Figure 15-28: Diagrammatic illustration of the direction of the x-ray beam and the right coronary artery in 30° LAO with 30° of cranial angulation. Cranial angulation of the image intensifier overcomes the problem of foreshortening of the posterior descending and left ventricular branches observed in Fig. 15-27. Lesions in the posterior descending or LV branches can be well visualized. When the right coronary artery originates anteriorly from the aorta, the proximal portion of the vessel is frequently well seen in this projection. With anomalous origin of the left anterior descending artery from the right coronary artery, this view is helpful because the standard LAO view produces considerable foreshortening of the anomalous artery. The direction of the x-ray beam is the same as in Fig. 15-25. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

THE LEFT CORONARY ARTERY

The ostium of the left coronary artery originates from the left sinus of Valsalva near the sinotubular ridge. The main left coronary artery usually courses to the left and slightly anterior. After a quite variable length, it gives rise at near right angles to the circumflex artery and continues in a straight line as the anterior descending artery (Figs. 15-29 and 15-30). The left orifice and the left main coronary artery are best seen in a direct frontal view or in a shallow LAO or RAO projection or a shallow LAO with 30° of cranial angulation. The diagonal artery may arise between the circumflex and anterior descending arteries as a trifurcation of the left main coronary artery, or the diagonal branch may originate from the anterior descending artery and course over the anterolateral free wall of the left ventricle. The diagonal branches are seen on the side in the RAO view; however, the origin is obscured by overlap with the anterior descending artery (see Figs. 15-29 and 15-30). The LAO view separates the anterior descending artery and diagonals somewhat; however, because of the frequent horizontal orientation of these arteries, there may be considerable foreshortening. Cranial angulation of the overhead intensifier with shallow LAO or RAO rotation is most helpful in separating the proximal anterior descending artery and its diagonal branches (see Figs. 15-25 and 15-26). The anterior descending artery continues in the interventricular groove toward the apex, giving rise at nearly right angles to the septal perforating arteries that go deep into the muscular septum. The first septal perforator may arise before or after the first diagonal and is usually the largest septal artery. The septal vessels differ from the epicardial arteries in that they are straighter and move little with cardiac action, in contrast to the buckling of epicardial arteries that frequently occurs with systole. The left anterior descending artery usually continues around the apex but may end short of the apex in association with an unusually long posterior descending artery. The anterior descending artery is usually best visualized in the RAO view and in a cranially angulated shallow oblique view unless the orientation of the anterior descending artery is unusually superior, in which case a caudally angulated LAO view or a straight lateral view may be helpful.

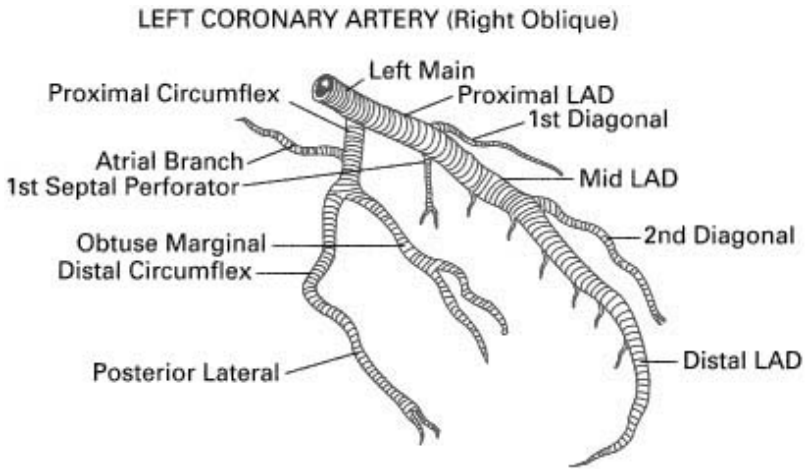

Figure 15-29: Anatomy of the left coronary tree in the right oblique view.

The circumflex coronary artery, after its right-angle origin from the left anterior descending artery, travels in the AV groove. Its course is quite variable. The artery may terminate in one or more large, obtuse marginal branches that course over the lateral to posterolateral LV free wall, or it may continue as a large artery in the interventricular groove and, in 10 to 15 percent of cases, give rise to a posterior descending artery, which more often arises from the right coronary artery (Fig. 15-31). When the circumflex artery supplies the major posterior descending artery, it is commonly referred to as a *dominant* circumflex artery. The circumflex artery in the AV groove is best seen in the LAO view, but surgically more important marginal branches are visualized best in the RAO view. Occasionally, proximal stenoses in the circumflex artery are best viewed in an RAO view with 15° of caudal angulation, which produces a view as though looking from the superior aspect of the liver toward the left shoulder.

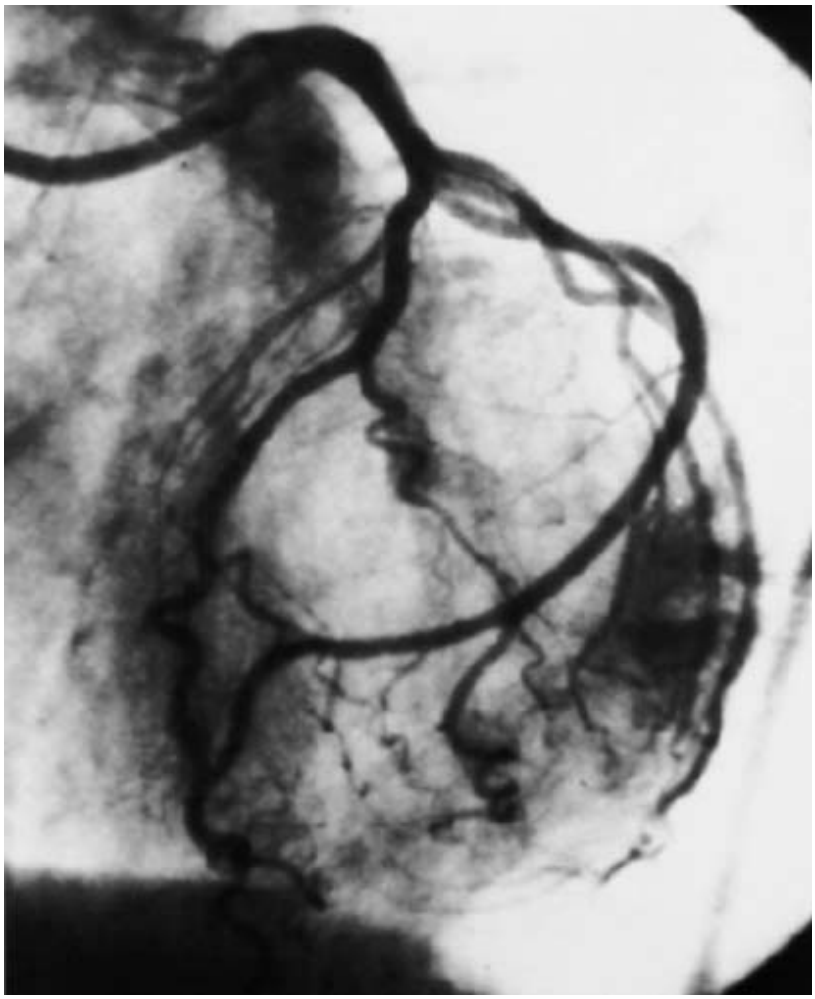

Figure 15-31: LAO view of the left coronary artery demonstrating dominant circumflex coronary artery giving rise to the posterior descending artery.

THE RIGHT CORONARY ARTERY

The right coronary artery orifice normally is located in the right sinus of Valsalva. It may be high near the sinotubular ridge or above it, in the midsinus, or occasionally low near the aortic valve. The artery commonly courses upward from the plane of the aortic valve and then travels in the right AV groove as a conduit to reach the posterior LV wall (Figs. 15-32 and 15-33). Along the way, several vessels arise. The conus branch and sinus node branches arise first, followed by small RV branches. At the acute margin of the heart, there is usually a large branch that courses over the right ventricle. In some cases this may supply the apical portion of the interventricular septum and therefore be of greater importance. The posterior descending artery usually arises before the right coronary artery reaches the crux of the heart (junction of the interventricular and interatrial septa). The posterior descending artery arises from the right coronary

artery at right angles and travels in the posterior interventricular groove, supplying the perforating branches to the basal and posterior one-third of the septum. A right coronary artery that supplies the major posterior descending branch has been referred to as a *dominant* right coronary artery. The posterior descending artery usually stops before reaching the apex, but it may curl around the apex in association with a short anterior descending artery to form the loop previously described. After giving rise to the posterior descending artery, the right coronary artery becomes intramyocardial at the crux, gives rise to the AV node artery, and subsequently returns to the surface, making an inverted U curve (see Fig. 15-33). The LV branches of the right coronary artery are variable and cover the same area as the posterolateral branches of a large circumflex system. The proximal conduit portion of the right coronary artery is well seen in standard RAO and LAO views. Because of its horizontal orientation, however, the origin of the posterior descending artery is well seen in the RAO view but foreshortened in the LAO view; to overcome this, cranial angulation of the intensifier is necessary. Pathologic studies indicate that lesions at the takeoff of the posterior descending artery frequently are overlooked if standard oblique views in the transverse plane are used.

Grading Stenoses

Visual inspection of the coronary arteriogram traditionally has been used to assess the severity of coronary artery stenosis. In our laboratory, a system of analyzing each arterial segment has been used, and the degree of stenosis is recorded as a reduction in lumen diameter expressed as a percentage, with total occlusion being 100 percent. Measurement of cineangiograms has been done with a programmable digital caliper system. In each available projection, the frame showing the most severe stenosis in end-diastole is chosen for measurement. The percentage of diameter stenosis recorded is a mean value of the measurements from two or three available projections. This method has been shown to reduce observer variability. Although cross-sectional area reduction is the measurement of greatest physiologic importance, use of diameter stenosis is in keeping with the American Heart Association recommendation that the diameter method be adopted for grading coronary artery stenoses.[132] A 50 percent reduction in diameter is equivalent to a 75 percent reduction in cross-sectional area, and a 75 percent reduction in diameter is equal to a 90 percent reduction in cross-sectional area. It is of great importance to identify which method of expressing stenosis is being used. From the standpoint of surgically significant lesions, it has been our practice to consider stenoses with greater than 50 percent diameter reduction, or greater than 75 percent cross-sectional area reduction, as lesions that may produce myocardial ischemia. Lesions in series and long stenoses are of added importance. Quantitative computerized methods for calculating coronary artery stenosis are used for clinical investigations and are also increasingly used for routine clinical coronary arteriography.[137] Techniques employing edge-detection algorithms are often applied clinically.

Pitfalls in Coronary Arteriography

There are a number of pitfalls in coronary arteriography that should be looked for and avoided.

1. *Short left main or double left coronary orifices*. When the left main orifice is very short or absent, selective injection of the anterior descending or circumflex arteries may be done (Fig. 15-34). If, on viewing an arteriogram, no circumflex or anterior descending artery is seen filling either primarily or through collaterals from the right coronary artery, the possibility that the artery was missed by subselective injection must be entertained.
2. *Orifice lesions*. The left and right coronary artery orifices need to be seen on a tangent with the aortic sinuses. Some backflow from the orifices is needed if the catheter is lying within the left main or proximal right coronary artery to avoid missing an orifice lesion.
3. *Myocardial bridges*. The anterior descending, diagonal, and marginal branches not uncommonly dip intramyocardially, and the overlying myocardium may act to compress the artery during systole (Fig. 15-35). If the coronary artery is not viewed carefully in diastole, this bridging may give the appearance of an area of stenosis.[138]
4. *Foreshortening*. When possible, avoid reading lesions in segments that are seen only coming toward or away from the image intensifier. Dense opacification of segments seen end-on may produce the appearance of a lesion in an intervening segment.
5. *Coronary spasm*. Catheter-induced spasm may give the appearance of a lesion (Fig. 15-36). When spasm is suspected (usually at the catheter tip in the right coronary artery), nitrates should be given, and the injection should be repeated in 5 to 10 min. Spontaneous coronary artery spasm is a separate problem, and when this is suspected, nitrates and atropine are avoided because the atropine may play a role in blocking coronary artery spasm. Provocation with ergot derivatives will identify most patients with spontaneous coronary artery spasm.[114-116]
6. *Anomalous coronary arteries.* Coronary arteries may arise from ectopic locations, or a single coronary artery may be present.[139] Only by ensuring that the entire epicardial surface has an adequate arterial supply can one be confident that all branches have been visualized.
7. *Totally occluded arteries or vein grafts*. Absence of vascularity in a portion of the heart may indicate total occlusion of its arterial supply. Usually, however, collateral channels permit visualization of the distal occluded artery unless it is an acute occlusion. Vessels filled solely by collaterals have very little pressure supporting their walls and may appear smaller than their actual lumen size, giving a false sense of pessimism about the possibilities for surgical anastomosis.

Limitations of Coronary Arteriography

Despite significant improvements in the quality of coronary arteriographic studies as a result of improved x-ray imaging systems, there remain a number of limitations of the method. Film interpretation is subjective. Different angiographers may interpret the same film differently, and the same angiographer may render a different interpretation at a time remote from the first reading.[140,141] It has been reported that the average standard deviation of estimation of any segmental stenosis by experienced angiographers may be as high as 20 percent and that disagreement about the number of major vessels with 70 percent stenosis may occur 30 percent of the time.[142] These reported studies, however, used only views in the transverse plane, imposing greater interpretive burdens than are encountered when sagittally angulated views are obtained. Further studies using sagittally angulated views would be expected to show less variability in interpreting coronary arteriograms. Inter- and intraobserver variability in interpreting coronary arteriograms is not unlike interpretive differences in chest x-rays or other diagnostic studies involving human error and judgment. Routine use of several readers has been shown to reduce interpretive error.[141] Although correlation of angiography with postmortem findings has been acceptable in most studies,[142-148] certain coronary pathologic-anatomic factors may favor angiographic underestimation of the degree of stenosis present in any arterial segment. In large part, this is due to the tendency for diffuse atheromatous narrowing of the coronary arteries to occur. In attempting to grade stenosis of an obviously narrow segment, one may not have a normal segment for comparison or may choose for comparison an apparently normal segment that in fact has diffuse tubular narrowing.[145-147] This leads to underestimation of the degree of stenosis present. Pathologic studies currently available probably overestimate the frequency of this problem, since the pathologic material available for study represents the severest end of the spectrum of the disease. Eccentric atherosclerotic plaques also may be underestimated unless the minor axis of the stenotic lumen is visualized. Sagittally angulated views are particularly valuable in this regard. Very discrete membrane-like lesions, which fortunately are rare, may be missed unless they are visualized directly in the plane of the lesion. Pathologic studies have shown poor correlation between left main coronary stenosis at autopsy and that at angiography, especially in the presence of a short left main coronary artery, and point out the importance of sufficient angiographic views and excellent interpretive skills in evaluating this critical

portion of the coronary circulation.[148] Quantitative computer techniques have shown excellent correlation between the cross-sectional luminal area of stenotic lesions at arteriography and direct planimetered measurements of distended postmortem specimens.[149] Dynamic phenomena that are not active at the time of the study may be important. "Hit and run" events such as coronary embolization or thrombosis with subsequent resolution, coronary artery spasm, and even primary coronary artery dissection may leave LV scars but not result in coronary angiographic findings.

