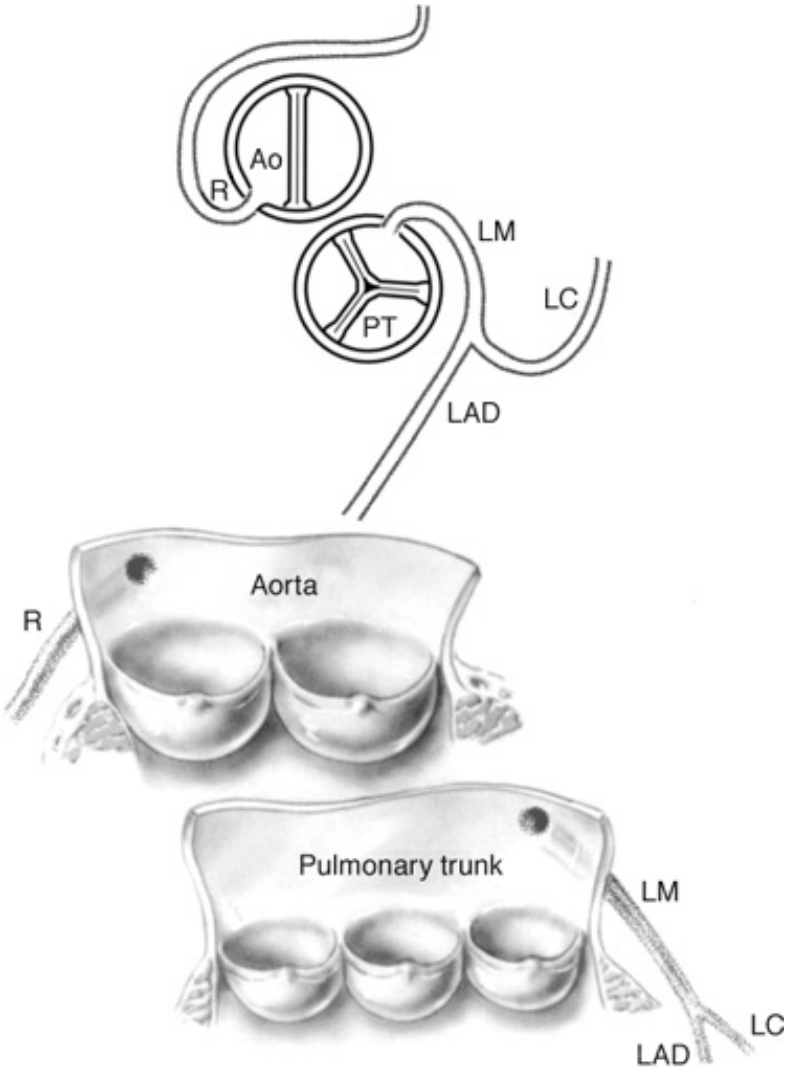

Figure 39-10: Anomalous origin of the main (LM) coronary artery from the pulmonary trunk causing acute myocardial infarction in an infant. Of interest is that both the anomalous LM and normal right coronary arteries arise in high-takeoff positions from the pulmonary trunk and aorta (Ao), respectively. LAD, left anterior descending; LC, left circumflex.

Myocardial Bridges (Tunneled Epicardial Coronary Artery)

The coronary arteries may dip into the myocardium for varying lengths and then reappear on the heart's surface (Figs. 39-11, 39-12, 39-13, 39-14, 39-15, 39-16, 39-17 and 39-18). The muscle overlying the intramyocardial segment of the epicardial coronary artery is termed a *myocardial bridge*, and the artery coursing within the myocardium is called a *tunneled artery*[25-63] (see Figs. 39-11, 39-12 and 39-13). Tunneled coronary arteries have long been recognized anatomically,[25] but suggested associations between myocardial ischemia and myocardial bridges have heightened their clinical relevance.[26,27]

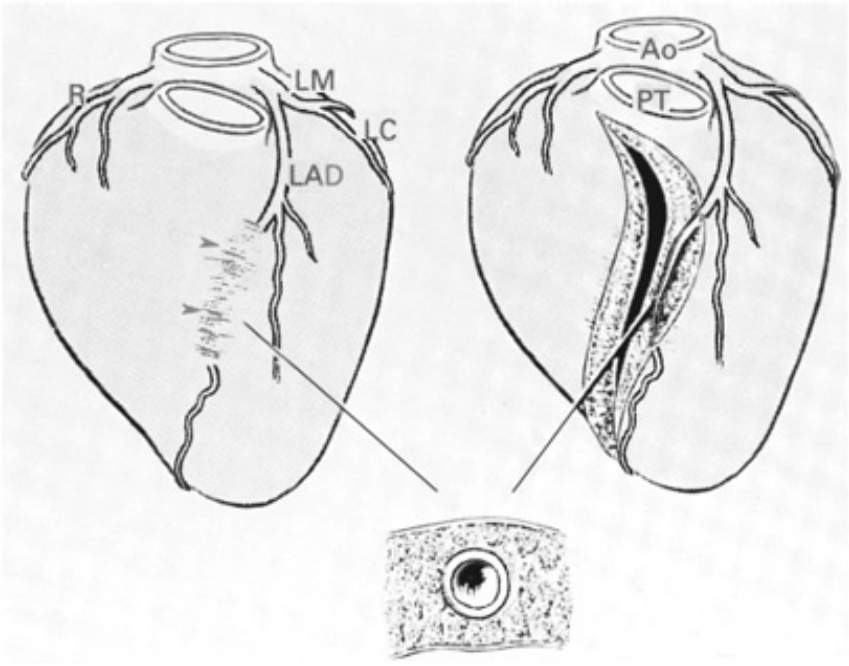

Figure 39-11: (*Left*) Diagram showing tunneled left anterior descending coronary artery (LAD) (*arrowheads*). (*Right*) Opened left ventricle showing intramyocardial segment. (*Below*) Transverse section of LV wall showing tunneled coronary artery surrounded by myocardium. (From Waller.[1] Reproduced with permission from the publisher, editor, and author.)

Tunneled coronary arteries have been presumed congenital in origin.[28] At least three factors have been postulated to account for differences between the high frequency of tunneled major coronary arteries observed at necropsy (5-86 percent[29,30,57]) and the lower frequency of tunneled coronary arteries observed angiographically (0.5-12 percent[26,31,32,58-60]) or associated with symptoms of myocardial ischemia (18 percent[32]): (1) length of the tunneled coronary segment, (2) degree of systolic compression, and (3) heart rate. Longer tunneled segments of coronary arteries,[27] more severe systolic diameter narrowing of the tunneled segment,[27] and tachycardia[33] may contribute to the production of myocardial ischemia with myocardial bridging (see Figs. 39-17 and 39-18). The length of coronary tunneling may not always be an important factor in causing myocardial ischemia, since three patients with left main intramyocardial tunneling of greater than 40 mm have been described without evidence of myocardial ischemia[34,35] (Fig. 39-19).

Treatment of symptomatic, clinically recognized myocardial bridges has involved beta and calcium-channel blockers (control of tachycardia and antispasmodic effects) and surgery. Several patients have now been reported[61-63] in which "supraarterial myotomy" (release of the myocardial bridge, excision of the myocardial bridge) has resulted in relief of symptoms and improvement in previously abnormal nuclear imaging tests. High-frequency intraoperative echocardiography has been used to image the intramyocardial coronary artery before and after surgical release.[61]

Coronary Artery Fistula

A *coronary artery fistula* is an abnormal communication between an epicardial coronary artery and a cardiac chamber, major vessel (vena cava, pulmonary veins, pulmonary artery), or other vascular structure (mediastinal vessels, coronary sinus)[5,64-113] (Fig. 39-20). This infrequent abnormality can affect persons of any age and is the most important hemodynamically significant coronary artery anomaly.[5,64-113] Many are small and found incidentally during coronary arteriography, whereas others are identified as the cause of a continuous murmur, myocardial ischemia and angina, acute myocardial infarction, sudden death, coronary steal, congestive heart

failure, endocarditis, stroke, arrhythmias, coronary aneurysm formation (rupture, emboli), or superior vena cava syndrome.[64-76] Of over 33,000 patients undergoing coronary arteriography,[34] coronary artery fistula occurred in 0.1 percent,[76] whether due to congenital[77-85] or acquired causes[76-113] (Table 39-3). Fistulas from the right coronary artery are more common than from the left,[64-113] and over 90 percent of the fistulas drain into the venous circulation.[64-113] Most fistulas are single communications, but multiple fistulas have been identified.[106] The natural history of coronary artery fistulas is variable, with long periods of stability in some and sudden onset or gradual progression of symptoms in others. Spontaneous closure is uncommon.[106-108] Surgical repair of the fistula is recommended for symptomatic patients and for those asymptomatic patients at risk for future complications (coronary steals, aneurysms, large shunts).[109-112] Transcatheter embolization of fistulas has been reported.[113] Direct connection between a major epicardial coronary artery and a cardiac chamber or major vessel (vena cava, coronary sinus, pulmonary artery) is the most common hemodynamically significant coronary artery anomaly[5] (see Fig. 39-19). Myocardial ischemia has been documented in some patients with coronary artery fistulas who have no evidence of coronary atherosclerosis.[5]

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CORONARY ANEURYSMS

Aneurysm formation of the coronary arteries may result from congenital or acquired conditions. Congenital coronary artery aneurysms are found most commonly in the right coronary artery.[114] Abnormal flow patterns within the aneurysm may lead to thrombus formation with subsequent vessel occlusion, distal thromboembolization, and myocardial infarction.[115] In general, angina pectoris or acute myocardial infarction present in patients younger than 20 years of age should prompt suspicion of a congenital coronary artery anomaly or a congenital coronary artery aneurysm.[114] Coronary artery aneurysms are found in about 1.5 percent of patients studied at necropsy or by coronary arteriography.[37] Coronary artery aneurysms, which may be multiple, can be congenital or the result of atherosclerosis, trauma, angioplasty, atherectomy, laser procedures, arteritis (including syphilis), mycotic emboli, mucocutaneous lymph node syndrome (Kawasaki's disease), systemic lupus erythematosus,[116] or dissection (spontaneous or secondary) (Table 39-4). Atherosclerosis-induced aneurysms are thought to result from primary thinning and/or destruction of the media and may represent up to 50 percent of the causes (see Table 39-4). Angioplasty, atherectomy, vasculitis, and arteritis also may damage the arterial wall (media) and lead to coronary aneurysms.

Table 39-4: Causes of Coronary Arterial Aneurysms

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CORONARY ARTERY EMBOLI

Coronary arterial emboli (Figs. 39-21 to 39-25) are clinically suspected in patients who develop severe chest pain with acute myocardial infarction in the presence of a prosthetic left-sided valve, active infective endocarditis, native left-sided valve stenosis, atrial fibrillation, LV aneurysm, dilated cardiomyopathy (see Fig. 39-22), known cardiac tumor, or during cardiac catheterization or cardiac surgery. Coronary emboli can be due to natural, iatrogenic, or "paradoxical" causes (Table 39-5; see also Figs. 39-21 to 39-25).[117-138] Coronary embolism most often involves the left anterior descending coronary artery.[36]

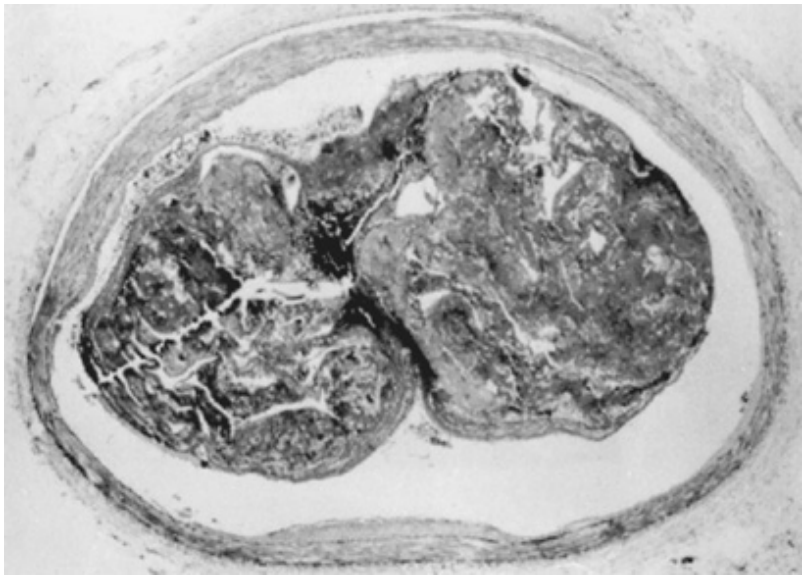

Figure 39-21: Coronary artery embolus. Fibrin-platelet thrombus occluding the left anterior descending coronary artery. The source of the embolus was not established, but the patient recently underwent cardiac surgery. (From Waller.[1] Reproduced with permission from the publisher, editor, and author.)

Table 39-5: Etiology of Coronary Artery Emboli

Natural	Iatrogenic
Vegetation Active infective endocarditis (native valve)	Cardiac surgery (ostial cannulization, prosthetic valve, patch repair)
Active infective endocarditis (prosthetic valve) Mural endocarditis	Cardiac catheterization and angiography (catheter thrombus, catheter fragments)
Noninfective (marantic) endocarditis Calcific deposit	Coronary angioplasty, other interventions, catheter balloon valvuloplasty and thrombolysis
Aortic valve stenosis Mitral valve stenosis	Prosthetic valves (thrombus, vegetation, occluders, leaflets, cloth covering, struts)

Intracardiac thrombus Left ventricle (myocardial infarction, cardiomyopathy, fibroelastosis with mural thrombus, ventricular aneurysm)	Cardioversion (left atrial thrombus, left ventricular thrombus) Cardiac resuscitation (thrombus)
Left atrium-appendage (low-cardiac-output states) Left atrium-body (mitral stenosis, native or prosthetic)	Trauma-blunt penetrating, nonpenetrating, foreign body (bullet)
Pulmonary veins (mitral stenosis)	'Paradoxical'
Intracardiac tumor Primary (myxoma)	Congenital heart disease (atrial septal defect, ventricular septal defect)
Secondary (extension from pulmonary veins, lymphatic extension, direct extension)	Probe patent foramen ovale defect (thrombophlebitis, right atrial catheters)
Coronary artery	Pulmonary hypertension (acquired atrial septal defect)
Plaque rupture (cholesterol)	Interatrial flap valve (fossa ovale aneurysm)
Thrombus dislodgment	

SOURCE: Waller.[1] Reproduced with permission from the author, editor, and publisher.

Coronary embolism is suspected as the cause of acute myocardial infarction when, at necropsy, the zone of necrosis is large but discrete (since there was little time to develop effective collaterals). Embolic coronary artery lesions can resolve completely and spontaneously and provide an explanation for angiographically normal coronary arteries several months following an acute myocardial infarction.[36]

The consequences of coronary embolism depend on two major factors (see Fig. 39-25): the size of the embolus and the size of the lumen of the artery in which it becomes impacted.[139,140] The smaller the embolus, the greater is the chance that it will travel distally to a small coronary arterial segment and the less is the likelihood of myocardial infarction or fatal arrhythmia.[139] An embolus so small that it travels distally and impacts in a single intramural vessel is probably clinically silent and observed only at necropsy.[139,140] The status of the coronary lumen before the embolus appears also determines the subsequent myocardial consequences. An embolus to a previously normal coronary artery is likely to migrate distally and result in localized myocardial infarction because of absence of collaterals. An embolus traveling to a previously diseased coronary artery is more likely to impact proximally. Emboli to the left main coronary arteries are rare but usually fatal[140] (see Fig. 39-24).

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CORONARY ARTERY DISSECTION

Separation of the media by hemorrhage with or without an associated intimal tear is termed *coronary artery dissection*. The medial separation forces the intimal-medial layer (wall of the true channel) toward the true coronary lumen and produces distal myocardial ischemia/infarction (Figs. 39-26 and 39-27). Coronary artery dissections may be primary or secondary[141-168] (Table 39-6). Secondary coronary artery dissections are more frequent, especially those associated as an extension from aortic root dissection (8 percent).[5] Primary coronary artery dissections may occur spontaneously or as a consequence of coronary angioplasty or angiography, cardiac surgery, or chest trauma (0.3 percent).[158] Most spontaneous coronary artery dissections occur in women who are most commonly postpartum; they may be associated with coronary artery wall eosinophils.[141-165] The left anterior descending artery is the one most frequently involved. Systemic hypertension does not appear to provide a significant factor of risk.[114]

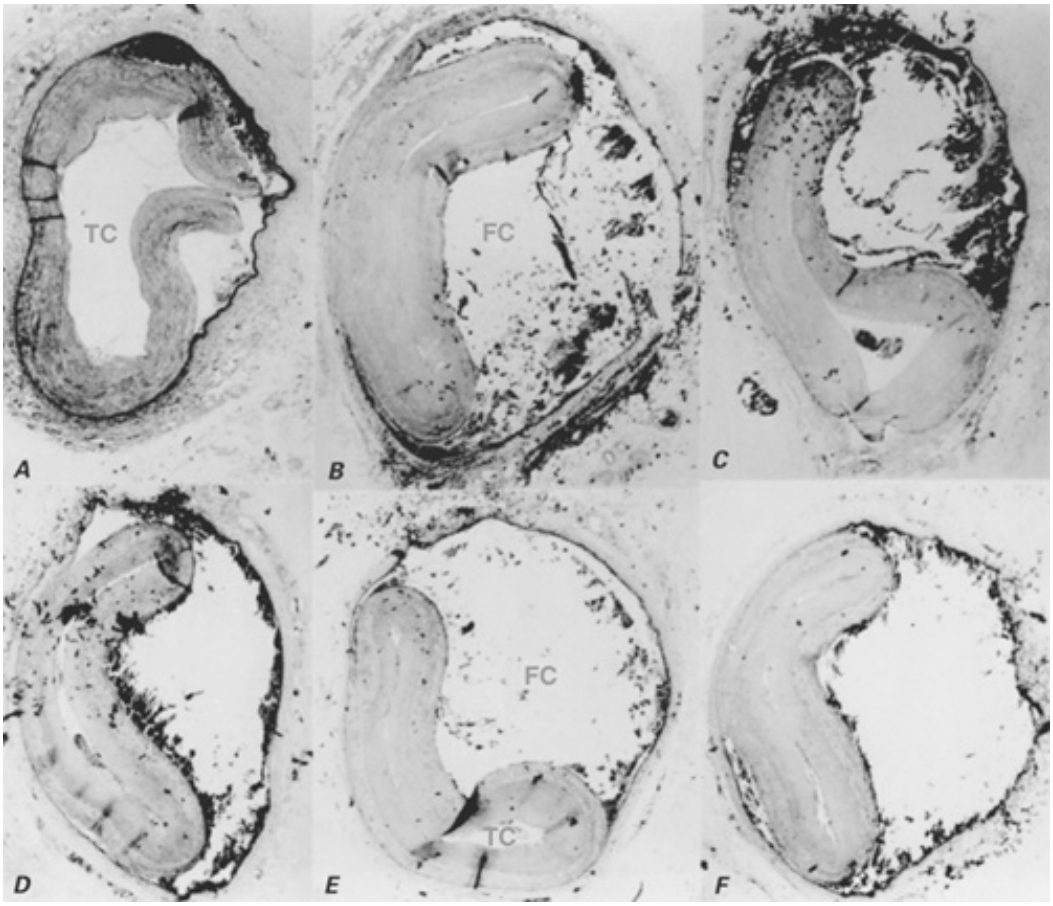

Figure 39-26: Coronary artery dissection. Serial cross section (*A-F*) showing dissection of the left anterior descending coronary artery. The true channel (TC) is severely compromised by external compression from the false channel (FC) ("dissection channel"). (From Waller.[1] Reproduced with permission from the publisher, editor, and author.)

Table 39-6: Causes of Coronary Artery Dissections[141-168]

I. Spontaneous
   A. Post- or peripartum[142,146,148,156,160,161,163,164,166,167]
   B. With or without eosinophilia[142,156,161,163]
   C. Idiopathic[145,150-152,154,158,159,162,163,165]
   D. Systemic hypertension[155]
   E. Coronary spasm
   F. Aortic root dissection[163] (hyperten-sion, medial degeneration)
   G. Arteritis[162]
   H. Fibromuscular hyperplasia

II. Trauma
   A. Post- or peripartum[146,148,160,164,167]
   B. Blunt chest[157] (penetrating, nonpene-trating)
   C. Coronary angiography[153]
   D. Coronary interventions[147,168] (angi-oplasty, atherectomy, laser, stenting,rotablade)
   E. Cardiac surgery (coronary bypass, cor-onary ostial cannulation, endarter-ectomy)
   F. Aortic root dissection[149] (surgery, non-penetrating, penetrating)

Spontaneous coronary artery dissection may result in sudden death or acute myocardial infarction and subsequent death. Parenthetically, localized and limited coronary artery dissection (i.e., intimal-medial tear) appears necessary for a clinically successful coronary artery balloon angioplasty procedure[143,144] (see also Chap. 45).

Coronary angioplasty dissections viewed in short- or long-axis tomographic images help distinguish dissections that are *therapeutic* (mechanism) from those which are *complications of angioplasty* (complications).[168] In the short-axis image, dissection involving more than 50 percent of the coronary medial circumference has been considered a complication. Similarly, in the long-axis image, dissections (antegrade, retrograde, or both) longer than 1 cm in length also have been defined as a complication of angioplasty (Fig. 39-28). A combination of dissection greater than 50 percent of the short-axis circumference and greater than 1 cm antegrade or retrograde of long-axis length may result in "intussusception" of intimal-medial tissue. Spiral dissections ("the ugly") are among the most serious dissection injuries after balloon angioplasty (Fig. 39-29). The spiral dissection as reviewed angiographically appears to alternate from side to side, extending antegrade and retrograde (see Fig. 39-29*A*), or it has an unaltered dissection course but appears alternating from limited angiographic views (see Fig. 39-29*B*).

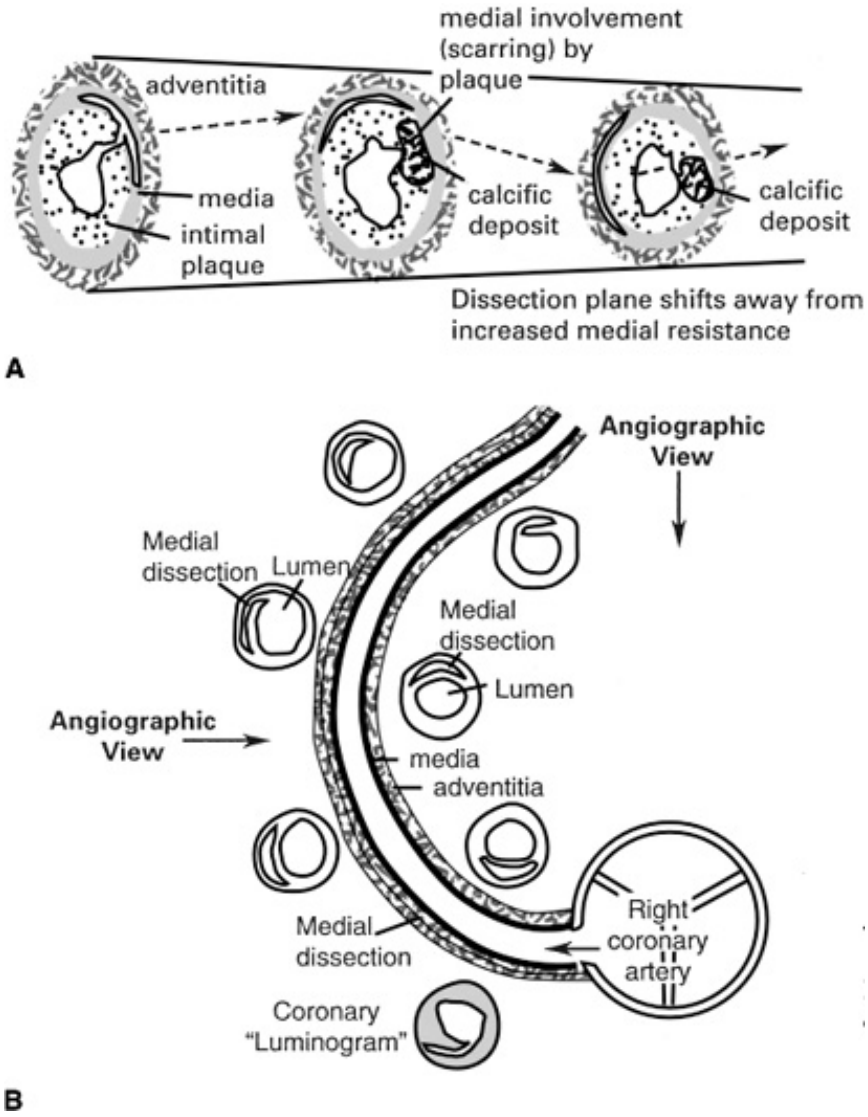

Figure 39-29: Diagram showing pathologic change accounting for angiographic appearance of coronary artery "spiral" dissection. *A.* Alteration in course of dissection. *B.* Angiographic appearance of unaltered course of dissection. Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CORONARY ARTERY SPASM

Coronary artery luminal narrowing produced by spasm has been associated with angina pectoris, acute myocardial infarction, and sudden death[141,169-195] (see also Chap. 41). Despite the extensive clinical information about coronary artery spasm, relatively few necropsy data are available.[169-181] Smooth muscle cells in the coronary artery wall may contract in response to various neurologic and pharmacologic stimuli and temporarily reduce the vessel lumen. Specific pathogenesis of this disorder is unknown.[180] Enhanced α-adrenergic tone[191] and various vasoactive substances-such as histamine, catecholamines, prostaglandins, and thromboxane[189-192]-are presently thought to be relevant factors. Necropsy findings have been reviewed in 13 previously reported patients and in 3 new patients[141,180,195] (Figs. 39-30 and 39-31).

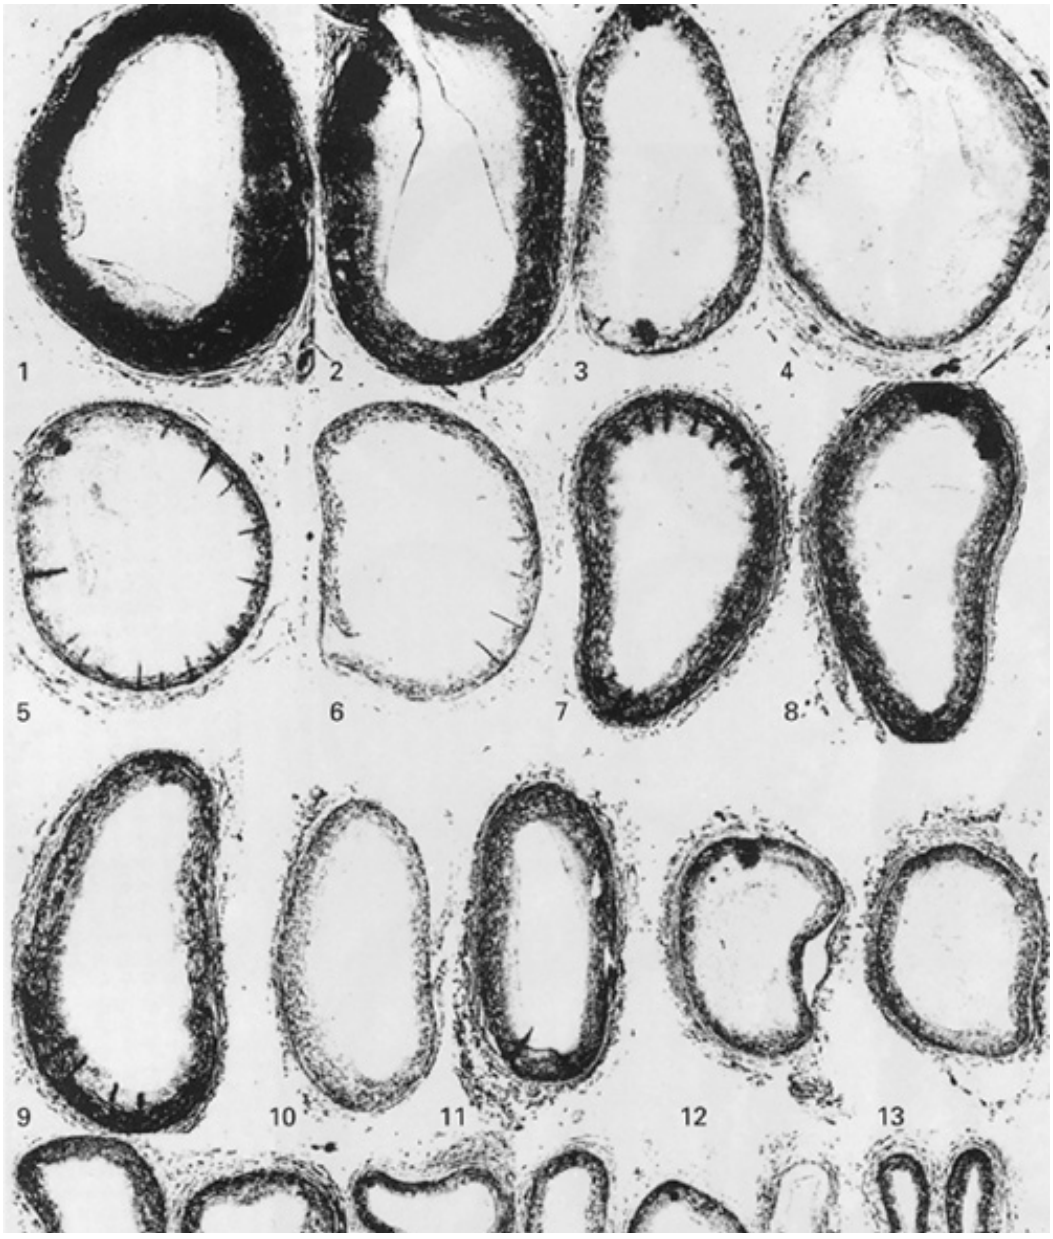

Figure 39-30: Coronary artery spasm. Composite of coronary artery cross sections of a patient with coronary spasm during life. Clinical spasm involved segments 3 to 7. Severe atherosclerotic plaque is seen in 8 of the 21 segments. (From Roberts et al.[180] Reproduced with permission from the author, editor, and publisher.)

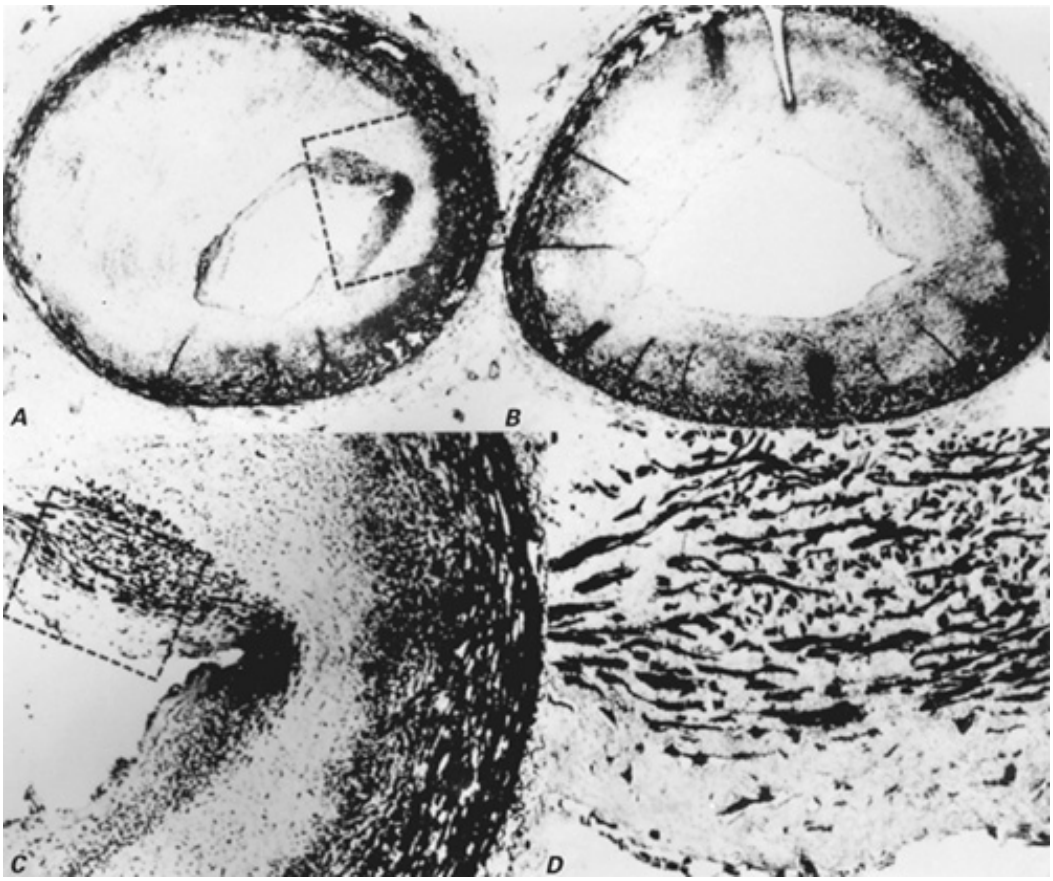

Figure 39-31: Coronary artery spasm. *A*, *B*. Histologic sections of the left anterior descending coronary artery at the approximate site of spasm showing severe luminal narrowing. *C*, *D*. Higher magnifications of the internal plaque showing the predominance of smooth muscle cells. (From Roberts et al.[180] Reproduced with permission from the author, editor, and publisher.)

Most of the 13 previous patients with clinical evidence of spasm had significant fixed coronary luminal narrowing due to atherosclerotic plaque, although coronary angiograms during life did not recognize these lesions found at necropsy.[141,195] In one of the original patients described by Prinzmetal et al.,[169] both major epicardial coronary arteries were "markedly scle rotic," and the "posterior coronary artery" was 80 percent narrowed. Of the subsequent 12 necropsy patients, 10 had at least one major artery severely narrowed by atherosclerotic plaque at necropsy.[169-181] The 3 necropsy patients with clinical spasm[141,180] all had severe luminal coronary narrowing by atherosclerotic plaque at least in the artery in which spasm had been demonstrated during life (see Figs. 39-30 and 39-31). In general, histologic sections of the left anterior descending artery at the

site of spasm disclosed luminal concentric plaque that had a predominance of smooth muscle cells, suggesting that the lesion may have been responsive to pharmacologic and neurologic stimuli compared with "garden variety" fibrotic and calcified atherosclerotic plaque (see Fig. 39-31). In a patient with normal angiograms and documented myocardial infarction, "intimal ridges" were observed on postmortem angiography; these were interpreted as evidence of spasm.[194] Similar ridges have been noted at necropsy in a patient with coronary artery spasm.[195] Histology of the ridges disclosed typical atherosclerotic plaque,[196] suggesting that varying degrees of dynamic muscular contraction may be superimposed on fixed atherosclerotic lesions, presumably related to the amount of smooth muscle present.[141] Coronary artery smooth muscle depletion ("medial attenuation"), which accompanies advanced degrees of luminal narrowing by atherosclerotic plaque, suggests diminished potential for coronary wall spasm.[196] It has been suggested recently that medial "contraction" bands may represent a morphologic-histologic marker for arteries that have spasm during life[197] (see also Chap. 41).

Eccentric atherosclerotic plaques have a segment of disease-free wall with preserved media that presumably has the potential for spasm.[198] In patients with clinical coronary spasm, unstable and stable angina pectoris, and episodes of silent myocardial ischemia, where 448 segments were narrowed by more than 75 percent in cross-sectional area by plaques, 15 percent of these segments had a variable arc of disease-free wall with normal media.[199] Other studies have found a similar 15 to 20 percent of the coronary wall normal in 70 percent of patients studied.[200-205] This disease-free coronary segment represents a site of "vasospastic potential" and could convert a hemodynamically insignificant lesion of less than 50 percent cross-sectional area into a hemodynamically significant one of more than 75 percent narrowing.

Three newly recognized associations and/or causes of coronary artery spasm include general anesthesia,[184] "allergic angina" (histamine-induced),[185] and postpartum bromocriptine use.[186] Acute ST-segment elevation has been noted following induction of general anesthesia in some patients with angiographically normal coronary arteries.[184] In postpartum women receiving bromocriptine in the presence of pregnancy-induced hypertension, acute myocardial infarction has occurred.[186] Coronary spasm also occurs with balloon angioplasty and coronary interventional procedures,[187] catheter-related angiography, and neurofibromatosis.[188]

Endothelial cell dysfunction has been proposed to explain coronary vasospasm.[189] In response to increases in shear stress, platelet products, and other agonists, normal endothelial cells release endothelium-derived relaxing factor (nitric oxide), resulting in vasodilation.[189] When endothelium is damaged, as occurs with hypertension, elevated cholesterol, smoking, or use of cocaine, endothelial nitric oxide is reduced or lost. Thus, when platelets aggregate at such sites with release of vasospastic substances such as serotonin (5HT) and thromboxane A_2, arterial smooth muscle cells contract, causing spasm.[190]

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CORONARY ARTERY TRAUMA

Coronary artery trauma may produce myocardial ischemia and/or acute myocardial infarction. Traumatic injury may result from a nonpenetrating blunt chest wall injury such as a steering-wheel impact, penetration trauma such as a laceration from a stab wound or bullet, coronary artery bypass surgery as from inadvertent ligation, laceration, or intimal dissection, or after coronary angiography or angioplasty resulting in dissection, rupture, or embolus. Nonpenetrating trauma may produce coronary artery injury and subsequent myocardial infarction due to coronary artery dissection, contusion and thrombosis, fistula formation, and/or coronary artery aneurysm formation.[5] Extensive coronary artery dissections occur more commonly as the result of catheter or cannula injury in normal or nearly normal arteries as opposed to coronary arteries with severe atherosclerotic plaque (see also Chap. 79).

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CORONARY ARTERY ARTERITIS (VASCULITIS)

Epicardial coronary artery arteritis (vasculitis) is a rare event but has been reported in several conditions (Table 39-7). The resulting coronary artery injury may lead to myocardial ischemia/infarction with or without associated coronary artery thrombosis. This type of coronary artery damage has been classified by route(s) of entry[24]: *direct extension* from adjacent organ or tissue infections, e.g., epicardial or myocardial abscess from aortic valve endocarditis, pericardial infections such as tuberculosis; *hematogenous spread* through the coronary lumen or vasa vasorum; and *unknown* route of entry. In the direct extension route of entry the adventitial layer of the artery is involved initially, whereas in the hematogenous route the coronary intimal layer is involved initially. Evidence of coronary artery arteritis has included[24] the following: (1) focal arterial necrosis with or without calcification, (2) acute coronary artery thrombosis or recanalized thrombus associated with underlying atherosclerotic plaque, (3) rupture of the vessel wall unassociated with trauma or an interventional procedure, (4) coronary artery wall thickening with secondary luminal narrowing, or (5) wall thickening with aneurysm formation.[204] Specific coronary artery lesions also may be seen with systemic diseases such as tuberculosis or polyarteritis (periarteritis).

A more recent classification of coronary artery vasculitides has been based on known and unknown causes and involvement of size of vessel (medium-sized, small-sized)[205,206] (Table 39-8). With the exception of infectious angiitis resulting from syphilitic, mycobacterial, or rickettsial infection, the causes and pathogenesis of most coronary artery vasculitides are either unknown or incompletely understood.[207] Vasculitic syndromes may be caused by deposition of immune complexes in the vessel walls.[209-214] The specific antigen has been identified in only a few cases, such as hepatitis B. Circulating immune complexes associated with hepatitis B infection may cause more than one type of vasculitic syndrome,[205] producing periarteritis nodosa in arteries of muscles and hypersensitivity angiitis in venules while eliciting the production of anti-immunoglobulin antibodies, leading to cryoglobulinemia. Thus a classification of vasculitides *based solely* on immunologic studies is incomplete[205] (see also Chap. 76).

General Concepts

The earliest vasculitic syndrome was named *periarteritis nodosa*[215] because of the nodules along the course of small arteries.[205] Because the inflammatory changes are not only periarterial, *polyarteritis* may be a better term.[216] Periarteritis nodosa has become a "wastebasket designation" of any vasculitis whose cause is unknown.[205] The term *necrotizing angiitis*[217] has been used to designate arterial and venous lesions; there are five types[217,218]: (1) hypersensitivity angiitis, (2) allergic granulomatous angiitis, (3) rheumatoid arteritis, (4) periarteritis nodosa, and (5) temporal arteritis. The term *hypersensitivity angiitis* has been considered synonymous with small-vessel vasculitis and is used to imply that the angiitis is due to an allergic response to proteins, drugs, vaccines, or infections.[205] Allergic *granulomatous angiitis* (Churg-Strauss syndrome) is a variant of polyarteritis characterized by necrotizing vasculitis with extravascular granulomas and eosinophilia associated with asthma or allergic rhinitis.[205,219-221] *Rheumatic arteritis*[222] describes vascular lesions in rheumatic diseases with both rheumatic and necrotizing vascular lesions. *Temporal arteritis* (giant-cell arteritis) involves large and small extracranial arteries, including the coronary arteries, and blindness may be a serious complication.[205,223-228] Despite its limitations, this classification[217,218] remains a basis for the diagnosis of vasculitides. The classification of coronary vasculitis is closely tied to that of vasculitides in general[205] and relates to the predominant type and size of vessels affected[229,230] (see Table 39-8 and Chap. 79).

Infectious Angiitis

Various microorganisms may cause vasculitis in vessels of any size and involve the vessel by extension of the acute or chronic infective process from an adjacent tissue or organ[24] or from the lumen by hematogenous spread (see Table 39-8). The inflammatory response produces variable reactions including suppurative inflammation (bacteria),[231] proliferative response (typhoid[232]), hemorrhagic response (anthrax), and histiocytic and granulomatous response (leprosy, syphilis, tuberculosis).[4,205] The most important angiitic infections affecting the coronary arteries include syphilis, tuberculosis, and syphilitic arteritis. All three stages of syphilis show arteritic features. The most important vascular lesion of tertiary syphilis, coronary ostial stenosis, seen in up to 4 percent of patients,[5,233-236] can occur independent of aortic involvement.[205,235] Syphilitic arteritis is characterized by a chronic inflammation with adventitial fibrosis and patchy destruction of media with a lymphoplasmacytic infiltrate. Gummas can be found in 20 percent of patients,[237] but spirochetes are detected rarely.[205] The first 3 to 4 mm of the left and right coronary arteries may be involved with an obliterative arteritis[114]; angina and acute myocardial infarction may result from syphilitic involvement.[236]

TUBERCULOUS ARTERITIS

Tuberculous coronary arteritis occurs mainly in patients with pericardial and myocardial

tuberculosis.[238,239] Granuloma may involve the adventitia, intima, or entire wall[24,239] and result from several infectious angiitic agents. Endocarditis and septicemia are the most common underlying causes of infectious angiitis and mycotic aneurysm formation.[205,240] Any type of gram-positive or gram-negative organism may be involved. Myocarditis with abscesses and pericarditis frequently accompany infectious coronary angiitis. Mucormycosis, aspergillosis, and *Candida* (Fig. 39-32) are examples of fungi and systemic yeast infections associated with coronary angiitis. Malarial parasites and parasitized red blood cells also may plug larger coronary arteries.[241] *Schistosoma haematobium* has been found in a major epicardial coronary artery associated with myocardial infarction.[242] Rickettsial infections may produce angiitis in small vessels of the heart[205,243]; these infections consist of a lymphomononuclear infiltrate with or without thrombosis. A direct toxic effect from rickettsiae may produce angiitis.[244] Viruses also have been implicated in vasculitis by direct invasion of immunologic mechanisms.[205] Virus-induced vasculitides in humans are represented by polyarteritis associated with hepatitis B antigenemia[205,245,246] and herpes zoster.[205]

Noninfectious Angiitis

Various noninfectious causes of angiitis involve large to medium-sized (predominately medium-sized and

small) blood vessels[205] (see Table 39-8).

TAKAYASU'S ARTERITIS

Takayasu's disease (pulseless disease) is one of the coronary vasculitides associated with aortitis; others are temporal arteritides and rheumatic disease (see also Chaps. 88 and 90). Takayasu's disease is a chronic, occlusive inflammatory disease of unknown etiology[205,247-256] with a worldwide distribution and greater incidence in young to middle-aged female Asians.[249,250] Involvement of the coronary arteries occurs in 15 to 25 percent of patients and may be the lethal complication[248,250-255,257] (Fig. 39-33), commonly involving the coronary ostium[248,257258-263] with segmental involvement of distal coronary arteries.[252-255,264] Rarely, diffuse coronary arteritis is produced by Takayasu's disease.[265]

(From Lie.[205] Reproduced with permission from the author, editor, and publisher.)

GRANULOMATOUS GIANT-CELL ARTERITIS (TEMPORAL ARTERITIS)

Granulomatous giant-cell arteritis may occur independently or, more commonly, may be associated with temporal arteritis in 10 to 15 percent of patients.[205,226-228,266-277] Histologically proven giant-cell coronary

arteritis is rare, and cases leading to fatal myocardial infarction are even rarer[205,266,269-272,274] (Fig. 39-34). The arterial wall lesion is a granulomatous inflammation with giant cells found along degenerative internal elastic membrane.[274] The intima becomes greatly thickened, and ultimately, the vessel is converted into a fibrous cord. Luminal thrombosis also may have been present in 16 patients with temporal arteritis reported by Harrison[275]; only 1 case involved the epicardial coronary arteries. Giant-cell arteritis of the intramural (intramyocardial) coronary arteries (Fig. 39-35) also may occur in association with temporal arteritis and giant-cell arteries[266] (see also Chaps. 76, 88, and 90).

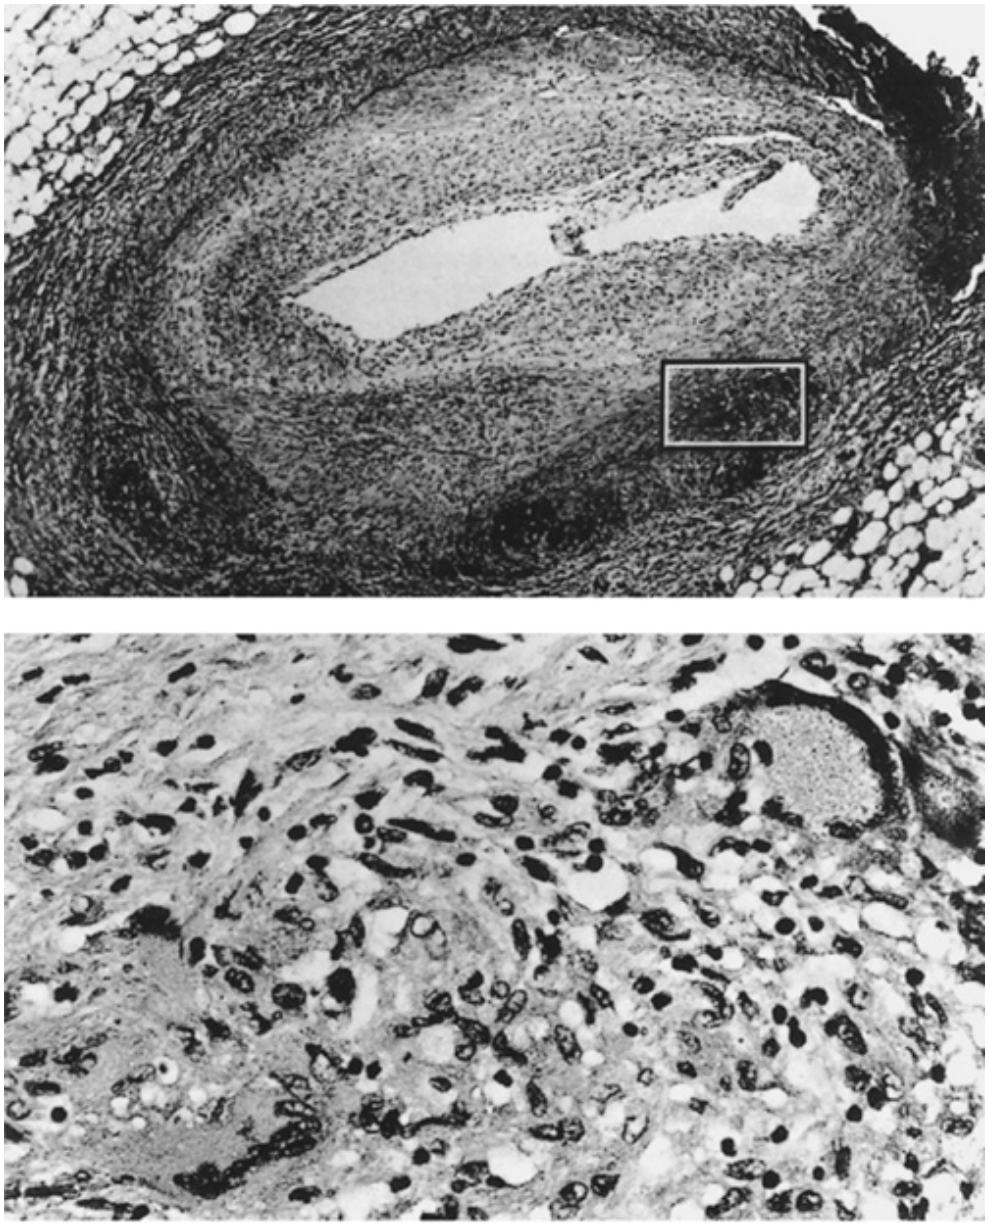

Figure 39-34: (*Top*) Low-power view of granulomatous coronary arteritis associated with giant-cell aortitis (hematoxylin-eosin, ×40). (*Bottom*) Close-up view of boxed area (hematoxylin-eosin, ×400). (From Lie.[205] Reproduced with permission from the author, editor, and publisher.)

(*Bottom*) Granulomatous coronary arteritis in disseminated visceral giant-cell angiitis (hematoxylin-eosin, ×160). (From Lie.[205] Reproduced with permission from the author, editor, and publisher.)

Rheumatic Arteritis

Rheumatic diseases commonly affect the aorta and are morphologically indistinguishable from granulomatous aortitis.[205,276-293] Coronary arteritis at necropsy has been detected in up to 20 percent of patients with rheumatoid arthritis, usually involving small intramural vessels.[276-297] The small-vessel arteritis also may involve conduction system vessels leading to various forms of heart block.[291-293] Rheumatoid coronary vasculitis producing myocardial infarction is rare.[282-285,296,297] Histologically, extraaortic rheumatoid vasculitis (coronary artery vasculitis) is usually a polyarteritis type of necrotizing angiitis[205,281,286-290] and not a giant-cell arteritis (Fig. 39-36). Small myocardial vessels also may be severely narrowed in ankylosing spondylosis. Occlusion of the left main ostium has been described.[293]

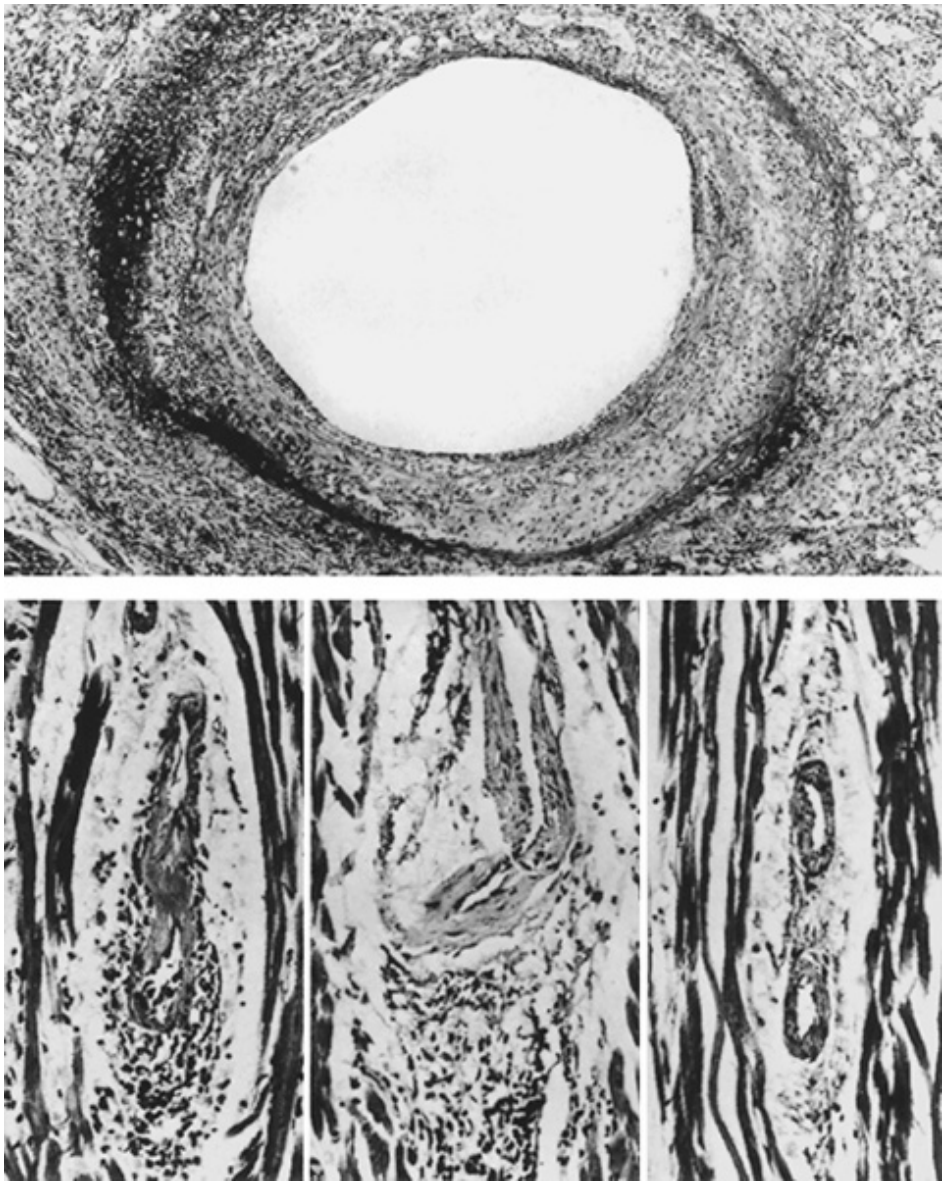

Figure 39-36: (*Top*) Polyarteritis-type necrotizing angiitis of epicardial coronary artery in rheumatoid arthritis (hematoxylin-eosin, ×160). (*Bottom*) Variations of small-vessel coronary artery arteritis in rheumatic fever (hematoxylin-eosin, ×160). (From Lie.[205] Reproduced with permission from the author, editor, and publisher.)

Buerger's Disease

Thromboangiitis obliterans (Buerger's disease), which is very rare[205,298-307] (Fig. 39-37), is a nonatherosclerotic, occlusive, inflammatory vascular disease of unknown cause occurring mainly in young males who are heavy smokers of cigarettes[205] (see also Chap. 90). In a few patients, the coronary arteries have shown focal polymorphonuclear infiltrates, histiocytes, and giant cells with or without coronary artery thrombosis.[304] Coronary involvement is rare,[304] although coronary thrombosis may be seen.[308] Buerger's disease involving a saphenous vein bypass graft also has been documented.[309]

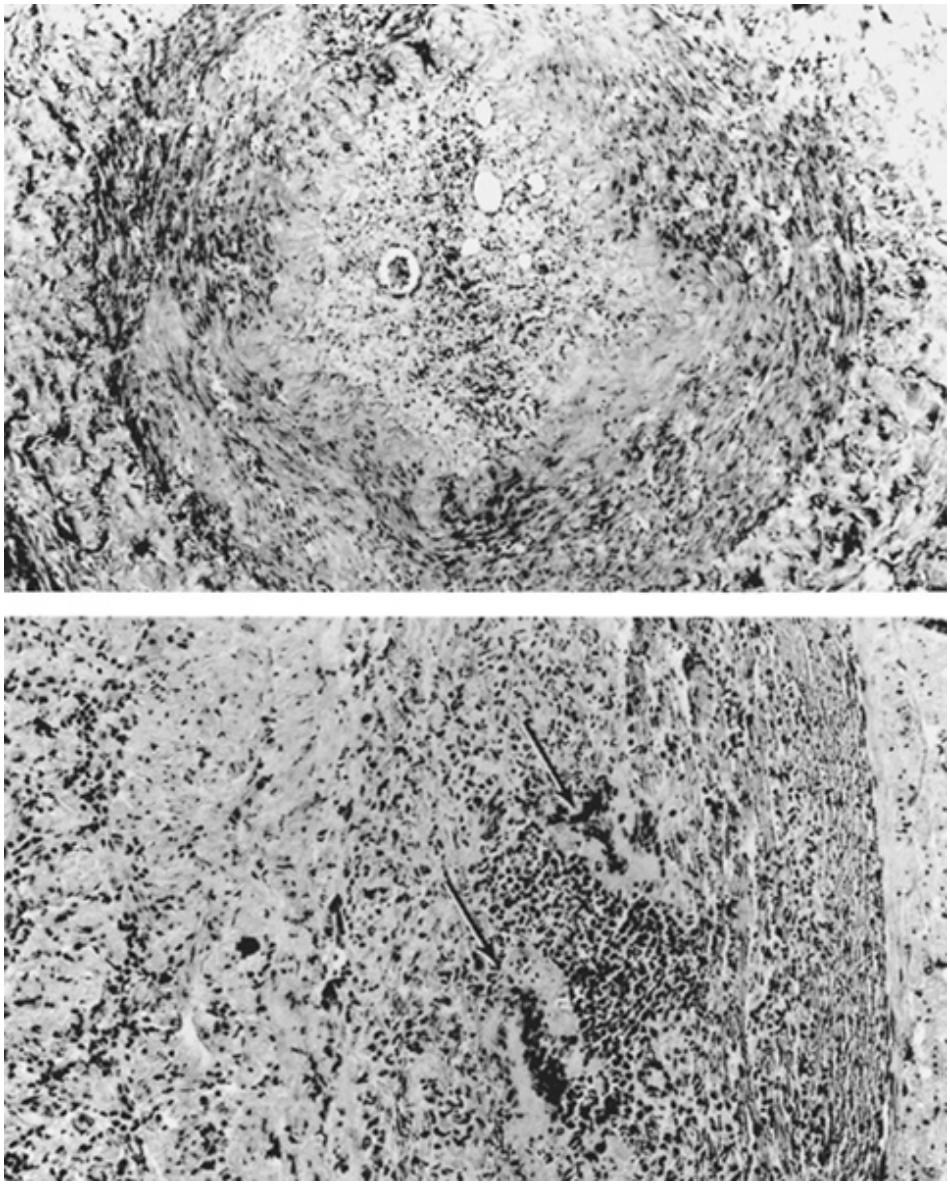

Figure 39-37: (*Top*) Subacute stage of Buerger's disease of coronary artery with organizing thrombus (hematoxylin-eosin, ×160). Polyarteritis (Necrotizing) Angiitis

CLASSIC POLYARTERITIS NODOSA

Classic polyarteritis nodosa is a chronic systemic disease manifest by infarction or hemorrhage in various target organs as the result of necrotizing vasculitis.[215] Male patients are affected twice as often as female, with a mean age of 45 years.[205,310-314] It is probably the most common cause of coronary angiitis with both epicardial and intramural coronary arteries being affected[24,310-320] (Fig. 39-38). In a review of 66 necropsy cases,[315] 41 (62 percent) had involvement of the epicardial coronary arteries, including 25 (61 percent) with involvement of both the epicardial and intramural coronary arteries, whereas 16 (39 percent) had only involvement of the intramural arteries. Frequently, various stages of acute disease and healing are seen in the same arterial segment. The acute phase has an acute cellular reaction with destruction of the media and internal elastic membrane.[316] The healing stage results in fibrous internal proliferation. Coronary arteries may dilate to form small berry-like aneurysms (becoming occluded by thrombus), rupture, or produce fatal myocardial infarction,[315,317-320] pericardial tamponade, or sudden death (see also Chap. 76).

(*Bottom*) Necrotizing angiitis with fibrinoid necrosis of intramural coronary artery (hematoxylin-eosin, ×160). (From Lie.[205] Reproduced with permission from the author, editor, and publisher.)

INFANTILE POLYARTERITIS

Polyarteritis nodosa occurring in infants under 2 years of age (infantile polyarteritis) differs from the clinical pathologic features of classic polyarteritis nodosa.[205,321-324] Infantile disease involves a higher frequency (79 percent) of coronary vasculitis and aneurysmal disease of the coronary arteries with sparing of vessels in other locations[205,321-324] (Fig. 39-39). Kawasaki's disease may involve children up to 8 or 10 years of age[205] rather than being confined to patients under age 2 as in infantile polyarteritis.[325]

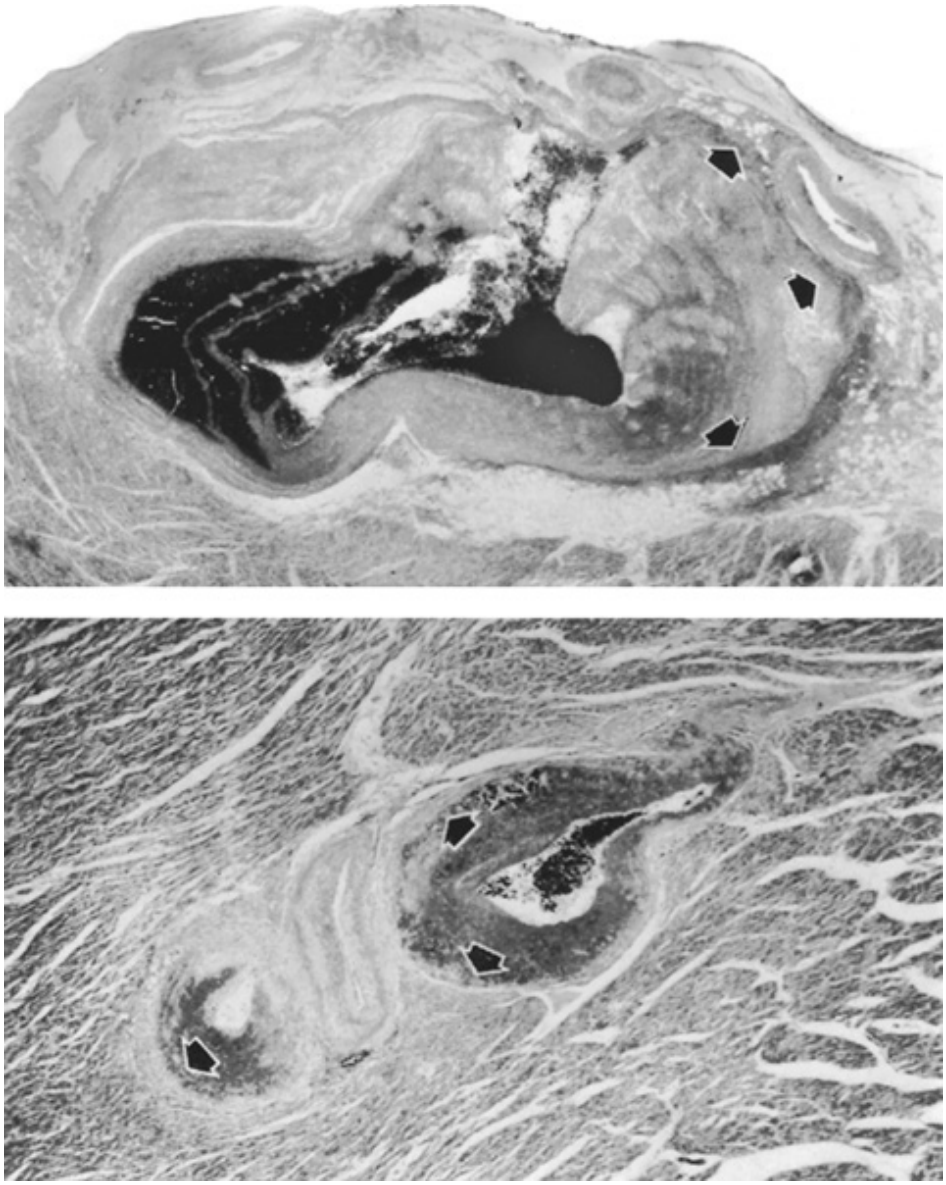

Figure 39-39: Necrotizing angiitis with aneurysmal disruption of epicardial (*arrows, top*) and intramural (*arrows, bottom*) coronary arteries in infantile polyarteritis nodosa (hematoxylin-eosin, ×160). (From Lie.[205] Reproduced with permission from the author, editor, and publisher.)

KAWASAKI'S DISEASE (MUCOCUTANEOUS LYMPH NODE SYNDROME)

Kawasaki's disease, or mucocutaneous lymph node syndrome, is an acute febrile exanthematous illness of children first described in the Japanese literature in 1967 and reported in the English literature in 1974.[326] It has been reported subsequently in children worldwide and in all racial groups.[327] In about 20 percent of children with the acute illness, a vasculitis of the coronary vasa vasorum leads to coronary arterial aneurysm formation, thrombosis, acute myocardial infarction, and sudden death.[326-339] Estimates of death from acute infarction or ventricular fibrillation range from 1 to 2 percent.[332-334] Late presentation with myocardial infarction secondary to dislodged aneurysmal thrombosis also may occur[332,333,335,337] (Figs. 39-40 and 39-41). Pathologically, the acute phase shows a necrotizing angiitis involving media and adventitial layers. Some children have survived into adulthood, with coronary artery aneurysms identified later in life[339] (see Figs. 39-40 and 39-41). The differential diagnosis of coronary artery aneurysms in adults includes previously undiagnosed Kawasaki's disease presumably occurring during childhood. Coronary arteriography results in 1100 children aged 4 months to 13 years identified 262 (24 percent) patients with the disease. In these, coronary occlusion was present in 76 percent, segmental stenosis in 5.7 percent, localized stenosis in 23.7 percent, aneurysms in 35.5 percent, and dilatation in 27.5 percent.[338] The incidence of both occlusion and segmental stenosis was lowest in the group studied shortly after onset of

the illness, whereas the prevalence of coronary aneurysm was highest in this early group.

Allergic Granulomatosis and Angiitis: Wegener's Granulomatosis and Churg-Strauss Syndrome

Wegener's granulomatosis is a necrotizing vasculitis of unknown cause classically involving the upper and lower respiratory tracts and the kidneys.[205,342-355] Cardiovascular involvement in Wegener's granulomatosis was described in one of three cases reported in 1936.[345] About 30 additional necropsy cases have been described subsequently, 14 of these (48 percent) showed small-vessel necrotizing coronary vasculitis[205,353,354] (Fig. 39-42). Fibrinoid necrosis of the small and medium-sized coronary arteries[342] and occlusion of larger epicardial coronary arteries with myocardial infarction[343] have been reported. In a large clinical series of patients with Wegener's granulomatosis, 12 percent had cardiac involvement largely manifest by pericarditis and coronary arteritis.[355] Some patients with this disease develop unusual cardiac complications such as pericardial tamponade and later constrictive pericarditis, high-grade atrioventricular block, and atrial tachycardia resistant to usual treatment measures. In this series,[355] all patients improved with cyclophosphamide therapy.

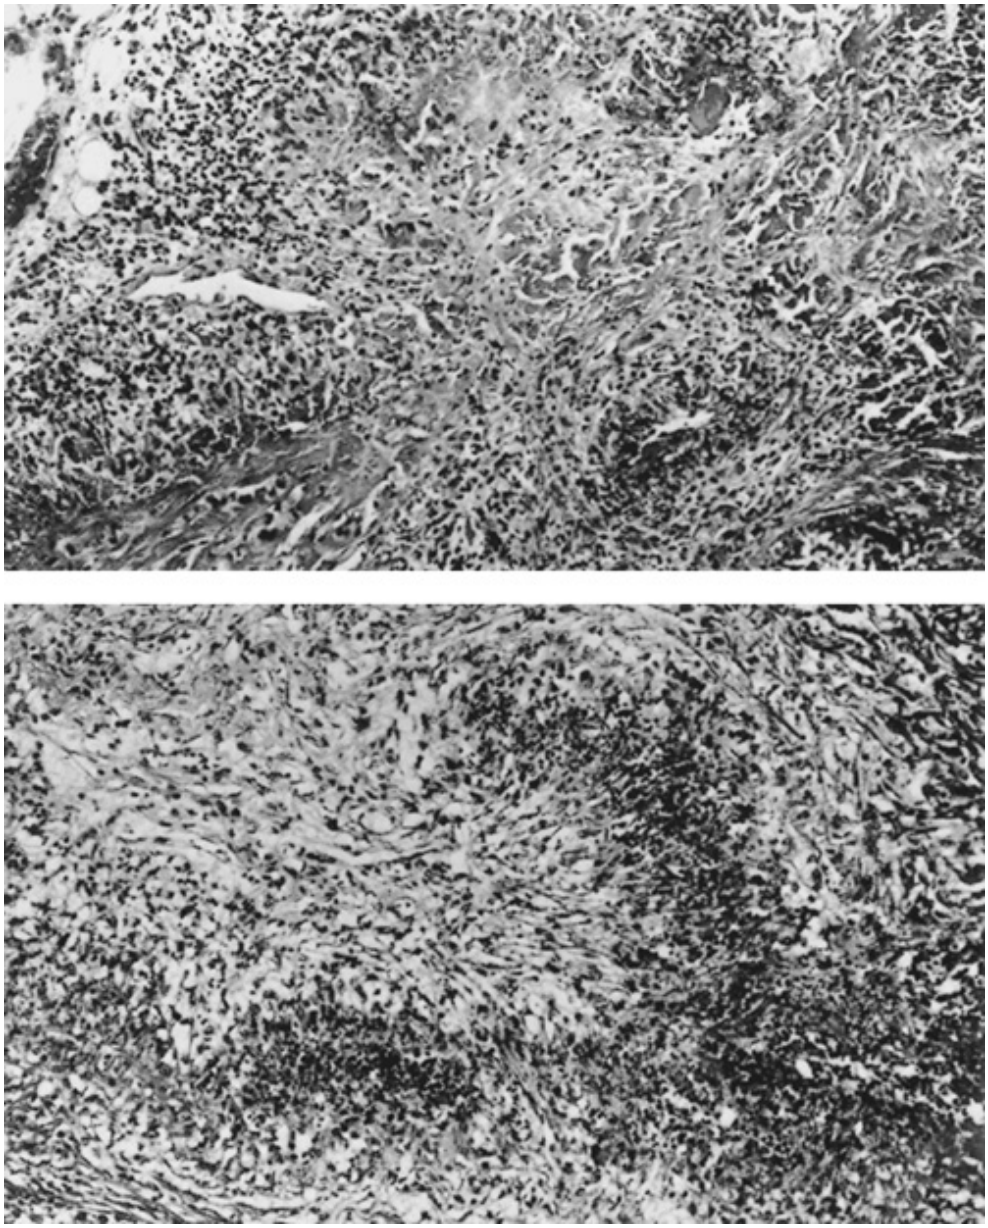

Figure 39-42: Granulomatous necrotizing angiitis of coronary arteries in Wegener's granulomatosis (*top*) and Churg-Strauss syndrome (*bottom*) (hematoxylin-eosin, ×160). (From Lie.[205] Reproduced with permission from the author, editor, and publisher.)

Churg-Strauss syndrome (allergic granulomatosis and angiitis) is a variant of polyarteritis nodosa[205,219] occurring in patients with asthma or an allergy history.[219-221,356] It is characterized by necrotizing angiitis with extravascular granulomas and eosinophilia. The heart is commonly involved with this disease, with granulomatous vasculitis of the coronary arteries (see Fig. 39-42). Granulomatous myocarditis may occur with or without the coronary angiitis[357] (see also Chap. 76).

Collagen Vascular Disease Vasculitis

Collagen vascular diseases generally involve arthritis, myositis, carditis, dermatitis, and inflammatory vascular changes to varying degrees.[358] They include systemic lupus erythematosus, rheumatoid vasculitis, systemic sclerosis, and polymyositis. Rheumatoid vasculitis was discussed earlier. One of the most common conditions with coronary artery vasculitis is systemic lupus erythematosus (Fig. 39-43). Several young patients with this disease and absent coronary atherosclerosis have suffered acute myocardial infarction[359-362] (see also Chap. 76). At necropsy, the coronary arteries in these patients have shown internal fibrous proliferation, possibly representing healed arteritis. Necrotizing vasculitis frequently leads to fatal coronary thrombosis and myocardial infarction,[205,360] rarely associated with thrombotic occlusion

of all three major arteries.[360] Smaller intramural coronary arteries are also involved frequently with fibrinoid necrosis and subsequent fibrosis.[114] Recently, myocardial infarction has been seen with a proximal right coronary artery aneurysm at necropsy. It was postulated that the coronary artery aneurysm represented a sequela of systemic lupus erythematosus arteritis similar to Kawasaki's disease.[362] Necrotizing vasculitis occurs less commonly in other entities of collagen vascular disease such as dermatopolymyositis,[363] systemic sclerosis,[364] Behçet's syndrome,[365] and Cogan's syndrome.[205,366]

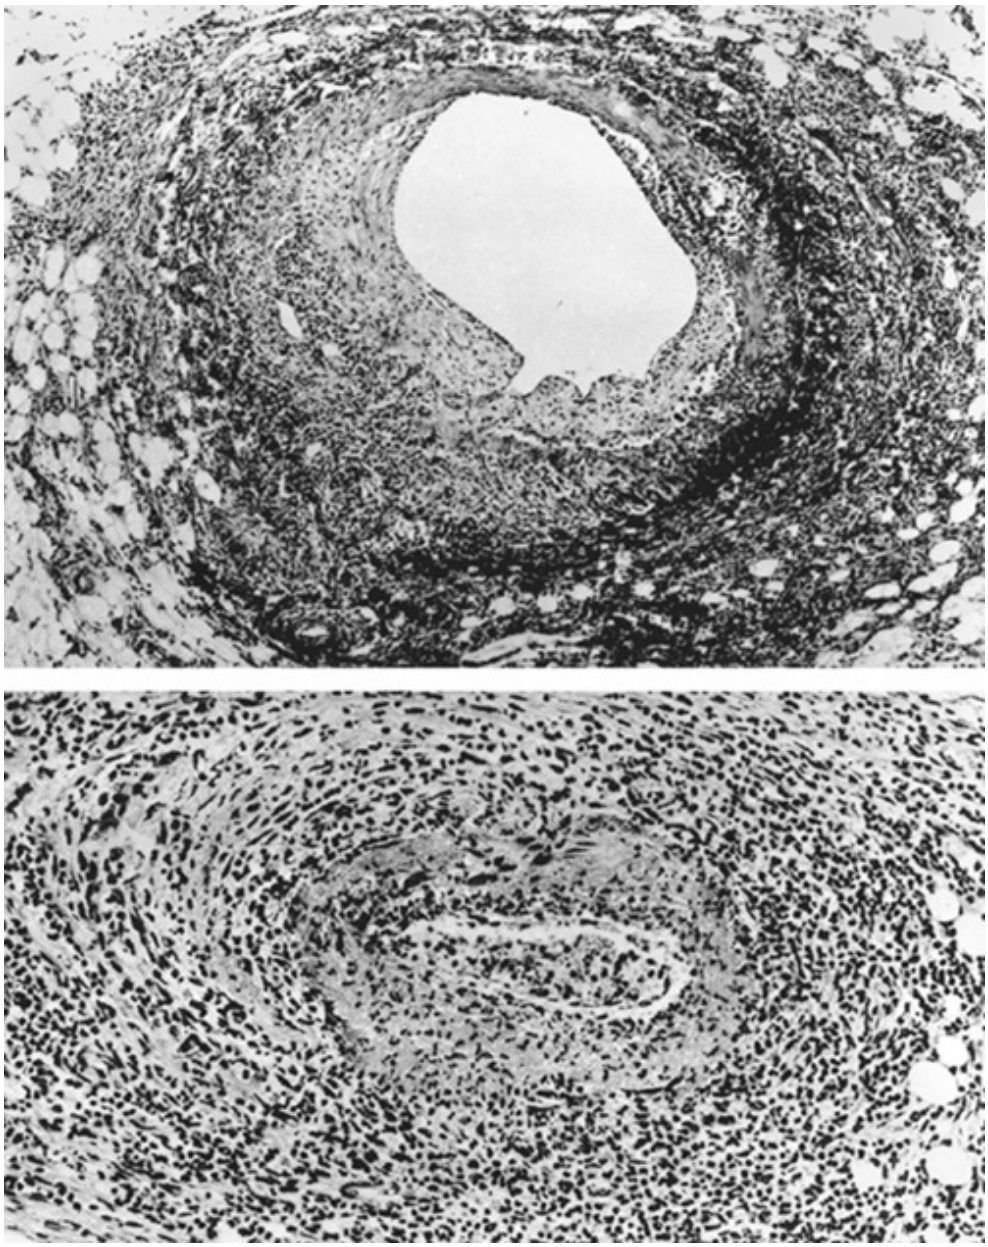

Figure 39-43: Necrotizing angiitis of epicardial (*top*) and intramural (*bottom*) coronary arteries in systemic lupus erythematosus (hematoxylin-eosin, ×160).

Hypersensitivity Angiitis (Allergic Vasculitis)

Hypersensitivity angiitis describes a miscellaneous group of necrotizing vasculitides that involve both epicardial and intramural coronary arteries.[205] This includes drug-induced vasculitis,[367] which, when generalized, may involve the heart. Histologically, drug-induced vasculitis cannot be separated from primary vasculitis or from hypersensitivity angiitis associated with a known underlying disease or malignancy such as serum sickness, mixed cryoglobulinemia, Schönlein-Henoch purpura, etc.[205] (see

Table 39-8). A correct diagnosis cannot be made without clinical information about drug use. Organ-transplantation arteritis[205,368] is also in this category, representing a form of immune-mediated vascular injury (see Chap. 32).

METABOLIC DISORDERS

Specific metabolic substances may accumulate in the walls of large and small coronary arteries as a result of inborn errors of metabolism. The deposition of this material may severely narrow the coronary artery lumen and produce acute myocardial infarction.[5] Inherited inborn errors of metabolism that are known to affect major epicardial coronary arteries include Hunter's and Hurler's diseases (mucopolysaccharidoses).[293,369-371] The involvement of the coronary arteries in these disorders may be so severe as to totally occlude the vessel and to produce myocardial ischemia/infarction. Other disorders of metabolism such as primary oxalosis,[372] Fabry's disease,[114] Sandhoff's disease (gangliosidoses),[373] and homocystinuria may affect smaller coronary vessels by severe intimal proliferation[374] (see also Chap. 62).

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

INTIMAL PROLIFERATION

Fibrous hyperplasia and smooth muscle proliferation in the coronary arteries may narrow the lumen severely and produce myocardial ischemia/infarction. The process may be associated with mediastinal irradiation,[375] fibromuscular hyperplasia of the renal arteries,[5] use of methysergide,[22,376] ostial cannulation during cardiac surgery, aortic valve replacement,[23] and unknown causes.[377,378-380] Up to 50 percent of patients undergoing cardiac transplantation develop significant narrowing of epicardial coronary arteries or total occlusion by intimal fibrous proliferation within 3 to 5 years after transplantation.[381] Myocardial infarction and sudden death may result from this "chronic rejection" process. Fibrosis of the intramural vessels also may occur. Intimal damage from immunologic rejection is believed to be the basis for the accelerated intimal fibrous hyperplasia involving the coronary arteries (see also Chap. 22). A morphologic assessment of 61 human cardiac allografts of short- and long-term survival has been provided.[382] Allographs were divided into two groups: fibrous lesions confined to the proximal region of epicardial arteries and those with diffuse necrotizing vasculitis of the entire system. Disease in the proximal region begins as concentric fibrous thickening. Diffuse disease (necrotizing vasculitis) invariably was associated with acute myocardial rejection with severe intimal lesions of large and small epicardial and intramural arteries.[382] These authors and others[383] have postulated that disease results from healing of a necrotizing vasculitis. Intravascular ultrasound[384] has shown intimal hyperplasia that was detected easily; its severity predicted the development of cardiac events, including myocardial infarction, unstable angina, or sudden death, despite the presence of a normal coronary arteriogram.

A similar histologic picture of intimal fibrous proliferation is seen in epicardial coronary arteries late after undergoing percutaneous balloon angioplasty[143,144] (Fig. 39-44). Intimal fibrous proliferation of the left main coronary artery has been reported late after balloon angioplasty of a lesion in the proximal left anterior descending coronary artery.[385] This may be due to intimal reaction from balloon rubbing of the intimal surface and/or extension of the fibrous process from the angioplasty dilation site (see also Chap. 45).

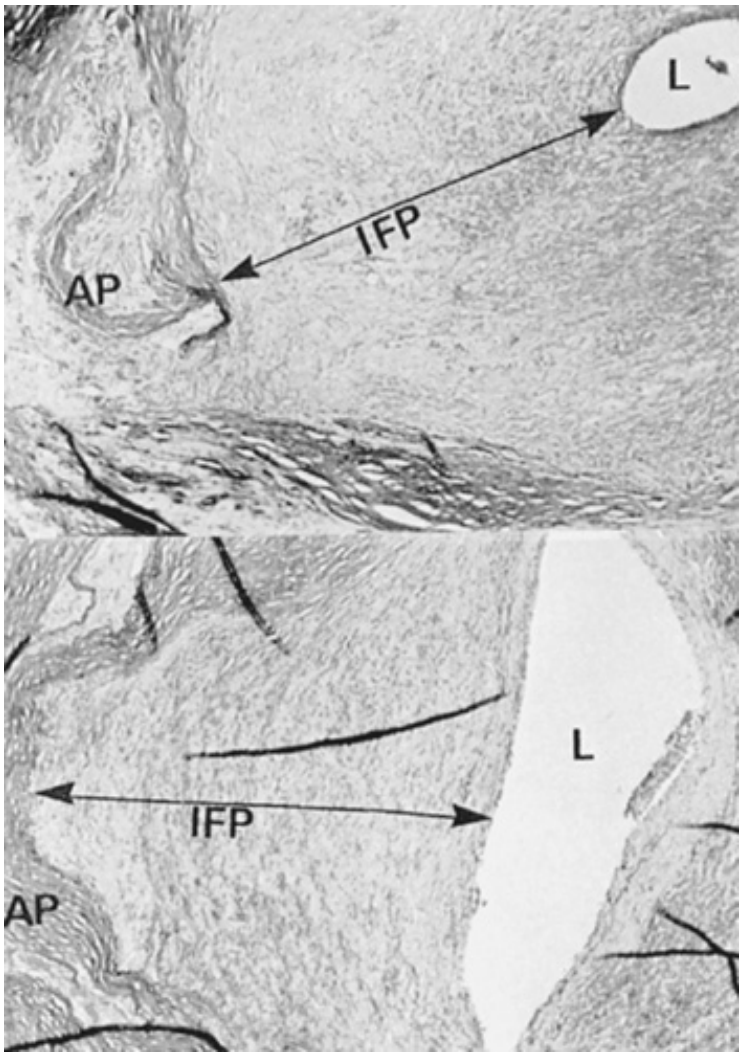

Figure 39-44: Intimal fibrous proliferation. Severe luminal narrowing of the left anterior descending coronary artery by intimal fibrous proliferation (IFP) several months after percutaneous balloon angioplasty. The IFP superimposes underlying atherosclerotic plaque (AP). L, lumen. (From Waller.[1] Reproduced with permission from the author, editor, and publisher.)

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

EXTERNAL COMPRESSION

External compression of the epicardial coronary arteries may result in severe luminal narrowing and progressive myocardial ischemia. External compression of a major epicardial coronary artery has been reported in patients with sinus of Valsalva aneurysms, chronic aortic dissection,[386] and epicardial tumor metastases.[387,388] Myocardial bridging (external muscle compression during ventricular systole) was reviewed earlier.

METASTATIC IMPLANTS

Myocardial metastatic lesions from various tumors-including carcinomas, sarcomas, and lymphomas-may mimic a healed myocardial infarct at necropsy (Fig. 39-45). The discrete location or locations of these metastatic deposits generally are unrelated to specific coronary arterial supply zones, and the lesions usually are surrounded by normal myocardium. These two gross observations suggest the lesions are metastatic tumor implants rather than healed myocardial infarcts (see also Chap. 77).

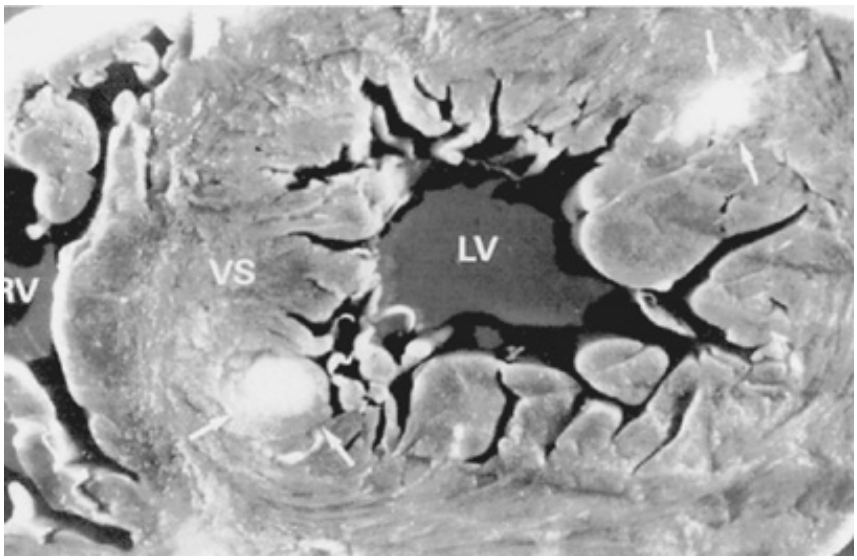

Figure 39-45: Metastatic deposits mimicking myocardial infarction. Transverse section of cardiac ventricle showing two discrete myocardial metastatic deposits of lymphoma. These whitish deposits may be mistakenly interpreted as healed myocardial infarctions in a patient with clean epicardial coronary arteries. LV, left ventricle; RV, right ventricle; VS, ventricular septum. (From Waller.[1] Reproduced with permission from the author, editor, and publisher.)

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

RADIATION-INDUCED CAD

Intimal proliferation of epicardial coronary arteries involving the ostium, main segment, or both is well known and increasingly reported.[375,389-400] "Accelerated" or "premature" coronary atherosclerosis has been noted in young individuals undergoing previous mediastinal irradiation for various types of malignancies.[401-404] Internal proliferation following mediastinal radiation 5 to 10 years earlier is described as "intimal thickening *without* medial abnormalities." The intimal lesions (ostial or main segment of artery) consists of fibrous tissue *without* extra cellular lipid deposits.[375,399] Coronary ostial stenosis has an incidence of 0.13 to 2.7 percent of patients undergoing mediastinal irradiation treatment.[375,399] A few patients have developed acute myocardial infarction or unstable angina as a result of the radiation-induced lesions treated by myocardial revascularization[394,398] or angioplasty[398] (see also Chap. 71).

Because of their fibrous nature, many radiation-induced lesions do not provide the best substrate for dilation techniques.[143,144,385] Chemotherapy-induced myocardial infarction in a young man without coronary disease has been reported.[405] Cardiac invasion by tumor, hypercoagulable states, and coronary artery spasm are possible etiologies.[405] Vascular toxicity, including myocardial infarction, has been reported following antineoplastic regimens containing *Vinca* alkaloids.[405]

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

CORONARY ARTERY THROMBOSIS WITHOUT UNDERLYING ATHEROSCLEROTIC PLAQUE (THROMBOSIS IN SITU)

Thrombotic occlusion of the coronary system unassociated with underlying atherosclerotic plaque may be seen with several hematologic diseases: thrombocytopenic purpura,[35] leukemia,[406] polycythemia vera,[407] sickle cell anemia,[114] and primary thrombocytosis.[408] Occasionally, acute myocardial infarction may be the initial manifestation of these hematologic disorders. A main factor responsible for the myocardial ischemia in these conditions is blockage of small intramural coronary vessels by platelet aggregates.[409] These platelet aggregates initially may form in the major coronary arteries and then embolize distally.

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

SUBSTANCE ABUSE

Cocaine abuse is now a major health hazard; more than 22 million Americans have tried cocaine at least once, and 5 million are current users.[410] Recent reports have documented that cocaine abuse can result in myocardial ischemia and infarction in the absence of CAD,[410-420] and cocaine-induced coronary artery vasoconstriction has been reported in patients following the intranasal administration of cocaine[415,421-424] (see also Chap. 71).

Several instances of coronary artery thrombosis and spasm have been reported in patients who abuse cocaine. Acute coronary thrombosis in association with cardiac events-including angina, acute myocardial infarction, and sudden death-has been reported.[410,413,422-424] In some instances, there is underlying atherosclerotic plaque; in others, the coronary arteries are normal. Coronary thrombosis occurring in coronary arteries free of atherosclerotic plaque suggests the role of cocaine-induced spasm, massive norepinephrine release in the heart, or possible primary thrombogenicity of cocaine or its metabolites.[421] Coronary spasm has been associated with cocaine use and has been postulated as a mechanism of myocardial infarction in cocaine users with clean coronary arteries.[410,425-431] In such cases, fibrointimal proliferation with coronary narrowing was attributed to underlying coronary artery spasm that caused focal vessel endothelial injury, platelet adherence, and aggregation. Platelets liberate platelet-derived growth factor (PDGF), which can induce intimal proliferative lesions. In patients with underlying coronary plaque, cocaine-induced spasm also may produce endothelial disruption at the surface of the plaque and promote platelet aggregation and further vasoconstriction from the release of platelet prostaglandins[432] (see also Chap. 71).

Recently, two drugs have been the center of debate over their potential for abuse versus use as psychotherapeutic agents and their complication in induction of arrhythmias.[433] Use of MDMA ("Ecstasy," 3,4-methylenedioxymethamphetamine) and MDEA ("Eve," 3,4-methylenedioxymethamphetamine) has been associated with five sudden deaths.[433] In three of these, "Eve" and "Ecstasy" may have induced fatal arrhythmias.

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

MYOCARDIAL OXYGEN DEMAND-SUPPLY DISPROPORTION

In this category are disease states in which there is failure to deliver adequate oxygen to the myocardium over a prolonged period or increased myocardial wall tension requiring increased oxygen supply. The classic example of the first situation is carbon monoxide poisoning,[4] which has been associated with extensive nontransmural infarction in the presence of normal epicardial coronary arteries. Prolonged shock from any cause also can result in extensive nontransmural necrosis and frequently is associated with transmural necrosis of the papillary muscles. One example of increased myocardial wall tension requiring increased coronary oxygen supply is aortic valve stenosis[4] (see Chap. 56). In the face of increased oxygen demand with increased muscle mass, coronary blood supply may be limited by poor perfusion resulting from the lower coronary arterial pressure. In addition, poor perfusion results from the high coronary arterial resistance caused by increased wall pressure on the intramural coronary arteries and the high LV end-diastolic pressure from a stiff ventricle, with further limitation of the time in diastole for coronary blood flow occasioned by tachycardia.[4] Excessive myocardial oxygen demand exceeding supply and resulting in myocardial ischemia/infarction also may be seen in thyrotoxicosis,[434] which reflects increased metabolic rates and the adverse affects of tachycardia.

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

INTRAMURAL CAD (SMALL-VESSEL DISEASE)

Acute myocardial infarction may result from abnormally thickened or totally occluded intramural coronary arteries in the presence of normal extramural (epicardial) coronary arteries. A few of the conditions in this category include (1) hypertrophic cardiomyopathy, (2) diabetes mellitus, (3) amyloid heart disease,[434] (4) neuromuscular disorders (Friedreich's ataxia, progressive muscular dystrophy), (5) cardiac transplantation, (6) rheumatoid arthritis, (7) collagen-vascular disorders (scleroderma, systemic lupus erythematosus), (8) metabolic abnormalities (mucopolysaccharidoses, gangliosidoses), and (9) polyarteritis nodosa.[435-439]

Histologic abnormalities of small-vessel coronary arteries have been reported in individuals who have died from toxic oil syndrome involving rapeseed oil adulterated with aniline.[440] Many of those who later died had scleroderma-like illnesses. Dense fibrosis of the sinus node, resembling scleroderma, was found with cystic degeneration of the sinus node (resembling lupus erythematosus) and fibromuscular dysplasia of small coronary vessels.

Chapter 39: NONATHEROSCLEROTIC CORONARY HEART DISEASE

NORMAL EPICARDIAL CORONARY ARTERIES

There have been relatively few necropsy reports of patients with acute myocardial infarction who had angiographically normal coronary arteries and normal coronary arteries at necropsy.[3,4,434,441,442] Of 100 consecutive necropsy cases of acute myocardial infarction,[3] 7 percent had infarcts without evidence of coronary luminal narrowing. In 10 patients with a typical picture of acute myocardial infarction who died within 25 days of onset of symptoms, the coronary arterial systems showed minimal or no luminal narrowing by atherosclerosis. No thrombotic material was observed in the coronary arteries despite the fact that the acute myocardial infarction was 2 days old in 5 patients and 3 to 4 days old in 3. Possible explanations for this have included coronary artery spasm, coronary artery disease in vessels too small to be visualized angiographically, or coronary artery thrombosis or embolus with subsequent clot lysis. Myocardial infarction in postpartum women with normal epicardial coronary arteries has included two additional causes for possible spasm in these patients: bromocriptine used for suppression of lactation[186,443-451] and antiphospholipid syndrome with elevated anticardiolipin antibody levels, false-positive syphilis serology, and a history of deep venous thrombosis.[452]

Part 6: CORONARY HEART DISEASE
Chapter 40:

DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

Authors: Robert A. O'Rourke, Robert C. Schlant, John S. Douglas, Jr.

Ischemic heart disease remains a major public health problem.[1] Chronic stable angina is the first indicator of ischemic heart disease in about 50 percent of patients. The reported annual incidence of angina is 213 per 100,000 population over the age of 30. The number of patients with stable angina in the United States approximates 16.5 million people, not including individuals who do not seek medical attention for their chest pain or who are shown to have a noncardiac cause of chest discomfort. Angina pectoris is a clinical syndrome that consists of discomfort or pain in the chest, jaw, shoulder, back, or arm. Typically it is precipitated or aggravated by exertion or emotional stress and relieved by nitroglycerin. Angina usually occurs in patients with coronary artery disease (CAD) affecting one or more large epicardial arteries. Angina often is present in individuals with valvular heart disease, hypertrophic cardiomyopathy, and uncontrolled hypertension, however. It also occurs in patients with normal coronary arteries and myocardial ischemia due to coronary artery spasm or endothelial dysfunction. The symptom of angina is often observed in patients with noncardiac disorders affecting the esophagus, chest wall, or lungs.

HISTORICAL PERSPECTIVE

In 1768, William Herberden presented his classic description of angina pectoris in a lecture before the Royal College of Physicians; it was published in 1772.[2] This classic description was published again with minor changes in a chapter entitled "Pectoris Dolor" in his *Commentaries on the History and Cure of Diseases*, which was translated from the Latin and published by his son, also named William Herberden, in 1802.[3] The following quotation is from the original lecture:

> There is a disorder of the breast, marked with strong and peculiar symptoms, considerable for the kind of danger belonging to it, and extremely rare, of which I do not recollect any mention among medical authors. The seat of it, and sense of strangling and anxiety, with which it is attended, may make it not improperly be called angina pectoris. Those who are afflicted with it are seized, while they are walking, and more particularly when they walk soon after eating, with a painful and most disagreeable sensation in the breast, which seems as if it would take their life away, if it were to increase or to continue: the moment they stand still all this uneasiness vanishes. In all other respects the patients are at the beginning of this disorder perfectly well, and in particular have no shortness of breath, from which it is totally different.
>
> After it has continued some months, it will not cease so instantaneous upon standing still; and it will come on, not only when the persons are walking, but when they are lying down, and oblige them to rise up from their beds every night for many months together; and in one or two very inveterate cases it has been brought on by the motion of a horse or a carriage, and even by swallowing, coughing, going to stool or speaking, or by any disturbance of mind. I have heard once and only one person, say that he had known it to attack him when he was up and standing still or sitting.

> ... but all the rest, whom I have seen, who are at least twenty, were men, and almost all above 50 years old, and most of them with a short neck, and inclining to be fat. When a fit of this sort comes on by walking, its duration is very short, as it goes off almost immediately upon stopping. If it comes on in the night, it will last an hour or two; and I have met one, in whom it once continued for several days, during all which time the patient seemed to be in imminent danger of death.
>
> But the natural tendency of this illness be to kill the patients suddenly, yet unless it have a power of preserving a person from all other ails, it will easily be believed that some of those, who are afflicted with it, may die in a different manner, since this disorder will last, as I have known it more than once, near twenty years, and most usually attacks only those who are above fifty years of age. I have accordingly observed one, who sunk under a lingering illness of a different nature.
>
> The os sterni is usually pointed to as the seat of this malady, but it seems sometimes as if it was under the lower part of it, and at other times under the middle or upper part, but always inclining more to the left side, and sometimes there is with it a pain about the middle of the left arm. What the particular mischief is, which is referred to these different parts of the sternum, it is not easy to guess, and I have had no opportunity of knowing with certainty. It may be a strong cramp, or an ulcer, or possibly both.

The syndrome of angina pectoris was described as rare in textbooks of medicine in 1866 (Austin Flint) and 1892 (William Osler). Paul Dudley White wrote: "[angina pectoris] was uncommon in my early professional years. But when the automobile came in the 1920s and the population at large became more prosperous and over nourished, the current epidemic of coronary heart disease, as shown mainly by the symptom angina pectoris, began and incidentally involved younger and younger men."[4] In the United States, the peak mortality rate from coronary heart disease (CHD) occurred about 1962 to 1965; since then, it has been decreasing steadily.[5]

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

ETIOLOGY AND CLASSIFICATION

Coronary atherosclerosis is the cause of angina pectoris in most patients (see Chaps. 35 to 38). Many nonatherosclerotic causes of CAD (Tables 39-1 and 39-2) also can produce angina pectoris or myocardial infarction. Other conditions particularly associated with angina pectoris include congenital coronary artery abnormalities (see Chap. 64), aortic stenoses (see Chap. 56) mitral stenoses with resulting severe right ventricular hypertension (see Chap. 52), hypertrophic cardiomyopathy (see Chap. 67), and systemic arterial hypertension[6] (see Chap. 51).

Disorders in which angina occurs less frequently include aortic regurgitation (see Chap. 56), idiopathic dilated cardiomyopathy (see Chap. 66), and luetic heart disease. Mitral valve prolapse (see Chap. 58) rarely causes true angina pectoris. Certain conditions may alter the balance between myocardial oxygen supply-demand and precipitate or aggravate angina pectoris, including severe anemia, tachycardia, fever, hyperthyroidism, and Paget's disease of bone.

The Canadian Cardiovascular Society Grading Scale (see Table 10-2) is commonly used to classify the severity of angina pectoris, with the most severe symptoms occurring at rest and the least severe only with excessive exercise.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

DIAGNOSIS

History and Physical Examination

The first step is to obtain a detailed description of the symptom complex in order to characterize the chest pain or discomfort. Five descriptors typically are considered: (1) location, (2) quality, (3) duration of the discomfort, (4) inciting factors, and (5) factors relieving the pain.[1]

After a description of the chest discomfort is obtained, the physician makes an integrated assessment of various components. The most commonly used classification scheme for chest pain divides patients into three groups: *typical angina*, *atypical angina*, or *noncardiac chest pain*[7,8] (Table 40-1).

Table 40-1: Clinical Classification of Angina

Typical angina (definite)
1. Substernal chest discomfort with a characteristic quality and duration that is 2. provoked by exertion or emotional stress and 3. relieved by rest or NTG.
Atypical angina (probable)
Meets two of the above characteristics.
Noncardiac chest pain
Meets one or none of the typical anginal characteristics.

SOURCE: Modified from Diamond et al.[7]

Angina is further labeled as *stable* when its characteristics are usually unchanged for 60 days or *unstable* (see Chap. 41). The presence of unstable angina predicts a much higher short-term risk of an acute coronary event. *Unstable angina* is defined as angina that presents in one of three major ways: *rest angina*, *severe new-onset angina*, or *prior angina increasing in severity* (see Chap. 41). Recently, the acute coronary syndromes of unstable angina and nonST-segment elevation myocardial infarction have been linked together by their similar presentation and treatment.[8a]

Usually, the discomfort of chronic stable angina pectoris is precipitated by physical activity, emotions, eating, or cold weather. Certain patients are able to describe accurately the extent and type of exercise at which they reproducibly experience their chest pain (see Chap. 10). Many patients with angina will develop chest discomfort if they walk up a hill after a large meal with a cold wind blowing in their face. Emotions, particularly anger, excitation, and frustration, often precipitate angina in patients with CAD. Cigarette smoking induces chest discomfort or lowers the exertion threshold for angina in some patients. A history of cocaine use should be sought because it can precipitate myocardial ischemia with or without infarction by coronary vasoconstriction.[9]

When stable angina pectoris develops, it often increases to a plateau over 10 to 30 s and usually disappears

within minutes if the exertion is discontinued. Occasionally, the angina will disappear despite continued physical activity, so-called walk-through angina. Most patients have discomfort that lasts only several minutes or up to 10 to 15 min, and rarely, up to 30 min (see Chap. 10).

The discomfort of angina is most often located substernally or just to the left of the sternum. Some patients, when describing the discomfort, clench their fist over their upper sternum (Levine's sign), a sign of high diagnostic accuracy. Less often, angina is located over the precordium. The discomfort is rarely localized only to the apex of the heart. Nevertheless, angina can be located anywhere from the epigastrium to the neck, and rarely it may be located only in the neck, throat, arm, or back.

The pain often radiates down the arms or to the neck, jaw, teeth, shoulders, or back. Radiation to the left side is more common, but both sides can be involved. The radiation, characteristically down the ulnar aspect of the arm, often is described as numbness. Increased heat or humidity also may lower the exertional threshold at which angina occurs.

Disorders that increase myocardial oxygen requirement (M_{O_2}) may exacerbate the occurrence of angina pectoris and sometimes may be associated with angina in the absence of moderate or severe CAD stenosis on coronary arteriography.

Patients with stable angina may have many episodes of myocardial ischemia that are asymptomatic or silent. Also, myocardial ischemia may result in symptoms from either systolic or diastolic left ventricular (LV) dysfunction without the chest discomfort characteristic of angina pectoris. Like chest discomfort due to angina, *angina equivalent* symptoms usually are associated with exertion and are relieved by rest and nitroglycerin. *Exertional dyspnea* likely is due to reduced diastolic LV compliance resulting from myocardial ischemia. *Exertional fatigue* or exhaustion probably results from an acute decrease in cardiac output due to diminished systolic LV function and/or associated mitral regurgitation from transient papillary muscle dysfunction.

In general, when myocardial ischemia is produced, an *ischemic cascade* occurs. Regional diastolic and systolic dysfunction precede global diastolic and then systolic dysfunction, which in turn often occurs prior to changes in the electrocardiogram (ECG) and before the symptoms of angina pectoris (Fig. 40-1). Noninvasive testing often is useful in detecting ischemia (see below). The detection of LV diastolic dysfunction by Doppler mitral valve recording or by diastolic filling curves using radionuclide ventriculography has many limitations (see Chaps. 13 and 16). Although diaphoresis and alterations in blood pressure and heart rate may occur, the physical examination is often normal. An examination performed during an episode of pain, however, can be useful. A fourth (most common) or third heart sound, a mitral regurgitant systolic murmur, reversed splitting of the S_2, bibasilar pulmonary rates, or palpable ectopic cardiac impulses that disappear when the pain subsides are all predictive of CAD (see Chap. 10). Carotid sinus pressure often terminates angina chest pain. Evidence of noncoronary atherosclerotic disease such as a carotid bruit, diminished pedal pulse, or abdominal aneurysm increases the likelihood of CAD. An elevated blood pressure, xanthomas, and retinal exudates point to the presence of CAD risk factors[6] (see Chap. 10).

Clinical Assessment of the Likelihood of CAD

The clinicopathologic study performed by Diamond and Forrester[10] demonstrated that it is possible to predict the probability of CAD after the history and the physical examination. By combining data from several angiographic studies performed before 1980, they showed that simple clinical observations of pain type, age, and sex were powerful predictors of the probability of CAD.

The utility of the Diamond and Forrester approach was confirmed subsequently in prospective studies at Duke and Stanford.[11-13] In both men and women referred for cardiac catheterization or for cardiac stress testing, the initial clinical characteristics most helpful in predicting CAD were determined. In these studies, age, sex, and pain type were the most powerful predictors (Table 40-2). Smoking, Q waves, or ST-segment-T-wavechanges on ECG, hyperlipidemia, and diabetes further strengthened the predictive abilities of these

models.[1,13]

Table 40-2: Pretest Likelihood of CAD in Symptomatic Patients According to Age and Sex* (Combined Diamond/Forrester and CASS Data)[7-10]

	NONANGINAL CHEST PAIN		ATYPICAL ANGINA		TYPICALANGINA	
Age, years	Men	Women	Men	Women	Men	Women
30-39	4	2	34	12	76	26
40-49	13	3	51	22	87	55
50-59	20	7	65	31	93	73
60-69	27	14	72	51	94	86

*Each value represents the percent with significant CAD on catheterization.
SOURCE: Modified from Gibbons et al.[1]

Special Tests for Diagnosis

Most special tests in patients with suspected stable angina are performed either to establish the diagnosis and/or to determine the risk for coronary events.[1] In general, men with a history of classic angina pectoris have a higher probability of having significant CAD on coronary arteriography than do women. Table 40-2 indicates the likelihood for each gender by age and characteristics of the chest discomfort. It also indicates why women have more false-positive responses to ECG exercise testing than do men (see Chap. 14). Terms useful in the evaluation and selection of diagnostic tests for CAD are listed in Table 40-3. Bayes' theorem states that the pretest prevalence of disease influences the posttest likelihood of significant CAD (see Chap. 14). Figure 40-2 illustrates the impact of Bayes' theorem when evaluating several diagnostic tests for CAD. More accurate data on the sensitivity and specificity of noninvasive testing for diagnosis of CAD are provided in Chaps. 13, 14, 16, and 17.