Risk of Coronary Arteriography

As with any invasive procedure, there is a finite risk to patients undergoing coronary arteriography. The magnitude of the risk is influenced by certain factors definable prior to the procedure (e.g., skill of the angiographer and instability of clinical symp toms) but primarily by the extent of the disease found at coronary arteriography and left ventriculography.[111,128,150-156] Physicians referring patients for coronary arteriograms must be aware of the complication rate in a given laboratory and, when practical, should achieve stability of clinical symptoms prior to study. This is not to say that unstable patients should not be studied, but the physician must balance the risk of the procedure and potential benefit against the risk of not doing the procedure. The frequency of major complications has decreased in active centers (Table 15-3).

Table 15-3: Complications of Coronary Arteriography

	CASS[a]		
	1979[151]	1983[154]	SCAI ,[b] 1990-1995[155]
Death	0.0020	0.0007	0.001 each year
Myocardial infarction	0.0025	0.0027	<0.001 each year
Cerebral emboli	0.0003	0.0007	<0.001 each year
Arterial complications	0.0080	0.0082	-
Ventricular fibrillation	0.0063	0.0038	0.003 (0.002 in 1995)

[a]Coronary Artery Surgery Study.[b]Society for Coronary Angiography and Interventions.

Major complications are of two types: Local arterial complications consist of arterial occlusion or stenosis, hematoma formation, false aneurysm, and infection; the other and more lethal group of complications relates to thromboembolic events or depression of myocardial function due to infarction or acute ischemia. Thromboemboli are more commonly due to multiple catheter and guidewire exchanges, during which thrombus material is stripped from the catheter surface at the puncture site only to be deposited on a subsequent catheter. The addition of systemic heparinization was felt to have reduced thromboembolic complications in some laboratories. The early CASS report[151] and that by Abrams and Adams,[150] however, found that the use of heparin did not influence complication rates. Of equal or greater importance may be the routine use of catheter debriding techniques, with vigorous aspiration and flushing of the catheter in the abdominal aorta to dislodge any retained thrombus material. Minor allergic reactions to contrast media in the form of urticaria occur commonly, but anaphylactic and pyrogenic reactions are exceedingly rare. Radiation exposure to the patient, estimated as 20 to 45 rem, has little risk unless multiple restudies are needed.

Reported mortality rates related to coronary arteriography range from 0.05 to 4 percent, and virtually all deaths occur in patients with severe, multivessel coronary disease or left main coronary artery stenosis.[126,150-153] Of 30 patients whose deaths were related to diagnostic cardiac catheterization at the Toronto hospital, 18 (60 percent) had left main coronary disease. In 89 percent (16 of 18) of left main disease patients and in 50 percent (4 of 8) of coronary disease patients without apparent left main disease, death was related to catheter-induced left main trauma. A widely quoted acceptable mortality rate for coronary arteriography is 0.1 percent. Patient selection, however, may play an important role in determining mortality. Studies in predominantly stable patients will result in a very low mortality rate. On the other hand, if a broad spectrum of patients is studied-including those with preinfarction angina, acute myocardial infarction, and complications of myocardial infarction such as heart failure, cardiogenic shock, ruptured interventricular septum, and ruptured papillary muscle-complication rates will be higher, depending on the frequency with which sicker patients are studied. The overall mortality rate in the CASS and Society for

Cardiac Angiography and Interventions reports was 0.07 to 0.1 percent. It was 0.05 percent for single-vessel disease, 0.07 percent for double-vessel disease, 0.12 percent for triple-vessel disease, and 0.8 percent in patients with left main coronary artery stenosis.[151,154] The point to be made is that laboratory and surgical teams must be prepared to act in the best interest of severely ill patients and not be overly concerned with an arbitrary mortality figure.

Left Ventriculography

Left ventriculography is the standard method for evaluating LV performance in the coronary angiography laboratory. The normal pattern of LV contraction is a uniform and almost concentric inward movement of all points along the endocardial surface during systole. Harrison introduced the term *asynergy,* which has been used to indicate a disturbance of the normal contraction pattern. The Ad Hoc Committee for Grading of Coronary Artery Disease of the American Heart Association[132] has recommended that five RAO segments and two LAO left ventricular segments be defined and characterized as to wall motion (Fig. 15-37). Herman and coworkers classified LV asynergy according to the severity of the contractile abnormality, and a similar classification of LV wall motion was recommended by the Ad Hoc Committee:

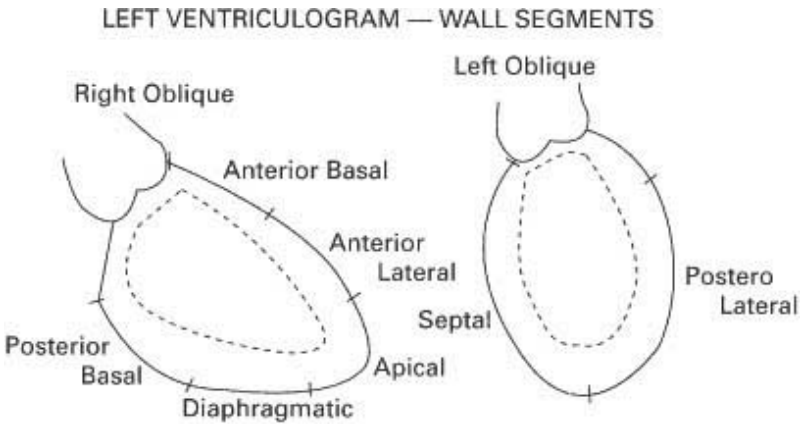

Figure 15-37: LV wall silhouette in RAO and LAO views.

- *Normal:* Normal wall motion of the indicated ventricular segment
- *Reduced:* Reduced velocity and/or amplitude of indicated wall segment
- *None:* Absence of appropriate wall motion of indicated ventricular segment
- *Dyskinetic:* Paradoxical wall motion of the indicated segment
- *Aneurysmal:* Bulging during systole and diastole with sharply defined margins of indicated ventricular segment
- *Undefined*

Many angiographers use the term *akinesis* when no wall motion is present and the term *hypokinesis* when wall motion is reduced.

The ability of the left ventricle to function as a pump is best analyzed by LV volume determinations. Single-plane and biplane volume determinations may differ significantly in patients with coronary artery disease and nonhomogeneous contraction patterns. In particular, the single-plane RAO or lateral left ventriculogram frequently underestimates overall LV contraction because it selectively visualizes the anterior and inferior free walls of the left ventricle, which are most commonly involved in myocardial infarction. Vogel et al.[157] found that the single-plane RAO left ventriculogram underestimated ejection fraction in 70 percent of patients with coronary artery disease. For this reason, biplane left ventriculography frequently is desirable in evaluating patients with coronary artery disease.

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

MEASUREMENTS OF CORONARY BLOOD FLOW AND PRESSURE

Coronary artery disease affects the vessel wall with a highly variable influence on the configuration of the lumen and subsequent resistance to blood flow. The functional characterization of a coronary stenosis identified on angiography remains a well-recognized limitation,[158-160] repeatedly documented by intravascular ultrasound (IVUS) imaging and ischemic testing. Measurements of coronary flow and pressure can be obtained directly using Doppler and pressure sensor angioplasty guidewires.[161]

Coronary Physiology

Coronary blood flow increases from a resting level to a maximum depending on myocardial oxygen demand and other hyperemic stimuli. Normally, epicardial resistance to flow is trivial, with flow normally controlled by the precapillary arteriolar resistance vessels. Coronary blood flow in a normal artery supplying normal myocardium can increase more than threefold in adults. However, some patients may have conditions affecting the microcirculation (LV hypertrophy, myocardial ischemia, diabetes, or other conditions impairing the microcirculatory responses) that can blunt the normal increase in coronary flow.

When a significant atherosclerotic stenosis produces epicardial conduit resistance, the distal vascular bed dilates to maintain satisfactory basal flow appropriate for myocardial oxygen demand. Friction and turbulence at the site of the stenosis produce energy loss and reduced pressure distal to the stenosis,thus resulting in a pressure gradient between proximal (aortic pressure) and distal coronary artery segments. As coronary flow increases across the stenosis, the distal pressure decreases along a curvilinear pressure-flow relationship of coronary stenosis resistance as described by Gould et al.[162,163] From this relationship, both coronary flow reserve (CFR) and pressure-derived fractional flow reserve (see below) can be elucidated and applied for coronary lesion assessment (Fig. 15-38). Because of the strong association of coronary flow with indirect ischemia testing,[164-167] directly measured coronary physiologic data can be used to determine coronary lesion significance and provide objective evidence of ischemia.

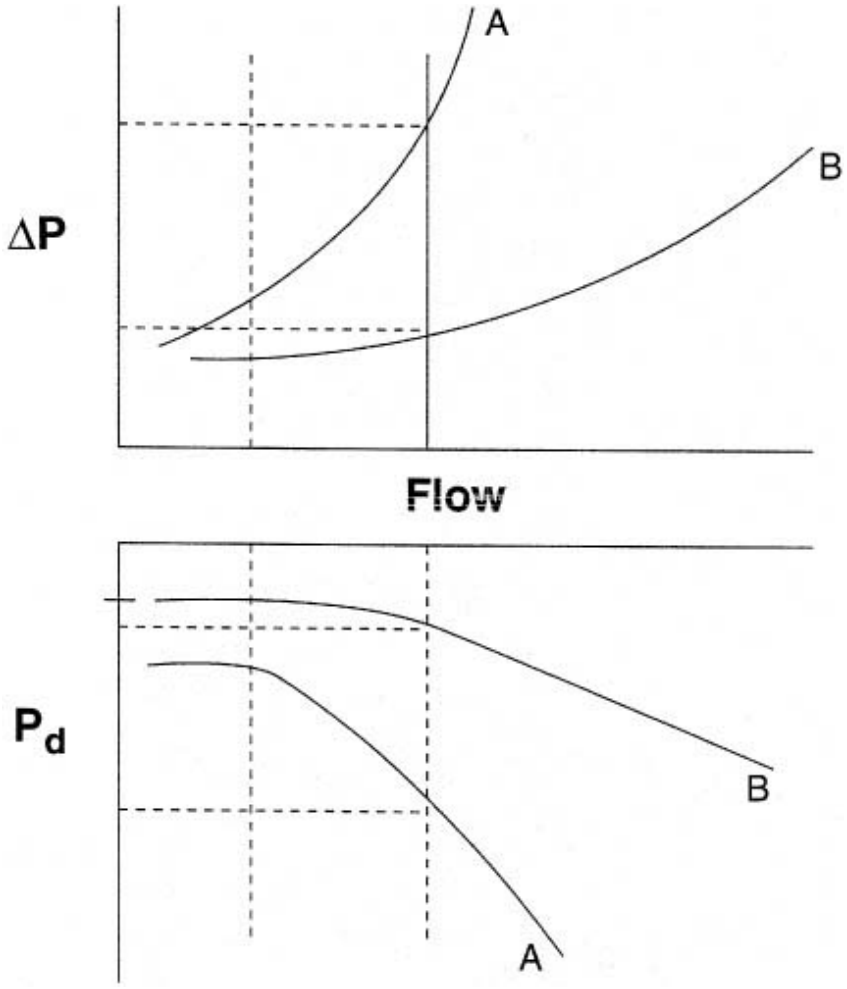

Figure 15-38: Coronary pressure-flow relationships for two stenoses of the same angiographic severity. (*Top*) P_a = aortic P = pressure gradient (aortic-distal coronary pressure, P_d) versus coronary flow. (*Bottom*) Absolute P_d versus flow. Increasing flow produces marked loss of P_d as well as an increase in P_d = distal coronary P. The loss of P_d in absolute terms determines myocardial perfusion pressure (P_d - venous pressure) and the potential for inducible ischemia.

Fundamental Concepts: Doppler Flow

A change in sound frequency occurs as a transmitter moves to or away from a receiver. The change in the sound frequency is proportional to the speed of the target or transmitter, a phenomenon called the *Doppler effect.* In practice, a piezoelectric crystal that both emits and receives high-frequency sounds is mounted on the tip of an intravascular device. The velocity of red blood cells flowing past the device through an artery can be determined from the *frequency shift,* defined as the difference between the transmitted and returning frequency, where

$$\text{AVA (in cm}^2) = \frac{F}{C \times 44.5\sqrt{P_1 - P_2}}$$

$$= \frac{\text{aortic valve flow (mL/s of systole)}}{1 \times 44.5\sqrt{\text{LVS} - \text{ASP}}}$$

Volumetric flow can be determined as the product of vessel area (cm^2) and flow velocity (cm/s), yielding a value in cubic centimeters per second. Absolute Doppler flow velocities represent changes in volumetric coronary flow when the vessel cross-sectional area remains constant over the measurement period. The Doppler guidewire velocity and volumetric relationship has been validated during intravascular measurement by Doucette et al.[168] and Labovitz et al.[169]

Fundamental Concepts: Fractional Flow Reserve

Pressure gradients (aortic-coronary mean pressure) at rest do not accurately characterize the ischemic potential of a stenosis.[170,171] Resting translesional pressure gradients measured during the early years of angioplasty were not accepted because of inadequate devices (nos. 3-4 French catheters) used under inappropriate circumstances (i.e., not during maximal hyperemia). The translesional gradient was incompletely interpreted (i.e., resting gradients rather than hyperemia-induced fractional flow reserve). A new concept based on the pressure-derived measurement of coronary perfusion, called *fractional flow reserve* (FFR),[170,171] is a measure of the fraction of maximal coronary blood flow that traverses the stenotic vessel as a percentage of blood flow through the same artery in the theoretical absence of the stenosis. This measurement is derived from the mean pressure distal to the stenosis divided by the mean pressure proximal to the stenosis at maximal hyperemia. The FFR reflects the true reduction in myocardial perfusion resulting from a stenosis rather than merely a stenosis pressure gradient. During maximal hyperemia, resistance is minimal across both the epicardial and microvascular beds. Because the ratio of the absolute distal coronary to aortic pressures is measured when myocardial resistance is minimal, the status of the microcirculation does not, in theory, affect the FFR. Unlike CFR, FFR is independent of hemodynamic and microcirculatory factors.[172,173] The normal value for FFR is 1.0 for each patient, coronary artery, myocardial distribution, and microcirculatory status (Figs. 15-39 and 15-40).