Table 40-3: Glossary of Terms

True positive (TP): Positive result in patient with disease
True negative (TN): Negative result in patient without disease
False positive (FP): Positive result in patient without disease
False negative (FN): Negative result in patient with disease

$$\text{Sensitivity: } \frac{TP}{TP + FN}$$

$$\text{Specificity: } \frac{TN}{TN + FP}$$

$$\text{Predictive value of a positive test: } \frac{TP}{TP + FP}$$

$$\text{Predictive value of a negative test: } \frac{TN}{TN + FN}$$

Bayes' theorem:

$$\text{Probability of disease presence with a positive test} = \frac{\text{sensitivity} \times \text{prevalence}}{(\text{sensitivity} \times \text{prevalence}) + [(1 - \text{specificity}) \times (1 - \text{prevalence})]}$$

$$\text{Probability of disease presence with a negative test} = \frac{(1 - \text{sensitivity}) \times \text{prevalence}}{[(1 - \text{sensitivity}) \times \text{prevalence}] + [\text{specificity} \times (1 - \text{prevalence})]}$$

If an exercise ECG test was performed by a 55-year-old woman with atypical chest pain and a pretest likelihood for coronary disease of 0.46, a positive ECG stress test response would indicate her posttest likelihood to be 0.86. If she had a positive thallium scan, her likelihood of disease would increase to 0.98; however, if her thallium scan were negative, the probability of disease would decrease to 0.63.

On the other hand, diagnostic tests should only be performed when necessary to answer a specific clinical question. Thus a diagnostic test may be of limited additional diagnostic value in patients with either a very high (>0.90) or a very low (<0.10) pretest risk for CAD.[1]

ELECTROCARDIOGRAM AND CHEST ROENTGENOGRAM

A resting 12-lead ECG should be recorded in all patients with symptoms suggestive of angina; however, it will be normal in up to 50 percent of patients with chronic stable angina. ECG evidence of LV hypertrophy or ST-segment-T-wave changes consistent with myocardial ischemia favor the diagnosis of angina pectoris. Evidence of prior Q-wave myocardial infarction (MI) on the ECG makes CAD very likely. Patients with a completely normal resting ECG rarely have significant LV systolic dysfunction.

The presence of arrhythmias (e.g., atrial fibrillation or ventricular tachyarrhythmias) on the ECG in patients with chest pain also increases the probability of underlying CAD; however, these arrhythmias frequently are caused by other types of cardiac disease. Various degrees of atrioventricular (AV) block occur in patients with chronic CAD but have a very low specificity for the diagnosis. Left anterior fascicular block, right bundle-branch block (RBBB), and left bundle-branch block (LBBB) often are present in patients with CAD and frequently indicate multivessel CAD. However, these findings also lack specificity for the diagnosis of chronic stable angina.

An ECG obtained during chest pain is abnormal in about 50 percent of patients with angina and a normal resting ECG. Sinus tachycardia is frequent; bradyarrhythmias are less common. ST-segment elevation or depression establishes a high likelihood of angina and indicates ischemia at a low workload, suggesting an unfavorable prognosis. Many high-risk patients with severe episodes of angina need no further noninvasive testing. Coronary arteriography usually defines the severity of CAD and determines the necessity and feasibility of myocardial revascularization. In patients with ST-segment-T-wave depression or inversion on the resting ECG, pseudonormalization of these abnormalities during pain is another indicator that CAD is likely.[14] The occurrence of tachyarrhythmias, AV block, left anterior fascicular block, or bundle-branch

block during chest pain also increases the probability of CHD and often leads to coronary arteriography.

The *chest roentgenogram* often is normal in patients with stable angina pectoris. Its usefulness as a routine test is *not* well established. It is more likely to be abnormal in patients with previous or acute MI, those with a noncoronary artery cause of chest pain, and those with noncardiac chest pain.

Coronary artery calcification increases the likelihood of symptomatic CAD. *Fluoroscopically detectable* coronary calcification is correlated with major vessel occlusion in 94 percent of patients with chest pain[15]; however, the sensitivity of the test is less than 40 percent.

Electron beam computed tomography (EBCT) (see Chap. 17) is being used with increased frequency. However, the specificity of a positive result may be as low as 49 percent, and the predictive accuracy is less than 70 percent. The role of EBCT in CAD diagnosis and risk stratification has been controversial.[16] A recent report of an ACC/AHA expert consensus writing group does not recommend EBCT for routine screening of asymptomatic patients for CAD or for its use in most patients with chest pain.[17] It also is of little use in detecting vulnerable plaques.[17a]

EXERCISE ECG STRESS TESTING

Exercise ECG stress testing is a well-established procedure that has been in widespread clinical use for many decades.[18] Although usually a safe procedure, both MI and death occur at a rate of up to 1 per 2500 tests[19] (see Chap. 14). Absolute contraindications include acute MI within 2 days, cardiac arrhythmias causing symptoms or hemodynamic compromise, symptomatic and severe aortic stenoses, symptomatic heart failure, acute pulmonary embolus or infarction, acute myocarditis or pericarditis, and acute aortic dissection.

For optimizing the information obtained, the protocol should be tailored to the individual patient, with exercise lasting at least 6 min.[20] Exercise capacity should be reported in estimated metabolic equivalents (METs) of exercise (1 MET is the standard basal oxygen uptake of 3.5 ml/kg/min) as well as in minutes.

The ECG, heart rate, and blood pressure should be monitored carefully and recorded during each stage of exercise, as well as during ST-segment abnormalities and chest pain, as detailed in Chap. 14.

Interpretation of the exercise ECG should include symptomatic response, exercise capacity, hemodynamic response, and ECG changes. The most important ECG abnormalities are ST-segment depression and ST-segment elevation (in leads without diagnostic Q waves) of greater than 1 mm for at least 60 to 80 ms after the end of the QRS complex. Although exercise testing often is terminated when subjects reach a standard percentage (often 85 percent of age-predicted maximum heart rate), there is a *great variability* in maximum heart rate among individuals. Many stress testing laboratories still utilize approaches that are not up to date.

A meta-analysis of 147 published reports describing 24,074 patients who underwent both coronary angiography and exercise testing found wide variation in sensitivity and specificity.[17] The mean sensitivity was 68 percent, and the mean specificity was 77 percent. When only studies that excluded patients with a prior MI were analyzed, the mean sensitivity was 67 percent, and the mean specificity was 72 percent. In the few studies that avoided workup bias by including only patients who agreed in advance to have both exercise testing and coronary angiography, the sensitivity was 50 percent, and the specificity was 90 percent.[1] In the most recent study of 814 men that minimized workup bias, sensitivity was 45 percent, and specificity was 85 percent.[21] Therefore, the true diagnostic value of the exercise ECG relates to its *relatively high specificity*. The modest sensitivity of the exercise ECG is generally lower than that of imaging procedures.

To improve the clinical usefulness of exercise ECG testing in the diagnosis of CAD, a treadmill score[20,22] was developed as well as a prognostic score that predicted 5-year survival using the amount of ST-segment depression, the degree of angina during exercise, and the duration of exercise.[23] Other methods employed include the ST/HR slope, calculated from linear regression of ST-segment depression against heart rate

(HR) during peak exercise,[24] and the simple ST/HR index, in which additional ST-segment depression is divided by the overall change in heart rate throughout the exercise period.[25] The cost-effectiveness of these techniques remains unknown.

Diagnostic testing is most valuable when the pretest probability of obstructive CAD is intermediate. In these conditions, the test result has the largest effect on the posttest probability of disease and thus on clinical decisions. Intermediate probability has been defined arbitrarily as between 10 and 90 percent; this definition has been used in several reports, including the ACC/AHA Exercise Test Guidelines.[18]

Special issues in ECG exercise testing include the effect of digoxin on ST-T wave changes, the usefulness of withholding beta-blocking drugs when possible, changes in ST-segment depression in patients with LBBB or RBBB, changes in the exercise ECG in patients with LV hypertrophy on ECG with or without repolarization abnormalities, and the usefulness of ECG testing in patients with resting ST-segment depression; these are discussed in great detail in Chap. 14 and ref. [18].

Exercise induced ST-depression usually occurs with LBBB and does not necessarily indicate ischemia.[26] However, in RBBB, ST-segment depression in the left chest leads (V_{5-6}) or inferior leads (II, aV_F) during exercise has the same significance as it does when the resting ECG is normal.

The difficulties of using exercise testing for diagnosing obstructive CAD in women have led to speculation that initial stress imaging may be preferable to standard ECG stress testing. There are insufficient data, however, to justify replacing standard exercise testing with stress imaging when evaluating women for CAD, and *women with a completely normal resting ECG* do not have a greater incidence of false-positive tests than men.[1]

REST ECHOCARDIOGRAPHY

Echocardiography can be useful for establishing a diagnosis of CAD and in defining the consequences of CAD in selected patients with chronic chest pain presumed to be chronic stable angina[1] (see Chap. 13). However, most patients undergoing a diagnostic evaluation for angina do not need a resting echocardiogram.[1]

Chronic ischemic heart disease, with or without angina, can result in impaired systolic LV function. The extent and severity of regional and global abnormalities are important considerations in choosing appropriate medical or surgical therapy.[25]

Echocardiographic findings that may help establish the diagnosis of chronic ischemic heart disease include regional systolic wall motion abnormalities, such as hypokinesis, akinesis, dyskinesis, and diminished segmental wall thickening.[27] Chronic CAD as a cause of ventricular septal wall motion abnormalities, however, must be distinguished from other conditions such as LBBB, presence of an intraventricular pacemaker, right ventricular volume overload, or prior cardiac surgery.[27]

Mitral regurgitation demonstrated by Doppler echocardiography may result from global LV systolic dysfunction, regional papillary muscle dysfunction, scarring and shortening of the chordae tendineae, papillary muscle rupture, or other causes.[27]

STRESS IMAGING FOR DIAGNOSIS

Patients who should undergo cardiac stress testing with imaging for the diagnosis of CAD as opposed to exercise ECG alone include those in the following categories: (1) complete LBBB, electronically paced ventricular rhythm, preexcitation syndromes, and other similar ECG conduction abnormalities, (2) patients who have greater than 1 mm of resting ST-segment depression, including those with LV hypertrophy or those taking drugs such as digitalis, (3) patients who are unable to exercise to a level high enough to give meaningful results on routine stress ECG (pharmacologic stress imaging should be considered), and (4)

patients with angina who have undergone prior revascularization, in whom localization of ischemia, establishing the functional significance of lesions, and demonstrating myocardial viability are important considerations. In our experience, false-positive ECG tests often occur in patients with hypertension, no evidence of LV hypertrophy on the ECG, but LV hypertrophy by echocardiography. Stress imaging is utilized in most patients with a history of hypertension even when the resting ECG is normal.

Several methods can be used to induce stress, including (1) exercise (treadmill or bicycle) and (2) pharmacologic techniques (dobutamine or vasodilator drugs). When the patient can exercise to an appropriate level of cardiovascular stress for 6 to 12 min, exercise stress testing generally is preferred to pharmacologic stress.[1]

Myocardial Perfusion Imaging

In patients with suspected or known chronic stable angina, the largest accumulated experience in myocardial perfusion imaging (MPI) has been with the isotope thallium-201; however, the available evidence suggests that the newer isotopes technetium-99m (^{99m}Tc) sestamibi and ^{99m}Tc tetrofosmin provide similar diagnostic accuracy (see Chap. 16). Thus, for the most part, these isotopes can be used interchangeably, with a similar diagnostic accuracy for CAD.[27]

MPI may use either planar or single-photon-emission computed tomography (SPECT), visual analyses, or quantitative techniques (see Chap. 16). Quantification using horizontal or circumferential profiles may improve the test's sensitivity, especially in patients with single-vessel disease. For the less commonly used thallium-201 planar scintigraphy, average reported values of sensitivity and specificity (uncorrected for posttest referral bias) have been in the range of 83 and 88 percent, respectively, for visual analysis and 90 and 80 percent, respectively, for quantitative analyses.[28] Thallium-201 SPECT generally is more sensitive than planar imaging for diagnosing CAD, localizing hypoperfused vascular segments, identifying left anterior descending and left circumflex coronary artery stenoses, and accurately predicting multivessel CAD. The average sensitivity and specificity of exercise thallium-201 SPECT imaging (uncorrected for referral bias) are in the range of 89 and 76 percent, respectively, for qualitative analyses and 90 and 70 percent, respectively, for quantitative analyses.[28]

Pharmacologic stress uses dipyridamole or adenosineinduced coronary vasodilatation as an adjunct to thallium-201 myocardial perfusion imaging.[29] Dipyridamole planar scintigraphy has a high sensitivity (90 percent average) and acceptable specificity (70 percent average) for the detection of CAD. Dipyridamole SPECT with thallium-201 or ^{99m}Tc sestamibi is as accurate as planar imaging, and results of myocardial perfusion imaging during adenosine infusion are similar to those obtained with dipyridamole and exercise imaging[30] (see Chap. 16). Evidence of CAD is demonstrated by redistribution defects comparing stress and resting scintigrams (ischemia), fixed defects at rest (scar), and LV dilatation or lung uptake of isotope during stress[28] (see Chap. 16).

Stress Echocardiography

Stress echocardiography is based on the assessment of myocardial thickening during stress compared with baseline (see Chap. 13). Echocardiographic findings suggestive of myocardial ischemia include (1) decrease in wall motion in one or more LV segments with stress, (2) diminution in systolic wall thickening in one or more segments during stress, and (3) compensatory hyperkinesis in complementary (nonischemic) wall segments.[27] The use of digital acquisition and storage, as well as side-by-side display of cine loops of LV images acquired at rest and at different levels of stress, has improved efficiency and accuracy in interpretation of stress echocardiograms.[27]

In 36 studies including 3210 patients, the reported overall sensitivities (uncorrected for referral bias) ranged from 70 to 97 percent. The average overall sensitivity was 85 percent for exercise echocardiography and 82 percent for dobutamine stress echocardiography.[24] The reported sensitivity of exercise echocardiography for multivessel disease was higher (approximately 90 percent) than the sensitivity for single-vessel disease (approximately 79 percent). In this series of studies, specificity averaged approximately 86 percent for

exercise echocardiography and 85 percent for dobutamine echocardiography.[27]

Pharmacologic stress echocardiography is best accomplished using dobutamine because it enhances myocardial contractile performance and wall motion, both of which can be evaluated directly by echocardiography (see Chap. 13). In 36 studies, average sensitivity and specificity (uncorrected for referral bias) of dobutamine stress echocardiography in the detection of CAD were 82 and 85 percent, respectively.[27]

Additional information concerning the sensitivity of exercise imaging in patients receiving beta blockers, the need for pharmacologic stress imaging in patients with LBBB, and the accuracy of myocardial perfusion and echocardiographic imaging in selected patient subgroups is included in Chaps. 13, 14, and 16.

Echocardiographic and MPI have complementary roles, and both add value to routine stress ECG under appropriate circumstances, as outlined earlier. The choice of which test to perform depends importantly on issues of local expertise, available facilities, and considerations of cost-effectiveness. A summary of the comparative advantages of stress myocardial perfusion imaging and stress echocardiography is provided in Table 40-4.

Table 40-4: Comparative Advantages of Stress Echocardiography and Stress Radionuclide Perfusion Imaging in Diagnosis of CAD

Advantages of stress echocardiography

1. Higher specificity
2. Versatility. More extensive evaluations of cardiac anatomy and function
3. Greater convenience/efficacy/availability
4. Lower cost

Advantages of stress perfusion imaging

1. Higher technical success rate
2. Higher sensitivity, especially for single-vessel coronary disease involving the left circumflex
3. Better accuracy in evaluating possible ischemia when multiple resting LV wall motion abnormalities are present
4. More extensive published data base, especially in evaluation of prognosis

SOURCE: From Gibbons et al.[1]

Coronary Angiography for Diagnosis

Direct referral for diagnostic coronary angiography in patients with chest pain, possibly due to myocardial ischemia, is appropriate when noninvasive tests are contraindicated or likely to be inadequate due to illness, disability, or physical characteristics.[1] Many patients with obesity, chronic obstructive pulmonary disease, bronchospasm, and heart failure are likely to have suboptimal imaging tests; diagnostic coronary angiography will provide accuracy diagnostic information with minimal risk.

Patients with noninvasive tests that are abnormal but not clearly diagnostic often require clarification of an uncertain diagnosis by coronary angiography. In certain cases, a second noninvasive test (imaging modality) may be recommended for a patient with a low likelihood of CAD but an intermediate risk treadmill result. Coronary angiography is likely to be most appropriate for a patient with a high-risk treadmill outcome.[1]

In individuals with symptoms consistent with but not diagnostic of stable angina, coronary angiography may be a necessity when the patient's occupation or activity could constitute a risk to themselves or others (e.g., pilots, firefighters, professional athletes).[1] When typical or atypical symptoms suggest stable angina and there is high clinical probability of severe CAD, direct referral for coronary angiography may be indicated and cost-effective.[31] In diabetic patients, the diagnosis of chronic stable angina can be particularly difficult because of the absence of characteristic symptoms of myocardial ischemia due to the autonomic and sensory neuropathy (see also Chap. 78). Thus a lower threshold for coronary angiography is appropriate. Special groups for the consideration of coronary angiography include women, who more often have atypical chest discomfort, and the elderly, in whom symptoms are common, noninvasive testing may be difficult, and comorbid conditions that mimic angina pectoris are frequent.[1] Coronary angiography is useful in patients in whom coronary artery spasm is suspected, in younger patients with signs or symptoms of myocardial ischemia possibly due to coronary anomalies, in patients with a history of cocaine use, and in patients experiencing sudden death or ventricular arrhythmias.[1,32] The ACC/AHA recommendations concerning the value of coronary angiography are listed in Table 40-5. Coronary angiographic findings in patients with chronic stable angina are depicted in Fig. 40-3.[32]

Table 40-5: Invasive Testing: Coronary Angiography (Recommendations for Coronary Angiography to Establish a Diagnosis in Patients with Suspected Angina, Including Those with Known CAD Who Have a Significant Change in Anginal Symptoms)

Class I

1. Patients with known or possible angina pectoris who have survived sudden cardiac death

Class IIa

1. Patients with an uncertain diagnosis after noninvasive testing in whom the benefit of a more certain diagnosis outweighs the risk and cost of coronary angiography
2. Patients who cannot undergo noninvasive testing due to disability, illness, or morbid obesity
3. Patients with an occupational requirement for a definitive diagnosis
4. Patients who by virtue of young age at onset of symptoms, noninvasive imaging, or other clinical parameters are suspected of having a nonatherosclerotic cause of myocardial ischemia (coronary artery anomaly, Kawasaki disease, primary coronary artery dissection, radiation-induced vasculoplasty)
5. Patients in whom coronary artery spasm is suspected and provocative testing may be necessary
6. Patients with a high pretest probability of left main or 3-vessel CAD

Class IIb

1. Patients with recurrent hospitalization for chest pain in whom a definite diagnosis is judged necessary
2. Patients with an overriding desire for a definitive diagnosis and a greater than low probability of CAD

Class III

1. Patients with significant comorbidity in whom the risk of coronary arteriography outweighs the benefits of the procedure
2. Patients with an overriding personal desire for a definitive diagnosis and a low probability of CAD

Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.
Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.
IIa: Weight of evidence/opinion is in favor of usefulness/efficacy.
IIb: Usefulness/efficacy is less well established by evidence/opinion.
Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful and in some cases may be harmful.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

DIFFERENTIAL DIAGNOSIS

Table 40-6 lists the differential diagnoses of angina pectoris. Usually, the distinction is clear if an accurate history is obtained and a complete, accurate physical examination is performed (see Chap. 10).

Table 40-6: Differential Diagnosis of Angina Pectoris

Cardiovascular

- Myocardial ischemia
  - Coronary atherosclerosis
  - Coronary vasospasm
  - Congenital coronary artery disease

Patients with hypertensive or valvular heart disease may have chest pain that is located at the apex rather than substernally and that is often associated with hyperesthesia of the left breast or precordium.[6] Many patients with no functional heart disease have pain over the LV apex that often occurs at rest. Chest wall pain, cervical arthritis, and subdeltoid bursitis can occur with exertion and are relieved by rest. Importantly, patients frequently have more than one type of chest pain.[1]

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

PATHOPHYSIOLOGY

In patients with stable angina pectoris due to atherosclerotic CAD, the correlation between the severity or extent of atherosclerosis and the magnitude of angina symptoms is poor. Also, no definite relation exists between the location of the chest discomfort and the site of the myocardial ischemia. Women have angina as the initial manifestation of CAD more often than men, who often present with acute MI. The pathology of coronary atherosclerosis is discussed in detail in Chap. 36. The nonatherosclerotic causes of CHD are discussed in Chap. 39.

A disparity between the supply of coronary blood flow (CBF) and the metabolic demands of the myocardium (M_{O_2}) is the primary factor in ischemic heart disease. This imbalance may result in clinical manifestations of ischemia when myocardial demand exceeds the capacity of the coronary arteries to deliver an adequate supply of oxygen. In normal hearts there is an excess CBF reserve so that ischemia does not occur even with very vigorous exercise.[34]

Arteriosclerotic disease in either the epicardial coronary arteries or in the coronary microvasculature may cause an imbalance between supply and demand at even modest levels of exercise. An understanding of the determinants of CBF and myocardial metabolic demand is important in the management of chronic ischemic heart disease.[6]

Myocardial Oxygen Demand

The major relevant determinants of M_{O_2} are heart rate, contractility, and systolic wall stress (Fig. 40-4). A detailed discussion of the major and minor determinants of myocardial oxygen demand is presented in Chaps. 3 and 37. Heart rate is one of the most important determinants of M_{O_2} and can be altered easily by medical therapy in most patients.[35]

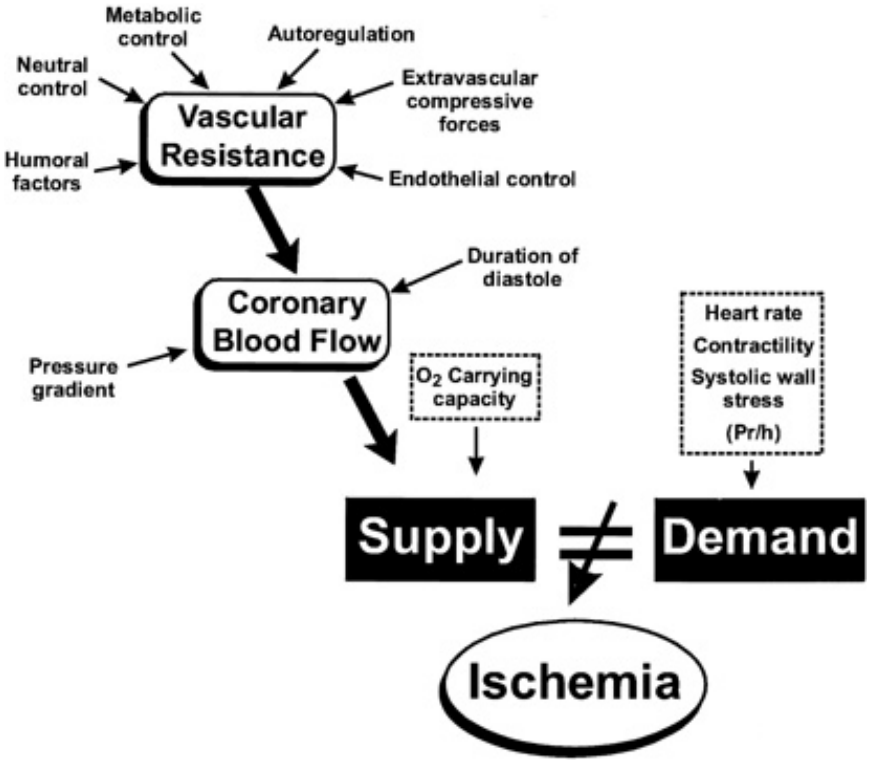

Figure 40-4: Factors controlling myocardial oxygen demand. *P*, systolic pressure; *r*, radius; *h*, wall thickness. (Modified from Ardehali A, Ports TA. Myocardial oxygen supply and demand. *Chest* 1990; 98:699-705. Reproduced with permission from the publisher and authors.)

Myocardial contractility, partially reflected in the isovolumic rate of change of LV pressure (*dP/dt*), is a major determinant of M_{O_2} but not usually a primary factor for therapeutic intervention. However, LV systolic wall stress is an important consideration in the medical treatment of angina pectoris.

Systolic wall stress is directly related to the LV systolic pressure (*P*) and radius (*r*) and inversely related to wall thickness (*h*). Thus, reducing systolic pressure afterload (i.e., treating hypertension) can decrease M_{O_2}. Decreasing preload by venodilation, and thus reducing LV size and oxygen consumption, is an important mechanism for the efficacy of nitrate therapy in angina pectoris. Positive inotropic agents actually may decrease M_{O_2} in patients with an enlarged left ventricle if the results of a diminished LV radius outweigh those of increasing contractility.

Myocardial Oxygen Supply

Oxygen supply to the myocardium depends on the oxygen-carrying capacity of the blood and on CBF (see Fig. 40-4). Although a decrease in oxygen-carrying capacity may contribute to the development or exacerbation of myocardial ischemia in severe anemia, myocardial ischemia related to oxygen supply usually results from inadequate CBF.

The arteriolar resistance vessels are normally the primary regulators of CBF because the epicardial arteries are low-resistance conduits. Narrowing of the large coronary arteries transiently by vasospasm or permanently by obstructive lesions may increase the coronary resistance sufficiently to reduce CBF.

In the past decade, the pathophysiologic role of the coronary microvasculature has been recognized,[36,37] either concomitantly with atherosclerotic narrowing of the large-conduit arteries

or predominantly in anginal syndromes with normal epicardial arteries (syndrome X).[38,39]

The determinants of CBF are relatively complex and include (1) metabolic control, (2) autoregulation, (3) extravascular compressive forces, (4) duration of diastole, (5) humoral agents composed of both circulating hormones and autocrine and paracrine factors produced within the arterial wall and in particular by the endothelium, (6) neural control, and (7) the difference between aortic diastolic pressure and right atrial pressure[6] (see Fig. 40-4).

CBF is relatively constant, being autoregulated during perfusion pressures between 60 and 160 mmHg.[40] Below a perfusion pressure of 60 mmHg, vasodilator reserve disappears, and blood flow is directly related to perfusion pressure. Experimentally, loss of vasodilator reserve occurs distal to lesions with an 85 percent decrease in diameter.[41] A decrease in CBF, likely due to vasoconstriction and loss of vasodilator reserve, has been observed despite an increase in blood pressure during cold pressor stimulation in patients with significant CAD.[42]

Extravascular compressive forces, including intrapericardial, intramyocardial, and intraventricular pressures, are important in the control of CBF and account for 30 to 50 percent of the vascular resistance.[6] Since intramyocardial and intraventricular pressures are maximal during systole and are exerted maximally on the subendocardium, LV subendocardial blood flow decreases during systole. Thus subendocardial blood flow is most vulnerable whenever total blood flow is decreased or M_{O_2} is increased and blood flow is limited. Because of the systolic compressive forces, the subendocardium is also critically dependent on the duration of diastole for its blood flow (see Chap. 37).

CBF is regulated by systemic hormones and by neural control mechanisms similar to other vascular beds. Angiotensin II is a coronary vasoconstrictor; beta-adrenergic agonists dilate and alpha-adrenergic agonists constrict coronary arteries, although there are some regional differences in distribution of receptors in vessels of different sizes.[6] Importantly, the integrated vasomotor response to the various vasoactive stimuli affecting a coronary artery or arteriole appears greatly influenced by the functional state of the endothelium (see Chaps. 6 and 37).

Endothelial Function and Coronary Vasomotor Control

The phenomenon of endothelial-dependent relaxation[43] and the identification of endothelial-derived relaxing factor as nitric oxide[44] are discussed in detail in Chap. 6. The defect in endothelial-dependent dilatation in atherosclerotic epicardial coronary arteries that vasoconstrict in response to stimuli that normally cause vasodilation, such as acetylcholine, exercise, or cold pressure testing, is discussed in Chap. 37, as is the role of dysfunctional endothelium in both the stable and unstable coronary artery syndromes.

The majority view is that endothelium-dependent vasodilator mechanisms are predominant in nondiseased epicardial coronary arteries. Thus interventions such as exercise,[45] mental stress,[46] cold pressure testing,[47] or even pacing-induced tachycardia,[48] which normally induce increases in M_{O_2} and flow, are associated with epicardial dilatation that is at least partially endothelial-dependent. The presence of even nonocclusive, early atherosclerosis appears to attenuate this vasodilator mechanism and results in prevailing constrictor forces.[6]

The local infusion of the alpha-adrenergic agonist phenylephrine does not constrict normal coronary arteries of patients with intact endothelial-dependent dilatation.[49] However, vasoconstriction occurs in even minimally diseased coronary arteries at low concentrations of phenylephrine. Thus in CAD there appears to be both loss of endothelial-dependent dilatation and

an enhanced vasoconstrictor sensitivity to catecholamines. This disordered vasomotor control is an important contributor to the variability in anginal threshold commonly observed in many patients.[50]

Moderate vasoconstriction of a minimal stenosis may have little hemodynamic importance, whereas the same degree of vasoconstriction of a higher-grade stenosis may markedly decrease blood flow and induce ischemia.

The Microvasculature and Coronary Ischemia

The recognition of the likely importance of the coronary microvascular resistance vessels in the pathogenesis of angina pectoris resulted from studies of patients with angina-like chest pain and angiographically normal epicardial coronary arteries.[51-55]

The coronary etiology of the chest pain is supported by the frequent but not universal evidence of ischemia in these patients during exercise testing[56]; many were found to have abnormal vasodilator reserve.[56] Specifically, in patients with angina and angiographically normal coronary arteries, endothelial-dependent vasodilatation of the resistance arteries, as reflected in the responses of CBF to infusion of the endothelial-dependent vasodilator acetylcholine, was diminished relative to controls.[58]

In contrast, the flow responses to the non-endothelial-dependent dilators, isosorbide dinitrate and papaverine were no different between patients and controls, suggesting that the intrinsic vasodilator capacity of the resistance arteries was not defective. Similar defects in endothelial-dependent increases in CBF have been observed in LV hypertrophy associated with hypertension, another condition that may be associated with angina pectoris with angiographically normal epicardial coronary arteries.[58]

The histopathology of biopsy specimens from patients with normal epicardial coronaries but with anginal syndromes has demonstrated capillary narrowing with swollen endothelium encroaching on the lumen as well as decreased capillary density. Thus the coronary microvasculature can develop dysfunction of vasomotor control mechanisms and of endothelial-dependent vasodilation that may become clinically significant in the setting of increased demand or M_{O_2}. In this situation, the loss of vasodilator reserve and/or the actual constriction of resistance arterioles may induce ischemia and chest pain.[6]

Spectrum of Pathophysiologic Mechanisms Associated with the Stable Coronary Ischemia Syndromes

Symptomatic myocardial ischemia due primarily to microvascular abnormalities in the control of coronary vascular tone partially explains the characteristics of stable angina syndromes. Angina pectoris or anginal equivalents, with a *relatively constant* threshold for inducing ischemic symptoms due to a fixed stenoses of an epicardial coronary artery, also in part determine the spectrum of angina symptoms. Most patients have a somewhat variable threshold for inducing angina from day to day or even at different times of the day.

Interestingly, the same activity that causes chest discomfort in the early morning may not do so in the afternoon or evening. Yet the patient may have a consistent level of exercise for inducing ischemia on protocol exercise testing because of the augmented M_{O_2} that is due to increases in heart rate, contractility, and blood pressure and the associated increment in systolic wall stress. This is explained by the presence of both flow-limiting epicardial coronary stenosis and associated episodic vasoconstriction.

Maseri et al.[50] have termed have termed this phenomenon *mixed angina*. Myocardial ischemia is induced by both an increase in M_{O_2} and a decrease in CBF. The site(s) of vasoconstriction may be at an epicardial stenoses, in the microvasculature, or at both locations.[61] The concept of a *variable flow reserve* that interacts with differing metabolic demands to produce intermittent ischemia is depicted in Fig. 40-5*A* and *B*.

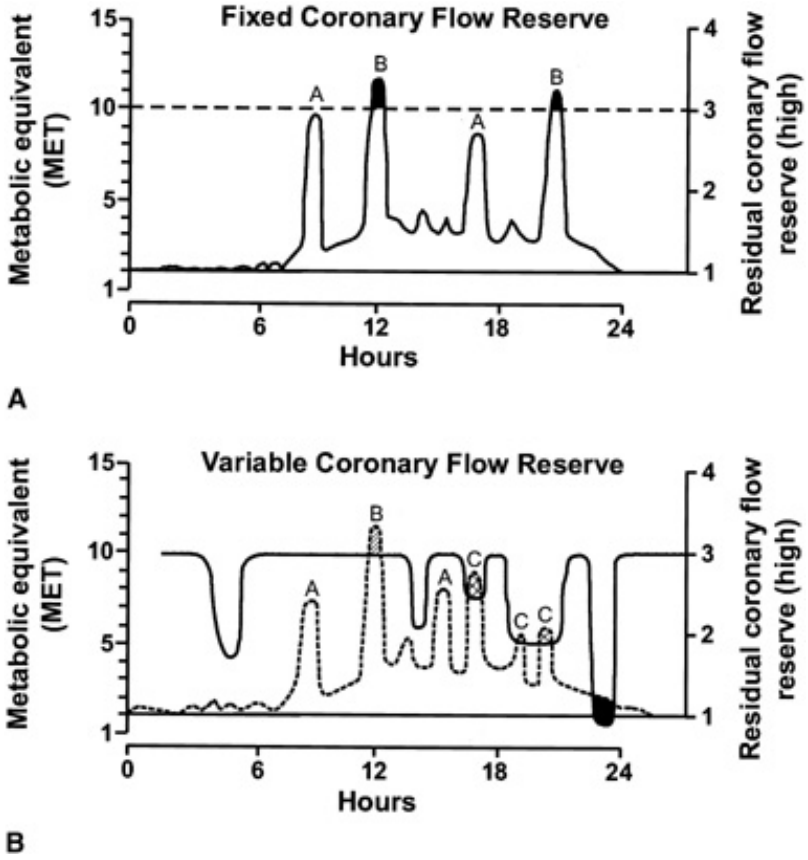

Figure 40-5: Concept of variable coronary flow reserve in the presence of variable atherosclerotic obstruction. *A*. Episodes not associated with ischemia. *B*. Ischemic episode occurring at levels of exercise exceeding threshold of residual coronary flow reserve. *C*. Ischemic episodes occurring at lower levels of exercise when residual coronary flow is reduced. *D*. Ischemic episodes occurring at rest in the presence of maximal reduction in residual coronary flow reserve. --, residual coronary flow reserve; - - -, variable atherosclerotic obstruction as measured by MED. (Modified from Cohn PF. Mechanisms of myocardial ischemia. *Am J Cardiol* 1992; 70:14G-18G; and Maseri A. Role of coronary artery spasm in symptomatic and silent myocardial ischemia. *J Am Coll Cardiol* 1987; 9:249-262. Reproduced with permission from the authors and publishers.)

In the stable anginal syndromes, the predominant vasoconstrictors are likely neural and hormonal, whereas in the unstable (acute) coronary syndromes, platelet and coagulation products as well as inflammatory mediators are important contributors (see Chap. 41). Patients with predominantly vasoconstrictor pathophysiology in an epicardial vessel have been classified as having *vasospastic angina* or *Prinzmetal's variant angina* (see Chap. 41).

Cellular Bases for the Clinical Manifestations of Ischemia

The cellular effects of myocardial ischemia are discussed in detail in Chaps. 36 and 37. The rapid decreases in systolic function and diastolic compliance that are associated with creatine phosphate

depletion and ionic shifts will increase LV enddiastolic pressure. Elevated pulmonary vascular pressures often stimulate mechanoreceptors and mediate the dyspnea response. Dyspnea may be associated with angina or may be present as an anginal equivalent in patients who do not develop chest discomfort.

The metabolic abnormalities due to ischemia cause cellular depolarization and the flow of electric currents between normal and ischemic areas that are reflected on the ECG.[6] ST-segment depression reflecting subendocardial underperfusion is the most common ECG manifestation of ischemia in chronic stable angina during ambulatory recordings or exercise testing.[62] The ST-segment depression observed during exercise testing or ambulatory ECG recordings is not commonly associated with complex or life-threatening ventricular arrhythmias; exercise-induced ventricular ectopic activity is not a reliable predictor of cardiac events in asymptomatic persons.[63]

The Coronary Ischemia Cascade

Studies in which hemodynamic and ECG recordings have been performed during spontaneous episodes of ischemia, either in unstable patients or during balloon inflation at angioplasty, have provided insights into the sequential responses evoked at the onset of ischemia and are consistent with those described in animals undergoing acute coronary artery ligation[64] (see Fig. 40-1).

After balloon inflation, impaired LV compliance occurs within a few seconds and is followed rapidly by systolic contractile dysfunction causing a decrease in LV ejection fraction of up to 30 percent within 10 s.[64] ECG changes occur at about 20 s, and angina, if it occurs, appears at between 25 and 30 s.

Considering this "ischemic cascade," there are likely to be episodes that do not progress to angina. Since many patients do not perceive coronary ischemic pain or have high pain thresholds, the common occurrence of asymptomatic (silent) ischemia in individuals with CAD is not surprising.

Hemodynamic measurements and ECG recording of patients with spontaneous or exercise-induced ischemia provide physiologic explanations for many of the classic clinical observations about angina.

As noted earlier, an anginal episode may be associated with new physical findings, including the development of an S_4, systolic bulging of the precordium, mitral regurgitation due to papillary muscle dysfunction, and reversed splitting of S_2. The fourth heart sound (S_4) reflects diastolic ventricular dysfunction and decreased ventricular compliance, whereas the remaining features reflect ventricular systolic dysfunction, including a prolonged LV ejection time accounting for the reversed splitting of S_2.

In addition, the crescendo-decrescendo nature of anginal pain is reflected in the crescendo-decrescendo pattern of the development and resolution of ischemic ST-segment changes and elevations in LV filling pressure recorded during exercise-induced angina.

Circadian Rhythm of Coronary Ischemia

The prevalence of MI, unstable angina, variant angina, and silent ischemia is greatest in the morning during the first few hours after awakening, and the threshold for precipitating anginal attacks in patients with stable angina also appears to be lowest in the morning.[65,66] Patients often develop ST-segment depression and angina at lower thresholds during exercise testing in the morning than later in the day. Studies with ambulatory ECG recordings have confirmed that the

incidence of both painful and painless episodes of ST-segment depression is highest in the morning[66] and, in particular, in the first few hours after awakening (Fig. 40-6).

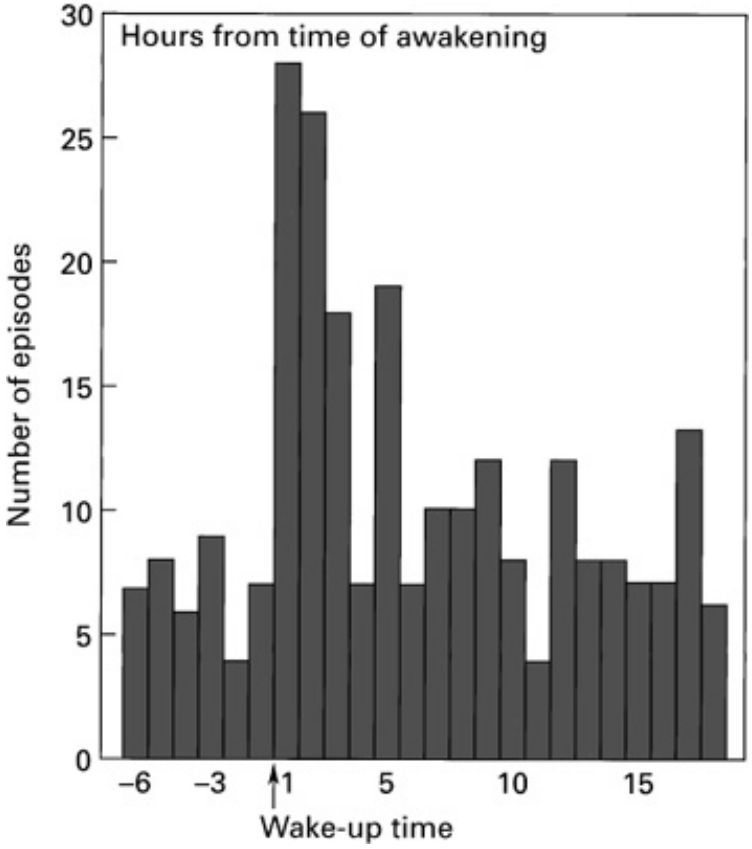

Figure 40-6: When the frequency of episodes is displayed hourly from the time of awakening, the peak activity occurs in the first and second hour after arising. (From Rocco et al.[67] Reproduced with permission from the authors and publishers.)

The diurnal variation in ischemic threshold is attributed to the endogenous rhythms of catecholamine secretion and to the sensitivity to coronary vasoconstrictors, both of which appear to peak in the morning. The increase in sympathetic nervous system activity is associated with increases in heart rate, blood pressure, contractility, and M_{O_2}. The lowered morning anginal threshold and the higher morning systolic blood pressure have *important therapeutic implications*. A decrease in the frequency of ischemia can be achieved by blunting the morning surge of beta-adrenergic stimulation by the administration of beta blockers. The control of hypertension by the *early morning use of antihypertensive drugs* is also important. In patients with recurrent morning angina, the use of nitroglycerin (TNG) soon after awakening may prevent angina in many instances.

Mechanisms of Anginal Pain

Angina pain is a useful warning system, but it is often too insensitive. Pain stimuli arise within the myocardium and most likely stimulate free nerve endings in or near small coronary vessels. Impulses travel in afferent unmyelinated or small myelinated cardiac sympathetic nerves through the upper five thoracic sympathetic ganglia to dorsal horn cells and through the spinothalamic tract of the thalamus and then to the cortex.[67]

Integration and modification of these impulses occur at several levels, including the cerebral

cortex. This modulation also may contribute importantly to the variability in anginal threshold. At the cortical level, psychosocial and cultural factors may alter the perception of pain. The radiation patterns of angina are determined by the levels of the thoracic spinal cord that share the sensory inputs from the heart and from somatic structures.

The nature of the stimuli causing angina has been difficult to delineate. The causes are probably chemical, and several molecules, including kinins, serotonin, hydrogen ions, and inflammatory mediators, have been proposed. By contrast, adenosine, which is increased during ischemia, has been shown to cause anginal-type pain during intravenous infusion in normal volunteers.[68] The precise mechanisms causing angina pain are yet to be defined.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

ASYMPTOMATIC (SILENT) ISCHEMIA IN STABLE CAD

The presence of unrecognized myocardial infarction due to the absence of pain was mentioned by Herrick in 1912.[69] The frequent presence of extensive CAD and MI at autopsies of apparently asymptomatic persons was recognized later.[70] Direct evidence of asymptomatic (silent) ischemia during ECG exercise testing and during ambulatory ECG recording stimulated interest in this clinical entity.[71]

Prevalence of Silent Ischemia

Asymptomatic ischemic episodes may be present in patients with any of the ischemic coronary syndromes, including unstable angina and silent ischemia after MI; they may be observed in patients who are totally asymptomatic or who have chest discomfort with some episodes of ischemia but not with others.[72] The prevalence of silent ischemic episodes approaches 40 percent in patients with chronic stable angina or in those with a history of instability.[73] The incidence of asymptomatic ischemia occurring in individuals with extensive CAD has been estimated at 5 percent.[74] ST-segment depression of 60 s or more on ambulatory recordings is uncommon in patients with no evidence of CAD.[75,76]

A prospective study of 68-year-old men with a 9.9 and a 6.6 percent prevalence of a history of angina pectoris or MI, respectively, demonstrated ST-segment depression on ambulatory ECG recordings. In 25 percent[77]; 92 percent of the "ischemic" episodes were asymptomatic, but ST-segment depression was associated with an increased risk of coronary events.

The true prevalence of silent ischemia is difficult to determine and obviously will depend on age and the presence and extent of CAD. In the presence of CAD, however, it is apparent that episodes of asymptomatic ischemia are often more common than are painful episodes.[78]

Pathophysiology of Silent Ischemia

An obvious possible explanation for painful as opposed to asymptomatic ischemia is that the ischemia, and thus the noxious stimulus, is more severe in the former. The correlation between the duration and severity of an ischemic episode and the development of anginal pain in chronic stable angina, however, is only fair.[79] Symptomatic episodes last slightly longer and have a slightly higher frequency of severe ST-segment depression than do painless ones, but there is considerable overlap. In several clinical studies, the intensity of the ischemic stimulus did not appear to account for the variability in the perception of pain in chronic ischemic heart disease.[80]

An alternative reason for lack of pain with myocardial ischemia is neurologic.[81] Neuropathy with defective sensory efferent nerves definitely occurs in some patients and is particularly prevalent in diabetics. Modification of pain stimuli in the central nervous system (CNS) may contribute importantly to the variable expression of ischemic pain. This modulation may occur in spinal centers because transcutaneous nerve,[81] esophageal,[82] and dorsal column stimulation[83] can increase anginal threshold. Modulation of pain-mediating efferent messages also may occur at

supraspinal centers. Psychological or cultural factors also may affect pain perception. Subsets of patients with predominantly painless ischemic episodes tend to have a higher threshold and tolerance for painful stimuli than those who experience pain.[84-86] Thus processing of pain signals in the CNS likely contributes to the variability of anginal threshold or to the absence of pain.

Diabetic patients have a relatively high incidence of painless MI and definite silent ischemic episodes as documented by exercise testing and ambulatory ECG recordings (also Chap. 78).[87-90]

Causes and Functional Consequences of Asymptomatic Ischemia

Ischemia caused by the increased M_{O_2} associated with exercise testing often is silent.[91] Ambulatory ECG recordings have provided insights into potential mechanisms of many episodes of painless or painful ischemia during daily living. The heart rate at the onset of ischemia is generally lower with ambulatory ECG recordings than with exercise testing.[92] These observations suggest that coronary vasoconstriction likely contributes to many episodes of silent ischemia.

Clinical Implications of Silent Ischemia

Asymptomatic silent ischemia is a common component of both acute and chronic coronary artery syndromes. Thus it may have the same clinical importance as symptomatic ischemia.[93] The important indicators of risk are the extent and severity of ischemia, regardless of how it is detected or manifested, and whether the disease is in a stable or unstable phase. Whether ECG monitoring for silent ischemia and changing therapy to decrease or eliminate it diminish morbidity and mortality in a cost-effective manner is unproven.[76]

Evidence of high-risk ischemia detected by exercise ECG testing, with or without myocardial imaging, and implications for treatment are discussed later. Therapeutically, it is appropriate to treat high-risk ischemia whether or not it is associated with pain. Persistent severe ischemia despite medical therapy should lead to consideration of myocardial revascularization.

The role of ambulatory ECG recordings *alone* without stress testing to detect asymptomatic ischemia in routine patient care is *minimal*, and ACC/AHA practice guidelines on this topic have been published recently.[76]

Treatment of Silent Ischemia

Most medical or interventional strategies that reduce symptomatic ischemia also will reduce asymptomatic ischemia.[94-96] The available data from early clinical trials of the treatment of asymptomatic (silent) ischemia in stable CAD have been summarized recently.[94-96] Nitroglycerin (TNG) is highly effective, and beta blockers appear to be somewhat more effective than calcium antagonists. Calcium antagonists may be most effective in preventing ischemia occurring at lower heart rates because coronary artery vasoconstriction may be a predominant factor in this situation. In patients with ischemic CAD, the total ischemic burden, and not just symptoms, may be the appropriate therapeutic target.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

RISK STRATIFICATION OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

The prognosis for the patient with chronic CHD is usually related to four patient factors.[1] *LV performance* is the strongest predictor of long-term survival in patients with CHD, and the ejection fraction (EF) is the most often used measure of the presence and the degree of LV dysfunction. The second predictive factor is the *anatomic extent and severity* of atherosclerotic involvement of the coronary arteries. The number of stenosed coronary arteries is the most common measure of this factor. The third patient factor affecting prognosis is evidence of a *recent coronary plaque rupture* indicating a much higher short-term risk for cardiac death or nonfatal MI. Worsening clinical symptoms with unstable features are an important clinical marker of a complicated plaque (see Chap. 41). The fourth prognostic factor is *general health and noncoronary comorbidity*.

History and Physical Examination for Prognosis

Useful information relative to *risk stratification* can be obtained from the history. This includes demographics such as age and gender, as well as a medical history focusing on hypertension, diabetes, hypercholesterolemia, smoking, peripheral vascular disease, and previous MI.

The physical examination can be useful in risk stratification by defining the presence or absence of signs that may alter the probability of *severe* CAD.[1] Useful physical findings include those suggesting vascular disease (abnormal fundi, decreased peripheral pulses, bruits), long-standing hypertension (high blood pressure, abnormal fundi), aortic valve stenoses or hypertrophic obstructive cardiomyopathy (systolic murmur, abnormal carotid arterial pulse, abnormal LV impulse), left-sided heart failure (third heart sounds, displaced LV impulse, bibasilar rales), and right-sided heart failure (elevated jugular venous pressure, hepatomegaly, ascites, peripheral edema).[1] Hubbard et al.[97] identified five clinical markers that independently predicted severe three-vessel and left main CAD, including age, typical angina, diabetes, male gender, and prior MI, which were used to develop a five-point cardiac risk score.

ECG and Chest Roentgenogram for Prognosis

Patients with chronic stable angina who have abnormalities on resting ECG are at greater risk than those with normal ECGs.[98] Evidence of one or more prior MIs on ECG indicates a greater risk for cardiac events. The presence of Q waves in multiple ECG leads, often accompanied by an R wave in lead V_1 (posterior infarction), commonly is associated with a markedly reduced left ventricular ejection fraction (LVEF), an important factor in the natural history of patients with CAD.[99] Persistent ST-segment-T-wave inversions, particularly in V_1 to V_3, are associated with an increased prevalence of future coronary events and a poor prognosis.[99]

On the chest roentgenogram the presence of cardiomegaly, a LV aneurysm or pulmonary venous congestion is associated with a poorer long-term prognosis than occurs in patients with a normal chest x-ray.

The presence of calcium in the coronary arteries on chest x-ray or fluoroscopy in patients with symptomatic CAD suggests an increased risk of cardiac events. Although the presence and amount of coronary artery calcification by electron beam computed tomography correlate to some extent with the severity of CAD, there is considerable patient variation.[16] Also, placques vulnerable to rupture with resulting acute coronary syndromes rarely contain much calcium.

Noninvasive Testing for Prognosis

ASSESSMENT OF LV FUNCTION

LV global systolic function and volumes are important predictors of prognosis in patients with cardiac disease.[1] In patients with chronic CHD, LVEF measured at rest by either echocardiography (usually qualitative and less reliable) or radionuclide ventriculography (RVG) is predictive of long-term prognosis. As LVEF decreases, subsequent mortality increases; a resting ejection fraction of greater than 35 percent is associated with an annual mortality rate of more than 3 percent per year.[1]

Radionuclide LVEF may be measured at rest using a gamma camera, a ^{99m}Tc tracer, and first-pass or gated equilibrium blood pool angiography (RVG) or by gated SPECT perfusion imaging using a technetium-based isotope[27] (see Chap. 16). LV diastolic function also can be estimated from RVG diastolic filling curves. LV systolic function can be measured by quantitative two-dimensional echocardiography (see Chap. 13), and LV diastolic function can be assessed by transmitral valve Doppler recording.[13]

In patients with chronic stable angina and a history of previous MI, segmental wall motion abnormalities are apparent not only in the zone(s) of prior infarction but also in areas with ischemic "stunning" or "hibernation" of myocardium that are nonfunctional but still viable.[100] In patients with CHD, the presence, severity, and mechanism of mitral regurgitation can be detected reliably using transthoracic and transesophageal two-dimensional imaging and Doppler echocardiographic techniques (see Chap. 13).

Echocardiography is the definitive test for detecting intracardiac thrombi.[27] LV thrombi are most common in stable angina pectoris patients who have significant LV wall motion abnormalities. In patients with anterior and apical infarctions, the presence of LV thrombi denotes an increased risk of both embolism and death (see Chap. 41).

ECG EXERCISE TESTING

Unless cardiac catheterization is clearly indicated, symptomatic patients with suspected or known CAD usually should undergo exercise testing to assess the risk of future cardiac events, unless they have confounding features on their resting ECG or are unable to exercise[1] (see Chap. 14). Also, demonstration of exercise-induced ischemia is desirable for most patients who are being evaluated for revascularization.

Several studies have shown that risk assessment in patients with a normal ECG who are not taking digoxin and who are physically capable *usually* should start with the exercise test[1,102] (see Chap. 14). In contrast, a stress-imaging technique should be used for patients with ECG evidence of LV hypertrophy, widespread resting ST-segment depression (>1 mm), complete LBBB, ventricular paced rhythm, or preexcitation.[17] The primary evidence that ECG exercise testing can be used to estimate prognosis and assist in management decisions consists of seven observational studies.[1,18] One of the strongest and most consistent prognostic markers is the *maximum exercise capacity*.[103,104]

A second group of *prognostic markers* relates to exercise-induced ischemia (see Chap. 14). ST-segment depression and ST-segment elevation (in leads without pathologic Q waves and not in aV_R) best summarize the prognostic information related to ischemia. Other variables are less powerful, including angina, the number of leads with ST-segment depression, and the configuration of the ST-segment depression and the duration of ST-segment deviation into the recovery phase.

The *Duke treadmill score* combines this information and provides a way to calculate risk.[103,105] The Duke treadmill score equals the exercise time in minutes minus five times the peak ST-segment deviation during or after exercise (in millimeters) minus four times the angina index (which has a value of 0 if there is no angina, 1 if angina occurs, and 2 if angina is the reason for stopping the test). Among outpatients with suspected CAD, two-thirds of patients with scores indicating low risk had a 4-year survival of 99 percent

(average annual mortality of 0.25 percent), and the 4 percent who had scores indicating high risk had a 4-year survival of 79 percent (average annual mortality rate of 5 percent) (Table 40-7). Recent studies indicate that this approach is equally applicable in men and women.[106]

Table 40-7: Survival According to Risk Groups Based on Duke Treadmill Scores

Risk Group (Score)	Percentage of Total	Four-Year Survival	Annual Mortality (percent)
Low (≥ +5)	62	0.99	0.25
Moderate (-10 to +4)	34	0.95	1.25
High (< -10)	4	0.79	5.0

SOURCE: From Gibbons et al.[1]

STRESS IMAGING FOR PROGNOSIS

Stress-imaging studies using radionuclide MPI techniques or two-dimensional echocardiography at rest and during stress are beneficial for risk stratification and determining the most effective treatment strategy for patients with chronic stable angina.[1] Whenever feasible, treadmill or bicycle exercise should be used as the most desirable forms of stress because exercise provides the most information concerning patient's symptoms, cardiovascular function, and hemodynamic response during usual activity (see Chap. 16). The inability to perform a bicycle or exercise treadmill test has been shown to be a serious and negative prognostic factor for patients with chronic CAD.[1]

In patients unable to exercise adequately, various types of pharmacologic stress (as discussed under diagnosis) are commonly used for *risk stratification*. The type of pharmacologic stress selected will depend on specific patient factors, including the patient's heart rate and blood pressure, evidence of bronchospastic disease, the presence of LBBB or a pacemaker, and the likelihood of ventricular arrhythmias. Pharmacologic agents often are used to increase workload or to cause an increase in overall CBF.[107,108]

MPI has played a major role in the risk stratification of patients with CAD.[27] Either planar (less common) or SPECT imaging using thallium-201 or ^{99m}Tc perfusion tracers, with images obtained at stress and during rest, provides important information concerning the severity of functionally significant CAD (see Chap. 16).

Stress echocardiography has been used more recently for detecting the presence and amount of ischemia in patients with chronic stable angina. Accordingly, the amount of prognostic data obtained with this approach is less extensive. The presence or absence of inducible myocardial wall motion abnormalities, however, has useful predictive value in patients undergoing exercise or pharmacologic stress echocardiography.[27,109-112] A negative stress echocardiographic study denotes a low cardiovascular event rate during follow-up.

MYOCARDIAL PERFUSION IMAGING FOR PROGNOSIS

Normal poststress thallium scan results are highly predictive of a benign prognosis even in patients with known CAD.[1] An analysis of 16 studies involving 3594 patients followed for an average of 29 months indicated a rate per year of cardiac death and MI of 0.9 percent, little different from that of the general population.[113,114] In a recent prospective study of 5183 consecutive patients undergoing myocardial perfusion imaging during stress and later at rest, patients with normal scans were at low risk (<0.5 percent per year) for the composite end point of cardiac death and MI during 642 ± 226 days of mean follow-up[115] (see Chap. 16).

The number, extent, and site of abnormalities on stress MPI reflect the location and severity of functionally significant coronary artery stenoses (see Chap. 16). Lung uptake of thallium-201 on postexercise or pharmacologic stress images is an indicator of stress-induced global LV dysfunction and is associated with pulmonary venous hypertension in the presence of multivessel CAD.[115] Transient poststress ischemic LV dilatation also correlates with severe two- or three-vessel CAD (see Chap. 16). SPECT may be more accurate than planar imaging for determining the size of defects, for detecting particularly left circumflex CAD, and for localizing abnormalities in the distribution of individual coronary arteries. More false-positive results are likely to result from photon attenuation during SPECT imaging, however.

The determination of both myocardial perfusion and LV function at rest may help determine the extent and severity of CAD.[1] This combined information can be obtained by performing two separate exercise tests (e.g., stress MPI and stress RVG), or by combining the studies after a single exercise test (first-pass RVG) with ^{99m}Tc-based agents followed by MPI, or by perfusion imaging using ECG gating. The use of ECG gated ^{99m}Tc sestamibi SPECT imaging at rest and with exercise or pharmacologic stress provides important prognostic information concerning LVEF and the extent of reversible ischemia (see Chap. 16).

Pharmacologic stress perfusion imaging for risk stratification is preferable to *exercise perfusion* imaging in patients with LBBB.[116] Recently, 245 patients with LBBB underwent SPECT imaging with thallium-201 (n = 173) or ^{99m}Tc sestamibi (n = 72) during dipyridamole (n = 153) or adenosine (n = 92) stress.[134] The 3-year survival was 57 percent in the high-risk group compared with 87 percent in the low-risk group (p = 0.001).

STRESS ECHOCARDIOGRAPHY FOR PROGNOSIS

Stress echocardiography is both sensitive and specific for detecting inducible myocardial ischemia in patients with chronic stable angina.[27] Compared with standard exercise treadmill testing, stress echocardiography provides additional clinical value for detecting and localizing myocardial ischemia. Several studies indicate that patients at low, intermediate, and high risk for cardiac events can be stratified by the presence or absence of inducible wall motion abnormalities on stress echocardiography testing.[109-112] The presence of ischemia on the exercise echocardiogram is independent and additive to clinical and exercise data in predicting cardiac events in both men and women.[117,118]

The prognosis is not benign in patients with a positive stress echocardiographic study, and morbid or fatal cardiovascular events are more likely. The overall event rates, however, are rather variable, and the cost-effectiveness of using routine stress echocardiographic testing to establish prognosis is uncertain.[1]

Coronary Angiography for Prognosis

The availability of powerful but expensive therapeutic strategies to reduce the long-term morbidity and mortality of CAD dictate that the patients most likely to benefit because of increased risk be determined. The assessment of cardiac risk and the need for further testing usually begin with simple, repeatable, and inexpensive assessments of history and physical examination that lead to noninvasive or invasive testing depending on outcome. Clinical risk factors generally are additive, and a crude estimate of 1-year mortality can be obtained from these variables. Methods for the accurate identification of vulnerable plaques, however, are lacking. Magnetic resonance imaging (MRI) offers significant promise in this regard.[1]

Risk stratification of patients with chronic stable angina by stress testing with exercise or pharmacologic agents has been shown to permit identification of groups of patients with low, intermediate, or high risk for subsequent cardiac events[1,27,28] (see ).

The randomized trials of coronary artery bypass grafting (CABG) demonstrated that patients randomized to initial CABG had a lower mortality than those assigned to medical therapy only if they were at substantial risk (annual mortality > 3 percent).[119,120] Coronary angiography is appropriate for patients whose mortality risk is in this range. Noninvasive test findings that identify high-risk patients are listed in Table 40-8.

Patients identified as at high risk generally are referred for coronary arteriography independent of their symptomatic status. The ACC/AHA guidelines for risk stratification using coronary angiography in patients with stable angina are listed in Table 40-9.

Table 40-8: Noninvasive Risk Stratification

High risk (greater than 3% annual mortality rate)

1. Severe resting left ventricular dysfunction (LVEF < 35%)
2. High-risk treadmill score (score ≤ -11)
3. Severe exercise left ventricular dysfunction (exercise LVEF < 35%)
4. Stress-induced large perfusion defect (particularly if anterior)
5. Stress-induced multiple perfusion defects of moderate size
6. Large, fixed perfusion defect with LV dilatation or increased lung uptake (thallium-201)
7. Stress-induced moderate perfusion defect with LV dilatation or increased lung uptake (thallium-201)
8. Echocardiographic wall motion abnormality (involving greater than two segments) developing at low dose of dobutamine (≤10 mg/kg/min) or at a low heart rate (<120 beats/min)
9. Stress echocardiographic evidence of extensive ischemia

Intermediate risk (1% < 3% annual mortality rate)

1. Mild/moderate resting left ventricular dysfunction (LVEF = 35%-49%)
2. Intermediate-risk treadmill score* (-11 < score < 5)
3. Stress-induced moderate perfusion defect without LV dilatation or increased lung intake (thallium-201)
4. Limited stress echocardiographic ischemia with a wall motion abnormality only at higher doses of dobutamine involving less than or equal to two segments

Low risk (less than 1% annual mortality rate)

1. Low-risk treadmill score (score ≥ 5)
2. Normal or small myocardial perfusion defect at rest or with stress
3. Normal stress echocardiographic wall motion or no change of limited resting wall motion abnormalities during stress

*Duke treadmill score; see text.

SOURCE: From Gibbons et al.[1]

Table 40-9: Recommendations for Coronary Angiography for Risk Stratification in Patients With Chronic Stable Angina

Class I

1. Patients with disabling [Canadian Cardiovascular Society (CCS) classes III and IV] chronic stable angina despite medical therapy
2. Patients with high-risk criteria on noninvasive testing regardless of anginal severity
3. Patients with angina who have survived sudden cardiac death or serious ventricular arrhythmia
4. Patients with angina and symptoms and signs of congestive heart failure
5. Patients with clinical characteristics that indicate a high likelihood of severe CAD

Class IIa

1. Patients with significant LV dysfunction (ejection fraction < 45%), CCS class I or II angina, and demonstrable ischemia but less than high-risk criteria on noninvasive testing
2. Patients with inadequate prognostic information after noninvasive testing

Class IIb

1. Patients with disabling CCS class I or II angina, preserved LV function (ejection fraction > 45%), and less than high-risk criteria on noninvasive testing

Class III

1. Patients with disabling CCS classes I or II angina who respond to medical therapy and have no evidence of ischemia on noninvasive testing
2. Patients who prefer to avoid revascularization

NOTE: See classes I-III as described at bottom of Table 40-5.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

TREATMENT OF CHRONIC STABLE ANGINA

There are two major purposes in the treatment of stable angina. The first is to prevent MI and death and thereby *increase the quantity of life*. The second is to reduce symptoms of angina and the frequency and severity of ischemia, which should *improve the quality of life*. Therapy directed toward preventing death has the highest priority. The choice of therapy often depends on the clinical response to initial medical therapy, although some patients (and many physicians) prefer coronary revascularization in situations where either may be successful. It must be stressed that the pharmacologic treatment of chronic CAD has greatly improved and may even be superior to revascularization therapy for many patients.[120a] Patient education, cost-effectiveness, and patient preference are important components in this decision-making process.

Pharmacotherapy to Prevent MI

ANTIPLATELET AGENTS

Aspirin exerts an antithrombotic effect by inhibiting cyclooxygenase and synthesis of platelet thromboxane A_2. In the Physicians' Health Study, aspirin given on alternative days to asymptomatic individuals was associated with a decreased incidence of MI.[121] In the Swedish Angina Pectoris Aspirin Trial (SAPAT), in patients with stable angina, the addition of 75 mg aspirin to sotalol resulted in a 34 percent reduction in primary outcome events of MI and sudden death and a 32 percent decrease in secondary vascular events.[122]

Ticlopidine is a thienopyridine derivative that inhibits platelet aggregation induced by adenosine diphosphate and low concentrations of thrombin, collagen, thromboxane A_2, and platelet-activating factor.[123] It has *not* been shown to decrease adverse cardiovascular events and may induce neutropenia and often thrombotic thrombocytopenia purpura (TTP).

Clopidogrel, also a thienopyridine derivative, is chemically related to ticlopidine, but it appears to possess a greater antithrombotic effect than ticlopidine. In a randomized trial that compared clopidogrel with aspirin in patients with previous MIs, stroke, or peripheral vascular disease, clopidogrel was slightly more effective than aspirin in decreasing the combined risk of MI, vascular death, or ischemic stroke.[124] Aspirin, 75 to 325 mg per day, should be used routinely in all patients with acute and chronic ischemic heart disease with and without clinical symptoms in the absence of contraindications. In those unable to take aspirin, clopidogrel may be used instead. Warfarin is the third choice.

ANTITHROMBOTIC THERAPY

Disturbed fibrinolytic function after exercise appears to be associated with an increased risk of subsequent cardiovascular death in patients with chronic stable angina, providing the rationale for long-term antithrombotic therapy. In small placebo-controlled trials among patients with chronic stable angina, daily subcutaneous administration of low-molecular-weight heparin deceased the fibrinogen level and improved the exercise time to ST-segment depression.[125] The clinical experience of such therapy, however, is extremely limited. The efficacy of newer antiplatelet and antithrombotic agents such as glycoprotein IIIb/IIa inhibitors and recombinant hirudin in the management of patients with chronic stable angina has not been established. Low-intensity oral anticoagulation with warfarin decreased the risk of ischemic events in a randomized trial of patients with risk factors for atherosclerosis but without symptoms of angina.[126]

LIPID-LOWERING AGENTS

Recent clinical studies have conveniently demonstrated that low-density lipoprotein (LDL)-lowering agents can decrease the risk of adverse ischemic events in patients with established CAD (see Chap. 38). In the Scandinavian Simvastatin Survival Study (4S),[127] treatment with an HMG-CoA reductase inhibitor in patients with documented CAD (including stable angina) and a baseline total cholesterol concentration between 212 and 308 mg/dL was associated with 30 to 35 percent reduction in both mortality rate and major coronary events. In the Cholesterol And Recurrent Events (CARE) study,[128] in men and women with previous MI and total cholesterol levels of less than 240 mg/dL and LDL-cholesterol levels of 115 to 174 mg/dL, treatment with a HMG-CoA reductase inhibitor (statin) was associated with a 24 percent reduction in risk for nonfatal MI. Thus lipid-lowering therapy should be recommended even in the presence of mild to moderate elevations of LDL-cholesterol in patients with chronic stable angina. Ongoing studies[128a,128b] suggest that a reduction of LDL-cholesterol below 100 mg/dL will further reduce cardiac events (see Chap. 38).

Antianginal and Anti-ischemic Therapy

Antianginal and anti-ischemic drug therapy consists of beta-adrenoreceptor blocking agents (beta blockers), calcium antagonists, and nitrates. Drug interactions are described in Chap. 81. There is a tendency for physicians to give *lower doses* of antianginal medications than those proven to be effective in clinical trials and after higher doses or combined therapy are neglected in patients who could be "angina-free," if treated more appropriately; this is particularly true with beta-blocker therapy. For example, the usual dose for angina is 50 to 200 mg of metoprolol twice daily.

BETA BLOCKERS

The decrease in heart rate, contractility, arterial pressure, and usually LV wall stress with beta blockers is associated with decreased M_{O_2}. A reduction in heart rate also increases diastolic coronary artery perfusion time, which may enhance LV perfusion. Although beta blockers have the potential to increase coronary vascular resistance by the formation of cyclic AMP, the clinical relevance of this pharmacodynamic effect remains to be demonstrated.

All beta blockers without intrinsic sympathetic activity appear to be equally effective in angina pectoris. In patients with chronic stable exertional angina, these agents decrease the heart rate-blood pressure product during exercise, and the onset of angina or the ischemic threshold during exercise is delayed or avoided.[1] When treating stable angina, it is essential that the dose of beta blockers be adjusted to lower the resting heart rate to 55 to 60 beats per minute. In patients with more severe angina, the heart rate can be reduced to less than 50 beats per minute if there are no symptoms associated with bradycardia and AV block does not develop (see Chap. 81). In patients with exertional angina, beta blockers attenuate the increase in heart rate during exercise, which ideally should not exceed 75 percent of the heart rate response associated with the onset of ischemia. It is often useful for the patient to perform exercise (sit-ups, running in place) before and after the institution of beta-blocker therapy. If the heart rate increase with exercise is not significantly reduced by therapy, the dose of the beta blocker is inadequate. Beta blockers are definitely effective in reducing exercise-induced angina. Three controlled studies comparing beta blockers with calcium antagonists[129-132] report equal efficacy in the treatment of chronic stable angina.

In patients with postinfarction stable angina and those who require antianginal therapy after revascularization, treatment with beta blockers appears to be effective in controlling symptomatic and asymptomatic ischemic episodes. Beta blockers are still the anti-ischemic drugs of choice in elderly patients with stable angina.[1]

Beta blockers frequently are combined with nitrates for treating chronic stable angina. This combination of therapy appeared to be more effective in several studies than nitrates or beta blockers alone.[133-135] Beta blockers also may be combined with calcium antagonists. For combination therapy, slow-released dihydropyridine derivatives or new-generation long-acting dihydropyridine derivatives are the calcium antagonists of choice.[1]

In the International Multicenter Angina Exercise (IMAGE) study,[132] both metoprolol and nifedipine were effective as monotherapy in increasing exercise time, although metoprolol was more effective than nifedipine. The combination therapy also increased the exercise time to ischemia compared with either drug alone. The absolute contraindications to the use of beta blockers are severe bradycardia, preexisting high-degree AV block, sick sinus syndrome, and severe, unstable LV failure (see Chap. 81). Asthma and bronchospastic disease, severe depression, and peripheral vascular disease are relative contraindications (see Chap. 81). Fatigue, inability to perform exercise, lethargy, insomnia, nightmares, worsening claudication, and impotence are frequently experienced side effects. Most patients with chronic CAD and diabetes can be treated with beta blockers (see Chap. 78).

CALCIUM ANTAGONISTS

These agents, also considered in Chap. 81, reduce the transmembrane flux of calcium by the calcium channels. There are three types of voltage-dependent calcium channels: L type, T type, and N type.

All calcium antagonists exert a negative inotropic effect, depending on dosage. In smooth muscle, calcium ions also regulate the contractile mechanism, and calcium antagonists reduce smooth muscle tension in the peripheral vascular bed, thus causing vasodilation. All the calcium antagonists cause dilatation of the epicardial conduit vessels and the arterial resistance vessels, the former being the primary mechanism for the beneficial effect of calcium antagonists for relieving vasospastic angina. Calcium antagonists also decrease M_{O_2} demand primarily by reducing the systemic vascular resistance and arterial pressure. The negative inotropic effect of calcium antagonists also decreases the M_{O_2}.

Randomized clinical trials comparing calcium antagonists and beta blockers have demonstrated that calcium antagonists are equally effective as beta blockers in relieving angina and improving exercise time to onset of angina or ischemia.[1] The calcium antagonists are effective in reducing the incidence of angina in patients with vasospastic angina.[136,137]

In a *retrospective case-controlled study* reported in patients with hypertension, treatment with immediate-acting nifedipine, diltiazem, and verapamil was associated with an increased risk of MI of 31 to 61 percent.[138] Although a subsequent meta-analysis of immediate-release and short-acting nifedipine in patients with MI and unstable angina reported a dose-related influence on excess mortality,[139] further analysis of the published reports failed to confirm an increased risk of adverse cardiac events with calcium antagonists.[140,141] Importantly, long-acting calcium antagonists, including slow-release and long-acting dihydropyridine and nondihydropyridine derivatives, are effective in relieving symptoms in patients with chronic stable angina. They should be used in combination with beta blockers when initial treatment with beta blockers is not successful or as a substitute for beta blockers when initial treatment leads to unacceptable side effects. Many patients with two- or three-vessel CAD are asymptomatic on combined beta blocker and calcium antagonist therapy. Some have further improvement on triple therapy (combined beta blocker, calcium antagonist, and long-acting nitrates). Further information concerning the potential side effects of the calcium antagonists is given elsewhere (see Chap. 81).

NITROGLYCERIN AND NITRATES

Nitrates are endothelium-independent vasodilators that produce beneficial effects by both reducing the M_{O_2} and improving CBF perfusion. The decreased M_{O_2} results from the reduction of LV volume and arterial pressure primarily due to reduced preload. Nitroglycerin also exerts antithrombotic and antiplatelet effects in patients with stable angina.[1]

Nitrates dilate large epicardial arteries and collateral vessels. The vasodilating effect on epicardial coronary arteries with or without atherosclerotic CAD is beneficial in relieving coronary vasospasm in patients with vasospastic angina.

In patients with exertional stable angina, nitrates improve exercise tolerance, time to onset of angina, and time to ST-segment depression during treadmill exercise testing. In combination with beta blockers or

calcium antagonists, nitrates produce greater antianginal and anti-ischemic effects in patients with stable angina.[142-145]

The interaction between nitrates and sildenafil (Viagra) is discussed in detail elsewhere.[146] The coadministration of nitrates and sildenafil significantly increases the risk of potentially life-threatening hypotension (see Chap. 81).

The major problem with long-term use of nitroglycerin and long-acting nitrates is development of nitrate tolerance.[147] Tolerance develops not only to antianginal and hemodynamic effects but also to platelet antiaggregatory effects.[148] The mechanism for development of nitrate tolerance remains unclear. For practical purposes, the administration or nitrates with an adequate nitrate-free interval (8-12 h) appears to be the most effective method of preventing nitrate tolerance. Unfortunately, this means that patients with unpredictable episodes of myocardial ischemia should not be treated with nitrate therapy alone because for part of each 24 h they will be "unprotected."

The primary consideration in the choice of pharmacologic agents for treatment of angina should be to *improve prognosis*. Aspirin and lipid-lowering therapies have been shown to reduce the risk of death and nonfatal myocardial infarction in both primary and secondary prevention trials. Beta blockers also reduce cardiac events when used as secondary prevention in postinfarction patients and reduce mortality and morbidity among patients with hypertension. Nitrates have not been shown to reduce mortality with acute infarction or in patients with chronic CAD.

Recommended drug therapy using calcium antagonists versus beta blockers in patients with angina-associated conditions are listed in Table 40-10.

Table 40-10: Recommended Drug Therapy (Calcium Antagonist versus Beta Blocker) in Patients with Angina and Associated Conditions

Condition	Recommended Treatment and Alternative	Avoid
Medical conditions		
Systemic hypertension	Beta blockers (calcium antagonists)	
Migraine or vascular headaches	Beta blockers (verapamil or diltiazem)	
Asthma or chronic obstructive pulmonary disease with bronchospasm	Verapamil or diltiazem	Beta blockers
Hyperthyroidism	Beta blockers	
Raynaud's syndrome	Long-acting slow-release calcium antagonists	Beta blockers
Insulin-dependent diabetes mellitus	Beta blockers (particularly if prior myocardial infarction) or long-acting slow-release calcium antagonists	
Non-insulin-dependent diabetes mellitus	Beta blockers or long-acting slow-release calcium antagonists	
Depression	Long-acting slow-release calcium antagonists	Beta blockers

Mild peripheral vascular disease	Beta blockers or calcium antagonists	
Severe peripheral vascular disease with rest ischemia	Calcium antagonists	Beta blockers
Cardiac arrhythmias and conduction abnormalities		
Sinus bradycardia	Long-acting slow-release calcium antagonists that do not decrease heart rate	Beta blockers, diltiazem, verapamil
Sinus tachycardia (not due to heart failure)	Beta blockers	
Supraventricular tachycardia	Verapamil, diltiazem, or beta blockers	
Atrioventricular block	Long-acting slow-release calcium antagonists that do not slow AV conduction	Beta blockers, verapamil, diltiazem
Rapid artrial fibrillation (with digitalis)	Verapamil, diltiazem, or beta blockers	
Ventricular arrhythmias	Beta blockers	
Left ventricular dysfunction		
Congestive heart failure		
Mild (LVEF ≥ 40%)	Beta blockers	
Moderate to Severe (LVEF < 40%)	Amlodipine or felodipine (nitrates)	Verapamil, diltiazem
Left-sided valvular heart disease		
Mild aortic stenosis	Beta blockers	
Aortic insufficiency	Long-acting slow-release dihydropyridines	
Mitral regurgitation	Long-acting slow-release dihydropyridines	
Mitral stenosis	Beta blockers	
Hypertrophic cardiomyopathy	Beta blockers, nondihydropyridine calcium antagonist	Nitrates, dihydropyridine, calcium antagonists

SOURCE: From Gibbons et al.[1]

Treatment of Risk Factors

The recommendations of the AHA for the treatment of risk factors are detailed in Chap. 38. *The risk factors to which interventions have been shown to reduce the incidence of CAD events include* (1) cigarette smoking, (2) LDL-cholesterol, (3) systemic hypertension, (4) LV hypertrophy, and (5) thrombogenic

factors (see Chap. 38).

The causal role of *LDL-cholesterol* in the pathogenesis of atherosclerotic CAD has been enhanced by recent randomized, controlled clinical trials of lipid-lowering therapy. Several primary and secondary prevention trials have shown that LDL-cholesterol lowering is associated with a reduced risk of CAD (see Chap. 38). Angiographic trials provide firm evidence linking cholesterol reduction to favorable trends in coronary anatomy.

Data from numerous observational studies indicate a continuous and graded relation between blood pressure and cardiovascular disease risk.[149,150] Hypertension predisposes patients to coronary events both as a result of the direct vascular injury caused by increases in blood pressure and by its effects on the myocardium, including increased wall stress and M_{O_2}.

CAD, diabetes, LV hypertrophy, heart failure, retinopathy, and nephropathy are indicators of increased cardiovascular disease risk in hypertensive patients. The target of therapy is a reduction in blood pressure to less than 130 mmHg systolic and less than 85 mmHg diastolic in patients with CAD and coexisting diabetes, heart failure, or renal failure.[149]

Treatment of *hypertension* begins with nonpharmacologic means. When lifestyle modifications and dietary alterations adequately reduce blood pressure, pharmacologic intervention may be unnecessary (see Chaps. 38 and 51).

When pharmacologic treatment is necessary (usually the case), beta blockers or calcium antagonists may be especially useful in patients with hypertension and angina pectoris; however, short-acting calcium antagonists should not be used.[151]

Epidemiologic studies have implicated *LV hypertrophy* as a risk factor for development of MI, congestive heart failure, and sudden death.[152] LV hypertrophy also has been shown to predict a poorer prognosis in patients with definite CAD.[153] In the Framingham Heart Study,[154] the subjects who demonstrated ECG evidence of LV hypertrophy regression on follow-up were at a substantially reduced risk for cardiovascular events.

Coronary artery thrombosis is a trigger of acute MI. Aspirin has been documented to reduce the risk for CHD in both primary and secondary prevention settings.[1] Elevated plasma fibrinogen levels predict CAD risk in prospective observational studies[155] (see Chap. 38).

Risk factors for which interventions are likely to reduce the incidence of coronary disease events include diabetes mellitus, high-density lipoprotein (HDL)-cholesterol, obesity, physical inactivity, and postmenopausal status (see Chap. 38).

Diabetes mellitus, which is defined as a fasting blood sugar level of more than 126 mg/dL,[156] is present in a significant minority of adult Americans. Data supporting an important role of diabetes mellitus as a risk factor for cardiovascular disease comes from a number of observational settings. This is true for both type I and type II diabetes. Atherosclerosis accounts for 80 percent of all diabetic mortality,[157,158] with CAD alone responsible for 75 percent of total atherosclerotic deaths (see Chaps. 38 and 78). The goal is to maintain a blood glucose HbA_1c level of less than 7 percent and a blood glucose level of less than 140 mg/dL. In diabetic patients with hypertension, microalbuminuria, or decreased LV systolic function, angiotensin converting enzyme (ACE) inhibitors appear indicated. This may apply to most diabetics with CAD.[158a]

Observational studies and clinical trials have demonstrated a strong inverse association between *HDL-cholesterol* and CAD risk (see Chap. 38). This inverse relation is observed in both men and women and among asymptomatic persons as well as patients with established CAD.[1] The National Cholesterol Adult Treatment Panel II has defined a low HDL-cholesterol level as less than 35 mg/dL.[159]

Obesity is a common condition associated with increased risk for CHD and mortality (see Chap. 38). New AHA guidelines for weight control have been published recently.[160]

Multiple randomized, controlled trials comparing exercise training with a "no exercise" control group have demonstrated a statistically significant improvement in exercise tolerance for the exercise group versus the control group.[1] The threshold for ischemia is likely to increase with exercise training because training reduces the heart rate-blood pressure product at a given submaximal exercise workload[1] (see Chap. 38).

When hormone production decreases in the perimenopausal period over several years, the risk of CAD rises in postmenopausal women. By age 75, the risk of atherosclerotic cardiovascular disease among men and women is equal.[1] The first published randomized trial of estrogen plus progestin therapy in postmenopausal women with known CAD did not show any reduction in cardiovascular events over 4 years of follow-up[161] despite an 11 percent lower LDL-cholesterol level and a 10 percent higher HDL-cholesterol level in those women receiving hormone replacement. Other randomized trials of hormone-replacement therapy in primary and secondary prevention of CAD in postmenopausal women are in progress.

Risk factors for which interventions may reduce the incidence of coronary disease events include psychosocial factors, triglycerides, lipoprotein (a), homocysteine, oxidative stress, and consumption of alcohol (see Chap. 38).

Triglyceride levels are predictive of CHD in a variety of observational studies and clinical settings.[162] However, much of the association of triglycerides with CHD risk is related to other factors, including diabetes, obesity, hypertension, high LDL-cholesterol, and low HDL-cholesterol[163] (see Chap. 38).

Lipoprotein(a) is a lipoprotein particle that has been linked to CHD risk in observational studies. Elevated lipoprotein(a) levels are largely genetically determined and found in 15 to 20 percent of patients with premature CHD.[164,165] Increased *homocysteine* levels are associated with increased risk of CAD, peripheral arterial disease, and carotid disease.[166,167] Elevated homocysteine levels can occur as a result of inborn errors of metabolism such as homocysteinuria, and homocysteine levels also can be increased by deficiencies of vitamin B_6, vitamin B_{12}, and folate, which commonly occur in older patients[167] (see Chap. 38).

Extensive laboratory data indicate that oxidation of LDL-cholesterol promotes and accelerates the atherosclerosis process.[168] Observational studies have documented an association between dietary intake of antioxidant vitamins (vitamin C, vitamin E, and β-carotene) and reduced risk for CHD[169] (see Chap. 38).

Observational studies have shown repeatedly an inverse relation of *moderate alcohol intake* to the risk of CHD events.[170] However, excessive alcohol intake can promote many other medical problems that outweigh its beneficial effects on CHD risk.

Risk factors associated with increased risk but that cannot be modified or when modified are unlikely to change the incidence of CHD events include age, male gender, and a positive family history of premature CHD. The latter is defined as definite MI or sudden death before age 55 in a father or other male first-degree relative or before age 65 in a mother or other female first-degree relative[1] (see Chap. 38).

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

MYOCARDIAL REVASCULARIZATION

There are currently two well-established revascularization approaches to treatment of chronic stable angina caused by coronary atherosclerosis. One is CABG surgery, in which segments of autologous arteries or veins are used to reroute blood around relatively stenotic segments of the proximal coronary artery. The other is percutaneous coronary interventions (PCIs) using catheter-borne or laser techniques to open usually short areas of stenoses from within the coronary artery. These techniques are described in greater detail in Chaps. 45 and 48. Revascularization is also potentially feasible with transthoracic (laser) myocardial revascularization in patients in whom neither CABG nor PCI is feasible (see Chap. 48). The recommendations of the ACC/AHA/ACP-ASIM for revascularization with PCIs or CABG in patients with stable angina are listed in Table 40-11.

Table 40-11: Revascularization for Chronic Stable Angina (Recommendations for Revascularization with PTCA or Other Catheter-Based Techniques and CABG in Patients with Stable Angina)

Class I

1. CABG for patients with significant left main coronary disease.
2. CABG for patients with three-vessel disease. The survival benefit is greater in patients with abnormal LV function (ejection fraction < 50%).
3. CABG for patients with two-vessel disease with significant proximal left anterior descending CAD and either abnormal LV function (ejection fraction < 50%) or demonstrable ischemia on noninvasive testing.
4. PCI for patients with two- or three-vessel disease with significant proximal left anterior descending CAD, who have anatomy suitable for catheter-based therapy, normal LV function and who do not have treated diabetes.
5. PCI or CABG for patients with one- or two-vessel disease CAD without significant proximal left anterior descending CAD, but with a large area of viable myocardium and high risk criteria on noninvasive testing.
6. CABG for patients with one- or two-vessel disease CAD without significant proximal left anterior descending CAD who have survived sudden cardiac death or sustained ventricular tachycardia.
7. In patients with prior PCI, CABG, or PCI for recurrent stenosis associated with a large area of viable myocardium or high-risk criteria on noninvasive testing.
8. PTCA or CABG for patients who have not been treated successfully by medical therapy and can undergo revascularization with acceptable risk.

Class IIa

1. Repeat CABG for patients with multiple saphenous vein graft stenoses, especially when there is significant stenosis of a graft supplying the LAD. It may be appropriate to use PTCA for focal saphenous vein graft lesions or multiple stenoses in poor candidates for reoperative surgery.
2. Use of PCI or CABG for patients with one- or two-vessel disease CAD without significant proximal LAD disease but with a moderate area of viable myocardium and demonstrable ischemia on noninvasive testing.
3. Use of PCI or CABG for patients with one-vessel disease with significant proximal LAD disease.

Class IIb

---

1. Compared with CABG, PCI for patients with two- or three-vessel disease with significant proximal left anterior descending CAD, who have anatomy suitable for catheter-based therapy, and who have treated diabetes or abnormal LV function.
2. Use of PCI for patients with significant left main coronary disease who are not candidates for CABG.
3. PCI for patients with one- or two-vessel disease CAD without significant proximal left anterior descending CAD, who have survived sudden cardiac death or sustained ventricular tachycardia.

Class III

---

1. Use of PCI or CABG for patients with one- or two-vessel CAD without significant proximal left anterior descending CAD, who have mild symptoms that are unlikely due to myocardial ischemia or who have not received an adequate trial of medical therapy and
    a. Have only a small area of viable myocardium or
    b. Have no demonstrable ischemia on noninvasive testing
2. Use of PCI or CABG for patients with borderline coronary stenoses (50% to 60% diameter in locations other than the left main coronary artery) and no demonstrable ischemia on noninvasive testing.
3. Use of PCI or CABG for patients with insignificant coronary stenosis (<50% diameter).
4. Use of PCI in patients with significant left main coronary disease who are candidates for CABG.

NOTE: PTCA is used in these recommendations to indicate PTCA or other catheter-based techniques, such as stents, atherectomy, and laser therapy. See classes I-III as described at the bottom of Table 40-5.

Patients with stable angina pectoris may be appropriate candidates for revascularization either by CABG surgery or PCIs. In general, this is an individual decision to be made by the patient with knowledge of the advantages or disadvantages either of medical therapy alone or revascularization with either CABG or PCIs.

There are two general indications for revascularization procedures: the presence of symptoms that are not acceptable to the patient either because of (1) restriction of physical activity and lifestyle as a result of limitations or side effects from medications or (2) the presence of findings that indicate clearly that the patient would have a better prognosis for revascularization than with medical therapy. Considerations regarding revascularization are based on an assessment of the grade or class of angina experienced by the patient, the presence and severity of myocardial ischemia on noninvasive testing, the degree of LV function, and the distribution and severity of coronary artery stenoses.

A recent meta-analysis of three major large multicenter randomized trials of initial surgery versus medical management (performed in the 1970s) as well as other smaller trials has confirmed the surgical benefits achieved by surgery at 10 postoperative years for patients with three-vessel disease, two-vessel disease, or even one-vessel disease that included a severe stenoses of the proximal left anterior descending coronary artery[119] (see Chap. 48).

The advantages of PCIs for the treatment of CAD include a low level of procedure-related morbidity, a low procedure-related mortality rate in properly selected patients, a short hospital stay, early return to activity, and the feasibility of multiple procedures. However, PCIs are not feasible in all patients; they are accompanied by a significant incidence of restenoses, and there is an occasional need for emergency CABG surgery (see Chap. 45).

Three randomized studies have compared PCIs with medical management alone for the treatment of chronic stable angina.[171-173] All these randomized studies of PCIs versus medical management have involved patients at a low risk of mortality even with medical management and did not assess patients with moderate to severe CAD (see Chap. 45). Multiple trials have compared the strategy of an initial PCI with initial CABG surgery for treatment of multivessel CAD (see Chaps. 45 and 48). The results of all these trials have shown that early and late survival rates have been equivalent for the PCI and CABG surgery groups. In the Bypass Angioplasty Revascularization Intervention (BARI) trial, the subgroups of patients with treated diabetics had a significantly better survival rate with CABG surgery.[174] This was true, however, on post hoc analysis of the clinical variables, including diabetes, which was not a prerandomization blocking variable.

The randomized studies of invasive therapy for chronic angina have all excluded patients who developed recurrent angina after previous CABG surgery. Few existing data define outcomes for risk-stratified groups of patients who develop recurrent angina after bypass surgery. Those which do indicate that patients with ischemia produced by late atherosclerotic stenoses in vein grafts are at a higher risk with medical management alone than those with ischemia produced by native-vessel disease.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

FOLLOW-UP OF PATIENTS WITH CHRONIC STABLE ANGINA

Published evidence of the efficacy of specific strategies for the follow-up of patients with chronic stable angina on patient outcome are nonexistent. The ACC/AHA/ACP-ASIM guidelines[1] for monitoring of symptoms and antianginal therapy during patient follow-up are as follows:

For the patient with successfully treated chronic stable angina, a follow-up evaluation every 4 to 12 months is appropriate. During the first year of therapy, evaluations every 4 to 6 months are recommended. After the first year of therapy, annual evaluations are recommended if the patient is stable and reliable enough to return for evaluation when anginal symptoms become worse or other symptoms occur.[1] At the time of follow-up, a general assessment of the patient's functional and health status and quality of life may reveal additional issues that affect angina. Symptoms that have worsened should follow reevaluation as outlined above. A detailed history of the patient's daily activity is critical because angina symptoms may remain stable only because stressful activities have been eliminated.

A careful history of the characteristics of the patient's angina including provoking and alleviating factors must be repeated at each visit. Detailed questions should be asked about common drug side effects. The patient's adherence to the treatment program must be assessed.

The physical examination should be determined by the patient's history. Every patient should have weight, blood pressure, and pulse noted. The jugular venous pressure, carotid pulse magnitude and upstroke, and presence or absence of carotid bruits should be noted. Pulmonary examination with special attention to rales, rhonchi, wheezing, and decreased breath sounds is required. A cardiac examination should note the presence of fourth and third heart sounds, a new or changed systolic murmur, the location of the LV impulse, and any change from previous examinations. Clearly, the vascular examination should identify any change in peripheral pulses and new bruits; the abdominal examination should identify hepatomegaly and the presence of any pulsatile mass suggesting abdominal aortic aneurysm. The presence of new or worsening peripheral edema should be noted.

The American Diabetes Association recommends that patients not known to have diabetes should have a *fasting blood glucose* measured every 3 years and an annual measurement of glycosylated hemoglobin for individuals with established diabetes. Fasting blood work 6 to 8 weeks after initiating lipid-lowering drug therapy should include liver function testing and assessment of the cholesterol profile. This should be repeated every 8 to 12 weeks during the first year of therapy and at 4- to 6-month intervals thereafter.

An ECG should be repeated when medications affecting cardiac conduction are initiated or changed. A repeat ECG is indicated for a change in the anginal pattern, symptoms or finding suggestive of an arrhythmia or conduction abnormality, and near or frank syncope. There is no clear evidence showing that routine, periodic ECGs are useful in the absence of a change in history or physical examination.

In the absence of a change in clinical status, low-risk patients with an estimated annual mortality rate of less than 1 percent over each year of the interval do not require repeat stress testing for 3 years after the initial evaluation.[1] These include those with low-risk Duke treadmill scores either without imaging or with negative imaging, those with normal LV function and normal coronary angiograms, and those with normal LV function and insignificant CAD. *Annual follow-up for noninvasive testing in the absence of a change in symptoms* has not been studied adequately; it may be useful in high-risk patients with an estimated annual mortality rate of greater than 5 percent. Follow-up testing should be performed in a stable high-risk patient only if the initial decision not to proceed with revascularization may change if the patient's estimated risk worsens. Patients with an immediate-risk (>1 and <3 percent) annual mortality rate are more problematic because of limited data. They may need testing at an interval of 1 to 3 years depending on the individual

circumstances. The ACC/AHA/ACP-ASIM recommendations for echocardiography, treadmill exercise testing, stress imaging studies and coronary angiography during patient follow-up are also listed in Table 40-12.

Table 40-12: Recommendations for Echocardiography, Treadmill Exercise Testing, Stress Imaging Studies, and Coronary Angiography during Patient Follow-Up

Class I

1. Chest x-ray for patients with evidence of new or worsening congestive heart failure.
2. Assessment of LV ejection fraction and segmental wall motion in patients with new or worsening congestive heart failure or evidence of intervening MI by history or ECG.
3. Echocardiography for evidence of new or worsening valvular heart disease.
4. Treadmill exercise test for patients without prior revascularization who have a significant change in clinical status, are able to exercise, and do not have any of the ECG abnormalities listed below in number 5.
5. Stress imaging procedures for patients without prior revascularization who have a significant change in clinical status and are unable to exercise or have one of the following ECG abnormalities:
    a. Preexcitation (Wolff-Parkinson-White) syndrome.
    b. Electronically paced ventricular rhythm.
    c. More than 1 mm of rest ST-segment depression.
    d. Complete left bundle-branch block.
6. Stress imaging procedures for patients who have a significant change in clinical status and required a stress imaging procedure on their initial evaluation because of equivocal or intermediate-risk treadmill results.
7. Stress imaging procedures for patients with prior revascularization who have a significant change in clinical status.
8. Coronary angiography in patients with marked limitation of ordinary activity. (CCS class III despite maximal medical therapy).

Class IIb

Annual treadmill exercise testing in patients who have no change to clinical status, can exercise, have none of the ECG abnormalities listed in number 5 above, and have an estimated annual mortality of >1%.

Class III

1. Echocardiography or radionuclide imaging for assessment of LV ejection fraction and segmental wall motion in patients with a normal ECG, no history of MI, and no evidence of congestive heart failure.
2. Repeat treadmill exercise testing in <3 years in patients who have no change in clinical status and an estimated annual mortality ≤1% on their initial evaluation as demonstrated by one of the following:
    a. Low-risk Duke treadmill score (without imaging).
    b. Low-risk Duke treadmill score with negative imaging.
    c. Normal LV function and a normal coronary angiogram.
    d. Normal LV function and insignificant CAD.
3. Stress imaging procedures for patients who have no change in clinical status and a normal rest ECG, are not taking digoxin, are able to exercise, and did not require a stress imaging procedure on their initial evaluation because of equivocal or intermediate-risk treadmill results.
4. Repeat coronary angiography in patients with no change in clinical status, no change on repeat exercise testing or stress imaging, and insignificant CAD on initial evaluation.

NOTE: See classes I-III as described at the bottom of Table 40-5.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

MANAGEMENT OF SPECIAL CATEGORIES

Systemic Arterial Hypertension

Patients with systemic arterial hypertension (SAH) often have angina pectoris. In most patients, significant coronary atherosclerosis of the epicardial blood vessels is present, but some patients with SAH may have angina pectoris or even fatal MI without significant obstruction of the large epicardial vessels. A major mistake is to send a patient for noninvasive testing when his or her hypertension has not been treated. In some patients there may be a marked increase in M_{O_2} that exceeds the CBF reserve, whereas others may have microvascular angina (syndrome X).

In many patients, treatment of the hypertension with a beta blocker, calcium antagonist, or angiotension-converting enzyme inhibitor also will decrease M_{O_2} and prevent the development of angina pectoris. In general, efforts should be made to control the blood pressure both at rest and during exercise. It is now know that many patients with an elevated systolic and/or diastolic blood pressure above the normal variation during exercise will develop severe fixed SAH. Efforts should be made to control the blood pressure both at rest and during exertion.

Chronic Obstructive Pulmonary Disease/Asthma

Beta blockers should be avoided in the subset of patients who have true bronchospastic lung disease, and the use of nitrates and calcium antagonists is preferred. Since many of these patients receive medications for their pulmonary disease that may increase their heart rate or even produce supraventricular tachycardia, it is preferable to use a heart rate-slowing calcium antagonist such as diltiazem or verapamil. Many patients with a history of only asthma or mild chronic obstructive pulmonary disease may be able to tolerate small doses of cardioselective beta blockers with careful monitoring.

Elderly Patients

In general, elderly patients tolerate calcium antagonists better than beta blockers. The presence of sinus tachycardia or atrial fibrillation is a relative contraindication to the selection of dihydropyridines such as nifedipine or amlodipine. In such patients, diltiazem or verapamil or even a beta blocker is preferable. On the other hand, beta blockers, verapamil, and diltiazem can exacerbate AV block, and verapamil produces constipation in many elderly patients. Also, some elderly patients develop postural hypotension from short-acting nitrates.

Peripheral Vascular Disease

Patients with peripheral vascular disease may have a worsening of their symptoms when treated with a nonselective beta blocker, permitting unopposed alpha-induced vasoconstriction. Alternatively, the worsening symptoms may be due to a decrease in arterial perfusion pressure. In general, it is preferable to treat patients with chronic stable angina who have peripheral vascular disease with nitrates and a calcium antagonist.

Diabetes Mellitus

Patients with chronic stable angina who have diabetes mellitus and hypoglycemic episodes due to insulin probably should be treated with nitrates and calcium antagonists (see Chap. 78). If it is necessary to use a beta blocker, a cardioselective agent should be chosen, since it is less likely to impair the recognition of and recovery from insulin-induced hypoglycemia. In most diabetics, cardioselective beta blockers are well tolerated. The BARI-II Diabetes Study is evaluating the efficacy at *early* myocardial revascularization in diabetes with CAD.

Chronic Renal Disease

While beta blockers and calcium antagonists normally can be used effectively in patients with chronic angina and chronic renal insufficiency, careful monitoring may be necessary because many beta blockers and calcium antagonists (see Chap. 84) are excreted primarily by the kidneys.

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

CHRONIC MANIFESTATIONS OF CHRONIC ISCHEMIC HEART DISEASE

Heart Failure

Patients with severe CAD that produces a loss of 20 percent or more of the myocardium or that results in a ventricular septal defect or significant mitral regurgitation may cause important LV failure. While there may be significant hypertrophy of the remaining myocytes and interstitium (see Chap. 20), the ventricle is unable to compensate completely, and heart failure often results with a decreased stroke volume and elevated diastolic filling pressures. A syndrome of heart failure may result that is clinically predominant and often more incapacitating than any symptom of angina pectoris (see Chap. 66).

Patients with severe LV dysfunction due to CAD have a poor prognosis. Usually it reflects permanent, irreversible loss of myocytes. In some patients severe chronic CAD is associated with persistently impaired LV function at rest due to reduced CBF that can be partially or completely restored to normal either by improving blood flow (more common) or by reducing oxygen demand. This concept of "hibernating" myocardium is important because there can be significant improvement following good LV revascularization. While this does not occur routinely, it must be considered before concluding that the LVEF of an individual patient is too low to consider revascularization surgery or that the etiology of the heart failure is not CHD. MPI imaging techniques, magnetic resonance imaging (MRI), dobutamine echocardiography, and positron-emission tomography (PET) are useful in detecting myocardial viability (see Chap. 19).

The treatment of patients with heart failure due to CHD is the same as for most patients with combined systolic and diastolic LV failure and includes diuretics, an ACE inhibitor, digitalis, beta blockers, and spironolactone (see Chap. 28).

Cardiac transplantation is also frequently performed for severe heart failure due to CAD (see Chap. 22). A patient with heart failure who has a large LV aneurysm may benefit from aneurysmectomy if there is sufficient remaining functioning LV tissue. Similarly, heart failure due to severe mitral regurgitation sometimes can be improved significantly by corrective mitral valve surgery, which is often combined with myocardial revascularization. The operative mortality for this procedure can be high; in patients with severe functional mitral regurgitation, mitral valve repair with a reduced annular size can improve patient symptoms considerably (see Chap. 48).

Cardiac Arrhythmias, Conduction Disturbances

Chronic ischemic heart diseases causes many cardiac arrhythmias. The basic management is discussed in Chap. 24. In general, beta blockers should be employed whenever there is no strong contraindication, and type IC antiarrhythmic agents should be avoided unless the patient is symptomatic. In patients with atrial fibrillation, the ventricular response rate should be controlled with digoxin.

Patients with chronic atrial fibrillation also should be maintained on warfarin (INR = 2-3) unless

there is a contraindication, in which case aspirin (80-325 mg/day) should be used. Patients in heart failure who have atrial fibrillation may benefit from an effective atrial contraction restored by electrical cardioversion. Unfortunately, large percentages revert to atrial fibrillation in the next few months. Nonetheless, cardioversion sometimes can improve overall function significantly even though for a short time. Patients with recurrent symptomatic ventricular tachycardia or ventricular fibrillation can be treated with an implantable cardioverter-defibrillator. The use of these devices is discussed in Chap. 29.

Embolic Disease

Patients with ischemic disease are likely to have systemic emboli, particularly patients with a history of systemic embolus, chronic atrial fibrillation, ventricular aneurysm, a large dyskinetic or hypokinetic area of myocardium, or a severely depressed LVEF. Such patients should be considered for chronic, long-term, low-dose warfarin therapy (INR = 2-3).

Chapter 40: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH CHRONIC ISCHEMIC HEART DISEASE

CHEST PAIN WITH NORMAL CORONARY ARTERIES

The combination of chest pain with many of the features of angina pectoris, although frequently atypical, and normal epicardial coronary arteries at cardiac catheterization has been known since the entity was first described in the 1960s. The early studies identified many of the features of what was subsequently characterized as a syndrome: female predominance, the frequent presence of ischemic ST-segment changes on the exercise ECG, inconsistent relationship between ECG changes and metabolic or hemodynamic evidence of ischemia, and pain that could be very severe, prolonged, variable in location, precipitated by unusual events, and unresponsive to usual antiischemic therapy.

The term *syndrome X* was applied to this diagnostic combination in 1973[175]; it is usually used to describe patients with the common features of angina-like pain and normal epicardial coronaries, but the term is also used to categorize groups that undoubtedly are pathophysiologically heterogeneous.[176-178] The continued use of this term is unfortunate and has been discouraged,[179] especially since there is a *metabolic syndrome X*, characterized by insulin resistance, hyperinsulinemia, and diabetes, that is associated with abnormal lipids, hypertension, and abdominal obesity[179] (see Chap. 78). A more specific term such as *angina with normal coronary arteriography* is preferable.

Part 6: CORONARY HEART DISEASE
Chapter 41:

DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

Author: David D. Waters

Unstable angina is an acute coronary syndrome that does not involve myocardial necrosis. It is characterized clinically by new-onset or worsening angina. The usual underlying pathophysiologic mechanism involves the rupture or erosion of an atherosclerotic plaque with thrombus formation that severely obstructs the coronary artery lumen. In 1996, 1,367,000 patients were hospitalized with this diagnosis in the United States.[1]

Important advances in the management of unstable angina have occurred in the last decade. Serum markers such as C-reactive protein and the troponins facilitate more accurate risk stratification. New therapies, specifically low-molecular-weight heparins and platelet glycoprotein (GP) IIb/IIIa receptor antagonists, have improved outcomes in high-risk patients. The introduction of coronary stents has reduced the incidence of acute vessel closure and restenosis. The exact indications for these newer therapies have not been defined completely across different strata of risk in patients with unstable angina. Physicians therefore must continue to integrate the results of new trials into their practice and exercise finely tuned judgment in the management of these patients. Unstable angina and the closely related condition non-ST-segment elevation myocardial infarction (NSTEMI) are very common manifestations of coronary artery disease.[1]

DEFINITION AND CLASSIFICATION

The term *unstable angina* has superseded older labels such as *preinfarction angina, acute coronary insufficiency*, and *intermediate coronary syndrome*. Unstable angina can be defined conveniently as new-onset or worsening angina within the previous 60 days or postinfarction angina (after the first 24 h from the onset of infarction).

Several systems have been proposed for classifying unstable angina. Distinguishing *primary* from *secondary* unstable angina is of clinical value. Acute worsening of a coronary stenosis (as described below) causes primary unstable angina by limiting coronary blood flow. Secondary unstable angina arises as a consequence of increased myocardial oxygen demand superimposed on severe underlying coronary disease. The major determinants of myocardial oxygen demand are heart rate, inotropic state, and the loading conditions of the left ventricle, primarily afterload. Thus, conditions with the potential to provoke secondary unstable angina include tachyarrhythmia, fever, hypoxia, anemia, hypertensive crisis, and thyrotoxicosis. Secondary unstable angina should resolve after successful treatment of the precipitating condition. Various classifications have been proposed for primary unstable angina, based on the presenting symptoms.[2-4] In 1973, Gazes and associates[2] defined three subgroups: (1) initial onset of progressive, crescendo angina and pain at rest in a patient previously free from symptoms, (2) the same presentation occurring suddenly in a patient with previously stable angina, and (3) episodes of prolonged pain at rest, lasting more than 15 min, not related to obvious precipitating factors.

The classification proposed by Braunwald (Table 41-1) includes three levels of severity and three clinical circumstances, yielding nine categories in all.[4] The presence or absence of electrocardiographic (ECG) changes and the intensity of medical therapy also were considered. A

higher clinical category was more commonly associated with intracoronary thrombus and complex lesions in one study.[5] The components of the Braunwald classification have been shown to correlate with clinical outcomes. Specifically, a 48-h pain-free interval and the absence of ECG changes are associated with decreased risk, while postinfarction unstable angina and the need for maximal medical therapy carry a higher risk.[6,7] The Braunwald classification sometimes is used to categorize patients for research purposes, but no system is widely used in clinical practice. Braunwald has proposed a pictographic system to display the pathophysiologic components that contribute to unstable angina in a specific patient (Fig. 41-1).[8]

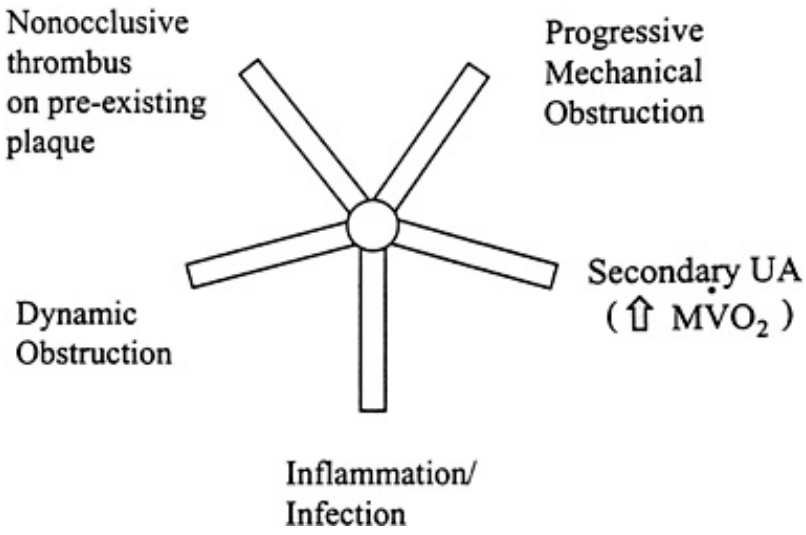

Figure 41-1: Framework for considering the pathophysiologic components that contribute to unstable angina in a specific patient. Varying contributions are possible from each of the five arms. Some patients will have predominantly one cause, while in others two or more mechanisms will contribute significantly. (From Braunwald,[8] with permission.)

The recognition of three specific forms of primary unstable angina is worthwhile because the pathophysiology, prognosis, and management of those forms are different. Variant, or Prinzmetal's, angina (discussed later in this chapter) is caused by coronary spasm and usually can be controlled with calcium channel blockers. Unstable angina within 6 months after coronary angioplasty almost invariably is caused by restenosis. Since the underlying mechanism is cellular proliferation instead of plaque rupture, antithrombotic drugs are not needed and intravenous nitroglycerin provides effective treatment.[9] Unstable angina in a patient with previous coronary bypass surgery often involves advanced atherosclerosis of venous bypass grafts and a lower likelihood of long-term symptomatic relief compared with other patients with unstable angina.[10,11] As is discussed below, patients with unstable angina should be classified according to their level of short-term risk. High-, intermediate-, and low-risk categories have been established on the basis of clinical and ECG data available at the time of the first assessment.[12]

Chapter 41: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

PATHOPHYSIOLOGY

Progression of coronary atherosclerotic plaque can be divided into five phases and different lesions (Fig. 41-2).[13] Disruption of a type IV or type VA lesion exposes the underlying thrombogenic substrate, leading to the formation of a thrombus. This acute type VI lesion can heal without producing symptoms. However, when the thrombus totally or subtotally occludes the lumen, an acute coronary syndrome may result. The factors that contribute to the development of an acute coronary syndrome (Table 41-2) also represent potential targets for therapy.

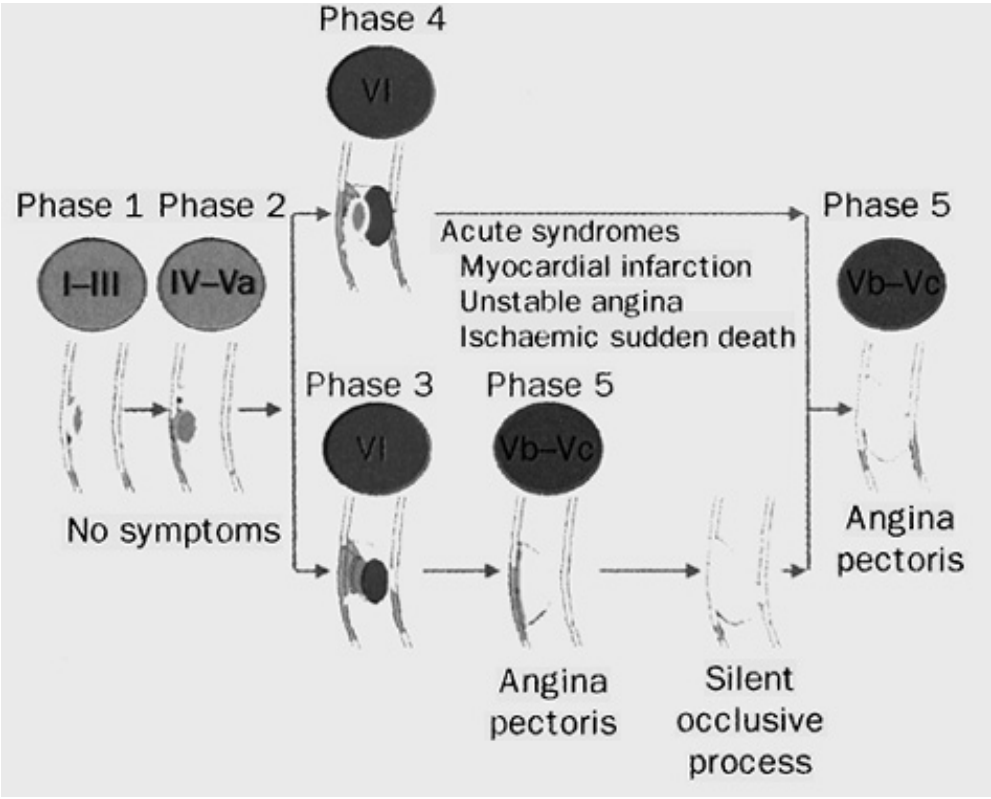

Figure 41-2: Phases of coronary lesion morphology and progression, with correlation to clinical syndromes. Unstable angina is caused by phase 2, type IV and type Va, lesions that are disrupted and progress to phases 3 and 4, type VI. (From Fuster et al.,[13] with permission.)

Table 41-2: Factors That Modulate the Development of Acute Coronary Syndromes

Coronary factors
Location of the culprit coronary lesion
Stenosis length, contour, and severity
Extent of plaque rupture or erosion
Inflammatory substrate
Endothelial function
Degree of coronary vasoconstriction
Extent of collaterals
Thrombotic factors
Platelet aggregability and reactivity
Leukocyte activation
Intrinsic clotting factors
Plaque tissue factor levels
Level of fibrinolytic activity
Blood viscosity
Systemic factors
Heart rate and blood pressure
Catecholamine levels (smoking, cocaine, stress)
Cholesterol levels, including Lp(a)

Plaque Disruption

The mechanisms involved in plaque disruption and the transformation of coronary atherosclerosis from a stable phase to an unstable phase have been studied intensively in recent years. Mechanical factors contribute to plaque disruption: A thin fibrous cap is more prone to rupture than is a thick one, and plaque rupture occurs commonly at the shoulders, where the plaque joins the adjacent vessel wall.[14] A lipid pool within a plaque influences the biomechanical properties of the plaque and increases the risk of rupture; conversely, fibrosis and calcification appear to decrease the risk of rupture.[14,15]

Plaque erosion, as well as plaque rupture, can initiate an acute coronary syndrome.[16] Erosion usually occurs centrally through a thinning cap as opposed to taking place at the plaque shoulders. Plaque erosion appears to be more common in women smokers, and plaque rupture in hyperlipidemic men.[17,18] In a study of women who died from sudden coronary death, plaque erosion was common in the premenopausal age group and plaque rupture was common in older women with hyperlipidemia.[18] Diabetes and hypertension were most common in women with healed infarcts. Macrophages and T cells invariably are found in close proximity to sites of plaque

rupture but are not prominent features of plaque erosion.

Inflammation

In addition to biomechanical factors, inflammation appears to play a key role in plaque disruption. Macrophages and T lymphocytes accumulate in atherosclerotic plaques because of the expression of adhesion molecules on monocytes, endothelial cells, and leukocytes.[19,20] Once within the plaque, these cells release growth and chemotactic factors and are involved in the local oxidation of low-density lipoprotein (LDL) cholesterol and other products. These processes stimulate smooth muscle cell proliferation and the production of foam cells.

T lymphocytes produce interferon-gamma (INF-gamma), a cytokine that markedly inhibits the production of collagen by smooth muscle cells in vulnerable regions of the plaque cap.[21] INF-gamma also inhibits the proliferation of smooth muscle cells. In addition to impaired synthesis of collagen, accelerated degradation of collagen and other components of the matrix contributes to weakening of the fibrous cap. The matrix metalloproteinases, a family of enzymes that includes collagenases and gelatinases, are released by foam cells and are able to degrade the collagen that provides strength to the fibrous cap.[21] Tissue inhibitors of metalloproteinases (TIMPs) normally are expressed by vascular smooth muscle cells; however, in the critical areas of the fibrous cap, foam cells predominate and smooth muscle cells are sparse. Under the influence of cytokines, smooth muscle cells produce a different form of gelatinase, with no increase in the production of TIMPs.

Elevated peripheral blood levels of specific matrix metalloproteinases have been reported in patients with acute coronary syndromes.[22] Furthermore, atherectomy specimens from patients with unstable angina, but not stable angina, exhibit active synthesis of a specific gelatinase.[23] Nuclear factor-κB (NF-κB) also has been found in the peripheral blood of patients with unstable angina but not stable angina.[24] NF-κB resides inactive in the cytoplasm of lymphocytes, monocytes, endothelial cells, and smooth muscle cells, where after stimulation it transcriptionally activates interleukins, interferon, tumor necrosis factor-alpha, and adhesion molecules. It is thus a specific marker of inflammation.

In a detailed study of 20 culprit lesions, macrophages and T lymphocytes were found to be clustered at the immediate site of plaque rupture.[25] These cells and nearby smooth muscle cells expressed high levels of the same human leukocyte antigen (HLA)-DR transplantation antigen, indicating both activation and "cross-talk" among the cells. Mast cells also have been found in culprit lesions of unstable angina patients but not stable angina patients.[26] These mast cells stained positively for TNF-alpha and were in proximity to macrophages containing matrix metalloproteinase and gelatinase. Taken together, these findings indicate that an inflammatory stimulus unleashes a biochemical storm within the susceptible plaque, leading to rupture of the fibrous cap.

C-reactive protein (CRP) is a nonspecific acute-phase reactant. Increased serum levels of CRP[27,28] were reported to be elevated in most patients with unstable angina and myocardial infarction but not in those with stable angina. The short-term prognosis was worse in unstable angina patients with elevated levels.[28] In a larger study of stable and unstable angina patients undergoing coronary arteriography,[29] CRP levels averaged slightly higher than normal in both groups, and an elevated CRP level was a strong predictor of coronary events over the subsequent 2 years. The cytokine interleukin-6, which is the main producer of CRP in the liver, is elevated in unstable angina but not in stable angina.[30] Interleukin-6 and interleukin-1 receptor antagonist levels were higher on admission in unstable angina patients who were destined to have a complicated course than in unstable angina patients without complications in a recent study.[31]

Infection

The stimulus that initiates the acute inflammatory process in unstable angina has not been identified. Atherosclerosis itself, as defined by the "response to injury" hypothesis, is a chronic, low-grade inflammatory condition.[32] Considerable controversy exists about whether infectious agents play a role either in atherogenesis or in the transformation of stable to unstable coronary disease.[33,34]

Chlamydia pneumoniae, cytomegalovirus, and *Helicobacter pylori* have been identified within human atherosclerotic lesions.[33] Mechanisms by which chlamydia may contribute to atherogenesis or plaque disruption have been identified: Chlamydia heat shock protein and human heat shock protein are located together within macrophages, where they stimulate TNF-alpha and matrix metalloproteinase production.[35] Also, antibodies against chlamydia heat shock proteins could cross-react against heat shock proteins produced by endothelium, resulting in endothelial damage and accelerated atherosclerosis.[36]

Antibodies to chlamydia, cytomegalovirus, and *Helicobacter* are found more often in patients with atherosclerosis than in controls.[33,34] However, these associations do not prove causality. Antibodies to these agents are found in a high proportion of the population, particularly in members of the lower socioeconomic classes.[37] In prospective studies, antibodies to cytomegalovirus or *Helicobacter* did not predict future cardiovascular events, although total mortality was higher in subjects with antibodies to *Helicobacter*.[37,38]

If infection contributes to the initiation of acute coronary syndromes, appropriate antibiotic treatment should reduce coronary events in infected individuals. In a small study of postinfarction patients, adverse cardiovascular events during follow-up increased with increasing antibody titers to chlamydia.[39] Patients with high titers were randomized to azithromycin or placebo, and events were reduced significantly in the antibiotic-treated group. However, in another small trial of azithromycin in coronary patients with a seropositive reaction to chlamydia, no reduction in events was seen despite a significant reduction in the levels of inflammatory markers.[40] In the ROXIS pilot study, patients with unstable angina or non-Q-wave infarction were randomized to either roxithromycin or placebo for 1 month, with a total follow-up of 6 months.[41] The drug reduced end point events significantly. Larger, more definitive trials to assess the effect of antibiotics in coronary patients are under way.

Platelets and Leukocytes

Platelet deposition onto the exposed, thrombogenic surface of a ruptured plaque represents an important step in the pathogenesis of unstable angina. Autopsy studies in accident victims with coronary atherosclerosis suggest that plaque ruptures are common.[42] Only a small fraction of disrupted plaques culminate in an acute coronary syndrome. The surface area exposed by plaque rupture or erosion and the features of the exposed surface determine in part the propensity for the development of thrombus. For example, atheromatous core may be up to six times as thrombogenic as are other substrates, such as collagen-rich matrix.[43]

Platelet function is also an important determinant of the outcome of plaque disruption and as such is a major target of therapy. Patients with stable coronary or peripheral vascular disease already have increased platelet reactivity compared with normal controls.[44,45] Healthy endothelium releases nitric oxide, which inhibits platelet aggregation. This protective mechanism is attenuated in patients with atherosclerosis.[46]

In unstable angina, platelets are activated and generate thromboxane and prostaglandin metabolites.[47] Severe or persistent unstable angina is associated with the highest thromboxane

output, and stabilization of unstable angina is accompanied by a return to normal levels.[48,49] Not only is the release of nitric oxide by the endothelium attenuated, the platelets themselves exhibit impaired nitric oxide production in patients with unstable angina.[50]

P-selectin is a membrane glycoprotein found both in the alpha granules of platelets and in endothelial cells. P-selectin mediates both platelet-leukocyte and endothelial cell-leukocyte adhesive interactions. Plasma P-selectin levels increase significantly in unstable angina and myocardial infarction but not in stable angina.[51] Neutrophils also are activated in unstable angina, and neutrophil-platelet adhesion is increased.[52] Neutrophil and monocyte adhesion molecules have been reported to increase in unstable angina,[20] particularly when measured in the coronary sinus soon after an episode of rest angina.[53]

Activated platelets and activated leukocytes thus interact in the acute phase of unstable angina to facilitate platelet-thrombus deposition. The interaction involves not only cellular elements but also the coagulation cascade.

Thrombosis and Fibrinolysis

Activated platelets and leukocytes interact to stimulate the coagulation system. Monocytes release tissue factor, a small glycoprotein that initiates the extrinsic clotting cascade, leading to an increase in thrombin generation.[54,55] Transient increases in thrombin-antithrombin III and prothrombin fragment 1+2 can be demonstrated in the hour after an ischemic attack in most patients with unstable angina.[56] This finding indicates that intermittent thrombus deposition, stimulated by all the mechanisms discussed above, causes transient coronary flow reductions and thus the symptoms of ischemia at rest.

Tissue factor is also present in the lipid-rich core of atherosclerotic plaque and may be one of the major determinants of the thrombogenicity of plaques when they rupture.[57] When tissue factor is specifically inhibited, platelet and fibrin deposition onto the ruptured plaque is reduced.[58] Tissue factor content is higher in unstable than in stable angina culprit lesions and correlates with areas of macrophages and smooth muscle cells.[59] Unstable angina patients with high circulating levels of tissue factor have unfavorable outcomes.[60] This finding implies that tissue factor plays a key role in the evolution of the unstable plaque.

Overactivity of other components of the coagulation system has been reported in unstable angina, including levels of factor XII, bradykinin precursor, and fibrinogen.[61] Lower tissue-type plasminogen activator (TPA) and plasminogen activator inhibitor-1 (PAI-1) levels indicate that impairment of the fibrinolytic system also is present in unstable angina.[61]

Vasoconstriction

Culprit lesions in unstable angina exhibit a heightened response to vasoconstrictor stimuli.[62] This response is not present in other coronary segments and also is not seen in the culprit lesions of patients with stable angina. One explanation for this is that endothelin levels are higher in culprit lesions in unstable angina patients as a result of the inflammatory component of those patients' condition.[63] However, under experimental conditions, the degree of vasoconstriction varies directly with the amount of platelet deposition.[64] The process of platelet aggregation and thrombus formation releases potent vasoconstrictors such as thromboxane A_2 and serotonin. Vasoconstriction, or the absence of appropriate vasodilation, probably contributes significantly to the development of ischemic episodes in patients with unstable angina and represents a potential target for therapy.

Evolution of the Culprit Lesion

The angiographic aspects of the culprit lesion have been defined before, during, and after an episode of unstable angina. If a patient with unstable angina has previously had a coronary angiogram, the culprit lesion usually can be documented to have progressed markedly since that time.[65] Lesions that progress to cause acute coronary events are usually not severely stenotic; in fact, two-thirds of them are less than 50 percent in diameter stenosis and thus would not be targets for revascularization.[66] Angiographic features of a lesion that predict that it will precipitate an acute coronary event include greater asymmetry, greater length, and a steeper outflow angle.[67]

At the time of an episode of unstable angina, the culprit lesion is likely to be asymmetric or eccentric, with a narrow base or neck, compared with control lesions.[68] These angiographic features reflect the underlying pathology: plaque disruption with thrombus. Obvious thrombus is visible at angiography in a minority of unstable angina patients. However, coronary angioscopy reveals plaque rupture with overlying thrombus in most culprit lesions.[69,70]

During the months after an episode of unstable angina, the culprit lesion is far more likely to progress and precipitate another coronary event than are other lesions in the same patient or lesions in stable patients.[71,72] Lesions with irregular borders, overhanging edges, or obvious thrombus at angiography are more likely to precipitate another event in the ensuing months than smooth lesions are. Whether more aggressive treatment with antiplatelet or antithrombotic drugs can modify the evolution of such complex lesions is not known.

Chapter 41: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

DIAGNOSIS

A patient with unstable angina seeks medical attention because he or she has recognized either that new symptoms have appeared or that a previously stable pattern of symptoms has become unstable. The diagnostic difficulty usually lies in determining whether the chest pain is due to myocardial ischemia. Patients with suspected unstable angina must be evaluated rapidly and efficiently. A prompt and accurate diagnosis permits the timely initiation of appropriate therapy, which is important because complications are clustered in the early phases of acute coronary syndromes and because appropriate treatment reduces the rate of complications.

Patients with chest pain lasting for longer than 20 min, hemodynamic instability, or recent syncope or presyncope should be referred to a hospital emergency department.[1] Other patients with suspected unstable angina may be seen initially either in an emergency department or in an outpatient facility where a 12-lead ECG can be obtained quickly.

Initial Evaluation

The initial assessment should be directed toward determining whether the symptoms are caused by myocardial ischemia and, if so, the level of risk. If chest pain and ST-segment elevation >1 mm in two contiguous leads are present, reperfusion with thrombolytic therapy or primary angioplasty should be considered without delay. In the absence of these findings, the patient's clinical features should indicate whether the probability that symptoms are due to myocardial ischemia is high, intermediate, or low (Table 41-3). In a patient known to have coronary disease, typical symptoms are highly likely to be caused by myocardial ischemia, particularly if the patient confirms that the symptoms are identical to previous episodes with objective documentation. However, even if chest pain has some typical features, it is unlikely to be related to myocardial ischemia in a young individual who is known not to have risk factors for coronary disease. In one prospective multicenter study, older age, male sex, and the presence of chest or left arm pain or pressure as the presenting symptom all increased the likelihood that a patient was experiencing acute myocardial ischemia.[73]

Table 41-3: Likelihood That Unstable Angina Symptoms Are Caused by Myocardial Ischemia

HIGH LIKELIHOOD
Any of the following features:
Known coronary disease
Definite angina in men age 60 years or older or women 70 years or older
Hemodynamic or ECG changes during pain
Variant angina
ST elevation or depression of at least 1 mm
Marked symmetric T-wave inversion in multiple precordial leads
INTERMEDIATE LIKELIHOOD
Absence of high-likelihood features and any of the following:

Definite angina in men younger than age 60 or women younger than 70 years
Probable angina in men 60 years or older or women 70 years or older
Probably not angina in diabetics or in nondiabetics with two or more other risk factors[a]
Extracardiac vascular disease
ST depression of 0.05 to 1 mm
T-wave inversion of at least 1 mm in leads with dominant R waves
LOW LIKELIHOOD
Absence of high- or intermediate-likelihood features but may have:
Chest pain, probably not angina
One risk factor but not diabetes
T waves flat or inverted <1 mm in leads with dominant R waves
Normal ECG

[a]Risk factors include diabetes, smoking, hypertension, and hypercholesterolemia.

SOURCE: Adapted from Braunwald et al.,[12] with permission.

When unstable angina is suspected in a patient younger than age 50, it is particularly important to ask about cocaine use regardless of social class or ethnicity.[1] As is discussed in Chap. 71, cocaine can cause coronary vasospasm and thrombosis in addition to its direct effects on heart rate and arterial pressure and has been implicated as a cause of acute coronary syndromes. Unstable angina may be more difficult to diagnose than is stable angina because of the absence of some of the distinguishing features. The characteristic relation between stable angina and physical exertion or other stressful activities is a key diagnostic feature of stable angina that is lacking in unstable angina. Unstable angina may be poorly relieved by nitroglycerin, whereas this is rarely true for stable angina. The duration of an episode of chest discomfort is usually longer and more variable in unstable angina than in stable angina.

The sensation of myocardial ischemia usually is located in the retrosternal area but may be felt only in the epigastrium, back, arms, or jaw. The description may include adjectives such as *burning, squeezing, pressurelike,* or *heavy* but rarely includes *sharp, jabbing,* or *knifelike*. The physician should be cautioned that atypical features do not completely rule out the possibility of unstable angina. For example, in one study of patients presenting to the emergency department, acute ischemia ultimately was found to be present in 22 percent of patients who used the terms *sharp* and *stabbing* to describe their symptoms and 7 percent of patients whose pain was reproduced on palpation.[74]

Nausea, sweating, or shortness of breath may accompany episodes of unstable angina. In elderly or diabetic patients, these symptoms may be the only indication that myocardial ischemia is present. Elderly and diabetic patients also have a greater likelihood of having multivessel disease. Women who present with unstable angina are more likely to have diabetes, hypertension, hyperlipidemia, and heart failure and to be older than men; they are less likely to be smokers and to have had a previous infarction or a previous coronary revascularization (Table 41-4).[75] At coronary angiography, they are less likely to have significant coronary lesions.[75] In a recent large series of unstable angina patients, female sex had an independent protective effect against death or myocardial infarction within the first 30 days, with an odds ratio of 0.65 (95 percent confidence interval of 0.49 to 0.87).[75]

Table 41-4: Clinical Features in Men and Women Presenting with Unstable Angina

	Men	Women	*p* value
Number of patients	2801	1690	
Age (median, 25th, 75th percentile)	64 (54, 71)	68 (60, 75)	<.001
Hypertension	45%	57%	<.001
Diabetes	17%	23%	<.001
Current or former smoker	74%	38%	<.001
Hypercholesterolemia	39%	47%	<.001
Prior myocardial infarction	38%	27%	<.001
Prior angina	82%	82%	.54
Prior congestive heart failure	6.1%	10.2%	<.001
Prior bypass surgery	16.6%	9.2%	<.001
Heart rate (median, 25th, 75th percentile)	71 (62, 83)	76 (67, 86)	<.001
Systolic blood pressure (mmHg)	138 (120, 150)	140 (125, 160)	<.001
Killip class 2-4 on presentation	9.6%	12.5%	<.001

SOURCE: Adapted from Hochman et al.,[75] with permission.

On physical examination, transient signs of left ventricular dysfunction such as basilar rales or a ventricular gallop may accompany or follow shortly after an episode of unstable angina. More ominous signs of severe transient left ventricular dysfunction, such as hypotension and peripheral hypoperfusion, fortunately are not encountered commonly. Physical examination may reveal precipitating causes of or contributing factors to unstable angina, such as pneumonia and uncontrolled hypertension.

The Electrocardiogram

An ECG must be obtained as part of the initial evaluation of a patient with suspected unstable angina. The diagnostic yield is enhanced greatly if a tracing also can be recorded during an episode of chest pain. A normal ECG during chest pain does not rule out unstable angina as a likely diagnosis; however, it does indicate that an ischemic area, if present, is not extensive or severe enough to induce ECG changes and thus is a favorable prognostic sign.

Transient ST depression of at least 1 mm (Fig. 41-3) that appears during chest pain and disappears after relief represents objective evidence of transient myocardial ischemia. When ST depression is a persistent feature of ECGs recorded with or without chest pain, the finding is less specific. A common ECG pattern in patients with unstable angina is a persistently negative T wave over the involved territory (Fig. 41-4). This usually indicates that a severe stenosis is present in the corresponding coronary artery.[76] Myocardial stunning distal to the culprit lesion probably accounts for this ECG abnormality.[77] Deeply negative T waves occasionally are seen across all the precordial leads and point to a proximal, severe left anterior descending (LAD) coronary artery stenosis as the culprit lesion.[78]

In unstable angina patients, the ECG may show Q waves from an old infarct or a left bundle branch block resulting from extensive prior left ventricular damage. Patients with such findings are at increased risk because they are less likely than other patients to be able to tolerate an additional insult to the myocardium.[79,80] Myocardial ischemia is less likely to induce ST-segment changes in a territory that has Q

waves, and when it does, the change usually consists of ST elevation.

ECG abnormalities may appear or evolve in the absence of new symptoms in patients with acute coronary syndromes. For example, the development of significant Q waves may be the first indicator that the diagnosis is myocardial infarction, not unstable angina. T-wave abnormalities may appear, worsen, or resolve. It is therefore worthwhile to obtain serial ECGs during the first 48 h as well as during episodes of chest pain. Continuous 12-lead ECG monitoring can be performed using new multiprocessor-controlled, programmable devices. The limited clinical experience with this technology suggests that it can detect episodes of ST depression when the presenting ECG is normal and that this information has prognostic as well as diagnostic value.[81] Continuous vector cardiography ST-segment monitoring has been used by investigators who have reached the same conclusion.[82]

Serum Cardiac Markers

In the traditional paradigm, elevated serum levels of cardiac enzymes or the MB isoenzyme of creatine kinase (CK) could be used to distinguish between unstable angina and acute myocardial infarction. The diagnosis of unstable angina could be retained when minor elevations in CK or CK-MB were detected by serial sampling, but it was recognized that this was a negative prognostic sign.[83]

The widespread availability of other serum cardiac markers, particularly the troponins, has enriched this paradigm. One-fifth to one-quarter of patients with unstable angina will have elevated levels of troponin T or troponin I on admission or soon thereafter, and most of them will have normal levels of CK-MB. Several large studies have demonstrated that elevations of either troponin T or troponin I are independent predictors of adverse events in populations with either unstable angina alone or unstable angina and non-Q-wave infarction.[80,82,84-88] The troponin complex in cardiac and skeletal muscle consists of three subunits, which have been termed T, I, and C. The amino acid sequence of troponins T and I but not troponin C differ in cardiac muscle versus skeletal muscle. Immunoassays based on monoclonal antibodies have been developed to detect cardiac troponin T and cardiac troponin I. The sensitivity and specificity of these two markers appear to be roughly equal when used in populations with a high prevalence of acute coronary syndromes.[88] However, troponin I theoretically could be more specific because it is less likely to be generated by skeletal muscle disease or injury.[88] A rapid bedside assay for cardiac troponin T has been developed,[89] and a positive result of this test has been shown to be predictive of in-hospital adverse events among patients with unstable angina or non-Q-wave infarction.[90] Early positivity indicates higher troponin levels and a worse prognosis than does later positivity.[90]

Troponin T or troponin I measurements may be normal early after the onset of an acute coronary syndrome and become positive later. Myoglobin, a low-molecular-weight heme protein found in both skeletal and cardiac muscle, may be detected as early as 2 h after the onset of symptoms but is not specific for myocardial damage.[91] CK-MB subforms are usually positive within 6 h, and troponin T or troponin I within 12 h.[91] Troponin levels remain elevated for 1 week and thus are useful in making a diagnosis when a patient presents late after a coronary event.

The pathophysiologic basis for troponin release in unstable angina has not been defined adequately. Some patients probably have non-Q-wave infarcts that are not extensive enough to result in CK-MB release. A total occlusion of the culprit lesion with early spontaneous reperfusion could be the usual underlying substrate. In other unstable angina patients, elevated troponin levels may reflect mild myocardial damage caused by platelet microemboli from the culprit lesion.[92] Whether troponin can be released without irreversible damage to cardiac myocytes is not known.

With respect to terminology, patients with unstable angina, elevated troponin, and normal CK-MB levels could be classified as having either unstable angina or non-Q-wave infarction. It seems reasonable to continue to label them as having unstable angina to distinguish them from patients with elevated CK-MB levels. These patients should, however, be treated as high risk compared with unstable angina patients with normal troponin levels.

Cardiac troponins are less useful for the diagnosis of unstable angina than they are for risk stratification.

Only a minority of unstable angina patients will have elevated troponin levels on admission, and so the diagnosis usually is made by other means. However, an elevated level may be the only objective evidence of the presence of an acute coronary syndrome in some patients.

Acute Myocardial Perfusion Imaging

Intermittent reductions in coronary blood flow distal to the culprit lesion theoretically could occur in unstable angina without either ECG abnormalities or release of serum cardiac markers. Acute rest myocardial perfusion imaging with either thallium or sestamibi therefore might be a sensitive and specific diagnostic test for unstable angina. In practice, sestamibi is more useful than thallium for this purpose because imaging can be delayed for up to several hours after injection as a result of the minimal redistribution of this imaging agent. ECG-gated images provide an assessment of wall motion in addition to perfusion.

Several groups of investigators have shown that acute rest sestamibi imaging is useful in risk stratifying patients who present with chest pain.[93-96] A perfusion defect indicates either unstable angina or myocardial infarction. Imaging cannot distinguish between an acute infarct and one that is old. An example of a patient with unstable angina and a positive acute rest sestamibi image is shown in Fig. 41-5. An imaging study may be interpreted as equivocal if a perfusion defect cannot be distinguished from soft tissue attenuation in a myocardial segment with normal wall motion.

The sensitivity and specificity of acute rest imaging are very high if sestamibi is injected during an episode of chest pain, but sensitivity decreases if the injection is done within the ensuing hours.[97] The negative predictive value of a normal perfusion study is extremely high when the injection is done during symptoms. However, acute rest imaging will miss a few patients with acute coronary syndromes (less than 5 percent with experienced readers) and so patient management decisions cannot be made solely on the basis of one test result.

Chest Pain Units

The evaluation of patients with chest pain who may have unstable angina or myocardial infarction is often fraught with uncertainty. Hospitalizing all such patients for an extensive workup when the probability that active coronary disease accounts for their symptoms is neither cost-effective nor necessary. However, missing the diagnosis of unstable angina may result in unnecessary myocardial infarction or death. The chest pain unit has been developed as a solution to this problem.

Most chest pain units are in or adjacent to the emergency department and employ a set of criteria designed to select low-risk patients.[98-100] These criteria usually include chest pain that may indicate myocardial ischemia but with a normal or unchanged ECG and a normal first set of cardiac enzymes.[100] In a study of over 10,000 patients presenting to emergency departments with chest pain, the likelihood of a major cardiovascular event declined over time, with 41 percent occurring within 12 h and 62 percent within 24 h.[101] Events could be predicted by a set of simple clinical measures available at baseline and updated at 12 h.[101] This information provides a rationale for the design of chest pain units.

In most units, CK-MB is measured at 3- to 4-h intervals for 9 to 12 h, sometimes with other serum markers. Patients receive an aspirin, an intravenous line, ECG monitoring, and 12-lead ECGs during chest pain and at specific intervals. If no evidence of active coronary disease is detected at the end of this observation period, a stress test may be performed for diagnostic and prognostic purposes.

Chest pain units have been reported to reduce the rate of missed infarctions from approximately 5 percent to 0.5 percent of patients, as estimated from return visits within 72 h.[100] Missed diagnoses of unstable angina probably are reduced as well, although this rate is difficult to measure. Hospitalizations, hospital days, and total costs are reduced because approximately 75 percent of patients are discharged directly from the unit.[99,100]

Although most chest pain units accept only patients at low risk for an acute coronary event, a randomized trial has demonstrated that patients with unstable angina who are judged to be at intermediate risk also can

be managed in this environment.[102] Nearly half the patients randomized to the chest pain unit strategy completed the observation period, had a negative stress test, and were discharged home, to be evaluated further as outpatients. The rate of serious complications, mainly myocardial infarction, was not significantly different at 30 days and 6 months between the two groups.

Chapter 41: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

RISK STRATIFICATION

The evaluation of a patient with unstable angina requires not only the establishment of the diagnosis but also an assessment of the short-term risk. This risk assessment determines the appropriate intensity of therapy. At the low end of the risk scale, a patient may be discharged home with aspirin and a beta blocker, to be followed as an outpatient. At the opposite end of the scale, a patient may be hospitalized in a coronary care unit, be treated with multiple drugs, and undergo coronary arteriography urgently as a prelude to revascularization.

Clinical Features

The 1994 report of the Agency for Health Care Policy and Research (Table 41-5) categorized unstable angina patients into low-, intermediate-, and high-risk groups on the basis of the data available at the time of the first assessment.[12] High-risk patients have ongoing chest pain that lasts longer than 20 min, reversible ST changes of at least 1 mm, or signs of serious left ventricular dysfunction. Low-risk patients have worsening angina without rest pain, are not older than age 65, and have a normal or unchanged ECG without evidence of a previous infarct.

The risk assessment should be updated during hospitalization because patients frequently change categories. Continuing angina with ST changes despite medical therapy is an ominous sign that should precipitate urgent coronary arteriography with a view to revascularization, because the risk of myocardial infarction is high. Most episodes of myocardial ischemia are silent, and some investigators have reported that episodes of ST depression detected by Holter monitoring are a better predictor of an unfavorable outcome.[103]

Serum Cardiac Markers

Troponin measurements should be used in the risk stratification of patients with unstable angina to supplement the assessment from clinical features and the results of the ECG. Elevated troponin levels strongly predict coronary events over the short term. The odds ratio for cardiac death or myocardial infarction within 30 days for an elevated troponin T was 2.7 (95 percent confidence interval of 2.1 to 3.4), based on 12 studies including a total of 2847 unstable angina patients.[88] The odds ratio for an elevated troponin I was 4.2 (95 percent confidence interval of 2.7 to 6.4), based on 9 studies of 1901 unstable angina patients.[88] The sensitivity and specificity of troponin T and troponin I are not significantly different.[88]

A major advantage of troponin measurements is that troponins contribute to risk independently of most of the other major predictors. For example, in one large study, elevated troponin T, age, hypertension, number of antianginal drugs, and ECG changes at baseline predicted cardiac death or myocardial infarction in a multivariate analysis.[84] In that study, the amount of troponin T elevation was also a predictor, with risk increasing for each quintile of troponin T elevation. The combination of troponin T elevation and ST depression identified a group at particularly high risk.

Measuring troponin not just at baseline but also at 8 and 16 h after admission has been shown to add useful prognostic information.[104] Elevated troponin levels predict an adverse outcome not just

in unstable angina patients but also in the broader population of patients with chest pain presenting to emergency departments.[105] Evidence from a trial of a low-molecular-weight heparin suggests that elevated troponin may be a marker that identifies patients who will benefit from antithrombotic therapy.[106]

High levels of the inflammatory markers CRP, serum amyloid A, and interleukin-6 are associated with a poorer prognosis in unstable angina patients.[28,31,107] Markers of activation of the coagulation system also have been reported to predict risk, including fibrinopeptide A[108] and fibrinogen.[109] The early rise in von Willebrand factor was an independent predictor of events within 30 days in one study.[110] However, in practice, the only serum marker that should be measured routinely for risk stratification in unstable angina is troponin T or I.

Stress Testing

Stress testing often is used as a risk assessment tool in patients with unstable angina. Low-risk and some intermediate-risk patients whose symptoms stabilize with medical therapy undergo stress testing for advanced risk stratification. Those with high-risk findings (Fig. 41-6) such as reversible perfusion defects or ST depression at low exercise levels undergo coronary arteriography, and those with negative or low-risk results are managed medically. This approach has been validated by studies in unstable angina patients demonstrating that these abnormalities correlate with a higher event rate during follow-up.[111-114] For example, in one study, 60 percent of patients with a reversible perfusion defect compared with 12 percent of those with a normal exercise sestamibi scan experienced cardiac death, nonfatal infarction, or rehospitalization for unstable angina during a 12-month follow-up.[114] Patients with low exercise tolerance, exercise-induced ST depression, and larger perfusion defects are more likely to have three-vessel coronary disease than are patients without these high-risk findings.[115]

Patients who complete a stay in a chest pain unit without objective evidence of myocardial ischemia can safely undergo stress testing for diagnostic and prognostic purposes.[116] In one study, 71 percent of chest pain unit patients completed stage 1 of a Bruce protocol without evidence of myocardial ischemia, and their rate of infarction or coronary revascularization over the next 6 months was only 2 percent.[116]

In patients who are unable to exercise, dipyridamole or dobutamine can be used as the stress and sestamibi imaging or echocardiography can be used as the method of assessment. Stress testing is not needed in patients whose clinical features already put them at high risk. Patients with continuing angina despite medical therapy. ST depression, or hemodynamic impairment during spontaneous attacks of rest angina or elevated troponin levels should proceed directly to coronary arteriography.

Coronary Angiography

Risk in coronary patients traditionally has been assessed according to the number of vessels with at least 50 percent diameter stenosis and the presence and severity of left ventricular dysfunction. Older studies indicate that these variables are important predictors of outcome in unstable angina.[117-119] However, their prognostic impact is probably less than it is in stable coronary disease because the risk of short-term events in unstable angina is dominated by features of the culprit lesion, such as whether it induces ST depression or troponin release. Culprit lesions are far more likely to progress and initiate other coronary events in the months after an episode of unstable angina than are other coronary lesions in the same patients.[71,72]

Among patients with unstable angina who undergo coronary arteriography, approximately one-quarter will have one-vessel, one-quarter two-vessel, and one-quarter three-vessel involvement; 10

percent will have significant left main stenosis; and the other 15 percent will have narrowings of less than 50 percent or normal vessels on angiography. Patients with left main stenosis of at least 50 percent or three-vessel disease with left ventricular dysfunction will obtain a survival benefit from coronary bypass surgery.[120,121] Although noninvasive testing is sensitive and specific enough to detect many of these patients, the only certain method for diagnosing these conditions is angiography.

At the other extreme, patients without significant lesions at angiography benefit from a reorientation of their management. Noncardiac causes of chest pain should be considered, as well as other potential diagnoses, such as syndrome X and variant angina. Antithrombotic and antiplatelet drugs often can be discontinued, and the need for antianginal medication can be reassessed. The unstable angina patients who are most likely to have no significant lesions at angiography tend to be women with no ST-segment abnormalities on ECG.[122] Nevertheless, the finding of no significant lesions at angiography is usually a surprise. These patients have a low coronary event rate during follow-up even though their symptoms often persist.[122]

Risk Stratification with Combinations of Predictors

In clinical practice, several variables usually are integrated into a global assessment of risk. The combination of ST-segment abnormalities and elevated troponin levels has been shown to be useful. In one study that used these two indicators, the risk of death or infarction within 30 days was 25.8 percent, 3.1 percent, and 1.7 percent in high-, intermediate-, and low-risk groups, respectively.[24] In a Thrombin Inhibition in Myocardial Ischemia (TRIM) substudy, the composite end point of death, myocardial infarction, or refractory angina within 30 days was predicted by ST depression, inverted T waves in at least five leads, elevated troponin or myoglobin levels, female sex, and age of 65 or higher.[123] Death or infarction occurred in 14 percent, 6 percent, and 3 percent of high-, intermediate-, and low-risk groups, respectively.

In summary, the short-term outcome of unstable angina can be predicted by a variety of methods (Table 41-5). Risk assessment should be updated during hospitalization as new information becomes available so that high-risk patients are not undertreated and low-risk patients are not overtreated. The most important predictors are the clinical presentation (Table 41-3), ST depression during attacks, elevated troponin levels, and continuing episodes in spite of medical therapy.

Chapter 41: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

PROGNOSIS

Prognosis in patients with unstable angina can be viewed as a composite of the prognosis expected from the extent of coronary disease and left ventricular function overlaid with the short-term risk associated with the culprit lesion and the unstable state. The short-term risk is related almost entirely to myocardial infarction and its complications and to recurrences of unstable angina. Risk is highest in the hours, days, and first month after the onset of symptoms. The incremental risk associated with the unstable state dissipates completely by 1 year.[71,72] For example, 11 percent of unstable angina patients in one series experienced a myocardial infarction between hospital discharge and 1 year but the subsequent annual infarction rate was less than 2 percent.[124]

Published data on the prognosis in unstable angina are influenced by patient selection and treatment and can be quite misleading. The inclusion and exclusion criteria for clinical trials may bias the prognosis by eliminating low-risk or high-risk patients. If younger patients with atypical symptoms and no objective evidence of myocardial ischemia are included in large numbers, the prognosis of the cohort under study will tend to be better. By contrast, if ECG changes or elevated troponin levels are required, the prognosis will tend to be worse. The prognosis has improved dramatically over the past two decades with the introduction of increasingly more sophisticated medical therapy and revascularization techniques. As recently as the early 1980s, aspirin was not used routinely in the treatment of unstable angina. Results from that era are therefore below current expectations.

In a compilation of 10 representative series with a total of nearly 2000 unstable angina patients, excluding those with new-onset or postinfarction angina, the mortality was 4 percent in the hospital and 10 percent at 1 year.[125] Survival without infarction was 89 percent at 1 month and 79 percent at 1 year. Among 4488 unstable angina patients in GUSTO-IIb, the mortality rate was 2.4 percent at 30 days, 5 percent at 6 months, and 7 percent at 1 year.[126] The infarction rate was 4.8 percent at 30 days and 6.2 percent at 6 months. Recurrent ischemia had a major impact on these rates; for example, the 30-day infarction rate increased from 2.3 percent to 7.2 percent to 21.7 percent in patients with no ischemia, ischemia, and refractory ischemia, respectively. These outcomes are representative of the results of modern therapy in the late 1990s.

Chapter 41: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

TREATMENT

The goals of treatment in unstable angina are to control symptoms and prevent myocardial infarction. Nitroglycerin, beta blockers, and to a lesser extent calcium channel blockers reduce the risk of recurrent ischemic attacks. Revascularization eliminates ischemia entirely in patients with favorable anatomy, and in some subgroups, coronary bypass surgery has been shown to prolong life. The risk of myocardial infarction is reduced by antiplatelet and antithrombotic therapy.

Nitroglycerin and Nitrate Therapy

In patients with unstable angina, sublingual nitroglycerin usually relieves attacks promptly, although it may be somewhat less efficacious than it is in stable angina patients. Patients with unstable angina often are treated with an infusion of intravenous nitroglycerin to prevent further attacks. A common starting dose is 10 μg/min. The dose can be increased in increments of 10 μg/min until symptoms are controlled or unwanted side effects develop. The most common adverse effects are headache, nausea, dizziness, hypotension, and reflex tachycardia.

The evidence that intravenous nitroglycerin prevents ischemic attacks in unstable angina patients is sparse (Table 41-6). In two studies of 35 and 40 patients, respectively, intravenous nitroglycerin reduced the number of angina episodes during treatment compared with a pretreatment period.[127,128] However, a placebo control group was not included in the design of either study. No studies of sufficient power have examined whether intravenous nitroglycerin or other nitrate preparations reduce the risk of infarction in unstable angina.

Table 41-6: Clinical Trials of Anti-Ischemic Therapy in Unstable Angina

Author[a]	Year	Active Treatment	Comparison Group	No. Patients	Duration of Study	End Point	Primary Results	Comments
Kaplan et al.[127]	1983	IV Nitroglycerin (NTG)	None	35	In hospital	Rest angina episodes	90% decrease in episodes	No control group
Curman et al.[128]	1983	IV NTG	Oral/topical nitrates	40	In hospital	Rest angina episodes	Fewer episodes in both groups	No difference between groups
Muller et al.[143]	1984	Nifedipine	Propranolol, oral nitrates	126	14 days	Angina relief	Equal angina relief in both groups	MI rate 9/63 in both groups
Gottlieb et al.[144]	1986	Propranolol	Placebo	82	4 weeks	Angina recurrence	Propranolol superior	Nitrates plus nifedipine in both groups

Théroux et al.[145]	1985	Diltiazem	Propranolol	100	5.1 months	Angina in hospital death/MI during follow-up (FU)	Equal angina relief in both groups	Equal rates of death/MI during FU
Andre-Fouet et al.[146]	1983	Diltiazem	Propranolol	70	In hospital	Angina	Equal angina relief in both groups	Diltiazem superior in variant angina patients
HINT[147]	1986	Nifedipine Metoprolol	Placebo	515	48 h	Recurrent angina death/MI	MI rate higher with nifedipine compared with meto-prolol	Angina relief when nifedipine added to meto-prolol
Gerstenblith et al.[150]	1982	Nifedipine	Placebo	138	4 months	Death/MI/coronary artery bypass grafting (CABG)	Nifedipine better than placebo	Nifedipine benefit in variant angina patients

[a]Several small studies are not included (see references [152,] [153,] [158,] and [159]).

Nitroglycerin acts through several mechanisms that could provide benefit in patients with unstable angina. As a venodilator at low doses and an arteriolar dilator at higher doses, it reduces preload and afterload and thus myocardial oxygen consumption. The drug directly dilates coronary stenoses and thus increases oxygen delivery to the ischemic region.[129] Nitroglycerin increases collateral flow and favorably redistributes regional coronary flow. Because of its preferential effect on capacitance vessels as opposed to resistance vessels, it does not have the potential to induce coronary steal, unlike other vasodilators.[130]

Nitroglycerin and longer-acting nitrates act by releasing nitric oxide in vascular smooth muscle through an enzymatic process.[130] Sulfhydryl-donating compounds are necessary for this activity, and their rapid depletion during chronic therapy with nitroglycerin or other nitrate preparations rapidly leads to tolerance to the hemodynamic effects of the drug.[131] In stable patients, intermittent nitrate therapy is recommended to circumvent nitrate tolerance; however, some studies have shown that a rebound increase in ischemic episodes occurs during nitrate-free intervals.[132] Rebound myocardial ischemia after abrupt interruption of intravenous nitroglycerin infusion also has been reported in unstable angina patients.[133]

A second strategy for avoiding nitrate tolerance involves the concomitant administration of a sulfhydryl donor such as captopril or *N*-acetylcysteine. Although this approach is not employed in patients with unstable angina, a randomized trial in 200 patients demonstrated that the combination of transdermal nitroglycerin and *N*-acetylcysteine reduced the incidence of death, myocardial infarction, and refractory angina requiring hospitalization over 4 months compared with placebo or transdermal nitroglycerin alone.[134] Combined therapy caused intolerable headache in one-third of patients, limiting its clinical utility.

Considerable data can be marshaled to support the argument that the antiplatelet effects of nitroglycerin explain that drug's efficacy in treating unstable angina. Early studies demonstrated that nitroglycerin inhibits platelet aggregation.[135] Nitroglycerin and other nitrates activate cyclic guanosine monophosphate (GMP) in platelets. Cyclic GMP modulates the availability of intracellular platelet calcium and thus influences the response of platelets to receptor-mediated activation.[135]

At therapeutic doses, nitroglycerin reduces platelet aggregability to adenosine diphosphate and thrombin in unstable angina patients.[136] The drug also has been shown to reduce platelet thrombin deposition in an

experimental model that simulates plaque rupture.[137] Platelet aggregation induced by thrombin and platelet thrombin deposition appear to be reduced by nitroglycerin even after tolerance to the hemodynamic effects of the drug has developed.[138] Intravenous nitroglycerin usually is replaced with transdermal nitroglycerin or an oral nitrate preparation after an angina-free interval of 1 or 2 days. In unstable angina patients who undergo coronary angiography and angioplasty, intravenous nitroglycerin usually is discontinued 12 to 24 h after the procedure. The doses of transdermal or oral nitrates that are prescribed for patients with unstable angina are similar to those used in stable angina patients. In most cases, they are lower than the doses found to be effective in preventing angina in clinical studies.

Beta Blockers

Ischemia occurs when myocardial oxygen demand exceeds the delivery of oxygenated blood to a territory of myocardium distal to the culprit lesion. The major determinants of myocardial oxygen consumption are heart rate, myocardial inotropic state, and left ventricular afterload. Treatment strategies to prevent episodes of unstable angina can be divided into those which increase regional blood flow and those which reduce myocardial oxygen demand.

Beta blockers are the most useful category of drug in reducing myocardial oxygen demand, primarily by slowing heart rate but also by decreasing myocardial contractility and afterload. Heart rate and arterial pressure often increase during episodes of rest angina.[139,140] This unwanted response can be limited by beta-adrenergic blockade.

Beta blockers attenuate the coronary vasodilating effect of beta-adrenergic stimulation and allow alpha-adrenergic vasoconstriction to predominate. In patients with Prinzmetal's variant angina, beta blockers may increase the frequency or duration of attacks,[141,142] presumably through this mechanism. However, in patients with unstable angina, the potentially harmful effect of beta blockers on coronary blood flow does not appear to be clinically relevant.

Although it is widely accepted that beta blockers are useful in controlling ischemic episodes in patients with unstable angina, the data to support this claim are mainly inferential or have been derived from small trials without placebo-treated controls (Table 41-6). These trials date from the early 1980s, an era when patients were not treated routinely with aspirin and heparin.

Muller and coworkers randomly allocated 126 patients with unstable angina to propranolol plus isosorbide dinitrate or to nifedipine for 14 days.[143] The principal end point-the absence of recurrent chest pain for at least 48 h-was attained with equal frequency in the two groups; however, the propranolol and nitrate combination was more effective in patients not previously taking a beta blocker, and nifedipine was more effective in patients who had been receiving beta blockers before admission. The incidence of myocardial infarction during the 14-day treatment period was 14 percent (9 of 63) in both groups. Four patients in the nifedipine group died, compared with none in the group treated with propranolol.

Gottlieb and associates randomized 81 unstable angina patients either to propranolol at a dose of at least 160 mg/day or to placebo.[144] Baseline therapy in all patients included long-acting nitrates and nifedipine 80 mg/day. The cumulative probability of experiencing recurrent angina was significantly lower in the propranolol group. Myocardial infarction during the 4 weeks of the trial occurred in 6 of 42 propranolol-treated patients and 3 of 39 controls, a difference that was not statistically significant.

Théroux and colleagues randomized 100 patients with unstable angina to propranolol 240 mg/day or diltiazem 360 mg/day.[145] Transient ST-segment changes during an episode of chest pain were a requirement for study entry, and patients with Prinzmetal's variant angina or those already being treated with a beta blocker were excluded. Both drugs significantly reduced the frequency of angina episodes during hospitalization, and their antianginal efficacy was approximately equivalent. After 5.1 months of follow-up, 2 of 50 patients in each treatment group had died; 4 propranolol-treated and 5 diltiazem-treated patients experienced myocardial infarction. Similar results were found with respect to angina relief in a randomized comparison of propranolol and diltiazem in 70 unstable angina patients.[146]

The largest trial of a beta blocker in unstable angina was the Holland Interuniversity Nifedipine/Metoprolol Trial (HINT).[147] The 338 patients not receiving a beta blocker on admission were randomized to nifedipine 60 mg/day, metoprolol 200 mg/day, both drugs, or double placebo therapy. The rate of recurrent ischemia or

myocardial infarction within 48 h, the main end point of HINT, was reached by 37 percent of placebo patients, 47 percent of nifedipine patients, 28 percent of metoprolol patients, and 30 percent of patients receiving combination therapy. Metoprolol was significantly better than nifedipine with respect to this end point. The trend in favor of metoprolol compared with placebo was not statistically significant.

Taken together, these trials indicate that beta blockers effectively reduce symptoms in unstable angina patients who are not already taking one of these drugs on admission. Whether or not a beta blocker also reduces the risk of myocardial infarction is uncertain. The trials in unstable angina are much too small to answer this question and are confounded by the use of nifedipine in the comparison groups. Five old randomized trials involving approximately 4700 patients with "threatened myocardial infarction" assessed the effect of acute intravenous beta blockade followed by oral treatment for 1 week.[148] Most patients in these studies had prolonged chest pain without ECG evidence of infarction on admission. A 13 percent reduction in the risk of infarction, from 32 percent to 29 percent, was reported in an overview of these trials, a difference of borderline statistical significance ($p < .04$). Neither antiplatelet nor antithrombotic therapy was used in these trials, and so their relevance to patients treated with current therapy is uncertain.

During chronic therapy, a long-acting beta blocker is preferable to a short-acting one because it can be given once per day. However, in the context of unstable angina, it is reasonable to try to achieve beta blockade within hours, not days. Therefore, beta blockade sometimes is initiated with intravenous boluses titrated to reduce heart rate. Early heart rate control is particularly important in high-risk patients and those with tachycardia or a high arterial pressure on admission. A reasonable target heart rate in unstable angina patients is 50 to 60 beats per minute at rest. The main contraindications to beta blockers in unstable angina are reactive airway disease, sinus node dysfunction or atrioventricular block, and severe heart failure. Most patients with chronic obstructive pulmonary disease will tolerate a beta blocker; a $beta_1$-selective agent (for example, metoprolol or atenolol) is theoretically less likely to provoke bronchoconstriction. In some patients with conduction system disease, permanent pacing may be indicated in part so that chronic beta blocker therapy can be given. Mild heart failure that is stable is not a contraindication to beta blockers in patients with unstable angina. Diltiazem or verapamil should be considered when a beta blocker cannot be used.

Calcium Channel Blockers

Calcium channel blockers increase coronary blood flow both globally and to the ischemic zone. Diltiazem and verapamil both slow heart rate, reduce afterload, and reduce myocardial contractility; they thus reduce myocardial oxygen demand. Most dihydropyridine calcium channel blockers induce a reflex increase in heart rate in the absence of beta blockade, a feature that is likely to mitigate any benefit in regard to myocardial ischemia. Dihydropyridine calcium channel blockers sometimes worsen myocardial ischemia and produce other "proischemic" complications in a minority of patients.[149]

The calcium channel blocker that has been used most often among the limited number of studies of unstable angina is the short-acting formulation of nifedipine. The rapid absorption and short half-life of this preparation produce frequent abrupt changes in arterial pressure and heart rate. Whether the poor results seen with nifedipine in trials of unstable angina and postinfarction patients would have been different with a long-acting formulation is open to debate.

As was noted above, in the study of Muller and colleagues[143] comparing propranolol and nifedipine in 126 unstable angina patients, nifedipine was more effective in controlling angina in patients who were already taking a beta blocker on admission but was less effective in other patients. The infarction rate during 14 days of treatment was 14 percent in both the propranolol and nifedipine treatment groups.

HINT was terminated prematurely because of a significantly higher rate of infarction in nifedipine-treated patients.[147] Among patients not already receiving a beta blocker on admission, recurrent ischemia or infarction within 48 h, the primary end point, occurred more often with nifedipine than it did with propranolol. However, among the 177 patients pretreated with a beta blocker, nifedipine was superior to placebo, with a relative risk for the primary end point of 0.68 (95 percent confidence interval of 0.47 to 0.97).

Gerstenblith and coinvestigators randomized 138 unstable angina patients taking propranolol and long-acting nitrates to nifedipine 80 mg/day or to placebo.[150] The primary end point of the trial-death, infarction, or coronary bypass surgery within 4 months-was reached by 43 of 70 placebo patients and 30 of 68 nifedipine-treated patients ($p = .03$). Nifedipine was particularly beneficial ($p = .02$) in the 52 patients with transient ST

elevation during attacks, who presumably had coronary spasm, with little difference seen between the groups for the remainder of the study patients.

The potential of nifedipine at a dose of 80 mg/day to prevent "threatened myocardial infarction" was assessed in a double-blind, placebo-controlled trial of 105 patients.[151] Entry criteria included chest pain lasting longer than 45 min and ECG ST-segment changes, and treatment was initiated a mean of 4.6 h after the onset of pain. The incidence of progression to infarction of 75 percent in both groups was not altered by nifedipine. A further 66 patients with documented infarction on admission also were randomized to the same treatments in another part of the trial. At the end of the 14-day treatment period, mortality among the entire 171 patients was higher in the nifedipine group: 7.9 percent versus 0 percent (p = .018).

Taken together, these trials provide fairly strong evidence that nifedipine is harmful when used in unstable angina patients who are not receiving beta blockers but that it may be helpful in controlling angina in patients with an adequate level of beta blockade. Even when the addition of nifedipine does control angina in patients whose unstable angina was previously refractory, the risk of infarction or death over the next few months in the absence of revascularization remains very high.[152] Long-acting formulations of nifedipine and newer dihydropyridines such as amlodipine have not been evaluated in unstable angina trials.

As was mentioned above, two trials compared diltiazem to propranolol in a total of 170 patients with unstable angina.[145,146] The two drugs were equally effective in controlling angina and were associated with equal rates of myocardial infarction. In two small series in which intravenous diltiazem was compared with an intravenous nitrate for the control of myocardial ischemic episodes, diltiazem was reported to be superior.[153,154]

Verapamil has not been studied in large numbers of patients with unstable angina. In two small, placebo-controlled trials, the frequency of ischemic episodes was reduced significantly.[155,156] Long-term follow-up of these patients showed continued control of symptoms but a high incidence of infarction and death.[157] Verapamil and propranolol were compared in two small clinical trials.[158,159] Both drugs reduced the frequency of ischemic episodes, with verapamil being somewhat superior to propranolol. Both diltiazem and verapamil are effective in preventing ischemic episodes caused by coronary spasm, a condition that was present in some of the patients in these trials.

Diltiazem and verapamil are reasonable choices for treating unstable angina patients for whom beta blockers are contraindicated. The scant evidence discussed above suggests that both drugs reduce the frequency of attacks in unstable angina, but there is no evidence that they prevent infarction. The combination of diltiazem or verapamil with a beta blocker is not commonly used in unstable angina because the effects of these calcium channel blockers on heart rate and myocardial contractility are additive to the effects of beta blockers.

Antianginal Therapy

An oral beta blocker at a dose that reduces heart rate and an intravenous nitroglycerin infusion are a reasonable treatment to control symptoms in a high-risk or intermediate-risk unstable angina patient. Low-risk and some intermediate-risk patients can be treated with oral or transdermal nitrates and beta blockers. A patient who develops unstable angina while taking two or three antianginal drugs should be treated with intravenous nitroglycerin, but the symptoms will be harder to control compared with an unstable angina patient who previously took no antianginal drugs.

In most patients hospitalized with unstable angina, symptoms do not recur after the institution of antianginal therapy. Patients with refractory unstable angina have a much higher risk of developing myocardial infarction than do patients whose angina is controlled with drugs. Patients who are labeled as refractory often become asymptomatic when medical therapy is intensified; for example, in one study an increase in medical therapy relieved symptoms in 83 percent of patients transferred because their unstable angina was refractory.[160] Intraaortic balloon counterpulsation prevents myocardial ischemia effectively in patients whose unstable angina is truly refractory.[161] This mechanical approach improves myocardial blood flow and reduces myocardial oxygen demand by collapsing the resistance to left ventricular ejection in early systole. Intraaortic balloon counterpulsation is needed for the control of symptoms in less than 1 percent of patients with unstable angina, but it also is used in high-risk patients at the time of coronary angioplasty to provide a margin of safety. Intraaortic balloon counterpulsation causes lower limb ischemia in approximately 10 percent of cases, but this complication almost always resolves after removal of the device.

Aspirin

Aspirin inhibits cyclooxygenase activity in all body cells. This inhibition is irreversible for the life span of a platelet, normally a median of 8 days. As a consequence, the platelet is unable to produce thromboxane A_2 , the platelet-specific prostaglandin that induces platelet aggregation. Aspirin also may influence the pathophysiology of unstable angina through other mechanisms. For example, aspirin inhibits prostacyclin production by the endothelium but also has been shown to block cyclooxygenase-dependent endothelium-derived vasoconstriction.[162]

Four trials have demonstrated conclusively that aspirin reduces the risk of myocardial infarction in patients with unstable angina (Table 41-7).[163-166] In the Veterans Administration study, 1338 men hospitalized with crescendo angina, prolonged pain, or pain at rest were randomized to aspirin 324 mg/day or placebo within 7 days.[163] The study duration was 12 weeks, and the primary end point was death or acute myocardial infarction. The principal outcome was reduced from 10.1 percent to 5.0 percent (p = .0005). In the Canadian multicenter trial, 555 unstable angina patients were randomized to aspirin 325 mg four times per day or placebo within 8 days of admission and were followed on therapy for a mean of 18 months.[164] The risk reduction for cardiac death or nonfatal myocardial infarction was identical to that in the Veterans Administration study at 51 percent, from 17.0 percent to 8.6 percent (p = .008). Sulfinpyrazone also was tested in this trial but showed no benefit.

Table 41-7: Clinical Trials of Aspirin in Unstable Angina

Author	Year	No. Patients	Dose	Duration of Follow-Up	Death/MI Rate in Aspirin Group, %	Death/MI Rate in Control Group, %	*p* value	Relative Risk	Comments
Lewis et al.[163]	1983	1266	324 mg/day	12 weeks	5.0	10.1	.0005	0.49	Men only
Cairns et al.[164]	1985	555	325 mg qid	18 months	8.6	17.0	.008	0.49	Not intention to treat
Théroux et al.[165]	1988	239	325 mg bid	6 days	3.3	11.9	.01	0.29	Treatment begun at 8 h
RISC[166]	1990	796	75 mg/day	3 months	6.5	17.1	.001	0.36	Men only, non-Q-wave MI included

Théroux and associates randomized 479 unstable angina patients to aspirin 325 mg twice daily or placebo at hospital admission, a mean of 8 h after the last episode of pain, with a mean follow-up of 6 days.[165] Patients also were randomized to intravenous heparin in a factorial design. Aspirin reduced the risk of death or myocardial infarction from 6.3 percent to 2.6 percent, a 63 percent decrease (p = .04). The Research Group on Instability in Coronary Artery Disease (RISC) randomized 796 men with unstable angina or non-Q-wave infarction within 4 weeks to aspirin 75 mg/day or placebo.[166] An additional 115 men were excluded per the protocol because their predischarge exercise tests revealed no evidence of myocardial ischemia. Aspirin reduced the risk of death and nonfatal infarction in both unstable angina and non-Q-wave infarction categories. At 5 days, the reduction was from 5.8 percent to 2.55 percent (p = .033), and at 30 days it was from 17.1 percent to 6.5 percent (p = .0001).

The results of these trials are remarkably consistent, and the risk reduction with aspirin for the prevention of death or nonfatal infarction is relatively large: from one-half to two-thirds. These findings attest to the central role platelets play in the pathophysiology of unstable angina. These studies show that the benefit from aspirin begins with the onset of unstable angina and extends for more than 1 year. Other trials have demonstrated that

aspirin reduces the risk of infarction in stable coronary patients, and so the drug should be continued for life after an episode of unstable angina. The dose of aspirin used in these trials ranged from 75 to 1300 mg/day. Gastrointestinal side effects increase with increasing dose levels. A dose of 325 mg acutely and a dose of 81 mg during chronic treatment are sufficient to inhibit the platelet cyclooxygenase pathway maximally.

Women were excluded from two of the four trials[163,166] and represented one-quarter to one-third of the patients in the other two studies.[164,165] However, it seems reasonable to assume that the benefit of aspirin extends to women with unstable angina, particularly since aspirin has been shown to reduce coronary events across the broad spectrum of patients with atherosclerosis.

The Antiplatelet Trialists' Collaboration meta-analysis of 145 trials with more than 100,000 patients randomized to antiplatelet therapy or placebo showed consistent benefit in cerebrovascular disease and stable and unstable coronary disease.[167] Almost all the antiplatelet therapy in these trials consisted of aspirin. Few treatments show a cost/benefit ratio that is superior to that of aspirin in the treatment of unstable angina.

Angiotensin-converting enzyme (ACE) inhibitors promote the release of prostaglandins, and inhibition of prostaglandin synthesis with aspirin or other nonsteroidal anti-inflammatory drugs attenuates the acute vasodilatory effect of ACE inhibition. In the SOLVED trial,[168] the CONSENSUS II trial,[169] and the GUSTO-1 trial,[170] a negative interaction between aspirin and ACE inhibitors was reported. However, in a data base of 11,576 patients with coronary disease, 5-year adjusted mortality was lower in ACE inhibitor-treated patients who also took aspirin than it was in those who did not in the presence or absence of heart failure.[171] On the basis of the information that is currently available, it appears reasonable not to withhold aspirin from coronary patients who are receiving ACE inhibitors in the absence of severe heart failure.

Ticlopidine and Clopidogrel

Ticlopidine and clopidogrel are thienopyridines, and their mechanism of action differs from that of aspirin (Fig. 41-7). Both drugs inhibit adenosine diphosphate (ADP)-mediated platelet activation.[172] Because they act independently of the arachidonic acid pathway, the antiplatelet activities of aspirin and either ticlopidine or clopidogrel are synergistic. Ticlopidine induces neutropenia in 1 to 3 percent of patients and also rarely causes severe adverse dermatologic effects. The drug also is limited by its slow onset of action: 3 to 4 days for the inhibition of platelet aggregation to exceed 50 percent and up to 2 weeks for the effect to plateau. The effect of ticlopidine also persists after treatment has been discontinued.

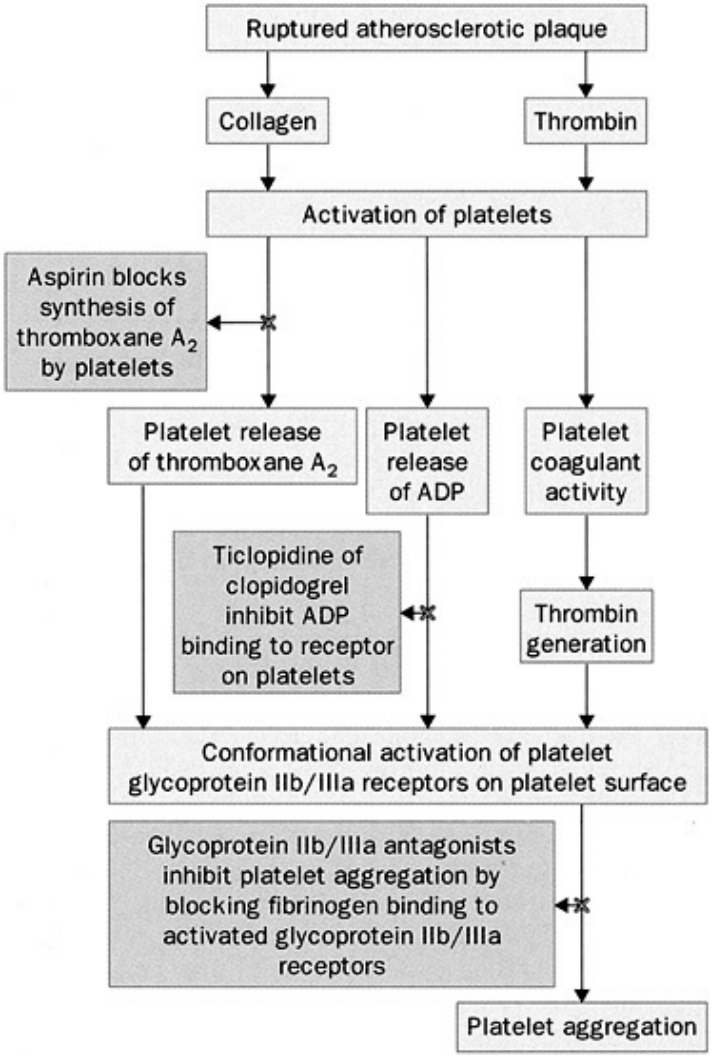

Figure 41-7: Sites of action of platelet inhibitors. (From Hirsh and Weitz,[219] with permission.)

Ticlopidine 250 mg twice per day was compared to conventional antianginal therapy without aspirin in a randomized but open-label trial in 652 unstable angina patients.[173] Over a 6-month follow-up period, the rate of fatal or nonfatal infarction was 7.3 percent in the ticlopidine group and 13.6 percent in controls, a 46 percent reduction (p = .009). However, the benefit of treatment developed only after 2 weeks; this is consistent with the known delayed onset of action of the drug. On the basis of this trial, ticlopidine has been considered as an alternative in unstable angina patients who cannot tolerate aspirin. Ticlopidine has been widely used with aspirin to prevent thrombotic complications in the weeks after coronary stenting, based on clinical trial evidence that it is superior to aspirin alone in this situation.[174] However, ticlopidine is rapidly being supplanted by clopidogrel for this indication because of the better safety profile of clopidogrel.

Clopidogrel is more potent than ticlopidine in inhibiting ADP-induced platelet aggregation in vitro and has a more rapid onset of action. Within 2 h of oral administration, antiplatelet activity can be detected, and the effect on platelet aggregation becomes maximal between 4 and 7 days. The usual dose is 75 mg once daily. The utility of clopidogrel in treating unstable angina is being assessed in a randomized clinical trial. In the *Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, clopidogrel reduced the combined end point of ischemic stroke, myocardial infarction, and vascular death by 8.7 percent (p = .043) for up to 3 years compared with aspirin in 19,185 patients with vascular disease.[175] Patients with peripheral arterial disease appeared to benefit more than did patients with previous infarction or stroke. The risk of gastrointestinal hemorrhage severe enough to stop the drug was higher with clopidogrel than it was with aspirin but was still less than 1 percent. Clopidogrel is not associated with the increased potential for neutropenia seen with ticlopidine. For these reasons, clopidogrel is preferred over ticlopidine in patients with unstable angina who do not tolerate aspirin.

Platelet Glycoprotein IIb/IIIa Receptor Inhibitors

Platelet membranes contain glycoprotein receptors, many of which are integrins.[176] Integrins are heterodimeric molecules composed of alpha and beta subunits. These subunits are combined in unique patterns to form receptors specific for various ligands. The $\alpha_{IIb}\beta_3$ integrin, or platelet IIb/IIIa receptor (Fig. 41-8), changes from its resting state to its active state when the platelet is activated by agonists or other platelets and serves as a receptor for fibrinogen and von Willebrand factor.[176] Fibrinogen binding is central to platelet aggregation and thrombus formation in the arterial circulation.

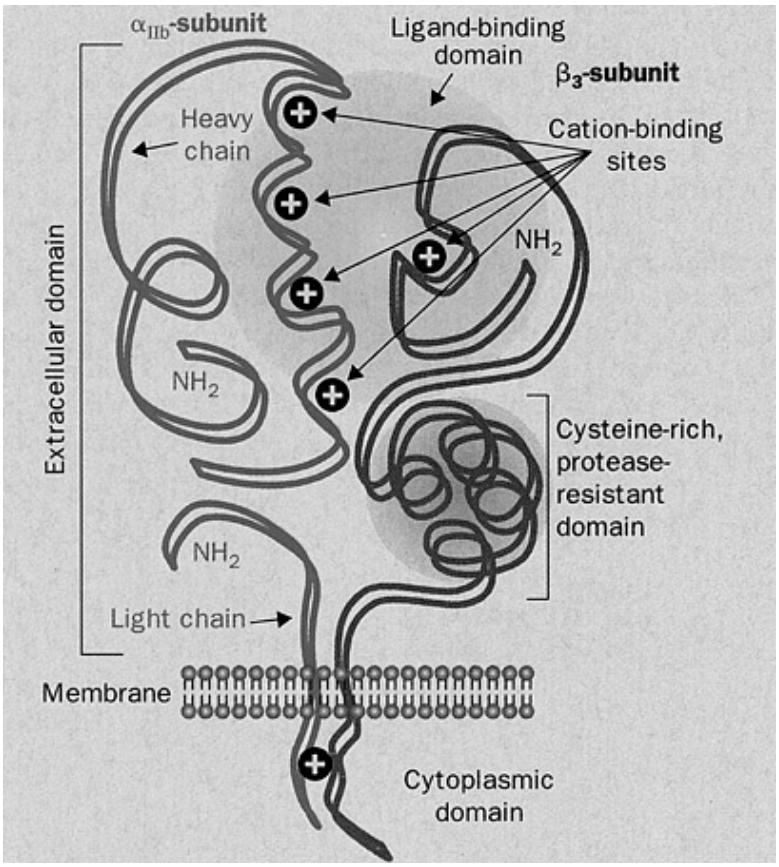

Figure 41-8: Schematic representation of the $\alpha_{IIb}\beta_3$ integrin, or the platelet IIb/IIIa receptor. (From Topol et al.,[176] with permission.)

Blockade of the platelet GP IIb/IIIa receptor is a theoretically attractive concept. Unlike aspirin and clopidogrel, which do not block thrombin-induced platelet aggregation, GP IIb/IIIa inhibitors block aggregation in response to all potential agonists (Fig. 41-7). Different receptors, GP Ib and GP IV, mediate platelet adhesion to the subendothelial matrix. Thus, hemorrhage should not be a major problem even with complete blockade of GP IIb/IIIa receptors.[176]

The first GP IIb/IIIa blocker to be approved and widely used clinically is abciximab, the Fab fragment of a monoclonal antibody to the $\alpha_{IIb}\beta_3$ integrin. Other GP IIb/IIIa inhibitors are either peptides or smaller molecules. Eptifibatide is the peptide GP IIb/IIIa inhibitor that has been approved for use in the United States. Tirofiban, lamifiban, fradafiban, xemilofiban, orbofiban, sibrafiban, roxifiban, lotrafiban, and lefradiban are all small-molecule GP IIb/IIIa inhibitors. Only tirofiban has been approved for use in the United States, but several of the other drugs are in the later stages of clinical development. All the currently approved drugs must be administered by parenteral infusion, but the last six compounds on the above list of small-molecule GP IIb/IIIa inhibitors will be for oral use.

Coronary Intervention Trials with GP IIb/IIIa Inhibitors

Platelet GP IIb/IIIa inhibitors have been evaluated mainly in patients with acute coronary syndromes (including

unstable angina and NSTEMI patients), patients undergoing coronary angioplasty, and patients in both categories (Fig. 41-9). The *Evaluation of c7E3 Fab for Prevention of Ischemic Complications (EPIC) trial enrolled 2099 patients considered at high risk for coronary angioplasty, including patients with unstable angina.[177] All these patients were treated with aspirin and heparin, and randomization was to placebo, a weight-adjusted abciximab bolus, or a bolus followed by an infusion of abciximab for 12 h. The primary end point was a composite of death, myocardial infarction, urgent repeat revascularization, or stent or balloon pump placement within 30 days after randomization. The event rate was 12.8 percent in the placebo group, 11.4 percent with bolus abciximab, and 8.3 percent in the bolus plus infusion group (p = .008 versus placebo). Benefit was most pronounced in unstable angina patients, with a 71 percent decrease in the primary end point and a 94 percent decrease in death or myocardial infarction (11.1 percent placebo versus 0.6 percent bolus plus infusion group, p < .0001). The benefit of abciximab in the EPIC patients persisted to 6 months[178] and 3 years.[179]

The Evaluation in PTCA to Improve Long-Term Outcome with abciximab GP IIb/IIIa blockade (EPILOG) trial compared a bolus plus 12-h infusion of abciximab to placebo in all but high-risk patients undergoing coronary angioplasty.[180] EPILOG is thus complementary to EPIC. Nearly half the EPILOG patients had unstable angina as their diagnosis, but patients with ECG changes within the 24 h preceding randomization were excluded. Randomization was to placebo plus standard-dose heparin and to abciximab with low-dose or standard-dose heparin. EPILOG was stopped after 2792 of the planned 4800 patients were enrolled because the composite end point of death, infarction, or urgent revascularization at 30 days was 11.7 percent in the placebo group and 5.2 percent and 5.4 percent in the abciximab groups (p < .0001). The clinical benefit of abciximab in EPILOG was maintained to 1 year.[181] Among unstable angina patients, the end point of death, myocardial infarction, or urgent intervention at 1 year was reached by 16.8 percent in the placebo group and 9.0 percent in the abciximab groups. Taken together, EPIC and EPILOG firmly established that abciximab reduces the rate of coronary events across a broad range of patients undergoing coronary angioplasty, including those with unstable angina.

The c7E3 Fab Antiplatelet Therapy in Unstable Refractory Angina (CAPTURE) trial differed from EPIC and EPILOG in that it evaluated pretreatment with abciximab before coronary angioplasty among high-risk unstable angina patients.[182] To qualify, patients had to have chest pain with ischemic ECG changes within 48 h despite intravenous heparin and intravenous glyceryl trinitrate. All these patients also received aspirin and heparin. Placebo or abciximab bolus plus infusion was begun 18 to 24 h before angioplasty and continued until 1 h after the procedure. After the enrollment of 1265 patients, the trial was stopped prematurely. The primary end point-death, myocardial infarction, or urgent intervention within 30 days-was reached by 15.9 percent of placebo patients and 11.3 percent of abciximab patients (p =.012). Clinical benefit developed before the angioplasty procedure (Fig. 41-10): The infarction rate during this short interval was 2.6 percent among placebo-treated patients and 0.6 percent among abciximab-treated patients (p = .029). In contrast to the EPIC and EPILOG trials, the benefit of abciximab treatment in CAPTURE was attenuated by 6 months.

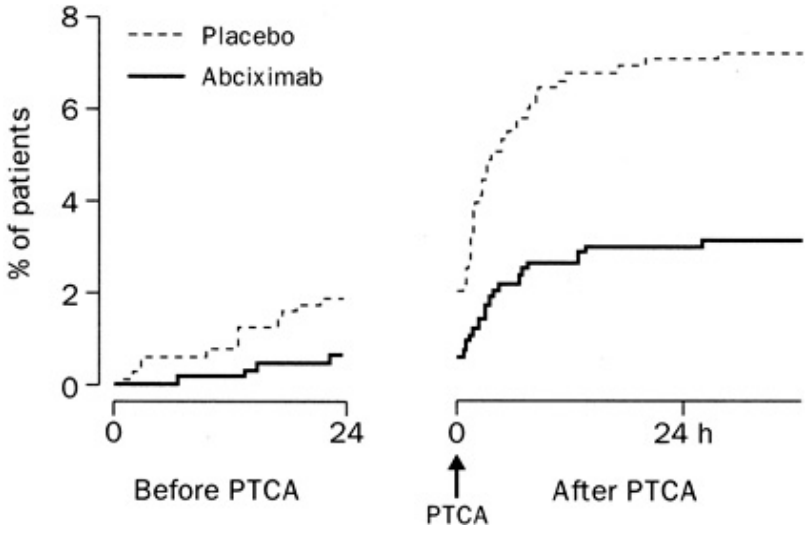

Figure 41-10: Reduction in the incidence of myocardial infarction with abciximab in the CAPTURE trial.[182] The benefit of abciximab was present both in the first 24 h before angioplasty (p = .029) and during and for the 24 h after angioplasty (p = .021). (From CAPTURE investigators,[182] with permission.)

Abciximab and coronary stenting were assessed in a wide spectrum of patients undergoing angioplasty in the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting (EPISTENT) trial.[183] Slightly more than one-third of the 2399 EPISTENT patients had unstable angina within 48 h. Randomization was to stenting plus placebo, stenting plus abciximab (bolus plus 12-h infusion), or balloon angioplasty plus abciximab. The primary end point-a composite of death, myocardial infarction, or the need for urgent revascularization within 30 days-occurred at a rate of 10.8 percent in the stent/placebo group, 5.3 percent in the stent/abciximab group (odds ratio 0.48, 95 percent confidence interval 0.33 to 0.69), and 6.9 percent in the balloon/abciximab group (odds ratio 0.63, 95 percent confidence interval 0.45 to 0.88). By 6 months, death or myocardial infarction had occurred in 11.4 percent of the stent/placebo group, 5.6 percent of the stent/abciximab group (odds ratio 0.47, 95 percent confidence interval 0.33 to 0.68, $p < .001$), and 7.8 percent of the balloon/abciximab group (odds ratio 0.67, 95 percent confidence interval 0.49 to 0.92, $p = .01$).[184] EPISTENT demonstrated that the benefit of abciximab during angioplasty extends to patients who receive elective stents.

The Second Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis (IMPACT-II) trial evaluated eptifibatide in 4010 patients undergoing angioplasty.[185] Patients received aspirin and heparin and were randomized to placebo, a bolus of eptifibatide followed by a lower-dose infusion for 20 to 24 h, or a bolus plus a higher-dose infusion. In each treatment group, 38 percent of patients had unstable angina. The primary end point was the 30-day composite of death, myocardial infarction, unplanned revascularization, or stenting for abrupt closure. The primary end point occurred in 11.4 percent of placebo patients, 9.2 percent of lower-dose infusion patients (odds ratio 0.79, 95 percent confidence interval 0.61 to 1.01, $p = .063$), and 9.9 percent of higher-dose infusion patients (odds ratio 0.86, 95 percent confidence interval 0.67 to 1.10, $p = .22$). The benefit seen in IMPACT-II with eptifibatide was thus of borderline statistical significance and was less impressive than the results seen with abciximab in EPIC, EPILOG, CAPTURE, and EPISTENT (Fig. 41-9).

The Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis (RESTORE) trial evaluated the small-molecule GP IIb/IIIa inhibitor tirofiban in 2139 patients with acute coronary syndromes who were undergoing angioplasty.[186] Two-thirds of the patients had unstable angina. All were treated with aspirin and heparin. Tirofiban or placebo was begun after the lesion was crossed with the guidewire and was continued for 36 h, longer than in the other trials, because of the rapid reversibility of platelet inhibition with tirofiban. The primary end point was a composite similar but not identical to the preceding trials: death, infarction, repeat target lesion angioplasty, coronary bypass surgery, or coronary stenting by 30 days. Although a statistically significant reduction in events was seen with tirofiban at day 2 and day 5 after the procedure, by 30 days (the primary end point), the rate was 12.2 percent in the placebo group and 10.3 percent in the tirofiban group, a 16 percent relative reduction ($p = .16$).

Taken together, these trials indicate that platelet GP IIb/IIIa inhibition at the time of angioplasty reduces ischemic complications. The benefit with respect to the primary end point of the trials was less with eptifibatide and tirofiban (15 to 20 percent) than with abciximab (30 to 60 percent); however, the 95 percent confidence intervals overlap, and the drugs have not been compared directly in the same trial. If variability in efficacy does exist, potential explanations might be that abciximab gradually dissociates from the GP IIb/IIIa receptor over 36 h after the drug is discontinued, that abciximab also blocks the $\alpha_v\beta_3$ vitronectin receptor, or that the dose of eptifibatide selected for IMPACT-II was too low. The risk of hemorrhage during angioplasty with GP IIb/IIIa inhibitors can be reduced by early sheath removal, meticulous care of arterial puncture sites, and lower, weight-adjusted doses of heparin than were used traditionally.

Acute Coronary Syndrome Trials with GP IIb/IIIa Inhibitors

In addition to the six large trials discussed above in which GP IIb/IIIa inhibitors were tested during coronary angioplasty, four large trials have assessed the value of these drugs in patients with unstable angina or non-Q-wave myocardial infarction (also known as NSTEMI). Whereas abciximab was the drug used most frequently in the angioplasty trials, eptifibatide and the small-molecule GP IIb/IIIa inhibitors predominated in the acute coronary syndrome trials (Fig. 41-9).

The Platelet Receptor Inhibition in Ischemic Syndrome Management (PRISM) study enrolled 3232 patients with an acute coronary syndrome including chest pain within 24 h.[187] One-quarter of these patients had non-Q-wave infarction, and the remainder had unstable angina with ECG abnormalities. With aspirin as baseline therapy, patients were randomized according to a double-blind protocol either to a weight-adjusted bolus plus infusion of tirofiban or to a bolus and infusion of heparin to maintain the activated partial thromboplastin time at twice the

control value. Treatment continued for 48 h, and the primary end point was a composite of death, myocardial infarction, or refractory ischemia during this period. The end point was reached by 5.6 percent of heparin-treated patients and 3.8 percent of tirofiban-treated patients (odds ratio 0.67, 95 percent confidence interval 0.48 to 0.92, $p = .01$). By 30 days, the primary end point with the addition of readmission for unstable angina was 17.1 percent in the heparin group and 15.9 percent in the tirofiban group, a difference that was not statistically significant. However, mortality at 30 days was lower in the tirofiban group at 2.3 percent compared with 3.6 percent ($p = .02$).

The Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study enrolled 1915 unstable angina and non-Q-wave infarction patients with prolonged or repetitive chest pains within 12 h and ECG changes.[188] Study treatment was continued for 72 h, and coronary angioplasty was done in 475 of the patients between 48 and 72 h. Randomization was to tirofiban, heparin, or tirofiban plus heparin, with all patients receiving aspirin unless it was contraindicated. The tirofiban bolus and infusion doses were one-third lower in patients treated with heparin than they were in those treated with tirofiban alone. The study was stopped prematurely for the group receiving tirofiban alone because of excess mortality at 7 days: 4.6 percent versus 1.1 percent among patients receiving heparin alone ($p = .012$). This early increase in mortality was explained by the investigators as most likely being due to chance, since no such increase was seen in PRISM. The frequency of the primary end point at 7 days-a composite of death, myocardial infarction, or refractory ischemia-was 17.9 percent in the heparin group and 12.9 percent in the heparin plus tirofiban group (odds ratio 0.68, 95 percent confidence interval 0.53 to 0.88, $p = .004$). This advantage persisted to 30 days and to 6 months. Death or myocardial infarction occurred within 7 days in 8.3 percent of the heparin-only patients and 4.9 percent of the heparin and tirofiban group ($p = .006$). This absolute difference of 3.6 percent narrowed slightly to 3.0 percent by 6 months, when the rates of death and infarction were 15.3 percent and 12.3 percent ($p = .06$). In the subset of patients who underwent angioplasty between 48 and 72 h, the risk of death, infarction, refractory ischemia, or rehospitalization for unstable angina over the next 30 days was reduced from 15.3 percent to 8.8 percent with combination therapy compared with heparin alone (odds ratio 0.55, 95 percent confidence interval 0.32 to 0.94). The benefit of combination therapy over heparin alone was of roughly equal magnitude in patients with unstable angina or non-Q-wave infarction.

The findings of PRISM and PRISM-PLUS are somewhat contradictory. PRISM indicates that tirofiban may be superior to heparin as acute therapy for unstable angina in patients taking aspirin. PRISM-PLUS suggests that the combination of aspirin, heparin, and tirofiban is superior to aspirin and heparin. The benefit of tirofiban added to aspirin and heparin among angioplasty patients in PRISM-PLUS was of greater magnitude and lasted longer than the benefit seen with this combination of treatment in RESTORE. However, the results of RESTORE are more credible because the number of patients was much larger: 2139 compared with 475 angioplasty patients in PRISM-PLUS. Pretreatment and selection biases might have influenced the angioplasty subgroup in PRISM-PLUS.

The Platelet glycoprotein IIb/IIIa in Unstable Angina Receptor Suppression Using Integrilin Therapy (PURSUIT) trial enrolled 10,948 patients with unstable angina or non-Q-wave infarction to eptifibatide or placebo.[189] Baseline therapy consisted of aspirin and heparin. Study drug treatment lasted for 3 days, with an additional day if coronary intervention was done near 72 h. The primary end point, a composite of death or nonfatal myocardial infarction at 30 days, was 15.7 percent in the placebo group and 14.2 percent in the eptifibatide group ($p = .04$). The treatment effect occurred consistently across most subgroups except for women, who had a statistically nonsignificant 10 percent higher event rate with eptifibatide. The absolute risk reduction of 1.5 percent was less than the 3.2 percent absolute risk reduction seen in PRISM-PLUS (Fig. 41-9). The Platelet IIb/IIIa Antagonism for the Reduction of Acute coronary syndrome events in a Global Organization Network (PARAGON) trial tested lamifiban, a small-molecule GP IIb/IIIa inhibitor that has not yet been approved for use in the United States.[190] Low-dose lamifiban and high-dose lamifiban, with and without heparin, were compared to a placebo plus heparin group. All patients received aspirin. A total of 2282 patients with unstable angina and ECG changes were enrolled. The primary end point of death or myocardial infarction at 30 days occurred at a rate of 11.7 percent in the placebo group, 10.6 percent in the low-dose lamifiban group, and 12.0 percent in the high-dose lamifiban group. These differences were not statistically significant. At 6 months, the composite event rate was 13.7 percent for the low-dose lamifiban group compared with 17.9 percent for controls ($p = .027$). The high-dose lamifiban plus heparin group experienced more intermediate or major bleeding than did controls: 12.1 percent compared with 5.5 percent ($p = .002$).

The oral small-molecule GP IIb/IIIa inhibitors have failed to reduce coronary events in three large, recently completed trials.[191,192,192a] In the Sibrafiban versus Aspirin to Yield Maximum Protection from Ischemic Heart

Events Post-acute Coronary Syndromes (SYMPHONY) study,[191] 9233 patients who had stabilized after an acute coronary syndrome were randomly assigned to aspirin, low-dose sibrafiban, or high-dose sibrafiban. The primary end point was a composite of death, nonfatal infarction, or severe recurrent ischemia at 90 days. Sibrafiban showed no additional benefit over aspirin, and was associated with more dose-related bleeding.

In the Evaluation of Oral Xemilofiban in Controlling Thrombotic Events (EXCITE) trial,[192] 7232 patients were randomized to placebo or oral xemilofiban beginning just before coronary angioplasty and continuing for 182 days. This trial was not limited to patients with unstable angina. The primary end point (a composite of death, nonfatal infarction, or urgent revascularization) was not reduced by active treatment. The Orbofiban in Patients with Unstable Coronary Syndromes-Thrombolysis in Myocardial Infarction 16 (OPUS-TIMI 16) trial[192a] enrolled 10,302 unstable angina patients to either of two doses of orbofiban or placebo. The trial was halted early because of excess mortality in one of the active treatment groups. The composite end point was not reduced by either dose of orbofiban at either 30 days or 10 months. The reason for the early increase in mortality is unclear, but may be related to intermittent platelet activation with the oral GP IIb/IIIa platelet inhibitors.

Guidelines for the Use of GP IIb/IIIa Inhibitors

Although GP IIb/IIIa inhibitors have firmly established their usefulness in a wide spectrum of patients undergoing coronary angioplasty, their value in unstable angina patients who are not undergoing intervention is incompletely defined. GP IIb/IIIa inhibitors have not been compared to clopidogrel or to low-molecular-weight heparins or studied in patients taking these drugs as background therapy.

The current high cost of these drugs makes it tempting to limit their use to high-risk patients. In a subgroup analysis from the CAPTURE study,[193] patients with troponin T elevations at study entry had a high event rate and derived a large benefit from abciximab therapy (odds ratio for death or myocardial infarction 0.32, 95 percent confidence interval 0.14 to 0.62, $p = .002$). Patients without elevated troponin T levels experienced a low event rate and did not benefit from abciximab.

Current guidelines recommend that eptifibatide or tirofiban be added to aspirin and heparin in the treatment of patients with some high-risk features or with refractory ischemia.[1] These drugs should be continued during coronary angioplasty and for 12 to 24 h after the procedure for tirofiban and for 24 to 72 h after the procedure for eptifibatide.[1] Abciximab also can be used in patients with unstable angina in whom angioplasty is planned within the following 24 h.[1] However, when abciximab is administered before diagnostic coronary angiography, the prolonged platelet inhibition it induces may force a delay in the urgent coronary bypass surgery that is needed for some patients. When aspirin and unfractionated heparin are used with GP IIb/IIIa inhibitors, the dose of heparin should be conservative during coronary procedures, and heparin should be discontinued after the procedure if it is uncomplicated.[1]

Heparin

Heparin binds with antithrombin to form a complex that inactivates thrombin and activated factors X, XII, XI, and IX.[194] The principal inhibitory effect of heparin on coagulation probably occurs through the inhibition of thrombin-induced activation of factor V and factor VIII. Fibrin binds thrombin and protects it from inactivation by the heparin-antithrombin complex. Platelets inhibit the anticoagulant effect of heparin by binding factor Xa and protecting it from inactivation.

The pharmacokinetics of heparin are complex, and the dose-response relationship is nonlinear. Heparin therapy is monitored to maintain the activated partial thromboplastin time (APTT) ratio within 1.5 to 2.5 times normal. The anticoagulant response to a standard dose of heparin varies widely among patients so that even when a weight-based nomogram is used in a clinical study, the APTT falls outside the therapeutic range more than one-third of the time.[195] Results in routine clinical practice are probably much worse. Pooled analyses of randomized trials have revealed an average incidence of major bleeding of 6.8 percent in continuous-infusion groups and 14.2 percent in intermittent-infusion groups (odds ratio 0.42, $p = .01$).[196]

Heparin was used to treat patients with unstable angina before that diagnostic term was used commonly,[2] but good clinical trial data in support of its use did not emerge until the 1980s (Table 41-8). In a randomized, double-blind, placebo-controlled trial of 214 patients with unstable angina, myocardial infarction developed

during 7 days of treatment in 9 (17 percent) of 54 patients taking placebo, 8 (13 percent) of 60 taking atenolol, 1 (2 percent) of 51 receiving heparin, and 2 (4 percent) of 49 on combined therapy.[197] The improved prognosis of heparin-treated patients was maintained during follow-up, and all five deaths occurred among patients who did not receive heparin. The impact of this trial was attenuated by a design problem in that 186 additional patients were withdrawn after randomization because of incorrect recruitment.

Théroux and colleagues randomized 479 patients with unstable angina to aspirin, heparin, combination therapy, or double placebo a mean of 8 h after the last episode of chest pain, with a mean follow-up of 6 days.[165] The results of this trial with respect to aspirin were discussed earlier in this chapter. The incidence of death or nonfatal myocardial infarction was reduced dramatically with heparin from 14 of 118 patients in the placebo group to 3 of 240 in the heparin groups (11.9 percent versus 1.25 percent, $p < .001$). Heparin also reduced the frequency of refractory angina 60 percent. The combination of heparin and aspirin was not superior to aspirin alone in the prevention of death or nonfatal infarction. In an extension of the trial, heparin and aspirin were compared directly in a total of 484 patients.[198] Death or myocardial infarction occurred in 3.7 percent of aspirin-treated patients and 0.8 percent of heparin-treated patients ($p = .035$).

Aspirin and heparin also were tested in a factorial design in the RISC trial.[166] RISC enrolled 796 men with unstable angina or non-Q-wave infarction. As was discussed above, aspirin exhibited a marked protective effect in this study. The effect of heparin on the event rate was not statistically significant, although a trend in its favor was seen during the 5 days in which it was administered. In two smaller trials comparing aspirin to aspirin plus heparin, no difference was seen between the treatment groups.[199,200] The Antithrombotic Therapy in Acute Coronary Syndromes (ATACS) trial randomized 69 patients in a pilot study and 214 patients in the main trial to aspirin alone or to aspirin plus heparin followed by warfarin.[201,202] The composite end point of recurrent angina with ECG changes, myocardial infarction, or death within 12 weeks was reduced in the main trial by combination therapy from 27 percent to 10.5 percent ($p = .004$). A meta-analysis of these trials concluded that the addition of heparin to aspirin in the treatment of unstable angina reduces the rate of myocardial infarction approximately one-third.[203]

The way in which heparin is administered may influence its efficacy in treating unstable angina. In a trial of unstable angina patients who were refractory to medical therapy, heparin significantly decreased the frequency of angina attacks and the number of episodes of silent myocardial ischemia when it was administered as a bolus followed by an infusion but not when it was given as a bolus every 6 h.[204] In another study of refractory unstable angina patients done by the same investigators, both subcutaneous heparin and heparin given as a bolus and an infusion profoundly reduced the frequency of myocardial ischemic episodes.[205]

Discontinuation of heparin in unstable angina patients can results in a reactivation of refractory ischemic episodes within hours.[206] Aspirin or warfarin may block this phenomenon. Rebound has been described with other thrombin inhibitors, but the mechanism has not been defined. However, it has been shown that thrombin generation increases and tissue factor pathway inhibitor levels decrease within 24 h of heparin cessation.[207] Gradual weaning from heparin, as opposed to abrupt cessation, results in less thrombin generation.[207] Mild thrombocytopenia occurs in 10 to 20 percent of patients treated with unfractionated heparin.[208] In 2 to 10 percent of patients, a more severe form of thrombocytopenia develops. This antibody-mediated response occurs within 5 to 10 days after the initiation of treatment and is associated with thromboembolic sequelae in 30 to 80 percent of cases.[208] Other adverse effects of heparin include osteoporosis, skin necrosis, alopecia, hypersensitivity reactions, and hypoaldosteronism.[196]

Low-Molecular-Weight Heparins

Unfractionated heparin consists of a heterogeneous mixture of polysaccharide chains ranging in molecular weight from approximately 3000 to 30,000. Low-molecular-weight heparins (LMWHs) are fragments of unfractionated heparin produced by enzymatic or chemical depolymerization processes that yield chains with average molecular weights of approximately 5000.[209] The main difference between the two types of heparin is that unfractionated heparin has equivalent activity against factor Xa and thrombin while LMWHs have greater activity against factor Xa.[209] The reason for this difference is that long heparin chains such as those present predominantly in regular heparin are required to bind both antithrombin and thrombin(Fig. 41-11).

Both types of heparin interfere with thrombin-induced platelet activation by inhibiting the thrombin-glycoprotein Ib interaction, but standard heparin is more potent than LMWHs in this regard.[210] However, a

disadvantage of regular heparin is that it inhibits activation of the protein C anticoagulant pathway more than a LMWH does.[211]

Compared with unfractionated heparin, LMWHs produce a more predictable anticoagulant response because of their better bioavailability, longer half-life, and dose-independent clearance.[209] The plasma half-life of a LMWH after subcutaneous injection ranges from 3 to 6 h, and so once- or twice-daily administration is feasible. In contrast to unfractionated heparin, monitoring is not required with the use of LMWHs, with the possible exception of plasma antifactor Xa levels in patients with renal insufficiency.[209] LMWH caused less bleeding than unfractionated heparin did in laboratory animal experiments and in some clinical trials.[209] The main disadvantage of LMWHs is that they are far more expensive than unfractionated heparin.

LMWHs are somewhat more effective than standard heparin in preventing deep vein thrombosis after general or orthopedic surgery, according to meta-analyses of clinical trials.[195] Thrombus size by venography and a small trial in patients with established venous thrombosis showed better outcomes with LMWHs compared with unfractionated heparin.[195] In light of these encouraging findings and the obvious practical advantages of LMWHs, trials of LMWHs for unstable angina were anticipated with enthusiasm.

The first of these trials, a small open-label trial, showed that LMWHs plus aspirin reduced the risk of myocardial infarction better than did standard heparin plus aspirin or aspirin alone.[200] In a more definitive trial, the Fragmin during Instability in Coronary Artery Disease (FRISC) study, 1506 patients with unstable angina or non-Q-wave myocardial infarction were randomly assigned to a weight-adjusted dose of the LMWH dalteparin twice daily or to placebo.[212] After 6 days, the dose was changed to 7500 IU once daily and was continued for 35 to 45 days. All patients without contraindications took aspirin. The primary end point-the rate of death or myocardial infarction during the first 6 days-was reduced with dalteparin (odds ratio 0.37, 95 percent confidence interval 0.20 to 0.68). The benefit of treatment persisted to 40 days but was attenuated, mainly because of an increase in events among smokers in the active treatment group after the dose was reduced from twice daily to once daily. The results of FRISC demonstrated that LMWH is superior to placebo in aspirin-treated patients with unstable angina, but a more important issue is how LMWH compares with intravenous unfractionated heparin.

The Fragmin in Unstable Coronary Artery Disease (FRIC) study was the first trial to address this question. In the open-label, acute phase of FRIC, 1482 patients with unstable angina or non-Q-wave infarction were randomized to either dalteparin, administered as in FRISC, or doseadjusted intravenous standard heparin for 6 days.[213] All the patients received aspirin. The primary end point-a composite of death, myocardial infarction, or recurrence of angina-was 9.3 percent in the dalteparin group and 7.6 percent in the standard heparin group. Although this difference is not statistically significant, fewer deaths occurred in the unfractionated heparin group (3 versus 11, $p = .05$). After 6 days, most of the patients continued to the double-blind phase of the trial, in which they were treated from days 6 to 45 with dalteparin 7500 IU subcutaneously once daily or with placebo. During this period, the composite end point was 12.3 percent in both groups. The authors concluded that dalteparin at this dose during the month after hospital discharge provided no additional benefit over aspirin but speculated that twice-daily treatment might.

Thus, in the Fragmin and Fast Revascularisation during Instability in Coronary artery disease (FRISC II) trial, 2267 patients with unstable angina or non-Q-wave infarction were randomly assigned to subcutaneous dalteparin twice daily or to placebo for 3 months after at least 5 days of treatment with open-label dalteparin.[214] Half the patients had ST depression at study entry, and more than half had troponin T elevations. After 30 days, the rate of death or nonfatal infarction was 3.1 percent with dalteparin and 5.9 percent with placebo (odds ratio 0.53, 95 percent confidence interval 0.35 to 0.80). However, by 3 months this difference had shrunk to 6.7 percent versus 8.0 percent, which was not statistically significant. In the subgroup with elevated troponin T levels at baseline, dalteparin reduced the relative risk of death or infarction to 3 months by 30 percent and the absolute risk by 2.7 percent ($p = .07$). In troponin-negative patients, treatment beyond 5 days with dalteparin showed no benefit.

The Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) study randomly assigned 3171 patients with unstable angina or non-Q-wave infarction to enoxaparin 1 mg/kg subcutaneously twice daily or to continuous unfractionated heparin for a period of 2 to 8 days.[215] All the patients received aspirin. The primary end point-a composite or death, myocardial infarction, or recurrent angina at 14 days-was 16.6 percent with enoxaparin and 19.8 percent with regular heparin ($p = .019$). This difference

persisted to 30 days, and the need for revascularization to this point also was reduced significantly with enoxaparin. An economic substudy indicated that total medical costs to 1 month were lower in enoxaparin-treated patients because the added cost of the drug was more than compensated for by savings from reduced events.[216]

The Thrombolysis in Myocardial Infarction (TIMI) 11B trial randomly assigned 3910 patients with unstable angina or non-Q-wave infarction to enoxaparin or standard heparin for 3 to 8 days, with 60 percent of the population continuing treatment with enoxaparin or placebo for 43 days.[217] Enoxaparin reduced events compared with unfractionated heparin during the acute phase of the trial (odds ratio 0.83, 95 percent confidence interval 0.69 to 1.00, $p = .048$). No additional benefit or loss of benefit was seen with continued therapy. In another trial, 3468 patients with unstable coronary disease were allocated randomly to unfractionated heparin or to 6 days or 14 days of treatment with the LMWH nadroparin.[218] No benefit of the LMWH was seen in this study; in fact, at 3 months the composite end point of death, infarction, or refractory ischemia occurred in 22.2 percent of unfractionated heparin patients, 22.3 percent of those in the 6-day LMWH group, and 26.2 percent of those in the 14-day treatment group ($p = .03$).