Pharmacologic Hyperemic Stimuli

Stenosis severity always should be assessed using flow measurements during maximal hyperemia. The most widely used maximal vasodilator agents are adenosine, papaverine, and dipyridamole. [174-176] The hyperosmolar ionic and low-osmolar nonionic contrast media do not produce maximal vasodilatation.

Intracoronary and intravenous adenosine produces hyperemia equivalent to papaverine[18] but has a much shorter half-life (Fig. 15-41). Intravenous adenosine produces similar hyperemia equal to that of intracoronary adenosine but in a sustained fashion. Both intracoronary and intravenous adenosine has an extremely high safety profile in low doses and has become the pharmacologic stimulus of choice in the catheterization laboratory.

Intracoronary adenosine should be injected through catheters without side holes because of inadequate delivery of adenosine for maximal hyperemia. Side hole guiding catheters require an approximate doubling of the intracoronary adenosine dose due to loss of drug during injection.[177]

Absolute and Relative Coronary and Fractional Flow Reserve

Absolute CFR is the ratio of maximal hyperemic to basal mean flow velocity in the target vessel (Fig. 15-42). This ratio is equivalent to a volumetric blood flow reserve if the cross-sectional area is unchanged during the measurements. CFR may underestimate the volumetric flow reserve in some vessels that may have intact endothelial function and flow-mediated vasodilatation. CFR is the summed response of flow through the conduit and the myocardial bed; thus an abnormal CFR does not separate a significant stenosis from an abnormal microcirculation (Fig. 15-43). Measurement of CFR in an angiographically normal vessel can serve as a reference value against which to compare the results in a target vessel. The relative CFR (rCFR), the ratio of CFR_{target} to $CFR_{reference}$, in theory, should identify whether an impaired target CFR is the result of a flow-limiting stenosis or microvascular abnormalities (Fig. 15-44). The normal absolute CFR is 2.7 ± 0.6[178] in adults in the cardiac catheterization laboratory with chest pain syndromes. Absolute CFR appears reproducible among angiographically normal vessels within a 10 percent variance. The average CFR measured using the flow-velocity technique in patients with normal coronary arteries undergoing cardiac catheterization differs little between patients who have had cardiac transplantation and those who have chest pain syndromes and angiographically normal arteries, with approximately 12 percent of patients having a CFR of less than 2.0. rCFR relies on the assumption that the microvascular circulatory response is uniformly distributed among the myocardial beds. The normal range for rCFR is 0.8 to 1.0.[179,180] The major limitations of rCFR include patients with three-vessel coronary disease who have no suitable reference vessel, patients in whom the target vessel supplies an area of

myocardial infarction with LV regional dysfunction, or patients in whom the microcirculatory responses are heterogeneous.

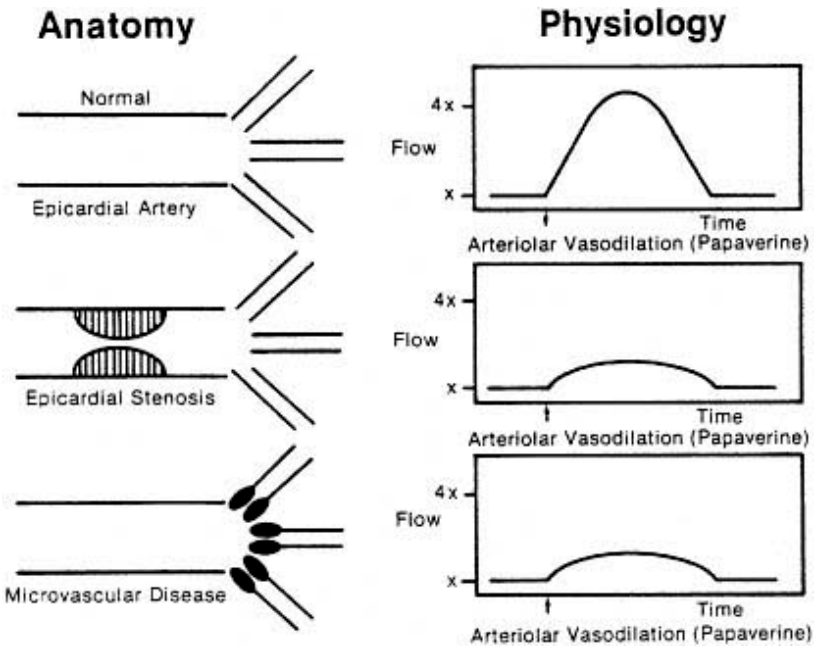

Figure 15-43: Comparison of coronary flow reserve (CFR) in arteries with normal (*top*) epicardial stenosis (*middle*) and abnormal microcirculation (*bottom*).

rCFR and FFR are more specific for flow limitations due to a stenosis than CFR. FFR, rCFR, and CFR were determined in 21 patients in 24 target vessels for stenosis severity ranging from 40 to 95 percent, with an average of 74 ± 15 percent.[179] Absolute CFR did not correlate with percentage area stenosis or FFR. FFR, as well as rCFR, showed a curvilinear relationship with percentage area stenosis ($r = 0.89$ and $r = 0.79$; $p < 0.0001$), with a close linear relationship between FFR and rCFR (0.91; $p < 0.0001$). rCFR closely correlated with FFR and percentage area stenosis. Absolute CFR, as expected, varied due to the influence of microvascular flow status (Table 15-4).

Table 15-4: Comparison of Absolute and Relative CFR and FFR

	Hemodynamic Independence	Independent of Microcirculation Abnormalities	Unequivocal Normal Values	Use in Multivessel CAD
CFR	-	-	Range > 2.0	+
rCFR	+	+	1.0	-
FFR	+	+	1.0	+

Intracoronary Blood Flow Measurements and Ischemia Testing

Several single-center studies[164-166,181-183] and one multicenter trial[167] have reported strong correlations with myocardial stress perfusion imaging and post-stenotic coronary flow velocity reserve. An abnormal distal hyperemic flow velocity reserve (<2.0) corresponded with reversible myocardial perfusion imaging defects with high sensitivity (86-92 percent), specificity (89-100 percent), predictive accuracy (89-96

percent), and positive and negative predictive values (94-100 and 77-95 percent), respectively.

The sensitivity of FFR for reversible ischemia (FFR < 0.75) was 88 percent, specificity 100 percent, positive and negative predictive values 100 and 88 percent, respectively, with a predictive accuracy of 93 percent (Table 15-5).

Table 15-5: Stress Testing and Directly Measured Coronary Hemodynamics

Other Lesion-Specific Flow-Velocity Measurements

There are four lesion-specific physiologic measurements: (1) the rCFR ratio ($CFR_{target}/CFR_{normal}$), (2) the translesional pressure gradient at hyperemia (FFR_{myo}), (3) the proximal-to-distal velocity ratio, and (4) the diastolic/systolic velocity ratio (DSVR). The most accurate and practical measurements are the rCFR and FFR, as discussed earlier.

The proximal-to-distal flow velocity ratio depends on coronary arterial branching, which results in decremental volumetric flow and cross-sectional vessel area from the proximal to the distal myocardial regions. Because both volume and cross-sectional area diminish along the course of the vessel, velocity

remains relatively constant (usually within 10 to 15 percent of the proximal velocity in vessel segments of more than 2 mm diameter). Maintenance of the flow velocity (but not volume) from the proximal to the distal part of the artery (i.e., the ratio of proximal-to-distal flow) can be used as a marker of lesion-specific disease within the artery. In normal arteries, the proximal-to-distal flow velocity ratio should be 1.0.[184] A strong correlation exists between translesional pressure gradients and the ratios of the proximal-to-distal total flow velocity integrals ($r = 0.8$, $p < 0.001$), with a weaker relationship between pressure gradients and QCA ($r = 0.6$, $p < 0.001$).[184] In angiographically intermediate stenoses (50-70 percent), angiography was a poor predictor of translesional gradients ($r = 0.2$, p = ns), whereas the flow velocity ratios continued to have a strong correlation with such gradients ($r = 0.8$, $p < 0.0001$). The proximal-to-distal flow velocity ratio demonstrated highly significant differences between patients with and without significant stenoses. A proximal-to-distal flow velocity integral ratio of less than 1.7 was associated with a gradient of less than 30 mmHg in more than 85 percent of patients. However, the proximal-to-distal ratio will be valid in arteries without branches or in those with ostial stenoses. The proximal-to-distal flow ratio index is sensitive but not lesion-specific.

Similarly, the phasic pattern of coronary flow (DSVR) reflects stenosis resistance. As a stenosis becomes more severe, diastolic flow is impaired first; then, as the stenosis increases, systolic flow is diminished. The normal DSVR is less than 1.8, 1.5, and 1.2 for the left anterior descending, circumflex, and proximal right coronary arteries, respectively.[185] A reduction in the normal DSVR generally indicates an important stenosis but is only a weak index for lesion-specific flow impairment. The relationship between DSVR and lesion severity requires a normally contracting myocardium in the region of the target stenosis to be accurate.

Case Example: Physiologic Assessment of Critical Circumflex Lesion

A 78-year-old woman presented with unstable angina. Coronary arteriography revealed a nondominant right coronary artery, a 90 percent midcircumflex lesion, and a mildly and diffusely diseased left anterior descending coronary artery (Fig. 15-45*A*, top left). CFR and translesional pressure were measured to demonstrate the effect of angioplasty on the coronary physiologic parameters and use these variables as an end point. Coronary angioplasty was performed using a Doppler flow wire. Before angioplasty, circumflex CFR was 1.1, left anterior descending CFR was 2.0, and rCFR was 0.5 (see Fig. 15-45*A*, top right and bottom). The FFR was measured before angioplasty using a pressure guidewire (see Fig. 15-45*A*, bottom). The FFR was 0.33. A pressure transducer pullback to verify gradient location is shown at the far right of the tracing (see Fig. 15-8*A*, far right). After angioplasty (see Fig. 15-45*B*, left), the angiographic result appears satisfactory; however, the CFR in the circumflex (CFR_{CFX}) is still impaired at 1.5 (see Fig. 15-45*B*, right). After stent placement for the impaired CFR_{CFX}, the angiogram is somewhat improved with a 0 percent residual stenosis, but the CFR_{CFX} is now 2.0, rCFR is 1.0, and FFR is 1.0 (see Fig. 15-45*C*, top right and bottom right), indicating a highly successful and correlative physiologic result for this angioplasty.

Summary

Coronary pressure and flow describe coronary lesion resistance. The strong correlation of directly measured coronary flow and pressure to indirect ischemia testing can facilitate clinical in-lab decisions. Use of in-lab physiology strongly complements coronary lumenology and continues to have important clinical and economic implications for and research into the coronary circulation of patients.

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

List of Figures

Figure 15-8: Time and concentration components of a normal indicator-dilution curve that has been replotted semilogarithmically, with extrapolation of the declining slope of concentration to eliminate the effect of recirculated indicator. The logarithm of the concentration on the ordinate is plotted against time on the abscissa. t_o, time of onset of injection of the indicator slug; t_i, time from t_o to the end of the injection; t_a, time from t_o to the first detectable appearance of indicator at the sampling site; t_p, time from t_o to the peak (maximal) concentration of the indicator; t_d, time when the declining concentration of indicator reaches a minimally detectable value; t_r, time from t_o to the time of the secondary concentration peak due to systemic recirculation of indicator; IT, the injection time. (From Wood EH, Swan HJC. Definition of terms and symbols for description of circulatory dilution curves. *J Appl Physiol* 1954; 6:797. Modified and reproduced with permission from the publisher and authors.)

Figure 15-9: Dimensions of the left ventricular (LV) cavity in end-diastole used for the calculation of the ventricular volume by the area-length method, biplane technique. A-P, anteroposterior plane; A_a, A_l, area, A-P and area lateral plane (planimetry); L_a, L_l, length or long axis of the left ventricle (measured); D_a, D_l, diameter of short axis, A-P lateral plane (derived; L_m, maximum length or long axis whether from the lateral A-P or lateral plane; h, wall thickness, LV. See text for formulas. (Left and middle portion of figures from Sandler and Dodge.[66] Right portion of figure from Dodge HT. Hemodynamic aspects of cardiac failure. *Hosp Pract* 1971; January:91. Illustration by B. Tagawa and A. Miller. Reproduced with permission from the publishers and authors.)

Figure 15-10: Using magnetic resonance phase-velocity mapping, aortic flow waveforms are obtained from an imaging slice placed in the aortic root. In a patient with moderate aortic valve regurgitation, increased forward flow occurred in systole and significant negative (regurgitant) flow rate occurred in diastole. The regurgitant volume was 32 mL per beat. No significant reverse flow is seen in the normal subject. (Used with permission of Chatzimavroudis GP, Walker PG, Oshinski JN, Franch RH, Pettigrew RI, and Yoganathan AP, Institute for Bioengineering and Biosciences, Georgia Institute of Technology, and F. Phillips Magnetic Resonance Research Center, Emory University Hospital, Atlanta, GA.)

Figure 15-11: Comparison of structure, iodine per particle, and side chain between standard and new contrast media. The number next to the proprietary name identifies the side chain it contains.

Figure 15-12: Selective left ventricular angiography. *A.* 60° LAO and 30° cranial position demonstrates closed membranous ventricular septal defect (VSD) at the site of a large septal aneurysm (*arrows*). *B.* 40° LAO and 30° cranial position outlines a closing muscular VSD. A jet of contrast media exits the funnel-shaped defect (*arrow*).

Figure 15-13: Valvular pulmonary stenosis (lateral view). Right ventricular injection of opaque medium. Contrast material exits through central orifice of pulmonary valve in form of a jet (*arrow*). RV, right ventricle; I, infundibulum of right ventricle; PA, pulmonary artery.

Figure 15-14: Partial anomalous drainage of pulmonary veins (frontal view). *A.* The catheter has been introduced into the right atrium and ventricle and positioned in the main pulmonary artery (PA), where selective injection is performed. *B.* Pulmonary venous phase. A large pulmonary vein (*arrow*) drains the upper lobe of the left lung, with anomalous venous return to the left innominate vein (LIV). SVC, superior vena cava; LA, left atrium.