In summary, trials of LMWH in unstable angina and non-Q-wave infarction have yielded conflicting results (Table 41-9). Two trials, ESSENCE and TIMI 11B, demonstrated that enoxaparin is superior to unfractionated heparin for the first few days of therapy. The only acute comparison between dalteparin and standard heparin, FRIC, had inadequate statistical power to detect a difference between treatments. Theoretically, enoxaparin may be superior to dalteparin because of its higher anti-factor Xa to anti-factor IIa ratio. The early benefit of LMWH treatment appears to dissipate over the ensuing months, and continuing therapy was not beneficial in most trials. However, in FRISC II, treatment from 5 days to 3 months with dalteparin produced an impressive reduction in death or infarction at 1 month, with gradual loss of that benefit thereafter.

Table 41-9: Major Clinical Trials of Low-Molecular-Weight Heparins (LMWH) in Patients with Unstable Angina or Non-Q-Wave Infarction

Trial	LMWH	No. Patients	Duration of Follow-Up	Death/MI Rate in LMWH Group, %	Death/MI Rate in Control Group[a], %	Relative Risk (RR) (95% Confidence Interval)	Comments
FRISC-I[212]	Dalteparin	1506	6 days	1.8	4.8	0.37 (0.20-0.68)	At 40 days, death/MI reduced from 10.7% to 8.0%; RR 0.75 (0.54-1.03)
FRIC[213]	Dalteparin	1482	6 days	3.9	3.6	1.07 (0.63-1.80)	From days 6-45, death/MI reduced from 4.7% to 4.3%; RR 0.92 (0.54-1.57)
FRISC-II[214]	Dalteparin	2267	3 months	6.7	8.0	0.81 (0.60-1.10)	At 30 days, death/MI reduced from 5.9% to 3.1%; RR 0.53 (0.35-0.80)
ESSENCE[215]	Enoxaparin	3171	14 days	4.9	6.1	0.80 ($p = .13$)	Death/MI/recurrent angina reduced from 19.8% to 16.6%; RR 0.80 (0.67-0.96)
TIMI-11B[217]	Enoxaparin	3910	8 days	4.6	5.9	0.77 (0.58-1.02)	Death/MI/urgent revascularization reduced from 14.5% to 12.4%; RR 0.83 (0.69-1.0)

FRAXIS[218]	Nadroparin	3468	90 days	8.8[b]	7.9[b]	1.10 (p = .46)	No benefit for any end point at any time point

[a]Control group treated with unfractionated heparin in all trials except FRISC-I.[b]Includes mortality only.

Heparin is recommended for the acute treatment of all unstable angina patients except those determined to be at low risk.[1] Unfractionated heparin should be started with an intravenous bolus of 60 to 70 units/kg followed by a constant infusion of approximately 16 units/kg per hour, adjusted to maintain the APTT at 1.5 to 2.5 times control, or to 50 to 70 s.[1] Subcutaneous administration of enoxaparin or dalteparin may be used instead of unfractionated heparin.[1] The dose of enoxaparin is 1 mg/kg twice daily, and the dose of dalteparin is 120 IU/kg (maximum of 10,000 IU) twice daily. Either standard heparin or an LMWH should be continued for 2 to 5 days, until the patient has been stabilized for 24 h, or until revascularization is performed.[1] The dose of unfractionated heparin should be conservative during coronary angioplasty when aspirin and GP IIb/IIIa inhibitors are being administered concomitantly, and heparin should be discontinued after an uncomplicated procedure.[1] Scant information is available on the combined use of LMWHs and GP IIb/IIIa inhibitors, particularly during coronary interventions; however, this combination is probably acceptable.[1]

Hirudin and Other Direct Thrombin Inhibitors

Hirudin is a 65-amino-acid polypeptide that was isolated from the salivary glands of the medicinal leech and now is produced through recombinant DNA technology.[219] Recombinant hirudin binds tightly to thrombin without requiring a cofactor, forming a slowly reversible complex. Hirudin has been shown to be more effective than heparin or LMWH in the prevention of venous thrombosis in patients undergoing total hip replacement[220] and has been approved for use in patients with heparin-induced thrombocytopenia.[219]

Hirudin and standard heparin were compared in 8011 patients with acute chest pain without ST elevation and in 4131 patients with ST elevation in the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) IIb study.[221] No differences in drug efficacy were seen between patients with and without ST elevation. A trend toward early benefit was seen with hirudin, with a 1.3 percent rate of death or myocardial infarction at 24 h compared with 2.1 percent in the heparin group (p = .001). However, by 30 days, the difference between the treatments for the primary end point of the trial was 8.9 percent versus 9.8 percent (p = .06).

The Organization to Assess Strategies for Ischemic Syndrome (OASIS-2) compared a slightly higher dose of hirudin to unfractionated heparin in 10,141 patients with unstable angina or suspected infarction without ST elevation.[222] Hirudin reduced the composite end point of cardiovascular death or myocardial infarction during the 3 days of treatment (odds ratio 0.76, 95 percent confidence interval 0.59 to 0.99), with statistically borderline benefit persisting to 7 days (p = .077). Major bleeding was more common with hirudin than it was with heparin.

Bivalirudin, a hirudin analog, was compared with heparin during coronary angioplasty in patients with unstable angina or postinfarction angina.[223] Bivalirudin caused less bleeding than heparin did and produced better results in the subgroup with postinfarction angina but did not significantly reduce the primary end point of the trial. Other direct thrombin inhibitors, such as argatroban and inogratran, have been investigated in acute coronary syndromes with disappointing results.[219] For example, inogratran was less effective than standard heparin in a trial involving 1209 patients with unstable coronary disease.[224]

Despite the encouraging early benefit compared with unfractionated heparin seen in GUSTO IIb and OASIS-2, hirudin is not currently recommended for use in patients with unstable angina.

Anticoagulation

Markers of ongoing thrombin generation remain elevated for months in some patients with unstable angina, and such markers have been correlated with increased risk.[108,225] In a small trial comparing aspirin to aspirin plus warfarin in unstable angina, the combination reduced progression of the culprit lesion compared with aspirin

alone.[226] Additionally, the combined-therapy group showed a trend toward fewer infarctions during the 10 weeks of the study. For these reasons, the combination of aspirin to block platelets and oral anticoagulants to suppress activation of the coagulation system has attracted interest for its potential to reduce events in the long term after an episode of unstable angina.

In the ATACS study, 214 unstable angina patients who were not previously taking aspirin were randomized to aspirin alone or to aspirin plus intravenous heparin followed by coumadin for 12 weeks.[202] The combination therapy significantly reduced ischemic events at 12 weeks, but most of the difference occurred early, during treatment with heparin, and the difference during coumadin therapy was not statistically significant.

The OASIS investigators conducted two pilot studies of anticoagulation in patients with unstable angina or non-Q-wave infarction.[227] In the first, aspirin plus a fixed low dose of warfarin, 3 mg/day, was compared with aspirin alone in 309 patients. The composite end point of death, infarction, or refractory angina during the 6 months of treatment was actually lower-3.9 percent versus 6.5 percent-in the group without warfarin, but the difference did not attain statistical significance. Major bleeding occurred in four warfarin plus aspirin and no aspirin-only patients, and minor bleeding was more common in warfarin patients. In the second phase of the pilot study, warfarin was given at a higher, adjusted dose to maintain the International Normalized Ratio (INR) between 2.0 and 2.5. Although only 197 patients were enrolled in this phase, the reduction in the composite rate of cardiovascular death, myocardial infarction, or refractory angina with warfarin was impressive (odds ratio 0.42) and approached statistical significance ($p = .08$). Long-term anticoagulation is being evaluated in a substudy of OASIS-2.

Thrombolytic Therapy

Myocardial infarction and unstable angina share a common pathophysiologic substrate: plaque rupture or erosion with overlying thrombosis. Thrombolysis effectively reopens occluded culprit arteries and reduces mortality in patients with acute infarction. It was therefore thought that thrombolytic therapy might prove useful in treating unstable angina.

A meta-analysis of nine small, randomized controlled clinical trials of thrombolysis in unstable angina, with heparin as background therapy, revealed an increased risk of myocardial infarction with active treatment (odds ratio 2.38, 95 percent confidence interval 1.15 to 4.94).[228] The failure of thrombolytic therapy for unstable angina and non-Q-wave infarction was confirmed in the TIMI-IIIB trial.[229] Among the 1473 patients randomized to intravenous tissue plasminogen activator or to placebo, the rate of fatal or nonfatal myocardial infarction at 6 weeks was 7.4 percent with thrombolysis and 4.9 percent with placebo ($p = .04$). In patients not receiving heparin initially, the event rate was 15.2 percent with TPA and 0 percent with placebo ($p = .01$). In another trial, urokinase was given at the time of coronary angioplasty in unstable angina patients to prevent ischemic events.[230] However, both acute closure and clinical end points were more common with the thrombolytic agent than with placebo.

The reason why thrombolytic therapy does not reduce events in unstable angina is not known. However, thrombolysis stimulates ongoing thrombin formation and also activates platelets.[228] These mechanisms are likely to be more important in patients with unstable angina than in patients with Q-wave-infarction. Thrombolytic therapy should be avoided in patients with unstable angina.

Coronary Revascularization

Coronary bypass surgery and coronary angioplasty frequently are performed in patients with unstable angina; however, the precise indications for revascularization, the choice of procedure, and its timing are controversial. Randomized trials comparing revascularization to medical therapy in patients with unstable angina were first performed more than 20 years ago. The results of all but the most recent trials are not applicable to current clinical decision making because major advances in medical and interventional practices have vastly improved the outcomes with both types of therapy. Randomized trials in this area are difficult to perform and interpret because of small sample sizes, frequent crossovers from medical to interventional treatment, and exclusion criteria that tend to eliminate the high-risk patients who might benefit the most from coronary revascularization.

An overview of the 10-year results from the clinical trials comparing coronary bypass surgery with medical treatment for stable angina indicate that patients with left main coronary artery stenosis or three-vessel disease obtain the greatest benefit from surgery.[121] In low-risk groups such as patients with single-vessel involvement,

no survival advantage can be demonstrated with bypass surgery. These conclusions also may be relevant to patients with unstable angina.

In the Veterans Administration Cooperative Study of Unstable Angina, 468 men age less than 70 years were randomized to medical or surgical therapy.[231-233] Those with left main coronary stenosis, previous bypass surgery, recent infarction, or ejection fractions less than 30 percent were excluded. Surgery consisted of saphenous venous bypasses only, a mean of 2.7 per patient, and 30-day surgical mortality was 4.1 percent.[231] By 2 years, one-third of the patients assigned to medical therapy had crossed over to surgery. Overall mortality at 5 years was 19 percent in medically assigned patients and 16 percent in bypass patients, a difference that was not statistically significant.[232] The rates of myocardial infarction also were not significantly different between the groups. High-risk subsets appeared to benefit from surgery; for example, 5-year mortality among patients with three-vessel disease was 11 percent in the bypass surgery group and 24 percent in the medical group (p = .02). For patients with three-vessel disease and left ventricular dysfunction, the mortality advantage for surgery is even greater: 29 percent compared with 9 percent ($p < .05$). Surgery appeared to nullify partially the increased risk associated with lower ejection fractions. By 10 years, mortality was 38 percent in the medical group and 39 percent in the surgical group.[233] The relationship between a low ejection fraction and a survival benefit from surgery persisted (Fig. 41-12).

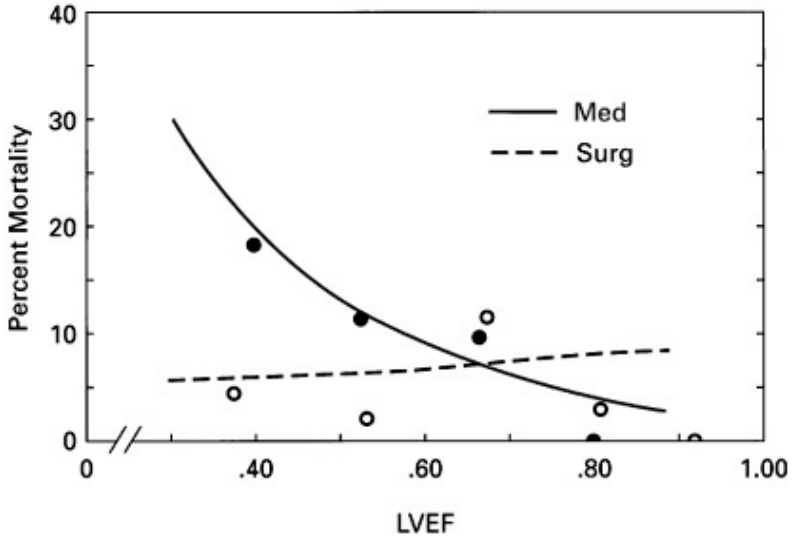

Figure 41-12: Mortality at 2 years according to baseline ejection fraction in the Veterans Administration Cooperative Study of Unstable Angina.[231] Although no overall mortality difference between the groups was seen, a relation between ejection fraction and outcome was evident. Survival was poor in medically treated patients with low ejection fractions. In surgically treated patients, survival was independent of ejection fraction. (From Luchi et al., [231] with permission.)

A common feature of the VA trial and trials in stable angina is that bypass surgery provides the greatest survival benefit to patients with the most advanced coronary disease and left ventricular dysfunction. Many patients with unstable angina are limited by exertional angina when they attempt to resume normal activities after the acute episode. Coronary bypass surgery effectively eliminates angina in 80 to 90 percent of cases. The long-term results of coronary bypass surgery for unstable angina have been good. In a compilation of more than 6000 patients from 14 reports from 1978 to 1988, operative mortality was less than 4 percent and 5-year survival was nearly 90 percent despite previous infarction in half the population, three-vessel disease in more than half, and left main stenosis in one-fifth.[234] Since that time, operative techniques have improved dramatically and the population of unstable angina patients undergoing bypass surgery has become older and sicker. These two factors have tended to cancel each other out, and so outcome statistics have remained relatively stable.

In its early phases of development, coronary angioplasty was applied to patients with unstable angina. The initial results were not as good as they were in patients with stable coronary disease. Advances in catheter technology have led to improved outcomes in all patient categories, with a narrowing of the gap between unstable and stable patients. The widespread use of coronary stents and GP IIb/IIIa inhibitors has further reduced the risk of coronary angioplasty in patients with unstable coronary disease.

Recent trials of coronary revascularization in unstable angina have compared an "aggressive" approach with a "conservative" approach. The aggressive approach involves early coronary angiography with revascularization by either coronary angioplasty or bypass surgery, depending on the coronary anatomy. Usually, patients with one or two severe narrowings are treated with angioplasty and those with more extensive disease undergo bypass surgery. The conservative approach limits coronary arteriography, usually to patients who require revascularization to control persistent symptoms and to those with very high-risk features.

In the TIMI IIIB trial, 1473 patients with unstable angina or non-Q-wave infarction were randomized within 24 h of chest pain to an early invasive or a conservative strategy.[229] The invasive group underwent coronary arteriography within 18 to 48 h after randomization, followed by a revascularization procedure when possible. Coronary arteriography was done in the conservative group for recurrent chest pain at rest with ischemic ECG changes, episodes of ST depression on ambulatory ECG monitoring, high-risk features on a stress test at the time of hospital discharge, severe angina after discharge, or hospitalization for a recurrence of unstable angina. Two-thirds of the patients had unstable angina, and the remainder had non-Q-wave infarction. Patients also were randomized in a factorial design to TPA or placebo, as was described above. The primary end point of the trial-death, myocardial infarction, or a failed symptom-limited exercise test within 6 weeks-occurred in 16.2 percent of patients randomized to the early invasive strategy and 18.1 percent of patients in the conservative group, a statistically nonsignificant difference. The rates of death (2.4 percent versus 2.5 percent) and nonfatal infarction (5.1 percent versus 5.7 percent) were almost identical with the two strategies. At 1 year, the cumulative rate of death or nonfatal infarction was 10.8 percent in the invasive group and 12.2 percent in the conservative group (p = not significant).[235] A major limitation of TIMI IIIB is that during the first 6 weeks, revascularization was performed in 63 percent of the invasive group and 50 percent of the conservative group. Such a small difference in the rates of revascularization is unlikely to produce a significant difference in end point events.

A major conclusion from TIMI IIIB was that rapid angiography and revascularization do not produce better outcomes than does a more leisurely approach that reserves angiography for patients who exhibit recurrent symptoms or high-risk features.

The Veterans Affairs Non-Q-Wave Infarction Strategies in Hospital (VANQWISH) trial[236] included no patients with unstable angina, but its results may be relevant to all acute coronary syndromes. The 920 patients were assigned randomly to an invasive approach or a conservative approach. The composite end point of death or nonfatal infarction occurred more frequently in the invasive group during the first year: At hospital discharge, the difference was 7.8 percent versus 3.3 percent (p = .004); at 1 month, 10.4 percent versus 5.7 percent (p = .012); and at 1 year, 24 percent versus 18 percent (p = .05). By the end of the 23-month follow-up, the difference between the treatment groups had narrowed and was no longer statistically significant. VANQWISH has been criticized because revascularization was actually performed in only 44 percent of the patients assigned to the invasive strategy but in 33 percent of patients in the conservative group. Additionally, in the invasive patients who underwent bypass surgery, the mortality rate within 1 month of surgery was 11.6 percent, higher than the norm for this type of patient.

In the FRISC II study described above, 2457 patients with unstable coronary disease were randomized in a 2 by 2 factorial design to dalteparin or to placebo and to an invasive or noninvasive treatment strategy.[237] More than half the patients had elevated troponin T levels, and nearly half had ischemic ECG changes; one or the other of these criteria was necessary for entry into the trial. In the invasive arm, coronary angiography was performed within a few days of admission and revascularization was done shortly thereafter if feasible. An important difference between FRISC II and TIMI IIIB or VANQWISH is that most of the invasive patients underwent revascularization and most of the noninvasive patients did not, allowing a true comparison between the two approaches (Fig. 41-13). In the invasive group, the mean time from enrollment to angioplasty was 4 days and the mean time to bypass surgery was 7 days. By 10 days, 71 percent of the invasive patients and only 9 percent of the noninvasive patients had undergone revascularization. At 6 months, these rates were 77 percent and 37 percent, respectively. The mortality rate within 30 days among invasive patients who had bypass surgery was only 2.1 percent.

The primary end point of FRISC II-death or nonfatal infarction at 6 months-occurred in 9.4 percent of invasive patients and 12.1 percent of patients in the noninvasive group (odds ratio 0.78, 95 percent confidence interval 0.62 to 0.98, p = .031). During the first 2 weeks, the rate of death or infarction was higher in the invasive group than in the noninvasive group as a result of events associated with the procedures, but the curves crossed at 4 weeks (Fig. 41-14). Patients in the invasive group had a reduction in angina of about 50 percent compared with

the noninvasive group during the first 6 months of follow-up ($p < .001$) and also were significantly less likely to be readmitted to the hospital. Dalteparin was effective in reducing events in the entire study and in the noninvasive group but had little effect in the invasive group (9.1 percent dalteparin versus 9.7 percent placebo event rates). The event rate during the first 2 months was lowest in the dalteparin/noninvasive group. FRISC II clearly demonstrated that revascularization improves outcomes for unstable angina patients with ischemic ST changes or elevated troponin levels if the procedures can be done with a low rate of complications. With modern antiplatelet and antithrombotic therapy, revascularization does not need to be done urgently, within the first day or two after admission, but should be done within the first week or two. The early benefit seen with antiplatelet or antithrombotic drugs tended to dissipate within the first month or two in some of the clinical trials of these drugs.

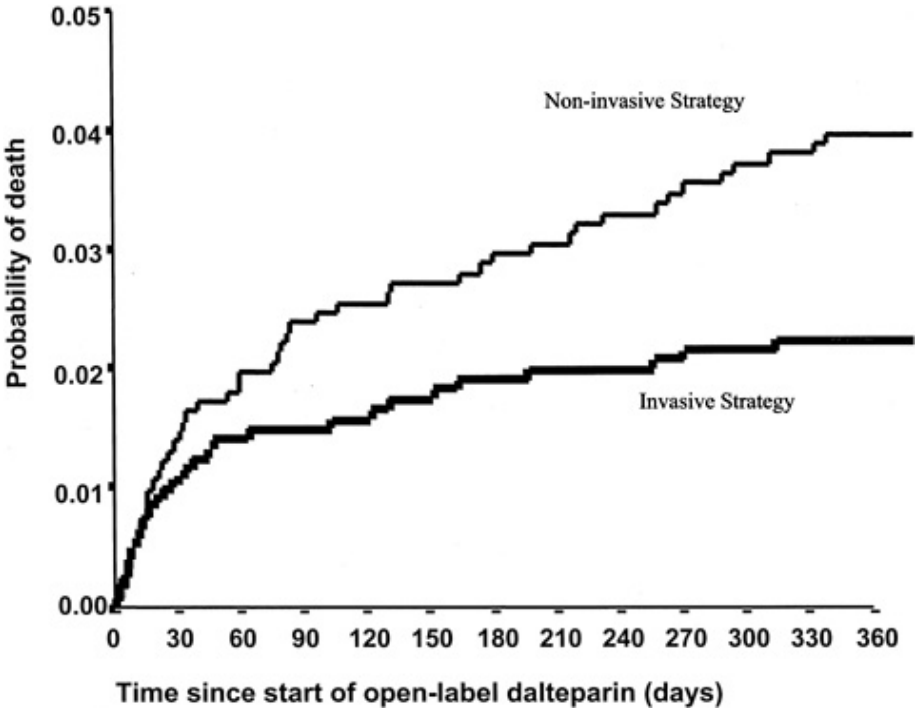

Figure 41-14: Incidence of death or myocardial infarction in patients randomized to the invasive and noninvasive strategies in the FRISC II trial.[237] At 6 months (the primary end point of the study), outcome was better in the invasive group ($p = .031$). This benefit persisted to 1 year. (Courtesy of Lars Wallentin, for the FRISC II investigators,[237] with permission.)

Survey data indicate that unstable angina patients who undergo revascularization outside clinical trial settings may not obtain benefit from the procedure. In the OASIS prospective registry of 8000 unstable angina patients treated in 95 hospitals in six countries, revascularization was performed in 49 percent of patients in the United States and Brazil, 34 percent of patients in Canada and Australia, and 17 percent of patients in Hungary and Poland.[238] The 6-month rates of death or myocardial infarction did not differ among patients in the three groups, although angina during follow-up was eliminated more effectively in countries with more intervention. Across the six countries, low-risk unstable angina patients benefited from being treated in a hospital with catheterization facilities, but the outcome of high-risk patients was significantly worse.

An Integrated Approach to Treatment

The treatment of unstable angina should be individualized to take into account the specific features of the disease and the particular circumstances of the patient. Nevertheless, the algorithms that have been developed recently provide a useful framework (Fig. 41-15). It should be remembered that unstable angina is an acute episode related to one active culprit lesion but that the patient has diffuse atherosclerosis. Coronary disease is a chronic condition that usually causes recurrent events that are spread out over many years. Thus, smoking cessation, cholesterol lowering, and control of hypertension and diabetes may be at least as important in the long term as are the specific treatment decisions related to the acute event. An episode of unstable angina may be viewed as an opportunity to improve the patient's profile with respect to secondary prevention.

Chapter 41: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

VARIANT ANGINA

In 1959, Prinzmetal and associates described a syndrome characterized by angina at rest with transient ST-segment elevation.[239] Exercise tolerance usually was well preserved, and the attacks were cyclical in nature, often occurring in the early morning hours. The attacks did not last longer than ordinary anginal episodes, and the ST-segment elevation disappeared rapidly as the chest pain receded. Ventricular arrhythmias and atrioventricular block sometimes occurred at the height of an attack, and both myocardial infarction and sudden death were common complications (see also Chap. 40).

With the advent of coronary angiography, it soon became apparent that the syndrome was caused by coronary spasm, usually focal and often at the site of a coronary stenosis.[240] The underlying coronary lesion can vary from a subtotal occlusion to a very mild stenosis, and in some cases the coronary arteries are angiographically normal. Coronary spasm occurs in more than one artery in some patients,[241] and the site of spasm can fluctuate from one vessel to another.[242]

Pathophysiology

A large number of etiologic explanations for variant angina have been proposed or rejected. Evidence of parasympathetic nervous system overactivity[243] and reduced sympathetic activity[244] has been presented; however, coronary spasm has been demonstrated in the transplanted, denervated heart,[245] making central neural mechanism unlikely. The frequency of attacks of variant angina is not reduced by alpha-adrenergic blockade,[246] blockade of serotonin receptors,[247] inhibition of thromboxane A_2 production,[248] or the administration of prostacyclin.[249] Magnesium deficiency,[250] hyperinsulinemia,[251] and vitamin E deficiency[252] have been reported to be present in patients with variant angina. Vitamin C attenuates the abnormal coronary vasoconstriction in patients with variant angina, purportedly by inhibiting oxygen free radical generation[253] (see also Chap. 37).

Whether nitric oxide activity at sites of coronary spasm is normal or abnormal is controversial.[254,255] A mutation of the endothelial nitric oxide synthetase (eNOS) gene recently was reported to be significantly more common in patients with coronary spasm than in controls.[256] Depressed endothelial nitric oxide production could predispose patients with this defect to coronary spasm.

Coronary spasm usually is localized to the site of an atherosclerotic lesion. Even variant angina patients with no evident narrowing at angiography invariably will have atherosclerosis demonstrable by intracoronary ultrasound at the site of focal spasm.[257] Asian patients with variant angina appear to have generalized coronary artery hyperactivity, whereas in white patients the abnormality is focal.[258]

The pathophysiologic consequences of coronary spasm are well understood. Severe spasm rapidly induces transmural ischemia, resulting in segmental dyskinesis and ST-segment elevation. If the ischemic zone is large, cardiac output and systemic arterial pressure decrease. The risk of serious ventricular arrhythmias increases with the severity and extent of ischemia. Prolonged spasm can

induce intracoronary thrombosis, which may persist to cause myocardial infarction.[259]

Clinical Features

Variant angina is uncommon, and the presenting symptoms are usually not remarkable enough to be distinguished immediately from those of unstable angina. Angina at rest occurs with a cyclical pattern, often with attacks occurring in the early morning hours. Exertional angina coexists in slightly more than half these patients, but with an extremely variable ischemic threshold.[260] Variant angina can appear during the recovery phase of myocardial infarction[261] or soon after coronary bypass surgery[262] or angioplasty.[263]

Most patients with variant angina are heavy cigarette smokers, but their age, sex, and risk factor profiles are otherwise similar to those of other coronary patients.[264] Those with angiographically normal coronary arteries tend to be younger and more often are women. One-quarter of variant angina patients have a history of migraine headaches, and one-quarter have symptoms of Raynaud's phenomenon.[265] Thus, in some cases variant angina may be part of a more generalized vasospastic diathesis. Syncope, presumably caused by ischemia-induced ventricular arrhythmia or atrioventricular block, during rest angina is a useful clue to the diagnosis. Rare cases of life-threatening ventricular arrhythmias caused by silent myocardial ischemia resulting from coronary spasm have been reported.[266,267]

Cocaine causes coronary vasoconstriction and can precipitate coronary spasm, sometimes with myocardial infarction. This topic is discussed in Chap. 71.

Physical examination of variant angina patients between attacks reveals no abnormalities. Routine laboratory tests, including cardiac enzymes, are normal.

Diagnostic Procedures

Variant angina can be diagnosed most easily by recording an ECG during an episode of rest angina. The ST-segment elevation that occurs during an attack disappears promptly after the administration of nitroglycerin. Coronary spasm can induce ST elevation, ST depression, or pseudonormalization of abnormally negative T waves (Fig. 41-16). When variant angina is suspected, ambulatory ECG monitoring or an event monitor sometimes can be useful to confirm the diagnosis. Exercise testing will provoke angina with ST elevation in approximately one-third of variant angina patients during an active phase of the disease.[268] This response to an exercise test often leads to the diagnosis of variant angina when it was not previously suspected. Provocative testing has been used to confirm the diagnosis of variant angina when a spontaneous attack cannot be documented. The cold pressor response, exercise, and hyperventilation are physiologic stimuli for coronary spasm, but each has a sensitivity that is too low to be useful clinically.[268] The pharmacologic agents ergonovine and acetylcholine provoke coronary spasm with a sensitivity of approximately 90 percent in patients with variant angina.[268,269] Intracoronary acetylcholine is probably the preferred method, but a temporary pacemaker must be placed before right coronary (or dominant left coronary) injections are done because of the high incidence of bradyarrhythmias and conduction disturbances from cholinergic effects in the atrioventricular node.

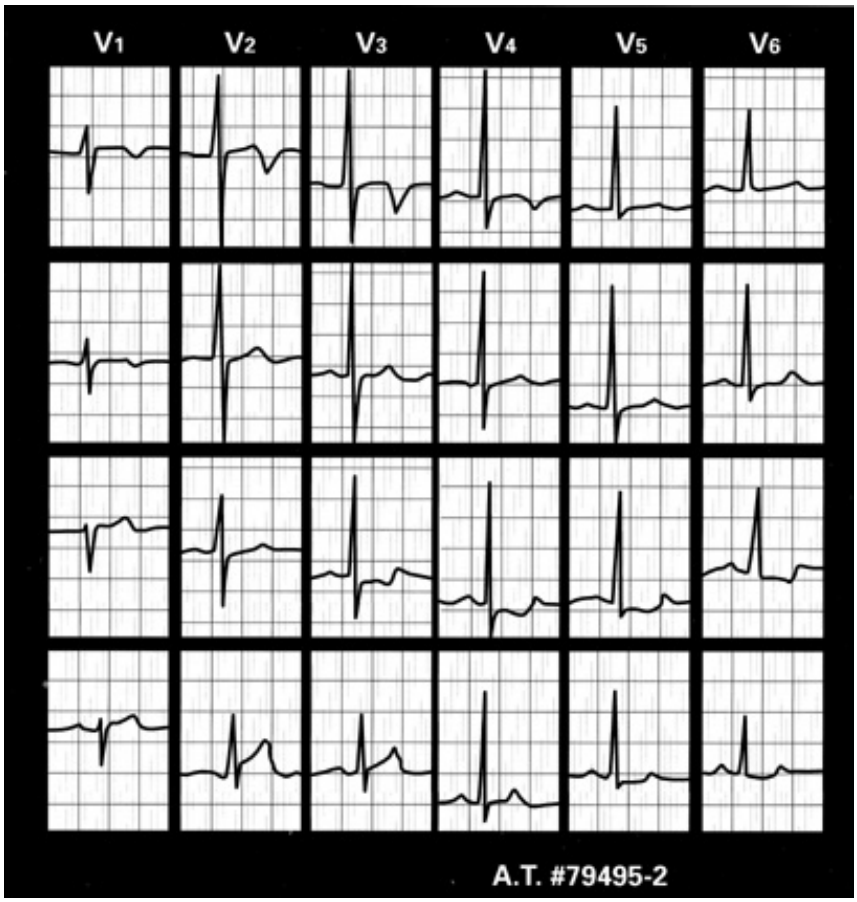

Figure 41-16: Electrocardiogram (leads V_1 to V_6) from a patient with active variant angina. Negative T waves are present in the control tracing (*top*). The other three tracings were recorded during separate episodes of rest angina and show pseudonormalization of T waves, ST depression, and ST elevation, respectively.

All patients with variant angina should undergo coronary angiography unless an absolute contraindication is present. Coronary angiography is the only certain method to distinguish between patients who have severe organic multivessel disease and those who have only mild narrowings or angiographically normal arteries.

Treatment

Variant angina is difficult to treat because attacks occur unpredictably and frequently without an obvious precipitating factor. For the patient's well-being, the goal of therapy therefore should be the elimination of all attacks. Spontaneous remission is a common outcome,[270] but myocardial infarction is a common complication within the first 3 months of diagnosis, particularly in patients with underlying multivessel disease.[271] Nitroglycerin relieves variant angina attacks within minutes and should be used promptly. Long-acting nitrates are effective in preventing variant angina attacks, but the development of nitrate tolerance limits their utility. Beta-adrenergic blockers should not be used in variant angina patients because of their propensity to increase the frequency and duration of attacks.[141,142]

Calcium channel blockers are very effective in preventing attacks of variant angina.[272-275] More than half the patients treated with one of these drugs become completely asymptomatic. The response is better at higher doses, for example, long-acting nifedipine 80 mg/day, diltiazem 360 mg/day, verapamil 480 mg/day, or amlodipine 20 mg/day. The efficacy of these drugs in preventing variant angina is roughly equal. Patients with an incomplete response to one drug often become angina-free on a combination of nifedipine and either diltiazem or verapamil. Evidence

from uncontrolled studies suggests that treatment with calcium channel blockers reduces the risk of myocardial infarction.[271,276]

Approximately 20 percent of variant angina patients will not respond to treatment with two calcium channel blockers plus a long-acting nitrate. Although not approved in the United States for this indication, amiodarone,[277] guanethidine,[278] and clonidine[278] have been reported to be effective in some of these refractory patients. Therapy for ventricular arrhythmias and conduction disturbances that complicate attacks in some cases should be directed toward the elimination of all episodes of spasm.[267] Patients with variant angina should be treated with low-dose aspirin, as are other patients with coronary disease, to reduce the risk of myocardial infarction, even though very high doses of aspirin have been reported to aggravate coronary spasm.[279]

Coronary bypass surgery should be considered in most patients with variant angina and multivessel atherosclerotic disease. Operative mortality and the perioperative infarction rate are higher than they are for comparable patients without variant angina.[280,281] However, surgery almost invariably eliminates variant angina, and the long-term outcome is excellent.[280] Bypass surgery will be successful when the anastomosis can be situated distal to the site of focal spasm but not when diffuse spasm involves the entire artery. Bypass surgery is not indicated for variant angina in the absence of significant organic stenoses.

Many patients with variant angina have coronary lesions that are ideal for angioplasty. When such patients are pretreated with calcium channel blockers and are given intracoronary nitroglycerin during the procedure, the primary success rate is high.[263,282] Coronary spasm may persist or recur after successful angioplasty, however, and calcium channel blockers therefore should be continued. The restenosis rate in variant angina patients is substantially higher than usual.[263,283] Whether coronary stenting improves outcomes for variant angina patients is not known. Coronary angioplasty is not indicated for patients with coronary spasm who have normal or nearly normal arteries on coronary angiography.

Prognosis

The long-term prognosis of variant angina has been reported for several large series of patients from different countries.[271276,280,284] The extent and severity of the underlying coronary disease appear to be the most important factors influencing the outcome (Fig. 41-17). Survival without infarction at 1 year in a consecutive series of 217 patients was 93 percent for those without stenoses of 70 percent or more, 86 percent for patients with single-vessel disease, and 65 percent for those with multivessel disease.[271] At 5 years, the corresponding figures were 83 percent, 74 percent, and 44 percent, respectively. Other variables that correlate with a poor outcome include the presence of abnormal left ventricular function, ventricular arrhythmias during attacks, multivessel spasm, and the absence of treatment with calcium channel blockers. The majority of these patients will become angina-free within months or years.[270] Variant angina will recur in rare cases after a long asymptomatic interval. More commonly, patients will develop other manifestations of coronary disease. Some evidence indicates that recurrent coronary spasm accelerates the progression of coronary atherosclerosis, with a histologic pattern of neointimal hyperplasia that resembles restenosis.[285,286]

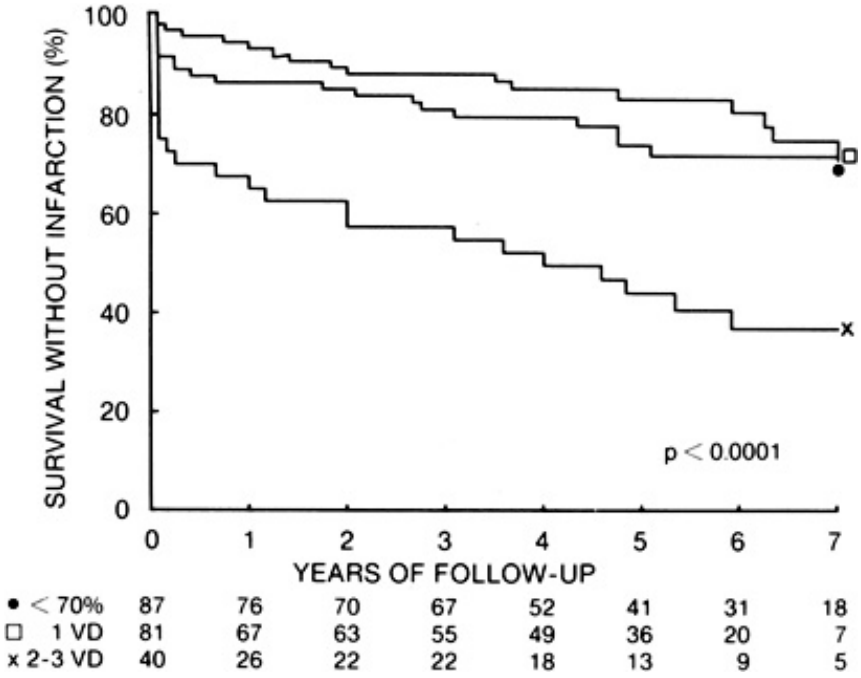

Figure 41-17: Survival without myocardial infarction in variant angina patients with no stenoses of 70 percent or more (▪), those with one-vessel disease (□), and those with multivessel disease (x). The outcome in the latter group of patients is much worse than that in the other two groups. Events are clustered in the early follow-up period. (From Walling et al.,[271] with permission.)

Chapter 41: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE ANGINA

List of Figures

Figure 41-11: Binding of unfractionated heparin (*top*) and low-molecular-weight heparin (*bottom*) to antithrombin. When bound to either form of heparin, antithrombin undergoes a conformational change that accelerates its interaction inactivating factor Xa. In contrast, formation of the heparin-antithrombin-thrombin complex (*top panel, bottom right*) requires the long saccharide chain of unfractionated heparin. (From Weitz,[209] with permission.)

Figure 41-12: Mortality at 2 years according to baseline ejection fraction in the Veterans Administration Cooperative Study of Unstable Angina.[231] Although no overall mortality difference between the groups was seen, a relation between ejection fraction and outcome was evident. Survival was poor in medically treated patients with low ejection fractions. In surgically treated patients, survival was independent of ejection fraction. (From Luchi et al., [231] with permission.)

Figure 41-13: Proportion of patients in the invasive and noninvasive treatment groups of TIMI IIIB,[229] VANQWISH,[236] and FRISC II[237] who underwent revascularization during the first year. The differences between invasive and noninvasive groups are small in TIMI IIIB and VANQWISH and large in FRISC II. This factor may partially explain why revascularization was shown to be beneficial in FRISC II but not in the other two trials. (Courtesy of Dr. Lars Wallentin, for the FRISC II investigators, with permission.)

Figure 41-14: Incidence of death or myocardial infarction in patients randomized to the invasive and noninvasive strategies in the FRISC II trial.[237] At 6 months (the primary end point of the study), outcome was better in the invasive group (p = .031). This benefit persisted to 1 year. (Courtesy of Lars Wallentin, for the FRISC II investigators,[237] with permission.)

Figure 41-15: Algorithm for managing patients with chest discomfort suggestive of unstable angina (*panel A*). The acute ischemic pathway (*panel B*) includes patients with documented unstable angina. This generalized guideline must be adapted to each patient's specific circumstances. (Adapted from the ACC/AHA guidelines for the management of patients with unstable angina,[1] with permission.)

Part 6: CORONARY HEART DISEASE
Chapter 42:

DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

Authors: R. Wayne Alexander, Craig M. Pratt, Thomas J. Ryan, Robert Roberts

BACKGROUND AND INTRODUCTION*

Progress in the understanding of the pathogenesis of acute myocardial infarction (AMI) and of its treatment epitomizes scientific, evidence-based medicine at its best. Although myocardial infarction has long been a clinically recognized entity resulting from coronary artery atherosclerosis, its relative importance is a modern phenomenon. Its appearance as a modern epidemic reflects increasing longevity, permitting manifestation of chronic "degenerative" diseases such as atherosclerosis; the adoption of high-fat diets based on meats, permitted by increasing affluence; and decreased exercise, made possible by the increased mechanization of society. Osler devoted only a few pages in his textbook, published in 1892, to the discussion of AMI.[3]

The modern era can be said to have begun with the autopsy studies of Herrick, who concluded in 1912 that the clinical syndrome of myocardial infarction results from acute thrombotic occlusion of a coronary artery, with resulting downstream necrosis.[4] This conclusion was generally accepted for 60 years, and the term *coronary thrombosis* was not uncommonly used as the equivalent of *heart attack* or, more formally, *acute myocardial infarction.* The conventional wisdom was challenged in 1972, when it was suggested that coronary artery thrombus may be the result rather than the cause of acute infarction, since autopsy studies-which were frequently performed several days after the acute event-did not uniformly show thrombus.[5] In retrospect, these findings can be explained by spontaneous lysis of a thrombus that had been occlusive for a sufficient amount of time to cause tissue necrosis. Definitive proof of the central role of thrombus formation in the pathogenesis of myocardial infarction came from angiographic studies performed during the first hours of the acute event,[6,7] a diagnostic strategy that had previously been thought to be contraindicated.[8]

The unequivocal demonstration of the role of the thrombus in AMI quickly led to the systematic testing of thrombolytic strategies to abort myocardial infarctions.[9-11] Analysis of data from several small trials of thrombolytic therapy with streptokinase suggested improved mortality in treated patients as early as 1982.[12] These early efforts were followed by a large number of major multicenter clinical trials on the treatment of AMI; these demonstrated in a rigorous fashion the efficacy of beta-adrenergic receptor blockers,[13] streptokinase versus no thrombolytic therapy,[14] and recombinant tissue plasminogen activator versus streptokinase[15] in reducing mortality. These and other major trials are discussed in detail further on. The major point to be made here is that large, adequately powered, randomized studies in the treatment of myocardial infarction have helped set a new standard and approach to the goal of enhancing the evidence-based practice of medicine while moving away from one based on previous practice patterns and intuitive extrapolations from pathophysiologic principles. Key to the success of these very large trials has been the generalizability achieved mostly by the use of broad-entry criteria that facilitated the rapid enrollment of suitable patients and provided robust statistical power to the studies.

The availability of data from well-designed clinical trials has permitted the development, by panels of experts, of evidence-based practice guidelines for the treatment of myocardial infarction.[1,16] Furthermore, the confidence with which recommendations can be made for any particular diagnostic or therapeutic approach can be graded on the basis of judgments as to the strength of the supporting evidence. Thus, a committee convened by the American College of Cardiology/American Heart Association (ACC/AHA) Task Force on Practice Guidelines was charged with revising the ACC/AHA statement, "Guidelines for the Early Management of Patients with Acute Myocardial Infarction," published in 1990.[16] The results of the deliberations of this committee, "Guidelines for the Management of Patients with Acute Myocardial Infarction," were published in late 1996[2] and have been updated.[1] The evidence and expert opinion supporting use of a therapy, intervention, or diagnostic procedure were weighed and expressed in ACC/AHA format as follows:

- *Class I*: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective.
- *Class II*: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.
- *Class IIa*: Weight of evidence/opinion is in favor of usefulness/efficacy.
- *Class IIb*: Usefulness/efficacy is less well established by evidence/opinion.
- *Class III*: Conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful. In general, recommendations in this chapter are associated with a class I, II, or III designation to guide the reader in weighing diagnostic and therapeutic options.

The pathophysiologic bases and consequences of coronary artery disease and myocardial infarction are discussed elsewhere: natural history and prognosis (Chap. 1); pathogenesis of atherosclerosis (Chap. 35); pathology of coronary atherosclerosis (Chap. 36); risk factors and prevention (Chap. 38); nonatherosclerotic causes of coronary heart disease (spontaneous coronary artery dissection, aortic dissection, thrombosis associated with the use of birth-control pills, emboli, congenital coronary anomalies, metabolic abnormalities, blunt chest trauma, vasculitis, and drug abuse, especially cocaine) (Chap. 39); pathophysiology of myocardial ischemia (Chap. 37); pathophysiology of coronary artery disease as related to myocardial ischemic syndromes (Chap. 35); and thrombogenesis and antithrombotic therapy (Chap. 44).

The following are important general facts about myocardial infarction:

1. Approximately 800,000 people in the United States experience AMI annually; of these, about 213,000 die. Of those who die, approximately one-half do so within 1 h of the onset of symptoms, before reaching a hospital.[1,17,18]
2. The majority of early deaths are the result of ventricular arrhythmias that can be readily aborted by defibrillation, either during prehospital care or in coronary care units (CCU) in the hospital.
3. The major cause of myocardial infarction is atherosclerotic disease of the epicardial coronary arteries, as noted. Although luminal narrowing resulting in hemodynamically significant obstruction of blood flow is the major cause of symptoms of coronary ischemia (Chap. 40), the majority of myocardial infarctions occur as a result of the disruption of arterial lesions that are not hemodynamically significant (<60 percent). This breakdown of the structural integrity of the arterial intima occurs because of weakening induced by proteolytic degradation of matrix proteins by products released from inflammatory leukocytes[19] and results in the exposure of blood to thrombogenic intimal material, causing obstructive clot formation. Local vasospasm may contribute to the obstruction. *These observations have led to the concept that the biological state of atherosclerotic lesions and not the extent of stenosis is the major determinant of whether or not plaque rupture and*

myocardial infarction occur.

4. Myocardial infarction, or ischemia, is a segmental process limited to the distribution of the affected artery. Impaired contractility usually occurs within seconds of the cessation of blood flow. The process usually begins in the endocardium and spreads toward the epicardium. If flow is restored before cell death occurs, prolonged contractile impairment (stunning) may occur.
5. Episodes of ischemia preceding coronary occlusion enhance the survivability of myocardial cells (*ischemic preconditioning*).
6. Irreversible cardiac injury occurs if occlusion is complete for at least 15 to 20 min. Irreversible injury occurs maximally in the area at risk when occlusion is sustained for 4 to 6 h, but most of the damage occurs in the first 2 to 3 h. Thus, restoration of flow within the first 4 to 6 h is associated with salvage of the myocardium, but the salvage is exponentially greater if restoration occurs in 1 to 2 h.
7. Restoration of blood flow by thrombolysis results in myocardial salvage and improved mortality. The extent of the benefit is dependent upon restoration of near-normal blood flow *(open-artery hypothesis)* and is inversely related to the time between the onset of occlusion (symptoms) and the restoration of blood flow.
8. The percentage of tissue at risk that undergoes necrosis (infarct size) depends on existing collateral flow, which is highly variable and difficult to predict.
9. The major predictor of long-term outcome is infarct size, which is inversely related to the ejection fraction.
10. Q-wave infarction (usually presenting as ST-segment elevation) is a distinct clinical entity, as compared with non-Q-wave infarction (usually presenting with ST-segment depression). There are differential features in their clinical courses. (Q-wave infarction, untreated, has a relatively high in-hospital mortality rate that is favorably influenced by thrombolysis, whereas non-Q-wave infarction has a lower in-hospital mortality and complication rate with a prolonged vulnerability to reinfarction. Thrombolysis may worsen the clinical outcome.) Although there is no close anatomic correlation between the presence and absence of Q waves and transmural and nontransmural myocardial infarction, the distinct clinical outcomes of patients presenting with ST-segment elevation and ST-segment depression have made this electrocardiographic feature a major initial decision point in assigning therapeutic strategies to patients presenting with symptoms compatible with AMI.
11. Because of their salutary effects on thrombus formation and ventricular arrhythmias, aspirin and beta-adrenergic blockers, respectively, have proved to be effective for secondary prevention in patients who have had a myocardial infarction. Aspirin has also been shown to be modestly effective for primary prevention in middle-aged males.
12. Lipid lowering and smoking cessation have both been shown to be effective in the primary and secondary prevention of myocardial infarction. The enormous progress that has been made in understanding the pathogenesis and treatment of myocardial infarction has resulted in substantial improvements in outcomes in recent years. Indeed, the "natural history" of treated patients has improved dramatically. The mortality rate in the pre-CCU era has been estimated to have been about 30 percent.[20] The mortality rate dropped dramatically, to about 15 percent, in the CCU era, which embraced the use of hemodynamic monitoring, defibrillation, and the use of beta blockers. The increased use of thrombolytics, coronary interventions, aspirin, and angiotensin-converting enzyme inhibitors has decreased the mortality of patients treated for the conventional ST-elevated AMI to 6 to 7 percent.[15,21] This, of course, cannot be claimed for patients in the Medicare population where it is generally accepted that patients over the age of 70 have a mortality rate that approximates 20 percent when admitted for the management of AMI. The major challenge, however, is to bring the principles and lessons learned from the efforts of the past decade to everyday clinical practice.

* The ACC/AHA Guidelines for the Management of Patients With Acute Myocardial Infarction,

1996 version, have been updated in 1999. The 1999 update did not reprint the whole document. Reference to the Guidelines in this chapter will refer to the 1999 citation[1] but may also refer to data in the 1996 document.[2]

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

CLINICAL ASPECTS

Predisposing Characteristics and Circumstances

The standard risk factors for the development of coronary artery disease (dyslipidemia, family history, age, male gender, cigarette smoking, diabetes mellitus, and hypertension) are well established and are discussed in Chap. 38. *Careful consideration of the probabilities of the presence of coronary artery disease is centrally important in the initial assessment and evaluation of testing results of any patient with chest pain.* The experienced clinician will calibrate his or her responses even within the context of algorithmic approaches to the evaluation of chest pain. For example, the 35-year-old male with atypical chest pain whose father died of coronary disease at less than age 50 and whose mother had a coronary bypass at age 55 would be viewed with a higher index of suspicion than he would be if both his parents and grandparents were alive and well. This higher level of concern might translate into ordering diagnostic modalities with a higher level of sensitivity and specificity for detecting coronary artery disease in the former as opposed to the latter case.

As discussed in Chaps. 35, 36, and 38, atherosclerosis generally, and including the disease in the coronary arteries, is a chronic inflammation representing the response of the arterial wall to the stress imposed by various risk factors. AMI has commonly been shown to occur as a result of the disruption of a coronary artery plaque at a site of a high density of inflammatory cells.[21] Thus, AMI can be thought of as resulting from the acute exacerbation of a chronic inflammatory response. There is increasing clinical evidence supporting this view. Thus, unstable angina, a frequent antecedent of myocardial infarction,[22] has been shown to be associated with elevated plasma levels of the acute-phase reactant C-reactive protein.[23,24] Observations from the Physicians' Health Study, which showed that subjects with the highest levels of C-reactive protein have an increased long-term risk of cardiac events, is also supportive of the concept that inflammatory responses are important in the pathogenesis of AMI.[25] *Thus, events precipitating myocardial infarctions can be viewed as exacerbating the arterial inflammatory response and/or increasing the physical forces impinging on a coronary artery lesion weakened by inflammation, which leads to rupture.*

Precipitating Events

There is little direct, but intriguing indirect, evidence that external factors might exacerbate the arterial inflammatory response. An association has been noted between AMI and antecedent mild respiratory syndromes.[25] It is possible that an infection, by activating systemic responses, could stimulate or activate previously quiescent atherosclerotic lesions. A more specific relation between AMI and an infectious agent has been posited in the case of *Chlamydia pneumoniae*.[26-28] Increased antibody titers to *C. pneumoniae* in subsets of patients have been associated with increased risk for acute infarction, and acute infarction-associated increases in circulating immune complexes, followed by a subsequent increase in antibody titers, have been observed.[29] Evidence exists for the presence of chlamydiae in atherosclerotic coronary artery lesions.[30] Thus, it is possible that *C. pneumoniae* infection contributes to the inflammatory responses in atherosclerosis and that acute reinfection activates the inflammatory response, leading to myocardial infarction. This area requires further investigation.

There is considerable evidence associating AMI with emotional or environmental stresses. It is likely that the majority of these stresses involve activation of the sympathetic nervous system, with increases in locally released and circulating catecholamines. Increased sympathetic drive increases cardiac oxygen consumption by increasing contractility and rate. Sympathetic stimulation will also increase shear forces and stress on vascular atherosclerotic lesions by augmenting contraction and torque and elevating blood pressure. Superimposition of these forces on a vessel weakened by inflammation can lead to plaque rupture.

Enhanced circulating catecholamine levels can increase the propensity for thrombus formation by activating platelets. Such a scenario likely explains the association (in about 4 to 7 percent of patients) between acute increases in physical exertion and the development of myocardial infarction, especially among those who do not exercise regularly.[31,32] Similarly, episodes of anger increase the risk of precipitating myocardial infarction in susceptible persons.[33] Distressing or changing life events reportedly occur with increased frequency in the months preceding a myocardial infarction.[34-36] Another well-controlled study, however, found no correlation between the occurrence of acute infarction and the presence of unusual life events for up to 4 weeks prior to the event.[31]

It is apparent that any acute stressful event or intervention can precipitate AMI in a patient with "active," susceptible coronary atherosclerotic lesions. Anesthesia and surgery are well known to enhance the risk of myocardial infarction, and cardiac events are the leading cause of perioperative morbidity.[37] Perioperatively, stress can be induced by tachycardia and hypotension,[38] anemia,[39] and hypothermia.[40] A study of patients with coronary disease undergoing noncardiac surgery has shown that the usual perioperative hypothermia was associated with a relative risk of cardiac events of 2.2, as contrasted to a similar group in whom normothermia was maintained.[41] The salutary effects of maintaining normothermia were thought to be due to the prevention of cardiac stress imposed by activation of the sympathetic nervous system. By extension, many of the stressful events-such as pulmonary emboli, stroke, hypoxia, allergic responses, blood loss, etc.-that have been associated with the precipitation of AMI can likely be related to the effects of adrenergic stimulation by an excess of catecholamines.

Myocardial infarction can occur because of low perfusion pressure in shock of any etiology and can arise in severe aortic stenosis even in the absence of coronary artery disease because of excessive oxygen demands in a very hypertrophic ventricle with, for example, marked tachycardia. Other nonatherosclerotic causes of myocardial infarction, including trauma, embolism, and dissection, are discussed in Chap. 39. Vasospasm in the absence of angiographically demonstrable coronary artery disease has been reported to have caused AMI in several patients during general anesthesia.[42] Also, it is likely that vasospasm plays a central role in cocaine-induced myocardial infarction.[43]

Personality Types

It has been claimed that so-called coronary-prone individuals exhibit certain personality traits, such as being a compulsive hard worker, being deadline-driven, and being excessively competitive. Categorizing people with such traits as "type A" and thus as being at increased risk for myocardial infarction was formerly widely discussed.[44] This concept is not widely accepted now,[45] and the psychological contributions to heart disease are generally considered to be more complex (see Chap. 80).

Circadian and Seasonal Variation

Results of the Multicenter Investigation of Limitation of Infarct Size (MILIS) study showed a marked circadian periodicity in the occurrence of myocardial infarction, with a peak prevalence between 6 A.M. and noon. The circadian rhythm was present whether the onset of the infarction was marked subjectively by the appearance of pain or objectively by plasma MB-CK (creatine kinase) levels. There was a threefold increase in the frequency of infarction at peak (9 A.M.) periods as compared with trough (11 P.M.) periods.[46] As a corollary, sudden death attributed to ischemic heart disease has a similar circadian periodicity. Available data suggest that the rhythms both for the occurrence of myocardial infarction and for deaths from ischemic events are actually bimodal. These rhythms are characterized not only by the morning peak but also by a secondary, less pronounced late-afternoon or early-evening peak (6 to 8 P.M.).[47] The mechanisms underlying this temporal distribution of ischemic events are not completely understood but are probably related to diurnal variations in thrombotic tendencies and to sympathetic nervous system activity. There is both an enhanced platelet aggregability[48] and a trough in intrinsic fibrinolytic activity during the morning hours.[49] A similar circadian variation is observed for cerebral infarction,[50] which further implicates an increased propensity for thrombosis in the morning hours. The blunting of the morning peak of myocardial infarction by both aspirin and beta-adrenergic blockers emphasizes the contributions of both the sympathetic nervous system and the coagulation pathways to the circadian rhythm of cardiovascular events.[51]

Other endogenous daily rhythms may be causally related. Ambulatory ST-segment changes in patients with coronary artery disease have demonstrated a close correlation between basal heart rate (which is higher in the morning) and the frequency of ischemic ST-segment changes.[52] These observations may be mechanistically related to the morning increase in tone noted in coronary artery segments with dysfunctional endothelium-dependent dilation in patients with chronic stable angina (see Chaps. 6 and 40).[53] Circadian variations in blood pressure[54] and plasma catecholamine levels[55] that parallel those of ischemic events have been observed. The morning increase in sympathetic activity not only increases the metabolic demand but may also cause coronary vasoconstriction that is unopposed by normal endothelial vasodilator mechanisms, as implied earlier.

There also appear to be exogenous rhythms that influence the development of AMI. In a working population, there is an increased risk for infarction on Mondays.[56] Seasonal variations have also been commented upon, with increases in the winter months of January through March.[57]

Symptoms

Prodromal symptoms antedating AMI are common and occur in at least 60 percent of patients.[58] Since at least 8 to 10 percent of AMIs are painless (not necessarily silent) and many ischemic episodes are silent,[59] it is apparent that the great majority of patients capable of sensing cardiac pain during periods of unstable angina do so in the hours, days, or sometimes weeks prior to the acute event. Most of these symptoms are anginal or angina-like, especially when assessed retrospectively in the context of the character of the pain of the acute infarct. The antecedent symptoms may also be anginal equivalents, such as paroxysmal dyspnea (see Chap. 40). The clinical features of unstable angina are discussed in Chap. 41. If one considers the general feeling of malaise and fatigue that many patients report having experienced prior to acute infarction, it is apparent that it is relatively unusual for the episode to be totally unheralded-a conclusion that is consistent with general clinical experience.

The classic symptoms of AMI involve chest discomfort that is commonly retrosternal or precordial in location and is described as pressure, aching, burning, crushing, squeezing, heavy, swelling, or bursting in quality.[60,61] Typically it has all the features of prolonged angina pectoris that was so eloquently phrased by William Heberden in his original description to the assembly of the Royal College of Physicians in 1772;

> There is a disorder of the breast marked with strong and peculiar symptoms considerable for the kind of danger belonging to it, and not extremely rare, which deserves to be mentioned more at length. The seed of it, and sense of strangling, and anxiety with which it is attended, may make it not improperly be called angina pectoris. They who are afflicted with it, are seized while they are walking (more especially if it be uphill, and soon after eating) with a painful and most disagreeable sensation in the breast, which seems as if it would extinguish life, if it were to increase or to continue; but the moment they stand still, all this uneasiness vanishes.

The location of chest pain is usually of little help in differentiating ischemia/infarction from other causes of chest pain,[62] but severe chest pain (as opposed to vague discomfort) and the presence of associated symptoms (dyspnea, nausea, diaphoresis, etc.) are more commonly associated with AMI.[63] The discomfort often radiates over the anterior chest and frequently into the left arm or both arms (particularly the medial aspect), and/or into the neck or jaw. In unusual instances, the pain may be in the back, particularly between the scapulae. There may be skip areas with retrosternal pain-associated with jaw, antecubital fossa, or wrist pain-or no pain between the two sites. Moreover, the pain may appear only in the referral area. The duration of the pain of infarction is prolonged, lasting conventionally longer than 15 min. While the intensity of the pain is usually steady following an initial crescendo, there is occasionally some waxing and waning. Sudden relief of pain may accompany reperfusion. Associated symptoms may include dyspnea, diaphoresis, nausea, and vomiting. Marked apprehension is common. Occasionally, presenting symptoms include syncope, acute confusion, agitation, stroke, or palpitations.

Approximately 23 percent of myocardial infarctions go unrecognized by patients because of the absence of symptoms or the lack of recognition of the significance of symptoms.[64] The common symptoms in this latter instance are nonclassic or atypical pain, dyspnea, nausea, vomiting, and/or epigastric pain. A

myocardial infarction may also masquerade as the development or worsening of congestive heart failure, the appearance of an arrhythmia, an overwhelming sense of apprehension, profound weakness, acute indigestion, pericarditis, embolic stroke, or peripheral embolus.[65] Presentation with painless myocardial infarction is more common in the elderly (age >65 years) than it is in the nonelderly, and this subgroup has an increased frequency of congestive heart failure as the initial presenting symptom.[66]

Physical Findings

GENERAL EXAMINATION

Features of the physical examination during AMI have been the subject of several reviews.[67,68] The patient is frequently sitting up because of a sense of suffocation or a feeling of shortness of breath. Most patients with cardiac pain or myocardial infarction have some sense of impending doom that is reflected in their facial expression. They may have a grayish appearance or one of panic or exhaustion. Diaphoresis is frequent. In severe cases, patients may be quite anxious, with an ashen or pale face beaded with perspiration. The patient should be examined in both the supine and left lateral decubitus position. The major findings pertaining to the heart appear on palpation of the precordium in the left lateral position. It is important to rapidly ascertain the vital signs and the nature, character, and rhythm of the arterial pulse; to observe the jugular venous pulse; to check the peripheral pulses; to palpate the precordium; and to auscultate the chest and precordium. Examination of the extremities should include subjective assessment of the temperature and color of the feet. The presence of very cool feet, especially with acrocyanosis in the setting of tachycardia, suggests low cardiac output.

The heart rate and rhythm are important indicators of cardiac function in the initial hours of myocardial infarction. *A normal rate usually indicates that the patient is not experiencing significant hemodynamic compromise.* In patients with inferior myocardial infarction, heart rates in the 50s and 60s are common in the initial hours. Up to 60 percent of these patients initially have bradycardia, but the rate gradually increases over the next few hours. The bradycardia, which may be associated with secondary hypotension, results from the stimulation of myocardial receptors with vagal afferents. *Persistent sinus tachycardia beyond the initial 12 to 24 h is predictive of a high mortality rate.* The pulse may be low in volume, reflecting decreased stroke volume. The blood pressure is usually normal but may be increased secondary to anxiety, or it may be decreased from cardiac failure. Blood pressure frequently normalizes temporarily with AMI in patients with hypertension. All peripheral pulses should be examined to observe their presence, and their status should be noted both to exclude current occlusion and to provide a baseline in case of future embolic events. The carotid pulse is most useful in assessing systolic upstroke time and stroke volume, which are decreased in the patient with a low output state.

The rhythm of the pulse is important because of the frequency of ectopic atrial and, in particular, ventricular beats in AMI. Observation of the jugular venous pulse is useful in determining whether ectopic beats are atrial or ventricular. A large A wave, indicating that the right atrium is contracting against a closed atrioventricular (AV) valve, suggests that the ectopic beat is ventricular. The respiratory rate is usually within the normal range. However, patients who are extremely anxious often exhibit hyperventilation, and those with pulmonary edema and cardiac failure have an increased respiratory rate associated with shallow inspirations. Abnormal breathing patterns, such as Cheyne-Stokes respirations, are rare unless the patient is in cardiogenic shock.

Examination of the jugular venous pulse is important with AMI, especially in patients with an inferior infarction, because insights can be gained into possible involvement of the right ventricle. The right ventricle is commonly involved with inferior infarction, but right-sided failure is seen only with major right ventricular involvement. It may be manifest by an elevated jugular venous pressure. In addition, in many patients with right ventricular infarction or ischemia, there is also a prominent A wave because of the decreased compliance of the right ventricle.[69] Kussmaul's sign, or an increase in the venous pressure on inspiration, may also be seen in right ventricular infarction/ischemia because of decreased right ventricular compliance. Generally, right ventricular failure commonly reflects left ventricular failure, with secondary elevation in pulmonary and right ventricular pressures. This circumstance usually occurs with large anterior or anterolateral infarction.

EXAMINATION OF THE LUNGS

Basilar rales are frequently detected in AMI. Cardiac failure diagnosed on the basis of mild signs of pulmonary congestion occurs in 30 to 40 percent of patients with otherwise uncomplicated myocardial infarction. A clinical classification proposed by Killip provides some uniformity in terms of describing cardiac failure and pulmonary congestion.[69a] Class I patients do not have any pulmonary rales or a third heart sound. Class II patients have rales of a mild-to-moderate degree, involving less than 50 percent of the lung fields, and may or may not have an S_3 gallop. Class III patients have rales more than halfway up the lung fields and an S_3 gallop. Class IV patients are those in cardiogenic shock.

CARDIAC EXAMINATION

Palpation of the precordium may reveal evidence of regional wall motion abnormalities. Palpation should be performed with the patient initially lying in the supine position; this is often adequate to ascertain whether there is a localized normal apical impulse and also permits assessment for dyskinetic impulses (see Chap. 10). Frequently, one may not feel any precordial impulse with the patient in the supine position because of the decreased intensity of contraction and/or body habitus. With the patient in the left lateral decubitus position, one may palpate a diffuse rather than a localized apical impulse, akinesis, or a paradoxical bulging during late systole; in some patients, there is a palpable atrial contraction corresponding to an audible S_4 gallop due to the decreased compliance of the left ventricle. One or more of these features of decreased contractility or lusitrophy and dysynergy are frequently present in the early hours of AMI, particularly with extensive damage.

The first and second heart sounds are often very soft because of decreased contractility. The first heart sound may also be diminished because of a prolonged PR interval. If there is tachycardia, a shortened PR interval may result in a somewhat accentuated first heart sound. The second heart sound is usually normal; however, with extensive damage, there may be a single second sound. Rarely, paradoxical splitting may reflect severe left ventricular dysfunction. A fourth heart sound is often audible in patients with AMI. A third heart sound is heard in probably only about 15 to 20 percent of AMI patients. A pericardial friction rub can be heard anytime between 24 to 72 h after the onset of myocardial infarction and, since its presence is often transient, frequently repeated auscultation is the best means of detection. The murmur of papillary muscle dysfunction is relatively common early in the course of infarction. This crescendo-decrescendo midsystolic murmur often reflects ischemia of the papillary muscles or the myocardial attachment rather than irreversible injury to these structures. This murmur usually disappears after the first 12 to 24 h if it is soft; however, if the murmur is moderate to loud in intensity, it may persist much longer, possibly throughout the patient's life. Mitral regurgitation is most commonly due to ischemia of the posteromedial papillary muscle (see also Chap. 10). Other findings on physical examination, such as the murmur of papillary muscle rupture or a ruptured ventricular septum, are described in appropriate sections under "Complications."

Diagnosis of Acute Myocardial Infarction

DIFFERENTIAL DIAGNOSIS

Myocardial infarction has typically been diagnosed on the basis of the triad of chest pain, electrocardiographic changes, and elevated plasma enzyme activity. Although AMI occurs without chest pain (20 to 25 percent of cases), chest pain remains the most common symptom and is usually responsible for the patient's seeking medical help. The differential diagnosis of prolonged chest pain is presented in Table 42-1. Chest pain, however, is not specific to cardiac disease, and it is often impossible on the basis of history alone to distinguish ischemia or infarction from other causes of chest pain. The differential diagnosis of chest pain is discussed in Chap. 40. Of patients presenting to the emergency department with chest pain, only about 14 percent are subsequently documented to have AMI.[70-73] Most patients at risk for myocardial infarction will be admitted to evaluate their chest pain unless definite noncardiac causes of chest pain-such as chest wall pain, hyperventilation, pleurisy, gastrointestinal pain, and so on-that are not imminently dangerous can be identified. In the CCU, only about 20 percent of patients admitted with chest pain have AMI.

Table 42-1: Differential Diagnosis of Prolonged Chest Pain

AMI
Aortic dissection
Pericarditis
Atypical anginal pain associated with hypertrophic cardiomyopathy
Esophageal, other upper gastrointestinal, or biliary tract disease
Pulmonary disease
Pleurisy: infectious, malignant, or immune disease-related
Embolus with or without infarction
Pneumothorax
Hyperventilation syndrome
Chest wall
Skeletal
Neuropathic
Psychogenic

ELECTROCARDIOGRAPHIC DIAGNOSIS

The electrocardiogram (ECG) is sensitive for detecting myocardial ischemia and infarction but is frequently not powerful enough for differentiating ischemia from necrosis (see Chap. 11).[70,71,74] Serial ECGs during AMI will show some evolutionary changes in the majority of patients.[75] An ECG obtained during cardiac ischemic pain frequently but not always exhibits changes in repolarization. The absence of electrocardiographic changes during pain provides evidence but not proof that the pain is not ischemic in nature. The early electrocardiographic changes of T-wave inversion or ST-segment depression may reflect ischemia or infarction. ST-segment elevation is more specific for AMI and reflects the epicardial injury-associated total occlusion of an epicardial coronary artery. The hallmark of AMI is the development of abnormal Q waves,[76,77] which appear on the average 8 to 12 h from the onset of symptoms but may not develop for 24 to 48 h. Abnormal Q waves usually reflect tissue death and the development of an electrical dead zone. Since abnormal Q waves do not develop immediately, they are not very helpful for initial diagnostic management and therapeutic triage except to signify the presence or absence of prior myocardial infarction. The diagnostic serial electrocardiographic changes consist of ST-segment elevation with the development of T-wave inversion and the evolution of abnormal Q waves (Fig. 42-1).[78] The appearance of abnormal Q waves is very specific to AMI; however, they are present in less than 50 percent of patients with documented AMI.[79] Most of the other patients who have AMI will have electrocardiographic changes restricted to T-wave inversion or ST-segment depression or no change at all. These patients represent the group with non-Q-wave infarction.[80]

The traditional concept that myocardial infarctions can be classified as transmural or nontransmural on the basis of the presence or absence of Q waves is misleading, since autopsy studies have demonstrated convincingly that pathologic Q waves may be associated with nontransmural infarction and may be absent with transmural infarction.[81-83] These misnomers have been replaced by the terms *Q-wave infarction* and *non-Q-wave infarction for transmural and nontransmural infarction*, respectively.[84] The evolution of a non-Q-wave infarction is characterized by a lack of development of an abnormal Q wave and by the appearance

of reversible ST-T-wave changes with ST depression that usually returns to normal over a few days, but is occasionally permanent. Differentiation between these two types of infarctions has become entrenched, since there are major differences in their pathogenesis, clinical manifestations, treatment, and prognosis (Table 42-2). The initiating events in the pathogenesis of Q-wave and non-Q-wave infarction are thought to be identical, namely, coronary occlusion induced by a thrombus superimposed on a plaque together with vasoconstriction (see Chap. 36). There is considerable evidence, however, to indicate that in non-Q-wave infarction, early spontaneous reperfusion occurs, the mechanism of which remains uncertain. In contrast, in Q-wave infarction, the coronary occlusion is sustained at least for a long enough period to result in extensive necrosis.

One explanation for early spontaneous reperfusion is the lack of sustained vasoconstriction, which may contribute to occlusion.[85] The evidence supporting the existence of early spontaneous reperfusion in non-Q-wave infarction is as follows:

1. Coronary angiographic studies performed in the early hours after onset show that only about 20 to 30 percent of patients have complete coronary occlusion of infarct-related vessels; however, for Q-wave infarction, it is about 80 to 90 percent.
2. Infarct size is routinely much less than observed with Q-wave infarction, which is consistent with salvage by early reperfusion.
3. Peak plasma CK levels are reached on an average of 12 to 13 h after onset of symptoms, indicating early washout of the enzyme, as opposed to about 27 h after Q-wave infarction.
4. Reperfusion-induced contraction necrosis is extremely common, as it is in patients who undergo early reperfusion induced by thrombolytic therapy.[86]
5. Acute mortality rates are around 2 to 3 percent, compared with 10 percent for Q-wave infarction.
6. The complications are minimal compared with those after a Q-wave infarction.
7. Finally, the long-term prognosis is characterized by recurrent episodes of reinfarction, so that after about 2 years, survival is the same as that after Q-wave infarction.[80,87-90]

Traditional teaching has held that AMI could not be diagnosed electrocardiographically in the presence of a left bundle branch block because of the unpredictability of the depolarization and repolarization patterns. It has been suggested that marked ST-segment deviation, beyond what could be anticipated from the conduction abnormality, could be useful in the diagnosis of AMI in the setting of a left bundle branch block.[91]

The resting ECG is insensitive for detecting the presence of atherosclerotic coronary heart disease; it is normal in 50 percent of patients with angiographically significant coronary obstruction.[92] Nevertheless, an abnormally wide Q wave on a resting ECG has been the standard criterion for the diagnosis of a myocardial infarction for over 60 years.[93]

The electrocardiographic criteria for the diagnosis of AMI as outlined in the MILIS study are the presence, in the setting of chest pain, of any one of the following: (1) new or presumably new Q waves (at least 30 ms wide and 0.20 mV deep) in at least two leads from any of the following: (a) leads II, III, or aV_F; (b) leads V_1 through V_6; or (c) leads I and aV_L; (2) new or presumably new ST-T- segment elevation or depression ($\geq$0.10 mV measured 0.02 s after the J point in two contiguous leads of the previously mentioned lead combination); or (3) a complete left bundle branch block in the appropriate clinical setting. An evaluation of these criteria in 1809 enzyme-confirmed infarctions found that 21 percent of the patients with an infarction had none of these changes.[94] Conversely, over 90 percent of patients who had ST-segment elevation of 0.1 mV, as described previously, were confirmed to have AMI. If the patients also had ST-segment depression in the so-called reciprocal leads, the infarction rate was 3 percent higher. Patients with a left branch bundle block or ST-segment depression without other abnormalities had a lower rate of infarction (46 and 52 to 56 percent, respectively) than those with ST-segment elevation. Furthermore, the presence of abnormal Q waves on the resting ECG accurately predicts the presence and location of left ventricular contraction abnormalities. In a study of 64 patients with abnormal Q waves on the ECG, all patients with abnormal Q waves in the anterior leads and 30 of 33 with abnormal Q waves in the inferior leads demonstrated contraction abnormalities in the corresponding left ventricular segments.[95] The evolution of a Q-wave myocardial infarction can be separated electrocardiographically into four phases: (1)

hyperacute, (2) acute, (3) subacute, and (4) chronic stabilized (Fig. 42-1; see Chap. 11).

In the hyperacute phase (Fig. 42-1), the earliest electrocardiographic manifestation of an acute infarction is usually a straightening of the normal upward concavity of the ST-T segment.[96] With further evolution, the straightened ST-T segment becomes elevated. The ST-T segment usually slopes upward, since the portion of the ST-T segment nearest the T wave is more elevated than the proximal portion. Also, the amplitude of the T wave is usually increased. Occasionally, the ST-T segment may be markedly elevated and yet retain its upward concavity. ST-T depressions in leads oriented toward the presumably noninfarcted myocardium were traditionally termed *reciprocal changes*. Studies have indicated that such ST-T depressions usually reflect more extensive infarction. In the subacute phase, the abnormal Q wave representing myocardial necrosis begins to appear, but the T-wave vector still points toward the infarct zone (Fig. 42-1). In the fully evolved phase, the ST-T segment begins to diminish in amplitude and becomes coved or convex upward. It blends into the now symmetrically inverted T waves (see Fig. 42-1). The abnormal Q waves (>0.03 s in duration and more than 25 percent of the R-wave amplitude) appear during this stage. During the chronic phase (Fig. 42-1), there is generally resolution of the ST- and T-wave changes, with the only residual change being an abnormal Q wave. Although the ST-T segments again become isoelectric, they are frequently horizontal, with a sharp-angled ST-T junction, rather than exhibiting the normal concavity. Occasionally, in small inferior infarctions, even the abnormal Q waves resolve.

Posterior myocardial infarction occurs in the posterior left ventricular wall. An isolated true posterior infarction is quite uncommon, since such an infarction is usually associated with an inferior or lateral infarction. Since there are no electrocardiographic leads oriented toward the posterior left ventricular wall, the electrocardiographic changes of a true posterior infarction are seen as mirror-image representations in leads V_1 to V_3. Schamroth described the criteria for a true posterior infarction as follows: R waves of 0.04 s in lead V_1 and in contiguous right precordial leads with upright T waves, and, in the acute phase, ST-segment depression and an R/S ratio $\geq$1 in leads V_1 and V_2.[96] Usually, there are associated changes of an inferior or lateral infarction. As the infarction evolves, the ST-segment depression decreases and the upright T-wave amplitude increases. It is helpful to turn the ECG upside down and look at it from the back while holding it to a strong light. The changes in leads V_1 and V_2, which might be overlooked on a direct glance, are seen as abnormal Q waves, ST-segment elevation, and T-wave inversion when viewed from this perspective.

Similarly, electrocardiographic diagnosis of right ventricular infarction offers special challenges. Since right ventricular infarction generally occurs in the presence of inferior left ventricular infarction, the resulting ST-segment elevation is usually overwhelmed in the conventional precordial leads overlying the right ventricle (V_2 and V_3) by the ST-segment elevation in the opposing left ventricular myocardium on the inferior surface. The right ventricular electrical forces might be manifest in this setting as a diminution of the usual reciprocal ST-segment depression seen in the right precordial leads in inferior infarction. If the injury to the inferior wall is minimal, ST-segment elevation will occasionally be seen in V_2 through V_4 in the presence of right ventricular infarction.[97] Otherwise, ST-segment elevation must be sought in the right chest leads, V_1, and V_{3R} through V_{6R}. ST-segment elevation in these leads provides reasonably strong evidence for the presence of right ventricular infarction.[98] A postmortem study has shown that a 25 percent or greater involvement of the right ventricle was necessary to produce ST-T-segment elevation.[99] Atrial infarction is usually reflected in PR-segment elevation or depression and P-wave abnormalities and is frequently associated with supraventricular arrhythmias, as discussed later.[100]

The phenomenon of "ischemia at a distance" reflects the occurrence, in AMI with ST-segment elevation, of ST-segment depression in other, frequently reciprocal leads. It remains uncertain whether these changes represent true reciprocal changes or subendocardial ischemia in the area, but the presence of the finding is associated with a less favorable prognosis than its absence.[101,102]

Criteria for electrocardiographic diagnosis of AMI in various areas of the heart are discussed more fully in Chap. 11. In view of a lack of sensitivity and specificity of the chest pain history or of the ECG, confirmation of the diagnosis of AMI is based on elevated plasma levels of cardiac-specific isoenzymes.

PLASMA DIAGNOSTIC MARKERS

Tissue Distribution of MB-CK, Troponin T, Troponin I, and Myoglobin

Myocardial necrosis is associated with the release of a variety of macromolecules, including enzymes, myoglobin, and contractile proteins that have been evaluated as potential diagnostic markers for AMI. The use of CK and MB-CK has become routine and is highly sensitive, specific, and cost-effective for diagnosing myocardial infarction.[103] The use of total CK alone without MB-CK yields a similar sensitivity, but specificity is markedly lower, in the range of 70 percent.[104] The use of total CK as a diagnostic marker for myocardial infarction is discouraged. CK consists of two monomers, each having a molecular weight of 43,000. The isoenzymes of CK are formed by the association of two M monomers (MM-CK), which predominate in muscle (hence the name); or of two B monomers (BB-CK), which predominate in the brain and internal visceral organs; and a hybrid form (MB-CK), found in the heart, composed of one M subunit and one B subunit. The isoenzymes MM, MB, and BB are located in the cytoplasm of the cell. There are separate genes for each of the monomers, which have been isolated, cloned, and sequenced.[105,106] About 5 percent of cellular MM-CK activity is associated with the M line of the sarcomere in both heart and skeletal muscle and a significant amount is in the Z line in heart muscle.

Fifteen percent of the CK in the myocardium is in the form of MB-CK, which provides for its sensitivity and specificity as a diagnostic marker of AMI. Several investigators have found small amounts of MB-CK in normal adult skeletal muscle,[107,108] whereas others have failed to detect any cytosolic CK other than MM-CK.[109,110] MB-CK is alleged to increase (1 to 5 percent) in skeletal muscle following injury such as chronic exercise,[111,112] inflammation,[113] trauma,[114] and electrical injury.[115] In hereditary muscle diseases, such as Duchenne muscular dystrophy (DMD), there is also increased MB-CK in the range of 1 to 5 percent. During the first 6 weeks of life in utero, only BB-CK is synthesized, while at about the eighth week, M-CK synthesis is induced and rapidly supplants the B-CK in skeletal and cardiac muscle, such that by about the twelfth week, MM-CK predominates.[116,117] It is believed that in DMD, the retained expression of the B-CK reflects the abnormal development of these muscles. It is postulated that in the case of the reaction to muscle injury, undifferentiated skeletal muscle cells differentiate to form mature skeletal myocytes and thus repeat the developmental program of fetal skeletal muscle, but the expression of B-CK is transient.[118] In the adult human heart, 15 percent of total CK activity is MB-CK and the remainder is MM-CK. Myoglobin, with a molecular weight of 17,000, is ubiquitously distributed throughout cardiac and skeletal muscles.[119]

Two new diagnostic cardiac markers have been introduced: troponin T and troponin I,[120] which are part of the sarcomere complex. Troponin T has a molecular weight of 38,000, and troponin I, 23,000. There are three genes for each of the troponins that encode for slow and fast skeletal and cardiac muscle.[121] Cardiac troponin I has 31 amino acids, which are not present in the skeletal forms. The recognition site of the antibody used in the assay is in the cardiac-specific region, which makes the test very specific as a marker for myocardial injury,[122] and since normal plasma levels of troponin I are near 0, it is also very sensitive. Furthermore, studies indicate that cardiac troponin I is not upregulated in skeletal muscle with hypertrophy or injury and the skeletal form is not upregulated in the heart with hypertrophy or injury.[123] Cardiac troponin T has 11 amino acids not present in the skeletal forms, which has permitted the development of a specific diagnostic test.[121] Troponin T has similar sensitivity to troponin I but the first generation assay had less specificity, while the second generation assay appears to have similar specificity to that of troponin I.[121]

Temporal Profiles of MB-CK, Myoglobin, Troponin I, and Troponin T Released into Plasma

Plasma MB-CK activity following myocardial infarction is significantly elevated, such that reliable diagnostic sensitivity (>90 percent) is reached within 12 to 16 h of the onset of symptoms. Maximal levels[124] of MB-CK are reached between 14 and 36 h, with a return to normal levels occurring after 48 to 72 h (Fig. 42-2). In patients with minimal cardiac injury, such as occurs in non-Q-wave infarction or following effective early reperfusion, plasma MB-CK activity reaches maximal activity at about 12 to 15 h. In contrast, after Q-wave infarction with reperfusion, it reaches maximal activity at an average of 28 h. The plasma temporal profiles of troponin I and troponin T are very similar to those of total CK and MB-CK. Troponin I and troponin T are released into the plasma so that reliable diagnostic sensitivity (>90 percent)

is reached by 12 to 16 h and maximal activity is reached by 24 to 36 h. The levels return to normal within 10 to 12 days.[124] Plasma myoglobin is increased within 2 h of the onset of symptoms and remains increased for at least 7 to 12 h.[119]

Early Diagnosis (6 to 10 h of Onset): MB-CK Subforms and Myoglobin

In the United States, over 5 million patients with chest pain go annually to the emergency department, but only about 10 percent with chest pain will subsequently be shown to have myocardial infarction.[124] About 50 percent of patients will have cardiac ischemia, 10 percent will have nonischemic cardiac pain, and about 30 percent will have pain of noncardiac origin.[124] It is important to have an early diagnosis to determine the initial therapeutic regimen and whether hospital admission is needed. In the United States, it is estimated that over $12 billion per year[125] is spent unnecessarily to exclude myocardial infarction in patients admitted to the hospital with chest pain without infarction. Thus, early, rapid diagnosis is required to triage patients, reduce costs, and select appropriate therapy in spite of the difficulty in distinguishing cardiac ischemia from infarction based on the patient's history, physical examination, and the ECG, as noted. This difficulty is emphasized by the observation that over 50 percent of AMI patients in the United States[126] have nonspecific ST-segment changes (non-Q-wave infarction) rather than ST-segment elevation (Q-wave infarction). The only specific electrocardiographic finding on admission for myocardial infarction is the recent development of ST-segment elevation or left bundle branch block. It is estimated that less than 50 percent of patients with AMI will have a diagnostic ECG, which represents only 5 percent of the total patients presenting with chest pain; thus, there is a need for an early objective marker (within 6 h of onset).[71] The ideal diagnostic test should have an assay performance time that is brief, and the marker must have a highly reliable negative predictive value, since only 10 percent of patients will have infarction, as noted. While a false-positive range of 5 to 10 percent is acceptable, a desirable false-negative range is 1 to 2 percent. Assessment of the plasma profile of the markers shows only two plausible candidates, namely, MB-CK subforms and myoglobin.

It was recognized for some time that MM and MB-CK, though present in tissue in single forms, exhibit different forms upon release into the circulation, as detected by electrophoresis.[127] In 1982, it was shown that upon release into the circulation, MM-CK is converted into three forms: MM-3, MM-2, and MM-1, and MB-CK is converted into MB-2 and MB-1, due to the proteolytic activity of carboxypeptidase-N, an enzyme present in the blood of all vertebrates.[128,129] Carboxypeptidase-N cleaves the terminal amino acid, lysine, from the M subunit of the MB-CK, which is positively charged, leaving the remaining molecule more negatively charged (MB-1). The more negative form (MB-1), upon electrophoresis, separates from the parent tissue form (MB-2), giving rise to the two forms of MB-CK in plasma. A new technique utilizing 1400 V, which provides separation of the MB subforms within about 6 min,[130] is coupled with automated densitometric quantification; this produces a value for MB-2 activity, the plasma ratio of MB-2 to MB-1, and total MB-CK activity.[131] The current assay for the MB-CK subforms is completely automated and requires about 25 min. In the plasma, the MB-CK subforms are in equilibrium, with a ratio of MB-2 to MB-1 of 1 to 1. Normally, the baseline plasma MB-CK activity is in the range of 2 to 4 IU/L, or a protein concentration of 3 to 5 ng/L. Thus, for a reliable diagnosis of myocardial infarction based on total MB-CK activity, one requires an increase above 9 IU/L, or, for protein, above 7 ng/L. When infarction occurs, MB-2, the tissue form, is initially released into the circulation in minute amounts so that total plasma MB-CK activity remains within the normal range, but the ratio of MB-2 to MB-1 changes markedly and provides the basis for an early diagnosis of myocardial infarction. In a large, blinded, prospective study involving 1110 patients presenting consecutively with chest pain, it was shown that MB-CK subforms reliably diagnosed myocardial infarction within 6 h of onset of symptoms.[131]

The introduction of troponins T and I necessitated the need to provide comparative diagnostic sensitivity and specificity for all of the markers. A large, multicenter, prospective, double-blind study, the Diagnostic Marker Cooperative Study (DMCS), was performed, comprising 1004 patients admitted consecutively with chest pain.[124] A serial analysis of all markers (MB-CK activity, MB-CK mass, MB-CK subforms, myoglobin, and cardiac troponin T and I) was performed on a sample taken on admission, at 1 h, every 2 h for up to 6 h from onset, and subsequently every 4 h for up to 24 h. Every effort was made to obtain the time of onset of symptoms. In keeping with previous observations, only 11 percent of the patients with chest pain were subsequently documented to have infarction (n = 118), of whom less than 47 percent had a diagnostic ECG (43 percent had ST-segment elevation and 4 percent had a left bundle branch block), with

the remainder having nonspecific ST-T changes (non-Q-wave infarction). Cardiac ischemia accounted for 51 percent and nonischemic cardiac pain for another 9 percent, while in 29 percent the pain was of noncardiac origin. The diagnostic sensitivity and specificity of each of the markers are indicated in Table 42-3. MB-CK subforms afforded a sensitivity and specificity of 91 percent for the diagnosis of infarction within 6 h of the onset of symptoms. Myoglobin had a sensitivity of 83 percent during the same interval. The negative predictive value of MB-CK subforms within the initial 6 h of onset was 97 percent and that of myoglobin was 95 percent. Thus, if a patient has a negative MB-CK subform test at 6 h after the onset of symptoms, one can reliably conclude that the patient does not have infarction. During the same interval of 6 h from onset, the total MB-CK (activity or mass assay) and troponins T and I afforded a sensitivity of only 65 percent. A major observation from this study-with significant diagnostic, therapeutic, and cost-saving implications-is the finding that MB-CK subforms correctly diagnosed 92 percent of the patients with myocardial infarction within 60 min of arriving in the emergency department. This was based on the results of the sample collected on admission to the emergency department and on a second sample collected 1 h later (Table 42-4). For the same two samples, however, myoglobin had a sensitivity of 83 percent. The mean time required to make the diagnosis of myocardial infarction using MB-CK subforms was 1.2 h ± 20 min from arrival in the emergency department, and a similar time was required to exclude those without infarction. It is evident from the data in Table 42-3 that total MB-CK, troponin T, and troponin I have high sensitivity and specificity for the diagnosis of myocardial infarction 12 to 16 h from the onset of symptoms. It is noteworthy that the sensitivity of myoglobin decreases after about 7 or 8 h because of rapid renal clearance and thus may not be reliable after 10 to 12 h, particularly in patients with minimal injury.

Table 42-4: Diagnostic Sensitivity of Myoglobin and MB-CK Subforms on Admission and 1 h Later

Markers	Sample on Admission (%)	Sample 1 h Later (%)
MB-CK subform	67	91
Myoglobin	63	78

Sampling Intervals and the Diagnosis of Infarction

In patients presenting within the first 10 h of the onset of myocardial infarction, the appropriate marker is either MB-CK subforms or myoglobin, since other markers lack the necessary sensitivity. It is recommended that a blood sample be taken immediately on admission, 1 h later, then every 2 h until 6 h from the onset of symptoms, and then, if positive, every 6 h for 24 to 48 h. The MB-CK subform assay provides a diagnosis based on the first two samples (initial and 1 h) in more than 90 percent of the patients with infarction. Once a sample is positive, one can sample every 6 h for 24 to 48 h. If the sample shows normal values for the MB-CK subforms, one must sample until 6 h from the onset of symptoms to reliably exclude infarction, at which time sampling can be discontinued. Sampling for 24 to 48 h in patients with positive MB-CK subforms is optional, but it is recommended for the following reasons: to obtain maximal total plasma MB-CK activity as a rough index of the extent of damage; to follow the decline in MB-CK subform activity as a baseline for subsequent procedures often performed, such as cardiac catheterization or percutaneous transluminal coronary angioplasty (PTCA); and to facilitate detection of early reinfarction, which accounts for 30 to 40 percent of in-hospital deaths in patients recovering from AMI. If the myoglobin is analyzed, a similar sampling algorithm is followed except that the interval required to exclude or include infarction with myoglobin may be longer, since with MB-CK subforms, 90 percent of patients with AMI are diagnosed within 60 min (two samples), whereas only 80 percent over the same interval will be diagnosed with myoglobin. Patients presenting 10 to 12 h or later after the onset of symptoms should have a sample taken on admission; if this is positive, it should be repeated every 6 h for 24 to 48 h. Total MB-CK, troponin T, or troponin I in this time frame will provide the desired diagnostic sensitivity and specificity. Normal total plasma MB-CK activity or protein concentrations at 12 to 16 h from the onset of symptoms excludes infarction with 95 to 100 percent reliability, as does a normal troponin T or I. Plasma myoglobin is not a reliable marker 8 to 10 h after the onset of symptoms. The upper level of normal for MB-2 is ≥2.6 IU/L, with a ratio of MB-2 to MB-1 of ≥1.7. The upper limit of normal for myoglobin is 85 ng/mL. The upper limit of total MB-CK activity is 9 IU/L, and for protein (mass) assays, 7 ng/mL. The upper limit of

normal for troponin T is 0.1 ng/mL and for troponin I 1.5 ng/mL. The following guidelines are suggested as enzymatic criteria for the diagnosis of myocardial infarction (Table 42-5).

Table 42-5: Enzymatic Criteria for Diagnosis ofMyocardial Infarction

Serial increase, then decrease of plasma MB-CK, with a change >25% between any two values
MB-CK >10-13 U/L or >5% total CK activity
Increase in MB-CK activity >50% between any two samples, separated by at least 4 h
If only a single sample available, MB-CK elevation > twofold
Beyond 72 h, an elevation of troponin T or I or LDH-1 > LDH-2

If there is a serial elevation in plasma MB-CK levels followed by a decrease to baseline, with a change of 25 percent or more between the two values or plasma MB-CK activity increases 50 percent or more between two samples separated by at least 4 h and not more than 12 h:

1. Preferably, the diagnosis is made on the basis of no fewer than two samples in a 24-h period, separated by at least 4 h.
2. If only a single sample is present, the diagnosis must be made on the basis of an elevation above normal by at least twofold.
3. In patients admitted beyond 72 h from the onset of infarction, troponin T or I is preferred, since MB-CK levels may have returned to normal. The preceding criteria for MB-CK have not been evaluated for troponin T or I but would probably serve as guidelines until further information is available. These principles are incorporated into the protocols for triaging patients in the emergency department, as illustrated in Fig. 42-3.

Limitations to Myoglobin, MB-CK, and Troponins I and T

Elevated plasma MB-CK as a diagnostic marker for myocardial infarction is associated with a very low incidence of false-negative results if samples are collected frequently and appropriately within 48 to 72 h of the onset of symptoms. However, false-positive results do occur, since trace amounts of MB-CK can be released from tissues other than the heart. Skeletal muscle injury may induce the synthesis of MB-CK and has been documented after crush injury,[114] electrical injury,[115] dermatomyositis and polymyositis,[113] and DMD,[132] as well as in professional athletes and marathon runners.[111,112] If one suspects that elevated plasma MB-CK activity is due to skeletal rather than cardiac muscle, the following should be considered:

1. The appropriate clinical setting, namely, skeletal muscle disease or trauma.
2. An atypical time course for the increase and decrease in plasma MB-CK activity, particularly if prolonged, as one might see in inflammatory disorders.
3. If MB-CK accounts for less than 5 percent of the total CK activity, then a skeletal muscle source should be suspected. Since tissues that contain MB-CK (other than the myocardium), such as skeletal muscle, contain only trace amounts (1 to 2 percent), elevated plasma MB-CK indicative of myocardial infarction should exceed 5 percent of total activity. At the time of peak plasma CK resulting from myocardial infarction, MB-CK levels usually make up 10 to 15 percent of the total activity.
4. A marked elevation of total CK activity of 20- to 30-fold suggests that the cause is more likely to be skeletal muscle injury. Hypothyroidism is associated with elevated levels of both total CK and MB-CK due to diminished clearance.[133] Occasionally, one sees what is referred to as macro CK-1, a complex of CK and macroglobulins, which migrates in the position of MB-CK upon electrophoresis[134,135] and results in a false-positive diagnosis of AMI. Macro CK-1 is common in elderly women and in patients who are chronically ill, with an overall stated incidence of 1.6 percent in hospitalized patients.[135] This is not a problem for assays utilizing MB-CK monoclonal antibody, as is currently the case for most MB-CK assays. Electrocardioversion causes a significant elevation

of total CK activity, but unless the procedure is repeated several times, it does not elevate plasma MB-CK. MB-CK is elevated in chronic renal failure;[136] however, it does not show any changes upon serial analysis and thus is not a significant diagnostic problem.

Troponin I has not been found to be elevated in patients with normal skeletal muscle, despite severe exercise or injury,[122] or in the blood of marathon runners.[137,138] Furthermore, in a study involving 100 patients undergoing noncardiac surgery with extensive skeletal muscle injury, only 1 patient had a slight elevation of cardiac troponin I.[139] Troponin I is not elevated in chronic renal failure.[122] *Troponin I is a more specific marker than MB-CK in patients with myocardial infarction and concomitant skeletal muscle injury, such as that following noncardiac surgery or severe muscle trauma.* An increase in troponin T has been reported in patients with polymyositis/dermatomyositis without cardiac involvement.[140] Wu et al.[141] reported that troponin T had lower specificity than MB-CK for myocardial damage. However, the antibody used in the assay for troponin T is reported to have a 3.6 percent cross-reactivity with skeletal troponin T,[142] which may account for this lack of specificity. A recent assay with a more specific monoclonal antibody shows similar specificity to that of troponin I.[121]

Rationale for Selecting a Diagnostic Marker

In view of the abundance of plasma markers and the increasing need to reliably triage patients with chest pain in a cost-effective manner, a careful choice must be made of which plasma marker or combination of markers will be utilized routinely. In selecting a marker for early diagnosis upon admission to the emergency department, there is essentially a choice between MB-CK subforms and myoglobin. MB-CK subforms, as compared with myoglobin, provide greater sensitivity as well as greater specificity overall for the early diagnosis of AMI. There has been extensive experience with the MB-CK subforms, while routine use of myoglobin for the diagnosis of infarction is minimal. Nevertheless, if patients with trauma are avoided, the specificity of myoglobin is quite acceptable, and it is the next best alternative for an early diagnosis, as indicated in Tables 42-3 and 42-4. Both assays are automated and simple to perform, requiring only about 25 min, and are identical in cost. For the diagnosis of patients presenting 10 h or later after the onset of symptoms, total MB-CK, which has been the standard for more than two decades, is extremely sensitive and specific. However, cardiac troponin I or cardiac troponin T, since they are not normally present in the blood and do not appear to be present in skeletal muscle, provide greater specificity than MB-CK in those clinical conditions in which there is concommitant skeletal muscle injury. It is also claimed that troponin I and T may provide increased sensitivity over that of MB-CK since they are not normally present in the blood; however, further studies are required before the claim of greater sensitivity can be accepted. The time required to assay each of these latter three markers is about 25 min, with identical costs. The choice of marker or markers used routinely may depend in part on the various tests with which the laboratory personnel are acquainted. However, there is no reason, based on diagnostic sensitivity and specificity, to assay all of these markers; in addition, the cost would be prohibitive. A single assay for both early and late diagnosis is the MB-CK subforms, which provide an early diagnosis and from which total MB-CK can be derived for the late diagnosis. Another is MB-CK subforms for early diagnosis, plus either troponin I or T for late diagnosis. Myoglobin provides an early diagnosis but is less specific and less sensitive than MB-CK subforms. In clinical situations where there is concommitant skeletal muscle involvement, MB-CK, if elevated, is less than 5 percent of total CK activity and is usually not a diagnostic problem. However, troponin I or T is more appropriate in those clinical conditions. The data from the DMCS indicate no advantage to simultaneously analyzing both MB-CK subforms and myoglobin for early diagnosis; similarly, for late diagnosis, there is no advantage to analyzing multiple markers.

Diagnosis of Acute Myocardial Infarction in Patients 48 h or more from the Onset of Symptoms

In patients admitted 48 to 72 h after the onset of symptoms, particularly when associated with minimal myocardial damage, plasma MB-CK may have returned to normal levels. In this situation, it has been traditional to utilize LDH isoenzymes, since LDH-1 activity peaks between 48 and 72 h and remains elevated for 10 to 14 days, but the preferred diagnostic marker is now troponin I or T. It is recommended that LDH, LDH isoenzymes, and SGOT (AST) be discontinued as diagnostic markers for AMI.

Diagnostic Assessment of Patients Undergoing Fibrinolytic Therapy or Angioplasty

Patients who receive fibrinolytic therapy or early angioplasty (within 4 to 6 h) for treatment of infarction should be assessed hourly for plasma MB-CK activity or one of the troponins for the first 4 to 6 h, then every 6 to 8 h for 36 h, with sampling reinitiated if chest pain or other features occur to suggest reinfarction. Following successful reperfusion, MB-CK is usually elevated within 30 to 60 min of the reperfusion and plasma activity reaches maximum levels within 10 to 15 h. Studies have shown that 15 to 20 percent of patients undergoing elective PTCA have elevated plasma MB-CK,[143-145] and these individuals have a worse prognosis over the subsequent 6 months.[146] It remains controversial whether routine sampling for MB-CK should be performed after elective PTCA, since changes in treatment based on increased MB-CK have not been assessed. In patients with triple-vessel disease or where complications are more likely, routine sampling with MB-CK subforms is recommended for 6 h; it should be discontinued if the results are normal. If they are positive, sampling should continue for at least 24 h, and the patient should be treated as having had myocardial damage. It is now recognized that increased plasma levels of MB-CK reflect cardiac cell death, and it is likely though not proven that cardiac troponin I and T do so also.

Diagnosis of Early Reinfarction

Diagnosis of early reinfarction (within 24 to 48 h) is difficult, since it represents an elevation superimposed on an already elevated plasma marker.[147,148] However, if MB-CK has returned to normal, then the diagnosis is relatively easy, since one sees a secondary increase in plasma MB-CK activity. Detection of early reinfarction with a secondary elevation in plasma MB-CK in patients who undergo successful thrombolysis is more appropriate, since MB-CK activity usually peaks within the first 10 to 15 h and returns to normal by 36 to 48 h. A secondary elevation of MB-CK activity 36 to 48 h after the onset of symptoms provides for a sensitive and specific diagnosis of reinfarction. In the latter situation, reinfarction is defined as an increase of 50 percent or more in the plasma MB-CK activity above the preceding baseline (mean of the two preceding samples) in at least two samples separated by a minimum of 4 h within a 24-h interval, with an absolute value of ±9 IU/L or 7 ng/L in at least one sample.[149] If the MB-CK activity is on the downslope from the antecedent infarction, a 25-percent increase is considered diagnostic; however, this is always less reliable than a secondary elevation after the return of MB-CK activity to baseline. These criteria were found to be reliable in three large clinical trials.[80,134,150] Confirmation of reinfarction occurring early, however, is more appropriately diagnosed using the MB-CK subforms. The MB-2 is near normal by 18 to 24 h and usually peaks at 10 to 12 h, so a well-defined downslope is apparent after 12 to 16 h. The other markers, cardiac troponin T and troponin I, since they remain elevated for 10 to 14 days, and, thus, because of the background, lack the necessary sensitivity. Myoglobin, since it returns to normal early after onset, is also a sensitive marker, but because of venipuncture or other minor skeletal muscle trauma commonly occurring in the hospital setting, makes it nonspecific.

Prognostic Role for Biochemical Markers in Assessment of Unstable Angina

Several studies have shown that patients presenting with the clinical diagnosis of unstable angina and minor elevations in MB-CK, troponin T, or troponin I have a more adverse outcome with respect to clinical events such as death, myocardial infarction, or the need for revascularization. In the GUSTO IIA trial,[151] of 835 patients with unstable angina, 36 percent had elevated troponin T and experienced increased mortality and other clinical events. Similarly, in the TIMI III trial,[152] of 1404 patients with non-Q-wave infarction and unstable angina, 41 percent had elevated troponin I and experienced increased mortality and other clinical events. In a study involving 593 patients with unstable angina, those with elevated MB-CK had increased mortality and other clinical events.[153]

It is now recommended that patients with unstable angina be assessed with one or more of these markers; however, treatment based on these indications and its long-term outcome have not been assessed. In the DMCS study,[154] there were 178 patients with unstable angina (rest pain of increased frequency or severity); the results of the various markers are shown in Fig. 42-4.[154] This is the only study in which the sensitivity of all of the markers has been compared. There is a dilemma with respect to the interpretation of elevated plasma markers in patients with unstable angina. Does this mean that these proteins are released due to ischemia (reversible injury) or that, in fact, limited infarction has occurred? Data[155] indicate release of CK reflects irreversible injury. In a series of conscious animal studies, it was shown that 20 min of coronary artery occlusion is consistently associated with increased plasma CK activity and, on light and electron microscopy, myocardial necrosis. In contrast, animals undergoing 10 min of coronary occlusion

who exhibited severe ischemia-as shown by ST-segment elevation, depletion of myocardial glycogen, and cell swelling-had no increase in plasma CK. In the group of animals undergoing 15 min of coronary occlusion, only 30 percent had increased plasma CK activity, and each of these also showed microinfarction of the myocardium as detected by light and electron microscopy.[155] This finding-coupled with the observation that patients with proven obstructive coronary disease during exercise-induced ischemia, as documented by thallium scintigraphy, exhibited no increase in plasma MB-CK or MB-CK subforms-provides the basis for interpreting elevated plasma MB-CK levels as reflective of irreversible injury.[156] Fibrinolytic therapy has been shown to be detrimental[157] in unstable angina; however, in non-Q-wave infarction, when given on an average of 9 h from onset, it showed no beneficial or detrimental effect. Early fibrinolytic, antithrombin, or antiplatelet therapy in patients with positive MB-CK subforms but ST-segment depression has yet to be evaluated. Similar studies have not been performed to determine whether increased troponin I or troponin T reflects cell death, although, since they are structural sarcomeric proteins, it is highly likely that their release does reflect cell necrosis. Since the molecular weight of troponin I is 23,000, however, and that of troponin T is 39,000, both of which are significantly less than that of MB-CK (82,000), leakage with myocardial ischemia will have to be excluded by appropriate studies.

Diagnosis of Myocardial Infarction after Surgery

Myocardial infarction after noncardiac surgery is also reliably determined from serial analysis of plasma MB-CK, MB-CK subforms, troponin T, or troponin I every 4 to 6 h.[104,158] There is a marked elevation of other enzymes due to tissue trauma, including total CK, but MB-CK, troponin T, and troponin I are highly specific to the myocardium. There is at least one study[139] showing that troponin I is more reliable than either total MB-CK or troponin T for the diagnosis of AMI in this setting. In the setting of cardiac surgery, however, MB-CK, like other cardiac markers, is almost always elevated due to manipulation and involvement of the myocardium and thus is not a reliable diagnostic index.[159,160] Nevertheless a severalfold elevation of MB-CK postoperatively is highly suggestive of periprocedural infarction, even in the absence of Q-waves, although it lacks specificity as a sole criterion. Multifold elevations of troponin T or troponin I probably have the same implications postoperatively.

Diagnosis of Previous Infarction

Determining whether a patient has had a remote infarction to account for the subsequent development of cardiac failure or other clinical conditions can be difficult. Until recently, the only reliable means of diagnosis was the presence of Q waves on the ECG. Since less than 50 percent of infarctions develop Q waves and since a significant percentage of these Q waves disappear with time, the ECG can be nonspecific and unreliable in diagnosing remote infarction.[161,162] Thallium-201 (^{201}Tl) perfusion scanning has been shown to be extremely reliable, sensitive, and specific in diagnosing remote infarction.[163]

Other Biochemical Alterations

The stress of myocardial infarction elicits numerous hormonal and metabolic responses. For example, both catecholamines and growth hormones are elevated. It is noteworthy, however, that serum cholesterol and lipoprotein fractions are relatively unchanged in the initial 1 to 2 days but decrease significantly over subsequent days and weeks. In establishing the baseline levels of these values for guiding future therapeutic interventions, measurements should be performed on admission or should be delayed for 6 to 8 weeks.[164,165] It should also be recognized that if myocardial infarction is occurring in individuals who have hypertension or for any reason are on medications such as diuretics, there may be significant electrolyte abnormalities that need to be treated, particularly in view of the increased propensity for arrhythmias, as with hypokalemia or alkalosis. The other abnormality seen on occasion is that of an increase in blood glucose following myocardial infarction, which, in some cases, particularly in patients with mild or moderate diabetes, may be associated with the development of significant ketoacidosis.[166,167] Not infrequently, it has also been shown that in the early days following myocardial infarction, the glucose tolerance curve is abnormal. It returns to normal after a few weeks. The white blood cell count is usually mildly to moderately elevated in 3 to 5 days.

Noninvasive Imaging in Acute Myocardial Infarction

CHEST ROENTGENOGRAM

The chest roentgenogram (x-ray) provides important information in the evaluation of chest pain and contributes to an integrative assessment of the clinical situation. Its usefulness in the early stages of evaluation of a patient with chest pain is frequently compromised by the fact that one is usually dealing with a portable study performed in the emergency department or in the CCU. Nonetheless, the chest film may assist in excluding causes of chest pain such as pneumothorax, pulmonary infarction with effusion, aortic dissection, skeletal fractures, and so on. In the patient with acute infarction, the chest film can be useful in establishing the presence of pulmonary edema, in assessing heart size to assist in determining whether or not cardiomegaly is present, and in deciding whether heart failure or myocardial or valvular disease is acute or chronic. It must be emphasized that severe left ventricular failure can be present without manifesting pulmonary edema on the chest x-ray and that, conversely, improvement in the x-ray appearance can lag behind hemodynamic resolution of pulmonary congestion (see Chap. 12).

ECHOCARDIOGRAPHY

Because of the quality of the images provided, their wide availability, and the portability of these modalities, two-dimensional and Doppler echocardiography have become very useful tools in the assessment of the patient with suspected AMI[168-170] (see also Chap. 13). Echocardiography is particularly valuable in assessing the patient with a nondiagnostic ECG. The presence of a regional wall motion abnormality provides strong supportive evidence of acute coronary ischemia and is generally present in transmural or Q-wave myocardial infarction.[171-174] Wall motion abnormalities are less common in non-Q-wave infarction but are still present in the majority of cases. Nonetheless, small infarctions can be missed, and a wall motion abnormality may not necessarily be acute.[175] Echocardiography also provides an assessment of ventricular function; it is useful in predicting the prognosis[176] and in diagnosing right ventricular infarction.[177] It can also provide information concerning alternative diagnoses such as aortic dissection and, coupled with Doppler, can provide information on such complications as ruptured chordae tendineae with mitral regurgitation and ventricular septal defect[178] (see Chap. 13). It is useful in detecting ventricular thrombus and pericardial fluid. Thus, echocardiography is extremely useful in the initial assessment of AMI. General guidelines on its clinical use, including those for myocardial infarction, have been published.[179]

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) offers great promise in assessing AMI (see Chap. 18A). Its major limitation is logistic, in that it requires transporting patients to the imaging facility-a major concern in the case of the acutely ill. It is potentially useful in the assessment of infarct size and viable myocardium and the extent of the ischemic insult as well as in estimating perfusion to ischemic and nonischemic areas.[180-182] Currently, MRI does not have a defined role in the routine management of AMI.

COMPUTED TOMOGRAPHY

Computed tomography (CT) is a powerful tool for cardiac imaging that gives high-resolution structural information (see Chap. 17). Ventricular thickness and dimensions can be assessed.[183] Also, CT is highly sensitive for detecting a left ventricular thrombus.[184] It has the same logistic limitations as MRI in the management of AMI. It does not have a routine role in the management of infarction. Whether electron-beam CT, with its very rapid acquisition times, can have a role in routine management requires further investigation (see Chap. 17).

RADIONUCLIDE SCINTIGRAPHY

The radionuclide techniques available for the diagnosis of AMI are discussed in detail in Chap. 16, and are summarized in Table 42-6.[185] Guidelines for the use of cardiac radionuclide scanning have been published and suggest that the indications for its use in the diagnosis of acute infarction are limited to the unusual case in which history, electrocardiographic changes, and plasma markers are unreliable or unavailable.[185] There

is no class I indication in the acute setting, and routine diagnostic use is not indicated (class III).[1,185] Radionuclide scintigraphy may have a diagnostic role in certain patients with right ventricular infarction by showing localized contractile abnormalities[186] or ^{99m}Tc pyrophosphate uptake (class IIa).[185]

Table 42-6: Uses of Radionuclide Testing in Acute Myocardial Infarction

DIAGNOSIS			RISK ASSESSMENT		
Indication	Test	Class	Indication	Test	Class
1. Right ventricular infarction	Rest RNA	IIa	1. Residual ischemia	Stress (exercise/pharmacological) thallium with redistribution	I
	^{99m}Tc pyrophosphate	IIa		Stress (exercise/pharmacological) sestamibi with redistribution	
2. Infarction not diagnosed by standard means - early presentation with successful reperfusion	Rest myocardial perfusion imaging	IIb	2. Myocardial infarct size	Tomographic thallium	IIa
	^{99m}Tc pyrophosphate	IIb		Tomographic sestamibi	IIa
3. Infarction not diagnosed by standard means - late presentation	^{99m}Tc pyrophosphate	IIa	3. Hibernating myocardium	Early, late thallium	IIa
4. Routine diagnosis	Any technique	III	4. Ventricular function	RNA	I

ABBREVIATIONS: RNA = radionuclide angiography; ^{99m}Tc = technetium 99m.
SOURCE: The ACC/AHA task force,[185] with permission.

ASSESSMENT OF INFARCT SIZE BY IMAGING

Infarct size can be assessed by echocardiography (see Chap. 13), computerized tomography (see Chap. 17), magnetic resonance imaging (see Chap. 18A), positron emission tomography (see Chap. 19), or radionuclide scintigraphy (Table 42-6[185]) (see Chap. 16). ^{99m}Tc sestamibi with tomographic imaging has been used to quantitate infarct size,[187,188] and shown to be inversely related to the patient's outcome.[189,190] Thallium 201 can also be used to measure infarct size.[185]

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

PREHOSPITAL CARE

Recommendations[1]:

Class I

1. Availability of 911 access
2. Availability of an emergency medical services (EMS) system staffed by persons trained to treat cardiac arrest with defibrillation, if indicated, and to triage patients with ischemic-type chest discomfort

Class IIa

1. Availability of a first-responder defibrillation program in a tiered response system
2. Education from health care providers to patients/families about the signs and symptoms of AMI, about accessing EMS, and about medications

Class IIb

1. Use of 12-lead telemetry
2. Prehospital thrombolysis in special circumstances (e.g., transport time is greater than 90 min)

As mentioned previously, modern in-hospital care of the AMI patient has resulted in a substantial reduction in mortality. Some 40 to 65 percent of deaths from AMI, however, occur within an hour of the onset of symptoms and prior to arrival at a hospital.[191,192] Most of these deaths are attributable to ventricular fibrillation (VF).[193] To achieve a further substantial decrease in the mortality rate, it will be necessary to reduce the incidence of deaths outside the hospital.[194] Since, as noted, the earlier thrombolytic therapy can be initiated in eligible patients, the better the outcome, it is also essential to bring patients with chest pain into the medical care system as soon as possible because of the need to shorten the time between the onset of symptoms and the initiation of thrombolytic therapy. To that end, in the United States, the National Heart, Lung and Blood Institute of the National Institutes of Health has instituted the National Heart Attack Alert Program as a coordinated plan to extend the ACC/AHA guidelines promoting rapid identification and treatment of patients with AMI.[195,196]

Recognition and Management

A further reduction in the mortality rate will require the combined efforts of the patient, bystanders, minimally trained "first responders" who are capable of applying defibrillation therapy, and/or paramedics as well as the patient's physician. It has been established that a prolonged delay time in responding to a patient's symptoms is the rate-limiting step in defining the prehospital phase of myocardial infarction. Mean delay time in such response is almost 3 h.[197] Most of this time is consumed in decision making, while failing to recognize or acknowledge the seriousness of the problem.[198] Additional components of the delay between the onset of

symptoms and the initiation of definitive therapy involve prehospital evaluation, treatment, and transport time and the time involved with the diagnosis and initiation of treatment in the hospital. The National Registry of Myocardial Infarction found, in a review of 48,128 patients with confirmed AMI, that the average duration of the prehospital phase, defined as onset of chest pain to hospital presentation, was 5.1 h.

STRATEGIES TO REDUCE DELAY

Patient-specific issues for decreasing the delay in seeking assistance primarily involve education. The patient must perceive the symptoms, recognize their possible significance, and conclude that medical help is appropriate. For some patients, the decision time is prolonged because of a lack of knowledge. It is interesting, however, that the length of time patients take to get help is not dependent on educational level, occupation, socioeconomic class, or past history of cardiac disease. In fact, patients with a past history of myocardial infarction or angina have an unexpectedly long decision time,[199] a situation that must be viewed, at least in part, as a failure by physicians to educate patients with established coronary artery disease as to the appropriate response to a change in or reappearance of their symptoms. In other cases, the decision time is prolonged by denial or by "diagnostic trials" with household remedies, patent medications, or previously prescribed drugs. It has been noted that only 10 percent of patients arriving at the hospital within 1 h of the onset of pain utilized nonprescription medications, while 41 percent of those arriving after 12 h did so.[191] The remainder of the delay time is consumed by "human factors," including the time a patient takes to modify existing social obligations and to prepare for going to the hospital. There is evidence that public education can reduce the time required for decision making.[198] It follows that effective efforts by the physician and his or her staff in educating patients with coronary artery disease will have similar effects in inducing appropriate responses to ischemic coronary symptoms. Prodromal symptoms occur in about two-thirds of patients with AMI, as discussed previously, and patients must be taught to recognize them.[194] Patients and their families must be given a specific plan of action after the recognition of symptoms that includes medications to be taken (nitroglycerin and possibly aspirin), mode of transportation to the hospital, and the location of the nearest hospital that offers emergency cardiac care. It is desirable that coronary patients have a copy of their resting ECG with them. They should be instructed not to delay by attempting to contact their physician and should be shown how to use the EMS system and how to contact it (911 in the United States). As opposed to personal transportation, utilizing EMS is desirable, because it permits the earliest possible access to expertise in defibrillation and resuscitation and facilitates evaluation in the field to prepare the hospital to receive the patient, as discussed later. The use of the EMS usually decreases the delay in initiating definitive care.[195] Since the capabilities of the EMS vary by locale, the physician must be familiar with the system in the patient's home area.

Instructions concerning medications to be taken at the onset of symptoms should be individualized. In general, patients are instructed to take nitroglycerin immediately at the onset of angina or a recognized anginal equivalent. If pain is not relieved, another nitroglycerin dose is taken at 5 min and a third at 10 min. If there is no relief by the third dose of nitroglycerin, the patient should be transported to the appropriate emergency facility. The physician should decide whether to incorporate the chewing of an aspirin tablet into this regimen when the decision is made to proceed to the hospital.

Bystanders and family members can play an important role in both shortening patient delay time and responding to an arrest. It has been shown that a spouse's presence accelerated the hospital arrival time.[193] Furthermore, if basic life support is initiated by a bystander within 4 min of cardiac arrest and if defibrillation is accomplished within 8 min, 40 percent of patients will survive and be discharged from the hospital.[200]

EMERGENCY MEDICAL SERVICES

Many communities in the United States are served by a two-tier ambulance service consisting of basic and advanced life support units. Since these are usually more basic support units, the response time of these units is shorter and should ideally be less than 5 min.[1,201] The first responders may be any of a variety of public service employees who are trained in CPR and defibrillation and have been taught to have a sense of urgency in order to identify and treat the AMI patient rapidly. Automatic external defibrillators are safe and effective and can be used by even minimally trained first responders to analyze rhythms and deliver defibrillatory shocks to convert VF.[1,202-206] Incorporation of automatic external defibrillators into emergency medical systems is highly desirable.[1] Minimally, it has been recommended that every ambulance transporting victims of cardiac arrest be equipped with a conventional defibrillator.[204]

The goal of any emergency medical system should be to include individuals who are trained in advanced life support techniques-including the use of antiarrhythmics as well as the administration of intravenous fluids and analgesics-and who can reach the patient as soon as possible in a vehicle equipped as a CCU. Undirected EMS technicians can spend excessive amounts of time evaluating a patient with chest pain and actually delay the ultimate initiation of appropriate therapy.[1] The time elapsed between receiving a 911 call and the actual arrival in the hospital has been assessed, and, at over 46 min, was substantially longer than estimates (under 26 min) taken from the paramedics involved.[198] Most of this field time was consumed by the paramedic on-scene time, which was not prolonged by acquisition of a 12-lead ECG. It has been demonstrated that, by the use of a standardized protocol (Table 42-7[1]), evaluation of the patient with chest pain by experienced emergency medical technicians, acquisition of a 12-lead ECG, and initiation of therapy can be accomplished within 20 min.[1] The protocol should facilitate determination of the likelihood of AMI and the presence of comorbid conditions in which thrombolytic therapy would be dangerous. It should also identify those suspected AMI patients who are at high risk. Patients in this category include those with sinus tachycardia, hypotension, or pulmonary edema or those with signs of shock. It is ideal to be able to record 12-lead ECGs in the field to be transmitted to the hospital physician. The availability of these data facilitates establishing the diagnosis and allows for accelerating preparations to administer thrombolytic therapy.[207-209]

PREHOSPITAL THROMBOLYSIS

As mentioned previously, there is unequivocal evidence that the earlier thrombolysis is administered to the AMI patient with ST-segment elevation, the more efficacious is the outcome;[14,210,211] in particular, the most favorable results are achieved when therapy is initiated within the first 1 to 2 h after the symptoms appear. It seems logical, therefore, that if thrombolysis could be initiated in appropriate patients during the prehospital phase by general practitioners or by EMS technicians guided by protocol, the 12-lead ECG, and communication with the emergency department physician, outcomes would be improved. Prehospital thrombolysis has been evaluated in several trials.[207,212-214] A meta-analysis of all of the trials showed a modest (17 percent) improvement in outcome, although none of the trials demonstrated significant improvement individually.[212] Prehospital thrombolysis, however, is fraught with a number of difficulties, beginning with the fact that only a small portion of chest pain patients (5 to 10 percent) have an AMI and are eligible to be treated with thrombolytics.[207,209,215,216] Thus, correctly selecting patients for thrombolytic therapy and avoiding its administration when not indicated or when contraindicated is difficult and has significant legal, medical, and economic implications. Because of these difficulties, prehospital thrombolysis should be emphasized

primarily in those circumstances in which it can be administered 60 to 90 min before reaching the hospital (because of a long transport time) or when a physician is in the ambulance.[1] Generally, emphasis should be placed on rapid screening and diagnosis in the field to facilitate hospital triage and thrombolytic administration within 30 min of the patient's arrival.

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

EVALUATION AND MANAGEMENT OF PATIENTS WITH CHEST PAIN IN THE EMERGENCY DEPARTMENT

Recommendation:[1]

Class I

1. Emergency department AMI protocol that yields a targeted clinical examination, a 12-lead ECG within 10 min, and administration of thrombolytic therapy, as appropriate, within 30 min.

Background

In general, the goals of the emergency department with respect to patients with chest pain are to rapidly identify those patients with AMI with both typical and atypical presentations so that appropriate therapy can be initiated; to recognize those patients with acute coronary syndromes (unstable angina) but without myocardial infarction and who, thus, are at high risk; and to assess accurately those patients at low risk who are candidates for noninvasive evaluation and early discharge.[217]

As mentioned previously, the earlier reperfusion therapy is initiated in the subset of patients with diagnostic ST-segment elevation, the more favorable the clinical results (Fig. 42-5).[210]

An important objective, obviously, should be a triage system that minimizes the number of patients at high risk (AMI or unstable angina) who are inadvertently discharged from the emergency department while also minimizing the admission to high-intensity CCUs of low-risk patients without myocardial infarction-a goal of increasing urgency in this era of intense pressures for cost containment. Of patients admitted to a CCU, for example, less than 20 percent will have AMI, as noted.[218,219] In contrast, even in the current era of an enhanced appreciation for atypical presentations, an increased potential for litigation, and a decreased threshold for admission to exclude myocardial infarction, the missed diagnosis rate has still been about 4 percent,[131] a percentage that appears not to have changed substantially since the 1980s.[220-222]

The reasons for misdiagnosis of acute coronary syndromes in the emergency department have been studied extensively and have been reviewed.[217] The misinterpretation of ECGs has been reported to occur in approximately 20 to 40 percent of missed AMIs.[222-224] Equally disturbing are the reports, which are indictments of training or focus, that patients are discharged even though the physician has recognized ischemic symptoms or electrocardiographic changes.[220,223,224] A major contributing problem is that even experienced clinicians are imprecise in their clinical judgment as to the presence or absence of myocardial infarction in a given patient. Sensitivities of 80 to 90 percent and specificities of approximately 70 to 80 percent in diagnostic precision in determining the presence or absence of AMI based on clinical impressions have been reported.[70,222,225] The diagnostic problem, however, is not limited to the diagnosis of myocardial infarction but also applies to whether unstable angina is present (see also Chap. 41). Patients who are admitted to the hospital with chest pain and only transient ST-segment changes and without aggressive therapy have a 22 percent incidence of death and myocardial infarction after a 28-month follow-up,[226] a figure not dissimilar to that for patients with an initial confirmed infarction. These similarities in outcome of unstable angina and myocardial infarction are not surprising, since the fundamental underlying pathophysiologic mechanisms-disruption of the atherosclerotic plaque and thrombus formation, with or without vasospasm-are likely to be identical, the major difference being the extent of luminal compromise by the thrombus. Thus, the clinical focus should not be simply to "rule out" AMI, but, taking a proactive approach, to "rule in" either acute infarction or unstable angina in an expeditious manner.[217] Once these

urgent conditions have been excluded or ascertained to be of low probability, the next level of concern is determining the presence of other acute cardiovascular or cardiopulmonary conditions, such as aortic dissection, pulmonary embolus, and pericarditis. The focus, subsequently, in a hierarchical fashion, is to establish whether or not stable coronary artery disease is present, to identify cardiovascular risk factors, and to consider noncardiac diagnoses, which, in nonurgent cases, can be evaluated further on an outpatient basis.

It has been suggested[217] that management of chest pain in the emergency department can be optimized by having the appropriate clinical focus, developing effective risk stratification approaches, and implementing systematic algorithmic protocols. There has been a great deal of interest in the development of actual or virtual chest pain units to facilitate the expeditious triage and management of patients with chest pain, as discussed later.

Initial Approach, Detection, and Assessment of Risk

Recommendations:[1]

Class I

1. Supplemental oxygen, intravenous access, and continuous electrocardiographic monitoring should be established in all patients with acute ischemic-type chest discomfort.
2. A 12-lead ECG should be obtained and interpreted within 10 min of arrival in the emergency department in all patients with suspected acute ischemic-type chest discomfort.

A major goal of the emergency department in dealing with patients with chest pain is the establishment of a routine approach that leads to a rapid (10 min) preliminary evaluation, acquisition of a 12-lead ECG, and establishment of intravenous access and continuous electrocardiographic monitoring (Fig. 42-3). The initial physical examination and assessment of the history are guided by the differential diagnosis of chest pain, with the goal of establishing whether or not myocardial ischemia is a likely or possible diagnosis. Blood is drawn for baseline cardiac marker levels, and if coronary ischemia is suspected and there are no contraindications, the patient is given aspirin of 160 to 325 mg to chew and swallow. Also, the patient with suspected coronary ischemia is given sublingual nitroglycerine unless the systolic blood pressure is less than 90 mmHg. This should be avoided with severe bradycardia or tachycardia. Because of the potentially catastrophic implications, the history of chest pain alone usually dictates entry into the system for evaluation. In general, the only patients with chest pain who are not systematically evaluated for myocardial ischemia would be those in whom a clear noncardiac cause, such as chest wall tenderness, can be demonstrated unequivocally to be the etiology of the presenting symptoms. Continuous ECG monitoring is essential because of the propensity for the development of sudden and potentially lethal ventricular arrhythmias in any patient with an acute coronary ischemic syndrome. Intravenous access is essential for therapeutic interventions under such circumstances as well as for more general purposes. Additionally, paroxysmal changes in the ST segment may be recognizable on the monitor. The differential diagnosis of chest pain and the clinical recognition of AMI were discussed previously. The causes of chest pain that are not the result of acute pathologic changes compromising the structural integrity of the large coronary arteries are listed in Table 42-8.

Table 42-8: Causes of Chest Pain Other Than Acute Coronary Artery Syndromes

Cardiovascular
Aortic dissection
Aortic stenosis
Pericarditis
Mitral valve prolapse
Microvascular angina
Hypertrophic cardiomyopathy
Syndrome X
Pulmonary embolus
Arrhythmia/palpitations
Noncardiovascular
Pleurisy
Pneumonia
Pneumothorax
Costochondritis
Gastrointestinal
Esophageal spasm/reflux
Acid peptic disease
Cholecystitis
Gastritis
Psychiatric
Panic attack
Cardiac neurosis
Depression
Malingering

As a general rule, and as previously mentioned, one should begin the evaluation of the patient with chest pain with the assumption that one is dealing with myocardial ischemia until proven otherwise. The three most serious and urgent alternative diagnoses that need to be considered specifically during the initial evaluation are aortic dissection, acute pulmonary embolus, and acute pneumothorax. Acute pericarditis and myopericarditis need to be considered as well.

Although relatively uncommon, aortic dissection must be considered and ruled in or out during the initial evaluation of the patient with chest pain, since specific intervention can decrease its high mortality. Furthermore, and not unexpectedly, administration of thrombolytic agents in the presence of aortic dissection is associated with high mortality.[227-229] Suspicion of dissection should be heightened especially

in hypertensive patients or in those with marfanoid habitus (see also Chaps. 62 and 88). Most patients with aortic dissection who have mistakenly received thrombolytic therapy did not meet the ECG criteria of ST-segment elevation that is usually required.[228] Aortic dissection is usually associated with sudden onset of a severe, tearing pain that may migrate and is frequently felt in the back at some point. Differential blood pressures in the arms may be noted, and pulse differences in the carotids or arms may be observed. An echocardiogram and, in particular, transesophageal echocardiography can be very efficacious in the diagnosis of aortic dissection (see Chaps. 13 and 88).

Pulmonary embolus can be life-threatening and should be suspected in anyone with a sudden onset of shortness of breath and chest pressure or pain, especially if there is a history of being sedentary or immobilized and/or of deep venous thrombosis. There may be a pleural rub, and the chest roentgenogram is usually normal, although arterial hypoxia may be present (see Chap. 53). Similarly, pneumothorax may be associated with persistent chest pain, hypoxemia, and evidence of hypoventilation on physical examination.

Acute pericarditis may mimic AMI in that the pain can be substernal and persistent. Frequently, however, there will be a positional component as well as characteristics of pleurisy, with accentuation by deep breathing. Furthermore, the diffuse ST-segment elevation may lead to a misdiagnosis of myocardial infarction. The key differentiating features in pericarditis include PR depression, the diffuse nature of ST-segment elevation in most leads, and the absence of reciprocal changes (see Chaps. 11 and 72). The presence of a pericardial rub is a key diagnostic finding. Echocardiography, by demonstrating a pericardial effusion in the case of pericarditis or a wall motion abnormality in the case of acute ischemia, can be helpful in making the appropriate diagnosis. Hemorrhagic pericardial effusions have been reported in patients given thrombolytic therapy in the setting of acute pericarditis.[227,228]

Although usually not urgent, it should be kept in mind that esophageal disorders, as assessed retrospectively by motility studies, are very common in patients presenting with chest pain in whom cardiac ischemia is ruled out[230-233] (see also Chap. 40). In fact, among all patients presenting with chest pain, gastroesophageal disease has been observed to be the most common etiology (42 percent), whereas ischemic heart disease was present in 31 percent and chest wall syndromes were responsible in 28 percent.[234] Because of the high frequency of gastrointestinal disease in patients with chest pain, "GI cocktails" or antacids have been used as a diagnostic tool to guide triage and disposition. Only 25 percent of patients with esophageal pain, however, have been reported to obtain pain relief with antacids.[235] Furthermore, coincidental, spontaneous relief of ischemic chest pain at the time of administration of the GI cocktail could be misleading. Similarly, administration of nitroglycerin as a diagnostic strategy for ischemic disease could be misleading, because it can relieve esophageal spasm. Moreover, it has been found that pain relief after nitroglycerin did not predict unstable angina or AMI in the chest pain patient.[236] The use of these "response-to-treatment" strategies as major decision points in the evaluation of chest pain has been discouraged.[217] This reservation, however, applies primarily to those patients without diagnostic ECG changes, and does not preclude giving sublingual nitroglycerin to patients with chest pain and ST-segment elevation as a test of vasospasm or Prinzmetal's angina.

DETECTION

The 12-Lead Electrocardiogram as a Guide to Management Strategy

The results of the 12-lead ECG guide the next level of decision making for the patient with chest pain thought to be compatible with myocardial ischemia (Fig. 42-3). The ECG interpretation is assigned to one of three categories: (1) ST- segment elevation in two or more leads or a presumptively new bundle branch block implicating acute coronary occlusion, usually thrombotic; (2) ST-segment depression and/or T-wave inversion implying subtotal occlusion or non-Q infarction; and (3) normal or nondiagnostic. The group with ST- segment elevation or a left bundle branch block is particularly important to define, as it is this group that has been shown to benefit from thrombolytic therapy. ST-segment elevation has a 46 percent sensitivity and a 91 percent specificity for the diagnosis of AMI.[94] There is no indication as yet of the benefit of thrombolytic therapy or primary angioplasty in those patients without ST-segment elevation or bundle branch block, however, appropriately focused randomized trials are lacking.

As discussed previously, the initial ECG is diagnostic in less than 50 percent of patients with AMI,[237,238] and the measurement of serum markers of myocardial damage plays a major role in diagnosis. Measurement of MB-CK is the benchmark laboratory test, and the specificity and sensitivity of samples taken 2 h apart during serial sampling have been reported to be 91 and 94 percent, respectively.[239] The limitations of conventional MB-CK measurements and the role of myoglobin and the troponins have been discussed. The rapid high-voltage method to separate MB-CK-1 and MB-CK-2 and to determine the ratio of the isoforms was described and may be particularly relevant to the initial evaluation in the emergency department, since it quickly provides information that not only facilitates establishing the appropriate diagnosis but also contributes to assigning a risk category to a patient.

RISK STRATIFICATION

Stratifying risk in the patient with AMI is an essential part of the management strategy during all phases of care. It permits not only the more precise calibration of treatment and diagnostic approaches with the level of risk but also, increasingly, facilitates the appropriate utilization of hospital resources. Traditional approaches to initial risk assessment have involved combinations of ECG changes and clinical manifestations. The ECG serves as a basis for initial risk assessment. ST-segment elevation or a new left bundle branch block in the patient with chest pain defines a high-risk group, and in those with elevated ST segments, the mortality correlates positively with the number of leads with the ST changes.[240] The presence of ST-segment depression or T-wave inversion also defines a high-risk group. In patients with unstable angina or non-Q-wave myocardial infarction, ST-segment depression on the initial ECG of at least 1 mm in two leads during pain predicted major clinical events in the subsequent 3 months.[241] A nondiagnostic or normal ECG is associated with low risk. For example, the incidence of myocardial infarction has been reported to be 10, 8, and 41 percent in patients who, at admission, had a normal, a nonspecific, or an abnormal ECG, respectively.[242] The incidence of complications paralleled the infarction rate-a predictable conclusion corroborated by other studies.[243,244] *High risk has been associated with age, ST-segment elevation or depression, T-wave inversions, and Q waves, as well as prolonged chest pain, especially if it radiates to cardiac referral areas.*[70,222,245-247]

Quantitative assessments of risk have been developed to guide the management of patients with chest pain in the emergency department.[244] *Predictors of an increased risk of complications included ECG evidence of ST-segment elevation or Q waves in two or more leads that are not known to have been present previously; ST-segment depression or T-wave inversions consistent with myocardial ischemia and not known to be present previously; pain worse than prior angina or the same as that experienced with prior myocardial infarction; systolic blood pressure of less than 100 mmHg; or rales bilaterally above the bases.* On the basis of these predictors, patients could be divided into four risk groups.[244] Furthermore, the risk could be updated if a complication occurred. This general approach can guide decisions concerning the level of intensity of the unit to which a patient is admitted and the length of observation required.

Blood levels of cardiac markers are prognostically important, as noted. In particular, increased levels of any of the markers-CKMB or the subforms or troponins (I and T), but not myoglobin (×1)-at presentation appear to be strong predictors of risk in patients with acute ischemic syndromes[151,152] (see Chap. 41).

INITIAL MANAGEMENT

As discussed, one frequently does not have a definitive diagnosis of AMI in the patient with chest pain in the emergency department, although this situation may ultimately be improved by the wider availability of the very rapid assays of blood cardiac markers, as discussed earlier. Nevertheless, the initial general treatment of the acute coronary syndromes is the same.

Routine General Measures

OXYGEN ADMINISTRATION

Recommendations for oxygen administration:[1]

Class I

1. Overt pulmonary congestion
2. Arterial oxygen desaturation (Sa_{O_2} less than 90 percent)

Class IIa

1. Routine administration of oxygen to all patients with uncomplicated myocardial infarction during the first 2 to 3 h

Class IIb

2. Routine administration of supplemental oxygen to patients with uncomplicated myocardial infarction beyond 3 to 6 h

Hypoxemia is not uncommon in patients with AMI, even with an uncomplicated course, and presumably because of ventilation-perfusion mismatch.[248] Oxygen administration has been reported to decrease ST-segment elevation in anterior myocardial infarction.[249] Thus, oxygen administration for up to several days has previously been routine. There is concern with this practice, however, since oxygen may increase vascular resistance, and there may not necessarily be increased delivery to tissues. Because of these concerns and because of the expense of prolonged oxygen administration, there appears to be little justification for extending its use in uncomplicated myocardial infarction with an (Sa_{O_2} of greater than 90 percent beyond 2 to 3 h.[1] Justification of its use in uncomplicated infarction can be based on its potential for limiting of ischemic injury and on the fact that nitroglycerin can induce ventilation-perfusion abnormalities due to its pulmonary vasodilator activity, thus contributing to hypoxia.

Oxygen administration should be continued in patients with pulmonary congestion and desaturation. In patients with complicated myocardial infarction, nasal oxygen or oxygen by face mask may be insufficient to maintain saturation, and positive-pressure breathing or intubation and mechanical ventilation may have to be considered. If necessary, they should be initiated promptly.

ANALGESIA

The alleviation of pain and anxiety remains an essential element in the care of the patient with AMI. The pain and accompanying anxiety contribute to excessive activity of the autonomic nervous system and to restlessness. These factors, in turn, increase the metabolic demands of the myocardium. Physician reassurance from the beginning is an essential part of treatment and should be provided with compassion, patience, and confidence. Optimal care of the patient with AMI requires a team of experienced individuals who can help alleviate anxiety by their air of competence and caring.

It is a common clinical observation that reperfusion in AMI is associated with rapid relief of pain, suggesting that the pain is due to ongoing ischemia of the viable myocardium rather than to the effects of tissue necrosis. Thus, the approach to pain consists of the dual strategy of relieving ischemia and attacking the pain directly. Anti-ischemic therapy consists of reperfusion, beta blockers (if appropriate), nitrates, and oxygen administration, as discussed. Narcotics not only relieve pain directly but also indirectly by diminishing the sympathetic nervous system's drive and catecholamine secretion, which will increase blood pressure and drive cardiac chronotrophic and inotrophic responses to increase oxygen consumption and ischemia. The increased sympathetic drive will also enhance the propensity for serious ventricular arrhythmias. Morphine, in most instances, is the drug of choice, since it is well tolerated and offers analgesia without significant cardiac depression.[250] It also relieves anxiety and the feeling of doom commonly described. Morphine sulfate can be given at doses of 2 to 4 mg every 15 min until adequate relief has been obtained, which, in some patients, may require 25 to 30 mg.[251] The peak effect of intravenous morphine occurs within 15 to 20 min, thus requiring titration. Morphine has frequently been given in inadequate doses because of fear of respiratory depression or hypotension. Respiratory depression is less common in patients with myocardial infarction than it is in patients generally, because of the anxiety and respiratory drive from hypoxia, and can be treated with intravenous naloxone should it occur.[1]

Hypotension related to morphine is usually orthostatic and volume-dependent and is less common in supine patients.[252] In patients with severe ongoing pain, it may be prudent to avoid concomitant administration of substantial doses of morphine and vasodilators, such as nitroglycerin. In patients with an acute inferior myocardial infarction with bradycardia with or without hypotension, the vagolytic narcotic meperidine may be substituted for the parasympathomimetic morphine. If the patient's anxiety is not controlled by the administration of narcotics, mild sedation with a benzodiazepine is appropriate. Diazepam in doses of 5 mg orally every 8 to 12 h or alprazolam in doses of 0.25 mg every 8 h are most often used.

NITROGLYCERIN

Recommendations for intravenous nitroglycerin[1]:

Class I

1. For the first 24 to 48 h in patients with AMI and congestive heart failure, large anterior infarction, persistent ischemia, or hypertension
2. Continued use (beyond 48 h) in patients with recurrent angina or persistent pulmonary congestion

Class IIa

1. None

Class IIb

1. For the first 24 to 48 h in all patients with AMI who do not have hypotension, bradycardia, or tachycardia
2. Continued use (beyond 48 h), perhaps in an oral or topical form, in patients with large or complicated infarction

Class III

1. Patients with systolic pressure less than 90 mmHg or severe bradycardia (less than 50 beats per minute)

Nitroglycerin has become very widely used in the treatment of AMI. It is an anti-ischemic agent not only by virtue of its actions to decrease preload and afterload, and thus to decrease oxygen demand, but also because of its vasodilator actions on epicardial coronary arteries and coronary collaterals. Consequently, and especially in patients with good collaterals, nitroglycerin is likely to increase flow into the ischemic regions.[253,254] Apart from relieving ischemia and pain, intravenous nitroglycerin, in early studies, appeared to reduce the likelihood of developing cardiac failure, infarct extension, or cardiac death. Both clinical data[255,256] and animal studies suggest that the early administration of nitroglycerin limits the extent of myocardial damage and favorably affects survival.[257] Long-term nitrates after reperfusion in animals favorably affect ventricular remodeling.[258]

Small, early trials before the widespread use of reperfusion suggested that the early administration of intravenous nitroglycerin was associated with improved morbidity and mortality. A meta-analysis of these trials suggested that the use of nitrates reduced the odds of mortality after AMI by greater than 30 percent.[259] The efficacy of nitrates in improving short-term mortality after AMI was tested prospectively in the GISSI-3 trial.[260] At 6 weeks, there was no significant difference between the nitrate and control groups. The power to distinguish between the two, however, was diminished, because about one-half of the control group received nitrates during the first 2 days at the discretion of the attending physician. The angiotensin-converting enzyme (ACE) inhibitor lisinopril was tested in a similar fashion in GISSI-3. Mortality was decreased slightly at 6 weeks. The combined use of nitrates and lisinopril was associated with decreased mortality at both 6 weeks and 6 months compared with the no-nitrate group or with the group that received lisinopril alone. There was no significant difference noted at 35 days in comparison with the control group in another large trial, International Study of Infarct Survival (ISIS-4), which evaluated the effects of nitrates

on mortality after myocardial infarction.[261] This trial was also compromised by the high frequency of discretionary nitrate use in the control group. A meta-analysis of all randomized, controlled trials involving the use of nitrates in AMI show a small, statistically significant reduction in mortality (about 5 percent).

The weight of the evidence does not justify the routine, long-term use of nitrates in uncomplicated AMI. The use of intravenous nitroglycerin early after acute infarction is justified because of its ease of titration, rapid onset, and ability to be quickly withdrawn in case of complications. Long-term use of nitrates is appropriate in the case of recurrent ischemia, large infarction, congestive heart failure, or hypertension.

COMPLICATIONS AND LIMITATIONS

The most serious complication of nitroglycerin is hypotension. The fall in blood pressure may cause reflex tachycardia, and, together with decreased perfusion pressure, may cause or worsen angina. Thus, nitroglycerin should be avoided with a systolic pressure of less than 90 mmHg. Caution should be exercised in the case of inferior wall infarction because of the possibility of right ventricular involvement. Nitroglycerin should be used only with extreme caution if at all in right ventricular infarction, because the right ventricle in this circumstance becomes extremely dependent upon preload, which can be diminished by the venodilating properties of the drug.[262] Similarly, nitroglycerin should be avoided in patients with severe bradycardia (heart rate less than 50 beats per minute), as hypotension may result.[263] If hypotension and bradycardia develop, nitroglycerin should be stopped, legs elevated, fluid administered, and atropine given if needed. Headache is a common side effect of nitrate administration.

Nitrate tolerance is common (see Chap. 81). With intravenous nitroglycerin, this may be recognized only as a diminution of clinical effect after 24 to 48 h. An increase in dose may be required.

DOSAGE OF NITROGLYCERIN

Long-acting nitrates should generally not be used as initial therapy in AMI. Intravenous nitroglycerin is preferable, as noted, because of rapidity of onset, ease of titration, and ease of removal in case of complications. Dose titration can be assessed by frequent determinations of blood pressure and heart rate. Invasive monitoring is not essential but is probably prudent if high doses are required or if there is hemodynamic instability or uncertainty about the adequacy of ventricular preload.

Treatment should be initiated with a bolus injection of 12.5 to 25 μg and should be followed by infusion by pump of 10 to 20 μg/min, with increases of 5 to 10 μg every 5 to 10 min while assessing hemodynamic and clinical responses.[1] Control of symptoms is a major end point; in the case of high left ventricular filling pressure, a decrease of 10 to 30 percent in pulmonary artery wedge pressure is the objective. Limitations of nitroglycerin dosing are a decrease in mean arterial pressure of 10 percent in normotensive patients or a decrease of 30 percent in hypertensive patients, but not below a systolic pressure of 90 mmHg, or an increase in heart rate of 10 beats per minute not to exceed 110 beats per minute.

Doses of nitroglycerin greater than 200 μg/min are associated with an increased risk of hypotension. The development of such high requirements may indicate tolerance, and alternative drugs such as ACE inhibitors or nitroprusside should be considered. If tolerance is the issue, responsiveness should return after a 12- to 18-h period off of nitroglycerin.

ASPIRIN

Recommendations for aspirin therapy[1]:

Class I

1. A dose of 160 to 325 mg should be given on day 1 of AMI and continued indefinitely on a daily basis thereafter.

Class IIb

1. Other antiplatelet agents such as dipyridamol, ticlopidine, or clopidogrel may be instituted if a true aspirin allergy is present or if the patient is unresponsive to aspirin.

Aspirin has become a standard part of the armamentarium for treating not only AMI but also atherosclerotic vascular disease generally. A 23 percent reduction in mortality at 35 days in patients treated with aspirin during the early stages of AMI was observed in the Second International Study of Infarct Survival (ISIS-2).[211] The reduction in mortality due to aspirin in combination with streptokinase was 42 percent. In a summary of a large number of clinical trials, aspirin has been shown to reduce the incidence of vascular events in patients with AMI at 1 month; a prior history of MI (2 years); a history of transient cerebral ischemia or stroke; and unstable angina.[264]

Aspirin irreversibly inhibits platelet cyclooxygenase, an enzyme that causes formation of thromboxane A_2, a mediator of platelet aggregation.[265] Its antithrombotic and side effects are discussed in detail in Chap. 44. Aspirin should be avoided in cases of true hypersensitivity. In the case of a history of bleeding from acid peptic disease, aspirin rectal suppositories can be used. Ticlopidine or clopidogrel, which are antiplatelet drugs acting as adenosine diphosphate receptor antagonists and can be used in acute infarction in patients in whom aspirin is contraindicated. Their actions do not develop immediately. They are discussed in Chap. 44. Clopidogrel is safer than ticlopidine and was shown to be more effective than aspirin in the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial.[266]

Aspirin is an effective antithrombotic at doses as low as 80 mg, but the rapid, acute effect probably requires 160 mg, which is absorbed and is thus clinically effective more quickly if the tablet is chewed rather than swallowed whole. *Thus the patient suspected of having a coronary ischemic syndrome should receive, early in the course, 160 to 325 mg of non-enteric-coated aspirin, which is chewed.*

Management after Triage into Electrocardiographic Subgroups

As discussed earlier, the initial ECG, as a first approximation, permits the assignment of patients with chest pain into subgroups that are distinguishable in terms of therapeutic responsiveness and risk. Thus, those with either ST-segment elevation and presumptively new bundle branch block or those with ST-segment depression and/or T-wave inversion are in high-risk groups, whereas those with either normal ECGs or nonspecific changes are in a low risk category. Furthermore, the high-risk groups can be subdivided into those (ST-segment elevation or new bundle branch block) who have a favorable therapeutic response to thrombolytics and those who do not (ST-segment depression and/or T-wave inversion). *It must be kept in mind that these initial categorizations do not necessarily define ultimate outcome. Thus, patients with no ST-segment elevation at presentation may, in fact, have unstable angina and ultimately have no infarction or may progress to have either a Q-wave or a non-Q-wave infarction. Similarly, those presenting with ST-segment elevation may have a non-Q-wave infarction, although the majority of these will develop Q waves.* This potential for variable outcomes provides the underlying rationale for close monitoring and continuous reassessment of clinical course, risk, and therapeutic strategies during the period of observation and for monitoring both in the emergency department and subsequently in other hospital units.

APPROACH TO THE PATIENT WITH ST-SEGMENT ELEVATION

The approach to the patient with chest pain and ST-segment elevation is guided heavily by the evidence that this subgroup has a high frequency of epicardial coronary artery occlusion by a thrombus that can be halted by prompt reperfusion.[267,268] Furthermore, multiple clinical trials of thrombolytic therapy have shown clinical benefit, but only in those with ST-segment elevation (Fig. 42-5).[210] This efficacy, however, has been shown in men, women, and diabetics and is manifest regardless of any history of previous myocardial infarction, existing heart rate, or recorded blood pressure (if less than 175 mmHg).[210] The greatest benefit is seen in patients with anterior myocardial infarction (and inferior infarction with right ventricular involvement), those with signs of a large infarction (systolic blood pressure less 100 mmHg or heart rate greater than 100 beats per minute), and in those with diabetes. Thus, the evaluation and management of the patient with ischemic chest pain and ST-segment elevation is focused on the rapid assessment of suitability for and delivery of reperfusion therapy. The approach to these patients is summarized in Fig. 42-6.[1]

During the initial evaluation, the patient will have had aspirin given, blood drawn, intravenous access established, a 12-lead ECG showing ST-segment elevation in at least two adjacent leads, nasal oxygen administered, appropriate analgesia, and continuous electrocardiographic monitoring initiated. The appropriate next steps are to administer a beta-adrenergic blocker, if not contraindicated, and to initiate evaluation for reperfusion therapy. Based on the data from nine major clinical trials of thrombolytic therapy summarized by the Fibrinolytic Therapy Trialists Collaborative Group, thrombolytic therapy is efficacious in AMI (although linearly decreasing with the passage of time) for up to 12 h after the onset of symptoms.[210] There was a statistically uncertain benefit from 13 to 18 h. Thus, the 12-h point was chosen as defining the time frame in which the risk-benefit ratio is clearly favorable for administering thrombolytic therapy (Fig. 42-5).

Beta-Adrenergic Receptor Blockers

Recommendations for early therapy[1]:

Class I

1. Patients without a contraindication to beta-adrenoceptor blocker therapy who can be treated within 12 h of onset of infarction, irrespective of administration of concomitant thrombolytic therapy or performance of primary angioplasty
2. Patients with continuing or recurrent ischemic pain
3. Patients with tachyarrhythmias, such as atrial fibrillation with a rapid ventricular response
4. Non-ST elevation myocardial infarction

Class IIb

1. Patients with moderate left ventricular failure (the presence of bibasilar rales without evidence of low cardiac output) or other relative contraindications to beta-adrenoceptor blocker therapy, provided they can be monitored closely

Class III

1. Patients with severe left ventricular failure

Beta-adrenergic receptor blockers interfere with the positive inotropic and chronotropic effects of catecholamines, thus reducing afterload (blood pressure) and therefore myocardial oxygen consumption. In the myocardial ischemic syndromes, these drugs should decrease ischemia and catecholamine-induced arrhythmias and should potentially reduce infarct size, in part by prolonging diastole and by improving subendocardial perfusion. Most of these theoretical advantages have, in fact, been borne out in clinical trials. The pharmacology of beta-adrenergic blockers is discussed in Chap. 81.

Many studies have demonstrated the clinical efficacy of beta blockers in the treatment of AMI. Analysis of pooled data from 28 trials revealed an average reduction of mortality of 28 percent at 1 week, and the majority of the benefit was seen in the first 48 h.[269] The Beta-Blocker Heart Attack Trial demonstrated that the benefits on mortality persisted and were about 20 percent after 2.5 years.[13] In the First International Study of Infarct Survival, patients were enrolled within the first 12 h from the onset of symptoms and atenolol, 5 to 10 mg, was immediately given intravenously and followed by oral atenolol, 100 mg daily.[13] Seven-day mortality was reduced by 14 percent. In the Metoprolol in Acute Myocardial Infarction (MIAMI) trial, metoprolol, 15 mg, was given intravenously in three divided doses early in the course and followed by 50 mg orally every 6 h for 48 h and then by 100 mg twice daily.[270] Mortality relative to placebo was reduced 12 percent at 15 days. In both of these trials, benefit was seen after 1 day and was sustained. Beta blockers have also enhanced therapeutic efficacy when given adjunctively with thrombolytic therapy. In the Thrombolysis in Myocardial Infarction phase II (TIMI-II) trial of conservative versus invasive strategies after treatment with recombinant tissue-type plasminogen activator (rt-PA), a subgroup was selected to receive either early intravenous followed by daily oral metoprolol or to begin oral metoprolol on day 6 after AMI.[271] The beta-blocker regimen was metoprolol, 15 mg, intravenously,

followed by 50 mg orally twice daily for 1 day and 100 mg twice daily subsequently. The alternative protocol involved beginning the oral metoprolol regimen on day 6. The immediate intravenous metoprolol regimen was associated with a 45 percent reduction in nonfatal reinfarction and a 27 percent reduction in recurrent ischemic events in comparison with the group beginning beta-blocker therapy on day 6. Thus, available data strongly support the use of beta blockers early in the course of acute Q-wave myocardial infarction in the absence of contraindications. As discussed later, the data supporting the use of beta blockers in non-Q-wave myocardial infarction are less compelling. The effects of beta blockers in Q-wave MI are summarized in Table 42-9. While metoprolol and atenolol are the only beta blockers approved for use by the Federal Drug Administration in the United States in AMI, it is generally thought that therapeutic efficacy is a class effect of beta blockers lacking intrinsic sympathomimetic activity.

Table 42-9: Effects of Beta Blockade in Q-Wave AMI

Reduces ventricular ectopy, atrial fibrillation, and nonfatal cardiac arrest
Reduces frequency of progression of threatened infarction to completed infarction
Reduces recurrent ischemia and infarction during first 6 weeks after initial event

The relative contraindications to beta-blocker therapy are as follows:[1] (1) heart rate less than 60 beats per minute; (2) systolic blood pressure less than 100 mmHg; (3) moderate or severe left ventricular failure; (4) signs of peripheral hypoperfusion; (5) PR interval greater than 240 ms; (6) second- or third-degree AV block; (7) severe chronic pulmonary disease; (8) history of asthma; (9) severe peripheral vascular disease; and (10) insulin-dependent diabetes mellitus. Since these contraindications are relative and not absolute, the clinician has the option of assessing the effects of beta blockade with the short-acting intravenous beta blocker esmolol, which has an onset of action within 5 to 10 min and a half-life of about 30 min. If the beta blockade is tolerated by the patient, long-acting oral beta-blocking drugs can then be used with increased confidence.

Thrombolysis

Recommendations[1]:

Class I

1. ST elevation (greater than 0.1 mV in two or more contiguous leads at any time during the observation period); time to therapy 12 h or less since the onset of continuous chest pain discomfort, causing hospital presentation; and age less than 75 years
2. Bundle branch block (obscuring ST-segment analysis and history suggesting AMI)

Comment

Treatment benefit is present regardless of gender, presence of diabetes, blood pressure (if <180 mmHg systolic), heart rate or history of previous myocardial infarction.[210] *Benefit is greater in the setting of anterior myocardial infarction, diabetes, low blood pressure (<100 mmHg systolic) or high heart rate (>100 beats per minute). The earlier therapy begins, the better the outcome with the greatest benefit decidedly occurring when therapy is given within the first 3 h; proven benefit occurs, however, up to at least within 12 h of onset of symptoms. Benefit is less with inferior AMI, except for the subgroup with associated right ventricular infarction (ST-elevation in V_{4R}) or anterior-segment depression indicative of a posterior current of injury as often occurs with occlusion of a large circumflex coronary artery.*

Class IIa

1. ST elevation (as earlier), age 75 years or older

Comment

Persons above age 75 benefit from thrombolytic therapy, but because of the high overall mortality rate, the relative benefit is reduced.[210]

Class IIb

1. ST elevation (as earlier), time to therapy (as previously) greater than 12 to 24 h
2. Blood pressure on presentation >180 mmHg systolic and/or >110 mmHg diastolic associated with a high-risk myocardial infarction

The potential for a therapeutic benefit of thrombolysis when the blood pressure is markedly elevated must be carefully considered against the increased risk of intracranial hemorrhage under these circumstances. Lowering the blood pressure pharmacologically before administering thrombolytics has been recommended but is of unproven benefit. If available, coronary artery bypass grafting or primary PTCA should be considered.[1]

Class III

1. ST-segment elevation, time to therapy >24 h, ischemic pain resolved
2. ST-segment depression only

Comment

In the absence of ST elevation, there is no evidence for benefit in patients with normal electrocardiographic or nonspecific changes. Using current thrombolytic regimens, there is some suggestion of harm (including increased bleeding risk) for patients with ST-segment depression only.[157,210] *When marked ST-segment depression is confined to leads V1-V4, there is a likelihood that this reflects a posterior current of injury and suggests a circumflex artery occlusion for which thrombolytic therapy would be considered appropriate. The prospective analysis of the late assessment of thrombolytic efficacy (LATE) trial*[272] *also casts some uncertainties about withholding thrombolytic therapy from this heterogenous group of patients.*

INDICATIONS FOR THROMBOLYTIC THERAPY

Reperfusion therapy should be given immediate consideration in all patients presenting with AMI. Patients with ST-segment elevation in two or more contiguous leads or a bundle branch block masking ST-segment changes occurring within 12 h of symptoms are candidates for thrombolytic therapy.[210,273] In the ISIS-2 trial,[274] patients with bundle branch block had a mortality of 28 percent when treated with a placebo versus 19.8 percent when treated with streptokinase and aspirin. A similar beneficial effect was noted in ISIS-3.[275] Patients of unknown age with bundle branch block and with the clinical features of AMI are candidates for thrombolytic therapy.[273] *Patients with ongoing symptoms suggestive of myocardial ischemia should be repeatedly evaluated by 12-lead ECGs as frequently as every 10 to 15 min in order to identify ST-segment elevation as soon as possible*. Conversely, ST-segment elevation in the absence of suggestive symptoms should raise such possibilities as early repolarization, pericarditis, and previous infarction with aneurysm formation. Elderly patients should not be excluded from thrombolytic therapy primarily because of their age or because of the increased risk of bleeding. In patients over 75 years of age enrolled in the GISSI-2 trial, there were 4.2 fewer deaths per 100 patients in those treated with streptokinase than there were in the control group;[276] while in ISIS-2, there were 3.3 fewer deaths per 100 patients in those patients over 70 years of age who were treated.[211] The results of ISIS-3,[275] GUSTO-I,[15] and GUSTO-III[277] showed benefit regardless of age or site of infarction.

Large, placebo-controlled clinical trials have consistently demonstrated reduced mortality in patients receiving thrombolytic therapy within 6 h of the onset of an AMI.[278] In comparison with conventional medical therapy, thrombolytic therapy reduces the 35-day mortality by 21 percent. It is estimated that 34 lives per 1000 patients treated are saved when thrombolysis is used within the first hour of symptom onset, compared to 16 lives saved per 1000 treated when thrombolytics are given 7 to 12 h after the onset of

symptoms.[1] The true benefit of thrombolytic therapy between 6 and 12 h has been somewhat unresolved; however, the ACC/AHA guidelines[1] have indicated acceptance that there may be a definite benefit between 6 and 12 h and have, therefore, recommended that the time limit for therapy be up to 12 h from the onset of symptoms. The EMERAS trial[279] showed an insignificant (14 percent) improvement in survival using streptokinase between 6 and 12 h after an infarction, while the LATE trial[280] observed a significant improvement (22 percent) in patients treated with rt-PA up to 12 h after infarction. Results of pooling the data from the LATE, EMERAS, and ISIS trials indicate a statistically significant improvement in survival with the use of thrombolytics up to 12 h after the onset of symptoms. Thus, the benefit of thrombolytics given between 6 and 12 h postinfarction is greater in patients classified with high-risk infarction, such as those with severe heart failure. In patients with anterior infarction, left bundle branch block, or severe hypotension, thrombolytic therapy should be given even if the precise time of onset of symptoms is unknown. Conversely, the young patient with inferior infarction having ST-T-segment elevation might not benefit greatly from thrombolytic therapy after 6 h from the onset of symptoms.

In contrast, patients with ST-segment depression, T-wave inversion, or no ECG changes have not been shown to benefit from thrombolytic therapy, as noted earlier.[281] A major problem in patients with nonspecific ST depresson or T-wave inversion is that less than 20 percent will have infarction as opposed to ST-segment elevation, in which case 90 to 95 percent will have infarction. To properly assess thrombolytic therapy in this group of patients without ST-segment elevation, one would need to have some objective marker other than the ECG to triage for infarction upon admission, which, until recently, was not possible (see previous discussion of MB-CK subforms). In the TIMI-III trial, the importance of differentiating non-Q-wave infarction from unstable angina was demonstrated, in that patients with unstable angina receiving rt-PA experienced an increased incidence of reinfarction and death compared with conventional therapy, and the trial had to be discontinued.[157] However, the mean time of initiating thrombolytic therapy in patients with non-Q-wave infarction was 9 h from the onset of symptoms and was probably too late to have a significant beneficial effect (see "Management of Non-Q-Wave Myocardial Infarction" later). An appropriate trial in which non-Q-wave infarction is diagnosed upon presentation to the emergency department within 20 to 30 min, as with MB-CK subforms or myoglobin, and is followed by thrombolytic therapy or PTCA is yet to be performed. This would be an important trial, since about 50 percent of infarctions in the United States are now non-Q-wave infarctions.[126]

CONTRAINDICATIONS TO THROMBOLYTIC THERAPY

The major contraindication to thrombolytic therapy is a cerebrovascular accident (CVA) within the preceding 3 months. A hemorrhagic CVA in the past is an absolute contraindication, whereas a nonhemorrhagic CVA in the more distant past with complete or nearly complete recovery is only a relative contraindication.[282] Patients who have undergone recent (within 2 weeks) major surgery or vaginal delivery are not candidates for thrombolytic therapy, and neither are those with active internal bleeding or bleeding from a peptic ulcer. Puncture of a noncompressible vessel within the previous 10 days makes thrombolytic therapy inadvisable. Other absolute contraindications to thrombolytic therapy include suspected aortic dissection, recent head trauma or known intracranial neoplasm, and pregnancy. Previous exposure to streptokinase or anistreplase (APSAC) requires the use of rt-PA in subsequent attempts at thrombolysis. Systemic arterial hypertension and cardiopulmonary resuscitation should no longer be regarded as absolute contraindications to thrombolytic therapy. The ISIS-2 trial found that, among patients with a systolic blood pressure greater than 175 mmHg, the mortality rate was lower in those receiving streptokinase than it was in control subjects (5.7 versus 8.7 percent).[274] Some practitioners consider a recorded blood pressure greater than 200/120 an absolute contraindication. A history of severe chronic hypertension with diastolic blood pressure greater than 100 mmHg, with or without drug therapy, is a relative contraindication. Most clinicians proceed with thrombolytic therapy in a high-risk patient if elevated blood pressure normalizes promptly, with the easing of pain and anxiety through the use of narcotics and more direct therapy, including nitroglycerin and beta blockers. Califf et al. noted that patients who had brief (<10 min), nontraumatic cardiopulmonary resuscitation had no evidence of tamponade or hemothorax with thrombolytic therapy.[283] Prior administration of cardiopulmonary resuscitation should be considered a relative contraindication, since the risk of further bleeding in the chest may not outweigh the benefit. Other relative contraindications include trauma or surgery less than 2 weeks previously, active peptic ulcer disease, and bleeding diathesis or current use of anticoagulants. The absolute and relative contraindications for thrombolytic therapy are summarized in Table 42-10.

Table 42-10: Absolute and Relative Contraindications to Thrombolytic Therapy

Absolute Contraindications	Relative Contraindications
Active internal bleeding	History of nonhemorrhagic cerebrovascular accident in distant past with complete recovery
Intracranial neoplasm or recent head trauma	Prolonged, traumatic CPR
Suspected aortic dissection	Recent trauma or surgery >2 weeks previously
Pregnancy	Active peptic ulcer disease
History of hemorrhagic cerebrovascular accident or recent nonhemorrhagic cerebrovascular accident	History of severe hypertension with diastolic blood pressure >100
Recorded blood pressure >200/120	Bleeding diathesis or concurrent use of anticoagulants
Trauma or surgery that is a potential bleeding source within previous 2 weeks	Previous treatment with SK or APSAC if being considered (does not apply to rt-PA)
Allergy to SK or APSAC if being considered	

ABBREVIATIONS: CPR = cardiopulmonary resuscitation; SK = streptokinase; APSAC = anistreplase; rt-PA = recombinant tissue plasminogen activator.

CHOICE OF THROMBOLYTIC AGENT

Four thrombolytic agents have been approved in the United States: streptokinase (SK), rt-PA, APSAC, and reteplase (r-PA). Each has been shown to limit infarct size, preserve ventricular function, and improve survival rates. These drugs and their pharmacologic properties are discussed in detail in Chap. 44.

In angiographic studies,[284,285] rt-PA and r-PA recanalized the coronary artery at 90 min in about 70 to 75 percent of patients, compared with 55 to 60 percent of those receiving SK or APSAC. Patency determined at 24 to 36 h is essentially the same for all four agents. The time course for this "catch-up" phenomenon in vessel patency, as defined by the GUSTO angiographic substudy, occurs within the first 3 h after administration of the lytic agent.[15] The ISIS-3 trial reported a 30-day mortality rate, which was the same for all three agents (10.5 percent for SK, 10.6 percent for APSAC, and 10.3 percent for rt-PA).[275] Conversely, the GUSTO trial found a 30-day mortality rate of 6.3 percent for the accelerated rt-PA regimen, which was significantly less than the 7.2 percent mortality with SK and subcutaneous heparin and less than the 7.4 percent mortality with SK and intravenous heparin[286] (Table 42-11). This absolute reduction of 1 percent reflects a 14 percent reduction in the risk of death, compared with that of SK or APSAC. A major difference why GUSTO I demonstrated an advantage for rt-PA and GISSI-2 or ISIS-3 did not was the manner in which heparin was used in GUSTO I. In GUSTO III,[277] rt-PA and r-PA exhibited similar beneficial results and a similar incidence of side effects. The 1-year follow-up on the GUSTO-I patients[287] showed that the 1 percent lower mortality rate compared with SK was maintained, which provided further evidence that rt-PA is more effective than SK.

Table 42-11: 30-Day Mortality Rates from the GUSTO Trial

Regimen	Mortality, %
SK and subcutaneous heparin	7.2
SK and intravenous heparin	7.4
Accelerated rt-PA and intravenous heparin	6.3[a]
Combination rt-PA and SK with intravenous heparin	7.0

[a]14% reduction in mortality rate was achieved with the accelerated rt-PA regimen versus the SK strategies ($p = 0.001$).
ABBREVIATIONS: SK = streptokinase; rt-PA = recombinant tissue plasminogen activator.

r-PA is a modified recombinant form of rt-PA with a longer half-life (15 min) and can be given as 2 boluses 30 min apart (see Chap. 44). In the initial open-phase trials (Reteplase Angiographic Phase II International Dose-Finding Trial: RAPID I and RAPID II),[288,289] patency was compared to that of rt-PA. In RAPID I, 60-min patency with r-PA was 78 percent, versus 66 percent for rt-PA, and TIMI-III flow was 51 percent, versus 33 percent for rt-PA. At 90 min after administration, patency was 85 percent for r-PA and 77 percent for rt-PA, with TIMI-III flow being 63 percent for r-PA and 49 percent for rt-PA. These results suggested slightly better patency rates with r-PA than with rt-PA. In the International Joint Efficacy Comparison of Thrombolytics (INJECT) trial of 6000 patients, r-PA was compared with SK.[290] The mortality and the incidence of complications for r-PA was identical to SK. This was followed by the GUSTO-III trial,[291] which compared r-PA with rt-PA, and showed that mortality and bleeding complications were similar. At 30 days, the mortality rate in the r-PA group was 7.43 percent; with rt-PA, it was 7.22 percent. The rate of hemorrhagic strokes was very similar: 0.91 percent for r-PA, versus 0.88 percent for rt-PA. The overall stroke rate was 1.67 for r-PA versus 1.83 for rt-PA. The rate of bleeding events was virtually identical between the two treatments. There remains some lack of clarity, since there were 10,000 patients in the r-PA limb and 5000 in the rt-PA limb, and the confidence limits were somewhat wide, leaving the interpretation open to some extent. Utilizing 95 percent confidence intervals, interpretation may be that rt-PA is 1.1 percent better than r-PA or that r-PA is 0.7 percent better than rt-PA. For this reason, there is still some uncertainty as to whether these drugs are truly equivalent.[291] Nevertheless, the generally accepted conclusion is that the two drugs have similar efficacy and safety.

Bolus administration of a thrombolytic agent, in addition to being more convenient, can be given with the assurance that the patient has received the full dose of the thrombolytic agent, which is not always the case in an infusion that will require 3 h or longer. Two new agents that can be given by bolus have reported results showing similar efficacy to alteplase: one is lanatoplase and the other TNK-tpa. Both agents were found to have comparable rates of intracranial hemorrhage in preliminary trials (0.9-1.1 percent) and are awaiting approval for use by the FDA.

The selection of a thrombolytic agent must be based on its adverse effects as well as upon its efficacy. The major risk with any thrombolytic agent is its propensity for causing bleeding, with the most devastating bleeding being a hemorrhagic stroke. In the GUSTO trial, the frequency of hemorrhagic stroke was 0.49 percent for SK and subcutaneous heparin, 0.54 percent for SK and intravenous heparin, 0.72 percent for rt-PA, and 0.94 percent for combined SK and rt-PA. There was a small but significant excess of hemorrhagic strokes for rt-PA and for the combined rt-PA and SK strategy ($p < 0.001$) compared with the SK arms. The combined end point of death or nonfatal hemorrhagic stroke was, however, significantly reduced in the rt-PA group, compared with the SK groups (6.6 versus 7.5 percent; $p = 0.004$).[286] One reason to choose rt-PA over SK is the 14 percent decreased risk of mortality. Nevertheless, a 10-fold greater cost of rt-PA must be considered. Choosing between rt-PA and r-PA, since both are equally effective and cost the same, may depend on choosing between monitoring an intrave-nous infusion of rt-PA versus 2 bolus injections of r-PA separated by 30 min.

Another thrombolytic agent, TNK-tPA, is in the process of clinical evaluation (see Chap. 44). It has a short half-life of about 17 min and can be given as a single bolus. It is highly fibrin-specific and somewhat

resistant to plasminogen activator inhibitor.[292] The phase II trial Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT-1)[293,294] was performed on 3235 patients, and the results were comparable to that of rt-PA in GUSTO-I and III. In the ASSENT-2 trial[293] the 30-day mortality was 6.17 versus 6.15 percent for rt-PA, and the bleeding rates were also similar. Another thrombolytic agent undergoing clinical trials is that of lanoteplase (see Chap. 44). Preliminary results showed no difference in 30-day mortality, which was 6.6 percent and 6.7 percent with alteplase and lanoteplase, respectively.[295]

DOSE AND ADMINISTRATION OF THROMBOLYTIC AGENTS

Streptokinase is given in a dose of 1.5 million U intravenously over 30 to 60 min. Since antibodies develop and may persist for several years, a subsequent need for thrombolytic therapy, as for early or late reocclusion, would require the use of rt-PA or r-PA. If the patient has had a streptococcal infection within 3 to 6 months, the use of rt-PA is preferable. Although APSAC is identical to SK as a thrombolytic agent, it can be given as a rapid infusion of 30 U over 5 to 10 min. Its therapeutic half-life is similar to that of SK, which is about 90 min. In contrast, the half-life of rt-PA is about 5 min. The FDA-approved dose of rt-PA is an initial bolus of 15 mg, followed by an infusion of 50 mg or 0.75 mg per kilogram of body weight over the next 30 min, and an infusion of 35 mg or 0.50 mg per kilogram of body weight over the subsequent 60 min, for a total of up to 100 mg given over 90 min. Reteplase is given as an initial bolus of 15 megaunits (MU), followed by a second bolus of 15 MU in 30 min.

OVERALL STRATEGY FOR REPERFUSION OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

The criteria for initiating thrombolytic therapy are as follows (Table 42-12):

Table 42-12: Criteria for Initiating Thrombolytic Therapy

Chest pain consistent with angina
ECG changes
ST ↑ ≥ 1 mm, ≥2 contiguous limb leads
ST ↑ ≥ 2 mm, ≥2 contiguous precordial leads
New left bundle branch block
Absence of contraindications

1. Patients presenting with chest pain suggestive of myocardial ischemia, having ST-T-segment elevation greater than 1 mm in two contiguous limb leads or greater than 2 mm in two contiguous precordial leads or new left bundle branch block and who are within 6 h of the onset of symptoms should receive thrombolytic therapy if there are no contraindications. In patients presenting between 6 and 12 h of the onset of symptoms, one must weigh more heavily the risk versus the benefit. Patients presenting after 12 h are no longer routinely considered for thrombolytic therapy.
2. Contraindications for thrombolytic therapy are absolute or relative, as discussed earlier (Table 42-10).
3. In patients receiving rt-PA or r-PA, it is recommended that heparin be given as a bolus at the initiation of infusion (60 U/kg) and then an additional maintenance dose of 12 U/kg/h (with a maximum of 4000 U bolus and a 1000 U/h infusion for patients weighing >70 kg), adjusted to maintain a partial thromboplastin time (PTT) at 1.5 to 2.0 times control (50 to 70 s) for 48 h. Continuation of heparin infusion beyond 48 h should be considered in patients at high risk for systemic or venous thromboembolism. In patients treated with nonselective thrombolytic agents (streptokinase, anistreplase, or urokinase), heparin should be given intravenously for those who are at high risk for systemic emboli (large or anterior myocardial infarction, atrial fibrillation, previous embolus or known left ventricular thrombus). It is recommended that heparin be withheld for 6 h

and that aPPT testing begin at that time. Heparin should be started when aPPT returns to 2 times control (approximately 70 s), then infused to keep aPPT 1.5 to 2.0 times control (initial infusion rate approximately 1000 U/h). After 48 h, a change to subcutaneous heparin or warfarin or aspirin alone should be considered.

4. Patients allergic to SK or APSAC who require thrombolytic therapy should receive rt-PA or r-PA. Patients who received SK or APSAC and who again require thrombolytic therapy should receive rt-PA or r-PA.
5. Patients presenting with ST-T-segment depression and chest pain are not candidates for thrombolytic therapy. These patients need to be triaged, as indicated in Fig. 42-3, as to whether their pain is of cardiac or noncardiac origin. If the former, those with either unstable angina (see Chap. 41) or non-ST-elevated infarction should be treated with intravenous unfractionated heparin or low-molecular-weight heparin subcutaneously. In all patients not treated with thrombolytic therapy who do not have a contraindication to heparin, subcutaneous unfractionated heparin (e.g., 7500 U bid) or low-molecular-weight heparin (e.g., Enoxoparin) 1 mg/kg bid should be used. In patients who are at high risk for systemic emboli, intravenous heparin is preferred.
6. As discussed subsequently and in detail in Chapter 46, PTCA as a primary procedure is an alternative to thrombolytic therapy only if performed in a timely fashion by individuals skilled in the procedure and supported by experienced personnel in high volume centers (class I). The individual must perform 75 such PTCA procedures per year, and the center a minimum of 200 PTCAs per year. PTCA is indicated in patients with a contraindication to thrombolytic therapy because of a severe bleeding diathesis or in those who are in cardiogenic shock (class IIa).
7. Elective angioplasty should be reserved for patients who develop ischemia or reinfarction or in whom thrombolytic therapy appears ineffective. In patients in whom angioplasty cannot be performed and who develop recurrent ischemia with possible infarction, the possibility of readministering a thrombolytic agent should be considered; rt-PA may be given in a full dose if the patient has not received it for 24 to 48 h.

Percutaneous Transluminal Coronary Angioplasty as a Primary Therapy for Acute Myocardial Infarction

Recommendations[1]:

Class I

1. "As an alternative to thrombolytic therapy in patients with AMI and ST segment elevation or new or presumed new LBBB who can undergo angioplasty of the infarct artery within 12 hours of onset of symptoms or >12 hours if ischemic symptoms persist, if performed in a *timely fashion* by persons skilled in the procedure** and supported by experienced personnel in an appropriate laboratory environment*."***[1]
2. "In patients who are within 36 hours of an acute ST-elevation/Q-wave or new LBBB MI who develop cardiogenic shock, are <75 years of age, and revascularization can be performed within 18 hours of onset of shock."[1]

Class IIa

1. "As a reperfusion strategy in candidates for reperfusion who have a contraindication to thrombolytic therapy."[1]

Class IIb

1. "In patients with AMI who do not present with ST elevation but who have reduced [less than Thrombolysis in Myocardial Infarction (TIMI) grade 2] flow of the infarct-related artery and when angioplasty can be performed within 12 hours of onset of symptoms."[1]

Class III

"This category applies to patients with AMI who

1. Undergo elective angioplasty of a non-infarct related artery at the time of AMI
2. Are beyond 12 hours after onset of symptoms and have no evidence of myocardial ischemia
3. Have received fibrinolytic therapy and have no symptoms of myocardial ischemia"[1]

Comment

There is serious concern that a routine policy of primary PTCA for patients with AMI will result in unacceptable delays in achieving reperfusion in a substantial number of cases and less than optimal outcomes if performed by less experienced operators. Strict performance criteria must be mandated for primary angioplasty programs so that such delay in revascularization and performance by low-volume operators and centers do not occur. Interventional cardiologists and centers must operate within a specified "corridor of outcomes" to include (1) balloon dilatation within 90 (±30) min of admission and diagnosis of AMI; (2) a documented clinical success rate with TIMI-2 through 3 flow attained in >90 percent of patients without emergency coronary artery bypass graft, stroke, or death; (3) emergency coronary artery bypass graft rate <5 percent among all patients undergoing the procedure; (4) actual performance of angioplasty in a high percentage of patients (85 percent) brought to the laboratory; and (5) mortality rate <10 percent. Otherwise, the focus of treatment should be the early use of thrombolytic therapy.

ANGIOPLASTY AS PRIMARY OR ADJUNCTIVE THERAPY TO THROMBOLYSIS

Detailed discussions of PTCA and its indications appear in Chap. 45. Comprehensive discussions of PTCA in the treatment of acute MI are presented in Chapter 46. Direct angioplasty has been compared with thrombolytic therapy in a meta-analysis of 10 randomized trials involving 2606 patients.[297] In 1290 patients treated with primary PTCA, the mortality rate at 30 days was 4.4 percent compared to 6.5 percent in 1316 patients treated with thrombolytic therapy. Pooled rates of nonfatal reinfarction or death were also lower in the PTCA as opposed to the thrombolysis groups. The incidence of stroke was also lower with PTCA than it was with thrombolysis. These authors concluded that "primary PTCA appears to be superior to thrombolytic therapy for treatment of patients with AMI, with the proviso that success rates for PTCA are as good as those achieved in these trials. Data evaluating longer-term outcome, operator expertise, and time delays before treatment are needed before primary PTCA can be recommended universally as the preferred treatment."[297] Registry data (Second National Registry of Myocardial Infarction) of 4939 patients with acute AMI (ST-segment elevation) who received primary PTCA and 24,705 who received alteplase showed similar in-hospital mortality (5.2 percent and 5.4 percent, respectively) in the absence of shock.[298] These results also add some caution against the general embracement of primary PTCA over thrombolysis in the treatment of ST-segment elevation myocardial infarction.

In the case of cardiogenic shock in AMI (ST-segment elevation/new left bundle branch block) primary angioplasty, if rapidly available, offers benefit over thrombolysis as part of a strategy of emergency revascularization.[299] In the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) Trial, a strategy of emergency revascularization was compared with initial medical stabilization and delayed revascularization based on clinical indicators. The 30-day mortality showed a favorable but not significant ($p = 0.11$) trend for emergency revascularization over initial medical restabilization in the case of mortality at 30 days (46.7 versus 56.0 percent, respectively). The mortality at 6 months, however, was significantly lower ($p = 0.027$) for the emergently revascularized group (53.5 percent) compared to the initially medical stabilized group (65.7 percent). Patients <75 years old had a more favorable outcome with emergency revascularization than did older patients (>75) with a 15.4 percent reduction in 30-day mortality (56.8 versus 41.4 percent, $p < 0.01$). Patients in the emergency revascularization group who were >75 years old fared worse than they did in the medical stabilization group. PTCA was the revascularization procedure in 60 percent, and coronary artery bypass grafting was used in 40 percent of patients with similar outcomes.

Thus, there is increasing evidence of the efficacy of PTCA as an alternative to thrombolysis in the treatment of ST-segment elevation/new left bundle branch block myocardial infarction. It is the method of choice in cardiogenic shock and in the presence of contraindications for thrombolytic therapy. There is increasing concensus that, in high-volume centers with skilled, experienced operators, PTCA is the procedure of

choice if it can be performed in a timely manner (generally within the first 2 h). Indeed a report showed a 53 percent reduction in 30-day mortality in patients having PTCA within the first 2 h of pain in comparison to those more than 2 h into their pain.[1,300] Because of the logistic issues involved (including transfer from a community hospital to an interventional center) in obtaining PTCA within an appropriate time frame, the approach of combining a low-dose thrombolytic (to obtain early patency) with PTCA outside of the 2-h time is being explored.[1] These and other issues including the use of stents are discussed in detail in Chapter 45.

Several caveats must be considered before embracing PTCA as the therapy of choice for AMI generally. Only about 20 percent of hospitals in the United States have cardiac catheterization laboratories and relatively few can perform PTCA on an emergency basis. In many cases the time delay involved in transferring a patient to a hospital capable of performing emergency PTCA may outweigh any benefit.[1] *The excellent results for emergency PTCA described earlier were achieved by highly experienced and enthusiastic investigators in hospitals that have devoted extraordinary support and personnel to achieving opening of the coronary artery within 60 to 90 min of arrival.*[1,301,302] Available data suggesting that emergency PTCA may be comparable to thrombolysis in many community settings were alluded to previously.

Heparin as Conjunctive or Adjunctive Therapy

Recommendations for heparin administration post-MI[1]:

Class I

1. Patients undergoing percutaneous revascularization.

Class IIa

1. Administer intravenously in patients undergoing reperfusion therapy with rt-PA (alteplase) or r-PA (reteplase).
2. Administer subcutaneously unfractionated heparin (7500 U BID) or low-molecular-weight heparin (enoxaparin 1 mg/kg bid) in all patients not treated with thrombolytic therapy who do not have a contraindication to heparin. Intravenous heparin is acceptable as an alternative and is preferred in patients who have a large or anterior myocardial infarction, atrial fibrillation, a known left ventricular thrombus, or a previous embolus and thus are at high risk for systemic emboli.
3. Administer intravenously in patients treated with nonselective thrombolytic agents (streptokinase or anistreplase) who are at high risk for systemic emboli (anterior or large infarction, history of embolus, atrial fibrillation, or demonstrable left ventricular thrombus).

It is recommended that heparin not be started immediately but that an activated partial thromboplastin time (aPTT) be drawn at 4 h and that heparin be started when the aPTT returns to less than twice control (about 70 s).

Lysis of a thrombus by any thrombolytic agent induces a surface that is perhaps the most thrombogenic known.[285,303] Furthermore, lysis with either rt-PA or SK has been shown to be associated with marked elevation of plasma levels of thrombin, which return to normal after 24 h.[304] Since aspirin has no effect on thrombin-induced platelet aggregation,[305] the use of heparin during the initial 24 to 48 h was assumed to be critical to prevent rethrombosis and reocclusion.

The necessity of heparin for maintaining coronary patency induced by rt-PA was established in the HART trial.[284] In this trial, 208 patients received rt-PA within 4 h of the onset of their infarction. Simultaneously, 50 percent of these patients received heparin administered as a bolus, followed by an intravenous infusion, while the remainder received only oral aspirin in a dose of 81 mg/day. Coronary angiographic studies performed at 18 to 81 h showed a patency of 82 percent in the group receiving heparin and 52 percent in the group receiving aspirin (Fig. 42-7). Stratifying the group on the basis of PTT established an excellent correlation between patency and PTT (Fig. 42-8). In patients with aPTT of <45 s, the patency was only 45

percent; patency was 83 percent or greater in patients with aPTT >45 s.[306] The findings of HART were confirmed by Bleich et al.,[307] who showed that rt-PA given with heparin had a patency of >90 percent; without heparin, the patency rate was 44 percent (Fig. 42-7). In the National Heart Foundation of Australia Study,[308] all patients received rt-PA, followed by intravenous heparin for 24 h. They were then randomized to continue heparin for 72 h or were switched to antiplatelet agents. The study found the patency rate at 72 h to be the same for both groups.

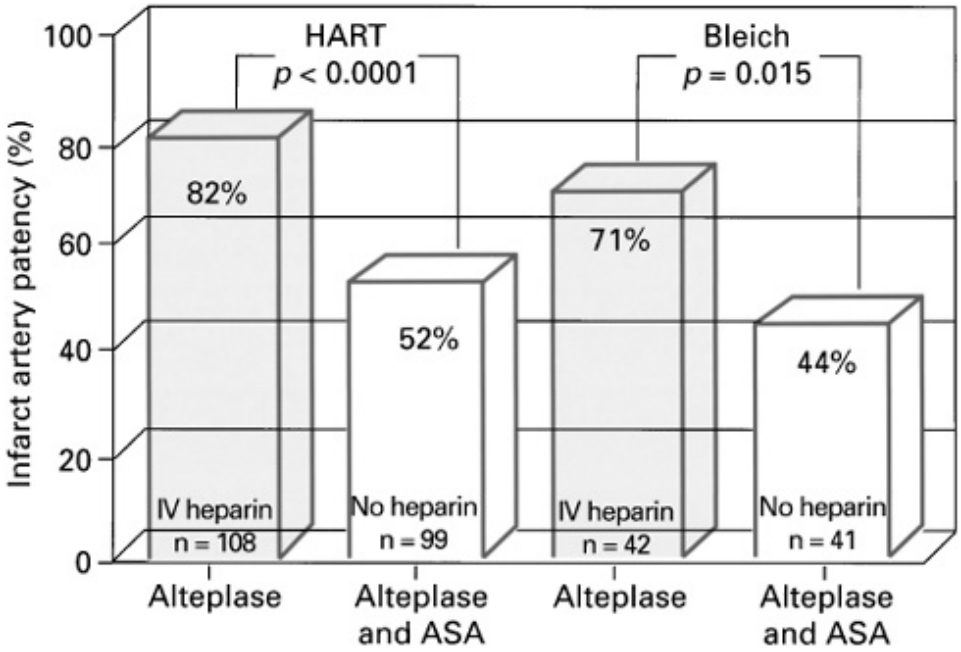

Figure 42-7: Influence of effective anticoagulation on early patency rates with rt-PA. Patency assessed angiographically at an average of 18 to 81 h is significantly greater in patients treated with intravenous heparin.

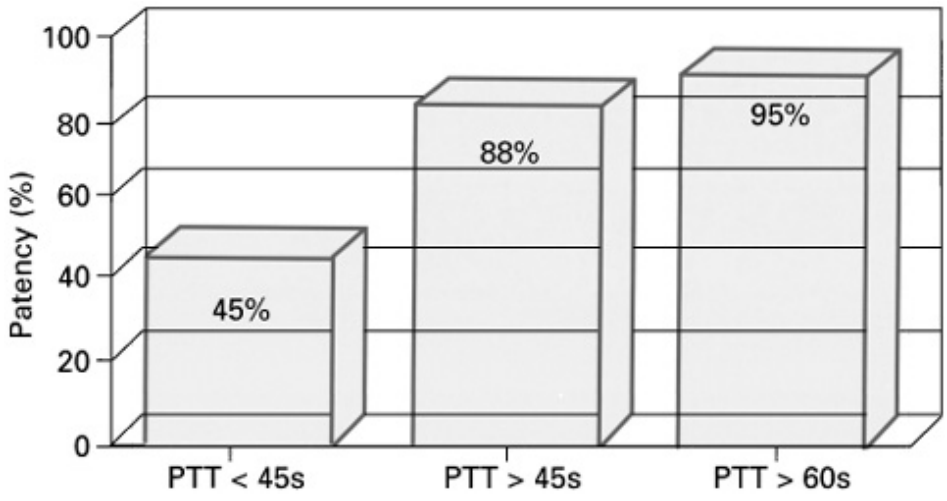

Figure 42-8: Retrospective analysis of the HART trial showing the relationship between increased PTT and coronary artery patency (*n* = 94). This illustrates the importance of heparin.

Heparin appears to act by preventing early reocclusion, at least after rt-PA.[309,310] The adjunctive heparin therapy in both GISSI-2 and ISIS-3 was administered by the subcutaneous route (12 h after thrombolytic therapy in GISSI-2 and 4 h afterward in ISIS-3). Such a heparin regimen seems to be suboptimal adjunctive

therapy for rt-PA and is believed to be the main reason why rt-PA was not shown to be superior over SK in GISSI-2 and ISIS-3. A subcutaneous heparin dose of 12,500 U twice a day used in the megatrials failed to provide therapeutic anticoagulation for at least 24 h in various cohort analytic studies.[311,312] The administration of SK without adjunctive heparin has not been properly tested. However, the ISIS data raise the possibility that it may not be necessary in the early hours, since the marked increase, after SK administration, in plasma levels of fibrinogen breakdown products, which inhibit platelet aggregation, may prevent rethrombosis and reocclusion.[273] In contrast, these platelet-inhibiting breakdown products are not present in high concentrations with the fibrin-selective agents, rt-PA and r-PA. The results of the SCATI trial argue for the existence of a beneficial effect of heparin even in patients treated with SK.[313] In the SCATI trial, patients receiving SK with subcutaneous heparin had a mortality rate of 4.5 percent, while those receiving SK without heparin had a mortality rate of 8.8 percent.[313] The combined data from these studies suggest that heparin is not necessary to achieve reperfusion but is essential in the first 24 h to maintain patency rates with rt-PA. While heparin may be beneficial when SK is used, subcutaneous administration of heparin appears adequate in this circumstance.[273] At present, heparin is recommended in a bolus of 5000 U intravenously followed by an infusion of 1000 to 1200 U/h to keep the PTT at 1.5 to 2.0 times normal. It is recommended that the PTT not be measured until 4 h after heparin therapy is initiated, because it has not yet reached a steady state. If the PTT has increased more than twofold over normal, the same dose of heparin should be continued; if PTT exhibits less than a twofold increase, the infusion rate of heparin should be increased. Initiation of heparin is recommended either during or following completion of thrombolytic therapy, as discussed earlier, and should be maintained in uncomplicated cases for 24 to 48 h.

The use of heparin has also been recommended conjunctively in patients with AMI who are not being treated with the drug for other reasons, i.e., postthrombolysis or postprimary PTCA. Currently, the American Association of Chest Physicians' guidelines recommend heparin 7500 U twice daily subcutaneously as prophylaxis against deep venous thrombosis.[264] Given the enhanced risk of stroke after AMI in patients with atrial arrhythmias, those with large and especially anterior and apical infarction, and those with history of previous stroke,[314] the ACC/AHA guidelines have incorporated this recommendation for broader prophylaxis against systemic embolization.[1] In high-risk patients, the intravenous route is probably preferable. Heparin therapy should be continued for 48 h and judgment should be made at that point about continuation based on individual patient characteristics. Heparin therapy, including precautions concerning the monitoring of platelet counts because of the risk of heparin-induced thrombocytopenia, is discussed in Chap. 44.

Low-molecular-weight heparins are cleavage products of heparin with a mean molecular weight of ~5000 which have higher anti-Xa activity and less antithrombin activity. Low-molecular-weight heparin preparations are widely used in non-ST-segment elevation acute coronary syndromes (unstable angina, non-Q-wave myocardial infarction) as discussed subsequently in Chapter 41. Low-molecular-weight heparins are being evaluated as adjunctive therapy for thrombolysis.[1] Their use has a class IIa recommendation in all patients with ST-segment elevation AMI who have not been treated with thrombolytics and who do not have a contraindication to heparin.[1] High-risk patients for systemic embolization should be treated with heparin, as noted.

Early Coronary Angiography in Patients with ST-Segment Elevation Not Undergoing Primary Percutaneous Transluminal Coronary Angioplasty

Recommendations[1]:

Class I

1. None

Class IIa

1. In the presence of cardiogenic shock or persistent hemodynamic instability

Class IIb

1. In the presence of evolving large or anterior infarction and evidence that thrombolysis has not resulted in arterial patency and if adjuvant PTCA is planned

Class III

1. Routine use of angiography and subsequent PTCA within 24 h of administration of thrombolytic agents

Routine immediate or delayed angioplasty is not recommended as a standard mode of therapy following thrombolysis. The TIMI-IIA and TIMI-IIB trials,[315] the TAMI study,[310] The European Cooperative Study Group trial,[316] and the SWIFT trial[317] all showed no reduction in the incidence of coronary reocclusion or hospital mortality rates and no evidence of improved ventricular function with routine immediate or delayed angioplasty compared with elective angioplasty in the case of manifest ischemia following thrombolytic therapy. The TIMI-II trial found that angioplasty either performed routinely at 18 to 48 h when anatomically appropriate or in response to induced or spontaneous ischemia did not improve survival or reduce the reinfarction rate at either 6 weeks or 1 year,[318] and neither did it reduce the need for surgery (Fig. 42-9). At present, the most widely accepted recommendation is to perform cardiac catheterization for possible angioplasty or bypass surgery in patients who develop angina or manifest evidence of myocardial ischemia during submaximal exercise testing or who develop hemodynamic or ischemic instability. Thus, if intervening with PTCA generally offers no demonstrable benefit after thrombolysis, there is little apparent reason to perform early coronary angiography routinely.

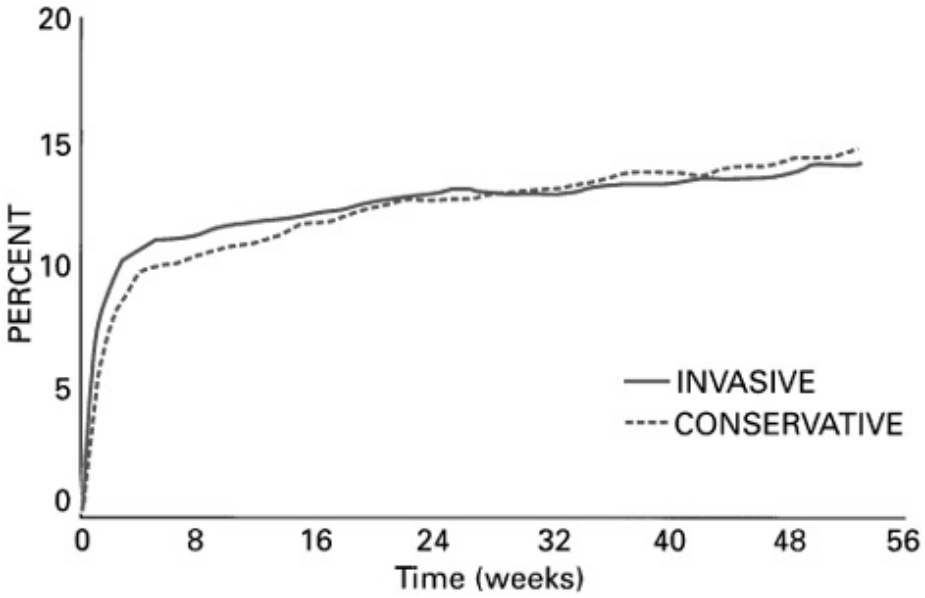

Figure 42-9: Kaplan Meier curves for death and infarction in patients assigned to the invasive or conservative strategies in TIMI-2. Routine cardiac catheterization after thrombolytic therapy and revascularization with PTCA or bypass grafting (when anatomically appropriate) was not a superior strategy to catheterization and revascularization when there is development of spontaneous ischemia or ischemia induced by exercise testing. (Reproduced with permission. Williams DO, Braunwald E, Knatterud G, et al.: One-year results of the thrombolysis in myocardial infarction investigation (TIMI) phase II trial. *Circulation* 1992; 85:533-542.[318] Copyright 1992 American Heart Association.)

Rescue angioplasty to open occluded arteries after presumptive failed thrombolysis has been advocated and, in fact, studies indicate that TIMI grade 3 flow can be achieved in a high percentage of these patients.[319] In the reported TIMI-IV trial, however, it was found that although a strategy of rescue angioplasty could restore flow that is superior to that of thrombolysis alone, the incidence of adverse events for the strategy as a whole was the same as for not undertaking PTCA (35 percent adverse event rate whether or not PTCA

was performed for an occluded artery). Both rates tended to be higher than the incidence in patients with patent arteries (23 percent, $p = 0.07$).[320] *Thus, rescue angioplasty as a routine strategy for failed or presumptively failed thrombolysis cannot be recommended.* This issue is discussed further in Chapter 46.

Patients with cardiogenic shock have a very high mortality (>70 percent) with or without thrombolysis. As noted previously, the results of the reported SHOCK Trial now provide data to suggest that emergency revascularization results in a 41.4 percent survival rate at 30 days.[299] All of these patients received intraaortic balloon assist whether they received revascularization urgently or whether they had initial medical stabilization. These data suggest that other means of metabolically manipulating the myocardial cell may be required for further advances in the management of this lethal complication of AMI.

Emergency or Urgent Coronary Artery Bypass Surgery

Recommendations[1]:

Class I

1. Failed PTCA with hemodynamic instability or persistent pain in patients with coronary anatomy suitable for surgery
2. AMI with medically refractory recurrent or persistent ischemia in patients who are not candidates for PTCA but who have coronary anatomy suitable for surgery
3. After myocardial infarction, at the time of surgical repair of mitral insufficiency or ventricular septal defect

Class IIa

1. Postinfarction cardiogenic shock with coronary anatomy suitable for surgery

Class IIb

1. Failed PTCA and a relatively small mass of myocardium at risk and if hemodynamically stable

Class III

1. When the anticipated operative mortality rate exceeds or equals the mortality rate associated with appropriate medical therapy coronary artery bypass grafting in cardiogenic shock in patients in whom other strategies have failed or where they have not been indicated has been associated with mortality rates from about 10 to 40 percent.[321-323] These results are generally better than those associated with PTCA. Thus, AMI patients with multivessel coronary artery disease or cardiogenic shock who have had unsuccessful thrombolysis and/or PTCA and are within 4 to 6 h of the onset of symptoms should be considered for emergency coronary artery bypass grafting.[1]

Arrhythmias Early in the Course of Acute Myocardial Infarction

BRADYCARDIA

Bradyarrhythmias are relatively common (30 to 40 percent) early in the course of AMI, especially in inferior infarction, or after reperfusion of the right coronary artery, because of the activation of vagal afferents that ultimately result in enhanced parasympathetic tone.[1] Atropine, because of its anticholinergic effects, can be very useful in this situation, since it enhances the discharge rate of the sinus node and facilitates AV conduction,[324] as well as reversing the peripheral effects of excessive cholinergic activity such as vasodilation with associated hypotension. Parasympathomimetic effects with bradycardia, hypotension, and nausea and vomiting are also produced by morphine and can be reversed by atropine. Atropine should be used sparingly and appropriately in AMI, however, because of the protective effect of vagal stimulation against VF.[325]

THE USE OF ATROPINE

Recommendations[1]:

Class I

1. Sinus bradycardia with evidence of low cardiac output and hypoperfusion peripherally or frequent ventricular premature complexes at the onset of symptoms of AMI
2. Acute inferior infarction with type I second- or third-degree AV block associated with symptoms of hypotension, ischemic discomfort, or ventricular arrhythmias
3. Sustained bradycardia and hypotension after administration of nitroglycerin
4. Morphine-induced nausea and vomiting
5. Ventricular asystole

Class IIa

1. In patients with inferior infarction and type I second- or third-degree block at the AV-nodal level (narrow QRS complex or known preexisting bundle branch block) who are symptomatic from the low output and/or vagal predominance

Class IIb

1. Vagal symptoms and sinus bradycardia associated with the administration of morphine
2. Patients with inferior infarction who are asymptomatic with type I second-degree heart block or third-degree block at the AV node
3. Second- or third-degree AV block of uncertain mechanism and unavailability of pacing

Class III

1. Asymptomatic sinus bradycardia and a rate of greater than 40 beats per minute with no signs of hypoperfusion or frequent ventricular premature contractions
2. Type II and third-degree AV block and third-degree AV block with new, wide QRS complex (i.e., block below the AV junction)

SINUS BRADYCARDIA, ATRIOVENTRICULAR BLOCK, OR VENTRICULAR ASYSTOLE

Atropine is indicated for the treatment of type I second-degree AV block, especially with complicating inferior myocardial infarction, and is useful at times in third-degree AV block at the AV node in restoring AV conduction or for increasing the junctional response rate.[1] By increasing the sinus node rate or by improving AV conduction, atropine may improve signs or symptoms of congestive heart failure, hypotension, or frequent, complex ventricular arrhythmias associated with AV block or sinus bradycardia; thus, pacemaker insertion may be avoided.[1] Treatment of sinus bradycardia or first- or second-degree AV block is generally not indicated in the absence of hemodynamic compromise,[1] and atropine should seldom be used in the treatment of type II AV block (location of block below the AV node). Symptomatic bradycardia that is unresponsive to atropine should be treated with pacing.

Atropine should be administered intravenously at a dosage of 0.5 to 1.0 mg and repeated as necessary to achieve an adequate heart rate every 3 to 5 min, up to a total maximum dose of 2.5 mg, which gives complete vagal blockade.[1] Atropine may also be efficacious in ventricular asystole and should be given intravenously at a dosage of 1.0 mg every 3 to 5 min during cardiopulmonary resuscitation up to a maximum of 2.5 mg if asystole persists.

At doses of 0.5 mg or less, atropine may produce, paradoxically, bradycardia and suppression of AV nodal conduction due to a central or peripheral parasympathomimetic effect.[326] Atropine dosage should be titrated carefully, because tachycardia can be induced and ischemia can be worsened. Thus, atropine should

be given in 0.5-mg increments, as noted, to achieve an adequate heart rate of 50 to 60 beats per minute.

HEART BLOCK

Heart block develops in about 10 percent of patients with AMI and is associated with an increased mortality during hospitalization, but it does not predict long-term mortality in those who survive to be discharged.[327-329] Intraventricular conduction delay or bundle branch block is also associated with increased in-hospital mortality.[210] The increase in mortality associated with heart block reflects the extent of myocardial damage, not heart block per se. Thus, a heart block in the setting of anterior myocardial infarction reflects extensive infarction and concomitant destruction of the conduction system and is associated with relatively high mortality. In contrast, heart block with inferior myocardial infarction may primarily reflect ischemia of the AV node rather than extensive tissue damage and is associated with a more favorable prognosis. Because of the overwhelming effect of the extent of myocardial damage on prognosis, pacing has not been shown to lessen mortality associated with AV block or bundle branch block.[328,330] It is likely, however, that pacing will benefit subgroups of these patients with severe slowing of ventricular rates but without extensive myocardial damage[330,331] by preventing hypotension, ischemia, and ventricular escape arrhythmias associated with the appearance of a heart block. In AMI, the risk of developing heart block is augmented by the presence of any evidence of conduction system abnormality including first-degree AV block, Mobitz type I or II AV block, left anterior or posterior hemiblock, or a left or right bundle branch block.[1]

TEMPORARY PACING EARLY IN THE COURSE OF ACUTE MYOCARDIAL INFARCTION

The "Guidelines for the Management of Patients with Acute Myocardial Infarction"[1] place increased emphasis on transcutaneous pacing in view of the availability of new systems that provide standby status for pacing in AMI patients who do not necessitate immediate pacing and are at intermediate risk for developing heart block. These systems use a single pair of multifunctional electrodes, permitting electrocardiographic monitoring, transcutaneous pacing, and defibrillation.[332] Transcutaneous pacing does not entail the risk and complications of transvenous pacing and, because invasive procedures may thus be avoided or delayed, is well suited for use in the patient who has undergone thrombolysis. Percutaneous pacing is painful; if prolonged pacing is required, the patient should be switched to transvenous systems.

Placement* of Transcutaneous Patches and Active (Demand)† Transcutaneous Pacing Recommendations[1,333]:

Class I

1. Sinus bradycardia (rate less than 50 beats per minute) with symptoms of hypotension (systolic blood pressure less than 80 mmHg) unresponsive to drug therapy†
2. Mobitz type II second-degree AV block†
3. Third-degree heart block†
4. Bilateral bundle branch block (alternating left and right bundle branch block or right bundle branch block with alternating left anterior and posterior fascicular block-irrespective of time of onset)*
5. Newly acquired or age-indeterminant left bundle branch block, right bundle branch block, and anterior or posterior fascicular block*
6. Right bundle branch block or left bundle branch block and first-degree AV block*

Class IIa

1. Stable bradycardia (systolic blood pressure greater than 90 mmHg, no hemodynamic compromise, or compromise responsive to initial drug therapy)*
2. Newly acquired or age-indeterminant right bundle branch block*

Class IIb

1. Newly acquired or age-indeterminant first-degree AV block*

Class III

1. Uncomplicated AMI without evidence of conduction system disease

As noted, transcutaneous pacing is intended to be temporary; if prolonged pacing is required, transvenous pacing should be instituted (discussed later). In addition, patients with a high probability of requiring pacing should have it instituted early on.[1] Technical aspects of transcutaneous pacing have been reviewed.[334]

VENTRICULAR ECTOPY, TACHYCARDIA, AND FIBRILLATION

Recommendations[1]:

Class I

1. Ventricular fibrillation should be treated with an unsynchronized electric shock starting with an energy of 200 J. If the initial shock is unsuccessful, a second shock of 200 to 300 J should be administered, and, if required, a third shock of 360 J should be given.
2. Polymorphic ventricular tachycardia (VT) lasting more than 30 s or causing hemodynamic collapse should be treated with an unsynchronized shock, initially of 200 J, and, if necessary, with a second shock of 200 to 300 J, to be followed by a shock of 360 J if the arrhythmia persists.
3. Sustained monomorphic VT associated with hypotension, with blood pressure of less than 90 mmHg, pulmonary edema, or angina should be treated with a synchronized electric shock of 100 J initially, to be followed by high-energy shocks if required.
4. Monomorphic VT that is sustained but not associated with hypotension, angina, or pulmonary edema should be treated with one of the regimens as follows:

   Lidocaine bolus from 1.0 to 1.5 mg/kg intravenously with supplemental boluses of 0.5 to 0.75 mg/kg every 5 to 10 min, up to a maximum loading dose of 3 mg/kg as needed. This loading regimen is followed by an infusion of 2 to 4 mg/min (30 to 50 mg/kg/min).

   Procainamide at a loading infusion rate of 20 to 30 mg/min to a maximum of 12 to 17 mg/kg total, which may be followed by infusion of 1 to 4 mg/min.

   Amiodarone infused initially at 150 mg over 10 min, followed by a constant infusion of 1.0 mg/min for 6 h, and then at a rate of 0.5 mg/min.

   Synchronized electrical cardioversion with an initial starting level of 50 J after anesthesia is induced briefly.

Note that drug metabolism can vary depending upon age, body size, and liver and renal function, and that doses may need to be adjusted accordingly.

Class IIa

1. Antiarrhythmic drug infusions may be utilized after an episode of ventricular tachycardia or fibrillation but should be discontinued after 6 to 24 h, when the need for further management of the arrhythmia is reassessed.
2. Metabolic abnormalities of electrolytes and acid-base balances should be corrected as prophylaxis against recurrence when the initial ventricular arrhythmia has been treated.

Class IIb

1. Polymorphic VT, which is refractory to drug treatment, should be managed by focusing on relieving

the presumptive underlying ischemia with beta blockers, intraaortic balloon pumping, and/or emergency revascularization. Amiodarone infusion, as noted earlier, may also be useful.

Class III

1. Treatment of isolated ventricular premature beats, couplets, runs of accelerated idioventricular rhythm, and nonsustained VT.
2. Use of antiarrhythmic drugs prophylactically during administration of thrombolytic agents.

Ventricular rhythm abnormalities are common during the early phases of AMI, with an incidence of VF within the first 4 h, so-called primary VF, of 3 to 5 percent, which declines rapidly thereafter.[335] Primary VF is thought to be the result of micro reentry mechanisms in the infarct zone.[1] Postulated triggering mechanisms include hypokalemia, hypomagnesemia, enhanced adrenergic tone, acidosis, increased intracellular calcium, increased free fatty acids, and reperfusion-induced production of free radicals.[336-338] Although the relative contribution of each of these factors to early VT/VF and the effects of their specific treatment are not known,[1] epidemiologic evidence suggests that there has been a decrease in the incidence of primary VF,[339] which may be related generally to more aggressive treatment strategies, including the use of beta blockers. Primary VF is associated with increased in-hospital mortality but not with increased long-term mortality for patients who survive and are discharged.[340]

Post-AMI VT occurs in about 15 percent of patients and is also most commonly manifest during the relatively early period.[335] Ventricular tachycardia is classified according to its electrocardiographic morphology (monomorphic or polymorphic) and by its duration and consequences: sustained (lasting more than 30 s and/or causing hemodynamic compromise earlier, which requires intervention) and nonsustained (not resulting in hemodynamic compromise and lasting less than 30 s).[1] Short runs (5 beats or less) of nonsustained VT are common in the early post-myocardial infarction period and do not require specific treatment.

Because primary VF is one of the major contributors to mortality in the first 24 to 48 h after AMI, a great deal of attention has been paid to attempting to define characteristics of ventricular premature beats that predict VT/VF in order to provide prophylaxis. The hierarchical classification of ventricular arrhythmias according to propensity to cause VT/VF-for example, early coupled R-on-T premature beats as opposed to late-cycle, coupled beats-has fallen out of favor because of the realization that the late-cycle premature beats were equally likely to induce VT/VF.[341]

Accelerated idioventricular rhythm normally occurs frequently during the first hours of AMI,[1] and occurs after thrombolysis as a reperfusion arrhythmia. In neither case is it a premonitory rhythm for VT/VF.[342-344] *Accelerated idioventricular rhythm should ordinarily be observed and not treated specifically.*[1] It has been suggested, however, that if accelerated idioventricular rhythm speeds up to a rate of about 120 beats per minute, it should be considered an automatic rhythm for which suppression with lidocaine should be considered.[341]

Formerly, it was common practice, in order to prevent VT/VF, to treat prophylactically with lidocaine either all patients with AMI or, selectively, those with patterns of premature ventricular contractions thought to predict VT/VF. This approach is no longer common practice, because meta-analysis of trials of lidocaine prophylaxis, although confirming a substantial reduction in primary VF, showed evidence of increased mortality, probably because of episodes of profound bradycardia and asystole.[345] Thus, *routine use of prophylactic lidocaine in AMI in the presence or absence of thrombolysis is not recommended.*

Two prophylactic approaches to the prevention of VT/VF, however, are recommended.[1] Routine administration of beta blockers, as described previously, has been shown to reduce the incidence of VT/VF. Also, since evidence suggests that hypokalemia is a risk factor for VT/VF,[337,338] it is recommended that serum potassium levels be kept above 4.0 meq/L by supplementation as necessary. Although the supporting evidence is less compelling, it is also considered to be good clinical practice to maintain serum magnesium

levels above 2.0 meq/L in AMI patients.[1]

TREATMENT OF VENTRICULAR TACHYCARDIA/FIBRILLATION

Electrical cardioversion of VT that is hemodynamically compromising should be performed immediately.[335] Rapid polymorphic VT should be considered the equivalent of VF and cardioverted with an unsynchronized shock of 200 J; monomorphic VT at a rate of greater than 150 beats per minute can be treated initially with a synchronized discharge of 100 J.[1,333] Urgent cardioversion for VT with rates of under 150 beats per minute is usually not needed. Ventricular tachycardia that is tolerated hemodynamically can be approached initially with trials of lidocaine, procainamide, or amiodarone, as outlined earlier, with attention being paid to need for dose modifications based on age and renal and hepatic function.