Figure 15-15: *A.* Selective right ventricular (RV) injection, frontal view opacifying the main pulmonary artery (MPA) and the left PA (LPA). The right PA does not opacify. *B.* Selective injection of the aortic root in the frontal viewopacifies the aberrant right PA (RPA) originating from the medial side of the ascending aorta (ASC AO).

Figure 15-16: The frontal view of the left ventricular (LV) cineangiogram of a young girl with partial AV canal shows the typical swan's neck contour of the LV outflow tract. Note the shorter than normal mitral valve annulus to LV apex distance (the LV inflow tract) in comparison with the LV apex to aortic valve distance (LV outflow tract).

Figure 15-17: Selective LV angiogram in a patient with ventricular septal defect and pulmonary atresia, frontal view. The right and left pulmonary arteries are supplied by a patent ductus arteriosus (PDA). A branch from the right subclavian artery (RSCA) fills a separate right pulmonary artery supplying the right middle and upper lobe.

Figure 15-18: Proposed mechanisms of contrast media-induced acute renal injury. RBC, red blood cells; RTE, renal tubular epithelial cells. (From Rocher.[102] Reproduced with permission of the author and publisher.)

Figure 15-19: (*Left*) A 30° RAO view of the aortic root demonstrating the left coronary orifice. (*Right*) A 60° LAO view of the aortic root demonstrating location of the right coronary orifice. (From Schoonmaker and King.[128] Reproduced with permission from the American Heart Association, Inc., and the authors.)

Figure 15-20: Diagram of the coronary circulation. Each arterial segment is evaluated carefully in all views and the degree of stenosis is determined. Left main coronary artery, 1, 2; left anterior descending coronary artery, 3, 5, 7, 9; diagonal branches, 6, 8; major septal perforating branch, 4; circumflex coronary artery in the atrioventricular groove, 10, 14, 16; ramus intermedius, 11; obtuse marginal branches, 12, 13, 15; posterior descending branch of the circumflex coronary artery, if present, 17; right coronary artery in the atrioventricular groove, 18, 19, 21, 23; large right ventricular branch of the right coronary artery, 20; posterior descending branch of the right coronary artery, 22; left ventricular branch of the right coronary artery, 24. (From King SB III, Douglas JS Jr. *Coronary Arteriography and Angioplasty*. New York: McGraw-Hill; 1985:363. Reproduced with permission from the publisher and authors.)

Figure 15-21: Diagrammatic representation of the standard RAO view of the left coronary angiogram, the direction of the x-ray beam, and the position of the overhead image intensifier. Most of the left coronary artery is well visualized in this projection, although there is considerable overlap of the middle left anterior descending artery and the diagonal branches. When the left main, circumflex, and diagonal branches have a leftward initial course, the long axis of these arterial segments is projected away from the image intensifier, preventing optimal visualization from the RAO view. The image intensifier is placed anteriorly in an RAO position relative to the patient. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-22: Diagrammatic representation of the LAO left coronary angiogram and the direction of the x-ray beam in this view. The value of this view depends in large part on the orientation of the long axis of the heart. When the heart is relatively horizontal, the left anterior descending (LAD) coronary artery and diagonal branches are seen end-on throughout much of the course. In this illustration, the longitudinal axis is an intermediate position and there is moderate foreshortening of the anterior descending and diagonal branches in their proximal portions (compare with Fig. 15-25). The LAO projection is frequently inadequate to visualize the proximal LAD and its branches; the left main segment, which is directed toward the image tube and therefore foreshortened, and the proximal circumflex coronary artery, which may be obscured by overlapping vessels, as in this illustration. The LAO projection is frequently used to visualize the distal LAD and its branches, the mid-circumflex coronary artery in the AV groove, and the distal right coronary artery that is filling via collaterals from the left coronary artery. The image intensifier is above the patient in an LAO position. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-23: Diagrammatic illustrations of the left lateral or 90° LAO view of the left coronary arteriogram and direction of the x-ray beam. The left lateral view of the left coronary artery is most useful for analyzing the proximal and mid-LAD by avoiding overlap with the diagonal branches, which commonly take an inferior course from the LAD in this projection. The most proximal portion of the diagonal branches may not be well visualized because the long axis of these segments may be in the direction of the x-ray beam. The leftward-directed left main segment is foreshortened in this view (compare with Fig. 15-22). In this view, the image intensifier is placed on the patient's left, and the x-ray beam has a right-to-left direction in the horizontal plane. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-24: Illustration of sagittal angulation of x-ray beam in coronary arteriography. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-25: Diagrammatic illustration of the left coronary angiogram in the 45° LAO with 30° cranial angulation and the direction of the x-ray beam used to produce this view. This is the most valuable view of the left coronary artery in most patients. Foreshortening of the left main and proximal left anterior descending and diagonal branches present in the LAO view is usually overcome by cranial angulation of the image intensifier. The proximal left coronary arterial segments are frequently visualized at an angle almost perpendicular from their long axis. The ostium of the left main coronary artery, the most proximal portion of the LAD, and the origin of the diagonal branches are usually well visualized without overlap (compare with Fig. 15-22). Some overlap may occur with branches of the proximal circumflex coronary artery, and this is frequently overcome by using a 60° LAO with 30° of cranial angulation. The value of the LAO with cranial angulation is considerably less when the proximal left coronary artery is superiorly directed, in which case caudal angulation of the image intensifier is frequently helpful. The direction of the x-ray beam in the 45° LAO with 30° of angulation is demonstrated. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-26: Diagrammatic illustration of the direction of the x-ray beam and the left coronary angiogram in the 15° RAO with 30° of cranial angulation. This view is particularly helpful in analyzing the mid-left anterior descending artery and the diagonal branch points. Overlap with diagonal branches is usually avoided. The origin of the circumflex artery may be well seen, as in this illustration. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-27: Diagrammatic illustration of the direction of the x-ray beam and the right coronary artery in the 45° LAO projection. This view is excellent for visualizing the proximal mid and distal right coronary artery in the AV groove since the direction of the x-ray beam is perpendicular to these arterial segments. Ostial lesions of the right coronary artery are now well visualized if the proximal right coronary artery takes an anterior direction from the aorta and therefore originates in a direction parallel to the x-ray beam. This usually can be overcome by turning to a more severe left oblique projection. The posterior descending and LV branches of the right coronary artery, which pass down the posterior aspect of the heart toward the apex, are severely foreshortened because the long axis of these vessels is in the same direction as the x-ray beam. The proximal posterior descending branches can be visualized by cranial angulation of the overhead intensifier (see Fig. 15-28) or from a right oblique view. The image intensifier is in the standard LAO position. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-28: Diagrammatic illustration of the direction of the x-ray beam and the right coronary artery in 30° LAO with 30° of cranial angulation. Cranial angulation of the image intensifier overcomes the problem of foreshortening of the posterior descending and left ventricular branches observed in Fig. 15-27. Lesions in the posterior descending or LV branches can be well visualized. When the right coronary artery originates anteriorly from the aorta, the proximal portion of the vessel is frequently well seen in this projection. With anomalous origin of the left anterior descending artery from the right coronary artery, this view is helpful because the standard LAO view produces considerable foreshortening of the anomalous artery. The direction of the x-ray beam is the same as in Fig. 15-25. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-29: Anatomy of the left coronary tree in the right oblique view.

Figure 15-30: RAO view of the left coronary artery showing high-grade stenosis of the left anterior descending proximal to the first septal perforating branch.

Figure 15-35: RAO view of left coronary artery system. *A.* Diastolic appearance of anterior descending artery showing smooth lumen. *B.* Systolic appearance showing obliteration of the lumen by an overriding muscular bridge.

Figure 15-36: *A.* LAO view of right coronary injection showing pericatheter spasm. *B.* Same view following nitroglycerin, showing relief of spasm.

Figure 15-37: LV wall silhouette in RAO and LAO views.

Figure 15-38: Coronary pressure-flow relationships for two stenoses of the same angiographic severity. (*Top*) P_a = aortic P = pressure gradient (aortic-distal coronary pressure, P_d) versus coronary flow. (*Bottom*) Absolute P_d versus flow. Increasing flow produces marked loss of P_d as well as an increase in P_d = distal coronary P. The loss of P_d in absolute terms determines myocardial perfusion pressure (P_d - venous pressure) and the potential for inducible ischemia.

Figure 15-39: Schematic drawing illustrating the rationale of comparing relative and fractional myocardial flow reserve in this particular group of patients. The relative flow reserve (RFR) is the ratio of hyperemic flow in the anterior region (depending on the stenotic left anterior descending coronary artery) to the hyperemic flow in the normal region (depending on the left circumflex coronary artery). The myocardial fractional flow reserve (FFR) is the ratio of hyperemic flow in the anterior region (depending on the stenotic left anterior descending coronary artery) to hyperemic flow in that same region in the hypothetical case of a normal left anterior descending coronary artery (*faint lines*). These measurements are derived from the mean pressure distal to the stenosis divided by the mean pressure proximal to the stenosis at maximal hyperemia. In the case of a similar decrease of myocardial resistance during hyperemia in the left anterior descending area and the left circumflex area, the value of both the relative and the fractional myocardial flow reserves should be identical. n, the hypothetical normal left anterior descending coronary artery; n', normal left circumflex coronary artery; s, stenotic left anterior descending coronary artery. (Reproduced with permission from de Bruyne B, Banohuin T, Melin J, et al. Coronary flow reserve calculated from pressure measurements in humans. Validation with positron emission tomography. *Circulation* 1994; 89:1013-1022.)

Figure 15-40: Hemodynamic and coronary flow velocity tracings demonstrating coronary flow reserve (CFR) and fractional flow reserve (FFR) data collection. Aortic (P_a) and distal coronary pressure (P_d) at baseline and during adenosine hyperemia (*at vertical line*). Coronary velocity shows a 2.2-fold increase with adenosine. FFR = 0.78.

Figure 15-41: Comparing changes in coronary blood flow velocity from baseline with different doses of adenosine and papaverine. (Modified with permission from Wilson RF, Wyche K, Christensen BV, et al. Effects of adenosine on human coronary arterial circulation. *Circulation* 1990; 82:1595-1606.)

Figure 15-42: (*Left*) Coronary flow velocity signals obtained in a normal circumflex artery (CFX) of a patient undergoing angioplasty of the right coronary artery. The top half represents continuous flow-velocity signals in real time. The electrocardiogram, aortic pressure, and spectral flow signals are provided from top to bottom. The scale is 0-120 cm/s. S and D, systolic and diastolic periods demarcated by the electrocardiogram, respectively. (*Right*) The trend plot of the continuous flow velocity measurement (average peak velocity, APV) is shown in the right-hand panel on the lower tracing. After intracoronary adenosine administration, APV increased from 11 to 29 cm/s, producing a coronary flow ratio (CFR) of 2.6. The duration of hyperemia is 45 s. The trend velocity scale is 0 to 40 cm/s. The time base is 90 s. (Reproduced with permission from Kern MJ, de Bruyne B, Pijls NHJ, et al. From Research to clinical practice: Current role of physiologically based decision making in the catheterization laboratory. *J Am Coll Cardiol* 1997; 30:613-620.)

Figure 15-43: Comparison of coronary flow reserve (CFR) in arteries with normal (*top*) epicardial stenosis (*middle*) and abnormal microcirculation (*bottom*).

Figure 15-44: Measurements of absolute and relative coronary flow (velocity) reserve (CFR) used to assess long 60 percent mid-left anterior descending (LAD) coronary stenosis in patient J.M. (*top right*). Left anterior descending CFR_{target} is 2.9, CFR_{ref} in the circumflex (CFX) artery is 3.0. Relative CFR (rCFR) is 0.9. Angioplasty was deferred.

Figure 15-45: *A.* Coronary angiography, relative coronary flow velocity reserve (rCFR), and fractional flow reserve (FFR) before angioplasty of a circumflex (CFX) coronary lesion in a 78-year-old woman. LAD, left anterior descending artery. *B, C.* Results of coronary angioplasty (PTCA) and eight-stentplacement with measurements of coronary flow reserve (CFR) and fractional flow reserve (FFR), as well as relative coronary flow reserve (rCFR) after the procedure.

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 16:

NUCLEAR CARDIOLOGY

Authors: Daniel S. Berman, Leslee J. Shaw, Guido Germano

OVERVIEW

During the last three decades, a number of noninvasive testing modalities have become widely available in clinical cardiology. Since the early 1970s, there has been a sustained growth of nearly 15 percent per year in the field of nuclear cardiology. Today, state-of-the-art nuclear cardiology allows for the measurement of both myocardial function and relative regional perfusion at rest and stress, providing accurate risk assessment in a wide variety of patient subsets. This chapter provides a synopsis of published evidence on the role of nuclear cardiology procedures in diagnosis and risk assessment with a view to effective clinical management of patients with suspected or known coronary artery disease (CAD). Positron emission tomography (PET) is discussed in Chap. 19.

Major Advances in Clinical Cardiology

Important experimental and clinical research has led to a substantial reduction in the risk of coronary artery disease events in westernized countries.[1] Current evidence from randomized trials notes a 35 to 50 percent reduction in mortality associated with ischemic heart disease and stroke.[2] A comparison of mortality statistics from 1973 to 1993 reveals a decrease in the total number of deaths, mostly affecting the young and middle-aged population (see Chap. 38). Improved outcomes were the result of improved diagnosis and effective risk-reducing therapies.[3,4] New therapies aimed at reducing blood pressure and cholesterol levels are effective strategies for the prevention of cardiovascular disease.[5] In the case of cholesterol lowering, a linear relationship between serum levels and CAD risk has been established, a 10 percent reduction in cholesterol levels being associated with a 30 percent reduction in disease incidence; and the widespread availability of effective, low-risk drugs has made major cholesterol reduction feasible.[6] An overview of randomized trials for coronary artery bypass surgery (CABS) indicates that the appropriate surgical treatment has resulted in an overall mortality reduction as compared with medical treatment.[7] These effective therapies have increased the importance of accurate risk assessment, ideally more accurately and quantitatively based than is feasible from historical information alone or nonimaging treadmill stress testing.

Despite the abundance of high-quality evidence on the effectiveness of medical and surgical management of patients, the body of evidence on the effectiveness of noninvasive testing in guiding management decisions is less well established. Nonetheless, evidence-based medicine is now the standard serving for the evaluation of new technologies and their assimilation into daily clinical practice. Nuclear cardiology is a well-established modality with large observational series available to provide the basis for effective medical management of patients with suspected or known CAD.