Ventricular fibrillation should initially be treated with an unsynchronized shock of 200 J, then incrementally with 200 to 300 J, and finally with 360 J as needed.[333] There are no definitive data concerning appropriate adjunctive therapy for fibrillation that is difficult to cardiovert.[1] The Advanced Cardiac Life Support (ACLS) protocol recommends the following hierarchical approach, as needed, to adjunctive therapy of resistant VF:[333] (1) epinephrine (1 mg intravenously); (2) lidocaine (1.5 mg/kg intravenously); and (3) bretylium (5 to 10 mg/kg intravenously). Intravenous amiodarone (150 mg intravenously bolus) may also be used.[1] In the case of resistant or recurrent VT/VF, electrolyte imbalances should be sought and corrected and ongoing ischemia suspected. Beta-adrenergic blockers should be used in recurrent VT or primary VF to decrease both sympathetic input to the heart and ischemia.[1] Intravenous amiodarone should be used in these life-threatening ventricular tachyarrhythmias.[346] *If ongoing ischemia is involved, intraaortic balloon pumping or emergency revascularization should be considered.*

APPROACH TO THE PATIENT WITH ISCHEMIC-TYPE CHEST PAIN AND WITHOUT ST-SEGMENT ELEVATION

As discussed previously, the initial criterion differentiating patients with symptoms compatible with AMI for therapeutic purposes is the presence or absence of ST-segment elevation. This distinction is important, because in the absence of ST-segment elevation, there is no therapeutic benefit to thrombolysis in the AMI patient (Fig. 42-5). Patients without ST-segment elevation are less likely to develop Q waves on the ECG, although about one-half of those who present with ST-segment elevation as well will not develop Q waves, especially if thrombolysis is utilized.[347,348] AMI in which Q waves do not develop is categorized as non-Q-wave myocardial infarction (NQWMI), and most patients (90 percent) present with ST-segment depression.[80,131] NQWMI currently accounts for about 50 percent of all AMIs.[87,126]

An important development over the last several years has been the understanding and acknowledgment that the coronary ischemic syndromes (unstable angina, NQWMI, ST-elevation myocardial infarction) represent a continuum that has come to be referred to as *acute coronary syndrome*. ST-segment elevation AMI is clinically distinct, as described. It is apparent that at the time of initial presentation, the clinician does not know whether the patient with chest pain that is compatible with coronary ischemia and with either ST-segment depression and/or T-wave changes or no ECG changes has unstable angina, NQWMI, or another condition. In the case of ST-segment depression and a compatible history, the initial approach in the emergency department is unchanged but the treatment and, especially, the use of drugs interferring with thrombus formation has changed dramatically.

NQWMI, like infarction with Q-waves, is precipitated by plaque disruption.[349,350] Total coronary occlusion demonstrated angiographically is much less common than in Q-wave myocardial infarction.[349] When total occlusion is present, it probably occurs in a well-collateralized vessel.[349,351] These observations-considered together with early data showing that NQWMIs involved loss of a smaller mass of myocardium than did Q-wave myocardial infarctions[352,353]-are consistent with the concept that either NQWMI is associated with less than total compromise of blood flow to a region of myocardium or that early reperfusion occurs. The evidence that early reperfusion is relatively common in NQWMI was reviewed previously. Because of the residual noninfarcted myocardium at risk distal to a disrupted plaque, moreover,

patients with NQWMI have a high propensity for recurrent ischemia, infarction, and death[89] and present an opportunity for secondary prevention (Fig. 42-10). Nondiagnostic ECGs (ST-segment depression, T-wave inversion) on admission and NQWMI are more common in the elderly and in those with a history of prior AMI.[208,351] Generally, the incidence of NQWMI may be increasing in concert with the aging population and with the increased use of thrombolytic therapy, beta blockers, and aspirin.[1]

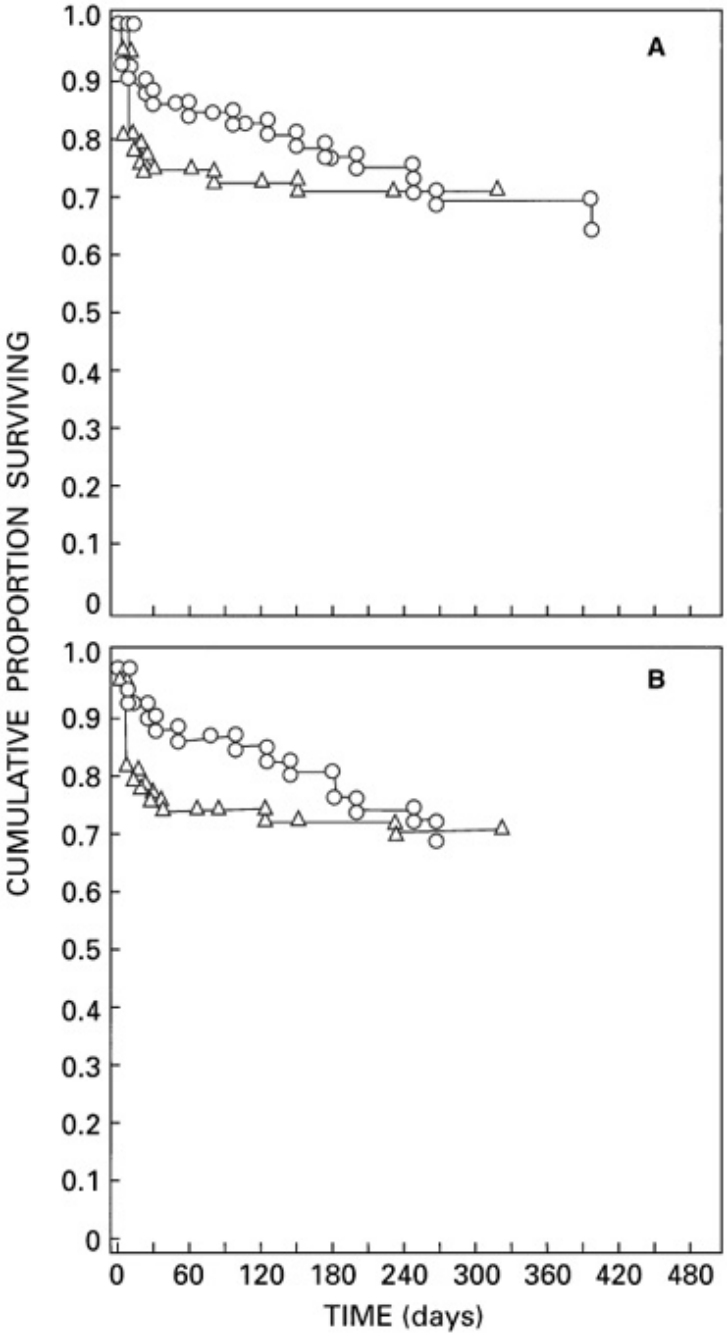

Figure 42-10: Comparison of the survival of patients with Q-wave infarction (triangles) to that of patients with non-Q-wave infarction with (circles). Early mortality was higher after Q-wave infarction than it was after non-Q-wave infarction and no recurrence (*A*), but survival was identical for patients with Q-wave infarction and those with non-Q-wave infarction and an early recurrent infarction (*B*). Long-term mortality rates are similar in Q-wave infarction and non-Q-wave infarction with or without early recurrence.

No therapeutic benefit of thrombolytic therapy was detected in patients with ST-segment depression in the first GISSI study and, in fact, mortality was slightly higher in the SK-treated group.[14] Patients with less

strikingly abnormal ECGs had a lower mortality rate (8 percent) than the control group with ST-segment depression (16.2 percent) but, similarly, there was no benefit to thrombolytic therapy. The ISIS-2 trial illustrated the same principles.[211] ST-segment depression was associated with relatively high mortality and was not decreased by thrombolytic therapy. The mortality rate was relatively low in patients with only T-wave abnormalities (5 percent) and normal ECGs (1 to 2 percent). In the TIMI-IIIB trial of rt-PA in NQWMI and unstable angina, no benefit was observed with thrombolysis as compared with aspirin and heparin.[157] Data from this trial do indicate that patients with NWQMI or unstable angina who have elevated troponin I on admission have an increased risk of nonfatal myocardial infarction or death in the ensuing 6 weeks. Two important conclusions can be derived from the available data: *(1) thrombolysis cannot be recommended in AMI patients without ST-segment elevation, and (2) in the NQWMI group and based on the admission ECG, there is a graded, decremental spectrum of risk ranging from ST-segment depression to T-wave inversion to normal*. The latter data are consistent with increasingly compelling evidence that the presenting ECG permits risk stratification across the range of the acute coronary syndromes increasing from normal ECG (lowest risk) in ascending order as: T-wave inversion; ST-segment depression; ST-segment elevation; ST-segment elevation and depression.[354]

Management of Non-Q-Wave Myocardial Infarction

MEDICAL MANAGEMENT

Recommendations[1]:

Glycoprotein IIb/IIIa Inhibitors

Class IIa

1. For non-ST-segment elevation myocardial infarction patients with high-risk features and/or recurrent, difficult to control ischemia and who do not have contraindications of risk of bleeding

Beta-Adrenergic Blockers

Class I

1. Non-ST-segment elevation myocardial infarction

Heparin

Class IIa

1. Low-molecular-weight heparin subcutaneously or intravenous unfractionated heparin in NQWMI

Early Coronary Angiography and/or Interventional Therapy

Class I

1. In cases of recurrent (stuttering) or persistent symptoms of ischemia, whether spontaneous or induced, in presence or absence of associated ECG changes

Calcium Channel Blockers

Class I

1. None

Class IIa

1. Verapamil or diltiazem may be given to patients in whom beta-adrenergic blockers are ineffective or contraindicated (i.e., bronchospastic disease) for relief of ongoing ischemia or control of a rapid ventricular response with atrial fibrillation after AMI in the absence of congestive heart failure, left ventricular dysfunction, or AV block.

Class IIb

1. In infarction without ST-segment elevation, diltiazem may be given to patients without left ventricular dysfunction, pulmonary congestion, or congestive heart failure. They may be added to standard therapy after the first 24 h and continued for 1 year.

Class III

1. Nifedipine (short-acting) is generally contraindicated in the routine treatment of AMI because of its negative inotropic effects and the reflex sympathetic activation, tachycardia, and hypotension associated with its use.
2. Diltiazem and verapamil are contraindicated in AMI with associated left ventricular dysfunction or congestive heart failure.

Although the situation may change with the increasing availability of very rapid assays for CK isoforms, it is important to remember that, at present, during the initial evaluation in the emergency department, the NQWMI patient-who by definition does not have diagnostic ST-segment elevation-cannot be distinguished from the patient with unstable angina and no myocardial necrosis. Thus, patients are admitted to the CCU or, if judged to be at relatively low risk, to a unit with continuous electrocardiographic monitoring but of less intensity, and *the initial pharmacologic approach, other than avoiding thrombolytic therapy, is identical* (Fig. 42-3). Serial ECGs and cardiac marker measurements should be performed and, in the case of recurrent pain with the development of ST-segment elevation, thrombolysis or primary PTCA should be performed. If the patient has recurrent, stuttering symptoms, angiography should be performed.

ANTITHROMBOTIC THERAPY Drugs Blocking the Glycoprotein IIb/IIIa Receptor

The glycoprotein IIb/IIIa receptor is found in the membrane of platelets.[355] When platelets are activated by a variety of stimuli, including thrombin, collagen, adenosine diphosphate, and epinephrine, the glycoprotein IIb/IIIa receptor changes confirmation to be receptive to one end of the fibrinogen dimer. Occupancy of a glycoprotein IIb/IIIa receptor by the other end of the dimer provides the basis for platelet aggregation. Thus, the glycoprotein IIb/IIIa receptor is considered the final common pathway of platelet aggregation.[356] Multiple therapeutic agents have now been developed to block the receptor.

1. Abciximab is a chimeric Fab fragment of a monoclonal antibody to the glycoprotein IIb/IIIa receptor. Although multiple clinical trials have documented the reduction in the composite of death and nonfatal myocardial infarction with abciximab in the setting of percutaneous interventions,[357-360] only one trial has been completed in the setting of non-ST elevation acute coronary syndrome.[357]
2. Eptifibatide is a cyclical heptapeptide, which binds to the receptor with a short half-life.[361]
3. Tirofiban is a small nonpeptide compound that also has a short half-life. It has been evaluated in over 5000 patients in 2 randomized trials of non-ST elevation acute coronary syndrome.[362-363]

The role of antiplatelet therapy in patients with non-Q-wave infarction is evolving. More than 30,000 patients with an acute coronary syndrome without ST-segment elevation (unstable angina and NQWMI) (see Chap 41) have now been randomly assigned into trials comparing glycoprotein IIb/IIIa inhibitors with a placebo in addition to treatment with aspirin and heparin. A direct comparison of the various IIb/IIIa inhibitors is not available and, thus, no specific choice of agent can be made at this time. The three agents available for clinical practice are described earlier. Only one trial[357] has been performed in patients with unstable angina and non-Q-wave infarction using abciximab. Eptifibatide[361] has been evaluated in a trial of 11,000 patients with non-ST elevation, 45 percent of whom had enzymes positive for myocardial necrosis. Tirofiban has been evaluated in 5147 patients in 2 randomized trials[362,363] of non-ST elevation. Again, about 45 percent of the patients in these trials had positive enzymes for infarction. An overview of these

trials shows a reduction in the composite end point of death and myocardial infarction and the need for revascularization and procedures.[364] There was no reduction in mortality and, when treatment was discontinued, no further beneficial or detrimental effects were observed. Thus, intravenous glycoprotein IIb/IIIa inhibitors are being accepted increasingly as treatment in NQWMI to stabilize the patients in the acute phase and have a IIa recommendation for patients at high risk and with refractory ischemia.[1] Unfortunately, none of the trials have assessed the effect of this therapy in NQWMI alone. It remains to be determined whether these agents will be effective for *routine* use in patients with NQWMI. Since these agents can only be given intravenously, they can only be given for stabilization of the acute phase.

Low-Molecular-Weight Heparin Low molecular weight heparins are antithrombotics that have higher anti-X_a activity than antithrombin (II_a) activity (see Chap 44). Clinically, there is usually only modest prolongation of the activated partial thromboplastin time (aPTT). The role of low-molecular-weight heparin has been extensively explored in patients with acute coronary syndrome, which include a significant proportion of patients with NQWMI (see also Chap. 41). In the FRISC trial of NQWMI and unstable angina, 746 patients received 7500 IU daily of dalteparin versus 760 patients who received a placebo which included aspirin.[364a] At the six-day evaluation there was a 63 percent reduction in death and nonfatal MI in the dalteparin group, but this difference had disappeared by 40 days. In the FRIC Study, dalteparin was given subcutaneously twice a day and was compared with intravenous heparin in patients with unstable angina and NQWMI, during the acute phase of the first 6 days and thereafter.[365] There was no difference in the composite end points either at 6 days or at 45 days. In the ESSENCE trial (Efficacy and Safety of Subcutaneous Exoxiparin in Non-Q-wave Coronary Events),[365a] the study compared the effectiveness of exoxiparin in unstable angina and NQWMI with that of dalteparin. This was a large multicenter double-blind trial where 3171 patients received either twice daily subcutaneous injections of enoxiparin (1 mg/kg) or continuous intravenous infusions of unfractionated heparin (UFH) during the acute period of 2 to 8 days after hospitalization. The primary end point was a composite of death or myocardial infarction or recurrent angina 14 days after hospitalization. In the enoxiparin group, the end point rate was 16.6 versus 19.8 percent for the UFH group. Patients treated with enoxiparin required less revascularization procedures which continued up until 30 days. A cost-effectiveness analysis showed that, despite a small increase in drug cost ($75 per patient), the lower rate of cardiac catheterization and revascularization procedures led to a savings of $1072 per patient if enoxiparin was used instead of UFH. There is considerable difference among the low-molecular-weight heparins, and enoxiparin is claimed to have a high antifactor X_a ratio than that of dalteparin. In another trial,[366] two different doses of enoxiparin were compared in patients with unstable angina and non-Q-wave infarction and the dose of 1 mg/kg every 12 h had a hemorrhage incidence of only 1.9 percent compared to 6.5 percent in doses of 1.25 mg/kg. TIMI 11B[367] enrolled 4020 patients with unstable angina and NQWMI and compared two strategies, UFH or enoxiparin. The analysis showed that at 48 h there were significantly fewer events in the enoxiparin group with a 24 percent reduction in relative risk compared to the group receiving UFH. This beneficial effect was maintained through day 43. Thus, it was concluded that enoxiparin is superior to UFH in the treatment of patients with unstable angina and NQWMI. One concern with all of these studies is there is no separation between NQWMI and unstable angina. *Nevertheless, there does appear to be a role for low-molecular-weight heparin in non-Q-wave infarction, and at the present time studies suggest that enoxiparin is superior to that of other preparations.*

There has been no prospective trial assessing aspirin in NQWMI, but retrospective analysis showed significant benefit.[368] It seems prudent to recommend aspirin (160 to 325 mg/day) for NQWMI (Class I).

BETA BLOCKERS IN NON-ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

No prospective studies of beta blockers have been performed solely in patients with NQWMI, but retrospective analyses of trials performed prospectively, involving both Q-wave infarction and NQWMI, generally show no effect of beta blockers on the reinfarction rate in patients recovering from NQWMI.[89,369,370] Beta blockers may be given to relieve pain or arrhythmia, as discussed previously for Q-wave myocardial infarction. The general benefit of beta blockers in the acute coronary syndromes has led to their being recommended (Class I) for use in NQWMI.[1]

CALCIUM CHANNEL BLOCKERS

The calcium channel blocker diltiazem (immediate-release form) has been shown to be effective in reducing reinfarction in the Diltiazem Reinfarction Study (DRS) (NQWMI)[80] and in the Multicenter Diltiazem Postinfarction Trial (MDIPIT) (Q-wave myocardial infarction and NQWMI)[371] in patients with preserved left ventricular function and with no evidence of congestive heart failure. The DRS study was performed during hospitalization only (14 days); diltiazem was given in the initial 24 to 48 h after NQWMI and was shown to reduce the reinfarction rate by 47 percent, as compared with conventional therapy over a 2-week period. In the long-term prospective, randomized, blinded MDIPIT study, no overall benefit of diltiazem over conventional therapy was observed. In MDIPIT, 20 percent of patients upon entry had pulmonary congestion or clinical cardiac failure, and diltiazem was associated with increased mortality in this subgroup. In the remaining 80 percent of patients, there was a 27 percent reduction in reinfarction and death in the group receiving diltiazem. Most of this benefit was in the prospective NQWMI substudy of 640 patients in whom diltiazem reduced reinfarction and death by 40 percent at the end of 1 year and 34 percent at the end of 4.5 years in patients without evidence of pulmonary congestion.[372] Analysis in the NQWMI subgroup for either end point alone (reinfarction or death) did not show a statistically significant benefit of diltiazem over the placebo. A meta-analysis of the heart-rate-lowering calcium channel blockers (diltiazem and verapamil) in 3 randomized, blinded clinical trials involving 5670 patients, with a mean follow-up of 550 days, showed a clinical event rate of 20 percent in the placebo group and 18 percent in the calcium channel blocker group ($p < 0.01$).[373] Verapamil has been studied somewhat less extensively than has diltiazem in the treatment of AMI; but when it is used within 2 weeks, a 16.7 percent reduction in death or myocardial infarction has been observed.[374] Verapamil has adverse effects on patients with heart failure or bradyarrhythmias when used within the first 24 to 48 h after AMI.[375,376] Most of the data on the use of calcium channel blockers in AMI were collected before the widespread use of aspirin, low-molecular-weight heparin, and platelet GIIb/IIIa inhibitors, and their precise role in the current management of AMI is somewhat ill defined. Currently in the treatment of non-ST-segment elevation AMI, diltiazem has a Class IIa recommendation only in patients in whom beta blockers are ineffective or contraindicated for relief of ongoing ischemia or control of a rapid ventricular response in atrial fibrillation.[1] The role of sustained-release diltiazem and aspirin is being studied in AMI after thrombolysis in the Incomplete Infarction Trial of European Research Collaborators Evaluating Prognosis Post-Thrombolysis (INTERCEPT).[377]

EARLY INVASIVE/INTERVENTIONAL STRATEGY: EARLY CORONARY ANGIOGRAPHY AND/OR INTERVENTIONAL THERAPY

Recommendations[1]:

Class I

1. Patients with recurrent (stuttering) epidoses of spontaneous or induced ischemia or evidence of shock, pulmonary congestion, or left ventricular dysfunction and hypotension

A prospective observational trial (VANQUISH) was performed comparing PTCA with conventional therapy in patients with NQWMI. The mortality was less in patients receiving medical therapy. A contrary view was presented by FRISC II.[378] In addition to the randomization to low-molecular-weight heparins, patients were assigned within 48 h to invasive or noninvasive early management. The invasive strategy consisted of early coronary angiography within 2 to 7 days, whereas the noninvasive strategy consisted of exercise testing with referrals to coronary angiography if the test was positive. At 6 months, the rate of death or myocardial infarction in the invasive group was 9.5 versus 12 percent in the noninvasive group ($p = 0.045$). In this study, men particularly benefited with a difference of 9.1 versus 13.9 percent for the conservative strategy. Further studies will have to be performed to determine whether the invasive strategy is preferred over conservative therapy. This must also be considered in light of the new medical therapy of glycoprotein IIb/IIIa inhibitors and low-molecular-weight heparins being evaluated. Currently, early angiography and/or interventional therapy is indicated (Class I) in non-ST segment elevation myocardial infarction only with spontaneous or induced ischemia.[1]

* Performance standard: balloon inflation within 90 (±30) min of admission.

** Persons who perform >75 PTCA procedures per year.[296]

*** Centers that perform >200 PTCA procedures per year and have cardiac surgical capability.[296]

* Put pacing system in place.

† Activate system.

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

PROTOCOLS, CLINICAL PATHWAYS, AND CHEST PAIN EVALUATION UNITS

There are increasing pressures, driven by both economic and clinical imperatives, to improve the management of patients with chest pain. The goal of controlling costs has contributed to the need to triage patients with chest pain accurately to levels of care that are appropriate to need and to facilitate evaluation and treatment in the shortest time that is commensurate with good medical care. For example, low-risk patients with normal ECGs frequently do not have to be admitted to the hospital, much less to the intensive care unit (ICU), and can have a total time in the health care facility of hours rather than of days. The medical necessity of achieving rapid, accurate diagnoses has been discussed earlier. These two driving forces have led to the development of predictive algorithms to guide triage decisions.[70,225] For example, one analysis provided evidence that patients with chest pain with ECG changes of ischemia or infarction were, depending on age, the only subgroup with a probability of AMI high enough (21 percent or moderate) to justify admission to the CCU as opposed to an intermediate care unit of reduced intensity.[379] While these algorithms have been shown to be effective in, for instance, reducing ICU admissions without compromising clinical care,[225,245] they have not been widely adopted for a variety of reasons, including the fact that most experienced clinicians are comfortable with their decision making in triaging patients with chest pain.[217]

The continuing need to improve the process of chest pain management has led to the development of clinical pathways, protocols, and practice guidelines that differ from predictive instruments in that they provide structure to the decision-making process rather than influence decision making.[217,380] A chest pain evaluation unit, which may either be a defined area, frequently near the emergency department, or a virtual entity embracing a team approach to chest pain evaluation and management, is frequently central to the strategy to systematize the approach to the patient with chest pain.

In general, the approach is to triage the patient to evaluation and management pathways according to risk based on electrocardiographic findings, history, and symptoms. For example, and at the opposite end of the clinical spectrum, the patient with ST-segment elevation would receive thrombolytic therapy within 30 min of arrival and be rapidly admitted to the CCU, whereas the low-risk patient with a normal ECG would be evaluated in a unit of low intensity and acuity and would be discharged within a matter of hours. There is a great deal of interest in the use of imaging modalities such as nuclear scanning with sestamibi or stress echocardiography to guide decision making in cases of intermediate or low probability for AMI during the initial evaluation period.[217] While the results using the systematized approach of a chest pain evaluation unit appear promising, further assessment is needed in large-scale trials to test both clinical value and cost-effectiveness before a specific strategy can be recommended. The general strategy of systematizing the approach to the patient with chest pain, however, is strongly encouraged.

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

MANAGEMENT AFTER HOSPITAL ADMISSION

General Approach

Recommendations[1]:

Class I

1. Selection of electrocardiographic monitoring leads based on infarct location and rhythm to maximize diagnostic utility
2. Bed rest with bedside commode privileges for initial 12 h in hemodynamically stable patients who are free of ischemic-type chest discomfort
3. Avoidance of the Valsalva maneuver and straining
4. Optimization of pain relief

Class IIb

1. Routine use of anxiolytics

Class III

1. Prolonged bed rest (more than 12 to 24 h) in stable patients without complications

The general issues involved in the management of the patient with suspected or manifest AMI in the intensive or moderate care unit are to provide for adequate monitoring for the detection of arrhythmia, ischemia, and hemodynamic instability; to provide the patient with a calm, supportive, and reassuring environment; to control the level of activity; to begin the education process for a lifetime of living with coronary heart disease; to control pain and inappropriate anxiety; and to treat adverse events promptly. It is assumed, as previously discussed, that oxygen therapy, beta-adrenergic blockers, aspirin, thrombolytics, unfactionated heparin, low-molecular-weight heparin, and nitroglycerin have been begun or given as appropriate in the emergency department. Also, it is assumed that a decision has been made about the appropriateness of adding glycoprotein IIb/IIIa inhibitors.

MONITORING

The patient must have continuous electrocardiographic monitoring and frequent hemodynamic evaluation by the assessment of blood pressure and heart rate. Electrocardiographic monitoring leads should be selected to maximize the ability of the CCU staff to detect and diagnose arrhythmias and recurrent ischemic ST-segment changes. Thus, the lead selected should ideally permit identification of the P wave as well as providing a QRS complex of adequate size. Furthermore, the lead should be selected to interrogate the area of known infarction or ischemia.[1] Blood pressure and pulse rate should be monitored with a frequency to be determined by the perceived level of acuity, but generally every one-half hour until stable and then every 4 h. Pulse oximetry is becoming standard. Precise orders should be given to notify the physician of, for example, systolic pressures >150 and <90 mmHg, heart rates >110 or <60 beats per minute, respiratory rate of >22 or <8 per minute, or significant decreases in blood oxygen saturation.[1]

ACTIVITY

Minimizing physical exertion is an important approach, in addition to minimizing sympathetic nervous

system drive by administering beta-adrenergic blockers and by controlling pain and excessive anxiety, so as to decrease myocardial oxygen demand and thus decrease myocardial ischemia and necrosis. *Prolonged bed rest and a severe limitation of activities such as self-feeding are no longer recommended except in the case of continuing ischemic pain and/or hemodynamic instability because of evidence that cardiovascular deconditioning and unfavorable shifts in intravascular volume develop very rapidly in immmobilized patients in the supine position*.[381] Losses of plasma volume occur that decrease preload and stimulate compensatory reflexes, enhancing sympathetic activity. These fluid shifts may be the major cause of cardiovascular dysfunction with prolonged bed rest.[382] It is prudent to prescribe about 12 h of bed rest and a bedside commode for the patient with uncomplicated AMI.[1] Subsequently, low-level activities such as routine self-care, assisted bathing, and brief ambulation should be permitted to prevent deconditioning.

The major coronary precaution that should be strictly adhered to is the avoidance of the Valsalva maneuver, which increases cardiac wall stress because of increases in systolic blood pressure and heart rate.[1] These changes in wall stress may cause localized repolarization abnormalities in the infarct zone that may precipitate ventricular arrhythmias.[383,384] Constipation should be avoided and stool softeners routinely prescribed. A bedside commode is preferable to a bedpan in all but the most unstable patients.

ANALGESICS AND ANXIOLYTICS

The importance of controlling chest pain and excessive anxiety and the use of morphine and diazepam were discussed previously (see "Evaluation and Management of the Patient with Chest Pain in the Emergency Department"). Morphine is sometimes used in inadequate doses because of fear of side effects, and anxiolytics may be overused. Ischemic chest pain, heart rate, blood pressure, and perceived anxiety level have not been found to be different in patients treated with diazepam or with a placebo.[385] Conversely, strong psychological support in hospitals has prolonged effects to prevent anxiety and depression after AMI.[386] Anxiolytics may be useful in treating symptoms of nicotine withdrawal in smokers during hospitalization. Psychosis manifesting as delirium and agitation is not uncommon, particularly in the elderly, during prolonged stays in the ICU ("ICU psychosis"). Intravenous haloperidol can be useful and safe in this setting. Drug-induced psychosis or delirium caused by lidocaine, for example, should be considered.

EDUCATION

Education of the AMI patient by both the CCU staff and the physician are essential components of medical management and should be begun early during hospitalization. Presenting the patient with information about the management of symptoms and prevention of a recurrence gives a sense of empowerment associated with changes in behavior[387] and decreased anxiety.[388] Information should be presented in a direct fashion at a relatively simple level and should emphasize issues relevant to patient behavior, such as control of chest pain, diet, smoking, and exercise, rather than the pathophysiology of the disease. Family members, and, in particular, the spouse should participate in the education process. Because of the substantial risk of cardiac arrest in the 18 months after AMI, family members should be taught cardiopulmonary resuscitation.[389,390] Ideally, educational materials can be presented in a permanent printed form so that the self-education process can continue after discharge and can supplement that given by health care professionals during cardiac rehabilitation and physician visits.

Adjunctive Therapy during the Early In-Hospital Period

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Recommendations[1]:

Class I

1. Patients within the first 24 h of a suspected AMI with ST-segment elevation in two or more anterior precordial leads or with clinical heart failure in the absence of significant hypotension or known contraindications to the use of ACE inhibitors

2. Patients with AMI and a left ventricular ejection fraction (LVEF) <40 percent or patients with clinical heart failure on the basis of systolic pump dysfunction during and after convalescence from AMI

Class IIa

1. All other patients within the first 24 h of a suspected or established AMI provided that significant hypotension or other clear-cut contraindications are absent
2. Asymptomatic patients with mildly impaired left ventricular function (ejection fraction of 40 to 50 percent and a history of old myocardial infarction)

Class IIb

1. Patients who have recently recovered from myocardial infarction but have normal or mildly abnormal global left ventricular function.

A number of clinical trials have shown that ACE inhibitors reduce left ventricular dysfunction and dilatation and slow the progression to congestive heart failure in patients with left ventricular dysfunction after AMI.[391-393]

The ACE inhibitors have also been shown, with few exceptions, to reduce mortality after AMI. Meta-analysis of 4 major and 11 minor trials involving, collectively, more than 100,000 patients showed an odds reduction in the ACE-inhibitor group of 6.5 percent ($2p = 0.006$).[394] Originally, there was some doubt about the timing of initiation of the ACE inhibitor after AMI because of the results of the Cooperative New Scandinavian Enalapril Survival Study (CONSENSUS) II.[395] In this randomized study, patients were assigned to intravenous placebo or enalapril during the first day of AMI and were subsequently given an oral placebo or enalapril. The trial was stopped in its early stages by the Safety Monitoring Committee because it was unlikely to show a positive effect and because of hypotension in elderly patients. The issue of timing of the initiation of ACE inhibitor therapy has been clarified subsequently. In GISSI-3, patients with either ST-segment elevation or depression were given oral lisinopril or were assigned to an open control group starting on the first day of AMI.[260] There was a significant reduction in mortality at 6 weeks (odds ratio 0.88), and the majority (60 percent) of lives saved were in the first 5 days. In ISIS-4, patients were assigned to an oral placebo or to captopril within the first 24 h, and a 7 percent mortality reduction was seen at 5 weeks in the captopril group.[261] The majority of the decrease in deaths was seen in the first 2 days. There was no increase in adverse events in the elderly in ISIS-4 or in GISSI-3. Thus, the hypotension in CONSENSUS II may be attributed to the use of intravenous enalapril.

Initiation of ACE-inhibitor therapy within the first few days after AMI in patients with left ventricular dysfunction and continuation of therapy over the long term was associated with a decrease in mortality and in fatal and severe nonfatal cardiovascular events in three other trials: Survival and Ventricular Enlargement (SAVE), captopril[392]; Acute Infarction Ramipril Efficacy (AIRE2), ramipril[396]; and Trandolapril Cardiac Evaluation (TRACE), trandolapril.[397]

Thus, trials of ACE inhibitors have shown clear evidence of benefit in AMI from their use early in the course of AMI. Efficacy may be greatest in those at highest risk, that is, patients with prior MI, anterior MI, tachycardia, or CHF. Therapy should begin within the first 24 h after hemodynamic stabilization, whether or not thrombolytic therapy has been administered. Intravenous forms should be avoided, and therapy should be started with low doses. The ACE inhibitors should not be given if systolic blood pressure is below 100 mmHg or if there are contraindications-that is, bilateral renal artery stenosis, renal failure, history of severe cough, or angioedema with previous treatment.[1] In the presence of significant left ventricular dysfunction, therapy should probably be continued indefinitely. Evidence from the Heart Outcomes Prevention Evaluation (HOPE) trial using the ACE inhibitor ramipril has shown significant decreases in cardiovascular events in high-risk individuals including, but not limited to, those with prior AMI.[398] These data, which will be discussed in more detail subsequently, provide support for the strategy of using ACE inhibitors in most patients indefinitely after acute MI.

MAGNESIUM

Recommendations[1]:

Class I

1. None.

Class IIa

1. Correction of documented magnesium (and/or potassium) deficits, especially in patients receiving diuretics before the onset of infarction.
2. Episodes of VT-torsades de pointes type-associated with a prolonged QT interval should be treated with 1 to 2 g of magnesium administered as a bolus over 5 min.

Class IIb

1. Magnesium bolus and infusion in high-risk patients such as the elderly and/or those for whom reperfusion therapy is not suitable.

The available data are conflicting but suggest that early (<6 h) administration of magnesium in high-risk patients may be associated with mortality reduction.

Magnesium has a number of potential cardioprotective effects, including vasodilatation,[399] inhibition of platelet function,[400] stabilization of cell membranes,[401] and protection against the cardiotoxic effects of catecholamines.[402]

Meta-analysis of 7 early randomized trials of the effects of magnesium in AMI was consistent with a significant benefit in mortality (odds ratio 0.44).[403,404] The Second Leicester Intravenous Magnesium Intervention Trial (LIMIT-2) was consistent with this interpretation in that the magnesium-treated patients in comparison with those not receiving magnesium had a 24 percent reduction in overall mortality ($p < 0.04$), a 25 percent decrease in the incidence of congestive heart failure in the CCU, and a 21 percent lower rate of coronary artery disease mortality at 4 years.[405,406] The large ISIS-4 trial, however, was negative and even raised the possibility of some harm.[261] Incorporation of the ISIS-4 data with that of the previous randomized trials and performance of meta-analysis resulted in the loss of the benefit that was previously apparent. It has been speculated that the lack of benefit in ISIS-4 was due to the relatively late administration of magnesium,[407] since the time to randomization in ISIS-4 was 8 h, as contrasted with 3 h in LIMIT-2. It may also have been a consequence of the low control-group mortality in ISIS-4 (7.2 percent) and the statistical inability to detect a treatment effect at this level.[408] That only 36 percent of patients in LIMIT-2 received thrombolytic therapy as opposed to 70 percent in ISIS-4 complicates interpretation further. Analysis of subgroups in ISIS-4 in which magnesium was administered within 6 h of the onset of symptoms or within 2 h of thrombolytic therapy also failed to demonstrate a therapeutic effect. Another randomized trial of intravenous magnesium in AMI patients who were not candidates for thrombolysis demonstrated a significant reduction of mortality in the treated group (4.2 versus 17.3 percent, $p < 0.01$), due primarily to a decrease in cardiogenic shock and congestive heart failure.[409]

The conflicting data that are available do not permit a recommendation that magnesium be used as standard general therapy in AMI. Magnesium should be used in situations where it would otherwise be recommended, as in the presence of magnesium deficiency or VT of the torsades de pointes type with a prolonged QT interval. Intravenous magnesium can be considered in high-risk patients, such as the elderly and in those for whom reperfusion is not suitable. Ongoing clinical trials are investigating the question further.

Management of the Low-Risk Patient

As discussed previously, there are increasing pressures to minimize resource utilization while not compromising safety in the patient with ischemic-type chest discomfort. As a practical matter, this means matching patient acuity and risk appropriately with the hospital facilities required to deal with their situation and to appropriately control time spent in these units. For example, the patient who is at low risk for AMI may be evaluated in the emergency department or in a chest pain evaluation unit, and if AMI or unstable angina are excluded, may be discharged within a matter of hours without having been formally admitted to the hospital. The patient with AMI who has an uncomplicated initial course and is at low risk for development of complications is a candidate for transfer out of the CCU within 24 to 36 h.[410-413] *Such a low-risk patient does not have a history of prior AMI and has not had recurrent ischemic pain, hypotension, congestive heart failure, persistent sinus tachycardia, heart block, or sustained VT. This patient may be a candidate for early discharge at 3 to 4 days.*

Patients who have been treated with thrombolytics are frequently candidates for early discharge from the CCU.[414-417] In this setting, the *absence* of early sustained VT or VF, as well as the absence of early sustained hypotension or shock, and the *presence* of a LVEF > 40 percent and of only one- or two-vessel coronary artery disease are independent predictors of freedom from late complications.[416]

Approaches to risk stratification and noninvasive testing, to guide management decisions in the post-AMI patient, are discussed subsequently (see "Noninvasive Risk Stratification in Patients Surviving Acute Myocardial Infarction"). Excessive diagnostic testing in all post-AMI patients, especially those at low risk, should be discouraged. The variability in practice in this regard, without demonstrable correlative changes in outcomes, suggests the need for more rigorous adherence to guidelines and protocols.[1]

As discussed previously, AMI can be diagnosed rapidly using serum cardiac markers. If AMI is effectively ruled out and the patient is at low risk (i.e., normal ECG and absence of the characteristics noted earlier, especially the absence of prolonged initial pain or the recurrence of pain), then noninvasive testing can establish the safety of early discharge (3 to 12 h) from the emergency department, chest pain evaluation unit, or CCU, for further evaluation as an outpatient.[217] In general, such patients do not necessarily need to be admitted to the CCU unless noninvasive testing is positive for ischemic heart disease. Patients with ischemic-type chest discomfort and intermediate probabilities of AMI-that is, duration of chest pain >20 to 30 min and nondiagnostic ECG changes (without significant ST-segment elevation or depression, T-wave inversion, or bundle branch block), without known coronary artery disease-should be admitted to an observation unit or to the CCU if an intermediate unit is unavailable. They should be placed on a fast track to rule in AMI or unstable angina, as previously outlined. If the clinical course is unrevealing and if early imaging is negative, then stress testing and further evaluation can be planned. Clinical decisions can usually be made within 12 h in this setting.[217]

Management of the High-Risk Patient with Acute Myocardial Infarction

The AMI patient at low risk is defined in the previous section by the absence of certain characteristics. By contrast, the *high-risk AMI patient is defined by the presence of one or more of these clinical features, which include recurrent chest pain; congestive heart failure and low cardiac output; arrhythmias and, in particular, recurrent or sustained VT or VF; mechanical cardiac complications of AMI such as ruptured papillary muscle or intraventricular septum; and/or inducible ischemia and extensive coronary artery disease.*

RECURRENT CHEST PAIN

The most common causes of recurrent chest pain after AMI are coronary ischemia and pericarditis.

Recommendations for diagnosis and treatment of recurrent chest discomfort[1]:

Class I

1. Aspirin for pericarditis

2. Beta-adrenergic blocking drugs (continue or initiate) intravenously, then orally for ischemic-type chest discomfort
3. for patients with recurrent ST-segment elevation
4. Coronary arteriography for ischemic-type chest discomfort recurring after hours to days after initial therapy and associated with objective evidence of ischemia in patients who are candidates for revascularization

Class IIa

1. Nitroglycerin intravenously for 24 h, then topically or orally for ischemic-type chest discomfort

Class IIb

1. Corticosteroids for pericarditis
2. Indomethacin for pericarditis

Recurrent Ischemia

Recurrence of chest pain in the patient who has had an AMI is a serious development and requires immediate attention to establish the correct diagnosis and initiate treatment, especially if the pain represents recurrent ischemia, which is a more serious development than if the pain is a manifestation of pericarditis. Early postinfarction angina is an important predictor of the severity of coronary artery disease and has an overall incidence of about 18 percent.[418] Postinfarction angina is defined as chest pain that is frequently similar to the original discomfort, occurring at rest or with limited activity during hospitalization 24 h or more after onset of the AMI. The pain may or may not be associated with ST-segment elevation or depression or with pseudonormalization of inverted T waves on the postmyocardial ischemia ECG.[419] The pain is usually a result of ischemia in the territory of the myocardium supplied by the vessel that precipitated the initial myocardial ischemia. At least three categories of patients are at high risk for postinfarction angina: (1) patients with NQWMI; (2) patients who have received thrombolysis; and (3) patients with multiple risk factors.[420-422] The incidence of postinfarction angina is almost twice as high after NQWMI (25 to 35 percent) than after Q-wave myocardial infarction. Thrombolytic therapy for AMI created a new high-risk group for postinfarction angina (35 to 45 percent incidence), with a 12 to 15 percent incidence of reinfarction during the early experience with lytic therapy for reperfusion.[423] Regardless of whether postinfarction angina occurs after Q-wave myocardial infarction, NQWMI, or thrombolytic therapy, it is more likely to occur in patients with two- or three-vessel disease than in patients with single-vessel disease.[418] Postinfarction angina is important because it is associated with a twofold increase in the incidence of reinfarction. The 1-year mortality rate and acute risk of reinfarction is two- to fourfold greater in patients with postinfarction angina associated with ECG changes than in patients without chest pain or in patients with chest pain but without associated ST-T changes.[424,425]

The incidence of reinfarction following NQWMI has previously been reported to be as high as 40 percent within the first month following the event,[426] but with current treatments with glycoprotein IIb/IIIa inhibitors and fractionated heparins and possibly diltiazem, the incidence is less than 10 percent, as discussed previously. The incidence of reinfarction following thrombolytic therapy has been reduced from 12 to 15 percent to 5 to 7 percent with the use of adjunctive therapy, including heparin, aspirin, nitroglycerin, and beta blockers, as discussed previously. Nevertheless, reinfarction, despite the use of heparin and aspirin, still accounts for one-quarter of all deaths that occur following thrombolytic therapy and thus remains a major concern.[427] Patients with Q-wave myocardial infarction who do not receive thrombolytic therapy were previously likely to have an incidence of postinfarction angina of only about 12 to 15 percent and a reinfarction rate of about 5 to 7 percent, although these absolute rates have probably decreased with the more widespread use of adjunctive therapy with beta blockers, aspirin, and ACE inhibitors. Death, ventricular arrhythmias, and severe congestive heart failure are early sequelae of reinfarction, and there is an increased rate of sudden death and cardiogenic shock.[110,113]

Diagnosis of reinfarction within 18 h after thrombolytic therapy is based upon the recurrence of ischemic-type chest pain, as noted, lasting at least 30 min, which may be associated with ST-T-wave changes. There

is a reelevation of MB-CK, and the diagnostic criteria were discussed previously. Adequate beta-adrenergic blockade should be achieved. Sublingual nitroglycerin should be administered, and restarting of intravenous infusion should be considered. Pain should be controlled. Coronary arteriography generally should be performed early after the redevelopment of ischemic chest pain, and it is common that a high-grade stenosis is found. If the lesion is suitable, PTCA should be performed, or additional thrombolysis should be administered if mechanical reperfusion is not feasible or available. With appropriate ECG changes-that is, ST-segment elevation-thrombolysis should be considered if cardiac catheterization and PTCA are not immediately available. If either APSAC or SK was used originally, it should not be readministered and rt-PA or r-PA should be utilized. These latter agents can be readministered. If multiple high-grade stenoses are found, coronary artery bypass grafting should be considered.

Pericarditis

Pericardial involvement associated with AMI assumes one of two forms. By far the most common type is pericardial inflammation overlying the necrotic segment of a transmural myocardial infarction. This particular pericarditis is usually an incidental finding in the course of a more significant illness. The less frequent form of postinfarction pericarditis is generally a delayed complication, which may represent an immunologic or autoimmune reaction. This pericarditis, a component of Dressler's syndrome, generally represents a major complication that often outlasts the basic illness (see also Chap. 72).

EARLY POSTINFARCTION PERICARDITIS

The prevalence of early postinfarction pericarditis, as reflected by the presence of typical symptoms and a friction rub, is 6 to 11 percent.[428,429] However, the general consensus among cardiologists is that this entity occurs far more frequently than is clinically recognized. This suspicion is supported by postmortem studies finding evidence of postinfarction pericarditis when it was not recognized clinically.[430] The pericarditis usually becomes evident between the second and fourth day following the AMI, but it may occur up to several weeks later. In comparison to post-AMI patients without pericarditis, those who develop the condition have larger infarcts, a lower ejection fraction, and a higher incidence of congestive heart failure.[431,432]

The most common manifestation of pericarditis other than the chest pain is a scratchy two- or three-component friction rub along the left sternal border. The friction rub may have only a single component and may be dismissed erroneously as a systolic murmur. The rub is evanescent, generally lasting 1 to 6 days. The pain of pericarditis is generally perceived by the patient to be different from that of the AMI. The location of the pain may be the same, but any radiation is usually to the neck, shoulder, or scapula rather than to the arms or jaw. Characteristically, the pain is aggravated by inspiration, swallowing, coughing, or recumbency. Fever, usually less than 39°C, frequently accompanies the pericardial inflammation and typically lasts longer than 3 days, unlike the fever in an uncomplicated myocardial infarction.[433] The ECG is frequently not helpful in these patients, partially because it is usually distorted by the infarction and perhaps because of the localized nature of the inflammation. The cardiac rhythm is generally sinus, but there is an increased prevalence of atrial fibrillation.[434] Since significant effusion is unusual with this form of pericarditis, the echocardiogram is of limited diagnostic value.

The treatment of choice is aspirin (160 to 325 mg daily), although higher doses (650 mg every 4 to 6 h) may be required.[1,435,436] Indomethacin is effective in relieving symptoms,[1] but experimentally causes thinning of scar formation.[437] Corticosteroids and ibuprofen provide pain relief but also have been associated with thinning of scar formation as well as with cardiac rupture.[438,439] The use of anticoagulants is relatively contraindicated in AMI complicated by pericarditis. Situations ordinarily calling for anticoagulation, such as mural thrombosis seen on echocardiography, require excellent clinical judgment in assessing the risk-benefit ratio if pericarditis is also present.

POSTMYOCARDIAL INFARCTION SYNDROME (DRESSLER'S SYNDROME)

The clinical features of this syndrome are fever, chest pain, evidence of polyserositis, and a tendency to recur.[435] The reported frequency is 1 to 3 percent of AMIs.[434,435] The incidence, however, has appeared to

diminish dramatically in the reperfusion era.[440] While there is usually a latency period of at least 1 week before its appearance, the pleuropericarditis may develop within the first week following the AMI.[441] The syndrome can occur in association with NQWMI, and it is usually associated with fever in the range of 38 to 39°C and occasionally up to 40°C. The chest pain is the most sensitive index of this syndrome and often precedes the fever. Aggravation of the pain by deep inspiration and turning is its most distinctive feature. The pericarditis is manifest by a friction rub, usually occurring between the second and eleventh week after the infarction and lasting from 3 days to 3 weeks. Pericardial effusion is common. While pericarditis is the dominant feature, as many as two-thirds of patients have pleural effusions. These effusions are usually small and are frequently bilateral but may be large and hemorrhagic. About one-quarter of patients have linear or patchy infiltrates in the lung bases.

The clinical features, pathologic findings, and prompt response to steroids all suggest an immunologic or autoimmune reaction. The presence of antimyocardial antibodies has been demonstrated in the majority of patients tested with the syndrome.

Treatment is similar to that of early postinfarction pericarditis but is more likely to require a course of oral corticosteroids. Recurrences are common for several months and require the reinstitution of corticosteroids with a more gradual tapering. Anticoagulants should generally be discontinued in the presence of postmyocardial infarction syndrome.[442]

HEART FAILURE IN ACUTE MYOCARDIAL INFARCTION

Pathophysiology and Hemodynamics

The immediate hemodynamic consequences of myocardial infarction include both systolic and diastolic dysfunction. Systolic dysfunction is secondary to a loss of contractile function of the infarcted and ischemic myocardium.[443] Experimentally, over a period of 1 to 3 min, the regional disturbance of contraction progresses from dyssynchrony (disturbed temporal sequence of contraction) through hypokinesis (diminished motion) and akinesis (total lack of motion) to dyskinesia (paradoxical systolic expansion).[444] This loss of contractile function results in a decreased systolic ejection, increased end-systolic volume, increased end-diastolic volume, and a secondary increase in diastolic filling pressure caused by the increase in ventricular volume. The diastolic impairment often precedes the systolic dysfunction, which is characterized immediately by a transient increase in left ventricular diastolic distensibility,[445,446] followed by decreased distensibility due in part to adenosine triphosphate depletion and restraint by the pericardium and perhaps ultimately by the infiltration of inflammatory fluid and cells. The hemodynamic consequence of the reduced distensibility is increased diastolic pressure. The systolic stress on the ischemic segment, which contributes to "cell stretch" and "cell slippage," results in expansion of the infarcted segment[447] and provides the stimulus for volume overload hypertrophy, characterized by sarcomere replication, fiber elongation, and chamber enlargement. The chamber enlargement accommodates the increased volume and allows the diastolic pressure to return toward normal.[444]

Cardiac failure develops when left ventricular function is reduced to 30 percent or more of normal and usually occurs within minutes or hours of the onset of a large infarction. Since even with sustained coronary occlusion only 60 to 70 percent of the ischemic region undergoes necrosis, compromise of cardiac function associated with AMI is transient (24 to 72 h) in perhaps more than two-thirds of the cases. *Unlike the situation with chronic heart failure, the circulatory volume is normal or decreased in acute ventricular dysfunction associated with myocardial infarction.* The usual clinical scenario is one of left ventricular dysfunction with pulmonary congestion and without hypoperfusion. There is sometimes biventricular failure, and in about 5 to 10 percent of cases there is predominantly right ventricular failure, as discussed later. The severity of the failure, its duration, and whether or not it is reversible are predominantly dependent on infarct size.[448,449] If more than 40 percent of the myocardium is destroyed, decompensation occurs, resulting in shock.[450-452] In a few patients, failure develops later as a consequence of expansion of the infarcted segment, reinfarction, or ischemia.[445] Less commonly, failure is precipitated by papillary muscle dysfunction or ventricular septal rupture. The compromised heart will also be negatively affected by supraventricular or ventricular arrhythmias, conduction disturbances, drugs with negative inotropic effects, fever, and hypovolemia.

Left ventricular dysfunction with the clinical signs of failure is said to occur in 30 to 40 percent of patients and usually develops when the abnormally contracting segment exceeds 30 percent of the left ventricular circumference.[453] Another factor contributing to cardiac failure is residual scarring from previous episodes of infarction, which limits the extent of compensation. After myocardial infarction, adjacent normal myocardium increases its contractility because of increased stimulation by catecholamines and also utilizes the Starling mechanism in an attempt to maintain cardiac output. The pathophysiology of heart failure is discussed in Chap. 20. That intravascular volume may be normal or decreased in acute heart failure in AMI is important in considering the therapeutic approach to low cardiac output and pulmonary congestion in acute infarction.

Right Ventricular Infarction

Until about 15 to 20 years ago, right ventricular infarction was recognized infrequently and was usually thought not to be of great consequence. Subsequently, it was shown that the majority of patients with acute inferior infarction had abnormal regional function of the right ventricle,[454-456] although typical hemodynamic abnormalities are seen in only 10 to 15 percent of patients.[457,458] Right ventricular function returns to normal in most of these patients, suggesting that substantial stunning, rather than massive infarction, has occurred[1] (see also Chap. 37).

Inferior myocardial infarction associated with right ventricular infarction defines a high-risk subset with a mortality rate of 25 to 30 percent, as opposed to an overall mortality of about 6 percent in inferior myocardial infarction.[457] This group should be approached aggressively with consideration for reperfusion therapy. *Right ventricular involvement should always be considered and should be specifically sought out in inferior myocardial infarction with clinical evidence of low cardiac output because the therapeutic approaches are quite different in the presence of right ventricular involvement from those for predominantly left ventricular failure.*

PATHOPHYSIOLOGY OF RIGHT VENTRICULAR INFARCTION

Right ventricular infarction is unusual in the absence of inferior infarction because occlusion of the right coronary artery proximal to the right ventricular branches usually also causes infarction in the inferior left ventricle, which is supplied by the distal distribution of the vessel.[459] The infarction usually involves the posterior septum and posterior wall rather than the right ventricular free wall. The relative sparing of the free wall results from the high degree of collateralization of the right ventricular arterial blood supply, from the blood flow derived from thebesian vessels, and from diffusion of oxygen from the ventricular cavity as well as from the fact that it is thin and has comparatively low oxygen demands because of its mass and low workload.[460-463]

The hemodynamic consequences of right ventricular ischemia or infarction share features previously described for the left ventricle. Thus, there is impairment of contractility and diastolic dysfunction related to dilatation and pericardial restraint. In a low-pressure volume pump, such as the right ventricle, this combination has even more deleterious effects than in the left ventricle and causes substantial increases in diastolic pressure and decreases in systolic pressure. If the right ventricular afterload is also increased because of left ventricular dysfunction, then right-sided output can decrease dramatically and the driving force becomes essentially the right atrial pressure. Under these circumstances, right atrial transport essentially becomes critical, and anything decreasing it, such as diminished volume and filling pressure or loss of AV synchrony, may cause severe decreases of right and, secondarily, left ventricular output.[422,464,465]

DIAGNOSIS OF RIGHT VENTRICULAR INFARCTION

As noted, right ventricular infarction should be considered in all cases of acute inferior myocardial infarction, especially in the setting of low cardiac output. A typical presentation would include inferior myocardial infarction, clear lung fields, and jugular venous distention. Jugular venous distention that is enhanced by inspiration (Kussmaul's sign) in the setting of inferior myocardial infarction is highly suggestive of right ventricular involvement but may not be manifest with volume depletion and might only become apparent with repletion.[466] A right atrial pressure >10 mmHg that is >80 percent of the pulmonary

wedge pressure is a sensitive and specific sign of right ventricular infarction.[467]

The differential diagnosis of heart failure or low cardiac output in inferior infarction includes (1) arrhythmia, such as atrial fibrillation, sustained ventricular arrhythmia, or high-degree AV block; (2) ongoing ischemia, such as ischemia at a distance if the occluded artery to the inferior wall was also supplying, through collaterals, the anterior wall; (3) previous infarction at another location; (4) a mechanical complication such as papillary muscle dysfunction or, less commonly, a ventricular septal defect; or (5) right ventricular infarction.[468] This differential diagnosis of causes of congestive heart failure in inferior AMI is summarized in Table 42-13.

Table 42-13: Differential Diagnosis of Congestive Heart Failure in Inferior AMI

Arrhythmia: high-degree AV block, atrial fibrillation, or sustained ventricular tachycardia
Ischemia at a distance, with the occluded artery to the inferior wall supplying the anterior wall via collaterals
Previous infarction at another location
Mechanical complication, such as papillary muscle dysfunction
Right ventricular infarction

ST-segment elevation in lead V_{4R} is the single most powerful predictor of right ventricular involvement in inferior infarction and identifies a patient subset with a markedly increased in-hospital mortality.[457] All patients with inferior infarction should be screened by recording ECG lead V_{4R}. Echocardiography can also be useful as an adjunctive diagnostic approach[179] and can be particularly valuable in detecting right-to-left shunting of blood through the foramen ovale, which can occur because of the high right atrial pressures in right ventricular ischemia. Such shunting can be a cause of hypoxemia unresponsive to oxygen administration in this setting.[469]

TREATMENT OF RIGHT VENTRICULAR ISCHEMIA AND INFARCTION

The major objectives in treating right ventricular infarction are to maintain right ventricular preload, provide inotropic support, reduce afterload of the right ventricle, and achieve early reperfusion.[262] The recommendations are summarized in Table 42-14.[1] Venodilators such as nitrates should be avoided, and diuretics should be used with caution. Volume loading with 1 to 2 L of saline will frequently restore cardiac output and correct hypotension; this should be the initial step. Excessive volume loading, however, may dilate the ventricle and decrease output. Inotropic support should be initiated if saline administration does not restore output and correct hypotension.[1] Dobutamine is an ideal initial choice.

The critical role of atrial transport in maintaining output in right ventricular infarction and the need to maintain AV synchrony have been discussed. High-degree AV block occurs in about 50 percent of patients in this setting, and AV sequential pacing can restore cardiac output.[470,471] Atrial fibrillation occurs in up to one-third of these patients, in whom prompt cardioversion should be considered if there is any evidence of hemodynamic compromise.[472] If there is significant left ventricular dysfunction, which may further compromise right ventricular function, as noted, afterload reduction by nitroprusside infusion or intraaortic balloon pumping is indicated.[1]

Reperfusion with thrombolytic therapy or primary PTCA improves right ventricular ejection fraction and hemodynamic status[473] and decreases the incidence of complete heart block.[473-475] Coronary artery bypass grafting should be considered if multivessel disease is found.

MANAGEMENT OF CONGESTIVE HEART FAILURE IN ACUTE MYOCARDIAL INFARCTION: GENERAL ISSUES

Hemodynamic Monitoring

Recommendations for balloon flotation right side of the heart catheter monitoring[1]:

Class I

1. Severe or progressive congestive heart failure or pulmonary edema
2. Cardiogenic shock or progressive hypotension
3. Suspected mechanical complications of acute infarction, i.e., ventricular septal defect, papillary muscle rupture, or pericardial tamponade

Class IIa

1. Hypotension that does not respond promptly to fluid administration in a patient without pulmonary congestion

Class III

1. Patients with acute infarction without evidence of cardiac or pulmonary complications

The balloon flotation (Swan-Ganz) catheter fundamentally permits one, in the setting of low cardiac output, to distinguish between inadequate ventricular filling pressures and inadequate systolic function. The former is treated with volume expansion and the latter with inotropic support and frequently afterload reduction. The catheter, even when used correctly, is not totally benign and during manipulation may precipitate VT and pulmonary hemorrhage or infarction. To minimize the risk of infection, the catheter should not be left in place longer than 5 days.[1]

INTRAARTERIAL PRESSURE MONITORING

Recommendations[1]:

Class I

1. Patients with severe hypotension (systolic arterial pressure less than 80 mmHg) and/or cardiogenic shock
2. Patients receiving vasopressor agents

Class IIa

1. Patients receiving intravenous sodium nitroprusside or other potent vasodilators

Class IIb

1. Hemodynamically stable patients receiving intravenous nitroglycerin for myocardial ischemia
2. Patients receiving intravenous inotropic agents

Class III

1. Patients with acute infarction who are hemodynamically stable. Arterial monitoring in AMI is useful in all hypotensive patients but especially in those who are in shock. The radial artery is the preferred site, although the brachial and femoral arteries can be used. Intraarterial catheters should not be left in place longer than 72 h because of the risk of thrombosis and infection.[1]

Intraortic Balloon Counterpulsation

Recommendations[1]:

Class I

1. Cardiogenic shock not quickly reversed with pharmacologic therapy as a stabilizing measure for angiography and prompt revascularization
2. Acute mitral regurgitation or ventricular septal defect complicating myocardial infarction as a stabilizing therapy for angiography and repair and revascularization
3. Recurrent intractable ventricular arrhythmias with hemodynamic instability
4. Refractory postmyocardial infarction angina as a bridge to angiography and revascularization

Class IIa

1. Signs of hemodynamic instability, poor left ventricular function, or persistent ischemia in patients with large areas of the myocardium at risk

Class IIb

1. In patients with successful PTCA after failed thrombolysis or those with three-vessel coronary disease, to prevent reocclusion
2. In patients known to have large areas of myocardium at risk, with or without active ischemia

By inflating in the aorta during diastole and by deflating during systole, the intraaortic balloon pump reduces afterload during ventricular systole and increases coronary perfusion during diastole. The decrease in afterload and increased coronary perfusion account for its efficacy in cardiogenic shock and ischemia. It is particularly useful as a stabilizing bridge to facilitate diagnostic angiography and revascularization and repair of mechanical complications of AMI. The use of the intraaortic baloon pump after AMI postthrombolysis or post-PTCA has not been uniformly successful in improving clinical outcome, including reocclusion rate or global or regional left ventricular function.[476] Thus, the routine use of the intraaortic baloon pump after either drug or mechanical reperfusion cannot be recommended.[1]

Diuretics and Positive Inotropic Agents

DIURETICS AND CARDIAC FAILURE IN ACUTE MYOCARDIAL INFARCTION

As previously mentioned, patients with failure due to AMI have normal total body water, and the transudation of fluid into the lungs may induce hypovolemia. As ventricular compliance is decreased, an increased left ventricular end-diastolic pressure is necessary to maintain cardiac output, since the heart operates on the steep portion of the ascending limb of Starling's curve.[477,478] The administration of a diuretic in this setting may be associated with a decrease in cardiac output.[479-481] Thus, diuretics should not be the drugs used initially in the treatment of pulmonary congestion in AMI. Their use early in the course should usually be guided by hemodynamic measurements from a Swan-Ganz catheter. Diuretic therapy may become appropriate later if salt and water retention occur and left ventricular filling pressures become excessively high->18 to 20 mmHg, for example.

INOTROPIC AGENTS IN CONGESTIVE HEART FAILURE ASSOCIATED WITH ACUTE MYOCARDIAL INFARCTION

Digoxin is a relatively weak inotropic agent and is not the drug of choice in acute heart failure in myocardial infarction. In a direct comparison, dobutamine was shown to increase cardiac output by 40 percent and to decrease left ventricular filling pressure, whereas digoxin increased cardiac output by only 10 percent and did not decrease filling pressure.[482] Since endogenous catecholamine levels can be quite elevated, digoxin may contribute little. The primary use of digoxin in AMI is to control heart rate in atrial fibrillation.

Dobutamine has favorable pharmacologic properties for use in heart failure in myocardial infarction (see

Chap. 21). It has a rapid onset of action and increases cardiac output because of its positive inotropic properties. It is a vasodilator and increases coronary flow. It decreases filling pressure, as noted. Dopamine has a tendency to increase heart rate more than dobutamine. With higher doses, dopamine may increase peripheral resistance and filling pressures, offsetting some of the positive inotropic effects. The phosphodiesterase inhibitor amrinone increases contractility and is a vasodilator that has been used in patients with heart failure due to AMI. There is concern that positive inotropic agents may increase infarct size. Evaluation of dobutamine in AMI showed that, as long as heart rate was not increased more than 10 percent above baseline, there was no increase in infarct size or in the incidence of reinfarction or arrhythmia.[483]

Management of Uncomplicated Cardiac Failure after Acute Myocardial Infarction

The major determinant of left ventricular dysfunction is the extent of myocardial injury.[448,449,484] The loss of contractile function in the initial minutes or hours (1 to 4) is potentially reversible and accounts in part for the transient nature of cardiac failure in the setting of uncomplicated AMI, as noted above. The presence of cardiac failure and its severity depend not only on the extent of damage but also upon the extent of injury from previous episodes.

Since the introduction of the Swan-Ganz catheter, considerable data have accumulated correlating hemodynamics with clinical features. In 1967, prior to invasive monitoring, Killip and Kimball[485] devised a clinical classification based on physical findings present on admission that provided a prognostic guide. That guide was followed by the classification of Forrester and colleagues,[486,487] based on extensive data obtained from invasive monitoring of patients with acute MI (Table 42-15). The latter classification combined the presence or absence of pulmonary congestion with the presence or absence of systemic hypoperfusion. They added the underlying hemodynamics to this classification based on the pulmonary arterial occlusive (wedge) pressure and the cardiac index. These classifications also provide important diagnostic and therapeutic guidelines, despite the observation that patients frequently cross over from one class to the other and are seldom restricted to one particular hemodynamic subset. Each classification illustrated that with increasing severity of ventricular dysfunction, there is an increased risk of mortality. Nevertheless, there is imprecision in predicting mortality rates from hemodynamics. Rackley and coworkers[488] observed that patients with a ventricular filling pressure >29 mmHg had a 100 percent mortality rate; those with a filling pressure >15 mmHg and a cardiac index <2 L/min per square meter of body surface had a mortality rate of 93 percent; while those with a ventricular filling pressure <15 and a cardiac index <2 L/min per square meter of body surface had a mortality rate of 63 percent.

In patients with uncomplicated AMI, there is no need to perform invasive monitoring if careful clinical observations are made. There should be repeated assessment of the heart and lungs; examination of the skin and mucous membranes; monitoring of the systemic arterial pressure, cardiac rhythm, and heart rate; and routine laboratory examinations, including chest x-ray and determinations of urine output and arterial blood-gas values. If there are clinical indications of pulmonary congestion and/or decreased peripheral perfusion, invasive monitoring includes the insertion of a Swan-Ganz catheter in order to monitor right ventricular hemodynamics and pulmonary artery occlusive pressure (which will reflect ventricular end-diastolic pressure) and to obtain serial determinations of the cardiac output. Occasionally, it may be necessary to insert an arterial catheter to measure the arterial pressure; however, one can usually follow the pressure adequately with the use of a sphygmomanometer or an automatic blood pressure monitoring device. Frequently, it is also essential to insert a Foley catheter to follow the urine output, particularly in patients with sustained hypotension or cardiogenic shock.

In most patients in whom cardiac failure is not complicated by mechanical factors-such as mitral valve rupture, ventricular septal rupture, pulmonary embolus, or tamponade-the failure is transient and of mild-to-moderate severity. If the cardiac output is normal, aggressive treatment is often not recommended.[149] In patients with rales at the base of the lungs with only minimal increase in heart rate and no other signs of hypoxemia (Killip class III), conventional therapy with morphine; nasal oxygen; intravenous, oral, or transdermal nitrates; and bed rest is adequate without any specific therapy for failure. In patients with extensive pulmonary edema who are normotensive and exhibit hypoxia and dyspnea (Forrester class II), the treatment of choice is nitroglycerin given intravenously at 0.1 μg/kg per minute and increased in increments of 5 to 10 μg/min, stopping at a dose that does not decrease the systolic blood pressure below 100 mmHg.

On the average, nitroglycerin in a dose of 0.5 μg/kg per minute is required in patients with evolving acute infarction and failure. Another vasodilator that has been used extensively in the past in AMI is sodium nitroprusside, which is initiated at 0.5 μg/kg per minute and increased by 10- to 20-μg/min increments every 10 to 15 min until the desired therapeutic point or a maximum of 10 μg/kg per minute is reached. Nevertheless, nitroglycerin is the preferred agent, since it has been shown to offer some cardioprotection when given in the early phase of myocardial infarction and to be both reliable and safe. In contrast, in experimental infarction in the dog, it has been shown that nitroprusside is more likely to redirect coronary flow away from the ischemic area to normal areas and to induce coronary steal.[253] The effect of nitroprusside on cardioprotection has been inconsistent and in one large study was shown to be detrimental.[489] In view of the data showing ACE inhibitors to be effective in cardiac failure, these agents are being used more generally in this setting. It is preferable that hemodynamics be monitored invasively (by Swan-Ganz catheter) when one gives a vasodilator to reduce the ventricular filling pressure to 15 to 17 mmHg while maintaining adequate cardiac output and coronary perfusion. Whether or not one monitors hemodynamics invasively will depend in part on the confidence that clinical features reflect the volume status. Mitral valve regurgitation due to papillary muscle dysfunction is commonly an aggravating factor even in mild-to-moderate cardiac failure and responds well to a vasodilator, as does systemic hypertension. Usually a vasodilator is not adequate, in which case an intravenous inotropic agent should be added. The inotropic agents are generally those of sympathomimetic drugs, including dobutamine, dopamine, and norepinephrine (see Chaps. 21 and 49). Dobutamine, a synthetic direct-acting agent, is preferred, as noted, and has actions that include vasodilatation, increased cardiac output, decreased ventricular filling pressure, and increased coronary flow.[490] The infusion should be initiated at 2 to 5 mg/kg per minute and should be increased such that adequate systemic pressure is maintained and the heart rate does not increase by more than 10 to 15 percent. Dobutamine is preferably titrated to cardiac output and ventricular filling pressure. The ventricular filling pressure should be decreased to a range of 14 to 18 mmHg while maintaining adequate cardiac output and blood pressure. In general, the objective is to maintain adequate cardiac output and blood pressure without inducing tachycardia while maintaining a filling pressure that is normal or minimally increased.

In patients with inferior infarction and low cardiac output, right ventricular infarction should be suspected, as discussed. If it is present, a Swan-Ganz catheter should be inserted to determine the filling pressure. Therapy with a positive inotropic agent, such as dobutamine, should be used after assuring that there is appropriate intravascular volume to facilitate right ventricular filling.[491,492]

In patients with borderline blood pressure and evidence of peripheral hypoperfusion, therapy should be initiated with an inotropic agent and not a vasodilator. Similarly, in patients with left ventricular failure and frank hypotension (<95 mmHg), a vasodilator must be avoided and initial therapy should be with a positive inotropic agent. Dopamine would frequently be the choice under these circumstances, since it exerts cardiovascular effects similar to those of dobutamine, but it also possesses an $alpha_1$-adrenergic activity and releases endogenous norepinephrine from sympathetic nerve endings. Low doses of dopamine (2 to 7 mg/kg per minute) are associated with increased stroke volume, cardiac output, and renal blood flow and moderate effects to increase peripheral resistance. High doses of dopamine induce significant vasoconstriction and may increase the left ventricular filling pressure due to increased afterload, which further exacerbates pulmonary congestion. Dopamine also has a more positive chronotropic effect than does dobutamine, which can be a disadvantage in AMI. Norepinephrine, which produces potent arteriolar and venous constriction, is used for hypotension in other settings but is otherwise relatively contraindicated in AMI. It is seldom used unless patients are hypotensive and do not respond to dopamine, amrinone or milrinone, or dobutamine. It is used in cardiogenic shock after dopamine has failed, since it is the major alternative that can be used for maintaining adequate perfusion pressure.

As indicated earlier, diuretics should be used with more caution in acute heart failure associated with AMI than in chronic heart failure, since volume expansion is usually not the primary problem. If high filling pressure (>18 to 20 mmHg) persists after adequate output is achieved with positive inotropic agents and/or vasodilators, diuretics may be added. However, this effect can be achieved by vasodilator therapy, which avoids the hypovolemia and hypotension that may occur secondary to the subsequent diuresis (1 to 2 h). The preferred diuretics are intravenous furosemide or ethacrynic acid.[493] These drugs also provide some acute venodilation.

Complicated Heart Failure after Myocardial Infarction

Some AMI patients present with acute, fulminating pulmonary edema (with severe respiratory distress; generalized inspiratory crackles and wheezing; expectoration of pink, frothy sputum; cool, clammy, diaphoretic skin; and cyanosis) and require much more aggressive therapy than do patients with uncomplicated AMI. The condition is usually associated with pulmonary artery wedge pressure exceeding 25 mmHg and an in-hospital mortality rate of at least 15 to 20 percent.[494] The systolic blood pressure is usually either low normal or borderline normal (95 to 105 mmHg). The maintenance of adequate oxygenation must be the primary concern. Administration of high concentrations (60 to 100 percent) of oxygen via a face mask is essential. If the patient appears moribund, endotracheal intubation should be performed. While an assessment of arterial blood gases is appropriate, the speed with which clinical events change in these emergent situations may demand that decisions be made without benefit of these values. After the institution of mechanical ventilation, positive end-expiratory pressure may be needed to maintain adequate oxygenation while keeping the inspired oxygen concentration within safe levels (FI_{O_2} < 60 percent). Positive end-expiratory pressure should be applied only with an awareness of its risks of pneumothorax and reduction in cardiac output secondary to decreased left ventricular preload.[494] Invasive hemodynamic monitoring is particularly useful in these patients. Therapeutic interventions, however, should not be delayed until the monitoring is established. The therapy for severe pulmonary edema should include intravenous morphine unless the patient is known to have chronic CO_2 retention. From 5 to 10 mg of morphine sulfate should be given slowly with careful observation for evidence of respiratory depression. If the systolic blood pressure is adequate (≥100 mmHg), nitroglycerin is administered intravenously. In the patient with severe pulmonary edema, the improvement in left ventricular pump performance afforded by the prompt reduction in systemic vascular resistance by nitroprusside[495] may be essential for the rapid reversal of this life-threatening situation (particularly if systemic hypertension had been present). Either nitroglycerin or nitroprusside will provide a reduction in preload. If the systolic blood pressure is 100 mmHg or less, treatment with a positive inotropic agent should probably be initiated, with the subsequent addition of a vasodilator or an agent to improve cardiac output. The adjunctive use of intravenous diuretics is the same as outlined for mild degrees of heart failure.

PERIPHERAL HYPOPERFUSION WITHOUT PULMONARY CONGESTION

Patients with clinical hypoperfusion without pulmonary congestion (with cool, cyanotic extremities, somnolence or confusion, and decreased urine flow) usually have a cardiac index <2.2 L/min. The mortality rate in these patients is four times greater than that in patients without hypoperfusion.[494] Invasive hemodynamic monitoring of the pulmonary capillary wedge pressure is essential. Volume augmentation is the initial therapeutic step in patients with a pulmonary capillary wedge pressure <15 mmHg. If possible, this pressure should be maintained below the level of pulmonary congestion (>20 mmHg). Vasodilators are usually not indicated at least until adequate filling pressures have been achieved and cardiac output is augmented with positive inotropic agents. This situation is commonly seen with severe biventricular infarction and thus should be suspected with inferior and right ventricular infarction. In this case, bradycardia should be treated with atropine if it is thought to be contributing to the systemic hypoperfusion. Excessive treatment with nitroglycerin and volume contraction from previous diuretic therapy can also contribute to systemic hypotension.

HYPOTENSION AND CARDIOGENIC SHOCK

Cardiogenic shock may occur when 40 percent or more of the left ventricle is destroyed.[450,451,496] It is the most common cause of in-hospital death with myocardial infarction. The incidence of cardiogenic shock was about 15 percent in the early 1970s, but it has now decreased to approximately 5 to 7 percent.[494] The mortality rate is frequently over 80 percent.[497] The most effective therapy in the treatment of cardiogenic shock is prevention, since its major determinant is infarct size.[448,498] Cardiogenic shock usually occurs within hours of the onset of infarction due to massive ischemia and necrosis.[498] In other cases, a relatively small infarction that is superimposed on extensive previous damage may precipitate cardiogenic shock. Less commonly, cardiogenic shock may develop days after the initial event. This occurrence is almost always due to development of new necrosis (extension or early reinfarction) in the area of the preceding infarction. The decrease in the incidence of cardiogenic shock is believed to be in part due to better treatment of angina and ischemia, together with the widespread use of thrombolytic therapy and other

cardioprotective agents. Cardiogenic shock by definition represents a more severe form of cardiac failure, resulting in decreased organ perfusion in addition to the conventional features of pulmonary congestion and left ventricular dysfunction. Cardiac failure with hypoperfusion and that regarded as cardiogenic shock may differ only in the severity of decreased perfusion. Clearly, every effort must be made to treat hypoperfusion whether or not it satisfies the strict criteria of cardiogenic shock. Characteristics of cardiogenic shock are (Table 42-16) (1) evidence of organ hypoperfusion with cold, clammy skin, especially on the feet and hands, that may be associated with peripheral cyanosis of the nail beds; (2) oliguria, disordered mentation, and systolic blood pressure <80 to 90 mmHg; (3) left ventricular end-diastolic pressure or, more commonly, pulmonary capillary wedge pressure >18 mmHg; (4) evidence of a primary cardiac abnormality; and (5) a cardiac index *not* >1.8 L/min per square meter of body surface. Hypotension or shock due to a primary abnormality of cardiac rhythm or conduction is not considered cardiogenic shock.

Table 42-16: Characteristics of Cardiogenic Shock

Evidence of hypoperfusion: cold clammy skin, especially of feet and hands; impaired mentation; and oliguria
Systolic blood pressure <80-90 mmHg
LVED pressure (or PCW pressure) ≥18mmHg
Evidence of primary cardiac abnormality
Cardiac index ≤1.8 L/m/m^2

ABBREVIATIONS: LVED = left ventricular end-diastolic; PCW = pulmonary capillary wedge.

The advantage of early revascularization in reducing mortality in the acute setting (SHOCK trial)[299] was discussed earlier. Since the prognosis is extremely poor for patients with cardiogenic shock due primarily to loss of muscle mass, reversible causes associated with a better prognosis must be excluded. Potentially reversible causes include mitral valve rupture, ventricular septal rupture, right ventricular infarction, pulmonary embolus, and cardiac tamponade. While the mortality associated with surgical correction of infarct-associated mitral rupture or ventricular septal defect is still high, it is far less than that associated with cardiogenic shock due solely to myocardial injury. The details of management of these mechanical causes of shock are discussed later. Hypotension may be due to inadequate fluid administration, to vasodilatation induced by such drugs as morphine and vasodilators, and occasionally to depressed contractility due to antiarrhythmic therapy. Inadequate filling pressure is a very important cause of hypotension and should be corrected immediately. It is particularly common in patients with inferior infarction, as noted. A Swan-Ganz catheter should be inserted to determine the circulatory status and assess the response to therapy.

Therapeutic objectives are to establish and maintain a systemic arterial pressure adequate for perfusing the vital organs and for reducing pulmonary congestion. The approaches to pulmonary congestion include the judicious use of morphine, and the maintenance of adequate oxygenation, together with endotracheal intubation and mechanical ventilation if necessary. In addition to instituting hemodynamic monitoring, one should assess urinary output using an indwelling catheter. If the pulmonary artery wedge pressure is <15 mmHg, prompt volume expansion to raise the capillary pressure to 18 to 20 mmHg should be initiated. The cornerstones of therapy are inotropic and vasopressor agents. If the systemic arterial pressure is below 80 to 90 mmHg, a pressor agent such as dopamine should be infused.[499] At relatively low doses of 2 to 5 mg/kg per minute, increases in stroke volume and cardiac output are mediated by beta-adrenergic stimulation and increases in renal blood flow are mediated by the dopaminergic-specific receptors. The alpha-adrenergic vasoconstrictor effects are manifest progressively at doses above 5 mg/kg per minute. The use of intravenous dopamine requires careful titration, beginning with a low dose and gradually increasing until an adequate (90 to 100 mmHg) systemic pressure is achieved. If high doses of dopamine are necessary to maintain adequate perfusion, a change to norepinephrine infusion should be considered. This drug is a potent arteriolar and venous constrictor that is mediated through alpha-adrenergic stimulation. It demonstrates relatively modest beta-adrenergic stimulation. It is, therefore, a very potent pressor agent with

less chronotropic or arrhythmogenic effects than dopamine.[267] The drug should be started at low doses of 1 to 4 mg/min. Extravasation should be avoided, since it will produce tissue sloughing.

When the systemic blood pressure is 90 mmHg or more, dobutamine is frequently the preferred agent. By increasing cardiac output, dobutamine may produce a rise in systemic blood pressure, but this increase would not be expected to be >10 to 15 mmHg.[500,501] Dobutamine will not support arterial pressure except by its effect on cardiac output. As the cardiac output rises, the left ventricular filling pressure should decline. Dobutamine therapy should begin with a dose of 2 to 5 mg/kg per minute with increases every 5 to 10 min. Inappropriate increases in heart rate are unlikely to occur with doses <15 to 20 mg/kg per minute.[483]

On occasion, the severity of cardiac pump dysfunction will require the use of two divergent therapeutic modalities in order to facilitate left ventricular emptying.[502] The most commonly utilized of these combined therapies is nitroprusside and dopamine. The principal advantage offered by nitroprusside in this combination is a reduction in left ventricular preload. The cardiac output is not appreciably increased by the addition of nitroprusside to dopamine therapy. The advantage offered by dopamine in this combination is an augmentation of cardiac output and the maintenance of systemic arterial pressure.[503] A less frequently used combination, dobutamine and nitroprusside, has been shown to result in higher cardiac output and lower pulmonary capillary wedge pressures than has resulted with either drug alone.[502] Stabilization of the patient with cardiogenic shock may be achieved by mechanical circulatory assist devices, such as the intraaortic balloon as demonstrated in the completed SHOCK Trial.[299] Aortic balloon counterpulsation reduces afterload while simultaneously improving coronary perfusion by increasing diastolic aortic pressure, as discussed. It is the only intervention that will increase diastolic aortic pressure without increasing myocardial oxygen demand. Aortic counterpulsation is often helpful for patients in cardiogenic shock due to a potentially reversible condition or in whom cardiac transplantation is being considered. Such conditions include an acute but still evolving MI or AMI with a severe mechanical complication (e.g., mitral regurgitation or ventricular septal defect). In such cases, aortic counterpulsation should be used to stabilize the patient's condition in preparation for salvage of the jeopardized but still viable myocardium or correction of the mechanical defect.[267] Intraaortic counterpulsation in patients without a reversible defect is now being used with greater frequency, especially in patients <75 years of age based on the compelling data emerging from the long-term follow-up of the SHOCK Trial patients.[299]

Restoration of coronary blood flow is the most effective therapy in salvaging patients with cardiogenic shock who are unresponsive to fluid and pharmacologic management in the early hours after a myocardial infarction. If angioplasty and/or coronary artery bypass grafting are not readily available, thrombolytic therapy should be tried if it has not already been utilized-although it has not been shown to improve survival in this setting.[504,505] These patients should be transferred quickly to a tertiary care center. Blood pressure should be stabilized with an intraaortic balloon pump, and cardiac catheterization should be performed as soon as possible. Assessment of correctable mechanical lesions, such as ruptured papillary muscles, can be made together with evaluation of coronary anatomy. Depending upon this anatomy, a judgment can be made as to whether to attempt PTCA or to proceed to coronary artery bypass surgery. Mechanical revascularization appears to improve survival in cardiogenic shock complicating AMI.[299,506]

MECHANICAL DYSFUNCTION CONTRIBUTING TO CARDIAC FAILURE

PAPILLARY MUSCLE RUPTURE

Rupture of the left ventricular papillary muscle occurs in approximately 1 percent of myocardial infarctions and accounts for 0.4 to 5.0 percent of infarct-related deaths.[507] It occurs slightly less frequently than ventricular septal rupture. The posteromedial papillary muscle is involved 6 to 12 times more frequently than is the anterolateral muscle.[508] Thus, papillary muscle rupture with an acute anterior myocardial infarction is uncommon. The rupture may occur distally and may involve one or several of the smaller heads of the muscle or, less commonly, may occur proximally and produce complete dehiscence of the papillary muscle.

Papillary muscle rupture is manifest by the sudden appearance of pulmonary edema, usually 2 to 7 days after the infarction. The abruptness of onset and severity of pulmonary edema are usually greater than seen

with ventricular septal rupture. A mid- or holosystolic murmur with wide radiation is usually audible. Although the murmur is generally loud, a thrill is rarely present, and the murmur may seem inconsequential. The diagnosis can be established by Doppler echocardiographic studies (see Chap. 13). The two-dimensional echocardiogram will generally show a flail mitral leaflet and may reveal a portion of the papillary muscle visualized as a mass attached to the chordae. Even when the flail leaflet is not observed, documentation of relatively intact ventricular systolic function in the postinfarction patient with pulmonary edema should suggest the diagnosis. The Doppler study will establish the presence and severity of the mitral regurgitation. Bedside right side of the heart catheterization can be used to exclude an oxygen step-up from the right atrium to the right ventricle, indicative of ventricular septal rupture, and to confirm elevated pulmonary capillary wedge pressures with tall V (regurgitant) waves characteristic of acute mitral regurgitation.

Studies in the presurgical era demonstrated a poor prognosis for these patients, with a 50 percent mortality rate in the first 24 h and a 6 percent survival rate for longer than 2 months.[442] Thus, immediate recognition and treatment are essential. Intraaortic counterpulsation alone or with vasodilator and inotropic therapy may frequently be required for temporary stabilization. During this period, the patient should undergo cardiac catheterization to define coronary anatomy and should be transferred to surgery for mitral valve replacement or repair.

PAPILLARY MUSCLE DYSFUNCTION

The sudden development of an apical systolic murmur after a myocardial infarction is much more often secondary to papillary muscle dysfunction than it is to rupture. Twenty percent of patients who die from infarction have histologic evidence of papillary muscle necrosis, usually without rupture.[509] Papillary muscle dysfunction is frequently compatible with long-term survival.

The posteromedial papillary muscle is involved with ischemia or infarction more commonly than the anterolateral muscle because the latter receives blood from two arteries (left anterior descending and circumflex), whereas the posteromedial muscle is supplied predominantly from the circumflex.[510] Dysfunction may be transient during ischemia. Papillary muscle ischemia is usually accompanied by ischemia of the contiguous ventricular wall.[511] Involvement of the contiguous ventricular wall is a key factor in the development of significant mitral regurgitation, since isolated papillary muscle ischemia or even infarction is usually not sufficient to cause important mitral regurgitation.[512]

Papillary muscle dysfunction typically presents with an apical systolic murmur. The murmur may be holosystolic, late systolic, or even early systolic. Echocardiography coupled with Doppler flow studies will confirm the presence of mitral regurgitation, grade its severity, and permit assessment of left ventricular function. There is generally no hemodynamic deterioration associated with the appearance of the murmur. It is the unusual patient who develops pulmonary edema, and these patients usually have concomitant significant left ventricular dysfunction. The ordinary patient with papillary muscle dysfunction will require no specific therapy for the regurgitation, while the unusual patient with severe regurgitation should be treated as in the case of papillary muscle rupture. In intermediate cases with moderate to moderately severe regurgitation where cardiac surgery is not contemplated, afterload reduction with ACE inhibitors should be considered.

VENTRICULAR SEPTAL RUPTURE

Rupture of the interventricular septum is estimated to occur in 1 to 3 percent of AMIs and accounts for approximately 5 percent of all infarct-related deaths.[513] Ventricular septal rupture occurs with an approximately equal frequency between anterior and inferior infarctions. There is a higher prevalence in first infarctions and the majority occur within the first week. Some 20 to 30 percent may develop as early as the first 24 h after the infarction.[514,515] Septal rupture rarely occurs after 2 weeks. Ventricular septal rupture is usually manifest by the appearance of a new harsh, holosystolic murmur along the left sternal border (often associated with a thrill) and sudden clinical deterioration with hypotension and pulmonary congestion. Right ventricular volume overload secondary to the shunt may produce signs of systemic venous congestion out of proportion to those of pulmonary venous congestion. Often the event is heralded by a recurrence of chest pain.

The diagnosis can be established by two-dimensional and Doppler echocardiographic studies that will demonstrate the site and approximate size of the rupture as well as the left-to-right shunt. Right-sided heart catheterization is useful in confirming the diagnosis (an increase in O_2 saturation of >5 percent from right atrium to right ventricle) and is an aid in managing the patient. The primary diagnostic concern is to exclude rupture of the papillary muscle. The presence of a thrill or an anterior infarction would be unusual with papillary muscle rupture, and results of the Doppler echocardiographic studies and/or the oxygen step-up on right side of the heart catheterization would confirm the presence of septal rupture.

When medical therapy alone is used, most patients with ventricular septal rupture deteriorate rapidly and virtually all patients die, many within 24 h after rupture. Except for the rare case in which there is no clinical or hemodynamic deterioration, medical therapy can be expected to be ineffective. *It is now axiomatic, that upon discovery of rupture of the ventricular septum, prompt surgical repair should take place, even for those patients who are clinically stable*. Inotropic and vasopressor agents may be required to sustain arterial blood pressure but can increase the left-to-right shunt. Prompt but temporary stabilization can be achieved with intraaortic balloon counterpulsation alone or in conjunction with vasodilator and inotropic drug therapy. Cardiac catheterization should be performed in an expeditious manner to define cardiac anatomy, left ventricular function, and mitral valve competence. An aggressive approach of immediate operative repair of these patients results in a short-term survival rate of 42 to 75 percent.[516-518] The 5-year actuarial survival rate for the operative survivors has been reported to be as high as 88 percent.[519] Surgical results are worse when ventricular septal rupture complicates inferior infarction and when there is combined right ventricular and septal dysfunction.[518]

CARDIAC RUPTURE

Cardiorrhexis, or rupture of the heart, occurs in up to 24 percent of fatal AMIs. After cardiogenic shock and arrhythmias, it is the most common cause of death. The free wall of the ventricle is the most common site of rupture.[520]

Rupture of the free wall generally occurs within the first 2 weeks of the infarction and may occur within the first 24 h.[514,515] Rupture occurring after this interval usually represents extension of the infarction or rupture through a false aneurysm.[521]

The rupture occurs primarily in the left ventricle, with a fairly even distribution between the anterior, inferior, and lateral walls. Given the relatively smaller number of lateral infarctions, the incidence of rupture with lateral wall infarctions would presumably be relatively smaller than at other sites.[522] Free wall rupture is more likely to occur with the initial myocardial infarction, in women, in the sixth decade of life or later, and in patients with systemic arterial hypertension, particularly if there is no associated ventricular hypertrophy.[514] The prolonged use of corticosteroids might predispose a patient to cardiac rupture.

Cardiac rupture generally presents as sudden, unanticipated death. Symptoms such as pain, agitation, sinus tachycardia, or vagally mediated bradycardia seldom precede death by more than minutes. Occasionally, intermittent chest pain and/or transient hypotension may precede and portend the final catastrophic event. Cardiac rupture is diagnosed terminally by the development of electromechanical disassociation in the setting of recurrent chest pain. Few cases, and only those with immediate recognition, can be salvaged. Even these few cases require heroic measures, such as immediate pericardiocentesis, emergency thoracotomy, and surgical repair.

OTHER COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTION

Pulmonary Embolism

The prevalence of deep venous thrombosis in AMI is reported to be between 12 and 38 percent. Patients with large infarctions in any location, anterior infarctions, evidence of congestive heart failure, and complicated infarctions have a greater frequency of deep venous thrombosis.[523,524] Reduced cardiac output and immobilization are additional predisposing factors for deep venous thrombosis (see Chap. 90).

Venous thrombosis is usually a minor and frequently unrecognized complication of infarction but is potentially life-threatening. A prevalence of pulmonary embolism of 10 to 15 percent and a prevalence of fatal embolism in 3 to 6 percent of cases has been reported in the past.[525] More recently, pulmonary embolism has been reported to account for less than 1 percent of deaths in myocardial infarction, probably because of earlier ambulation and better therapy of low output.[521]

Early mobilization combined with therapy directed toward improving cardiac output, when appropriate, is probably the most effective means of preventing pulmonary emboli. Prophylactic anticoagulant therapy is not routinely recommended for all patients after a myocardial infarction but is advisable for patients with increased risk factors for deep venous thrombosis and pulmonary embolism.

Systemic Emboli

Emboli to the cerebrovascular, renal, mesenteric, iliofemoral, or other arterial systems may complicate the AMI. The reported prevalence of clinically apparent systemic emboli in patients with myocardial infarction varies from 0.6 to 6.4 percent.[526,527] These emboli result from dislodgement of left ventricular thrombi, which are found in 20 to 40 percent of anterior myocardial infarctions. A ventricular thrombus is unusual in patients with an inferior infarction.[527,528] The predilection of the apical wall for thrombus development appears to be related to a combination of stagnant blood flow and poor wall contractility. Severe depression of left ventricular function is not a prerequisite for thrombus formation. The development of a mural thrombus in a small infarction (CK < 1000 U), however, is unusual.[529,530] Thrombus morphology and mobility would seem to correlate with systemic embolization.[526,531,532] Pedunculated and freely mobile thrombi have been thought to have a greater chance of embolization. At least two studies, however, could not correlate risk of embolization to any particular thrombus morphology.[527,530]

Left ventricular thrombosis usually occurs within the first 3 days after a myocardial infarction,[530,533] but may occur at any time during the hospital course. Early mural thrombosis occurs in large infarctions that have an unfavorable prognosis.[530] Systemic embolization occurs an average of 14 days after AMI and is unlikely to occur after more than 4 to 6 weeks.[534] Anticoagulation appears to reduce the incidence of mural thrombus formation[535] and the prevalence of systemic embolization.[526,528,529] All patients with an anterior myocardial infarction should have two-dimensional echocardiography performed within 24 to 72 h following the infarction, with particular emphasis on the two- and four-chamber apical views. Those with a severe apical wall contraction abnormality (akinesis or dyskinesis) should receive heparin for several days, followed by warfarin (INR 2 to 3) for 1 to 3 months. In patients with a left ventricular thrombus demonstrated by echocardiographic studies, chronic warfarin therapy (Chap. 44) is continued for approximately 3 months. Warfarin administration should be maintained indefinitely for atrial fibrillation.

Two-dimensional echocardiography has a sensitivity of 83 to 95 percent and a specificity of 86 to 90 percent in diagnosing a mural thrombus.[527,529,531,536] Angiography has a sensitivity of 20 to 63 percent and a specificity of 67 to 75 percent.[526,537] Occasionally, a technically unsatisfactory echocardiogram may require the use of alternative noninvasive imaging modalities. Both computed tomography and magnetic resonance imaging offer a similar sensitivity and perhaps superior specificity to echocardiography in this setting.[537]

Ventricular Aneurysm

The true prevalence of ventricular aneurysm after myocardial infarction is not well defined. Probably the best approximation comes from postmortem studies estimating a 3 to 15 percent prevalence.[533,538] The CASS registry documented angiographically defined left ventricular aneurysms in 7.6 percent of patients with coronary artery disease. The location of the aneurysm is usually anterior, anteroapical, or apical. True posterior ventricular aneurysms located in the diaphragmatic wall between the septum and insertion of the posterior papillary muscle have been observed but are quite uncommon.[539]

Pathologically, the aneurysmal area is characterized by a thinned-out transmural scar that has completely lost its trabecular pattern. The scar, which may eventually calcify, is clearly delineated from surrounding ventricular muscle. Aneurysms characteristically have a wide base (the diameter of the mouth is equal to or

larger than its greatest internal diameter), and one-half are lined by a laminated thrombus.[540]

As many as 80 percent of chronic ventricular aneurysms can be diagnosed clinically by the presence of an abnormal precordial impulse, most often located in the third left intercostal space at the midclavicular line; a typical bulge on the left ventricular border on chest x-ray, frequently with calcification around the apex; and ECG evidence of a large anterior infarction with ST-segment elevation persisting beyond 2 weeks following the infarction. Two-dimensional echocardiographic studies can confirm the diagnosis.[527] Left ventricular aneurysms are associated with a reduced survival rate. The prognosis for these patients, however, is primarily related to the left ventricular dysfunction and not to the presence of the aneurysm. True ventricular aneurysms rarely rupture. In fact, the survival rate for patients with an aneurysm is no different than that for patients without an aneurysm but with a similar degree of left ventricular dysfunction. Moreover, the incidence of sudden death is no different. Whether or not clinical recognition of the presence of a ventricular aneurysm is important in the management of the patient after an AMI remains to be answered.[536]

Most patients with ventricular aneurysms should be treated the same as any other postinfarction patient with a similar degree of left ventricular dysfunction. Vasodilators, digoxin, anticoagulants, and antiarrhythmics should be used, based not on the presence of the aneurysm but as dictated by presence of heart failure, mural thrombi, and life-threatening arrhythmias. Occasionally, surgical resection of the aneurysm is justified in order to correct refractory heart failure, recurrent life-threatening arrhythmias, or multiple systemic emboli. The aneurysm resection should usually be combined with coronary bypass grafting and, in cases of ventricular arrhythmias, should be guided by electrophysiologic mapping.

Pseudoaneurysm

A pseudoaneurysm is a rare complication of myocardial infarction, the prevalence of which is not known. The probable sequence of events in the development of a pseudoaneurysm is as follows: occurrence of a transmural infarction with localized pericarditis arising at the site of infarction; development of adhesions between the visceral and parietal pericardium; rupture of the infarcted myocardium, with the extravasated blood confined by the adherent pericardium; progressive enlargement of the aneurysmal sac; and development of thrombus within the sac.[521]

Unlike a true ventricular aneurysm, a pseudoaneurysm has a narrow base (site of rupture). The wall is composed only of a thrombus and pericardium, and the risk of rupture is high.[541] While the neck is small (its diameter is <50 percent of the diameter of the fundus), the pseudoaneurysm may progressively enlarge to become larger than the left ventricle. The pseudoaneurysm may be clinically silent or may present as progressively worsening heart failure, an abnormal bulge on the cardiac border, persistent ST-segment elevation in the area overlying the infarction, or systolic murmurs.[542]

The diagnosis can be established by two-dimensional echocardiographic studies, ventriculographic radionuclide studies, MRI, or left ventriculographic contrast studies.[541] Surgical resection is always indicated.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES COMPLICATING ACUTE MYOCARDIAL INFARCTION

Arrhythmias and conduction disturbances that are likely to be significant problems during the early phases of AMI and their management have been discussed earlier, under "Evaluation and Management of the Patients with Chest Pain in the Emergency Department." The arrhythmias and conduction abnormalities discussed include sinus bradycardia, AV block, idioventricular rhythm, VT, and VF. In general, the acute management of these rhythm disturbances is the same in the early and in the late phases of AMI. Sustained VT and VF are exceptions, however, in that their occurrence after the first 24 h has more ominous implications for long-term electrical instability and sudden cardiac death. Other rhythm and conduction abnormalities that may be manifest throughout the course of AMI and are not characteristically associated with the early phases, are discussed here.

Ventricular Ectopy, Ventricular Tachycardia, and Ventricular Fibrillation

The management of VT and VF after the first 24 h of hospitalization for AMI is similar to that discussed for the early phase. The occurrence of symptomatic, sustained VT or VF in the later phases of the hospital course, however, suggests that a chronic arrhythmogenic focus may be developing in the damaged ventricle. These ventricular arrhythmias are classified as secondary and indicate increased risk for subsequent sudden cardiac death.

Sinus Tachycardia or Atrial Premature Beats

Sinus tachycardia following AMI is common and is frequently an unfavorable prognostic sign. The increased heart rate enhances myocardial oxygen demand, while the decreased diastolic time decreases diastolic coronary flow. Patients with a large area of infarcted myocardium may have sinus tachycardia on the basis of left ventricular dysfunction, which causes reflex sympathetic nervous system activation. Other obvious causes of sinus tachycardia-such as fever, anxiety, pain, pulmonary embolism, anemia, hypovolemia, or hypoxemia-must be evaluated and treated. Sinus tachycardia may occur as a result of the effects of drugs, such as dobutamine, dopamine, theophylline, and atropine.[543] In the absence of precipitating causes, a persistent sinus tachycardia most likely reflects progressive left ventricular dysfunction, which should be evaluated and managed accordingly.

Frequent atrial premature complexes are relatively common in AMI and are caused by atrial ischemia or infarction and pericarditis.[543-547] No specific therapy is indicated; rather, attention should be given to the underlying disease process.

Paroxysmal Supraventricular Tachycardia

Episodes of paroxysmal supraventricular tachycardia occur rather commonly in AMI and are usually transient.[544] Underlying causes are similar to those of atrial premature complexes. For reasons discussed, the tachycardia may worsen ischemia. Rate control is essential, and the therapeutic approaches-which may include carotid sinus massage, adenosine, digoxin, verapamil, or diltiazem-are discussed in Chaps. 23 and 24.

Atrial Flutter and Atrial Fibrillation

Atrial flutter is relatively uncommon in AMI, whereas atrial fibrillation has an incidence of 10 to 15 percent.[544,545] Atrial fibrillation is associated with an increased in-hospital mortality rate, probably because it is associated with large infarcts and is seen relatively more commonly in older patients and those with cardiac failure, complex ventricular arrhythmias, advanced AV block, atrial infarction, and pericarditis.[548] The pathophysiologic implications are similar to those for paroxysmal supraventricular tachycardia in that a rapid ventricular response can worsen ischemia and infarction by increasing oxygen consumption. Furthermore, the loss of atrial transport can worsen cardiac output and lead to hemodynamic instability.

Atrial fibrillation increases in incidence with age; it occurs in less than 5 percent of patients with AMI under the age of 60 and in about 16 percent of those over age 70.[1] The incidence of atrial fibrillation has been reported to be lower in patients receiving thrombolytic therapy than in control patients.[549]

Systemic embolization occurs more commonly in AMI in the presence of atrial fibrillation (1.7 percent) than in its absence (0.6 percent). Fifty percent of these emboli occur during the first hospital day and 90 percent have occurred by the fourth day.[550] Thus, heparin therapy is indicated in patients not already receiving it, despite that the rhythm is usually transient.

If the patient experiences new or worsening pain, ischemic ST changes, or hemodynamic instability during atrial fibrillation with a rapid ventricular response rate, immediate electrical cardioversion is indicated. In the conscious patient, brief anesthesia is indicated (see Chaps. 24 and 29).

If the clinical situation is less urgent, the ventricular rate can be reduced with drugs. Rapid digitalization with intravenous digoxin is effective but will not result in an immediate response, which may take 1 to 2 h.

In the absence of contraindications such as congestive heart failure or bronchospastic pulmonary disease, intravenously administered beta-blocking drugs are highly effective in slowing the ventricular rate. Intravenous administration of the calcium channel blockers, verapamil or diltiazem, can also be effective in slowing the ventricular response, but these are not considered to be first-line drugs (except possibly in the setting of NQWMI).

Firm recommendations have not been made about the use of class I and III antiarrhythmics to prevent the recurrence of atrial fibrillation in AMI.[1] Since recurrence is associated with a worse prognosis, however, it seems prudent to consider amiodarone or sotalol or, alternatively, quinidine or procainamide. Neither anticoagulation nor antiarrhythmic therapy should be continued for the long term. With stable sinus rhythm, either or both, as the case may be, should be stopped after 6 weeks.

Junctional Rhythm

An escape AV junctional rhythm at a rate of 40 to 60 beats per minute in patients with inferior myocardial infarction and high-degree heart block is not uncommon.[544] Therapy usually is not required. Accelerated junctional rhythms are occasionally seen in AMI, more likely at rates of 70 to 130 beats per minute,[551] but are rarely seen at considerably higher rates. Treatment generally focuses on the underlying conditions, such as ischemia or digitalis toxicity.

Heart Block

First-, second-, and third-degree AV blocks have been discussed briefly. First-degree block is frequently seen in AMI, and especially in inferior myocardial infarction. This is attributable to ischemia or enhanced vagal activity. It can be worsened by drugs such as beta blockers. Treatment is seldom required.

Second-degree AV block is also relatively common, especially Mobitz type I or Wenckebach block. This block, characterized by progressive lengthening of the PR interval before the atrial beat, is not conducted and may occur in as many as 10 percent of AMI patients.[552] It is associated with a narrow QRS and frequently is the result of AV node ischemia in inferior myocardial infarction. It is usually transient, and its presence does not affect the prognosis. Mobitz type II block is uncommon but is associated with more serious complications and a worse prognosis. It usually occurs with anterior myocardial infarction and reflects trifascicular block. It is characterized by a wide QRS and a nonvarying PR interval before a nonconducted atrial beat. Heart block may develop suddenly and is an ominous sign, with a mortality of about 80 percent. It is usually permanent.

Third-degree AV block, or complete heart block, occurs in about 5 percent of patients with AMI and is most commonly seen with inferior infarction, usually with block at the AV node. As indicated, complete heart block in inferior myocardial infarction is usually transient and may occur early or late in the hospital course with the same implications for prognosis. There is some increase in in-hospital mortality rates in this setting, but complete heart block in inferior myocardial infarction is not an independent predictor of poor long-term prognosis.[328] In contrast, patients with anterior infarction who develop third-degree AV block have a mortality rate of 80 percent.[553] Implications for temporary and permanent pacing are discussed subsequently.

Intraventricular Conduction Disturbances

The development of bundle branch block during AMI usually signifies an extensive infarct. In one multicenter trial, the presence of bundle branch block was associated with a twofold increase in the in-hospital mortality rate (28 versus 14 percent), compared with the absence of bundle branch block.[331,554] Data indicate that the presence of bundle branch block identifies patients who (1) are more likely to develop congestive heart failure, (2) are more likely to develop high-degree heart block, (3) are more likely to have an episode of ventricular fibrillation, and (4) have a higher mortality rate.[554]

Indications for Temporary Transvenous Pacing

Recommendations[1]:

Class I

1. Asystole
2. Symptomatic bradycardia (including sinus bradycardia with hypotension and type I second-degree AV block with hypotension not responsive to atropine)
3. Bilateral bundle branch block (alternating or right bundle branch block with alternating left anterior fascicular/posterior fascicular block; any age)
4. New or indeterminate-age bifascicular block (right bundle branch block with left anterior or posterior fascicular block) with first-degree AV block
5. Mobitz type II second-degree AV block

Class IIa

1. Right bundle branch block and left anterior or left posterior fascicular block (new or indeterminate)
2. Right bundle branch block with first-degree AV block
3. Left bundle branch block, new or indeterminate
4. Incessant VT, for atrial or ventricular overdrive pacing
5. Recurrent sinus pauses (greater than 3 s) not responsive to atropine

Class IIb

1. Bifascicular block of indeterminate age
2. New or age-indeterminant isolated right bundle branch block

Class III

1. First-degree heart block
2. Type I second-degree AV block with normal hemodynamics
3. Accelerated idioventricular rhythm
4. Bundle branch block or fascicular block known to exist before acute myocardial infarction

Cardiac pacing is discussed in Chap. 31. The indications generally agreed on for temporary pacemaker insertion in AMI include asystole, complete heart block in the setting of anterior myocardial infarction, new onset of right or left bundle branch block with persistent Mobitz II second-degree AV block in the setting of anterior myocardial infarction, or other symptomatic bradycardias unresponsive to atropine.[200]

Bundle branch block in the setting of AMI, as noted, identifies a population at risk for both electrical and mechanical complications. Such patients must be monitored for evidence of transient high-degree heart block. Prolonged intermediate care with telemetry monitoring and repeat assessments of heart failure status are important.

Permanent Pacing

Recommendations[1]:

Class I

1. Persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or complete heart block after AMI
2. Transient advanced (second- or third-degree) AV block and associated bundle branch block
3. Symptomatic AV block at any level

Class IIb

1. Persistent advanced (second- or third-degree) block at the level of the AV node

Class III

1. Transient AV conduction disturbances in the absence of intraventricular conduction defects
2. Transient AV block in the presence of isolated left anterior fascicular block
3. Acquired left anterior fascicular block in the absence of AV block
4. Persistent first-degree AV block in the presence of bundle branch block that is old or age-indeterminate

The use of permanent pacemakers is discussed in detail in Chap. 31. The subject is reviewed extensively in the ACC/AHA guidelines for pacemaker implantation.[555] That temporary pacing may have been required in the course of AMI does not necessarily indicate a need for permanent pacing. Patients who have had permanent pacemakers inserted after AMI usually have a relatively unfavorable prognosis primarily related to the extensiveness of the underlying disease and myocardial damage.[1] Thus, these patients are at increased risk for death from progressive congestive heart failure and VTs. The generally accepted indications for insertion of a permanent pacemaker after AMI are summarized in the previous recommendations.

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

DISCHARGE FROM THE CORONARY CARE UNIT

The length of stay in the CCU should be based on the risk of developing VT and VF. The risk of developing primary VF after AMI decreases exponentially, with the majority of arrhythmic deaths occurring within the first 24 h. After the third day, the episodes of life-threatening arrhythmias are fairly evenly distributed over the remainder of the hospitalization.[556] Thus, a patient with an uncomplicated infarction can be transferred from the CCU on the third day. Since 31 to 34 percent of in-hospital deaths from AMI occur after discharge from the CCU and half of them are sudden and unexpected, certain patients need more prolonged cardiac monitoring.[557,558] Those patients who are prime candidates for late-hospital sudden deaths manifest, while in the CCU, one or more of the following: (1) the arrhythmias of pump failure (sinus tachycardia, atrial flutter, or atrial fibrillation); (2) the arrhythmias of electrical instability (VT or VF); (3) acute interventricular conduction disturbances; (4) evidence of circulatory failure (congestive heart failure, pulmonary edema, or significant hypotension); or (5) large anterior infarction. The effectiveness of prolonged monitoring of this select group of patients in an intermediate care unit following CCU discharge is evident in a doubling of the rate of successful resuscitations.[559,560] Patients who do not fit into these high-risk subgroups can be discharged from the CCU to a medical unit without continuous monitoring. The wide availability of continuous monitoring in many hospitals in nonacute care units, however, permits easy further monitoring even on lower-risk patients and is preferable if available.

The activity permitted the patient with uncomplicated infarction has changed immensely during the last two decades. In an uncomplicated myocardial infarction, the patient does not need to be confined to the bed for longer than 24 h. In fact, the patient may use a bedside commode from the time of admission. The safety and benefits of chair rest were initially promoted by Samuel Levine and Bernard Lown in 1951.[561] Upon transfer from a CCU, the patient should be started on a program of progressive ambulation. The speed with which the patient progresses from one stage to the next depends on the severity of the infarction, the presence or absence of complications, the patient's age, and the presence of comorbid conditions. The length of hospitalization following an AMI should likewise depend on these same factors. If the patient has not manifested the arrhythmias of pump failure or electrical instability, evidence of circulatory failure, or advanced AV block during the first 4 days of hospitalization, he or she is very unlikely to do so at any later time.[562] This patient could probably be discharged after 7 or fewer days in the hospital.[563] The last 2 to 3 days of the hospitalization are generally necessary to resolve the questions pertaining to residual ventricular function, the presence or absence of ventricular ectopy, and the adequacy of the remainder of the coronary circulation. In addition, time is needed for instruction in risk-factor modification (see Chap. 50). As discussed previously, time in the hospital is being shortened, especially after successful thrombolysis.

Noninvasive Risk Stratification in Patients Surviving Acute Myocardial Infarction

The purpose of risk stratification of patients surviving AMI assumes that the information provided will enhance decision making, resulting in improved long-term outcome. While numerous tests provide prognostic information, only some have resulted in a treatment strategy that improves outcome. No single noninvasive cardiac test better exemplifies this potential "benefit gap" than ventricular premature beats after AMI which are associated with an increased risk of death; however, no antiarrhythmic intervention has been demonstrated to reduce mortality; some have even paradoxically increased the mortality rate.

Survivors of AMI have a substantial risk of incurring subsequent cardiovascular events. Noninvasive risk assessment provides useful information to individualize the extent of further workup and therapy by: (1) targeting specific long-term therapies that are established to alter mortality and morbidity; (2) identifying high-risk patients requiring aggressive diagnostic tests and therapies; (3) identifying low-risk groups as

targets for a conservative approach emphasizing established long-term prophylactic therapies; (4) providing information that facilitates counseling the patient on prognosis; (5) provide data to recommend an exercise program; and (6) provide information used in planning and prioritizing modifications of lifestyle.

Three interrelated prognostic factors are the focus of predischarge assessment: (1) assessment of left ventricular function, (2) detection of residual myocardial ischemia (jeopardized myocardium), and (3) assessment of the risk of arrhythmic (sudden cardiac) death. Most proposed algorithms of noninvasive test selection focus on these three important clinical areas.[564,565] High-risk patients can be clinically identified, as previously discussed, without such noninvasive assessments because of evidence of one or more of the following: decompensated congestive heart failure, angina associated with electrocardiographic changes, in-hospital cardiac arrest, spontaneous sustained VT, or the development of a high-degree heart block.[566-569] In contrast to these high-risk groups, the majority of postinfarct patients have a relatively benign hospital course. In these patients, noninvasive testing can accurately identify a group at very low risk whose annual mortality is 1 to 3 percent.[416,417,570,571] The practical consequences of identifying a low-risk group is that emphasis is focused on early discharge, lifestyle modification and targeted prophylactic medical therapy rather than expensive, invasive diagnostic testing.

As discussed previously, there is general agreement that early coronary angiography and aggressive interventional therapy are indicated for patients with recurrent episodes of spontaneous angina or ischemia, in patients with evidence of persistent decompensated congestive heart failure or cardiogenic shock. In the following sections, the emphasis is on the noninvasive evaluation of asymptomatic patients.

ASSESSMENT OF LEFT VENTRICULAR FUNCTION AND LEFT VENTRICULAR EJECTION FRACTION

Many clinical features are associated with an increased risk for the development of congestive heart failure, including anterior and anterolateral infarction, papillary muscle dysfunction, and recurrent AMI as well as the development of transient episodes of high-degree heart block. Congestive heart failure in the setting of inferior AMI associated with right ventricular infarction is also a prognostically important category, necessitating an aggressive management strategy, as discussed. Measurement of LVEF is mandatory in such patients but also useful in patients without such obvious left ventricular dysfunction. Left ventricular ejection fraction can be assessed by either echocardiographic, radionuclide, or angiographic techniques.[572,573] Left ventricular ejection fraction is an important determinant of survival after AMI regardless of reperfusion status. In-hospital mortality is directly related to the severity of left ventricular dysfunction. In the absence of significant ischemia or ventricular arrhythmias, patients with a LVEF ≥40 percent have mortality rates in the range of 5 percent over 1 to 2 years, whereas a LVEF of 30 to 39 percent or <30 percent have mortality rates that increase to 10 to 15 percent compared to 20 to 25 percent, respectively.[564,572,573] Although measured much less frequently, the end-systolic volume index is also an accurate predictor of survival following AMI.[573,574]

Clinical reflections of the degree of left ventricular systolic dysfunction include the patient's exercise capacity as judged by exercise testing and/or the New York Heart Association clinical classification, which is an independent predictor of outcome. Patients with good exercise capacity, even in the presence of a reduced ejection fraction, have a superior long-term outcome in comparison with those who cannot perform mild-to-moderate exercise.[575]

ASSESSMENT OF MYOCARDIAL ISCHEMIA

Exercise Testing: Timing and Protocol Selection

During hospitalization, in patients recovering from AMI, a practical and safe approach to exercise testing has been to utilize a submaximal treadmill exercise protocol (modified Naughton or modified Bruce protocol) rather than the standard Bruce protocol.[576] The target for completing the test is often symptom-limited exercise to a specific heart rate goal (e.g., 70 to 75 percent age-predicted) or to a peak work level (e.g., 5 metabolic equivalents, or METs) unless other factors (≥2 mm ST depression, chest pain, ventricular arrhythmia, or hypotension) arise first (see Chap. 14). The exercise ECG most accurately reflects the risk of

subsequent ischemic events when baseline ECG is normal.

Exercise testing is also useful in planning the exercise prescription for a cardiac rehabilitation program (see Chap. 50). For safety, patients should be angina-free and free of cardiac failure before exercise testing. Patients selected in this fashion under the supervision of a physician are at minimal risk for complications.[570,571,577,578] One caveat is that in most of these studies, patients exercised 1 to 2 weeks after AMI, a time frame incompatible with managed care early discharge strategies.[577,578]

CLINICAL SIGNIFICANCE OF PREDISCHARGE SUBMAXIMAL EXERCISE TESTING

Numerous studies have analyzed the predictive value of predischarge exercise testing during a 6- to 12-month follow-up after AMI.[570,571] Exercise variables of prognostic significance are exercise-induced ST-segment depression, ST-segment elevation, development of angina during exercise, inadequate blood pressure response to exercise, or exercise of short duration. From the practical standpoint, it is important to consider all of these exercise variables rather than to focus solely on the presence or absence of ST-segment depression. Done appropriately, submaximal exercise testing consistently identifies a high-risk group for recurrent cardiac events (AMI, unstable angina) or mortality in the first year after the AMI. However, the relative risk for mortality or cardiac events associated with a "positive exercise test" varies greatly between studies (twofold to more than 15-fold versus a "negative test"). A normal submaximal exercise test identifies a very low risk group (1 to 3 percent mortality rate for the first year).[570,571,578] Thus, a negative test result is adequately reassuring to encourage early discharge as well as discourage an aggressive diagnostic approach. The ACC/AHA guidelines support the widespread use of submaximal exercise testing in uncomplicated patients before discharge.[1]

For patients with a normal exercise test before discharge, symptom-limited maximal exercise testing can be repeated 2 to 6 weeks after AMI. The maximal exercise test can be used to identify additional high-risk patients.[579,580] The magnitude of this additional ischemia detection, however, as compared to a submaximal exercise test prior to hospital discharge, appears to be modest. Since many cardiovascular events can occur in the first 4 to 6 weeks, predischarge assessment of ischemia is preferred. Evidence of exercise-induced ischemia generally mandates cardiac catheterization to define the coronary anatomy and the consideration of revascularization (see algorithm in Fig. 42-11).[1] The consensus opinion of the ACC/AHA guidelines management group is that exercise testing is still useful in the risk stratification of patients who have received thrombolytic therapy, and it retains a class I indication in uncomplicated patients postinfarction.[1,581,582]

The clinical inference is that the detection of ischemia should lead to coronary arteriography. A randomized trial supports the performance of coronary arteriography in post-myocardial infarction patients with evidence of inducible ischemia before hospital discharge. In the DANAMI trials of 503 patients that survived AMI who were randomized to receive thrombolytic therapy, those patients with evidence of inducible ischemia prior to discharge had a nearly twofold higher cardiac event rate than did a group receiving early invasive intervention.[583] These study results are supportive of the usefulness of coronary arteriography in asymptomatic AMI patients with inducible ischemia.

Ambulatory Electrocardiographic Detection of Myocardial Ischemia

A number of studies have assessed the presence of silent myocardial ischemia (usually defined as ≥1-mm ST-segment depression for ≥30 s) using 24-h ambulatory electrocardiographic monitoring in patients who have survived AMI. Some of the episodes of transient ST-segment depression on ambulatory ECGs are associated with chest pain and typical angina symptoms, but the majority of these ischemic episodes are silent. Many of these episodes of "silent ischemia" occur during levels of low activity and/or mental stress.[584-587] As with other modalities to measure ischemia, the detection of ambulatory electrocardiographic ischemia has been predictive of a poor outcome in long-term follow-up trials in patients surviving AMI. The correlations among exercise testing, ambulatory ECGs, and ischemia detected by thallium appear to overlap but are not identical.[588] No studies show that the reduction in episodes of silent ischemia result in an improved outcome. Thus, routine ambulatory electrocardiographic assessment of ischemia is not recommended.[1]

Alternatives for Evaluating Myocardial Ischemia

THALLIUM-201 SCINTIGRAPHY

There are several alternatives to standard exercise testing. One well-studied technique is exercise thallium-201 scintigraphy, as discussed previously (see Chap. 16). Exercise thallium-201 scintigraphy has a number of potential advantages over routine exercise testing: (1) it can be used when the 12-lead ECG is uninterpretable for ischemic ST-segment shifts because of baseline changes such as a left bundle branch block where it has a class I indication; (2) it allows assessment of reversible and irreversible perfusion defects, both within and outside the vascular region involved in the AMI; (3) the technique of single-photon emission computed tomography (SPECT) thallium scintigraphy provides a semiquantitative evaluation of ischemia; (4) exercise thallium-201 scintigraphy offers superior sensitivity and specificity for the detection of multivessel disease when compared with standard exercise testing; and (5) if pharmacologic adenosine stress is used, it can be safely performed on day 3 or 4 after myocardial infarction.[589,590]

High-risk patients are identified if (1) perfusion defects exist in more than one discrete vascular zone; (2) there is distinct evidence of redistribution; or (3) there was evidence of increased lung uptake. Low-risk patients are defined by thallium scintigraphy showing involvement of a single vascular region without redistribution, with no evidence of increased lung uptake. A high-risk thallium-201 scintigram is correlated with multivessel coronary disease. Thallium scintigraphy has been shown to be excellent at identifying high-grade stenoses of 90 percent or greater, especially high-grade lesions of the left anterior descending coronary artery.[590]

As in routine exercise testing, a limited number of studies have evaluated the value of pharmacologic stress thallium tomography in patients with thrombolytic therapy, with some conflicting results. Provocative pharmacologic studies using thallium-201 tomography also predicted risk of subsequent ischemic events after AMI.[589] Adenosine tomography also offers the advantage of allowing the safe assessment of ischemia as early as 3 to 4 days following AMI. In the era of cost containment and pressure for early hospital discharge, this approach, although not proven, may be beneficial in identifying patients who can safely be discharged early.[589]

Since adenosine single photon emission computed tomography (SPECT) can safely be performed early in asymptomatic post-myocardial infarction patients,[591] it may gain more general acceptance as the preferred test for post-myocardial infarction ischemia. At present ACC/AHA guidelines only give a class I indication to performing this test when the 12-lead ECG is abnormal (uninterpretable). Adenosine SPECT imaging can identify high-risk patients and also can track the relation between therapeutic changes and subsequent changes in risk of cardiac events by tracking changes in perfusion defect size. In a preliminary trial, cardiac event-free survival was 96 percent at 1 year for patients in whom the ischemic burden could be reduced to ≤9 percent by pharmacologic and/or invasive therapy.[591]

Other radionuclide techniques are useful in the evaluation of patients after AMI, but the focus here has been on thallium scintigraphy, which provides prognostic information by the detection of myocardial ischemia. Other techniques include the use of radionuclide angiography for the assessment of ventricular function, including the evaluation of right ventricular infarction, and the use of technetium pyrophosphate to estimate myocardial infarct size and hibernating myocardium. These are summarized in Table 42-6.[185] Only exercise and pharmacologic thallium studies have a class I indication for the evaluation of ischemia.[1] The choice between stress thallium and standard exercise testing depends on ECG interpretability, availability, cost, and clinical experience.[591]

EXERCISE ECHOCARDIOGRAPHY

Exercise two-dimensional echocardiography is an alternative technique for identifying postinfarction ischemia. A reversible segmental wall motion defect is felt to represent an area of significant ischemia. Studies from specialized centers with expertise in echocardiography have shown that exercise or pharmacologic stress echocardiographic studies have a high sensitivity and specificity in identifying

patients with multivessel coronary disease (see Chap. 13).[592-594]

The definition of high risk on dobutamine stress echocardiograms includes (1) the presence of four or more akinetic or diskinetic segments in the infarct territory during low-dose dobutamine (an index of infarct size); (2) the presence of two or more coronary artery territories demonstrating abnormal wall motion at rest or during peak-dose dobutamine; and (3) a lack of improvement in wall thickening (i.e., lack of viability) within the infarct region during low-dose dobutamine infusion.[592,593] As with thallium scintigraphy, the findings of dobutamine stress echocardiograms may provide comparable or superior risk stratification to that of coronary angiography. The procedure is predictive of cardiac events in patients treated with thrombolytic agents as well as in those who did not receive thrombolytic therapy.[594]

Prospective studies to identify the incremental value of exercise echocardiograms compared to routine exercise testing after AMI have not been performed. In general, negative tests with exercise, dipyridamole, or dobutamine echocardiography are associated with a low rate of cardiac events.[592-595] Variation among institutions in expertise in the quality of echocardiographic study and interpretation are limitations to a widespread recommendation for the preferred use of echocardiography.

A multinational study provides long-term verification for the use of pharmacologic stress echocardiography in post-myocardial infarction patients with single-vessel coronary artery disease.[596] Either persantine or dobutamine stress resulted in useful long-term prognostic information, with stress echocardiographic "ischemia" detection associated with high 4-year rates of myocardial infarction. The investigators emphasized that stress echocardiography provided effective risk stratification at a relatively low cost.[596]

META-ANALYSIS OF VARIOUS METHODOLOGIES OF EXERCISE TESTING POST-MYOCARDIAL INFARCTION

In their comprehensive meta-analysis of alternative methodologies of post-myocardial infarction exercise testing by Peterson and colleagues, a few general patterns are apparent (Table 42-17). All exercise testing modalities share a high negative predictive value. However, all testing modalities have a rather dismal positive predictive value. None of the more sophisticated technologies appear to have a positive predictive value for subsequent cardiac events that substantially exceed simple stress echocardiography. The prognostic value of the testing modalities appear equally valid in patients with thrombolytic therapy.[597]

Exercise Testing in Uncomplicated Patients

Recommendations[1]:

Class I

a. Stress electrocardiography
b. Before discharge, for prognostic assessment or functional capacity (submaximal at 4 to 6 days or symptom-limited at 10 to 14 days)
c. Early after discharge for prognostic assessment and functional capacity (14 to 21 days)
d. Late after discharge (3 to 6 weeks) for functional capacity and prognosis if early stress was submaximal
e. Exercise, vasodilator stress nuclear scintigraphy, or exercise stress echocardiography when baseline abnormalities of the ECG compromise interpretation

Class IIa

1. Dipyridamole or adenosine stress perfusion nuclear scintigraphy or dobutamine echocardiography before discharge, for prognostic assessment in patients judged to be unable to exercise
2. Exercise two-dimensional echocardiography or nuclear scintigraphy (before or early after discharge for prognostic assessment)

Class III

1. Stress testing within 2 to 3 days of AMI.
2. Either exercise or pharmacologic stress testing at any time to evaluate patients with unstable postinfarction angina pectoris.
3. At any time, to evaluate patients with AMI, who have uncompensated congestive heart failure, cardiac arrhythmia, or noncardiac conditions that severely limit their ability to exercise.
4. Before discharge, to evaluate patients who have been selected for cardiac catheterization. In this situation, the exercise test may be useful after catheterization to evaluate function or identify ischemia in a distribution to correlate with coronary stenoses judged to be of borderline severity.

Suggested Algorithm for the Evaluation of Myocardial Ischemia after Myocardial Infarction

Based on all of the evaluable data, the task force on practice guidelines for the management of AMI created a strategy for the evaluation of myocardial ischemia after AMI in low-risk patients, presented in Fig. 42-11.[1] If there are clinical indications of a high-risk patient, as detailed earlier, such patients are considered for early cardiac catheterization and coronary angiography (strategy I).[1] The evaluation of myocardial ischemia in low-risk patients is alternatively presented for strategies II and III. Strategy III favors using a submaximal exercise test or alternative imaging study prior to hospital discharge. Strategy II alternatively suggests that a symptom-limited exercise test be performed soon after hospital discharge. Regardless of whether exercise testing or a more sophisticated exercise imaging study is ordered in the hospital, a negative test does not preclude the repeat evaluation for myocardial ischemia once the patient is fully ambulatory, after 3 to 6 weeks.

ASSESSMENT OF THE RISK OF ARRHYTHMIC (SUDDEN CARDIAC) DEATH: OVERVIEW

Although the technology to assess the risk of arrhythmic death in patients after AMI has improved in sophistication, antiarrhythmic therapies to reduce risk have thus far proved disappointing. For comparison, there is consensus that the identification of postinfarction patients with a LVEF of ≤40 percent mandates the use of ACE inhibitors.[392,393,598] Likewise, the identification of asymptomatic postinfarction patients with ischemia indicates the need for early performance of coronary angiography to assess the potential for PTCA or coronary artery bypass surgery.[1] Unfortunately, the identification of asymptomatic but high-risk patients for arrhythmic death after AMI is not similarly associated with a successful treatment strategy. This section addresses AMI patients who are asymptomatic and have not had sustained VT or VF-identifiers that all agree require aggressive management, most commonly the placement of an implantable cardioverter defibrillator (ICD).

The preponderance of evidence is that the majority of asymptomatic AMI patients who experienced arrhythmic (sudden cardiac) death have had sustained VT and/or VF.[599] A review of selected clinical trials of antiarrhythmic therapy focusing on patients after AMI is presented in Table 42-18[392,393,598,600,605] for the purpose of demonstrating the total deaths attributable to arrhythmic or sudden cardiac death, which vary widely in the placebo groups of these trials. The Cardiac Arrhythmia Suppression (CAST) trials[600,601] and the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT)[604] identified high-risk patients after AMI using the criteria of ventricular arrhythmia on ambulatory ECGs. In the placebo groups, the range of death attributable to arrhythmia varied from 48 to 66 percent. The Survival and Ventricular Enlargement (SAVE) trial,[392] the European Myocardial Infarction Amiodarone Trial (EMIAT),[603] and the Survival With Oral d-sotalol (SWORD)[602] trial identified patients after AMI using an ejection fraction cutoff. The range of deaths attributable to arrhythmia in the placebo group was 45 to 67 percent. Patients in trials with a mixture of etiologies of left ventricular dysfunction including old AMI, such as the Studies of Left Ventricular Dysfunction (SOLVD) prevention and SOLVD treatment trials, have a lower percentage of deaths attributable to arrhythmia.[393,598] The wide discrepancy in arrhythmic death rates and the variety of screening tests used to identify "high-risk" patients highlight a significant deficit in current arrhythmic death classification.[605]

Table 42-18: Review of Representative Clinical Trials: Placebo Cause-Specific Mortality

Trial (No. of Placebo Patients), Entrance Criteria	Mean Follow-up (months)	Annualized Mortality, %	Arrhythmia/SCD, %
CAST I[600] (743), VPC ≥6/VT/AMI	10	4.2	62
CAST II[601] (574), VPC ≥6/VT/AMI/EF ≤40%	18	6.4	66
SAVE[392] (1116), EF ≤40%/AMI 3-16 d	42	7.1	45
SOLVD PREV[598] (2117), No CHF/EF ≤35%	37	5.3	31
SOLVD Rx[393] (1294), CHF (II/III) + EF ≤35%	41	11.7	22
SWORD[602] (1572), MI, EF ≤40%	5	1.5	67
EMIAT[603] (743), MI + <40%	21	7.8	49
CAMIAT[604] (596), MI + VPC ≥10 or VT	20	4.7	48

ABBREVIATIONS: SCD = sudden cardiac death; CAST = Cardiac Arrhythmia Suppression Trial; VPC = ventricular premature complexes; VT = ventricular tachycardia; AMI = acute myocardial infarction; EF = ejection fraction; SAVE = Survival and Ventricular Enlargement; SOLVD = Studies of Left Ventricular Dysfunction; PREV = prevention; CHF = congestive heart failure; Rx = treatment; SWORD = Survival With Oral d-Sotalol; EMIAT = European Myocardial Infarction Amiodarone Trial; CAMIAT = Canadian Amiodarone Myocardial Infarction Arrhythmia Trial.

The changing proportion of deaths attributable to arrhythmia and other causes after AMI is conceptually depicted in Fig. 42-12. Sustained VT and VF occur most frequently in the first year following AMI.[564] As ischemic cardiomyopathy develops over many years, deaths attributable to VT/VF decrease and proportionately more "sudden deaths" are attributable to asystole, electromechanical dissociation, or a high-degree heart block.[606] Also, noncardiac conditions emulate the circumstances of VT or VF (for instance, massive pulmonary embolism, ruptured abdominal or thoracic aortic aneurysm, or massive stroke).[605] Thus, the temporal influence on cause-specific mortality after AMI is an important consideration. Risk stratification for arrhythmic death is clearly more relevant immediately following myocardial infarction (Fig. 42-12).

This discussion is limited to tests available for evaluating asymptomatic patients. The preponderance of evidence does not support a class I or even a class IIa indication for any of the modalities to be discussed: ambulatory ECG, heart rate variability, signal averaged ECG, or electrophysiologic testing. What is lacking in each is the absence of compelling data that the identification of "arrhythmic death risk" is coupled with a strategy to improve outcome.[1]

Ambulatory Electrocardiographic Recordings: Ventricular Arrhythmias

Asymptomatic spontaneous ventricular arrhythmias detected on ambulatory ECGs are predictive of an increased risk of arrhythmic (sudden) death in the first 1 to 2 years following AMI.[564,607] The mechanism responsible for the majority of arrhythmic deaths in post-myocardial infarction patients is, as noted, sustained VT or VF.[599] Vulnerability for arrhythmic death appears to be highest in the first year after AMI,

probably accounting for one-half of the first-year mortality.[564,607] Thus, it appears that arrhythmic death risk should be assessed prior to hospital discharge. The use of ambulatory electrocardiographic recording to identify a "high-risk" group, however, has a poor positive predictive value.[600,608] As seen in Table 42-19, postinfarction patients with no baseline ventricular arrhythmia on ambulatory electrocardiographic recording uniformly have a low risk for arrhythmic death.[564,608] Frequent premature ventricular complexes and nonsustained VT are generally associated with a two- and threefold increased risk, respectively.[13,564,607,608] As can be deduced from the data in Table 42-19, for every 100 patients identified with "warning arrhythmias," only 4 to 7 will have arrhythmic death in the following 1 to 2 years. Thus, a treatment strategy that would include routine prophylactic administration of an antiarrhythmic drug would necessitate a superb safety profile, since approximately 95 percent of the patients cannot benefit but all would be exposed to potentially lethal proarrhythmic risk. Such hazards have been documented in prophylactic antiarrhythmic drug trials.[600-602] Thus, ambulatory ECG has an adequate negative predictive value, but a poor positive predictive value, consistent with its class IIb rating.

Ambulatory Electrocardiogram Recordings: Heart Rate Variability

Heart rate variability, measured by the standard deviation of the RR interval on monitored electrocardiographic leads, is an indirect assessment of proportional autonomic tone. Extensive variability in the heart rate connotes a preponderance of parasympathetic activity, whereas less variability in the heart rate is consistent with proportionately more sympathetic activity.[609-611] In animal models, enhanced sympathetic activity increases the vulnerability of the ischemic myocardium to the development of VF.[612]

Clinical trials have assessed the relation of heart rate variability to mortality rate in patients surviving AMI. Depressed heart rate variability is associated with an increased risk of death. Multivariate analysis has identified reduced heart rate variability as an independent predictor of arrhythmic death.[609-611,613] In one study, patients selected for depressed heart rate variability and ventricular arrhythmias, excluding patients with the lowest ejection fractions, identified a patient population in whom 75 percent of the deaths were presumed arrhythmic.[614] Heart rate variability measured after thrombolytic therapy still has clinical relevance, and an improvement in heart rate variability correlated with TIMI grade 3 flow.[615]

Practical approaches to minimizing cost, while focusing noninvasive testing on a targeted group, are under evaluation. In a study of 729 survivors of AMI prior to hospital discharge from St. George's Hospital in London, a 24-h heart rate variability index was compared to a 5-min analysis of an ectopic-free segment of the Holter recording, measuring the standard deviation of normal-to-normal RR intervals (SDNN).[616] The 5-min analysis of SDNN measurement was a useful and inexpensive tool to select patients for more extensive 24-h heart rate variability index evaluation.[4]

At present, while heart rate variability is a very promising method of evaluating parasympathetic and sympathetic effects in the heart, it cannot be recommended as a standard clinical test in AMI patients, unless and until trials demonstrate clinical benefits of a treatment strategy based upon the knowledge of this marker of sudden cardiac death.[1,617]

Baroreflex Sensitivity

Baroreflex sensitivity is another autonomic marker that is a measure of the change in heart rate (anticipated reduction) to an increase in blood pressure. In this respect, it provides an index of the ability to reflexly increase cardiac vagal activity. Heart rate variability, in contrast, is a marker of vagal tone.[618]

The importance of these two autonomic markers is demonstrated by the results of the Autonomic Tone and Reflexes After Myocardial Infarction (ATRAMI) trial, a study of 1284 patients with a recent (≤28 days) myocardial infarction.[619] One-year mortality was increased in patients with a reduced baroreflex sensitivity as well as a low heart rate variability (see Table 42-20).[618] There was an additive value to the measurement of the two markers: If both are low there is a 15-fold increased risk of death than if both markers are normal (15 versus 1 percent; $p < 0.0001$). The interaction of LVEF and these autonomic markers is also apparent from Table 42-20, each being associated with a twofold greater risk of death in patients with LVEF <35

percent than it is in those with better preserved left ventricular systolic function. It is reasonable to conclude that both baroreflex sensitivity and heart rate variability have independent prognostic value for stratifying the risk of death after myocardial infarction.[74]

Table 42-20: Multivariate Analysis of Influence of Baroreceptor Sensitivity and Heart Rate Variability on Relative One-Year Mortality Risk after AMI

Variable Examined	Variable in Analysis	Groups	RR	95% CI	P
Baroreflex sensitivity	LVEF	35-50%	2.1	0.90-4.69	0.08
		<35%	4.7	2.04-10.9	0.0003
	BRS (ms/mmHg)	3.0-6.1	1.7	0.81-3.69	0.15
		<3.0	2.8	1.24-6.16	0.01
	VPCs per h	≥10	1.8	0.94-3.46	0.07
Heart rate variability	LVEF (%)	35-50%	1.9	0.87-4.49	0.10
		<35%	3.9	1.69-9.25	0.001
	SDNN	70-105	1.9	0.86-4.04	0.11
		<70	3.2	1.42-7.36	0.005
	VPCs per h	≥10	1.8	0.97-3.50	0.06

ABBREVIATIONS: RR = relative rate; CI = confidence interval; LVEF = left ventricular ejection fraction; BRS = baroreflex sensitivity; VPC = ventricular premature complex; SDNN = standard deviation of all normal beats.

Signal-Average Electrocardiogram

Time-domain analysis of the signal-averaged ECG can be used to detect low-amplitude, high-frequency potentials at the end of the QRS complex, termed *ventricular late potentials*. The presence of late potentials identifies patients likely to have inducible sustained monomorphic VT during programmed electrical stimulation and is associated with an increased risk of subsequent arrhythmic events.[609,620,621] The predictive value of late potentials is best established in patients with AMI and is of less established value in other patient populations.

In some studies, the presence of an abnormal signal-averaged ECG, of frequent ventricular premature complexes on the ambulatory electrocardiographic recording, and left ventricular aneurysm were independent predictors of VT, regardless of whether or not a patient had received thrombolytic therapy.[621] If results of the signal-averaged ECG are negative-that is, there are no afterdepolarizations-the negative predictive value in this population is good and the likelihood of subsequent arrhythmic death is low. As with the evaluation of heart rate variability, the interpretation of the signal-averaged ECG can be improved by combining it with other variables, especially the LVEF. Even when multiple tests are combined for assessing the risk of sudden cardiac death, the strength is in their negative predictive value rather than their positive predictive value, which usually falls below 50 percent.[620,621] There is an adverse prognostic consequence of a positive signal-averaged ECG and an occluded infarct-related artery.[622] The routine use of signal-averaged ECGs in AMI is not at present recommended.[1]

Invasive Electrophysiologic Testing (Programmed Electrical Stimulation)

Invasive electrophysiologic assessment has been evaluated in two distinct populations who survived AMI. The first and relatively small group had a cardiac arrest or an episode of sustained VT following an AMI. In such patients, the risk of recurrent cardiac arrest or arrhythmic events is high, and electrophysiologic studies are an alternative for assisting in therapy selection.[623]

The much larger patient population are those with an increased risk of arrhythmic death based upon the results of one or more noninvasive tests, as discussed previously. Performing electrophysiologic studies on all asymptomatic "high-risk" patients is not justified.[1] Reports on the utility of electrophysiologic studies have been inconsistent in predicting total mortality and are only slightly more consistent in identifying patients likely to have subsequent arrhythmic events.[624,625]

Results from the Multicenter Automatic Defibrillation Implantation Trial (MADIT) are somewhat relevant to this issue.[626] Patients in MADIT had had a prior Q-wave infarction with a LVEF of <35 percent and were selected if programmed electrical stimulation induced sustained VT that was nonsuppressible with intravenous procainamide. Patients were randomized to an implantable cardioverter-defibrillator group and/or conventional arrhythmic therapy. Although total mortality was less in the cardioverter-defibrillator group, the relevant point is that this invasive screening appeared to identify a high-risk group for subsequent arrhythmic death.[626] This study alone is not sufficient, however, to support the wider use of electrophysiologic testing in asymptomatic postinfarction patients for at least two reasons: (1) imbalances in the use of beta blockers between the two treatment strategies cloud the results, and (2) these patients were many years from their index infarction. Therefore, the relevance to predischarge risk assessment of AMI is tenuous.

Assessing Arrhythmic Death: Conclusions

In the ACC/AHA guidelines, none of the noninvasive techniques is generally agreed upon to be beneficial, useful, and effective, either unequivocally (class I) or based upon the weight of evidence or opinion (class IIa) for predicting arrhythmic death. These techniques have class IIb indications, meaning that their usefulness and efficacy are not well established by either scientific evidence and/or general opinion.[1] In addition to their poor positive predictive value, no clinical trial has demonstrated that the use of any one or a combination of these modalities of testing identifies a high-risk population in whom an intervention strategy results in clinical benefit. Unless and until such studies are carried out to show that targeting a high-risk population and using the data to direct subsequent prophylactic therapy result in patient benefit, these modalities of risk assessment remain interesting tools for investigational studies and for use on selected individual patients. Other assessments of risk for sudden death, such as QT dispersion, are in an even earlier investigational stage, and at present, there is little supporting evidence that they are useful and effective in improving the management and outcome of AMI patients.[1,627]

Coronary Angiography and Percutaneous Transluminal Coronary Angioplasty

Recommendations[1]:

Class I

1. Patients with spontaneous episodes of myocardial ischemia or episodes of myocardial ischemia provoked by minimal exertion during recovery from infarction
2. Before definitive therapy of a mechanical complication of infarction such as acute mitral regurgitation, VSD, pseudoaneurysm, or left ventricular aneurysm
3. Patients with persistent hemodynamic instability

Class IIa

1. When myocardial infarction is suspected to have occurred by a mechanism other than thrombotic occlusion at an atherosclerotic plaque. This would include coronary embolism, certain metabolic or hematologic diseases, or coronary artery spasm.
2. Survivors of AMI with depressed left ventricular systolic function (left ventricular ejection fraction

less than or equal to 40 percent), congestive heart failure, prior revascularization, or malignant ventricular arrhythmias.
3. Survivors of AMI who had clinical heart failure during the acute episode but subsequently demonstrated well-preserved left ventricular function.

Class IIb

1. Coronary angiography performed in all patients after infarction to find persistently occluded infarct-related arteries in an attempt to revascularize the artery or identify patients with three-vessel disease
2. All patients after a non-Q-wave myocardial infarction
3. Recurrent VT or VF or both, despite antiarrhythmic therapy, in patients without evidence of ongoing myocardial ischemia

Class III

1. Routine use of coronary angiography and subsequent PTCA of the infarct-related artery within days after thrombolytic therapy
2. Survivors of myocardial infarction who are thought not to be candidates for coronary revascularization

The selection of patients for cardiac catheterization and coronary angiographic studies prior to hospital discharge should be based on identifying patients at risk for ischemic events and on whether the information provided by cardiac catheterization and coronary angiography will change patient management.

Studies analyzing the prognostic utility of cardiac catheterization prior to hospital discharge are from the prethrombolytic era and demonstrate that the angiographic extent of coronary artery disease was related to survival.[628,629] Other trials have addressed the utility of routine coronary angiographic studies in patients who have received thrombolytic therapy.[630-633] The timing of cardiac catheterization during hospitalization has been addressed in several studies. In general, studies that have compared acute or early cardiac catheterization to a more conservative approach of performing cardiac catheterization and coronary angiographic studies only for patients with spontaneous recurrent angina or exercise-induced ischemia have demonstrated no benefit to the strategy of routine catheterization.[1,271]

Figure 42-11 presents a strategy for identifying symptomatic and asymptomatic high-risk patients who should have cardiac catheterization and coronary angiographic studies before discharge. Patients who have a complicated clinical course characterized by refractory cardiac failure, unstable angina, an episode of sustained VT, or cardiac arrest should be studied, as discussed previously. An aggressive approach to these patients is justified because of the observed 1-year mortality rate, ranging from 10 to 25 percent.[634] In the case of patients with symptomatic cardiac failure, right heart catheterization should be included.

The recommended algorithm for selecting asymptomatic, uncomplicated post-AMI patients for cardiac catheterization is also presented in Fig. 42-11. Decision making focuses on the presence or absence of myocardial ischemia. Because of the high incidence of residual ischemia in patients with a non-Q-wave infarction, the task force for guidelines for coronary angiographic studies after myocardial infarction recommended such studies in all non-Q-wave infarctions.[635] The more conservative recommendation here emphasizes evidence of objective ischemia. Where patients have received thrombolytic therapy, it seems reasonable that those who have evidence of residual ischemia are still at increased risk of future ischemic events and should undergo coronary angiography prior to discharge. Consideration of PTCA following coronary angiographic studies should be based on established clinical and anatomic guidelines[1,636] (see Chap. 45). Coronary artery bypass surgery should be considered in those groups in whom it has been shown to be of proven benefit: patients with triple-vessel disease, patients with ischemia, and those with significant left ventricular dysfunction (see also Chap. 48).[637]

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

SECONDARY PREVENTION AND CARDIAC REHABILITATION

Risk Factor Reduction

The relation between the level of activity of the inflammatory response in the arterial wall (which is the characteristic feature of atherosclerosis) and the tendency of the structural integrity of the artery to break down, with the resultant exposure of thrombogenic material and clot formation, is discussed in Chap. 35. The inflammatory response is caused and/or exacerbated by the presence of the classic risk factors. It follows that favorably modifying the risk factors would, intuitively, reduce coronary events. There is now abundant evidence that this is the case. Thus, since those who have had AMI are among those at highest risk for recurrence, management strategies to mitigate this risk are very important in patient management.[638]

SMOKING

Smoking has multiple cardiovascular effects that can promote AMI, including enhanced platelet aggregation, coronary vasospasm, and vascular inflammation. Smoking cessation is an essential goal after AMI, since the recurrence rate and death rate after AMI are doubled by the continuation of smoking (see also Chap. 38).[639] After AMI, however, risk associated with smoking declines rapidly to that of the nonsmoking cohort survivors within 3 years.[640] The psychological and physiologic aspects of smoking should be addressed, and a number of programs have been developed to deal with these needs. Most smokers who have quit, however, have done so without an organized program.[641] The role of the physician in motivating the patient to quit smoking is extremely important and the likelihood of success appears to be directly related to the extent of his or her involvement. Transdermal nicotine patches and oral preparations can be used to aid withdrawal but are not risk-free and should be used temporarily and adjunctively with physician counseling and/or a formal program in behavior modification.[642] The transdermal patches or oral nicotine preparations should not be used during the period just after AMI and should not be used concurrently with smoking. Difficult cases are probably handled best by referral to a formal smoking cessation program. Clonidine hydrochloride has also been used to ameliorate symptoms of smoking withdrawal as well as in conjunction with behavioral intervention.[638]

DYSLIPIDEMIA

Recommendations[1]:

Class I

1. Institute of the American Heart Association (AHA) step II diet, which consists of <7 percent of total calories as saturated fat and <200 mg/day of cholesterol in all patients after recovery from AMI.
2. Patients with low-density lipoprotein (LDL) cholesterol levels >125 mg/dL, despite consuming the AHA step II diet, should be placed on drug therapy with the goal of achieving a target LDL cholesterol <100 mg/dL.
3. Patients with normal plasma cholesterol levels who have a high-density lipoprotein (HDL)

of less than 35 mg/dL should be placed on an exercise regimen to atttempt to increase it.

Class IIa

1. Drug therapy may be added to diet therapy in patients with LDL cholesterol levels <130 mg/dL but >100 mg/dL after an appropriate trial of the AHA step II diet alone.
2. Patients with normal total cholesterol levels, but with HDL cholesterol <35 mg/dL despite dietary and other nonpharmacologic therapy, may be started on drugs such as niacin in an attempt to raise HDL levels to more protective levels.

Class IIb

1. Drug therapy using either niacin or gemfibrozil may be added to diet regardless of LDL and HDL levels when triglyceride levels are >200 mg/dL.

The β-hydroxy- β-methylglutaryl-CoA (HMG-CoA) reductase inhibitors are the most effective drugs in lowering LDL cholesterol. Niacin is effective in raising HDL and, in combination with resins, is also effective in lowering LDL. Triple therapy with a reductase inhibitor, niacin, and resin can be useful in resistant cases. Drug therapy of dyslipidemias is discussed in Chap. 38.

As mentioned earlier, patients who have had an AMI are generally at high risk for recurrence. Furthermore, an abnormally elevated serum cholesterol level is a powerful risk factor for death in this group.[643,644] Early primary prevention studies and relatively small angiographic trials showed decreases in cardiovascular event rates with cholesterol-lowering therapy (see Chap. 38). Large secondary prevention trials have provided compelling evidence that in patients who have had an AMI, therapy with HMG-CoA reductase inhibitors to lower serum cholesterol levels that were either initially elevated-as in the Scandinavian Simvastatin Survival Study (4S)[645] or within "average" range as in the Cholesterol and Recurrent Events (CARE) trial[646]-was effective in reducing both cardiovascular and total mortality as well as cardiovascular events. In CARE, a treatment effect was not observed in the group with baseline LDL values <125 mg/dL. The guidelines of the expert panel of the National Cholesterol Education Program provide target goals for patients with manifest coronary artery disease. These goals are as follows: LDL cholesterol, 100 mg/dL (2.59 mmol/L); HDL cholesterol, >35 mg/dL (0.91 mmol/L).[647]

Serum lipid levels are decreased within several hours after AMI, presumably by the inflammatory response to tissue necrosis.[648] Evaluation of serum lipid levels should be made within the first 6 to 8 h from onset of symptoms or after recovery at 6 to 8 weeks. All AMI patients should have serum lipids evaluated and treated intensively in order to achieve target goals. Treatment should start in the hospital with initiation of the AHA step II diet. With established very high lipid levels (for example, LDL cholesterol >200 mg/dL), many clinicians would have a low threshold for initiating drug therapy early on, anticipating that diet therapy alone might not be sufficient for achieving target LDL goals. Although low HDL is a powerful risk factor for AMI, the benefit of treating it is unproven. It seems prudent to attempt to raise HDL levels by prescribing an exercise regimen. Niacin is also efficacious in raising HDL levels; it may be used, especially if indicated as adjunctive therapy with HMG-CoA reductase inhibitors or with resins, to lower LDL. There is less certainty about indications for treating elevated triglycerides, but it seems prudent to treat levels >400 mg/dL with diet and perhaps with fibrates or niacin (see Chap. 38).

INACTIVITY

There have been numerous studies of post-AMI patients documenting the beneficial effects of

aerobic exercise on functional capacity and myocardial oxygen demand at a given submaximal workload.[649] Such exercise can decrease angina pectoris and ischemia. Conversely, a sedentary lifestyle is a risk factor for coronary artery disease. Meta-analysis of cardiac rehabilitation studies has shown a reduction in mortality in the exercise group as opposed to a control group.[649] These analyses have not permitted separating the effects of exercise per se from the other beneficial aspects of the programs. The greatest benefits of exercise are those observed with moderate, regular exercise as contrasted with the nonexercise group. The benefit can be obtained by exercising about 4200 kJ a week, which can be achieved by walking about 1.5 miles (2.4 km) per day. Long-term, regular exercise training can best be sustained by participating in a supervised exercise program beginning several weeks after discharge from the hospital.[638,649] A standard exercise program might involve three 20- to 30-min sessions three to four times per week at 60 to 75 percent of maximal aerobic capacity. This target activity level should be achieved progressively over several weeks, and progress should be monitored by the physician at regular intervals. The exercise regimen should be initiated and guided by monitored exercise testing.

Regular aerobic exercise should be prescribed for post-AMI patients in stable condition at an intensity, duration, and frequency as determined by formal testing and clinical judgment. Optimum benefit is achieved in a supervised program, although asymptomatic, stable patients can exercise without direct supervision but should receive regular monitoring by a physician (see also Chap. 50).

LOW-ESTROGEN STATES (FEMALES)

Recommendations[1]:

Class IIa

1. Hormone replacement therapy (HRT) with estrogen plus progestin for secondary prevention of coronary events should not be given de novo to postmenopausal women after myocardial infarction.
2. Postmenopausal women who are already taking HRT with estrogen plus progestin at the time of an AMI can continue this therapy.

Estrogen replacement therapy and the primary or secondary prevention of cardiovascular disease continues to be a somewhat contentious and emotional issue that involves weighing the potential efficacy of ERT in reducing cardiovascular risk against the possible increases in breast cancer rates.[650,651] Clinical trials have demonstrated that estrogen with or without progestins lowers both LDL cholesterol and fibrinogen,[652] an effect that would be expected to reduce cardiovascular risk. Contrary to conventional wisdom and expectations, the first large double-blind, placebo-controlled trial to assess the effects of estrogen and progestin treatment on the secondary prevention of coronary heart disease in postmenopausal women showed no reduction in any cardiovascular outcome after 4.1 years of follow-up.[653] Furthermore, the Heart and Estrogen-Progestin Replacement Study (HERS) Research Group reported a significant trend for more primary cardiac events in the treatment group than it did in the placebo group in year 1, although there were fewer events in years 4 and 5 in the treatment group than there were in the placebo group.[653] These observations led to the recommendation that, post-AMI, women on hormone replacement therapy at the time of the event should continue but that initiation of therapy could not be recommended[1].

Drug Therapy

BETA-ADRENERGIC BLOCKERS

Recommendations for long-term therapy in post-AMI patients[1]:

Class I

1. All post-AMI patients except those at low risk without clear contraindications should receive long-term therapy. Treatment should begin early in the course, preferably acutely, and should be continued indefinitely.

Class IIa

1. Low-risk patients without definite contraindications should be considered for beta-adrenergic blocker therapy
2. Survivors of non-ST elevation myocardial infarction

Class IIb

1. Patients with moderate or severe left ventricular failure or other relative contraindications of beta-adrenoceptor blocker therapy, provided they can be monitored closely

Class III

1. None

The benefits of beta-blocker therapy given early in the course of AMI were previously discussed. Multiple clinical trials have also demonstrated the benefits of long-term treatment of post-AMI patients with beta blockers.[654] Long-term efficacy has been demonstrated for propranolol,[13] timolol,[655] and metoprolol.[656] Mortality has been shown to be reduced by about 25 to 35 percent. The beneficial effect is highest in high-risk patients with large (usually anterior) myocardial infarction, and compensated left ventricular dysfunction. The beneficial effects in low-risk patients are less clear, but the consensus is that these patients should probably be treated because of the relatively favorable side-effect profile.[1] This recommendation extends to the patient with NQWMI although, as discussed, the data are less compelling. Beta blockers with intrinsic sympathomimetic activity should not be used in this context.

ASPIRIN

The role of aspirin during the early phases of AMI was discussed earlier. Aspirin use over the long term after AMI is also associated with a reduction in mortality. Meta-analysis of 6 major trials of aspirin treatment showed an overall reduction in vascular mortality in the treated group of 13 percent, with 31 and 42 percent reductions in nonfatal infarction and nonfatal stroke, respectively.[657] These trials used relatively large aspirin doses (300 to 1500 mg/day), but one trial showed efficacy at only 75 mg/day,[658] suggesting that long-term use of more modest doses would be effective. Thus, aspirin at relatively low doses is recommended for all patients with AMI in the absence of contraindications (see also Chap. 44).

ANTICOAGULATION

Anticoagulation can reduce mortality, recurrent myocardial infarction, and stroke after AMI, as indicated by an analysis of multiple trials.[654] Because of relatively high rates of bleeding with warfarin, the need for monitoring, and, in particular, the efficacy and low risk of aspirin, the role of warfarin is rather limited to those at increased risk for developing mural thrombi.[638] In addition, those post-AMI patients with demonstrable left ventricular thrombus and atrial

fibrillation should be anticoagulated. The duration of anticoagulation should be limited to 3 months in the case of left ventricular thrombus.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The ACE inhibitors and recommendations for their use early in the course of AMI were previously discussed. Studies have documented their efficacy in secondary prevention. The reduction in late morbidity and mortality was most obvious in those with large infarctions with reduced ejection fraction and in those with anterior myocardial infarction. In these patients, left ventricular remodeling and progression to heart failure were reduced.[392,396,659] The beneficial effects of ACE inhibitors have been less obvious when low-risk patients were included.[660] The decrease in ischemic events in the SAVE trial[392] and in other ACE-inhibitor trials suggests that the threshold for use of ACE inhibitors for long-term therapy may be lowered by many clinicians to include those with only modest left ventricular dysfunction. Thus, ACE inhibitors have been recommended for chronic use after AMI in those patients with significant left ventricular dysfunction, and their use should be considered in those with only mild-to-moderate left ventricular dysfunction (ejection fraction <45 percent).

The publication of the Heart Outcomes Prevention Evaluation (HOPE) trial in patients with significant risk factors for cardiovascular events showed significant reduction in new events and new-onset diabetes mellitus in those treated with the ACE-inhibitor ramipril.[398] It is likely that the recommendations for use of ACE inhibitors will be extended to all patients at high risk for cardiovascular events regardless of blood pressure or left ventricular function.

Modification of Lifestyle and Cardiac Rehabilitation after Acute Myocardial Infarction

Because of the relatively high risk of recurrence and the need for lifelong modification of lifestyles and risk factors, most post-AMI patients should be enrolled in a cardiac rehabilitation program that emphasizes dietary modification, risk factor reduction, and exercise. The low-risk patient does not require prolonged supervised exercise, as previously discussed. All patients, however, can benefit from a structured environment to launch a lifetime of healthy living. Cardiac rehabilitation is discussed in Chap. 50 and risk factors and the prevention of coronary artery disease are discussed in Chap. 38.

There has been considerable reinvigoration of interest in the potential of dietary interventions in secondary prevention after AMI since the publication of the results of the Lyon Diet Study[661] and of the GISSI-Prevention Study.[662] Both of these studies showed dramatic (>30 percent) reduction in recurrence of cardiovascular events in patients in whom a diet and supplements rich in omega-3 fatty acids was added to adequate conventional therapy. Thus, in view of the minimal or absent risk it seems prudent to recommend that patients incorporate into their dietary regimes sources of omega-3 fatty acids (fish: especially tuna, salmon, and sardines; nuts such as walnuts; and probably fish oil supplements).

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

List of Tables

Chapter 42: DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

List of Figures

Figure 42-1: Electrocardiographic evolution of acute anterior and inferior myocardial infarction. *A*. Hyperacute phase. There is marked ST-segment elevation in V_2 to V_5 in the anterior infarction and in II, III, and aV_f in the inferior infarction. In the inferior infarction, there are reciprocal changes or posterior involvement as reflected in the ST-segment depression in the precordial leads. There are no QRS changes in either case. *B*. Acute phase. Q waves indicating myocardial necrosis develop during this phase. There is some persis-tent ST-segment elevation and the T-wave vector generally points toward the infarct zone. *C*. Subacute phase. QRS changes are well developed and ST-segment elevation is still present. The T vector, or, more precisely, the terminal portion of the T vector, begins to point away from the infarct zone. *D*. Chronic phase. Minimal or no ST-segment elevation is present, and the T wave is directed away from the infarct zone. (From Wagner et al.,[78] with permission.)

Figure 42-2: Typical plasma profiles for the MB isoenzyme of creatine kinase (MB-CK), aspartate amino transferase (AST), and lactate dehydrogenase (LDH) activities following onset of acute myocardial infarction.

Figure 42-3: Algorithm for the initial assessment and evaluation of the patient with acute chest pain in the emergency department. The emergency department should be organized to facilitate the rapid triage of chest pain patients so that the initial evaluation, the obtainment of a 12-lead ECG, and the establishment of intravenous access and continuous monitoring are accomplished within 10 min. The path in the decision tree is determined by the results of the 12-lead ECG. The presence of ST-segment elevation diagnostic of acute myocardial infarction or of presumptively new bundle branch block suggestive of this diagnosis should lead to the immediate consideration of the suitability of the patient for reperfusion therapy, which, if indicated, should be initiated within 30 min of the patient's arrival. The primary PTCA option is applicable only in those settings in which it is immediately available and can be performed by highly qualified interventional cardiologists. In general, patients should not be transferred for angioplasty if thrombolysis is an option, especially if significant delays will be incurred. Thrombolysis is not indicated in patients with only ST-segment depression.

Figure 42-4: The above analysis is based on a prospective, multicenter, double-blind study involving the consecutive enrollment of 995 patients presenting to the emergency department. Diagnostic sensitivity and specificity for myocardial infarction of all markers (MB-CK subforms, myoglobin, total MB-CK-activity and mass, troponin T, and troponin I) were assessed serially every 1 to 2 h for 24 h. There were 119 (12.5 percent) patients with infarction and 203 (21 percent) with unstable angina. MB-CK subforms were most sensitive and specific (91 and 89 percent) within 6 h of onset versus myoglobin (MG) (78 and 89 percent). For late diagnosis, total MB-CK activity (derived from subforms) was the most sensitive and specific (96 and 98 percent) at 10 h from onset, followed by troponin I (cTnI) (96 and 93 percent), but not until 18 h, and troponin T (cTnT) (87 and 93 percent) at 10 h. In unstable angina, MB-CK subforms were increased in 29.5 percent, myoglobin in 23.7 percent, troponin I in 19.7 percent, and troponin T in 14.8 percent. (Data from Roberts et al.[154])

Figure 42-5: Proportional effects of fibrinolytic therapy on mortality during days 0 to 35 subdivided by presentation features. "Observed minus expected" (O-E) number of events among fibrinolytic-allocated patients (and its variance) is given for subdivisions of presentation features, stratified by trial. This is used to calculate odds ratios (ORs) of death among patients allocated to fibrinolytic therapy to that among those allocated control. The ORs (squares with areas proportional to the amount of "statistical information" contributed by the trials) are plotted with their 99 percent confidence intervals (CIs) (horizontal lines). Squares to the left of the solid vertical line indicate benefit (significant at $2p < 0.01$ only where the entire CI is to left of vertical line). Overall result and 95 percent CI represented by diamond, with overall proportion reduction in the odds of death and statistical significance given alongside. (From Fibrinolytic Therapy Trialists' Collaborative Group,[210] with permission.)

Figure 42-6: Evaluation of patients with ST-segment elevation. Algorithm for initial decision making in regard to reperfusion therapy in patients with suspected acute myocardial infarction and ST-segment elevation. Whether or not to administer thrombolytics or to perform primary PTCA is determined by the time from onset of symptoms. For patients in whom more than 12 h have elapsed since the onset of symptoms, reperfusion should be considered only if there are persistent or recurrent symptoms associated with ST-segment elevation. For patients with ST-segment elevation and duration of symptoms between 7 and 12 h, the decision to proceed with a reperfusion strategy requires careful clinical judgment in weighing the risk/benefit issues, as discussed in the text. (Modified from Ryan et al.,[1] with permission.)

Figure 42-7: Influence of effective anticoagulation on early patency rates with rt-PA. Patency assessed angiographically at an average of 18 to 81 h is significantly greater in patients treated with intravenous heparin.

Figure 42-8: Retrospective analysis of the HART trial showing the relationship between increased PTT and coronary artery patency ($n = 94$). This illustrates the importance of heparin.

Figure 42-9: Kaplan Meier curves for death and infarction in patients assigned to the invasive or conservative strategies in TIMI-2. Routine cardiac catheterization after thrombolytic therapy and revascularization with PTCA or bypass grafting (when anatomically appropriate) was not a superior strategy to catheterization and revascularization when there is development of spontaneous ischemia or ischemia induced by exercise testing. (Reproduced with permission. Williams DO, Braunwald E, Knatterud G, et al.: One-year results of the thrombolysis in myocardial infarction investigation (TIMI) phase II trial. *Circulation* 1992; 85:533-542.[318] Copyright 1992 American Heart Association.)

Figure 42-10: Comparison of the survival of patients with Q-wave infarction (triangles) to that of patients with non-Q-wave infarction with (circles). Early mortality was higher after Q-wave infarction than it was after non-Q-wave infarction and no recurrence (*A*), but survival was identical for patients with Q-wave infarction and those with non-Q-wave infarction and an early recurrent infarction (*B*). Long-term mortality rates are similar in Q-wave infarction and non-Q-wave infarction with or without early recurrence.

Figure 42-11: Strategies for exercise test evaluations soon after myocardial infarction. If patients are at high risk for ischemic events based on clinical criteria, they should undergo invasive evaluation to determine if they are candidates for coronary revascularization procedures (strategy I). For patients initially deemed to be at low risk at time of discharge after myocardial infarction, two strategies for performing exercise testing can be used. One is a symptom-limited test at 14 to 21 days (strategy II). If the patient is on digoxin or if the baseline ECG precludes accurate interpretation of ST-segment changes (e.g., baseline left bundle branch block or left ventricular hypertrophy), then an initial exercise imaging study can be performed. Results of exercise testing should be stratified to determine need for additional invasive or exercise perfusion studies. A third strategy is to perform a submaximal exercise test at 5 to 7 days after myocardial infarction or just before hospital discharge. The exercise test results could be stratified using the guidelines in strategy I. If exercise test studies are negative, a second symptom-limited exercise test could be repeated at 3 to 6 weeks for patients undergoing vigorous activity during leisure or at work. (From Ryan et al.,[1] with permission.)

Figure 42-12: A theoretical view of approaches to identify a postmyocardial infarction population dying of ventricular tachycardia/fibrillation. This concept is presented in a qualitative fashion and represents estimates based on the literature (see text). SCD, sudden cardiac death; NSCD, non-sudden cardiac death; VT, ventricular tachycardia; VF, ventricular fibrillation; MI, myocardial infarction; EMD, electromechanical dissociation; CHF, congestive heart failure.

Part 6: CORONARY HEART DISEASE
Chapter 43:

THE ELECTROCARDIOGRAM IN ACUTE MYOCARDIAL INFARCTION

Authors: Anton P. Gorgels, Domien J. Engelen, Hein J. J. Wellens

The possibility of treating an acute coronary occlusion by thrombolytic therapy or intracoronary interventions such as percutaneous transluminal coronary angioplasty (PTCA) and stenting makes it necessary to determine, rapidly and precisely, which coronary artery is involved, the size of the area at risk, and the results of the intervention. The larger the area at risk, the more important the attempt to restore or improve perfusion of that area.

In recent years, much effort has been put into correlating electrocardiographic (ECG) changes during the acute ischemic episode with findings from coronary angiography performed at the same time. If specific ECG patterns can be recognized, it will be possible to determine, noninvasively, the culprit coronary artery and the size of the ventricular area that is jeopardized.

This chapter discusses the outcome of such studies. It shows that this information is helpful in decision making during acute myocardial infarction and the chapter is therefore placed in the section on coronary heart disease. Chapter 11 provides a general discussion on the value and limitations of the ECG in the diagnosis of cardiac disease (see also Chaps. 40-42).

CLINICAL PRESENTATION OF ACUTE MYOCARDIAL INFARCTION IN RELATION TO THE INFARCT VESSEL

The presentation of acute myocardial infarction is different depending on the coronary artery involved. The left anterior descending branch (LAD) is the most important coronary artery and supplies the anterior, lateral, septal, and frequently the inferoapical segments of the left ventricle. It also perfuses the proximal part of the bundle branches. The extent of ischemia and the prognosis is dependent on the site of occlusion in the LAD.[1] Involvement of the distal conduction system may result in impaired conduction, varying from right bundle-branch block (RBBB) with or without fascicular block to complete atrioventricular (AV) block.[2-4] The clinical picture may include heart failure and, in the subacute phase, ventricular tachycardia and fibrillation and an increased 1-year mortality.[5] The right coronary artery (RCA) perfuses the sinus node (in 55 percent of patients), the right ventricle, the AV node, the posteromedial papillary muscle, and the inferior part of the left ventricle and variably also the posterior and lateral segments.

Ischemia due to occlusion of the RCA leads to ST elevation in the inferior leads. Usually there is less extensive left ventricular (LV) involvement than in LAD occlusion, but the clinical picture may be impressive due to (1) activation of the vagal nervous system and/or (2) ischemia of the sinus and atrioventricular (AV) node, leading to sinus bradycardia and delay or block in the AV node, (3) right ventricular involvement with cardiogenic shock, and (4) ischemia of the papillary muscle, leading to mitral regurgitation.

The circumflex (CX) branch perfuses the posterior wall and variably the inferior and lateral segments. In case of predominant posterior wall involvement following occlusion of the CX, abnormalities in ventricular activation occur in the second half of the QRS complex and are

therefore difficult to pick up on the 12-lead ECG, frequently causing underestimation of the area at risk and undertreatment of the patient.[6]

Chapter 43: THE ELECTROCARDIOGRAM IN ACUTE MYOCARDIAL INFARCTION

THE ELECTROCARDIOGRAM IN ANTERIOR WALL INFARCTION

The ECG signs of an anterior wall infarction are ST elevation in precordial leads V_2, V_3, and V_4. The behavior of the ST segments in the other precordial and frontal leads is dependent not only on the anterior area but also on the contribution of the septal, lateral, and inferoapical areas. When they are involved in the ischemic process, the anatomic extent and the amount of ischemia of each of these areas determine the vector of the ST segment. This may result in typical patterns of leads showing ST segment changes, predicting the area at risk, and frequently also pointing to the site of occlusion in the LAD (Table 43-1). The ST segment's behavior in anterior wall infarction will be determined by the presence or absence of ischemia in three left ventricular areas: (1) the basoseptal area, perfused by the proximal septal branch, (2) the basolateral area, perfused by the first diagonal or the intermediate branch, and (3) the inferoapical area, when the distal LAD wraps around the apex. Involvement of the proximal septal and/or diagonal branches will lead to four different types of LAD occlusion: (1) proximal to the septal and first diagonal branch (40 percent of cases), (2) distal to these two branches (40 percent), (3) proximal to the first diagonal but distal to the septal branch (10 percent), and (4) proximal to the septal but distal to the first diagonal (or intermediate) branch (10 percent).

Table 43-1: ECG Identifying the Site of Coronary Vessel Occlusion in Acute Infarction

Anterior wall infarction
Proximal to first septal and/or first diagonal branch of the LAD
Distal to first septal and/or first diagonal branch of the LAD
Inferoposterior wall infarction
1. Distinction between RCA and CX coronary artery 2. Proximal or distal in RCA RV infarction

ABBREVIATIONS: CX = circumflex; LAD = left anterior descending coronary artery; RCA = right coronary artery; RV = right ventricle.

DOMINANCE OF BASAL AREA: PROXIMAL LAD OCCLUSION

An example of an occlusion proximal to the first septal and first diagonal branches is shown in Fig. 43-1. Typical features include ST elevation in aV_R and ST elevation of ≥2.5 mm in V_1, ST depression in the inferior leads and in V_5,[7-9] and an abnormal Q in aV_L. Figure 43-2, Plate 82, depicts the likely mechanism of these findings. There is global involvement of the left ventricle with a contribution to the ECG from all ischemic areas. Because of the larger mass of the basal part of the vector, the ST segment will point in a superior direction (Fig. 43-2, left panel). In the frontal plane, this results in ST elevation in leads aV_R and aV_L (Fig. 43-2, right panel). The cranially positioned lead V_1 will also record ST elevation. This upward orientation of the ST vector causes reciprocal ST depression in the inferior leads[10,11] and also sometimes in the lateral leads (V_5 and V_6). Local conduction delay in the lateral area will lead to widening of the Q wave in lead aV_L.

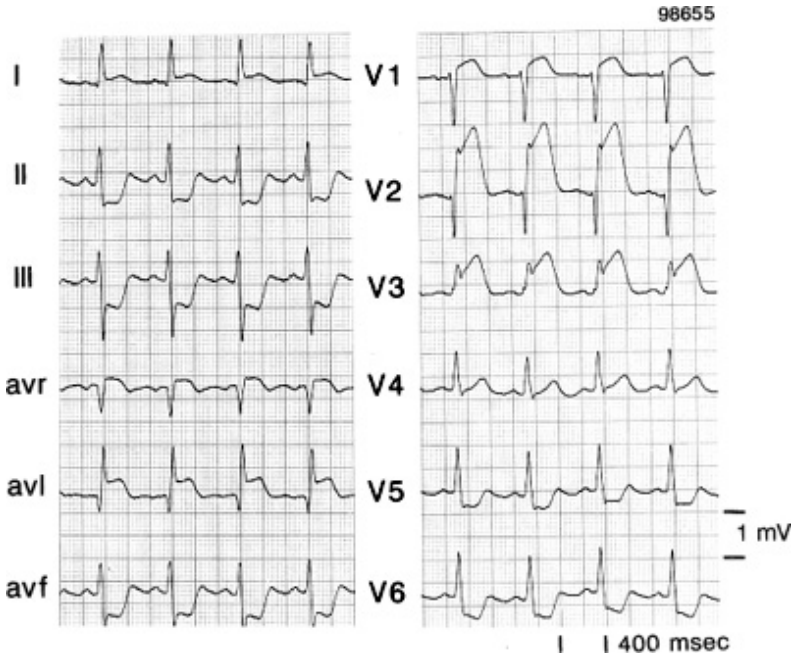

Figure 43-1: Acute anterior wall infarction in proximal LAD occlusion. Anterior wall infarction is present, as indicated by ST-segment elevation in leads V_2 and V_3. In addition, the precordial leads show marked ST-segment elevation in lead V_1 and ST-segment depression in leads V_5 and V_6. The extremity leads show ST-segment elevation in lead aV_R and ST-segment depression in inferior leads II, III, and aV_F.

DOMINANCE OF INFEROAPICAL AREA: DISTAL LAD OCCLUSION

Figure 43-3 shows an example of an acute anterior wall infarction due to a distal LAD occlusion (after the proximal septal and diagonal branches). Typical is the absence of ST-segment depression in the inferior leads.[12,13] Sometimes also, wide Q waves are recorded in V_4 through V_6.

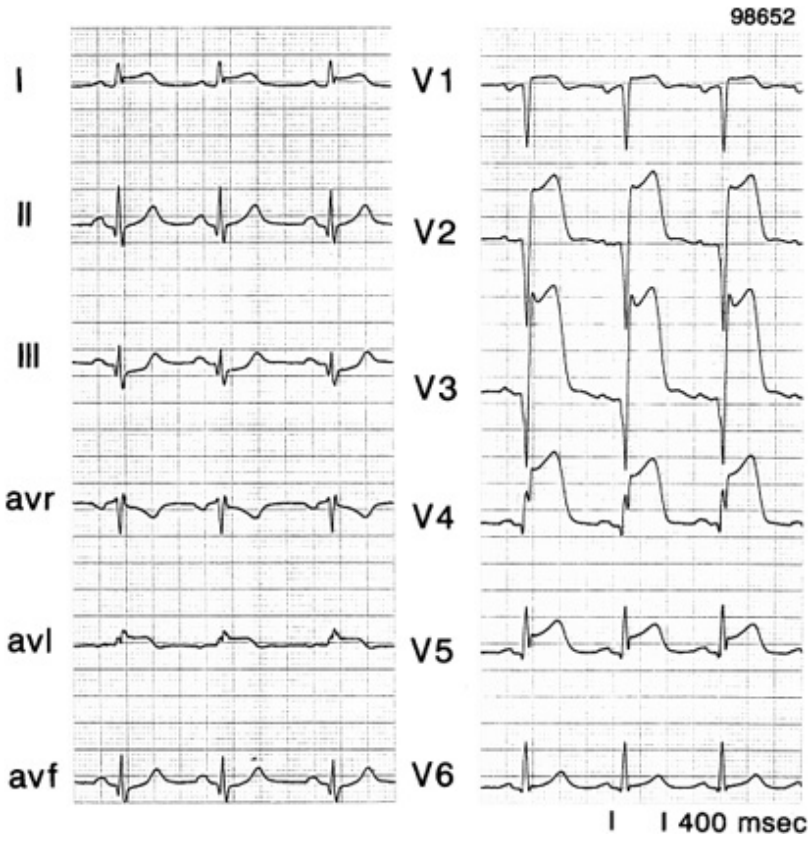

Figure 43-3: Acute anterior wall infarction in distal LAD occlusion. Signs of acute anterior wall infarction are seen, but ST-segment elevation is present in the inferior leads. Note also ST-segment depression in lead aV_R.

In this situation, the inferoapical part is the dominant ischemic area, therefore the ST vector will point inferiorly (Fig. 43-4, left panel, Plate 83). The inferior leads will become isoelectric or even positive (Fig. 43-4, right panel, Plate 83, and Table 43-2). The Q waves in the left precordial leads are likely caused by the combination of local conduction delay in that area combined with persistence of the regular septal Q wave in these leads.

Table 43-2: ECG Criteria Identifying the Site of Occlusion in the LAD Territory

Criterion	Occlusion site	Sensitivity	Specificity	PPA	NPA
CRBBB	Proximal to S1	14	100	100	62
ST ↑ V_1 ≥2.5 mm	Proximal to S1	12	100	100	61
ST ↑ aV_R	Proximal to S1	43	95	86	70
ST ↓ V_5	Proximal to S1	17	98	88	62
Q aV_L	Proximal to D1	44	85	67	69
ST ↓ II ≥1.0 mm	Proximal to S1/D1	34	98	93	68
Q V_5	Distal to S1	24	93	71	53
ST ↓ aV_L	Distal to D1	22	95	87	46
No ST ↓ III	Distal to S1/D1	41	95	92	53

ABBREVIATIONS: D1 = first diagonal branch; NPA = negative predictive accuracy; PPA = positive predictive accuracy; S1 = first septal branch.
SOURCE: From Engelen et al.,[15] with permission.

DOMINANCE OF SEPTAL AREA: FIRST DIAGONAL (OR INTERMEDIATE) BRANCH NOT INCLUDED

Figure. 43-5 presents an example of a case in which a large anterobasal-lateral area is not involved because the occlusion is proximal to the first septal but distal to the first diagonal or intermediate branch. Signs of a proximal first septal branch occlusion are present, such as ST-segment elevation in aV_R, ST-segment elevation ≥2.5 mm in V_1, and ST-segment depression in V_5. As reported elsewhere, the right precordial lead V_{3R} may also show ST-segment elevation.[14] Lead aV_L now shows ST-segment depression and the inferior leads positive ST segments. Figure 43-6, Plate 84, is a diagrammatic presentation of this situation. The left panel shows the rightward orientation of the ST-segment vector, leading (right panel) to the greatest negativity of the ST segment in aV_L and most positivity in lead III, whereas leads aV_R and II are less positive-almost isoelectric. Negativity in lead aV_L is highly specific for an occlusion site behind the first diagonal branch (Table 43-2).

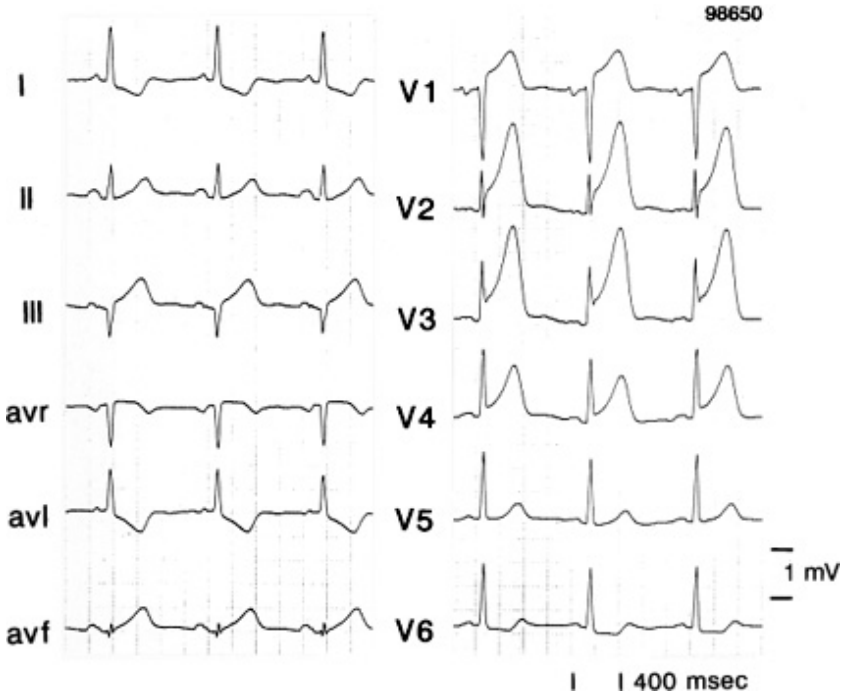

Figure 43-5: Acute anterior wall infarction due to LAD occlusion distal to the first diagonal but proximal to the first septal branch. The precordial leads show evidence of acute anterior wall infarction, but lead aV_L shows ST-segment depression.

DOMINANCE OF THE LATERAL AREA, FIRST SEPTAL BRANCH NOT INCLUDED

Figure 43-7 shows the ECG of an acute anterior wall infarction with an occlusion site distal to the first septal but proximal to the first diagonal branch. Typical features are Q waves in the left lateral leads, ST-segment depression in lead III, and the absence of this finding in lead II. Figure 43-8, Plate 85, shows the distribution of ischemia in that situation, leading to the ST-segment vector, pointing in a left lateral direction (left panel), and leading to the described changes in the ST segment. Local conduction delay in the lateral area with persistence of the septal Q wave results in widening of the Q wave in leads

aV_L and V_5 (right panel).

Electrocardiographic Criteria to Identify the Site of Occlusion in Anterior Wall Infarction

The ECG criteria to identify the site of occlusion in anterior wall infarction, summarized in Table 43-2, are particularly useful in patients presenting with a first acute anterior infarction.[15] In contrast to sensitivity, the specificity of these criteria is high, indicating that their presence accurately predicts the occlusion site, but their absence does not exclude it.

Right bundle-branch block remains, as previously described,[2] a very specific marker of an occlusion site before the first septal branch. ST-segment elevation in V_1 must be considerable to be sufficiently specific ($\geq$ 2.5 mm) for that situation. In contrast, any ST-segment elevation in aV_R, apart from being specific, is the most sensitive marker. ST-segment depression in V_5 is not a very frequent marker, but it is specific. Lead aV_L is the most useful lead to identify an occlusion site, proximal (Q wave) or distal (negative ST segment) to the first diagonal branch.

Chapter 43: THE ELECTROCARDIOGRAM IN ACUTE MYOCARDIAL INFARCTION

THE ELECTROCARDIOGRAM IN INFEROPOSTERIOR WALL INFARCTION

The myocardium of the inferoposterior area of the left ventricle is perfused by the right coronary artery (RCA), and the circumflex (CX) coronary artery. The right ventricle and the AV node are usually supplied by the RCA. As indicated in Table 43-1, the objective of the ECG in inferoposterior infarction is to recognize not only the culprit coronary artery but also whether the right ventricle is involved secondary to an occlusion of the RCA proximal to the right ventricular branch.

The Distinction between a Right Coronary Artery and a Circumflex Coronary Artery Occlusion

As shown in Figs. 43-9 and 43-10, the distinction between an RCA or CX occlusion can be made by determining the ST-segment vector during the acute phase of myocardial infarction. Because RCA occlusion predominantly results in inferoseptal ischemia, the ST-segment vector is directed toward lead III; in CX occlusion, the ischemia is located in the inferoposterolateral region leading to an ST-segment vector pointing toward lead II. Therefore, in RCA occlusion, ST-segment elevation is greater in lead III than lead II (resulting in ST-segment depression in lead I and aV_L). A greater amount of ST-segment depression in aV_L than in lead I further improves the sensitivity in diagnosing anRCA occlusion.[16] In CX occlusion, lead II will show more ST-segment elevation than lead III (with lead I showing an isoelectric ST segment or, in case of important lateral ischemia, ST-segment elevation).

The amount of ST-segment depression in the precordial leads and the number of precordial leads showing ST-segment depression will depend on the extent of posterior wall ischemia. This area is supplied by the posterior descending branch, depending on which coronary artery is dominant-the RCA or CX. The lateral leads V_5 and V_6 are of little value in differentiating between an RCA or CX occlusion. ST-segment elevation in these leads implies a larger perfusion territory of the culprit coronary artery and a need for aggressive reperfusion therapy.[17]

Diagnosing Right Ventricular Infarction

Is the right ventricle (RV) involved in inferoposterior infarction? The RV is supplied by one or more branches of the RCA. Occlusions in the RCA have therefore been classified as occurring before (proximal) or after (distal) the RV branch(es) (Fig. 43-11). RV involvement is of importance because it may lead to cardiogenic shock due to underfilling of the left ventricle, an increased incidence of high degree AV nodal conduction delay during the actue phase, and a higher incidence of sustained ventricular tachycardia in the chronic (scar) phase of MI. As shown in Figs. 43-12 and 43-13, the best way to diagnose RV involvement is to record lead V_{4R}.[18] ST-segment elevation in lead V_{4R} with a positive T wave predicts an RCA occlusion proximal to the right ventricular branch, an isoelectric ST segment with a positive T wave points to a distal RCA occlusion, and a negative T wave indicates an occlusion of the CX.[19,20] Sufficient ST-segment elevation in the inferior leads of the standard ECG is needed to use the findings from V_{4R} reliably (Fig. 43-14).

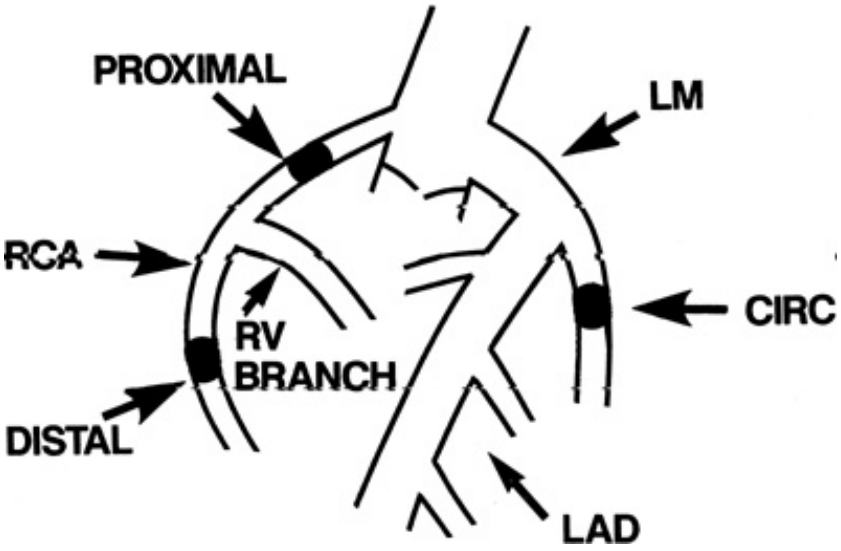

Figure 43-11: Diagram showing the coronary arteries and the possible sites of coronary artery occlusion leading to inferoposterior myocardial infarction. In the right coronary artery (RCA), the occlusion may be before (proximal) the right ventricular (RV) branch or after it (distal). As shown in proximal RCA occlusion, the RV is involved in the infarction.

ST-Segment Depression in the Anterior Leads

ST-segment depression in the anterior leads in inferior wall infarction reflects posterior wall involvement. ST-segment depression may extend from V_1 through V_6 (Fig. 43-10). Recent data indicate that larger infarctions with more postinfarction complications and a higher mortality rate are present in patients with precordial ST-segment depression.[21-23] The extent and amount of ST-segment depression should therefore play a role in decision making about the aggressiveness of reperfusion therapy. Maximal ST-segment depression in leads V_4 through V_6 is more frequently seen in patients with three-vessel disease, and they have a lower LV ejection fraction.[24] ST-segment depression in the precordial leads may occur both with RCA or CX involvement (Fig. 43-10). Absence of ST-segment depression points to the RCA as the infarct vessel.[25] Isolated ST-segment depression may present the difficulty of differentiating acute CX occlusion, resulting in true posterior wall infarction, from nonocclusive myocardial ischemia. In this regard, it has been suggested that localization of maximal ST-segment depression in V_2 or V_3 is predictive of acute CX occlusion.[26] Also, the use of additional leads V_7 through V_9 has been recommended.[27,28]

Isolated Right Ventricular Infarction

Rarely, the ECG shows only minor changes in the inferior leads and the predominant ST-segment elevation is seen in leads V_1, V_2, and the right precordial leads.[29] This picture reflects a predominant RV infarction and is found in case of a small RCA, a collaterally filled RCA, or an isolated occlusion of an RV branch.

Atrioventricular Conduction Disturbances in Acute Myocardial Infarction

ATRIOVENTRICULAR NODAL BLOCK

Different degrees of AV nodal conduction delay and block may occur in inferior wall infarction,

especially when the proximal RCA is involved (Fig. 43-15). High-degree (second or third) AV nodal block is present in about 20 percent of acute inferior infarction ECGs[30] and should suggest a proximal RCA occlusion with RV involvement.[31] AV nodal block is accompanied by a higher in-hospital morbidity and mortality, not only in the prethrombolytic[32] but also in the thrombolytic era.[33] Early reperfusion is indicated to reduce infarct size and restore normal AV conduction.

SUBATRIOVENTRICULAR NODAL BLOCK

The development of bundle-branch block with or without hemiblock during the acute phase of anterior myocardial infarction indicates proximal LAD occlusion and is therefore a marker for the need to reopen the vessel promptly. Also, in the thrombolytic era, the development of bundle-branch block and complete AV block indicates a poor short-term prognosis and stresses the necessity of an aggressive reperfusion attempt.[34-36] When left anterior fascicular block occurs in the setting of acute inferior wall infarction, additional LAD disease should be suspected (Fig. 43-16).[37]

LIMITATIONS

The findings described above are from studies where occlusion of a single coronary vessel led to the characteristic ECG changes. The presence of multivessel disease, an old myocardial infarction, and occlusion of a vessel that, by collaterals, is perfusing the territory of another coronary artery may affect and change the ECG in such a way that precise identification of the site of occlusion in the culprit coronary artery and the size of the area at risk is no longer possible. This is also the case in the presence of a conal branch from the RCA protecting the superior portion of the interventricular septum in acute anterior wall myocardial infarction.[38] The ECG is also of limited value when ventricular activation is altered, as in preexistent left bun dle-branch block, ventricular preexcitation, and a paced ventricular rhythm.

Chapter 43: THE ELECTROCARDIOGRAM IN ACUTE MYOCARDIAL INFARCTION

CONCLUSION

In acute cardiac ischemia the aggressiveness of (reperfusion) therapy should be determined by the size of the area at risk. As shown in this chapter, the inexpensive electrocardiogram can be of great help in providing that information.

Chapter 43: THE ELECTROCARDIOGRAM IN ACUTE MYOCARDIAL INFARCTION

List of Figures

Figure 43-10: *Left panel:* The typical picture of a RCA occlusion. ST-segment elevation in lead III is higher than in lead II, resulting in ST-segment depression in lead I. In this patient with a dominant RCA complete AV block, right atrial and posterior wall infarction is also present. *Right panel:* An example of a CX occlusion. ST-segment elevation is more marked in lead II than in lead III, leading to a positive T wave in lead I.

Figure 43-11: Diagram showing the coronary arteries and the possible sites of coronary artery occlusion leading to inferoposterior myocardial infarction. In the right coronary artery (RCA), the occlusion may be before (proximal) the right ventricular (RV) branch or after it (distal). As shown in proximal RCA occlusion, the RV is involved in the infarction.

Figure 43-12: Characteristic ST-T-segment changes in lead V_{4R} in cases of proximal RCA, a distal RCA occlusion, or a CX occlusion (see text).

Figure 43-13: Three panels showing the behavior of the right precordial leads in inferoposterior myocardial infarction caused by a proximal RCA, distal RCA, or CX occlusion. See also Fig. 43-12.

Figure 43-14: The relation between ST-segment elevation in leads II, III, and aV_F and in the right precordial leads in proximal RCA. Note that changes diagnostic for RV involvement in lead V_{4R} have disappeared 7½ h after the onset of chest pain. As shown there is a relation between the amount of ST-segment elevation in the inferior leads and lead V_{4R}.

Figure 43-15: Three-to-two AV nodal Wenckebach phenomenon in a patient with an acute inferoposterior myocardial infarction. ST-segment elevation in lead III is higher than in lead II, indicating a right coronary artery (RCA) occlusion. Lead V4R (not shown) indicated an ST-segment elevation of 3 mm with a positive T wave, pointing to a proximal RCA with RV involvement.

Figure 43-16: *Left panel:* Sinus tachycardia with a prolonged PR interval and right bundle-branch block (RBBB) in a patient with an acute anterior wall myocardial infarction. These findings point to a LAD occlusion proximal to the first septal branch. *Right panel:* Same patient after primary PTCA of the proximal LAD occlusion. Note disappearance of PR prolongation and RBBB. The precordial QRS picture indicates a small anterior wall infarction.

Part 6: CORONARY HEART DISEASE
Chapter 44:

THROMBOGENESIS, ANTITHROMBOTIC, AND THROMBOLYTIC THERAPY

Authors: Christopher P. Cannon, Valentin Fuster

IMPORTANCE OF THROMBOSIS IN ACUTE CORONARY SYNDROMES

Because nearly 2 million patients annually experience an acute coronary syndrome in the United States, with more than double that figure worldwide, cardiologists and other health care professionals have focused on improving the management of acute coronary syndromes, with one of the most prominent advances being thrombolytic therapy for patients with ST-segment elevation myocardial infarction (MI).[1] More recently, however, there have been numerous advances in antithrombotic therapy, for both patients with ST-elevation MI as well as the much larger group of patients with unstable angina and non-ST-elevation MI.

Rupture or erosion of an atherosclerotic plaque with superimposed nonocclusive thrombus is by far the most common cause of acute coronary syndromes (see also Chaps. 35 and 36). However, angiographic studies have shown a major difference in the severity of the thrombus, based on the presence or absence of ST-segment elevation: In ST-elevation MI the infarct-related artery usually has a 100 percent occlusion,[2,3] whereas in unstable angina/non-ST-elevation MI the culprit artery usually has a severe obstruction (80 to 95 percent) but is patent with coronary perfusion (Fig. 44-1).[4,5] Thus, because of the advent of acute reperfusion therapy, a classification of ST-elevation MI versus unstable angina/non-ST-elevation MI provides the critical information regarding the pathophysiology and acute management of acute coronary syndromes (Fig. 44-1).

Evolution of Athero(thrombo)sclerosis

Atherosclerosis is a silent process that usually commences 20 to 30 years prior to a patient's presentation with a clinical syndrome (see Chaps. 35 and 36).[6,7] Hypercholesterolemia, smoking, hypertension, and other coronary risk factors damage the endothelium and initiate the atherosclerotic process.[6-8] When the endothelium is dysfunctional, macrophages bind to endothelial adhesion molecules and can infiltrate the endothelial cell. Low-density lipoprotein (LDL) molecules are able to penetrate into the vessel wall, and the macrophages digest the LDL, becoming foam cells, which thereby create a lipid-filled atherosclerotic plaque.[7,9] Oxidized LDL may also have a direct toxic effect on the endothelium and smooth muscle cells, which contribute to instability of the atherosclerotic plaque. Such plaques, which usually are lesions with less than 50 percent stenosis, are more prone to rupture.[10-14]

Then, multiple factors contribute to plaque rupture, including endothelial dysfunction, plaque lipid content,[15] local inflammation causing breakdown of the thin shoulder of the plaque,[16] coronary vasoconstriction, local shear-stress forces, platelet activation,[17,18] and the status of the coagulation system (i.e., a potentially prothrombotic state),[19,20] all of which culminate in the formation of a platelet-rich thrombus on the disrupted plaque.[21-23]

It should be noted however, that more than 95 percent of all plaque ruptures are clinically silent.[24,25] Angiographic studies have shown that many high-grade lesions often appear in segments of the coronary artery that were previously normal.[26] The erratic and unpredictable growth of plaques is caused by plaque disruption or fissuring and intracoronary mural thrombosis.[27,28] The mural thrombus then undergoes fibrous organization and contributes, often asymptomatically, to the progression of the disease.[27,28] Thus, this process of plaque disruption and local thrombosis is ongoing in patients with clinically "stable" coronary artery disease, a point that reemphasizes the importance of long-term antithrombotic therapy in patients with coronary artery disease.

Percutaneous Coronary Intervention

Percutaneous coronary intervention (PCI) with angioplasty, stenting, or other modalities is associated with denudation of the endothelium and deep vessel injury. This results in exposure of thrombogenic elements in the atherosclerotic plaque and the vessel wall, which predisposes this area to platelet deposition and fibrin formation, leading to intravascular thrombosis.[29,195] Therefore, therapy to prevent acute occlusion following coronary intervention should be directed against both platelets and the coagulation cascade.

Saphenous Vein Bypass Grafting

Disease of the saphenous vein graft is a special case in coronary atherosclerosis. Occlusion rates are 8 to 18 percent per distal anastomosis 1 month postoperatively and 16 to 26 percent at 12 months.[30] Vein graft disease can be divided into three phases: an early postoperative phase (within 1 month after surgery) related to thrombotic occlusion, in which platelet activation and fibrin formation are implicated; an intermediate phase (within the first postoperative year) characterized by intimal hyperplasia, resulting in a form of accelerated atherosclerosis that may have a superimposed thrombotic tendency; and a late phase (after the first postoperative year) characterized by graft atherosclerosis similar to that of the native coronary arteries.[30,196] Therefore, the predominant pathogenetic mechanism in saphenous vein bypass grafting is related to both platelet activation and fibrin generation, particularly in the early postoperative phase.

Role of Endothelial Dysfunction and Inflammation in Early Coronary Atherosclerosis

At areas of plaque injury, there is early adherence of leukocytes and platelets.[31] These early cellular responses lead to the further migration and proliferation of smooth muscle cells, monocytes, and lymphocytes at areas of injury. Vascular endothelial cell injury leads to a cell-mediated response that is very similar to the inflammatory response, which leads to a complex cascade of events that culminate in atherosclerosis and eventually clinical vascular syndromes.[31,32] Activated T cells release cytokines, and monocyte chemotactic factor enhances the adhesion and migration of circulating monocytes and influences lipoprotein uptake by the macrophage and promotes foam cell formation.[31]

In postmortem studies of the atheromatous plaque, disrupted atheromatous plaque were found beneath thrombi in 84 percent of patients,[33] and these culprit lesions contained significantly more macrophages than quiescent lesions.[34] Furthermore, the macrophages and T lymphocytes at the site of plaque disruption were found to be in an activated state.[32] Other studies have localized matrix metalloproteinases to human atherosclerotic plaque, which may contribute to their disruption.[35] Studies of lymphocyte function and expression in patients with unstable angina revealed that this state is associated with the activation of a specific T-cell subset ($CD\text{-}4^{+}$/CD-28 null) that produces interferon-γ, an activator of monocytes, and the production of matrix metalloproteinases.[36] Other complement peptides, including C3-binding protein, localized in areas of endothelial injury and inflammation are chemotactic for monocytes. Clinical studies of patients

with acute coronary syndromes have reflected a heightened systemic inflammatory response as measured by elevated circulating levels of markers such as C-reactive protein and other acute-phase reactants.[37-42]

Role of Platelets and Thrombosis in the Progression to Acute Coronary Syndromes (Figs. 44-1 to 44-6)

The central role of coronary artery thrombosis in the pathogenesis of acute coronary syndromes is supported by six sets of observations: (1) at autopsy, thrombi can usually be identified at the site of a ruptured plaque;[21,22,24,43] (2) coronary atherectomy specimens obtained from patients with acute myocardial infarction (AMI) or unstable angina demonstrate a high incidence of acute thrombotic lesions;[44-47] (3) coronary angioscopic observations indicate that thrombus is frequently present;[48-54] (4) coronary angiography has demonstrated ulceration or irregularities suggesting a ruptured plaque[10,55] and/or thrombus in many patients;[5,56] and (5) evidence of ongoing thrombosis has been noted with elevation of several markers of platelet activity and fibrin formation;[6,57-64] and (6) the clinical outcome of patients with acute coronary syndromes is improved by antithrombotic therapy with aspirin,[65-68] heparin,[67-71] low molecular weight (LMW) heparin,[72-75] and platelet glycoprotein (GP) IIb/IIIa inhibitors.[76-78]

The thrombotic response to plaque disruption/fissuring is primarily determined by five local factors: (1) extent of plaque disruption (e.g., ulcer), (2) character of exposed contents (e.g., lipid pool), (3) degree of stenosis and surface irregularities that activate platelets (i.e., change in geometry after plaque disruption), (4) the surface of residual thrombus (recurrence), and (5) vasoconstriction. In addition, systemic factors appear to enhance thrombogenicity, which may occur in a very stenotic plaque denuded of endothelium without plaque fissuring.[24,79] This balance of local and systemic factors has important effects on outcome, as described below.

Plaque Disruption

NON-PLAQUE-RELATED FACTORS PREDISPOSING PLAQUE TO RUPTURE

Passive plaque disruption is related to physical forces, especially where the fibrous cap is thinnest, i.e., where it is most heavily infiltrated with foam cells and, as a result, the weakest. Pathologic studies have shown that vulnerable plaques are commonly composed of cellular elements and an atheromatous lipid-filled core separated from the arterial lumen by a fibrous membrane or cap.[15,24,25] For eccentric plaques, the shoulder region, that between the plaque and the adjacent vessel wall is most vulnerable.[15,24,54] Based on studies examining both intact and disrupted plaques and in vitro mechanical testing of isolated fibrous cap, vulnerability to rupture depends on three primary factors: (1) circumferential wall stress or cap "fatigue;" (2) location, size, and consistency of the atheromatous core; and (3) blood flow characteristics, such as the impact of flow on the proximal aspect of the plaque.[54]

PREDISPOSING FACTORS IN ACTIVE PLAQUE

Recent evidence points to a large number of inflammatory cells, notably monocyte-derived macrophages, as being present in disrupted plaque.[15,24,25] Macrophage-derived products, such as matrix metalloproteinases (MMPs), collagenases, and other proteolytic enzymes, degrade the matrix of the plaque, weaken the fibrous cap, and thus predispose plaque to rupture.[35] In culture, monocyte-derived macrophages have been found to degrade the collagen of the fibrous cap while simultaneously expressing MMP-1 (interstitial collagenase) and inducing MMP-2 (gelatinolytic).[80] Recent evidence has suggested that circulating oxidized LDL may influence matrix turnover in atherosclerotic plaque by causing macrophages to produce and release more matrix-degrading metalloproteinases (MMP-9), which increase matrix degradation, alter arterial

remodeling, and thus predispose plaque to rupture.[81] It was also found that high-density lipoprotein (HDL) inhibited this process, thus possibly explaining HDL's favorable mechanism of action. When oxidized LDL overloading occurs, macrophages appear to enter into apoptotic death, periods during which induction of MMPs and tissue factor appears to occur. The end result of plaque disruption is acute overlying thrombosis.

Inflammation/Infection

Recent evidence has also pointed to a role for inflammation, which appears to be key in the development of atherosclerosis[82,83] and in the development and recurrence of unstable angina.[37,39,84,85] Infectious agents, notably *Chlamydia pneumoniae*, appear to be one of the underlying causes of diffuse inflammation in the pathogenesis of coronary artery disease.[86-88] Others for which there is some, albeit less strong, evidence include *Heliobacter pylori* and *Cytomegalovirus*.[86] It is important to note that an etiologic relationship between these infectious agents to the development of acute coronary syndromes has not been definitively established.[88-90] On the other hand, evidence from several animal models,[91-94] and pilot treatment trials in patients,[95-97] suggests *Chlamydia pneumoniae* may be an important and *potentially treatable* cause of unstable angina or MI, and larger trials are ongoing.

Acute Thrombosis

Plaque disruption and thrombus formation/remodeling lead to a variable degree of luminal obstruction to blood flow and can present clinically as stable or unstable angina or acute MI or lead to sudden death (Fig. 44-1).[98] At the time of plaque disruption, a number of local and systemic thrombogenic factors may influence the degree and the duration of thrombus deposition. Such a thrombus may then either be partially lysed or become replaced in the process of organization by the vascular repair response.

Substrate and Tissue Factor-Dependent Thrombosis (Figs. 44-2 and 44-3)

The disruption of an atherosclerotic plaque exposes various vessel wall components to the circulating blood, and each have varying degrees of thrombogenicity. Among the various types of plaques, which included normal intima, fatty streaks, sclerotic plaques, fibrolipid lesions, and plaques with lipid-rich cores, it was the lipid-rich plaque (abundant in cholesterol ester) that displayed the highest thrombogenicity and the most intense tissue factor staining compared with the other plaque types.[99]

Tissue factor is a LMW glycoprotein that, after being exposed to circulating blood factors, initiates the extrinsic clotting cascade and is believed to be a major regulator of thrombosis and hemostasis (see Fig. 44-7). Tissue factor forms a high-affinity complex with coagulation factors VII/VII; the tissue factor-factor VIIa complex activates factors IX and X, which in turn lead to thrombin generation.[100] Atherectomy specimens from the culprit lesion in patients with unstable angina demonstrated a strong relationship between tissue factor and macrophages.[16] Experimental studies using a specific inhibitor of tissue factor (tissue factor pathway inhibitor) found that acute thrombus formation was reduced in lipid-rich plaques exposed to this specific inhibitor.[101] Such information supports the important role of tissue factor activity in acute thrombosis after coronary plaque rupture and opens new avenues of possible therapeutic intervention in the treatment and/or prevention of acute coronary syndromes.

Recent observations indicate that after plaque disruption there is a first layer of fibrin formation, as a result of the activation of tissue factor and the coagulation cascade[1]; this precedes significant platelet deposition, as a result of thrombin generation by the coagulation cascade[1]; eventually, if

the fibrin-platelet thrombus occludes the artery, further and significant fibrin formation takes place proximally as a result of stasis. Therefore, the coronary occlusive thrombus is like a "sandwich" composed of fibrin-platelet-fibrin.

Hypercoagulable-Dependent Thrombosis (Table 44-1)

There is evolving evidence that circulating monocytes and white blood cells may be involved in tissue factor expression and thereby influence the thrombogenicity of the circulating blood.[102] Activation of the circulating inflammatory cells in patients leading to acute coronary syndromes has been suggested by high titers of C-reactive protein preceding these events.[85,103-105] Hypercholesterolemia, a high-catecholamine drive such as smoking, emotional stress, cocaine use, certain chemotactic determinants, and perhaps infections may also trigger such hypercoagulable phenomena. In support of this hypothesis are studies evaluating lipid-lowering therapies that have found that normalization of the serum cholesterol reduced blood thrombogenicity.[106]

Several hemostatic determinants, such as fibrinogen, von Willebrand factor, and factor VIIa have been associated with an increased risk of cardiovascular disease. The association with fibrinogen is the most powerful and consistent. Abnormal levels of plasminogen activator inhibitor 1 (PAI-1) and tissue-type plasminogen activator (t-PA) antigen (a marker of endothelial dysfunction) are associated with an increased risk of cardiovascular events.[107] For instance, increased levels of PAI-1 have been found on young survivors of MI.[108] In a healthy cohort of patients, high baseline levels of endogenous t-PA have been found to be significant predictors of the risk of future MI.[108]

Vasoconstriction

Although the vast majority of acute coronary syndromes are caused by the disruption or erosion of a plaque with superimposed thrombus, other mechanisms that alter myocardial oxygen supply and demand must be considered. Studies by Maseri and colleagues have indicated that vasoconstriction has an important role.[109] In acute coronary syndromes, vasoconstriction may occur in response to a mildly dysfunctional endothelium near the culprit lesion or, more likely, may be a response to deep arterial damage or plaque disruption of the culprit lesion itself. Thus, with regard to this second type of vasoconstriction, it seems that a predisposition exists for platelet-dependent and thrombin-dependent vasoconstriction at the site of plaque disruption and thrombosis that may be significant but transient.[109] Thus, platelet-dependent vasoconstriction, mediated by serotonin and thromboxane A_2 (TXA_2),[110] and thrombin-mediated vasoconstriction occur if the vascular wall has been damaged substantially by deendothelialization, which suggests a direct interaction of these substances with the vascular smooth muscle cells.

Mechanism of Thrombosis

Thrombosis is comprised of two interrelated stages: primary hemostasis and secondary hemostasis.[111,112] The first stage of hemostasis is initiated by platelets as they adhere to damaged vessels and form a platelet plug. The second phase involves activation of the coagulation system, which is comprised of a series of inactive proteins (zymogens) that are activated by proteolytic cleavage into active enzymes that ultimately cleave fibrinogen to fibrin to form a hemostatic clot (Fig. 44-7).[113] These two phases are dynamically interactive, however, since activated platelets can provide a surface for coagulation enzymes, and the ultimate enzyme of coagulation, thrombin, is a potent platelet activator.

Platelet Aggregation

Platelets play a key role in the transformation of a stable atherosclerotic plaque to an unstable lesion. With rupture or ulceration of an atherosclerotic plaque, the subendothelial matrix (e.g.,

collagen and tissue factor) is exposed to the circulating blood. Platelets mediate the "primary hemostasis" at the site of a ruptured plaque: the first step is *platelet adhesion* via the GP Ib receptor, as well as von Willebrand factor (Fig. 44-3). This is followed by *platelet activation*, which leads to (1) a shape change in the platelet (from a smooth discoid shape to a spiculated form, which increases the surface area upon which thrombin generation can occur); (2) degranulation of the alpha and dense granules, thereby releasing TXA_2, serotonin, and other platelet aggregatory and chemoattractant agents; and (3) expression of GP IIb/IIIa receptors on the platelet surface with activation of the receptor, such that it can bind fibrinogen. The final step is *platelet aggregation*, i.e., the formation of the platelet plug. Fibrinogen (or von Willebrand factor) binds to the activated GP IIb/IIIa receptors of two platelets, thereby creating a growing platelet aggregate.

Glycoprotein IIb/IIIa Receptor

The platelet GP IIb/IIIa receptor is a member of the integrin receptor superfamily of complexes that mediate cell-protein and cell-cell interactions.[114] The GP IIb/IIIa receptor is a calcium-dependent heterodimer, composed of two different subunits (α_{IIb} and β_3), both of which span the platelet membrane. The GP IIIa subunit contains a four-amino-acid sequence that is crucial for binding of fibrinogen and other ligands.[114] The first three amino acids are arginine-glycine-aspartic acid (RGD). LMW peptide and nonpeptide GP IIb/IIIa inhibitors have been developed to bind to the RGD sequence of the receptor, thereby interfering with the binding of fibrinogen to the GP IIb/IIIa receptor.

Antiplatelet therapy has been directed at decreasing the formation of TXA_2 (e.g., aspirin), inhibiting the adenosine diphosphate (ADP) pathway of platelet activation (e.g., ticlopidine and clopidogrel), and directly inhibiting platelet aggregation (e.g., GP IIb/IIIa inhibitors).

Secondary Hemostasis

Simultaneously with formation of the platelet plug, the plasma coagulation system is activated. Traditionally, the coagulation cascade has been divided into two pathways: the *extrinsic* or contact system and the *intrinsic* system (Fig. 44-7). Recent evidence, however, has revised the understanding of coagulation into a single interrelated system.[115-117] The extrinsic pathway, initiated by release of tissue factor, is now felt to be the predominant mechanism of initiating hemostasis.[115,117] Ultimately, factor X is activated and leads to formation of thrombin, which in turn cleaves fibrinogen to fibrin (Fig. 44-3).

Thrombin plays a central role in arterial thrombosis: (1) it converts fibrinogen to fibrin in the final common pathway for clot formation, (2) it is a powerful stimulus for platelet aggregation, and (3) it activates factor XIII, which leads to cross-linking and stabilization of the fibrin clot.[111] Thrombin molecules are incorporated into coronary thrombi and can form the nidus of rethrombosis (i.e., reocclusion or reinfarction) as the thrombus undergoes fibrinolysis. Accordingly, effective thrombin inhibition is an important part of the therapy for acute coronary syndromes (see page 1394).