Era of Cost Containment in Medical Practice

Declining reimbursement levels coupled with an ever-increasing emphasis on cost containment

has led many to advocate development of a body of evidence to justify use of any medical procedure. For a nonivasive test, justification may be defined as assessing its economic and clinical incremental value as compared with other modalities. A synthesis of evidence reviewed in the recent ACC/AHA/ACP-ASIM guidelines for the management of patients with chronic stable angina revealed an abundance of data on the clinical incremental value of nuclear cardiology procedures.[8] Selected reports are also available on economic data for nuclear cardiology procedures as compared with other noninvasive tests used in cardiology.[9]

Historical Perspectives in Nuclear Cardiology

Continuous growth in the field of nuclear cardiology over the last three decades has been facilitated by the development of improved perfusion tracers, enhancements in scintillation cameras, and dramatic improvements in computer technology and specialized computer hardware and software, allowing for rapid assessment of patient data. In 1999, nearly 5 million myocardial perfusion studies were performed in the United States, a rate nearly threefold higher than other stress imaging tests. Major growth in procedure use has occurred in the outpatient setting, with an ever-increasing proportion of tests being performed in nonhospital facilities. The Anger scintillation camera, the imaging device used today for virtually all of nuclear cardiology except PET, became clinically available in the late 1960s. In the 1990s, the principal advances were the wide use of dual and triple detector cameras that improved image quality and shortened acquisition time as well as dramatic increases in the speed of computer systems that decreased processing time and made gated single-photon emission tomography (SPECT) clinically feasible. In 1973, Liebowitz et al. introduced thallium 201 (^{201}Tl) for medical use.[10] Following its commercial availability, ^{201}Tl quickly became the myocardial perfusion imaging agent of choice, a position it maintained until the technetium 99m (^{99m}Tc) perfusion agents became widely accepted. In 1990, ^{99m}Tc sestamibi was approved for use in the United States. Owing to its more favorable physical properties and better image quality, this agent has become the most frequently used radiopharmaceutical in the United States. Another ^{99m}Tc-based agent, tetrofosmin, was approved in the United States in 1997 and has also demonstrated widespread growth. By 1998, some 72 percent of nuclear cardiology tests used a ^{99m}Tc myocardial perfusion imaging agent.

State-of-the-Art Nuclear Cardiology

With the recent widespread availability of powerful computer systems as well as multidetector SPECT systems, gated myocardial perfusion scintigraphy has become routine; it was performed in 66 percent of myocardial perfusion SPECT studies in the United States in 1999, providing objective assessments of global and regional myocardial function in addition to traditional perfusion assessment. The increasing acceptance of the gated myocardial perfusion SPECT technique is a consequence of its becoming a powerful clinical tool to address a variety of clinical questions arising in the assessment of patients with known or suspected CAD. Although radionuclide angiography played a prominent role in noninvasive testing in decades past, in the 1990s the use of this modality became largely replaced by echocardiography and gated perfusion SPECT. Some important clinical applications of this modality remain, however, and are discussed in the latter portion of this chapter.

Chapter 16: NUCLEAR CARDIOLOGY

MYOCARDIAL PERFUSION SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY

A large number of acquisition protocols and techniques are used in nuclear cardiology today. Most of them are based on the Anger scintillation camera or a variation of it. The Anger scintillation camera (or gamma camera) consists of one or more scintillation detectors, typically made of high-density materials such as NaI, sodium iodide. Myocardial perfusion scintigraphy can be performed with either planar or SPECT approaches. With the planar technique, generally three two-dimensional (2D) images are obtained, usually 10 to 15 min each. Myocardial perfusion SPECT consists of imaging the 3D distribution of a radioactive perfusion agent in the myocardium. For SPECT acquisition, the camera detectors rotate around the patient in a circular or elliptical fashion, collecting a "projection image" at every few degrees. The 3D distribution of radioactivity is then mathematically "reconstructed" from the 2D projection images, usually using a process called "filtered-backprojection" and incorporating a variety of filters that enhance the images.

Multidetector cameras have come to be more commonly purchased than single-detector systems, and their increasing diffusion is an important factor supporting the increasing utilization of gated SPECT. Dual-detector cameras with the two detectors positioned at 90 degrees allow completion of 180-degree SPECT acquisitions in half the time taken by a single detector system for the same count level, or collection of twice the counts in the same time, and are therefore highly efficient for gated cardiac SPECT for imaging perfusion and function. A gated SPECT acquisition is similar to a standard SPECT acquisition, since in both cases the camera detector(s) rotates around the long axis of the patient, acquiring a number of planar ("projection") images at regular angular intervals (Fig. 16-1). What distinguishes the gated from the nongated technique is that, in the former, a number (8 or 16) of projection images is acquired at each projection angle, with each image (also called an interval or frame) corresponding to a specific portion of the cardiac cycle. A gated SPECT acquisition results in a standard SPECT data set ("summed" gated SPECT), from which perfusion is assessed, and a larger gated SPECT data set, from which function is evaluated. Gated SPECT has become the most commonly performed perfusion SPECT protocol as a direct consequence of the ease and modest expense with which perfusion assessment is "upgraded" to perfusion/function assessment and of the documentation of incremental information by the combined measurements.

As long as adequate count statistics are achieved, there is no limitation as to the specific perfusion agent that can be imaged with the gated SPECT technique. The quality of the gated SPECT study is directly related to the number of counts in its individual frames. Count statistics are influenced by numerous factors, including injected dose, acquisition time, patient size, number of detectors, collimation, number of frames, and count acceptance criteria.

Radiopharmaceuticals

THALLIUM 201

A cyclotron-generated radionuclide with a half-life of 73 h, ^{201}Tl emits gamma rays from 68 to 80 kev (94 percent abundant) and at 167 kev (10 percent abundant). Owing to its relatively long half-life, the absorbed radiation dose is such that recommended injected doses are limited to 2 to 4

mCi. ^{201}Tl has excellent physiologic properties for myocardial perfusion imaging. Importantly for stress myocardial perfusion scintigraphy, a linear relationship between blood flow to viable myocardium and ^{201}Tl uptake is maintained during exercise[11] up to very high levels of flow (e.g., vasodilator stress, >3 mL/min/g), where a "roll-off" in uptake occurs.[12] After intravenous injection, thallium is rapidly extracted throughout the body roughly in proportion to the distribution of cardiac output.[13] As an unbound potassium analog, ^{201}Tl redistributes over time. At equilibrium its distribution of ^{201}Tl is proportional to the regional potassium pool, reflecting the amount of viable myocardium. Thus, following intravenous injection and initial myocardial uptake, approximately half of the ^{201}Tl washes out of the normal myocardium over 5 to 8 h.[14] Differential washout rates between hypoperfused but viable myocardium and normal zones and washin to initially hypoperfused zones are the fundamental mechanisms of ^{201}Tl redistribution.

A factor governing the washout rate of ^{201}Tl is the concentration gradient between the myocardial cell and the blood. There is slower blood clearance of ^{201}Tl following resting or low-level exercise injection. Diffuse slow washout rates, mimicking diffuse ischemia, may be observed in normal patients who do not achieve adequate levels of stress. Hyperinsulinemic states slow redistribution, leading to an underestimation of viable myocardium; thus, fasting is recommended prior to and for 4 h following ^{201}Tl injection.[15]

An inverse relationship between the degree of coronary stenosis and subsequent redistribution of ^{201}Tl (i.e., late redistribution) has been reported.[16] Redistribution may occur early in areas with minor stenoses (where hyperemia postexercise would be expected), and late in regions with critical stenoses (in which poststress hyperemia is unlikely and resting hypoperfusion slows the delivery of thallium to the region).[17]

^{99m}Tc SESTAMIBI AND TETROFOSMIN

^{99m}Tc is produced from a molybdenum-99m generator, has a half-life of 6 h, and emits monoenergetic gamma rays at 140 kev. The whole-body radiation dose is estimated to be 16 mrad/mCi, in contrast to 240 mrad/mCi associated with ^{201}Tl. Owing to this more favorable dosimetry, larger doses of ^{99m}Tc myocardial perfusion imaging agents are used than with ^{201}Tl, usually in the range of 30 mCi. ^{99m}Tc sestamibi belongs to a class of compounds called *isonitriles* and is a complex organic compound that behaves physiologically as a monovalent cation. Following its extraction from the blood, ^{99m}Tc sestamibi is bound by mitochondria, and only a limited amount of myocardial washout (or washin) occurs over time.[18,19] As with ^{201}Tl, the initial uptake of ^{99m}Tc sestamibi is a function of myocardial perfusion to viable tissue. In general, ^{201}Tl has a higher myocardial uptake (as measured by the percent injected dose per gram of myocardium) throughout the range of flow, secondary to a higher extraction fraction than ^{99m}Tc sestamibi (approximately 85 percent compared with 65 percent).[20,21] At very low levels of flow, extraction of these tracers appears to increase, affecting ^{99m}Tc sestamibi more than ^{201}Tl.[22]

^{99m}Tc tetrofosmin is extracted by the myocardium and bound in mitochondria, like sestamibi. The extraction fraction of this agent is slightly lower than that of sestamibi.[23] There is less hepatic uptake with this tracer than with ^{99m}Tc sestamibi, resulting in more favorable heart/liver ratios early following resting injection.[24,25]

OTHER ^{99m}Tc MYOCARDIAL PERFUSION AGENTS

^{99m}Tc teboroxime belongs to another class of ^{99m}Tc myocardial perfusion agents, which are neutral lipophilic complexes of boronic acid called BATO compounds. ^{99m}Tc teboroxine appears to have a higher extraction fraction than ^{201}Tl. The high extraction fraction with this agent plateaus at a higher flow rate than any other agent.[26,27] These highly desirable extraction characteristics of

teboroxime are counterbalanced by a rapid washout from the myocardium.[28] Thus, the kinetic properties of ^{99m}Tc teboroxime require that initial imaging be completed within the first few minutes after tracer injection in order to reflect blood-flow distribution at the time of injection. This limits its use to multiple-detector systems.[29] Due to the requirement for very rapid imaging, ^{99m}Tc teboroxime is the most technically demanding of the available myocardial perfusion tracers.

^{99m}Tc NOET is a neutral lipophilic myocardial perfusion imaging agent based on a Tc-nitrido core.[30] Although an extraction fraction as high as 76 percent with this tracer has been reported under hyperemic conditions,[31] there are other reports of much lower extraction than that associated with ^{201}Tl.[32] There appears to be redistribution over time of this tracer, related in part to the absence of intracellular binding and in part to higher circulating blood levels of radioactivity with this tracer as compared with ^{99m}Tc sestamibi.[31] ^{99m}Tc NOET overall may have kinetic and imaging properties very similar to those of ^{201}Tl, with the advantage of the higher photon flux associated with the higher injected dose that is possible with a ^{99m}Tc agent.[33] The redistribution of ^{99m}Tc NOET appears to be almost complete after 90 min of reflow, potentially shortening the clinical protocols applicable for assessment of myocardial viability with this tracer. A disadvantage of this tracer, like that of ^{201}Tl, is the lack of flexibility in the timing of postexercise imaging and the ability to repeat imaging.

^{99m}Tc furifosmin appears to be very similar to ^{99m}Tc tetrofosmin,[34,35] with an extraction fraction lower than that of ^{99m}Tc sestamibi. Neither ^{99m}Tc NOET nor ^{99m}Tc furifosmin have been approved for clinical use in the United States at this time.

Imaging Protocols and Image Interpretation

^{201}Tl PROTOCOLS

With ^{201}Tl, a variety of SPECT acquisition protocols are available (Fig. 16-2). When ^{201}Tl alone is employed as the radiopharmaceutical, the usual acquisition protocol uses some combination of stress with redistribution and/or reinjection imaging. The latter, as initially described, involved obtaining an additional image in patients with nonreversible ("fixed") perfusion defects following reinjection of one-half of the dose used at stress, with imaging performed immediately thereafter[36] (Fig. 16-2*A*). This protocol improves detection of viable myocardium over standard-stress 4-h redistribution imaging.[37] Since it requires three image acquisitions and a decision as to whether the reinjection is needed, a two-acquisition sequence with stress and redistribution/reinjection imaging is commonly performed. If no fixed defects are noted, with this approach further imaging is not required. If, on the other hand, following the 4-h reinjection/redistribution image, fixed defects are present, 24-h imaging results in a small but significant improvement in detection of viable myocardium[16,37] (Fig. 16-2*B*). An alternate protocol that appears to be gaining popularity is to give sublingual nitroglycerin prior to the reinjection of ^{201}Tl. With this approach, the frequency of further improvement at 24-h imaging may be substantially reduced; i.e., we consider it likely that a stress- and nitrate-augmented early reinjection protocol will reduce the benefit of, and thus the need for, 24-h imaging.[38] The other form of thallium imaging in frequent use is the rest/redistribution protocol, considered to be the most effective ^{201}Tl protocol for the assessment of viable myocardium[39,40] (Fig. 16-2*C*).

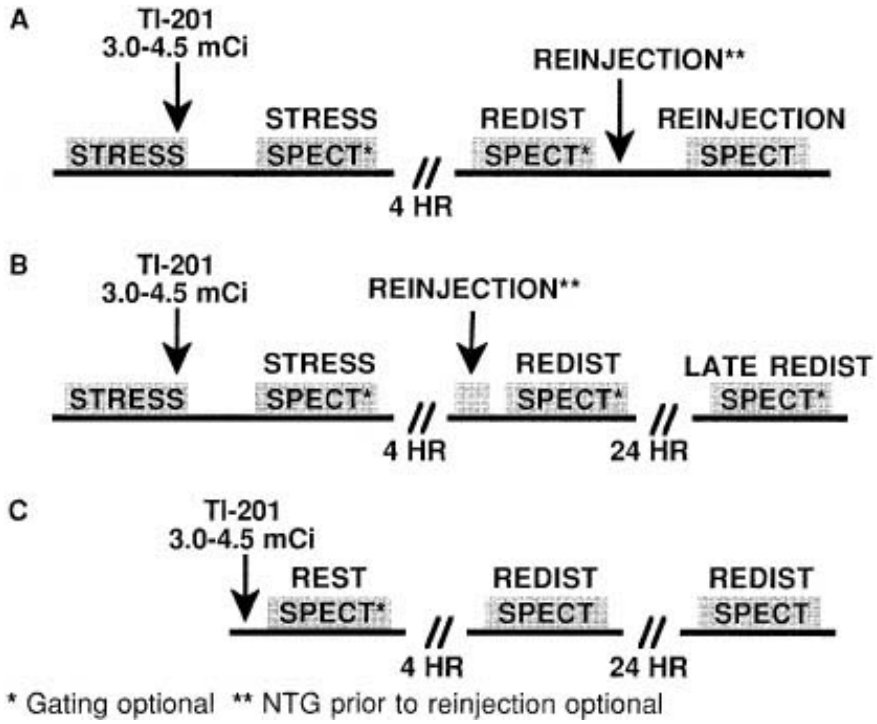

Figure 16-2: 201Tl protocols. *A.* Stress/redistribution (redist), reinjection. *B.* Stress/reinjection/late redistribution. *C.* Rest/redistribution.

With a ^{201}Tl SPECT protocol, most investigators utilize all-purpose rather than high-resolution collimators,[41] although some prefer high-resolution collimators.[42,43] If high-resolution collimators are used, lengthening of the time of acquisition for ^{201}Tl SPECT should be considered-compared with ^{99m}Tc-based SPECT protocol-to provide adequate SPECT count statistics. This is particularly relevant for late redistribution imaging, because of the lower count rate due to radioactive decay. The timing of the initial poststress acquisition is particularly important with thallium, since excessive delay could result in decreased sensitivity for detection of coronary artery disease, owing to early redistribution of the radiopharmaceutical. However, SPECT acquisition of either the ^{201}Tl or the ^{99m}Tc myocardial perfusion agent should begin ≥10 min following exercise injection because of the frequent observation of an artifactual perfusion defect due to "upward creep of the heart."[44] This phenomenon is related to the increased depth of respiration very early postexercise, which is associated with an average lower position of the diaphragm in the chest compared with the normal ventilatory state. This causes the heart to gradually move cephalad during the early portion of SPECT acquisition, resulting in a form of motion artifact after reconstruction. By delaying acquisition until 10 to 15 min after exercise stress, this "upward creep" artifact is avoided. Although initially described with ^{99m}Tc sestamibi, gated SPECT can also be performed with ^{201}Tl, particularly with multidetector system. LVEF measurement with gated ^{201}Tl SPECT correlates highly with that of ^{99m}Tc sestamibi SPECT.[45]

^{99m}Tc SESTAMIBI OR TETROFOSMIN PROTOCOLS

Owing to the absence of clinically significant redistribution, separate rest and stress injections are standard with ^{99m}Tc sestamibi or tetrofosmin SPECT (Fig. 16-3).[46,47] A benefit of the absence of redistribution is that image acquisition can be repeated if imaging artifact is suspected. In this regard, imaging in the prone position, as well as in the supine position, increases the specificity of myocardial perfusion SPECT with ^{99m}Tc sestamibi or tetrofosmin.[47] A variety of protocols can be used with these agents, including 2-day stress/rest, same-day rest/stress, same-day stress/rest, and dual isotope. From the standpoint of defect contrast and optimal image quality, the 2-day

stress/rest protocol is ideal (Fig. 16-3*A*). With the 2-day stress/rest protocol, both the stress and the rest study are obtained following the injection of high doses of ^{99m}Tc sestamibi or tetrofosmin, allowing the acquisition of high-quality, high-count images for the accurate assessment of perfusion and function. The principal drawback of this protocol is its requirement for two imaging days, resulting in a delay in the delivery of final information to be used in patient management. The same-day low-dose rest/high-dose stress protocol[48] (Fig. 16-3*B*) has the disadvantage of causing a reduction in stress defect contrast, as approximately 15 percent of the radioactivity observed at the time of stress imaging comes from the preexisting resting myocardial distribution. The same-day low-dose stress/high-dose rest sequence[49,50] (Fig. 16-3*C*), on the other hand, has the advantage of requiring image acquisition times essentially identical to those used for ^{201}Tl imaging, making it easy for a laboratory to alternate between the two protocols. The principal drawback of this approach is that less than ideal count rates are associated with the most important stress image set, and it is difficult to assess defect reversibility accurately.[51] With respect to the assessment of myocardial viability, all stress/rest or rest/stress ^{99m}Tc sestamibi or tetrofosmin imaging protocols have theoretical limitations in distinguishing severely hibernating myocardium from infarction. These constraints do not apply to ^{201}Tl because of its redistribution properties.[52,53] Viability assessment with ^{99m}Tc sestamibi or tetrofosmin may be improved by the administration of nitroglycerin prior to the rest-injection study.[54,55]

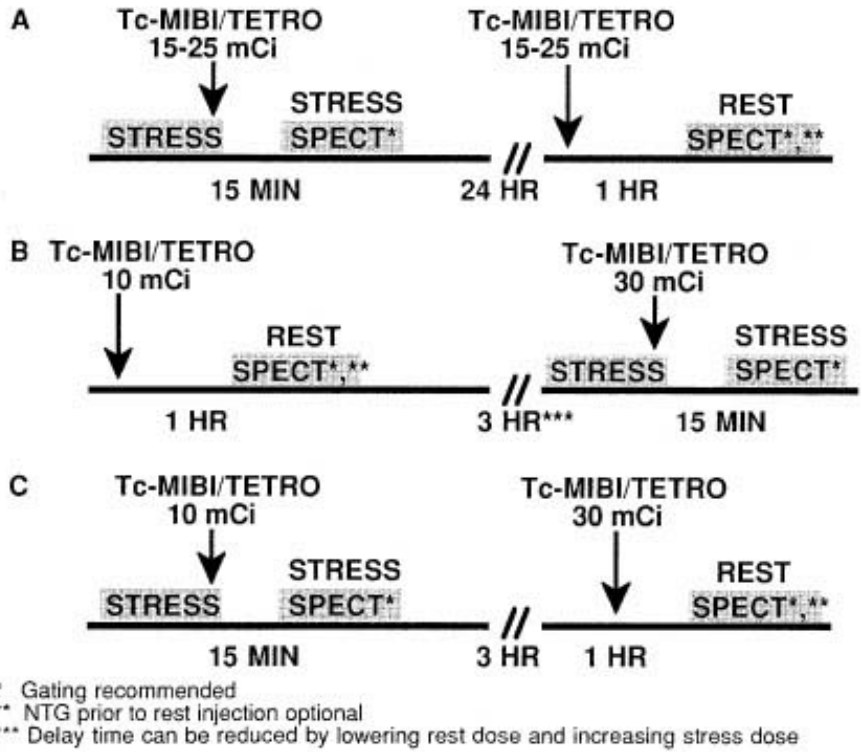

Figure 16-3: Two day (*A*), same-day rest-stress (*B*), and same-day stress-rest (*C*), 99mTc sestamibi or tetrofosmin protocols. Tc = 99mTc; MIBI = sestamibi; Tetro = tetrofosmin.

A common alternative to the standard ^{99m}Tc sestamibi or tetrofosmin protocols is a rest ^{201}Tl/stress ^{99m}Tc sestamibi dual-isotope SPECT (Fig. 16-4).[56] Dual isotope imaging takes advantage of the Anger camera's ability to collect data in different energy windows and can be performed with simultaneous or separate rest/stress acquisitions. The separate acquisition approach using rest ^{201}Tl/stress ^{99m}Tc sestamibi or tetrofosmin does not require correction for cross-contamination between the two radioisotopes,[56] whereas this correction is likely to be required with the simultaneous dual-isotope approach.[57] Of note, with this protocol, if defects are

present on the rest ^{201}Tl study, redistribution ^{201}Tl SPECT can be performed before or 24 h after the ^{99m}Tc sestamibi or tetrofosmin injection.[58]

ATTENUATION CORRECTION

Several camera manufacturers have recently provided hardware and software implementation of attenuation correction protocols, and these have undergone preliminary validation.[59,60] In general, these attenuation corrections are imperfect, reducing but not eliminating apparent perfusion defects due to soft tissue attenuation in normal patients. At times, true perfusion defects might be obscured or eliminated by the application of these approaches. The artifactual elimination of perfusion defects is usually due to filtering or to scatter from adjacent organs, which becomes more apparent after attenuation correction. It is prudent to visualize attenuation-corrected tomographic data sets simultaneously with noncorrected datasets.

20-SEGMENT VISUAL ANALYSIS

The use of a semiquantitative scoring system in which each of 20 segments is scored according to a 5-point scheme provides an approach to interpretation that is more systematic and reproducible than simple qualitative evaluation. The 20-segment scoring system is based on three short axis slices [distal (apical), mid-, and basal] to represent the entire LV, with the apex represented by two segments visualized in a midvertical long-axis image. Each of the 20 segments has a distinct name and number, as indicated in Fig. 16-5. Each segment is scored as follows: 0 = normal, 1 = slight reduction of uptake (equivocal), 2 = moderate reduction of uptake (usually implies a significant abnormality), 3 = severe reduction of uptake, 4 = absence of radioactive uptake.[61] Perfusion defects with scores of three or four can be reported as consistent with a critical (≥90 percent) coronary stenosis.[62,63]

The 20-segment scoring system standardizes the visual interpretation of scans, reduces the likelihood of overlooking significant defects, and provides an important semiquantitative global index that can be used for overall assessment of extent and severity of abnormality. Each segment roughly corresponds to 5 percent of the LV. Recently a 17-segment scoring system has been proposed in which the smaller size of the apical short-axis slice is accounted for by dividing the slice into four segments, while the apex is considered a single segment.[64]

SUMMED SCORES

The 20-segment, 5-point scoring system lends itself to the derivation of summed scores (i.e., global indices of perfusion) (Table 16-1).[65] The summed stress score (SSS) is defined as the sum of the stress scores for the 20 segments. The summed rest score (SRS) is defined as the sum of the rest scores or redistribution scores, and the summed differences score (SDS), measuring the degree of reversibility, is defined as the difference between the summed stress score and the summed rest score. It is essential to consider the normal regional variation of count distribution typical of myocardial perfusion scintigraphy before assigning a perfusion score. For example, the basal interventricular septum (membranous septum) has reduced blood flow, and (because of its depth) is subject to greater attenuation than other portions of the myocardium. This "normal septal dropout," frequently observed as an apparent defect on the basal septal slices, should be assigned a score of 0 rather than a score suggesting the presence of abnormality. Risk groups may be defined using the SSS,[66,67] where a score <4 is considered normal or nearly normal, scores of 4 to 8 are mildly abnormal, scores of 9 to 13 moderately abnormal, and summed stress scores >13 severely abnormal.

The 20 myocardial segments can be ascribed to individual coronary territories.[56,68] The inferior and basal septal segments are ascribed to the PDA (posterior descending artery), the lateral

segments to the left circumflex coronary artery, and the mid- and distal septal as well as all anterior slices to the left anterior descending coronary artery. Although isolated apical abnormalities are usually associated with left anterior descending disease, the left circumflex or right coronary artery can also supply the apex. If only anterior wall segments are abnormal, sparing the apex and the septum, the abnormalities are usually considered to represent disease of the diagonal branch of the left anterior descending coronary artery. The coronary assignment is altered for regions at the border between specific vessels territories, depending on the pattern of perfusion defect abnormality in the adjacent segments. At times, a dominant perfusion defect in a specific vascular territory will "tail" into a contiguous territory of another vessel. In these circumstances, the defect would generally be attributed to the vessel associated with the dominant defect. This pertains most commonly to the inferoseptal and inferolateral walls, but also to the anterolateral wall. Regarding the septum, if an inferoseptal defect is present (excluding the basal inferoseptal segment, which is generally a right coronary artery territory), the septal abnormalities would be assigned to the left anterior descending or right coronary artery, depending on which of these vessels had a perfusion defect. Similarly, if an inferolateral or anterolateral defect but not both were present in patients with adjacent defects in either the anterior or inferior wall, the lateral wall defect would be assigned to the vessel attributed to the neighboring defect. In general, isolated septal defects (without anterior wall or inferior wall involvement) are rare; isolated lateral wall defects (in the absence of anterior wall or inferior wall defects) would be attributed to the left circumflex coronary artery.[56]

GATED SPECT

Gated perfusion SPECT can be used to quantify a variety of global function parameters, including LVEF, end-diastolic volumes, and end-systolic volumes. Diastolic function assessment is generally not performed with gated SPECT, since it requires too large a number of gating intervals.[69] Regional parameters of function that can be quantitated from gated perfusion SPECT images include LV myocardial wall motion and thickening. Quantitation of gated perfusion SPECT images can be performed by employing algorithms adapted from other imaging modalities, including methods resembling equilibrium radionuclide angiography data processing[70,71] and biplane Simpson's rule analogs or by fully 3D algorithms. The most common algorithms are fully 3D and are based on the automatic detection of endocardial and epicardial surface points.[72-76]

In validation studies of gated perfusion SPECT LVEF published to date,[77] it is apparent that the agreement between gated SPECT and gold standard measurements of LVEF is generally very good to excellent. Indeed, it has been pointed out that 2D "gold standards" may be intrinsically less accurate than gated SPECT algorithms operating in the 3D space because of geometric assumptions required by the former.[72] The normal threshold for the global LVEF measured from gated SPECT images is slightly lower than that measured using other imaging modalities, or approximately 45 percent, due to an approximate 3-4 point underestimation of true LVEF associated with the use of only eight gating intervals.[77] Normal limits for eight-frame LVEF and LV volumes have been recently reported.[78-80] LVEFs can be slightly overestimated in analyzing gated SPECT images of small hearts.[81] Figure 16-6 illustrates an example of perfusion SPECT quantitative perfusion analysis (including the 20-segment scores) and quantitative gated SPECT from a patient with severe disease of the left anterior descending coronary artery.

ASSESSMENT OF MYOCARDIAL VIABILITY

The presence of myocardial viability is implied with the myocardial perfusion tracers if the degree of uptake at rest, redistribution, or following nitrate-augmented rest injection[82-86] is normal. If a region has severely reduced or absent uptake of radioactivity in these settings, it is considered to

be nonviable. Areas with moderate reduction of counts in these conditions (score 2 at redistribution or nitrate-augmented rest) are usually partially viable, and patients in this group have a variable response in terms of postoperative improvement. Some have utilized a cutoff percentage of maximal counts in the myocardium for predicting viability in a region in question[87,88]; others use the number of standard deviations below normal. An example of rest-redistribution imaging of myocardial viability is illustrated in Fig. 16-7 for a patient with poor LVEF (<35 percent) evaluated for CABS.

OTHER ABNORMALITIES

In addition to perfusion defects, several nonperfusion abnormalities can be observed with myocardial perfusion SPECT including size of the LV, transient ischemic dilation (TID) of the LV,[89,90] RV myocardial uptake pattern, RV size, and abnormalities of lung uptake or other abnormal extracardiac activity.