Hemostatic System

This is a complex, overlapping system that consists of blood vessels, platelets, procoagulants and anticoagulants, profibrinolytic components, and inhibitors. For clarity, the following sections deal with each component of the hemostatic mechanism individually. However, all of these processes are intimately related and inseparable.

ROLE OF VESSEL WALL CONTRACTION AND ENDOTHELIUM

The immediate control of bleeding from a small severed vessel is vasoconstriction, which is soon followed by local perivascular and intravascular activation of platelets and coagulation components. TXA_2 produced and released by activated platelets may play a role in persistent vasoconstriction, as do products released by stimulated endothelium (e.g., endothelin) or generated during coagulation (bradykinin generated by activated factor XII and fibrinopeptide B).

In normal vessels, circulating platelets do not adhere to normal (unstimulated) endothelial cells in vivo. This may relate to the fact that both platelets and endothelium have a negative charge and thus would be mutually repulsive. The negative electrical charge of endothelial cells is due to a pronounced glycocalyx, consisting of proteoglycans, of which heparan sulfate (a heparin-like substance that binds antithrombin III) is the most important. Stimulated or injured endothelial cells lose their negative surface charge. The nonthrombogenic nature of endothelium is also partly due to the lack of surface molecules as tissue factor.

The thromboresistance of normal endothelium also depends on several substances produced by endothelial cells. They include potent vasodilators and inhibitors of platelet function, such as prostacyclin [prostaglandin I_2 (PGI_2)] and nitric oxide (NO), which serve to prevent platelet adhesion to endothelium.[118,119] Anticoagulant properties include heparin-like glycosaminoglycans and a thrombin-binding protein called thrombomodulin.

The production of prostacyclin by endothelium is stimulated by contact with activated platelets or leukocytes by stretching of the arterial wall (pulsatile pressure) and by some drugs. PGI_1 has strong antiplatelet and vasodilator properties and thus acts as the biological antagonist of TXA_2. A direct link between impaired biosynthesis of PGI_2 in the vessel wall and thrombosis or atherosclerosis is suggested by the decreased capacity of endothelium to generate prostacyclin with age, atherosclerosis, and risk factors such as high cholesterol, heavy smoking, and diabetes. NO is formed from L-arginine by an oxidation pathway that requires several cofactors. NO relaxes smooth muscle cells through stimulation of guanylate cyclase, which, in turn, generates cyclic guanosine monophosphate (cyclic GMP).[120] By the same mechanism, it is also a potent inhibitor of adhesion and aggregation of platelets.

There is a clear synergism between prostacyclin and NO in preventing platelet activation. NO is effective only in the immediate vicinity of its site of release because hemoglobin almost immediately inactivates any NO that enters the bloodstream. It has been suggested that a deficiency in NO production contributes to the pathogenesis of atherosclerosis and to the development of complications of diabetes. Thrombomodulin is a transmembranous protein that serves as an endothelial receptor for free thrombin.[121] In the complex that is formed and which does not require calcium, thrombin loses its procoagulant activity and expresses its anticoagulant role by activating protein C.

ROLE OF PLATELETS

The exterior coat of platelets, the glycocalyx, contains many distinct glycoproteins that are important for platelet function. They include integrins and leucine-rich glycoproteins. These surface glycoproteins mediate platelet adhesion and aggregation as receptors for adhesive proteins and agonists. The platelets contain dense bodies, alpha granules, actin filaments, microtubules, and an open canalicular system, which all have their respective functions in the formation of a hemostatic plug (Fig. 44-2).

In normal conditions, platelets are quiescent and circulate freely in the blood because they do not

attach to a normally functioning endothelium. Vessel injury, however, exposes subendothelial connective tissue to various elements to which platelets can adhere.[122,123] This phenomenon-platelet adhesion-is the initial event and one of the most crucial steps in platelet plug formation. The adhesive proteins collagen and fibronectin (and, to a lesser extent, laminin, microfibrils, and thrombospondin) are present in subendothelium and interact readily with von Willebrand factor, whereby this large protein changes its conformation. This allows platelets to bind to von Willebrand factor via their surface GP Ia/IIa and Ic/IIa receptors (Figs. 44-3 and 44-4). Particularly collagen, a ubiquitous structural component of the vessel wall, is important and may provide scaffolding on which other adhesive proteins assemble. Von Willebrand factor, which has two collagen-binding sites, is an absolute requirement for platelet adhesion but only at high shear rates, whereas fibronectin plays a significant role in platelet adhesion at lower shear rates.

After adhesion, platelets lose their discoid shape, form extended pseudopods, and spread out over the injured surface. Through the action of activators such as collagen and eventually thrombin and norepinephrine, the adhered platelets soon become activated, whereby other platelet receptors are expressed and several mediators stored in platelet granules are released.[124] This release reaction seems to be initiated by contraction of a circumferential band of microtubules. Stored granules are discharged through the open canalicular system after fusion of the granular membrane with the membranes of the open canalicular system. Among the granular agents released are ADP, serotonin, β-thromboglobulin, platelet factor 4, platelet growth factor, and TXA_2.[125,126]

These released substances, particularly ADP and TXA_2, induce binding of platelets to one another, a phenomenon called *platelet aggregation*. This process increases the size of the hemostatic plug at the site of injury and, by recruiting additional circulating platelets, transforms the initial monolayer of platelets into an aggregate. The platelet surface GP IIb/IIIa undergo a conformational change in the aggregation process, so that they can interact with plasma fibrinogen and other adhesive proteins as fibronectin and endothelial thrombospondin, which serve to link platelets together into a tighter aggregate (Fig. 44-7).[124,127]

The prostaglandins also play an important role in mediating the platelet release reaction and aggregation (Fig. 44-4). Collagen and epinephrine appear to trigger the activation of one or more phospholipases in the platelet membrane. Phospholipase A_2 acts on phosphatidylcholine to release arachidonic acid from the platelet membrane. Arachidonic acid is metabolized by cyclooxygenase to unstable proaggregating prostaglandin endoperoxide intermediates (prostaglandins G2 and H2). TXA_2 is formed by the action of thromboxane synthase on PGH_2; it further promotes platelet activation, thrombus growth, and local vasoconstriction.

On the other hand, the vascular endothelial cells synthesize prostacyclin (PGI_2), starting from arachidonic acid or from platelet-derived PGG_2. Prostacyclin stimulates adenylate cyclase and leads to an increased level of cyclic adenosine monophosphate (cyclic AMP) in the platelet (Fig. 44-5). Cyclic AMP, in turn, inhibits the discharge of calcium from the dense tubular system and thus prevents platelet aggregation and secretion. Phosphodiesterase enhances the breakdown of cyclic AMP.

Arachidonic acid also serves as a substrate for the formation of leukotrienes, a pathway mediated by lipoxygenase in the leukocytes. Thus, eicosanoids derived from arachidonic acid in platelets, endothelial cells, and leukocytes provide short-acting biological mediators that further promote not only platelet activation and local vasoconstriction but also platelet inhibition and vasodilatation. In addition, they intervene in local immune-mediated reactions.

ROLE OF BLOOD FLOW

Blood flow influences platelet function by shear stress. Exposure of platelets to very high shear stress leads to spontaneous aggregation even in the absence of exogenous agonists. Furthermore, some coagulation reactions are accelerated in the presence of high shear, and the ability of the endothelium to secrete tissue plasminogen activator over the basal level is increased two- to threefold.

ROLE OF BLOOD COAGULATION

Activated platelets provide a microenvironment that enhances the acceleration of fibrin formation at the site of injury. They rearrange their surface lipoproteins so that phospholipids, on which coagulation factors can concentrate, are now exposed to the bloodstream. This is accompanied by the exposure of high-affinity binding sites for the activated factors V, VIII, IX, and X. Thus, activated platelets provide a suitable surface on which the activation of prothrombin to thrombin is accelerated dramatically. Thrombin occupies a central position in the coagulation process. It is formed as the end product of a complex chain of reactions that transform, in sequence, a number of coagulation factors present as precursors (zymogens) in plasma into activated factors. Table 44-1 lists the well-recognized coagulation factors with their Roman numeral designations and synonyms and some of their properties. The coagulation factors are numbered roughly in the order of their discovery and do not reflect the sequence of reactions. Coagulation factors interact mainly on the membrane of activated platelets and other stimulated cells and tissue factor (a membrane protein exposed to the blood, e.g., after trauma) on which coagulation factors bind. Because of the low concentration of these factors in plasma and the abundant presence of circulating inhibitors, the interaction of procoagulants and their subsequent activation can proceed only slowly in the fluid phase of blood.

Coagulation factors are activated one by one, mainly through limited proteolysis. When the letter "a" accompanies a Roman numeral (e.g., factor VIIa), this indicates that the factor is in its activated form rather than in its naturally occurring precursor form (e.g., factor X). All activated factors are serine proteases: they split arginyl bonds in their specific substrate, and the latter then becomes another activated coagulation factor (waterfall or cascade sequence of events). In contrast, factors V and VIII, tissue factor and high molecular weight (HMW) kininogen are not proenzymes but function rather as cofactors. They can thus be considered as regulatory proteins (cofactors) that influence the reaction rate. These cofactors (except tissue factor) still require activation by minor proteolysis, while tissue factor X, present in extravascular spaces, must make contact with blood to function. The traditional coagulation scheme distinguishes an intrinsic from an extrinsic activation pathway.

The Intrinsic Pathway of the Coagulation System: Activation of Factors XII, XI, X, and IX

All factors participating in the intrinsic pathway are present in circulating blood, and the reaction sequence is initiated by contact of platelets and/or coagulation components with a subendothelial tissue. Antigen-antibody complexes and activated platelets may also serve this purpose, as can fissured atherosclerotic plaques and foreign surfaces, such as those in an extracorporeal circulation or renal dialysis. In vitro, this initial contact phase involves the interaction of factor XII (Hageman factor), factor XI, prekallikrein, and HMW kininogen with a foreign surface (a surface other than normal endothelium or blood cells).

When circulating factor XII meets negatively charged surfaces such as glass and kaolin, it binds via its heavy chain to the surface. Upon adsorption, bound factor XII exerts traces of biological activity. For the mechanisms of this phenomenon, conformation changes of the molecule with exposure of the enzyme site in the light chain have been postulated (Fig. 44-6). Factor XI and prekallikrein exist in plasma as equimolar complexes with HMW kininogen, and these complexes are bound to initiating surfaces via the HMW kininogen moiety. HMW kininogen transports both

factor XI and prekallikrein to an appropriate surface. Surface binding is assumed to serve to bring factor XII, prekallikrein, and factor XI to a close spatial orientation. Binding of factor XII to a negatively charged surface also makes the molecule more susceptible to proteolytic cleavage. Initially, traces of factor XIIa presumably generate traces of kallikrein from prekallikrein by splitting of a single peptide bond. Kallikrein will now activate more rapidly factor XII in a feedback loop, which, in turn, will generate more kallikrein, and the reciprocal activation of these two surface-bound molecules continues until the substrates are locally exhausted. Of note, a potent vasoactive substance, bradykinin, is released from HMW kininogen upon the activation of factor XII and generation of kallikrein. The latter also activates pro-urokinase, enhancing fibrinolytic activity.

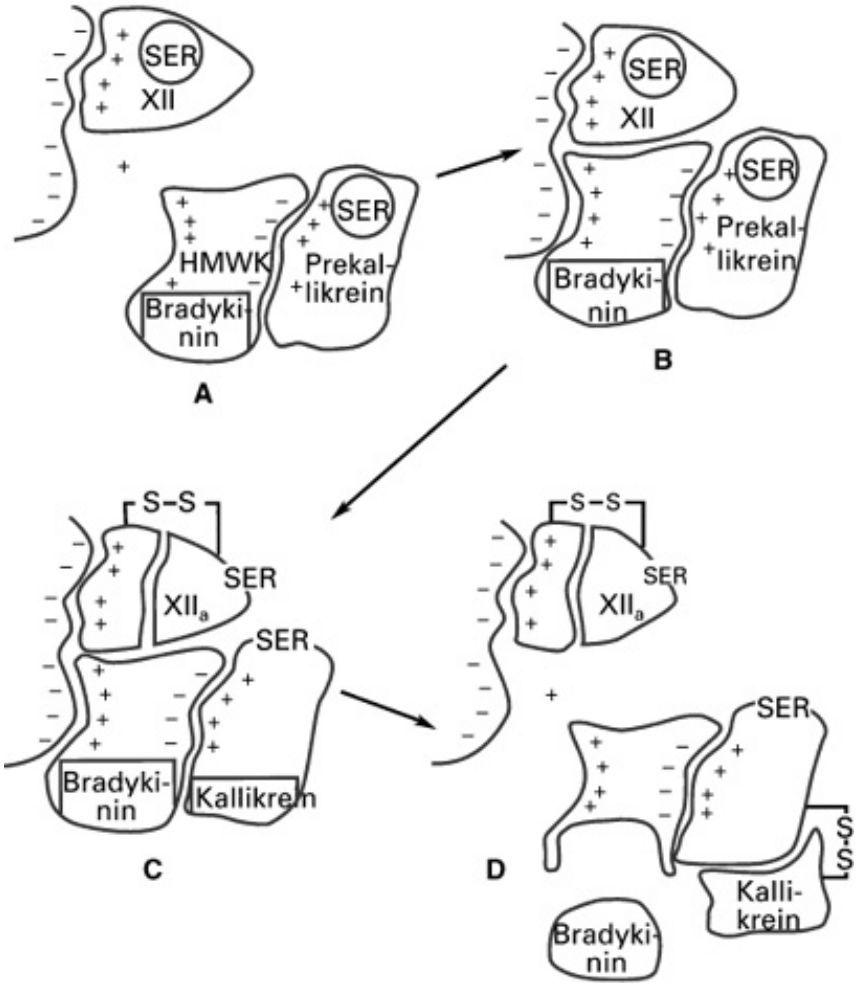

Figure 44-6: In the intrinsic pathway of coagulation, *contact activation* refers to a series of reactions following adsorption of factors XII and XI as well as prekallikrein and high molecular weight kininogen to highly negatively charged surfaces. The contact activation does not require calcium and results in surface-induced conformational changes of the molecules. *A-D*. Sequence of events. SER = serine protease.

Factor XIIa converts in vitro the next factor of the coagulation cascade, factor XI, from its zymogen form to its enzymatic constellation. Factor XI also circulates in plasma complexed with HMW kininogen; the latter protein thus serves as helper protein carrying factors XII and XI in the blood (Fig. 44-7). The in vivo activation of factor XI is less clear. It is possible that factor XII-independent activation of factor XI is mediated by thrombin. Both factor XIIa and thrombin cleave the same internal peptide bond (Arg369-Ile) in each of the two chains of the factor XI molecule, leading to the formation of two heavy and two light chains.

Factor XIa bound to the surfaces by HMW kininogen interacts upon activation with factor IX in a calcium-dependent two-step reaction. Each light chain of factor XIa contains a catalytic site, while its heavy chain has the binding site for factor IX and HMW kininogen. Binding of calcium ions to factor IX (a vitamin K-dependent protein) induces a conformational change in the molecule, which facilitates its binding to the heavy chain of factor XIa, which is essential for the optimal rate of factor IX activation. Platelets can also be reckoned to be important in the intrinsic system as they contain HMW kininogen, which can be expressed when the platelets are activated, as they indeed are on fissured and sclerotic plaques and foreign surfaces.

Activated factor IX, thrombin-modified factor VIII, negatively charged phospholipid (e.g., activated platelets), and calcium ions form a multimolecular complex coined *tenase* because it activates directly factor X; the glutamic acid (Gla) residues of factors IXa and Xa mediate their binding to phospholipid (Fig. 44-7).

Congenital deficiency of the three contact factors (factor XII, prekallikrein, and HMW kininogen) is not associated with bleeding, and only half of factor XI-deficient patients have bleeding problems with an intensity not related to the factor XI level. The significance of the contact phase is, therefore, speculative; however, it may become relevant in particular therapeutic settings. Indeed, extracorporeal circuits may be regarded as a giant test-tube condition, and the contact activation becomes important under these circumstances. Beyond the contact phase, the intrinsic activation system is important, already in physiologic conditions, as individuals with a severe deficiency of factor VIII or IX (two forms of hemophilia) have a serious bleeding condition.

The Extrinsic (Tissue Factor) Pathway of the Coagulation System: Activation of Factors VII and X

In the extrinsic system, membrane-bound tissue factor starts off the chain of events by forming a complex with factor VII in the presence of calcium ions (Fig. 44-7). Tissue factor is as a dimer composed of two identical subunits with interacting enzyme-binding sites.[128,129] It is present on nonvascular cell surfaces and on microvesicles shed from cell surfaces. It was hypothesized that the normal distribution of tissue factor represents a hemostatic envelope ready to activate coagulation when vascular integrity is disrupted. Vascular endothelial cells and monocytes also can produce and express tissue factor activity upon stimulation with interleukin 1 or endotoxin, which suggests that cytokines may modulate tissue factor expression and fibrin deposition at the site of inflammation. Tissue factor is an integral membrane protein composed of protein and phospholipid components, both of which are required for its procoagulant activity. Factor VII is a single-chain protein that, in this form, already has some enzymatic activity and can complex with tissue factor. By cleavage of an Arg-Ile bond, however, the molecule of factor VII splits in a light chain and a heavy chain (containing the active site) linked by two disulfide bonds. This activation increases the coagulant activity of factor VII about 100-fold. However, the activation of factor VII occurs only after it has bound to tissue factor. The tissue factor-factor VIIa complex then combines with the substrate (factor X), producing a further conformational change in factor VIIa, so that it binds still more tightly to tissue factor, precluding dissociation of factor VIIa from tissue factor. The tissue factor-factor VIIa complex activates primarily factor X but also factors IX and XI, which interconnect the intrinsic and extrinsic activation pathways and play a prima ballerina role in the activation of coagulation.[13] Tissue factor accelerates these reactions as a cofactor, apparently by inducing a conformational change in factor VIIa.

It should be noted that phospholipids of the platelet membrane, in conjunction with factor Xa, can also activate factor VII-another bridge between the intrinsic and extrinsic pathways. Thus, the earlier concepts of a clearly separate intrinsic and extrinsic activation system are becoming obsolete. That factor VII is essential to ensure normal hemostasis is underlined by the bleeding condition of patients with severe congenital factor VII deficiency.

The Pathway in Common: The Formation of Prothrombinase, the Enzyme Converting Prothrombin to Thrombin

Factor X stands at the crossroad of the extrinsic and intrinsic activation pathways.[130] This means that factor X can be activated either by the tenase complex (IXa, phospholipid, VIIIa, and Ca ions) or by the tissue factor-factor VIIa complex (Fig. 44-7). In both instances, activation of factor X results from the cleavage of a single peptide bond between Arg and Ile, releasing an activation peptide and unmasking an active site on the heavy chain.[131] This is brought about by the enzymatic activity residing in factor IXa, which is part of the tenase complex. The presence of proteolytically modified factor VIII-whether by thrombin, factor Xa, or factor IXa-by separation of factor VIII from von Willebrand factor enhances 10,000-fold the rate of activation of factor X by factor IXa. Factor VIIIa has no enzymatic activity and is thus a helper protein (a cofactor) which, to exert its function, binds to phospholipid vesicles, provided phosphatidylserine is available on the platelet membrane.[16,132] In fact, specific binding sites are available on activated platelets for factor VIII that are distinct from the binding sites for factor V expressed during stimulation of platelets. As shown below, activated protein C degrades factor VIIIa. Thus, factor VIII must be activated for hemostasis and inactivated for the maintenance of the fluidity of blood.

To be fully active, factor Xa has to form a stoichiometric 1:1 complex with factor Va; the latter molecule enhances the activation of prothrombin by factor Xa 300,000-fold. Normal plasma contains factor V in trace amounts (25 n*M*, while factor X is about 200 n*M*) and in an inactive state; its activation requires three specific enzymatic cleavages, which can be brought about by thrombin or less efficiently by factor Xa. The association of factor Va with factor Xa on an anionic phospholipid is termed *prothrombinase*. Factor Va increases the turnover (k_{cat}) 1000-fold, which means that the number of thrombin molecules generated by the enzyme upon saturation by the substrate is multiplied by a factor of approximately 1000. In contrast to the vitamin K-dependent procoagulation factors (prothrombin and factors VII, IX, and X), which bind to phospholipids via calcium bridges with their Gla domain, factor Va does not bind to phospholipids via calcium bridges but penetrates into the lipid bilayer.

The Action of Prothrombinase on Prothrombin

The multimolecular complex prothrombinase initially cleaves one Arg-Ile bond in the prothrombin molecule, producing meizo-thrombin. This intermediate molecule remains membrane bound through the retained Gla domain linkage and activates the inhibitor protein C but lacks procoagulant properties either on platelets or on fibrinogen. To obtain the latter property, another arginine bond (Arg-Thr) has to be cleaved, yielding alpha-thrombin, which, lacking a Gla-containing region, is released from the cell surface.

For the different reactions pertaining to the coagulation cascade system, it is being assumed that all coagulation factors immobilize on phospholipids (stimulated platelets or perturbed endothelial or white cells) and that reaction products are shuttled between assembled complexes. An alternative but less efficient possibility is that reaction products dissociate from the phospholipid membranes to become free in solution. Single-membrane channeling protects critical enzymes from inactivation by plasma inhibitors (e.g., antithrombin III) as well as from dilution by blood flow.

The Pivotal Role of Thrombin

Thrombin represents the culmination of the coagulation cascade; its action on fibrinogen is most dramatic, because thrombus formation is a visible process. Thrombin itself is responsible for its own nonlinear generation caused by positive feedback activation, whereby thrombin enhances

neoformation of thrombin (Fig. 44-8). In addition, thrombin is a pivotal molecule for numerous other functions. The action of thrombin on platelets results in the release of platelet factor V exteriorization and in the transbilayer movement of its inner membrane surface (flip-flop reaction). Thrombin activates three of the four cofactor or helper proteins (factors V and VIII and thrombomodulin but not tissue factor). Thrombin furthermore activates factor XIII, which increases the strength and renders the fibrin more resistant to thrombolysis. Thrombin can increase the production and release of prostacyclin, NO, ADP, and PAI-1 from the normal endothelium, protecting the microcirculation against thrombosis. Thrombin inhibits its own production by a negative feedback mechanism via the thrombomodulin-protein C and S system. Thrombin is also involved in other biological effects, such as chemotaxis and mitogenesis. It also elicits a potent mitogenic response in fibroblasts and macrophages, thereby modulating inflammatory reactions at the site of vascular injury.

The Conversion of Fibrinogen to Fibrin

Fibrinogen is a large paired molecule held together by disulfide bridges. Each symmetric half-molecule consists of one set of three different polypeptide chains termed Aα, Bβ, and γ. The two half-molecules are joined in the central amino-terminal domain in an antiparallel manner by three interchain disulfide bridges, two of which are between γ chains and the other between α chains.

Thrombin splits an arginine-glycine bond, first at the amino end of the two Aα chains and later at the amino end of each of the two Bβ chains so that each molecule releases in sequence two small aminopeptides A (FPA) and two small fibrinopeptides B (FPB) from fibrinogen and thus converts this molecule to fibrin monomers that are still soluble (Fig. 44-9). The FPA release exposes a polymerization site in the central region of the fibrinogen molecule (E domain) that subsequently aligns with a complementary site in the outer region (D domain) of another fibrin monomer to form staggered overlapping two-stranded fibrils. The slower FPB release exposes an independent site for noncovalent intermolecular interaction, resulting in complementary alignment of fibrin monomers. Subsequently, lateral association of fibrin monomers occurs, and the network becomes thicker and branched, still through a nonenzymatic process. These coupled monomers of fibrin, called *polymers*, are still soluble unless they become too large and precipitate; the resulting gel of fibrin forms the skeleton of a thrombus and traps red and white cells.

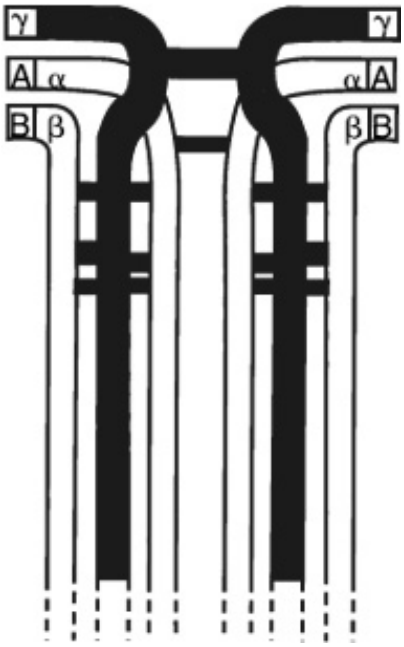

Figure 44-9: Structure of fibrinogen. This glycoprotein is a paired molecule, each half consisting of three homologous chains; Aα, Bβ, and γ. The horizontal connecting lines are disulfide bonds. Thrombin cleaves first the A peptide and then the B peptide. The disulfide knot of the dimer fibrinogen is clearly depicted. The entire sequence of 2946 amino acids has been elucidated.

The structural stability of the fibrin network is achieved through covalent cross-linking.[133] Thrombin activates factor XIII (*fibrin-stabilizing factor*), a transglutaminase that, in the presence of calcium, forms peptide bonds between side chains of suitable lysine (donor) and Gla (acceptor) residues. The result of such a lysine cross-link is that the thrombus becomes firmer and more resistant to thrombolysis. It should be noted that fibrin-bound thrombin (approximately 40 percent of the thrombin generated) retains its coagulant and platelet-activating properties and is protected from inactivation by circulating heparin-antithrombin III.[134] During thrombolysis, fibrin-bound thrombin is released and can cause rethrombosis. Hirudin, hirulog, and similar antithrombin III-independent synthetic thrombin inhibitors, which are smaller than heparin, can inhibit fibrin-bound thrombin. Of note, two other plasma proteins (fibronectin and α2-plasmin inhibitor) are also covalently cross-linked to fibrin by factor XIIIa and are incorporated in the fibrin mesh.

Connections Between the Intrinsic and Extrinsic Pathways of Coagulation

The concept of separating the two pathways of the coagulation system that merge in a common pathway from the activation of factor X on is a didactic schematization that is increasingly blurred as feedback mechanisms and interactions between the two pathways are found.[129] For example, the factor VIIa-tissue factor complex can activate factors IX and XI directly; factors IXa and Xa can activate factor VII. The extrinsic pathway seems to play a major role in the initiation of in vivo coagulation, while the intrinsic pathway is now thought to be required for continuous growth and maintenance of fibrin formation.

Activation of coagulation factors in successive stages is based on the classical cascade. It will be appreciated that the speed with which these reactions develop increases gradually, as in a system of electronic amplification. Also, here one should realize that nature acts in concert rather than in a sequence of solitary actions. Of course, this is a common feature in biological systems. In the case of the coagulation system, it is the more remarkable because it operates largely outside the cell without the controls imposed by intracellular compartmentation.

Coagulation: A Series of Surface-Catalyzed Events

With the exception of fibrinogen, prothrombin, and plasminogen, the coagulation factors are present in the fluid phase of blood at very low concentrations. Their encounter in solution is possible and their interaction slow, though this can be remarkably accelerated, up to 100,000-fold, after adsorption and concentration on surfaces. Modified endothelium, stimulated platelets, denuded subendothelial structures (e.g., collagen), fissured atherosclerotic plaques, and foreign surfaces (extracorporeal circulation conduits) allow the attachment of passing platelets (adhesion) and the absorption of coagulation proteins. One way for this to occur is by binding mediated through calcium bridges between negatively charged phospholipids (tissue factor, activated platelets, and microvesicles) and the γ-carboxyglutamic acid (Gla) residues of the four vitamin K-dependent procoagulants (prothrombin and factors VII, IX, and X), and two endogenous anticoagulants (proteins C and S). Coumarin drugs interfere in the vitamin K cycle, so that less glutamic acid is formed and binding of these proteins to phospholipids is impeded. Assembly on surfaces increases the local concentration of clotting factors considerably and creates an optimal steric relationship (better alignment) for their interaction. This means that a lipid-bound enzyme has a greater affinity for the substrate than the free circulating enzyme. Inhibitors of activated coagulation factors are much less effective in binding to phospholipid surfaces; thus binding of activated coagulation factors to such a surface protects them against endogenous inhibitors.[135] Interaction between coagulation factors is accelerated by the presence of a phospholipid

interphase (decrease of K_m value) and the efficiency is also improved by the presence of the helper protein factors V and VIII (increase of K_{cat}).

NATURAL INHIBITORS OF THE COAGULATION SYSTEM

Several mechanisms help to prevent uncontrolled formation of fibrin in the circulation. First, coagulation remains a strictly localized process because it requires negatively charged surfaces, which are in the first place provided by activated platelets. Platelet activation, in turn, is limited to sites of vessel injury and fissured atherosclerotic plaques. In addition, the flowing blood will rapidly dilute any inadvertently activated clotting factor before it perpetuates the reaction sequence to form fibrin. Finally, a number of proteins circulate in the blood to inhibit the coagulation process at various stages of the cascade. Four of them appear particularly important in preventing thrombosis: antithrombin III, protein C, tissue factor pathway inhibitor, and thrombomodulin.

Antithrombin III inhibits thrombin and the activated forms of several coagulation factors, but inhibition of thrombin and of factor Xa is particularly important and clinically relevant.[136] Thrombin forms a tightly bound, stable complex with antithrombin III; this occurs at a relatively slow rate that is enormously enhanced by heparin (see below) and also appreciably by heparan sulfate, a substance very similar to heparin, which is found on the intraluminal surface of vascular endothelial cells. The inhibition of thrombin is due to ternary complex formation between thrombin, antithrombin III, and heparin. The inhibition of factor Xa is the result of the formation of a binary complex between antithrombin III and factor Xa.

The protein C-thrombomodulin pathway of thrombin inhibition represents the major natural anticoagulant system (Fig. 44-10). Protein C is a proenzyme formed in the liver; vitamin K is required in its synthesis. On the surface of either platelets or endothelium, protein C is activated by thrombin to become a circulating serine protease that inhibits factors Va and VIIIa. Complex formation between thrombin and thrombomodulin, a potent cofactor present on the endothelial surface, catalyzes the activation of protein C. Protein S is another vitamin K-dependent protein that does not possess serine protease properties but appears to function as a cofactor for activated protein C by facilitating its binding to membrane phospholipids.[137] In plasma, protein S circulates free or bound to C4b-binding protein, a component of the complement system. Only free protein S serves as a cofactor of activated protein C. In addition to being a powerful anticoagulant, activated protein C initiates fibrinolysis by releasing t-PA from the endothelium and neutralizing PAI.

Tissue factor-factor VIIa complex is inactivated by the tissue factor pathway inhibitor (TFPI), previously called lipid protein-associated coagulation inhibitor.[129,130,135] TFPI appears to be the only plasma component inhibiting the catalytic activity of factor VIIa-tissue factor complex. Factor VIIa cannot be neutralized effectively unless it is bound to tissue factor.[129] This is in contrast to other coagulation components, which are neutralized more effectively as free reactants than after they interact in complexes.[138] TFPI first interacts with factor Xa to form Xa-TFPI complexes, which then form a quarternary Xa-TFPI-VIIa-tissue factor complex with resulting loss of the activity of VIIa-tissue factor complex. The plasma concentration of TFPI is low, but a larger pool of TFPI bound to vascular endothelium is present from which TFPI can be released into the blood by heparin.

Thrombomodulin is located on the surface of all endothelial cells except those in the microcirculation of the human brain. When thrombin is generated within a vascular space, excess thrombin is bound to thrombomodulin. Thrombomodulin exerts three types of activities: (1) it inhibits thrombin-induced activation of platelets, factor V, and fibrinogen; (2) it promotes the activation of protein C after formation of the thrombomodulin-thrombin complex; and (3) it enhances the inhibition of thrombin by antithrombin III. Thus, thrombomodulin modifies the

substrate specificity of thrombin; the procoagulant activity is switched off, and at the same time its anticoagulant activity is tremendously increased.

The Fibrinolytic System

This system is essential for removing excess fibrin deposits to preserve vascular patency. The role of fibrinolysis in the maintenance of blood fluidity is well illustrated by an increased incidence of venous thromboembolism in patients with abnormal, nonfunctional plasminogen. Similarly, the overproduction of PAI-1 in transgenic mice leads to an increased risk of venous embolism.

COMPONENTS OF THE FIBRINOLYTIC SYSTEM

Plasminogen

This is present in human plasma at a concentration of about 2 μM, which is about twice the concentration of α_2-antiplasmin. The native molecule, denoted Glu-plasminogen, after its NH_2-terminal glutamic acid, is a single-chain glycoprotein, consisting of 791 amino acids.[23] Plasminogen is organized in seven structural domains (Fig. 44-11). From the NH2-terminal end, there is a *preactivation peptide*, five sequential, homologous, looped kringle structures, and the T-proteinase domain with the catalytic site composed of His^{603}, Asp^{646}, and Ser^{741}. The kringle domains contain lysine-binding sites that play a crucial role in the specific recognition of fibrin, cell surfaces, and α_2-antiplasmin.[139-141]

Plasminogen is converted to a two-chain serine protease called *plasmin* by cleavage of a single Arg^{561}-Val^{562} peptide bond between kringle 5 and the proteinase domain. The serine-containing active site is situated in the B or light chain. Plasmin may catalyze the release of the preactivation peptide from Glu-plasminogen, forming degraded plasminogen with amino-terminal lysine, valine, or methionine commonly called *Lys-plasminogen*. Lys-plasminogen is more easily activated to plasmin than Glu-plasminogen.[141] Plasmin digests a number of proteins, including fibrin, fibrinogen, and factors V and VIII, as well as a number of esters and amides.

Natural Plasminogen Activators

Plasminogen may be converted to plasmin by a number of agents called *plasminogen activators*. The principal circulating plasminogen activator in humans is *tissue-type plasminogen activator* (t-PA). This a 70-kDa serine proteinase, which in its native form consists of a single polypeptide chain. t-PA is converted by plasmin to a two-chain form by hydrolysis of the Arg^{275}-Ile^{276} peptide bond. In contrast to most single-chain forms of serine proteinases, single-chain t-PA possesses significant catalytic activity. The amino-terminal region is composed of several domains with homologies to other proteins: a finger domain, a growth factor domain, and two looped kringle structures (Fig. 44-12). The region constituted by residues 276 to 527 represents the serine proteinase part with the catalytic site, composed of His^{322}, Asp^{371}, and Ser^{478}.[142] These distinct domains in t-PA are involved in several functions of the enzyme, including its binding to fibrin, fibrin-specific plasminogen activation, rapid clearance in vivo, and binding to endothelial cell receptors. Binding of t-PA to fibrin is mediated via the finger and the second kringle domains. The presence of fibrin markedly enhances the plasminogen-activating property of t-PA, as it not only binds t-PA and plasminogen but also greatly increases the affinity of t-PA for plasminogen. Thus, fibrin appears to concentrate both t-PA and plasminogen on its surface and to enhance their interaction (see Ambrose et al.[26] and Fuster et al.[28]). Plasmin so formed on fibrin surfaces has its lysine-binding and active sites occupied and is relatively protected from the inhibitory action of α_2-antiplasmin.

Single-chain urokinase-type plasminogen activator (scu-PA) is a 54-kDa glycoprotein containing 411 amino acids (Fig. 44-12). The plasma concentration of scu-PA is about 2 ng/mL. Upon proteolytic cleavage of the Lys^{158}-Ile^{159} peptide bond, the molecule is converted to a two-chain derivative (tcu-PA, urokinase). The catalytic triad is located in the carboxy-terminal polypeptide chain and is composed of Asp^{255}, His^{204}, and Ser^{356}. The amino-terminal chain contains an epidermal growth factor domain and one kringle domain. The epidermal growth factor domain is responsible for the binding of single-chain u-PA to its receptor, which is present on the surface of a variety of cells. The u-PA receptor is essential for localization of u-PA-mediated plasmin formation to the pericellular environment.[143,144] A LMW tcu-PA (33 kDa) can be generated from tcu-PA by hydrolysis of the Lys^{135}-Lys^{136} peptide with plasmin. A LMW scu-PA (32 kDa) can be generated by proteolytic cleavage of the Glu^{143}-Leu^{144} peptide bond.[145]

ENDOGENOUS INHIBITORS OF THE FIBRINOLYTIC SYSTEM

α_2-Antiplasmin (α_2-plasmin inhibitor) belongs to the serine proteinase inhibitor superfamily (serpins). Like other inhibitors of this class, serpins react with their target proteinases by formation of a 1:1 molar reversible complex, followed by covalent binding between the hydroxyl group of the active-site serine residue of the proteinase and the carboxyl group of the P1 residue at the reactive site ("bait region") of the serpin (Fig. 44-11).

α_2-Antiplasmin is present in plasma at a concentration of about 1 μM. It is a 67-kDa glycoprotein containing 464 amino acids and about 13 percent carbohydrate.[146] The reactive site of the inhibitor is the Arg^{364}-Met^{365} peptide bond. α_2-Antiplasmin is unique among serpins by having a carboxy-terminal extension of 51 amino acid residues; this contains a secondary binding site that reacts with the lysine-binding sites of the kringles 1 to 3 of both plasminogen and plasmin. α_2-Antiplasmin (plasminogen-binding form) becomes partly converted in the circulating blood to a non-plasminogen-binding, less reactive form (about 30 percent of the total) that lacks the 26 carboxy-terminal residues. Two forms of α_2-antiplasmin are present in about equal amounts in purified preparations of the inhibitor. The amino-terminal Gln^{14} residue of α_2-antiplasmin can cross-link to Aa chains of fibrin, in a process that requires Ca^{2+} and is catalyzed by activated coagulation factor XIII. This renders the thrombus less sensitive to thrombolysis. Other serpins are α_2-macroglobulin and α_1-antitrypsin.

Two principal inhibitors specific for plasminogen activators have been identified in humans, and a number of additional subsidiary inhibitors of this type have been described. They are also members of the serine protease inhibitors (serpin) family.

PAI-1 is a 52-kDa single-chain glycoprotein consisting of 379 amino acids.[147,148] The reactive site of the inhibitor is the Arg^{346}-Met^{347} peptide bond. PAI-1 is stabilized by a tight binding to the cell-adhesive protein vitronectin. PAI-2 exists in two different forms with comparable kinetic properties and is detected only in pregnant women.[149]

REGULATION OF THE FIBRINOLYTIC SYSTEM

Formed fibrin, whether in normal wound seals or in tissue damaged by any stimulus, is lysed in the body as a result of its unique property of adsorbing small quantities of plasminogen and t-PA and local generation of plasmin, which is protected from inactivation by inhibitors.

Activation of plasminogen by t-PA is enhanced in the presence of fibrin or at the endothelial cell surface. Fibrinolysis may be inhibited at the level of plasminogen activation or at the level of plasmin. Fibrinolysis is also regulated as a result of increased or decreased synthesis and/or

secretion of t-PA and of PAI-1 from the vessel wall[150] or by changes in their rates of elimination by the liver.[151]

Synthesis and Secretion of Tissue-Type Plasminogen Activator

Vascular endothelial cells synthesize and secrete t-PA to the circulating blood.[150] The plasma concentration of free t-PA is less than 1 ng/mL. The half-life of t-PA in the circulation is only about 5 min because of rapid hepatic clearance; some t-PA is inactivated by PAI-1. Various stimuli-such as venous occlusion, physical exercise, catecholamines, bradykinin, or desmopressin-produce a rapid increase (within minutes) in the level of t-PA in the blood. This response is too rapid to represent increased synthesis but may reflect release of t-PA from cellular storage pools, as well as decrease in hepatic clearance due to a reduced hepatic blood flow.[152] A storage pool of t-PA in endothelial cells has not been conclusively identified.[153]

A variety of agents have been shown to increase the synthesis of t-PA by cultured endothelial cells, including thrombin, histamine, butyrate, phorbol myristate acetate, basic fibroblast growth factor, activated protein C, butanol and alcohol derivatives, and retinoids. The increase of t-PA induced by histamine, thrombin, and phorbol myristate acetate in endothelial cells is paralleled by increased levels of t-PA mRNA as a result of enhanced transcription of the t-PA gene.[153] Overexpression of t-PA in endothelial cells using a retroviral expression vector did not alter the morphology, attachment, proliferation, migration, or invasion in the in vitro systems. Potentially such t-PA-transduced cells could increase local fibrinolysis and may thus be useful for in vivo therapeutic interventions.[154]

Synthesis and Secretion of Plasminogen Activator Inhibitor 1

PAI-1 mRNA has been demonstrated in a large variety of tissues, suggesting that common cells in these tissues, such as endothelial or smooth muscle cells, may be the site of production.[155] PAI-1 is found in plasma, platelets, placenta, and extracellular matrix. The concentration in plasma is in the picomolar range but may increase to about 2 n*M* during pregnancy, most likely as a result of release of the inhibitor from placenta. Both active and latent PAI-1 are cleared rapidly, with half-lives in rabbits of approximately 15 and 5 min.[156,157] For unknown reasons, PAI-1 exhibits a circadian variation; the plasma concentration peaks in the morning and reaches a trough in the late afternoon and evening;[158] t-PA exhibits a diurnal variation, which is opposite to that observed for PAI-1.

PAI-1 mRNA is increased and PAI-1 protein detected in endothelial cells juxtaposed to thrombi, in smooth muscle cells adjacent to the neointima, and in macrophages. The augmented arterial wall expression of PAI-1 induced by thrombosis may shift the local balance between fibrinolysis and thrombosis toward the latter.[159]

Only a few studies have reported a downregulation of PAI-1 synthesis in endothelial cells, either by forskolin or by endothelial cell growth factor combined with heparin.[160] PAI-1 is not stored within cells but is rapidly and constitutively secreted after synthesis. An exception is formed by platelets that store PAI-1 in their alpha granules; activation of platelets thus results in release of PAI-1.

α2-Antiplasmin

This forms an inactive 1:1 stoichiometric complex with plasmin. The half-life of plasmin

molecules on the fibrin surface, which have both their lysine-binding sites and active site occupied, is estimated to be 2 to 3 orders of magnitude longer than that of free plasmin (Fig. 44-11).

Plasminogen Activator Inhibitors

PAI-1 reacts very rapidly with single-chain and two-chain t-PA and with two-chain u-PA (tcu-PA).[161,162] PAI-2 primarily inhibits tcu-PA. The inhibition rate of scu-PA, single-chain t-PA, and two-chain t-PA by PAI-2 is about 10, 1200, and 150 times slower, respectively, than that by PAI-1. PAI-1 and PAI-2 do not react with scu-PA.[161]

Like other serpins, PAI-1 inhibits its target proteinases by formation of a 1:1 stoichiometric reversible complex, followed by covalent binding between the hydroxyl group of the active-site serine residue of the proteinase and the carboxyl group of the PI residue at the reactive center ("bait region") of the serpin. The rapid inhibition of both t-PA and u-PA by PAI-1 involves a reversible high-affinity second-site interaction that does not depend on a functional active site. In the presence of fibrin, single-chain t-PA is protected from rapid inhibition by PAI-1. It has, however, also been reported that PAI-1 binds to fibrin and that fibrin-bound PAI-1 may inhibit t-PA-mediated fibrin clot lysis.[163]

The active form of PAI-1 converts to a latent form that can be partially reactivated by denaturing agents. In addition, inhibitory PAI-1 may convert not only to latent PAI-1, which can be reactivated, but also to substrate PAI-1, which may be irreversibly degraded by target proteinases, including t-PA, u-PA, and thrombin.[164]

Plasminogen Activation by Tissue-Type Plasminogen Activator at the Fibrin Surface

The main role of t-PA most likely is in the dissolution of fibrin.[139,165] t-PA is a poor enzyme in the absence of fibrin, but the presence of fibrin strikingly enhances the activation rate of plasminogen.[166] Plasmin formed on the fibrin surface has both its lysine-binding sites and active site occupied and is thus only slowly inactivated by α_2-antiplasmin (half-life of about 10 to 100 s); in contrast, free plasmin, when formed, is rapidly inhibited by α_2-antiplasmin (half-life of about 0.1 s).

During fibrin clot lysis, single-chain t-PA is converted to two-chain t-PA at the fibrin surface. This conversion is probably of little physiologic relevance, since the activity of single-chain t-PA and two-chain t-PA is enhanced to the same extent in the presence of fibrin or fragment-X polymer.[167] Fibrin-bound single-chain t-PA may adopt a conformation similar to that of two-chain t-PA. Whether conversion of Glu-plasminogen to the more easily activatable Lys-plasminogen contributes significantly to the increased plasminogen activation rate during fibrinolysis is still somewhat controversial.

Binding studies[168,169] as well as kinetic studies have revealed that lipoprotein-a- (Lp-a-) competes with plasminogen for binding to fibrin as a result of binding of Lp(a) to fibrin via its lysine-binding domains. As for plasminogen, binding of Lp(a) to fibrin is enhanced by partial proteolytic degradation of the fibrin surface.[168] As a functional consequence of the competition between Lp(a) and plasminogen for binding to fibrin, the fibrin-dependent enhancement of plasminogen activation by t-PA is inhibited.[169,170]

PATHOPHYSIOLOGY OF FIBRINOLYSIS

Increased levels of PAI-1 activity resulting in a decreased fibrinolytic capacity have been reported in several thrombotic disease states, including venous thromboembolism, obesity, sepsis, coronary artery disease, and acute MI.[158,171] Increased levels of PAI-1 have also been found in association with the insulin resistance syndrome in which a significant correlation was found between plasma PAI-1 levels and body mass index, triglyceride levels, insulin levels, and systolic blood pressure. Obese people-particularly those with android obesity-also have high PAI-1 levels.

Increased plasma levels of PAI-1 are one of the major disturbances of the hemostatic system in patients with coronary heart disease, and multiple interrelations with established metabolic risk factors have been observed. Increased PAI-1 levels have also been demonstrated in atherosclerotic lesions within the vessel wall. Therefore, both systemically and locally increased PAI-1 concentrations could have a pathogenic role in the development of atherosclerotic disease.

Many case-control or cross-sectional studies have demonstrated high plasma PAI-1 levels in patients who have had a MI or unstable angina. A relationship between deficient fibrinolysis due to high PAI activity levels and recurrent MI (within 3 years) was demonstrated in young men who had survived their first MI. On the other hand, PAI-1 activity was not predictive for recurrent infarction (nor was t-PA antigen) in a group of older patients followed over 5 years. In a cohort of patients with angina pectoris, high basal t-PA antigen levels were found to be associated with an increased risk of MI, while no correlation was observed with PAI activity.[172,173]

Attempts to demonstrate a relationship between plasma PAI-1 levels and the severity of vessel wall damage have led to conflicting results in cross-sectional studies. Analysis of the data of the European Concerted Action on Thrombosis (ECAT) angina pectoris study demonstrated that there was a weak distinction between patients with and patients without significant coronary stenosis; the former had significantly higher plasma levels of PAI-1. NO association could be observed with the extent of coronary atherosclerosis. There are multiple interrelations between plasma PAI-1 levels and other risk factors of atherothrombosis, such as those involved in the metabolic syndrome of insulin resistance. In the ECAT angina pectoris study, in which insulin determination was available for almost 1500 patients, two- to threefold differences in PAI-1 levels were observed in comparing the lowest and the highest quintile of insulin, body mass index, or triglyceride.[174]

Chapter 44: THROMBOGENESIS, ANTITHROMBOTIC, AND THROMBOLYTIC THERAPY

ANTITHROMBOTIC DRUGS

Given the importance of thrombosis in acute coronary syndromes, thrombolytic and antithrombotic therapy has become the primary therapy for most conditions. This chapter reviews the numerous agents in clinical use or expected for clinical use in the coming years. The mechanism of action of the agent and the major evidence supporting its use in clinical medicine are reviewed; readers will also be referred to the specific chapter of that clinical syndrome for additional perspective on its use in context with the full treatment strategies.

Platelet Inhibitors

Platelet inhibition can be achieved in numerous ways (Fig. 44-12). These include inhibition of platelet cyclooxygenase (aspirin or sulfinpyrazone), inhibition of ADP receptors (ticlopidine or clopidogrel), or inhibition of the platelet GP IIb/IIIa receptor. Platelet inhibition can also be achieved by inhibition of thromboxane synthase with or without blockade of endoperoxide-thromboxane receptors, modulation of platelet adenylate or guanylate cyclase (prostacyclin analogs), interference with the function of the platelet GP Ib-IX receptor (monoclonal antibodies to GP 1b-IX), synthetic peptides to the A1 von Willebrand factor domain, recombinant von Willebrand fragments covering the A1 domain, and peptides that bind to but do not activate the platelet-receptor domain that interacts with thrombin. In this chapter, only platelet inhibitors that have been investigated in clinical trials are reviewed.

Aspirin

This permanently acetylates cyclooxygenase, thereby blocking the synthesis of TXA_2 by the platelet (Fig. 44-5). By decreasing the amount of TXA_2 released, which would act to stimulate other platelets, this decreases overall platelet aggregation at the site of the thrombus. This inhibition of cyclooxygenase is permanent-and thus the antiplatelet effects last for the lifetime of the platelets-on order of 7 to 10 days. Aspirin selectively inhibits TXA_2 formation (Fig. 44-5) but only partially impedes platelet aggregation induced by ADP, collagen, and low concentrations of thrombin.[175]

Aspirin does not inhibit adherence of the initial layer of platelets to the subendothelium or atherosclerotic plaques, and the release of granule contents is not opposed. Thus, the effects of platelet-derived growth factors and other mitogens on smooth muscle cells are not inhibited.[176] Aspirin also impairs thrombosis by a mechanism that seems to be unrelated to platelet cyclooxygenase, as, for instance, the acetylation of guanosine triphosphate-binding proteins, thrombin receptors, and prothrombin.[177] The salicylate moiety of aspirin also antagonizes the lipoxygenase pathway of arachidonate metabolism in platelets, and the demonstration of two cyclooxygenase enzymes (COX-1 and COX-2)[178] may further elucidate the antithrombotic mechanism of aspirin.[179] Aspirin is known to have an anti-inflammatory effect at high doses, but whether an anti-inflammatory effect is present at doses used in acute coronary syndromes is not clear.

DOSE

The ideal dose of aspirin for the primary or secondary prevention of cardiovascular disease is not determined. A dose of 40 mg was found to achieve maximal inhibition of TXA_2. Doses between 75 and 1300 mg/day have produced similar reductions in cardiovascular event.[65-68] Thus, there does not appear to be a dose response in efficacy of aspirin. In the Second International Study of Infarct Survival (ISIS-2), a dose of 160 mg/day was shown to have a mortality benefit, so this dose is the minimum initial dose recommended for acute therapy.[180] For safety (e.g., gastrointestinal bleeding), the rate of bleeding appears

to be slightly higher with higher doses, and thus a dose of 75 to 81 mg daily could be an appropriate dose for long-term therapy, although major bleeding is relatively rare (<1 percent) even at a dose of 325 mg daily.[181]

ADVERSE EFFECTS

Absolute contraindications for aspirin therapy are few but include documented aspirin allergy (e.g., asthma), active bleeding, severe thrombocytopenia (<20,000 cells/mL), or a known platelet disorder. In patients with gastrointestinal complaints (e.g., dyspepsia) with long-term aspirin therapy (i.e., aspirin intolerance), this would not be expected to be an acute problem of in-hospital treatment, and aspirin therapy is recommended for acute therapy, with evaluation of the cause of the disorder or consideration of alternate antithrombotic therapy in the subacute phase of the patient's acute coronary syndrome.

CLINICAL USE

Aspirin is a critical antithrombotic agent in coronary artery disease. In the setting of acute ST-elevation MI, aspirin decreased reocclusion by over 50 percent in a meta-analysis of 32 angiographic trials[182] (Fig. 44-13). Aspirin also was found to decrease reinfarction significantly in the large ISIS-2 trial and most importantly reduced mortality by 23 percent.[180]

Several major studies have demonstrated clear beneficial effects of aspirin in patients with unstable angina and non-ST-elevation MI, with an approximately 50 percent reduction in the risk of death or MI in patients presenting with unstable angina or non-Q-wave MI (Fig. 44-13).[65-68] The first study from the Veterans Administration (VA) Cooperative Study Group documented a 51 percent reduction in the risk of death or MI in patients presenting with unstable angina, and the overall benefits of aspirin were maintained during the 1-year follow-up period.[65] The Canadian multicenter trial confirmed the large risk reduction by aspirin for the development of death or MI among patients with unstable angina/non-ST-elevation MI.[66] The Montreal Heart Institute study demonstrated the effectiveness of both aspirin, as well as heparin, in reducing the incidence of death or MI.[67] A more recent study by the Research on Instability in Coronary Artery Disease Group (RISC) extended these observations to all patients with acute coronary syndromes, showing an approximately 70 percent reduction by aspirin in subsequent risk of death or MI in patients with either unstable angina or non-ST-elevation MI.[68]

Following MI, aspirin reduces subsequent cardiac events, providing secondary prevention (Table 44-2).[183,184] These benefits have now been observed to persist for up to 4 years of follow-up with chronic antiplatelet therapy.[184] Thus, aspirin has had a dramatic effect in reducing adverse clinical events and is primary therapy for all acute coronary syndromes.

In PCI, aspirin has been used as background therapy in most trials, and one small trial did find a reduced rate of thrombotic cardiac events in patients randomized to aspirin compared with placebo.[185] In coronary artery bypass grafting (CABG), aspirin is also an important component of therapy. Without aspirin therapy, graft occlusion occurred in 16 to 26 percent of patients by 1 year.[30] The VA Cooperative Study randomized patients to five treatment arms: (1) aspirin 325 mg/day, (2) aspirin 325 mg three times daily, (3) 325 mg daily of aspirin and dipyridamole 75 mg daily, (4) sulfinpyrazone 267 mg daily, or (5) placebo. Early graft patency was significantly higher in patients randomized to aspirin at any dose, with benefit persisting at 1 year. The dose of 325 mg daily of aspirin was as effective as the 325 mg three times daily. Sulfinpyrazone and dipyridamole added no benefit to aspirin.[186]

PRIMARY PREVENTION OF ACUTE MYOCARDIAL INFARCTION

Two studies examining the use of aspirin in primary prevention of MI (Table 44-3) were conducted. In the United States, in the Physicians' Health Study, more than 22,000 male physicians of ages 40 to 84 were randomized to receive 325 mg of aspirin every other day or placebo for 5 years. There was a 44 percent relative reduction in MI in the aspirin-treated group, although the absolute incidence of such event was less than 1 percent in the low-risk population (Fig. 44-13). This effect was limited to those older than 50

years. The incidence of cardiovascular death was not different.[187] In a British primary prevention trial of more than 5000 male physicians, two-thirds were randomized to receive 500 mg/day of aspirin and one-third were advised to use no aspirin. After 6 years, there was no difference in the rate of MI.[188] However, a large number of protocol crossovers (both physicians stopping aspirin in the aspirin group, and physicians taking aspirin in the placebo group) diluted the power of the study to show a significant difference.

Table 44-3: Aspirin in Primary Prevention (U.S. Physicians' Health Study and British Doctors' Trial Results)

	Reduction (% ± SD)			
	United States	British	Overview	
End Point	Physicians' Health Study	Doctors' Trials	Both Trials	*p*
Nonfatal myocardial infarction	44 ± 9	3 ± 19	32 ± 8	<.0001
Nonfatal stroke	↑19 ± 15	↑13 ± 24	↑18 ± 13	NS
Total cardiovascular deaths	2 ± 15	7 ± 14	5 ± 10	NS
Any vascular event	18 ± 7	4 ± 12	13 ± 6	NS

In summary, aspirin has been shown to be beneficial in essentially every condition in which it has been tested. Its use is strongly recommended in all guidelines of management of coronary artery disease.[189,190]

Thienopyridines: Ticlopidine and Clopidogrel

The thienopyridines are inactive in vitro but potent antiaggregating agents in vivo, indicating the importance of at least one active transient metabolite. The metabolic activation takes place in the liver as a portojugular shunt abolishes the antiaggregating effect. Ticlopidine and its chemical analog clopidogrel are noncompetitive but selective antagonists of ADP-induced platelet aggregation and act by specifically blocking GP IIb/IIIa activation (Fig. 44-5) specific for the ADP pathway. Since the two compounds are chemically related, their mechanisms of action are considered similar. Ex vivo studies indicate that the antiaggregating effect is concentration dependent; the rate of recovery is linked to platelet survival, suggesting a permanent effect on platelets.[191]

The two agents are believed to inhibit the binding of adenosine 5′-diphosphate (ADP) to its platelet receptor.[191-195] Initial studies reported that this ADP receptor blockade led to direct inhibition of fibrinogen binding to the GP IIb/IIIa complex.[196,197] There is also evidence that ticlopidine may interfere with von Willebrand factor, resulting in less binding of von Willebrand factor to platelet receptors.[197-199] Recent studies suggest there are at least two types of ADP receptors.[191,193,200] The first type is a low-affinity type 2 purinergic receptor that is G-protein coupled and results in mobilization of calcium from internal stores.[201] This leads to a conformational change in and activation of the GP IIb/IIIa receptor complex, fibrinogen binding, and platelet aggregation. The second type of ADP receptor (P2Y1) is of high affinity and is responsible for platelet shape change and rapid calcium influx.[201,202] Because ticlopidine and clopidogrel do not affect shape change or calcium influx, they appear to achieve their effect by interacting with the low-affinity type 2 purinergic receptor.[191,193,201] This interference with a specific ADP-dependent

step of GP IIb/IIIa complex activation results in less platelet aggregation and, thus, ultimately impairs thrombus formation.[193,203,204] Despite these numerous in vitro studies, the mechanism(s) of action of ticlopidine and clopidogrel<@>are still not fully characterized. Further insights would be greatly facilitated by the cloning of the type 2 purinergic ADP receptor.

Ticlopidine and clopidogrel have been tested in several animal models of platelet-dependent arterial or venous thrombosis and found to be more effective than sulfinpyrazone, dipyridamole, and aspirin. Other effects are a reduction in fibrinogen levels and blood viscosity and improvement in decreased erythrocyte deformability.

TICLOPIDINE

This was studied in a randomized trial of patients with unstable angina involving 652 patients. The control group did not receive aspirin because at the time of protocol design it was not routinely used to treat unstable angina. At 6-month follow-up, ticlopidine led to a significant 46 percent reduction in vascular death or nonfatal MI.[205] Of note, there was no difference in the number of events over the first 10 days, consistent with the delayed onset of the antiplatelet effect of ticlopidine. Thus, ticlopidine appears to be comparable to aspirin for secondary prevention of events after unstable angina/non-ST-elevation MI.

The effectiveness of ticlopidine has been shown in patients with transient ischemic cerebral attacks and stroke, and peripheral arterial or ischemic heart disease.[195] The first large trial of its effectiveness in 3069 patients with recent transient or mild persistent focal cerebral or retinal ischemia has shown that ticlopidine has a more pronounced effect on death from all causes or nonfatal stroke than aspirin.[206]

Ticlopidine has also been demonstrated to be effective in combination with aspirin for prevention of thrombosis and recurrent ischemic events in patients undergoing coronary stent implantation. The first randomized trial [Intracoronary Stenting and Antithrombotic Regimen (ISAR)] confirmed the advantage of an antiplatelet regimen over an anticoagulant regimen.[207] A total of 517 patients were randomized to intravenous heparin for only 12 h and ticlopidine, 250 mg twice daily, and aspirin, 100 mg twice daily, for 4 weeks; or to intravenous heparin for 5 to 10 days, aspirin, 100 mg twice daily, and phenprocoumon [target international normalized ratio (INR) = 3.5 to 4.5] for 4 weeks. At 30-day follow-up, the ticlopidine group had 75 percent fewer cardiac end points than the phenprocoumon group (1.6 versus 6.2 percent, p = .01) and no episodes of stent thrombosis (versus 5.0 percent, $p < 0.001$).

A larger, adequately powered study has now shown an impressive benefit of a ticlopidine-containing regimen over both anticoagulation and aspirin-only regimens. The Stent Antithrombotic Regimen Study (STARS) trial randomized 1653 patients to either aspirin, 325 mg once daily, plus warfarin (target INR = 2.0 to 2.5); aspirin plus ticlopidine, 250 mg twice daily; or aspirin alone for 1 month.[208] The primary end point was death, MI, target vessel revascularization, or stent thrombosis to 30 days. The primary end point was significantly lower among patients treated with aspirin plus ticlopidine, 0.5 percent, compared with 3.6 percent for those treated with aspirin alone, and 2.7 percent for those who received aspirin plus warfarin (p = .001).[208] Two other randomized trials have also found significant benefit favoring ticlopidine plus aspirin, compared with aspirin and warfarin regimens.[209,210]

A recent analysis has shown added benefit in patients who are pretreated with ticlopidine for several days prior to PCI.[211] A series of 175 patients treated with ticlopidine prior to stenting were evaluated. Ticlopidine pretreatment of at least 3 days was associated with a significant reduction in periprocedural MI [odds ratio = 0.18; 95% confidence interval (CI) = 0.04 to 0.78; p = .01] compared with pretreatment of less than 3 days. Thus, patients with effective ADP inhibition at the time of PCI appear to have greater benefit from the drug.

SIDE EFFECTS

The most common adverse effects associated with ticlopidine are gastrointestinal: diarrhea affects about 20 percent of treated patients. Other effects are skin reactions (urticaria, pruritus, and erythema) and hemorrhagic disorders (epistaxis, ecchymoses, and menorrhagia). These effects are generally not severe and

resolve after discontinuation of ticlopidine. Ticlopidine has also been reported to increase total cholesterol by 9 percent.[206]

The most potentially serious problem is bone marrow depression (leukopenia, thrombocytopenia, and pancytopenia); close monitoring is therefore essential for at least the first 12 weeks of ticlopidine therapy.[212,213] Ticlopidine-associated neutropenia and thrombocytopenia occur in approximately 1 percent of patients. Of these, a small percentage develop thrombotic thrombocytopenic purpura (TTP), which can be fatal in 25 to 40 percent of cases.[214,215] In a recent survey of 43,322 patients, the incidence of TTP following ticlopidine use for stenting was 1 case per 4814 patients treated (0.02 percent; 95% CI = 1 case per 2533 to 1 case per 10,541 patients treated).[215] Thus, if ticlopidine is used, short courses (2 to 3 weeks) and biweekly monitoring of complete blood count are generally recommended.

CLOPIDOGREL

This is chemically related to ticlopidine, and their mechanisms of action are considered similar. Clopidogrel is approximately six times as potent as ticlopidine in the inhibition of ADP-induced aggregation of human platelets. The onset of action of clopidogrel is more rapid than ticlopidine, especially when using a loading dose of 300 mg or more, which achieves effective platelet inhibition within 2 to 5 h.[216]

Clopidogrel has been tested for secondary prevention in a broad population of patients with atherosclerosis in the Clopidogrel Versus Aspirin in Patients at Risk for Ischemic Events (CAPRIE) trial, which enrolled 19,185 patients, of which one-third had experienced an MI within 35 days and had documented peripheral arterial disease or an ischemic stroke from 1 week to 6 months prior to randomization.[181] Patients were randomized to either clopidogrel, 75 mg once daily, or aspirin, 325 mg once daily; mean follow-up was 1.9 years. Overall, clopidogrel was associated with an 8.7 percent reduction relative to aspirin in the combined end point of ischemic stroke, MI, or vascular death (5.32 versus 5.83 percent per year; $p = .042$) (Fig. 44-14).[181]

Curiously, among the 6302 patients who had an MI within 35 days of randomization (mean, 17.6 days), there was a statistically insignificant 3.7 percent increase in the combined end point of MI, stroke, and vascular death ($p = .66$).[181] Of the patients in the peripheral vascular disease and stroke strata, however, 2144 had a history of MI. In a post hoc secondary analysis of all 8446 patients with a history of MI, clopidogrel was associated with a 7.4 percent decrease in the combined end point, which is similar to the benefit of clopidogrel observed in the overall trial (combined end point reduction of 8.7 percent).[181] In addition, the relative benefit of clopidogrel on the components of the primary end point was greatest in preventing MI: clopidogrel produced a significant 19.2 percent reduction in MI ($p = .008$), while there were nonsignificant 5.2 and 7.6 percent reductions in stroke and vascular death, respectively (Fig. 44-14).[217] Based on these data, the Food and Drug Administration (FDA) approved clopidogrel for secondary prevention of vascular events among patients with symptomatic atherosclerosis. Very recent data have shown that selected high-risk subgroups of patients in the CAPRIE trial, such as those with prior CABG or diabetes, had a much greater benefit. For patients with prior CABG, clopidogrel reduced the annual rate of vascular death, MI, or stroke from 22.3 to 15.9 percent ($p = .001$).[218] Thus, clopidogrel is a suitable alternative to aspirin and appears to afford some benefit over aspirin. Clopidogrel is also the drug of choice in patients who have a true aspirin allergy.

Interest now has turned to the combination of clopidogrel plus aspirin. Experimental data have shown synergy between the two agents in their antithrombotic effects.[219] Trials are currently ongoing for patients with unstable angina/non-ST-elevation MI testing the combination of clopidogrel plus aspirin compared with aspirin alone.

Clopidogrel also appears to be as effective as ticlopidine in preventing stent thrombosis.[195,220-225] As previously noted, current regimens usually begin with a loading dose of 300 mg, which achieves effective platelet inhibition within 2 to 5 h,[216] followed by 75 mg daily. The current duration of treatment following stenting is 30 days, but a trial is currently examining whether there is added benefit from longer treatment.

SIDE EFFECTS

Clopidogrel is not associated with neutropenia and an extremely low (3 to 4 per million) rate of thrombotic thrombocytopenic purpura, and it was associated with a lower rate of gastrointestinal bleeding compared with aspirin.[181] In the CAPRIE study, adverse events with clopidogrel were proportionally less frequent than those previously reported for ticlopidine.[181] In CAPRIE, of 19,185 patients followed up for a mean of 1.91 years, only 0.10 percent in the clopidogrel group developed a significant reduction in neutrophil count (<1.2 × 10 g/L) compared with 0.17 percent in the aspirin group.

Thromboxane Synthase Inhibitors

These have been developed with the expectation not only of suppressing TXA_2 biosynthesis (Fig. 44-5) but also of sparing or even enhancing the formation of prostacyclin by the vascular endothelium. Thromboxane synthase inhibition offers the potential advantage over aspirin-type cyclooxygenase inhibitors of reorienting the arachidonic cascade toward an overproduction of inhibitory prostanoids (PGI_2 and PGD_2) and a reduction in TXA_2 formation. However, specific inhibition of TXA_2 synthase produces an accumulation of cyclic prostaglandin endoperoxides, which occupy and activate TXA_2 and endoperoxide receptors on platelets and endothelium and thus attenuate the inhibitory effect of PGI_2 and PGD_2.

Most thromboxane synthase inhibitors have moderate potency and brief duration of action and do not result in a sufficiently sustained inhibition of TXA_2 production to be clinically effective. Moreover, some individuals are poor responders to drugs of this type. The increased generation of endoperoxides that share the same receptors as TXA_2 is another problem that will not be solved by more potent and long-acting drugs of this class.[226] Although thromboxane synthase inhibitors have shown some benefit in experimental models, their effects in clinical trials in patients with coronary artery disease have been disappointing.

Thromboxane Receptor Blockers

The more recently developed thromboxane receptor blockers specifically impede the action of both TXA_2 and endoperoxides on their presumed common receptors on platelets (Fig. 44-5) and prevent vasoconstriction induced by TXA_2. These agents leave the normal pattern of thromboxane and prostacyclin formation unaltered. Thromboxane receptor antagonists prolong bleeding time more than thromboxane synthase inhibitors. As expected, TXA_2 synthesis is not inhibited and PGI_2 generation not augmented by specific thromboxane/endoperoxide receptor antagonists. Unfortunately, the results of the initial clinical studies with such agents have been disappointing.[227]

Combined Thromboxane Synthase Inhibitors and Receptor Blockers

Some compounds have a dual activity. Ridogrel is a potent TXA_2 synthase inhibitor with modest additional TXA_2/prostaglandin endoperoxide receptor antagonist properties (at least 100-fold less).[228] Although the animal pharmacology was very promising, the preclinical evaluation was deceptive. Ridogrel was testing as adjunctive antiplatelet therapy with thrombolysis in the Ridogrel Aspirin Patency Trial (RAPT).[229] A total of 907 patients with acute MI treated with streptokinase were randomized to aspirin or ridogrel. The primary end point was coronary patency [Thrombolysis in Myocardial Infarction (TIMI) flow grades 2 and 3] at predischarge angiography to be performed between 7 and 14 days after admission. No difference was observed between the two groups: 72.2 percent in the ridogrel and 75.5 percent in the aspirin group. The incidence of major in-hospital clinical events during hospital stay was similar in both groups. However, in a post hoc analysis, a lower incidence of new ischemic events (reinfarction, recurrent angina, or ischemic stroke) was observed with ridogrel: 13 versus 19 percent in the aspirin group (p = .025). There was no excess in major bleeding complications, including hemorrhagic stroke. With only modest results, this agent has not been developed for widespread clinical use.

Dipyridamole

This is a pyrimidopyrimidine compound whose antithrombotic action is not well understood. It is felt to decrease platelet aggregability but also decrease platelet adhesion to prosthetic valves, increase platelet survival, and decrease red blood cell deformability.[230] It has been shown in one study to reduce embolism from prosthetic cardiac valves when combined with warfarin.[230] In CABG, neither dipyridamole (nor sulfinpyrazone) added to the benefit of aspirin in maintaining graft patency.[186] Thus, its role in coronary artery disease is limited.

Sulfinpyrazone

This is a weak antiplatelet agent that, after metabolism to a sulfide form, acts as an incomplete and reversible inhibitor of platelet cyclooxygenase, although other actions may exist. In one trial of unstable angina, patients were randomized to receive 1300 mg/day of aspirin, 800 mg/day of sulfinpyrazone, the combination of both, or placebo. After 18 months, the incidence of death and MI was reduced in the aspirin group, but sulfinpyrazone demonstrated no benefit.[231]

Platelet Glycoprotein IIb/IIIa Receptor Blockers

This is a potent class of platelet inhibitors. GP IIb/IIIa receptor antagonists block the binding of fibrinogen to specific membrane GP IIb/IIIa integrin receptors, thus preventing platelet aggregation induced by various platelet agonists. Whereas platelet activation is produced by a wide variety of stimuli, the final common step to platelet aggregation is fibrinogen binding. Thus, no matter what stimuli there are for platelet activation, the platelet is inhibited by the GP IIb/IIIa inhibitor-making it an order of magnitude more effective than aspirin (or ticlopidine) at inhibiting platelet aggregation. When testing platelet aggregation in the laboratory, aspirin inhibits ADP-induced platelet aggregation by approximately 5 to 10 percent, ticlopidine and clopidogrel inhibit platelet aggregation by approximately 30 percent, and the doses of the GP IIb/IIIa inhibitors being tested clinically inhibit platelet aggregation by approximately 80 to 90 percent.

Types of Glycoprotein IIb/IIIa Inhibitors

There are three broad categories of GP IIb/IIIa inhibitors: (1) the monoclonal antibody fragment to the IIb/IIIa receptor, abciximab; (2) the intravenous peptide and nonpeptide small molecule inhibitors, such as eptifibatide and tirofiban; and (3) the oral GP IIb/IIIa inhibitors, such as xemilofiban, orbofiban, sibrafiban, and roxifiban.

The first platelet GP IIb/IIIa antagonists to be developed were murine monoclonal antibodies.[232] In vitro, these antibodies completely inhibit platelet aggregation and, in animal models of angioplasty injury and thrombolysis, prevent thrombosis and augment the activity of thrombolytic agents. Because of concerns about their immunogenicity, the derivative product chimeric monoclonal 7E3 Fab (c7E3 Fab, abciximab) was created via genetic recombination. This new molecule consists of the mouse-derived variable regions from the original molecule linked to the constant region derived from human immunoglobulin G. Abciximab binds to the GP IIb/IIIa receptor and to a broader group of integrins, such as the vitronectin receptor, which appears to be important in neointimal proliferation. In addition, abciximab has been shown to inhibit thrombin generation by tissue factor most likely due to its dual blockade of GP IIb/IIIa and $\alpha_v\beta_3$.[233]

Abciximab binds very tightly to the GP IIb/IIIa receptor.[234] Thus, the antiplatelet effect lasts much longer than the infusion period-a potential benefit on improving efficacy. On the other hand, if bleeding occurred, stopping the drug will not reverse the antiplatelet effect immediately; transfusion of platelets, however, will allow the antibodies to redistribute among all the platelets, thereby reducing the level of platelet inhibition. Abciximab also binds to other integrins on the platelet receptor, such as the vitronectin receptor,[114] but the clinical significance of this cross-reactivity is not yet established.

The peptide and peptidomimetic inhibitors (e.g., tirofiban and eptifibatide) are competitive inhibitors of the GP IIb/IIIa receptor.[235,236] Tirofiban and eptifibatide are RGD- and KGD-containing agents that bind to the fibrinogen binding site of the GP IIb/IIIa receptor. The level of platelet inhibition is directly related to the

drug level in the blood. With these short-acting agents the ratio of drug molecules to GP IIb/IIIa receptors is greater than 250, whereas for the "tight-binding" agents (e.g., abciximab) the ratio is approximately 2.

Since both inhibitors have short half-lives, when the drug infusion is stopped,[235,236] the antiplatelet activity reverses after a few hours, which is a potential benefit for avoiding bleeding complications. On the other hand, for prolonged antiplatelet effect, the drug needs to be given intravenously for a longer period. The inhibitors developed to date have been specifically targeted to the GP IIb/IIIa receptor and not to cross-react other integrins.

The third group of GP IIb/IIIa inhibitors are the oral agents. These are also competitive inhibitors and are usually pro-drugs, which are absorbed and then converted to active compounds in the blood.[237-241] The oral agents all have longer half-lives, such that they can be given once, twice, or three times daily to achieve relatively steady levels of GP IIb/IIIa inhibition. With oral dosing, long-term therapy (i.e., longer than 1 year) is possible. As with the intravenous compounds, two major groups of drugs exist in the oral class: those with competitive inhibition and short "off time" from the receptor-where a high drug level is critical to achieving high levels of platelet inhibition-and those that have "tight" binding to the platelet (similar to abciximab) with the majority of the drug circulating bound to platelets.

Potential Mechanisms of Benefit of Glycoprotein IIb/IIIa Inhibitors

Several potential mechanisms exist for how GP IIb/IIIa inhibition may improve clot resolution and clinical outcome in patients' acute coronary syndromes. First, by blocking platelet aggregation in the platelet-rich arterial thrombus, it prevents propagation of the thrombus. GP IIb/IIIa inhibitors may also be able to *disaggregate* a recently formed platelet plug. Second, by preventing accumulation of a large number of platelets at the lesion, it decreases the amount of platelet phospholipid membrane, a cofactor needed for thrombin generation in the clotting cascade. Third, a thrombus rich in platelets may resist thrombolysis (either thrombolytic therapy or endogenous thrombolysis), owing in part to the increased presence of PAI-1, a potent natural inhibitor of fibrinolysis that exists in high concentrations in platelets.

Glycoprotein IIb/IIIa Inhibition During Coronary Angioplasty

The FDA had approved three agents for use during PCI, including abciximab (ReoPro) and eptifibatide (Integrilin) for elective and urgent PCI. In addition, tirofiban (Aggrastat) is approved for the treatment of patients with unstable angina and non-ST-elevation MI undergoing PCI. Abciximab is administered as a 0.25-mg/kg bolus and an infusion of 0.125 μg/kg per minute for 12 h following PCI. Although lower doses are approved, the most widely used dose is that from the unstable angina trial,[76] a dose of eptifibatide is 180-μg/kg bolus and infusion of 2.0 μg/kg per minute. A recent trial also showed benefit of this regimen with an added second bolus of 180 μg/kg 10 min after the first. The dose of tirofiban used in the angioplasty trial Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis (RESTORE), and an ongoing trial, is a bolus of 10 μg/kg over 3 min followed by 0.15 μg/kg per minute.

ABCIXIMAB

Initial testing of GP IIb/IIIa inhibitors began in patients undergoing PCI. In the Evaluation of c7E3 for the Prevention of Ischemic Complications (EPIC) trial of patients undergoing high-risk PCI, abciximab bolus and infusion had a 35 percent lower rate of death, MI, or urgent revascularization at 30 days compared with the placebo group (8.3 versus 12.8 percent, $p = .008$).[241a] In long-term follow-up, significant benefit has been observed at 6 months and 3 years.[242,243] Similar reductions in major cardiac events were observed in the Evaluation in PTCA to Improve Long-Term Outcomes with Abciximab Glycoprotein IIb/IIIa Blockade (EPILOG) trial of elective PCI. Death, MI, or urgent revascularization at 30 days for abciximab plus low-dose heparin group was 5.2 versus 11.7 percent for heparin alone, a 58 percent risk reduction ($p < 0.001$).[243a] The abciximab plus standard-dose heparin also had a significant reduction in ischemic complications to 5.4 percent ($p < 0.001$).[243a] Death or MI was similarly reduced by more than 50 percent when adding abciximab (Fig. 44-15). When using a lower dose of heparin with abciximab, there was no difference in the incidence of major bleeding or the need for transfusion between abciximab-treated

patients and placebo. Thus, a low-dose heparin regimen can be recommended with abciximab (70-U/kg initial bolus with an additional 20 U/kg if the activated clotting time is less than 200 s).

Abciximab was also found to be beneficial when started 24 h *prior* to a PCI in the Chimeric 7E3 Fab Antiplatelet Therapy in Unstable Refractory Angina (CAPTURE) trial, which studied 1265 patients with refractory angina undergoing PCI.[253] All patients had undergone cardiac catheterization and had a planned PCI the following day. Death, MI, or urgent revascularization was reduced by abciximab from 15.9 to 11.3 percent ($p = .012$).[253] As in all the trials, the major benefit is in reductions of periprocedural MI as well as the need for urgent revascularization. A meta-analysis, however, has shown that there is a significant reduction in *mortality* when GP IIb/IIIa inhibition is used.[243b] These data highlight the clinical importance of thrombosis and of effective antithrombotic therapy in PCI.

The benefit of GP IIb/IIIa inhibition with coronary stenting was shown in the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting (EPISTENT) trial.[243c] Compared with stenting alone, the rate of death, MI, or urgent revascularization at 30 days was significantly reduced in both abciximab groups-from 10.8 to 5.3 percent for stent plus abciximab ($p < 0.001$) and 6.9 percent for balloon angioplasty with abciximab ($p = .007$).[243c] Benefits were maintained at 6 months[244] and 1 year, with a significant reduction in 1-year mortality among patients treated with stent plus abciximab compared with stent alone.[245]

EPTIFIBATIDE

This has been studied in two PCI trials and one large unstable angina trial. In the Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis (IMPACT-II) trial of patients undergoing elective or urgent PCI, patients were randomized to eptifibatide at one of two doses or placebo, continued for 20 to 24 h after the procedure. These doses (infusion rates of 0.5 and 0.75 mg/kg per hour) however were found after the trial was completed to achieve only 50 to 60 percent platelet inhibition. The primary end point of the trial was a composite of death, MI, urgent need for revascularization, or stent placement for abrupt vessel closure at 30 days. There was a trend toward a lower composite event rate in the low-dose and high-dose eptifibatide-treated groups compared with placebo (9.2 and 9.9 percent versus 11.4 percent, respectively; $p = .063$ for low-dose eptifibatide).[8]

More recently, the Enhanced Suppression of the Platelet Receptor IIb/IIIa with Eptifibatide Therapy (ESPRIT) trial tested a higher dose, 180-μg/kg bolus followed by an infusion of 2.0 mg/kg per hour, with a second bolus of 180 μg/kg given 10 min after the first bolus. This dose was similar to that used in the Platelet IIb/IIIa Underpinning the Receptor for Suppression of Unstable Angina Trial (PURSUIT)[76] (see also page 1397) and was targeted to achieve 85 to 95 percent platelet inhibition. The second bolus was added to ensure no fall in the level of inhibition of platelet aggregation at the early periprocedural time point. In this trial, patients enrolled had either stable angina or unstable angina or a recent, but not acute, MI. The primary end point was death, MI urgent revascularization, or thrombotic bailout at 48 h. There was a 37 percent reduction in death or MI (10.5 versus 6.6 percent, $p = .0017$) (Fig. 44-16).[246] Death or MI at 48 h was reduced from 9.2 to 5.5 percent ($p = .0013$), a relative 40 percent reduction. Death, MI, or target vessel revascularization was reduced from 9.3 to 6.0 percent ($p = .0045$).[246] Thus, eptifibatide in the new double-bolus and infusion regimen led to a substantial reduction in early complications from PCI.

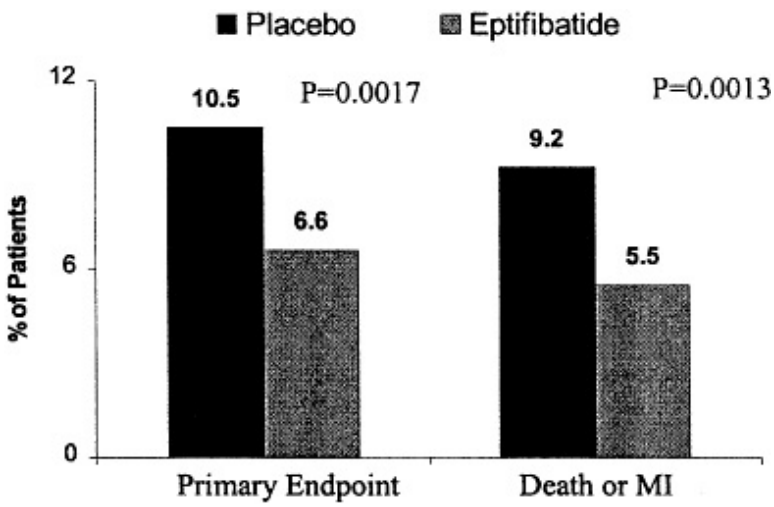

Figure 44-16: Primary Results from the ESPRIT trial of eptifibatide in coronary stenting. (Presented by Tcheng J at American College of Cardiology, March 2000.)

TIROFIBAN

This is a nonpeptide GP IIb/IIIa receptor antagonist. The compound has a short half-life (approximately 3 h).[247] Intravenous infusion of tirofiban for 1 or 4 h in healthy male volunteers dose-dependently inhibited ADP-, collagen-, arachidonic acid-, and thrombin-induced platelet aggregation.[247,248] Bleeding time was also significantly increased.

The RESTORE trial enrolled 2139 patients undergoing high-risk PCI and randomized patients to tirofiban (10-mg/kg bolus followed by infusion of 0.15-mg/kg per hour for 36 h). Tirofiban led to a lower, but not statistically significant, rate of the primary composite end point (death, MI, revascularization for target vessel ischemia, or stent placement for abrupt vessel closure at 30 days), (10.3 versus 12.2 percent, a 16 percent risk reduction, $p = .16$).[249] Death, MI, or urgent revascularization to 30 days was reduced by tirofiban by 24 percent (8.0 versus 10.5 percent, $p = .052$). In this trial, however, systematic collection of cardiac enzymes periprocedurally was not carried out, and thus a major end point was not ascertained as in the other trials. A trial is currently under way that will directly compare abciximab and tirofiban in PCI.

PRIMARY PERCUTANEOUS CORONARY INTERVENTION

The final area of coronary intervention that has been tested is for *primary* PCI, i.e., for acute ST-elevation MI. After favorable results in a subgroup of the EPIC trial were observed,[250] the ReoPro and Primary PTCA Organization and Randomized Trial (RAPPORT) trial was conducted, comparing abciximab with placebo.[251] Although the prespecified 6-month end point of death, MI, or any target vessel revascularization was not significantly reduced, abciximab was able to reduce the 30-day incidence of death, MI, or urgent revascularization by 48 percent, from 11.2 to 5.8 percent ($p = .03$). This beneficial effect was sustained at 6 months (17.8 versus 11.6 percent, $p = .05$).[251] Two other randomized trials have also shown benefit of abciximab in primary PCI, each with a similar 50 percent reduction in death, MI, or urgent revascularization at 30 days.[251a,251b]

Another important observation has been made regarding treatment of patients with ST-elevation MI with GP IIb/IIIa inhibitors in the emergency department 30 to 90 min *prior* to performing a PCI. Early TIMI grade 3 flow is achieved in 20 to 30 percent of patients, with a TIMI grade 2 or 3 flow achieved of approximately 50 percent.[251a-251c,281,283] Thus, use of GP IIb/IIIa inhibitors can "facilitate" the PCI by providing better preprocedural flow and consequently better procedural outcomes.

Thus, given this broad experience with GP IIb/IIIa inhibitors in PCI (Fig. 44-15), and with reductions in death or MI of approximately 50 percent, their use has become a new therapeutic standard for PCI.

Glycoprotein IIb/IIIa Inhibitors in Unstable Angina and Non-ST-Elevation Myocardial Infarction

As of the time of this printing, the FDA had approved three agents for the treatment of unstable angina and non-ST-elevation MI: tirofiban and eptifibatide (Integrilin); abciximab (ReoPro) is approved for use in patients with unstable angina with a planned PCI. For unstable angina, abciximab can be administered as a 0.25-mg/kg bolus and an infusion of 0.125 μg/kg per minute for 12 to 24 h. Although in the CAPTURE trial it was administered for 24 h prior to, and only 1 h after, the procedure, in all the other trials abciximab was continued for 12 h after PCI. The approved dose of tirofiban is that used in the Platelet Receptor Inhibition for Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) trial: a loading dose of 0.4 μg/kg per minute over 30 min, followed by 0.1 μg/kg per minute. Patients with renal insufficiency (creatinine clearance < 30 mL/min) should receive half the usual rate of infusion. The dose of eptifibatide is 180-μg/kg bolus and infusion of 2.0 μg/kg per minute.

TIROFIBAN

PRISM-PLUS studied 1915 patients with documented unstable angina and non-ST-elevation MI with either electrocardiographic changes or positive enzymes.[78] The combination of tirofiban, heparin, and aspirin significantly lowered the rate of death, MI, or recurrent refractory ischemia at 7 days (primary end point) compared with heparin plus aspirin (12.9 versus 17.9 percent, respectively, a 32 percent risk reduction, p = .004).[78] This benefit was predominantly due to a 47 percent reduction in MI (p = .006) and a 30 percent reduction in refractory ischemia (p = .02). These benefits were achieved early and include a significant 66 percent reduction in death or MI at 48 h (0.9 versus 2.6 percent, p = .01).[78] Importantly, these benefits were preserved during follow-up: the 30-day rate of death or MI was also reduced by 30 percent (from 11.9 to 8.7 percent, p = .03).[78] Long-term follow-up to 6 months also showed a significant reduction in events (32.1 versus 27.7 percent, p = .02).[78]

The benefit of tirofiban plus heparin and aspirin was found across all subgroups evaluated, including men and women, elderly and young, unstable angina and non-ST-elevation MI patients, and those with ST-segment depression or elevation, *and* in those with no ST-segment or T-wave changes.[78] As expected, the absolute benefit in number of events prevented was greater in higher-risk patient subgroups, such as the elderly, diabetics, those who were already taking aspirin, and those with ST-segment changes or positive cardiac markers. The benefit of tirofiban plus heparin was also found in all types of management strategies: patients managed medically derived a 25 percent reduction in death or MI rate at 30 days, those who also had angioplasty had a 34 percent reduction, and those who were sent on to bypass surgery also derived a 30 percent benefit. Thus, benefit of adding tirofiban to aspirin plus heparin is derived in all patient groups treated.

A beneficial effect of tirofiban was also observed in the PRISM study, which randomized 3232 patients with unstable angina and non-ST-elevation MI to either heparin or tirofiban, with all patients receiving aspirin.[77] The primary goal of this study was to examine the effects of GP IIb/IIIa inhibition during medical therapy only; thus, the end point was a composite of death, MI, and refractory ischemic conditions at 48 h, and coronary procedures were not permitted by the protocol during the first 48 h. Tirofiban-treated patients had a significantly lower composite event rate than the placebo group (3.8 versus 5.6 percent, representing a 32 percent reduction, p = .01).[77] At 30 days, the improvement on the composite end point of death or MI was no longer statistically significant (death or MI, relative risk = 0.80, p = .11). Thus, the effects of GP IIb/IIIa inhibition with tirofiban appear to have greater long-term effects when used in conjunction with heparin (as was done in the PRISM-PLUS trial) (see below).

EPTIFIBATIDE

This was studied in the PURSUIT trial involving 10,948 patients with unstable angina and non-Q-wave MI. Patients received aspirin and heparin and were randomized to in one of three arms: high-dose eptifibatide, low-dose eptifibatide, or placebo. By study design, the low dose was dropped after an interim analysis because of a reasonable safety profile of the high dose. Eptifibatide (180-μg/kg bolus and infusion of 2.0 μg/kg per minute) reduced the rate of death or MI at 30 days from 15.7 to 14.2 percent (p = .042).[76] This

benefit of reducing 15 events per 1000 patients treated was achieved after only 72 h (while the patients were on study drug): 7.6 percent for placebo compared with 5.9 percent for eptifibatide (p = .001). Among patients undergoing early angioplasty or stenting while on study drug, benefits were more dramatic: 16.7 percent for placebo compared with 11.6 percent for eptifibatide (p = .01).[76] In this group, there were reductions in death or MI observed both prior to PCI and during the first 24 h after PCI.[252] Severe or moderate hemorrhage was more common in the eptifibatide group, 12.8 versus 9.9 percent ($p < 0.001$).

ABCIXIMAB

The Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) IV-Acute Coronary Syndromes (ACS) trial recently reported (Topol, European Congress of Cardiology, Amsterdam 2000) no benefit of Abciximab in patients with unstable angina and non-Q-wave MI, who did not undergo PCI. On the other hand, among patients with unstable angina who undergo PCI (i.e., those managed with an early invasive strategy), abciximab has been shown to be beneficial. In the CAPTURE trial, 1265 patients with refractory angina had undergone cardiac catheterization and had a planned PCI the following day. They were then randomized to abciximab or placebo (in addition to aspirin and heparin) that was administered for 24 h *prior* to a PCI. Death, MI, or urgent revascularization was reduced by abciximab from 15.9 to 11.3 percent (p = .012).[253]

LAMIFIBAN

This nonpeptide synthetic compound that binds reversibly to the integrin IIb/IIIa with a K_D of 5 nM has been effective in several animal models of thrombosis.[254] The inhibition of the ADP-induced aggregation curve parallels the receptor occupancy obtained during in vitro radioligand-binding studies (approximately 50 percent inhibition with 50 percent receptor occupancy of GP IIb/IIIa). The half-life of the free drug is 40 min and that of the bound drug is 9 h. A dose-finding study was conducted in patients with unstable angina.[255]

The Canadian Lamifiban Study of 365 patients with unstable angina showed a lower rate of death or MI at 30 days (2.5 versus 8.19 percent for placebo, p = .03).[256] These results were not observed in the larger Platelet IIb/IIIa Antagonism for the Reduction of Acute Coronary Syndromes in a Global Organization Network (PARAGON) A study, which involved 2282 patients. In that study, death or MI at 30 days was 11.7 percent for placebo (aspirin plus heparin) compared with 10.6 percent for low-dose (1 μg/min) lamifiban and 12.0 percent for high-dose (5 μg/min) lamifiban (p = NS).[257] The findings on 6-month follow-up, however, suggest a possible benefit of low-dose lamifiban plus heparin: death or MI to 6 months was 12.6 percent for low-dose lamifiban plus heparin compared with 17.9 percent for placebo (p = .025).[257]

The PARAGON-B trial evaluated a dose of lamifiban based on renal function, so as to ensure optimal dose level. In this trial, 5225 patients with unstable angina or non-ST-elevation MI were enrolled and treated with lamifiban versus placebo. The primary end point, death, MI, or severe recurrent ischemia, was not significantly reduced in the overall group (11.8 versus 12.8 percent for heparin, p = .329).[258] In those with positive troponin T at baseline, however, there was a significant reduction in events (from 19 to 11 percent for lamifiban, p = .018). This agent is not being developed for commercial use.

Meta-analysis

Figure 44-15 shows a meta-analysis of all the large GP IIb/IIIa inhibitor trials through 1999 in PCI or unstable angina.[259] The results show a consistent benefit on death or MI rate at 30 days (highly statistically significant, $p < 0.0000001$).[259] Although some differences exist in the relative benefits, it is currently believed that these may relate more to trial design and end-point assessment than differences between the drugs. Thus, it is felt that the benefit in reducing death or MI is a class effect of all the GP IIb/IIIa inhibitors. Direct comparisons between the agents are ongoing to determine the relative benefits of one agent compared with another. Thus, GP IIb/IIIa inhibition in patients with unstable angina/non-ST-elevation MI or PCI reduced death or MI rate at 30 days, representing a significant advance in the treatment of these acute coronary syndromes. These data highlight the importance of acute thrombosis and of platelet

inhibition in acute coronary syndromes and establish GP IIb/IIIa inhibition as a new standard of care in the treatment of these conditions.

Need for Heparin with Glycoprotein IIb/IIIa Inhibitors

The data from several of the trials suggest that GP IIb/IIIa inhibitors should be administered with concomitant heparin. This notion was first suggested by the dropping of the tirofiban-alone arm from the PRISM-PLUS trial, as compared with the superiority of the heparin plus tirofiban arm in that trial. Subsequently, the two other trials in unstable angina have found very similar results: In the PARAGON-A trial, there was a greater benefit when using triple antithrombotic therapy (aspirin, heparin, and the GP IIb/IIIa inhibitor), and this has also recently been reported in a dose-ranging study with lamifiban.[257] The third trial that recently demonstrated the need for heparin was the PURSUIT. A recent abstract found that, among the 90 percent of patients in whom physicians decided to use heparin, a greater benefit on reduction in death or MI rate was observed (14 percent reduction, from 16.9 to 14.6 percent, $p = .013$) compared with a 41 percent *increase* in death or MI rate among the patients not treated with heparin.[260] Although these data may be confounded by other issues, they are consistent with the other trials. Thus, it appears important to use heparin with GP IIb/IIIa inhibitors when treating patients with unstable angina and non-ST-elevation MI. This fits our understanding of the pathophysiology of thrombus formation in acute coronary syndromes, which involves both platelets and the clotting cascade. Since one agent is a potent antiplatelet and the other is an anticoagulant, it follows that both together will have greater benefit. The next question in the field is the safety and efficacy of LMW heparin in combination with GP IIb/IIIa inhibitors.

Angiographic Observations: Establishing the Paradigm of Benefit

Data on thrombus resolution are available from two trials: PRISM-PLUS and CAPTURE. An angiographic substudy was performed as part of the PRISM-PLUS trial to investigate the mechanism of benefit of tirofiban.[261] It was observed that the coronary thrombus was smaller in patients treated with tirofiban plus heparin and aspirin compared with heparin and aspirin. The percentage of patients who had definitive thrombus was reduced from 24 to 17 percent, and there was a 23 percent improvement in overall thrombus grade ($p = .022$).[261] Similarly, coronary flow, using the TIMI flow grading system,[3] was significantly improved, with TIMI grade 3 flow improving from 74.5 to 81.9 percent, with a 35 percent overall improvement in flow ($p = .002$).[261] Similar data are also available from the CAPTURE trial.[262] Together these data establish the pathophysiologic link between the potent platelet inhibition achieved by tirofiban, a reduction in thrombus, and improvement in coronary blood flow, and consequent improvement in clinical outcome for patients.

Reducing Infarct Size with Glycoprotein IIb/IIIa Inhibition

A new concept in the field of GP IIb/IIIa inhibition is that these agents appear to be able to reduce the size of an evolving non-ST-elevation MI or even prevent the development of myocardial necrosis, based on evidence from two trials.[263,264] In the PRISM-PLUS troponin substudy, patients randomized to tirofiban plus heparin had a significantly lower peak troponin than did patients who received heparin and aspirin alone.[264] This was also true among patients who had a negative CK-MB on admission. In the PURSUIT trial, it was observed that the size of the MI (either index or recurrent MI) measured by peak CK-MB, was significantly smaller in patients treated with eptifibatide. Thus, these potent antiplatelet therapies appear to have an immediate effect in reducing the severity of the presenting illness, something that has been observed for patients who develop acute coronary syndromes while already taking aspirin.[265-267]

Another new concept in GP IIb/IIIa inhibition is that there appears to be a greater benefit of treatment when administered earlier relative to the onset of pain. In an analysis from PURSUIT, the absolute reduction in death or MI rate with eptifibatide was 2.8 percent for patients treated within 6 h from the onset of pain and was less for those treated between 6 to 12 and 12 to 24 h after onset of pain. No benefit was observed in patients treated 24 h after the onset of pain. Similar data have been observed in PRISM-PLUS (unpublished data).

Glycoprotein IIb/IIIa Inhibitors Plus Thrombolysis for Treatment of Acute Myocardial Infarction

Although thrombolytic therapy has proved to be a major advance in the treatment of patients with acute MI,[180,268] current thrombolytic regimens have several limitations: (1) failure of initial reperfusion,[269,270] (2) inadequate perfusion with delayed flow (TIMI grade 2 flow),[269,270] (3) imperfect myocardial perfusion,[271] and (4) infarct-related artery reocclusion/reinfarction in a significant percentage of patients.[270,272] Because platelets play a central role in coronary thrombosis-especially failed reperfusion, reocclusion, and reinfarction-attention has turned to the GP IIb/IIIa inhibitors as a means of improving current reperfusion regimens.[259,273]

MECHANISMS OF THROMBOLYTIC RESISTANCE

Lack of initial reperfusion, which could be termed *thrombolytic resistance*, appears to be due to several mechanisms (Table 44-4): (1) Fibrinolytic agents act only on the fibrin portion of the thrombus, leaving activated platelets as a source of rethrombosis. (2) Platelets elaborate PAI-1, which inhibits the action of the thrombolytic agent; platelets also release other agents, such as TXA_2, which causes local vasoconstriction.[274] (3) Lysis of clot-bound fibrin exposes clot-bound thrombin, which remains catalytically active and can cleave fibrinogen to fibrin, facilitating rethrombosis.[275] In addition, thrombosis can stimulate further thrombin production and activation of platelets.[276] (4) thrombolytic therapy also has a direct platelet-activating effect, leading to increased levels of TXA_2 and platelet-activating factor.[274,277] The presence of aspirin does not abolish the platelet-activating effect of fibrinolytic therapy.[274] Thus, thrombolysis promotes platelet activation and therefore actually creates an environment that may lead to subsequent rethrombosis and/or reocclusion.

Table 44-4: Potential Mechanisms of Thrombolytic Resistance

1. Only fibrin is lysed by thrombolytic agent
2. Plasminogen activator inhibitor 1
3. Thromboxane A_2
4. Clot-bound thrombin
5. Activation of platelets

INITIAL STUDIES

Preclinical studies were performed that first tested GP IIb/IIIa receptor inhibitors with thrombolytics to accelerate reperfusion time and reduce the risk of reocclusion.[278,279] The Thrombolysis and Angioplasty in Myocardial Infarction 8 (TAMI-8) trial[280] established the clinical feasibility of combining GP IIb/IIIa inhibitors with thrombolytic therapy. After receiving t-PA plus heparin and aspirin, patients received incremental doses of m7E3, a murine monoclonal antibody to the GP IIb/IIIa receptor. A consistent dose-dependent increase in platelet aggregation was observed, and a clear relationship between GP IIb/IIIa receptor occupancy and extent of platelet inhibition was established.[280]

Concomitant Full-Dose Thrombolytic Therapy Plus Glycoprotein IIb/IIIa Inhibition

The combination of eptifibatide and t-PA, as tested in the Integrilin to Manage Platelet Aggregation and Combat Acute Myocardial Infarction (IMPACT-AMI) trial, significantly increased the rate of TIMI grade 3 infarct related artery (IRA) flow upon angiography at 90 min (66 percent, as compared with 39 percent in the placebo group, $p = .006$).[281] A subsequent trial combining full-dose streptokinase with ascending dosages of eptifibatide found modest improvements in TIMI grade 3 flow in the infarct-related artery, but there was an increased rate of major bleeding.

The Platelet Aggregation Receptor Antagonist Dose Investigation and Reperfusion Gain in Myocardial Infarction (PARADIGM) trial compared different lamifiban dosage levels to placebo in 353 patients presenting within 12 h of acute MI symptom onset. Patients received aspirin and heparin and either t-PA or streptokinase at standard doses.[282] Lamifiban was associated with improved myocardial reperfusion as measured by early resolution of ST-segment elevation, but no difference in the composite clinical end point was noted. Lamifiban also was associated with increased rates of gastrointestinal, coronary bypass related, and catheterization access-site bleeding complications.

In summary, with the strategy of concomitant full-dose thrombolytic therapy and full-dose GP IIb/IIIa inhibition, it has been difficult to balance efficacy and safety, so attention has turned to combining full-dose GP IIb/III inhibitors with reduced doses of thrombolytic agents.

Reduced-Dose Thrombolysis Plus Glycoprotein IIb/IIIa Inhibition

The combination of a *reduced*-dose thrombolytic agent and a GP IIb/IIIa inhibitor was tested in the TIMI-14 trial using t-PA, streptokinase, and reteplase, and in Strategies for Patency Enhancement in the Emergency Department (SPEED) using reteplase.

The international TIMI-14 trial dose-ranging phase enrolled 681 patients with ST-elevation MI who met standard eligibility criteria.[283] The patients were randomized within 12 h of acute ST-elevation MI symptom onset to one of four reperfusion regimens (each encompassing several dosage levels): standard-dose t-PA alone (the control arm), reduced-dose t-PA plus abciximab, reduced-dose streptokinase plus abciximab, or abciximab alone. All patients received aspirin and heparin. The initial heparin dosage was a 70-U/kg bolus and an infusion of 15 U/kg per hour in the t-PA control arm, and a 60-U/kg bolus with an infusion of 7 U/kg per hour in the arms that included abciximab.

Abciximab alone was associated with 90-min TIMI grade 3 flow rates in 32 percent of patients and 90-min patency in 48 percent of patients.[283] The combination of streptokinase and abciximab produced only modest improvement in early TIMI grade 3 flow. TIMI grade 3 flow at 90 min was achieved in 42 percent of patients in the 0.5-MU (million units) group, 39 percent of patients in the 0.75-MU group, and 47 percent of patients in the 1.25-MU group. The 1.5-MU regimen, plus abciximab, was discontinued after four of six patients developed a major hemorrhage, one of whom developed an intracranial hemorrhage (ICH).

Dose ranging with t-PA found that the best angiographic results were obtained using a 50-mg dose given as a 15-mg bolus and a 35-mg infusion over 60 min. At 90 min, TIMI grade 3 flow was achieved in 77 percent of patients compared with 62 percent for t-PA alone ($p = .02$). Overall patency of the IRA was achieved in 93 percent of patients with the combination of abciximab and t-PA compared with 78 percent for t-PA ($p = .09$). An even greater difference was observed at 60 min when adding GP IIb/IIIa inhibition: the standard t-PA dose achieved only 43 percent TIMI grade 3 flow at 60 min compared with 72 percent for 50 mg t-PA plus abciximab ($p = .0009$). Major hemorrhage was similar among the t-PA plus abciximab and control groups, approximately 6 percent in each. In-hospital mortality was similar in all groups, ranging from 3 to 5 percent.

Thus, the addition of the GP IIb/IIIa receptor inhibitor abciximab to 50 mg of t-PA increased the rate of TIMI grade 3 flow at 60 min by an absolute 29 percent, representing a relative 67 percent improvement over standard therapy. At 90 min, the addition of the GP IIb/IIIa receptor inhibitor improved TIMI grade 3 flow by an absolute 15 percent (a relative 25 percent improvement). These results indicate that the combination of GP IIb/IIIa receptor inhibition with reduced-dose thrombolytic therapy appears to be a promising new regimen for enhancing both the speed and extent of reperfusion in acute ST-elevation MI.

Results from the SPEED trial[283a] similarly demonstrated improvements in early TIMI grade 3 flow with reteplase, indicating that the combination of low-dose thrombolytic therapy with t-PA or reteplase appears to be a potentially promising new regimen for improving both the speed and extent of thrombolysis in acute MI. There are numerous other ongoing angiographic and larger mortality trials that are exploring further the potential role of GP IIb/IIIa inhibitors with reduced-dose thrombolytic therapy.

SAFETY

One of the concerns with any antithrombotic agent is bleeding. Although the initial EPIC study showed increased bleeding when using abciximab plus heparin during angioplasty compared with heparin alone,[284] a strong interaction with the dose of heparin was observed. In the subsequent EPILOG trial, the rate of major bleeding was identical between heparin control patients and those receiving abciximab and low-dose heparin.[285] Similarly, the rate of major bleeding has generally not been significantly increased in other trials with intravenous administration.[77,78,249,286] Thus, use of lower doses of heparin and careful monitoring of the level of anticoagulation help avoid bleeding complications in patients receiving GP IIb/IIIa inhibitors. With regard to monitoring the degree of platelet inhibition, trials to date have used weight adjusted dosing of the GP IIb/IIIa inhibitors, but investigation is currently ongoing to determine when and where monitoring of platelet function might be useful clinically.[287,288]

Another concern, especially when adding GP IIb/IIIa inhibition to thrombolytic therapy, is the risk of ICH. Fortunately, GP IIb/IIIa inhibitors generally have a low risk of ICH when used alone, and no apparent increase compared with aspirin and heparin in the major trials.[76-78,249,257,284-286,289] The risk of ICH when combined with thrombolytic therapy may be largely due to the risk from the latter agent, but larger trials will be needed to define the exact rate.

THROMBOCYTOPENIA