Transient Ischemic Dilation of the Left Ventricle

TID is considered present when the LV cavity appears to be significantly larger in the poststress images than at rest (Fig. 16-6)[89,90] and may actually be an apparent cavity dilation secondary to diffuse subendocardial ischemia (obscuring the endocardial border). This explains why TID may be seen for several hours following stress, when true cavity dilation is probably no longer present.[91] The correlation between TID of LV and lung uptake is weak, suggesting that there may be different pathophysiologic mechanisms for each; their measurements may be complementary in assessing the extent and severity of CAD for risk stratification.[92] TID was initially reported to be moderately sensitive and highly specific for critical stenosis (greater than 90 percent narrowing) in vessels supplying a large portion of the myocardium (i.e., proximal left anterior descending or multivessel 90 percent lesions).[89,90] Dipyridamole-induced TID has similar implications as those associated with exercise.[91] TID can easily be measured by slight modifications of the quantitative gated SPECT algorithms. The upper limits of normal for the TID ratio in dual-isotope imaging has been reported to be 1.22. Patients who have TID of the LV (TID > 1.22) are likely to have severe and extensive CAD (>90 percent stenosis of the proximal left anterior descending coronary artery, or of multiple vessels).[90]

Increased Lung Uptake of Radioactivity

Increased lung uptake of ^{201}Tl was first described by Boucher et al., as noted on the anterior view of planar thallium images.[93] It is generally accepted that increased pulmonary uptake of thallium reflects increased pulmonary capillary wedge pressure. When noted at rest, it reflects increased pulmonary capillary wedge pressure at rest,[94] and when noted with stress (either exercise or pharmacologic), it indicates the presence of increased pulmonary capillary wedge pressure during stress.[95] Nonischemic causes of increased pulmonary capillary wedge pressure, such as mitral regurgitation, mitral stenosis, etc., are also associated with increased pulmonary thallium uptake. Increased thallium lung uptake after exercise has been shown to have incremental prognostic information over myocardial perfusion defect assessment.[96] Only a few studies have examined the implications of increased pulmonary uptake of ^{99m}Tc sestamibi, with differing results.[95,97-99] It is possible that the differences among these reports are largely explained by the frequent greater delay in imaging of ^{99m}Tc sestamibi following stress than is associated with imaging of ^{201}Tl. The impact of the starting time of poststress acquisition of ^{99m}Tc sestamibi studies on lung uptake has been confirmed by Hurwitz et al.,[98] who found a good correlation between lung-heart ratio and angiographic findings on immediate images (4 min after stress), whereas no such correlation was found on the late images. By delaying 1 to 2 h following stress, increased pulmonary uptake that would have been present initially might no longer be present at the time of imaging. The

prognostic implications of increased exercise sestamibi lung uptake as well as the findings of increased uptake in pharmacologic stress with this tracer have not yet been explored.

EXERCISE PROTOCOLS

Exercise stress is the most commonly performed form of stress for myocardial perfusion SPECT. Exercise stress allows assessment of exercise capacity and symptoms as well as ST-segment response, providing additional clinical information that can be useful in daily clinical decision making (see Chap. 14). For exercise nuclear imaging, (1) an indwelling intravenous line for injection of the tracer at peak exercise is inserted, (2) injection of the tracer is performed at maximal stress, and (3) exercise is continued for an additional minute to allow optimal myocardial tracer concentration.

PHARMACOLOGIC STRESS PROTOCOLS

For patients who cannot achieve an adequate level of stress, pharmacologic stress testing is generally performed.[100-104] Generally, if the patient cannot perform ≥5 METs or more of exertional stress or fails to achieve ≥85 percent of maximal predicted heart rate a pharmacologic stress protocol should be encouraged. The preferred form of pharmacologic stress for myocardial perfusion SPECT is the use of coronary vasodilators-dipyridamole or adenosine, providing a three- to fivefold increase in coronary flow. Dipyridamole blocks the cellular reuptake of adenosine, increasing the extracellular adenosine concentration. Increased extracellular adenosine, either with adenosine infusion or dipyridamole, causes coronary vasodilation. The comparative effects of the vasodilators, exercise, and dobutamine are illustrated in Fig. 16-8. In general, the diagnostic accuracy of myocardial perfusion scintigraphy using pharmacologic stress is equivalent to that of exercise, despite the differences in flow rates.[100]

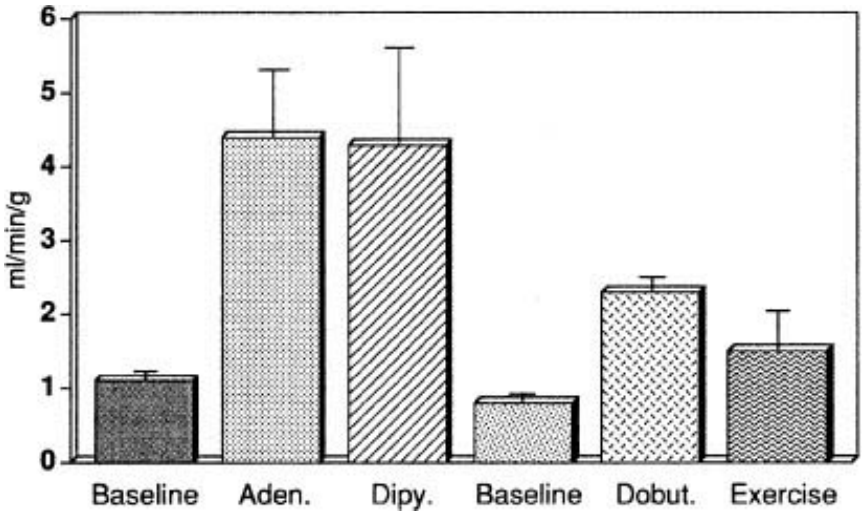

Figure 16-8: Coronary blood flow at baseline, exercise, dobutamine (Dobut.), adenosine (Aden.), and dipyridamole (Dipy.) stress measured with 13*N*-labeled ammonia. Baseline results are listed twice because of slight differences in absolute results. (Reproduced with permission from Iskandrian et al.[111])

Importantly, methylxanthines, such as theophylline or caffeine, block adenosine binding and can eliminate the effects of dipyridamole or adenosine on coronary vasodilation. Since the half-life of caffeine is variable[105] with either dipyridamole or adenosine, it has been recommended that patients be off caffeine-containing compounds for 24 h prior to imaging. There is no currently

available means of identifying patients in whom the pharmacologic effects of adenosine or dipyridamole have been blocked by caffeine; in contrast to exercise, the heart rate or blood pressure does not provide accurate information regarding response.[106]

Dipyridamole is usually infused at 0.142 mg/kg/min for 4 min, although some investigators have recommended increasing the dose by 50 percent.[100,101] The maximal effect occurs approximately 3 to 4 min after termination of the infusion. Side effects are common and transient, including nonspecific chest pain, shortness of breath, dizziness, and flushing. Severe side effects are rare, being noted that in only 1 of 10,000 in the largest study to date.[102] The side effects can usually be reversed by intravenous administration of aminophylline, usually 75 to 125 mg, although additional administration of nitroglycerin may occasionally be needed. Due to the potential side effect of severe bronchospasm, dipyridamole is contraindicated for patients with asthma. Adenosine is infused intravenously, usually at a dose of 140 mg/kg/min over 6 min, with administration of the radiopharmaceutical at the midpoint of the infusion.[107] Minor and transient side effects occur more frequently with adenosine, than with dipyridamole.[107] With adenosine, there is an increased incidence of advanced atrioventricular (AV) block. As the half-life of adenosine is very short (several seconds), side effects usually remit quickly within termination of the infusion. Adenosine is considered contraindicated for patients with equal to or greater than first-degree AV block, sick sinus syndrome, or bronchospasm.

COMBINED PHARMACOLOGIC AND EXERCISE TESTING

It has become increasingly common to combine vasodilator stress with low-level exercise. This is generally accomplished by beginning exercise at the end of the dipyridamole infusion. With adenosine stress, exercise is initiated during the adenosine infusion.[108]

DOBUTAMINE STRESS

An alternative to vasodilator stress is inotropic stress, usually performed with dobutamine.[109,110] At the present time, dobutamine stress is usually reserved for patients with asthma or those who have recently ingested caffeine. Dobutamine stress is associated with a lower rate pressure product and a lower degree of hyperemia in the myocardial bed than with exercise[111,112] or vasodilator stress (Fig. 16-8). Side effects are more common than with the vasodilator stress, including, more commonly, premature ventricular contractions serious side effects are rare.[113] Thus, dobutamine is not considered the agent of first choice for myocardial perfusion scintigraphy. Arbutamine, another inotropic agent, is not currently available in the United States.[114,115]

LEFT BUNDLE-BRANCH BLOCK

Patients with LBBB may frequently demonstrate reversible defects in the interventricular septum in the absence of CAD.[116] The mechanism has been postulated to be a true septal ischemia that occurs in LBBB in the presence of marked tachycardia. This perfusion defect may indicate a decrease in flow resulting from an increase in early diastolic compressive resistance, in turn caused by delayed ventricular relaxation.[117] In view of this pathophysiology, stress techniques that do not increase heart rate as markedly as exercise are preferred in LBBB; i.e., adenosine or dipyridamole testing without walking is generally considered preferable in LBBB patients.[118,119]

Nonperfusion Myocardial SPECT

Radionuclide imaging has an inherent advantage over other cardiac imaging techniques for assessment of myocardial metabolic and biochemical processes. Two nonperfusion myocardial scintigraphic applications in common use in other countries are fatty-acid imaging and imaging of myocardial innervation. The most commonly used radionuclide for these purposes is iodine 123

(^{123}I). From a biochemical standpoint, ^{123}I is an excellent metabolic imaging tracer, since it is easily incorporated into a wide variety of compounds by a halogen exchange reaction in which the iodine replaces a methyl group. Unfortunately, none of the ^{123}I-labeled compounds is currently commercially available for routine use in the United States.

FATTY ACID IMAGING

A comprehensive review of this subject has recently been provided by Tamaki.[120] Two principal types of fatty acid compounds have been described for myocardial imaging. Straight-chain fatty acid imaging has been most commnly performed with ^{123}I iodophenyl pentadecanoic acid (IPPA). With this tracer, initial uptake allows assessment of myocardial perfusion at rest or exercise.[121] The washout of ^{123}I IPPA appears to be related to fatty-acid metabolism (primarily beta oxidation) and can provide information about myocardial ischemia and myocardial viability. In ischemic but viable myocardium, IPPA washout is slower than normal but faster than in infarcted tissue.[122] This intermediate range of IPPA washout has been shown to be predictive of improvement in LV function after revascularization. Iskandrian et al.[123] have suggested that defect reversibility was more commonly seen with IPPA SPECT than with rest/redistribution ^{201}Tl SPECT. Despite these promising features for assessment of myocardial perfusion and viability through sequential SPECT acquisitions, this radiopharmaceutical has not yet become commercially available in the United States.

The other major class of fatty-acid compounds for SPECT are modified branched-chain fatty acids. These agents provide superior imaging quality with the Anger scintillation camera, since the washout of the modified branched-chain fatty acid is slower than that of the straight-chain agents due to partial metabolic trapping in the myocardium. Betamethyl iodophenylpentadecanoic acid (BMIPP), first introduced by Knapp et al.,[124] has become widely used in Japan and Europe. This tracer appears to uncover an "ischemic memory" and may have unique capability for the assessment of previously severely ischemic myocardium. Discordant radiopharmaceutical uptake, with less BMIPP uptake than with ^{201}Tl, has been described in patients with unstable angina and those with acute myocardial infarction who were acutely revascularized.[125] This finding likely represents a persistent metabolic abnormality out of proportion to the perfusion abnormality at the time of injection. Furutani et al.[126] have suggested that this finding allows assessment of the amount of myocardium at risk in the subacute phase of the myocardial infarction (MI). For patients revascularized during acute MI, the size of the BMIPP defect 1 week after revascularization reflects the area of risk measured by ^{99m}Tc perfusion imaging before revascularization.[126a] In 50 consecutive patients with MI receiving BMIPP and thallium scans (average follow-up 23 months), discordant BMIPP uptake compared with ^{201}Tl was the best predictor of future cardiac events, followed by the number of coronary stenoses. In unstable angina, a decrease in BMIPP has been reported under resting conditions, even after chest pain has resolved.[127]

IMAGING OF MYOCARDIAL INNERVATION

Imaging of myocardial innervation is another application of the tracer technique to cardiac imaging recently reveiwed by Dae.[128] The sympathetic nerves of the myocardium take up exogenously administered catecholamines with high affinity.[129] An analog of a false nerve transmitter is meta-^{125}I-iodobenzylguanidine (MIBG). MIBG is taken up in myocardial sympathetic nerve endings in a manner similar to norepinephrine,[130] but it is not metabolized. In regionally denervated myocardium, MIBG uptake is decreased while perfusion is unchanged.[131] In the setting of ischemic heart disease, it is generally held that ischemia must be severe enough to cause myocardial necrosis before regional denervation (and subsequent decreased MIBG uptake)

occurs.[132] In "syndrome X," abnormal cardiac MIBG uptake has been reported in 75 percent of patients, with the abnormality out of proportion to perfusion defects supporting the cardiac origin of chest pain in this syndrome.[133] Furthermore, in diabetic patients, assessment of myocardial MIBG uptake may be useful in defining autonomic dysfunction early in the course of type I disease.[134] Asymmetric uptake of MIBG has been shown for patients with ventricular tachycardia and no CAD.[135,136] Regional decreases of MIBG uptake in the basal left ventricle have also been demonstrated in a high proportion of patients with arrhythmogenic RV cardiomyopathy,[137] and abnormal MIBG uptake has been reported in idiopathic ventricular tachycardia and ventricular fibrillation.[138]

In nonischemic cardiomyopathy, abnormality of MIBG distribution and washout has been reported.[139] Generally, in congestive heart failure, excessive stimulation of the cardiac nervous system is believed to lead to further depression of cardiac function and may play a role in sudden death.[140] Recent studies have suggested that impaired cardiac sympathetic innervation in heart failure patients can be assessed by MIBG.[141] The late myocardial-to-mediastinal MIBG uptake 4 h after injection was shown to be the most powerful predictor of cardiac death, providing incremental information over clinical variables in a large clinical study. Furthermore, MIBG imaging may be useful in predicting the effectiveness of beta-blocker therapy for patients with dilated myocardial myopathies.[142,143] The pattern of a low heart-to-mediastinal ratio on 4-h delayed MIBG images appears to be predictive of a poor response to beta-blocker therapy.[128]

INFARCT-AVID IMAGING

Hot-spot (infarct-avid) imaging methods for detecting acute MI are among the oldest techniques in nuclear cardiology. These techniques have included ^{99m}Tc pyrophosphate myocardial scintigraphy,[144-148] indium 111 (^{111}In) antimyosin antibody scintigraphy,[149] and ^{99m}Tc glucarate imaging.[150] Although these methods have been documented to be sensitive and specific for the detection of myocardial necrosis, they are not widely utilized owing to the needed delay between injection and imaging. Antimyosin antibody, not available in the United States, is highly specific for myocardial necrosis and has been shown to be useful in the assessment of myocarditis[151] and the necrosis associated with cardiac transplant rejection.[151a] A new agent, ^{99m}Tc glucarate, a small molecule similar to glucose with rapid blood pool clearance, is taken up acutely in the necrotic myocardium[150,152] and becomes positive in the very early hours after onset of necrosis.

Chapter 16: NUCLEAR CARDIOLOGY

RADIONUCLIDE ANGIOGRAPHY (RNA)

Among the first applications of nuclear techniques in cardiology was the assessment of cardiac function using RNA or radionuclide ventriculography (RNV). The techniques of RNA can be performed by either equilibrium or first-pass methods. With the equilibrium approach, a blood-pool tracer (usually ^{99m}Tc-labeled red blood cells) images using a large number of cardiac beats after equilibration is attained within the intravascular compartment. With the first-pass approach, imaging is performed only during the initial transit of radioactivity through the central circulation. With both methods, assessments can be made of LVEF, RVEF, LV regional wall motion, and LV volumes.

The first-pass technique is a type of dynamic acquisition that uses rapid temporal sampling (20 to 100 frames per second) to look at the initial transit of a radionuclide bolus through the central circulation. This form of imaging is limited to the planar approach. The perfusion agents ^{99m}Tc sestamibi and ^{99m}Tc tetrofosmin can be used with success in first-pass studies.[153] Acquisition is completed in less than 1 min and can be performed in any desired view; in practice, however, these studies are usually limited to a single acquisition and are most commonly performed in either the anterior or right anterior oblique view.

Equilibrium RNA uses ECG-gated acquisitions, in which each frame corresponds to a specific portion (interval or gate) of the cardiac cycle, identified relative to the R wave on the patient's ECG. Because of the use of a multiple-gated acquisition, the term *MUGA scan* has also been applied to this technique. The cardiac cycle is divided in as many as 8 to 64 intervals and data from multiple cardiac cycles are averaged to ensure adequate count statistics. For equilibrium-gated RNA, the imaged radiopharmaceutical must stay within the vascular compartment during the imaging period. Although labeled proteins such as ^{99m}Tc albumin could be employed for blood pool imaging, labeled red blood cells are most commonly employed, labeled either through in vivo or in vitro methods. The latter provides the highest target-to-background ratio. Acquisition typically takes 5 to 10 min per view and multiple planar views are obtained. For exercise RNA, image acquisition can be as brief as 2 min.

Because of the ability to image the blood pool radiopharmaceuticals for a substantial time period, SPECT acquisition is also practical with equilibrium radionuclide angiography.[154,155] It has recently been shown that equilibrium blood pool SPECT acquisition and processing are essentially the same as for myocardial perfusion SPECT, and thus can be easily adopted in the laboratory where myocardial perfusion SPECT is being performed. Methods for automatically assessing LVEF from gated blood pool SPECT have been developed and validated.[156] Since the SPECT approach avoids the overlap of cardiac chambers inherent in planar imaging, it enhances assessment of regional function and may well become the method of choice for radionuclide angiography.

For exercise RNA, again either equilibrium or first-pass techniques can be employed. With the first-pass technique for exercise radionuclide angiography, a multicrystal camera has been most commonly used.[157] The advantage of first-pass over equilibrium RNA is that ventricular function assessments at the true peak of exercise can be obtained, since the procedure is accomplished in less than 30 s. For this purpose, patients can use either bicycle[157] or treadmill[158,159] exercise. At

the peak of exercise, the patient's chest is placed against the surface of the scintillation camera and a bolus injection is made, usually with 15 to 30 mCi of ^{99m}Tc radiopharmaceutical; most commonly, a 40-frames-per-second acquisition is used for the 30 s. Subsequently LVEF is computed, most commonly in a semiautomatic fashion using a count-based technique applied to motion-corrected, background-corrected scintigraphic data. LVEF is computed from the portion of the first pass of radionuclide through the central circulation that corresponds to the left ventricular filling and emptying phase. In a similar fashion, the first-pass scintigraphic data can be used to evaluate RVEF by processing the data acquired during the RV phase of the first pass.

For the equilibrium RNA, EFs of the LV[160-162] or RV[163] can be measured. The preferred method for measurement of EF from equilibrium RNA is referred to as the "area-counts" technique. This method takes advantage of the proportionality between the volume of a cardiac chamber and the number of counts emitted from that chamber following injection of a blood-pool radiopharmaceutical. Thus, a background-corrected curve of ventricular activity versus time is a curve of relative volume versus time of the corresponding ventricle. From this curve, EF can be measured as a function of the peak (relative end-diastolic) and the nadir (relative end-systolic) volume by the formula EDC - ESC/EDC, where EDC and ESC represent background-corrected counts in the end-diastolic and end-systolic frames, respectively. It is generally accepted that for most accurate measurement of LVEF, 16 frames or more per cardiac cycle are required. For measurement of RVEF, it has been demonstrated that carefully placed regions of interest over the RV at end-diastole and end-systole, using a left periventricular background region of interest, provide an effective method for assessment of RVEF. Very high degrees of correlation have been reported between LVEF and contrast ventriculography. Good correlation has been demonstrated between RVEF measurements using equilibrium RNA and RV first pass measurements.[163] RNA is considered one of the "gold standards" for assessing LVEF on the basis of its accuracy and reproducibility.[164,165]

Chapter 16: NUCLEAR CARDIOLOGY

CLINICAL APPLICATIONS OF NUCLEAR CARDIOLOGY

The principles of diagnostic and prognostic accuracy outlined below are followed by a review of the evidence for the most common indications for nuclear cardiology procedures in the outpatient and inpatient cardiology settings.

Selecting the Appropriate Test Candidates

BAYESIAN THEORY: INTEGRATION OF PRETEST PROBABILITY ASSESSMENT INTO TEST INTERPRETATION

The central premise underlying patient selection for nuclear imaging is the ability to determine clinically an individual patient's likelihood of CAD or risk of important cardiac outcomes. The accurate evaluation of pretest clinical risk allows for the appropriate selection of patients who would most likely benefit from referral to nuclear imaging. The clinical pretest risk assessment may be estimated using published nomograms or from available computerized programs (see Chaps. 14, 38, and 40). Integrated predictive models based on clinical history and physical examination parameters have been developed from large patient registries and are published in the form of a nomogram for estimating the likelihood of CAD as well as cardiac survival. A review of models indicating the likelihood of clinical disease, aimed for use in varying populations, is presented in Chap. 38. For patient populations, several models have been developed with a large proportion of symptomatic patients designed to predict significant and extensive CAD as well as cardiac survival.[166-171] One of these approaches uses a validated computer algorithm to determine CAD likelihood based on age, sex, symptom classification, and conventional cardiac risk factors (resting systolic blood pressure, smoking history, glucose intolerance, resting ECG ST-segment abnormalities, and family history of early CAD).[171]

The rationale for selection of patients for noninvasive diagnostic and prognostic testing is based upon Bayesian theory (Chaps. 14 and 40), by which the posttest probability is a function of the patient's pretest clinical risk and the sensitivity and specificity of the test. The ability to shift posttest probabilities is directly related to pretest probability of disease or event risk. The greatest shift in posttest probabilities of disease occurs in those patients with an intermediate pretest probability of CAD.

Diagnostic Accuracy

Detection of CAD is one of the most common indications for performing myocardial perfusion SPECT. This referral is most appropriate in patients who are at intermediate risk of CAD, often including those with an abnormal rest electrocardiogram (ECG) where interpretation of exertional ST-segment changes is problematic.

A clinical algorithm for the purpose of simple detection of CAD based on these concepts, including the known sensitivity and specificity of treadmill ECG testing, is illustrated in Fig. 16-9.[172] Patients with a low probability (<0.15) of having angiographically significant (>50 percent stenosis) CAD can be identified even before standard exercise tolerance test (ETT) is performed. Patients with a low pre-ETT likelihood of CAD do not require further diagnostic testing, although continued medical follow-up or a "watchful waiting" approach is recommended. Patients with a low-intermediate pre-ETT likelihood of CAD (0.15 to 0.50) would undergo standard ETT as the next diagnostic step. Those who continue to have an intermediate likelihood of CAD after ETT (or those with an indeterminate ETT, as with LBBB, LVH, perfusion, ejection, etc.) and those whose pre-ETT likelihood of CAD is in the 0.50 to 0.85 range (in these patients even a negative ETT would not result in a low likelihood of CAD) will benefit from stress nuclear

testing. Patients with a high pre-ETT likelihood of CAD (>0.85) are generally considered to have an established diagnosis of CAD and would not need nuclear stress testing for diagnostic purposes. A variation of this approach was recently published in the "ACC/AHA/ACP-ASIM Guidelines for Management of Patients with Chronic Stable Angina."[8] The application of nuclear testing for diagnosis and the intermediate likelihood of CAD has been given a class I indication (condition for which there is general agreement that a given procedure is useful and effective).[8]

Table 16-2 presents uncorrected sensitivities and specificities of myocardial perfusion SPECT for the detection of angiographically significant (≥50 to 70 percent stenosis) CAD. From the ACC/AHA/ACP-ASIM stable angina guidelines (Chaps. 14 and 40), in populations referred to nuclear SPECT (i.e., a large proportion with uninterpretable ST segments), there is an improved predictive accuracy-defined as [(true positives + true negatives)/total]-by nuclear testing over pretest information and ECG stress testing.[8,173] Despite the differences in the extraction characteristics of the various nuclear tracers, there have been few reports that reveal marked differences in test sensitivity. Owing principally to a reduction in soft tissue artifact, there is an increase in test specificity with ^{99m}Tc-based agents as compared with ^{201}Tl imaging in women.[174] SPECT acquisition can be repeated with ^{99m}Tc-based agents when either attenuation or motion artifact is suspected further increasing specificity. A major limitation to the use of test statistics such as sensitivity and specificity for CAD is that they require referral to cardiac catheterization for calculation. In estimating the true sensitivity and specificity of noninvasive testing, referral or workup bias must be taken into account.[47,175] Sensitivity is the proportion of patients with disease who are correctly detected as abnormal by the test, and specificity is the proportion of patients without disease who are correctly detected as normal by the test. As routine patient workup results in preferential catheterization of patients with abnormal test results, the resulting observed test sensitivity is enhanced and the specificity is decreased. In general, referral bias leads to an overestimation in test sensitivity and a lowering in test specificity.[176] Once the test becomes used as a "gatekeeper" to catheterization, sensitivity and specificity can no longer be accurately measured. Thus, due to referral bias, test specificity becomes a poor measure of the ability of a test to exclude disease.

Table 16-2: Sensitivity and Specificity of Stress Myocardial Perfusion SPECT for Detecting CAD (≥50% stenosis), Without Correction for Referral Bias Results from the ACC/AHA/ACP/ASIM Guidelines for Chronic Stable Angina*

*From Ref. [8]. †Average of reported sensitivities and specificities.

The normalcy rate has been advocated as an improved measure for this purpose.[47] This has been defined as the percentage of patients with normal test results in a population with a low likelihood of disease. A synthesis of data on nuclear SPECT normalcy rates has been reported to be in the range of 80 to 90 percent with ^{201}Tl testing and generally greater than 90 percent with ^{99m}Tc sestamibi SPECT; it would be expected to be similar to the latter for ^{99m}Tc tetrofosmin SPECT (Table 16-3).

Table 16-3: Normalcy Rate of Stress SPECT in Patients with a Low Likelihood of CAD (<5 to 10%)

Year	Author	Reference	Stress	Isotope	Normalcy Rate	%

Principles of the Use of Nuclear Cardiology for Risk Stratification/Patient Management

The most rapidly growing area of application of myocardial perfusion SPECT is risk stratification based on increased acceptance of a new paradigm in patient management. A risk-based approach to patients with suspected CAD appears better suited to the modern environment of cost containment and dramatic improvements in medical therapy than the approach focusing on simple diagnosis, in which the patient with suspected disease undergoes coronary angiography and then is frequently revascularized. With the risk-based approach, the focus is not on predicting who has CAD but on identifying and separating patients at risk for cardiac death, patients at risk for nonfatal myocardial infarction, and patients at low risk for either event.

The basic concept in the use of nuclear tests for risk stratification is that they are best applied to patients with an intermediate risk of a subsequent cardiac event, analogous to the optimal diagnostic application of nuclear testing of patients with an intermediate likelihood of having CAD. For prognostic testing, patients known to be at high or low risk for event would not be appropriate patients for cost-effective risk stratification with nuclear imaging since they are already stratified in the era of cost containment, the intensity of management and the effectiveness of therapy is tailored to patient risk. For low-risk patients, minimal further diagnostic testing results in the avoidance of excessive downstream costs. In contrast, high-risk patients are appropriately aggressively managed and usually undergo coronary angiography with consideration of revascularization. In chronic CAD, it has been suggested that a greater than 3 percent per year mortality rate can be used to identify patients with minimal symptoms whose mortality rate can be improved by coronary artery bypass grafting.[7] For purposes of risk assessment, it has been proposed that low risk be defined as a less than 1 percent cardiac mortality rate per year. Thus, intermediate-risk could be defined by patients in whom the cardiac mortality is in the range of 1 to 3 percent per year.[8] Since the

mortality risk for patients undergoing either coronary artery bypass grafting or angioplasty is greater than 1 percent per year,[177] mildly symptomatic patients with a less than 1 percent mortality rate would not be candidates for revascularization to improve survival and would be appropriately classified by this rate as at a low risk of death. Note that while, for diagnostic testing, nuclear imaging would be most appropriate in patients with an intermediate likelihood of CAD, for risk stratification this appropriateness extends to the groups of patients with a high likelihood of CAD.

PHYSIOLOGIC BASIS FOR RISK ASSESSMENT IN MYOCARDIAL PERFUSION SPECT

The basis for the power of nuclear testing for risk stratification is found in the fact that the major determinants of prognosis in CAD can be assessed by measurements of stress-induced perfusion or function. These measurements include the amount of infarcted myocardium, the amount of jeopardized myocardium (supplied by vessels with hemodynamically significant stenosis), and the degree of jeopardy (severity of the individual coronary artery stenosis). An additional important factor in prognostic assessment is the stability (or instability) of the CAD process. This last consideration may help to interpret what appears to be a paradox: nuclear tests, which in general are expected to be positive only in the presence of hemodynamically significant stenosis, are associated with a very low risk of either cardiac death of nonfatal MI when normal; in contrast, it has been observed that most MIs occur in regions with pre-MI lesions causing less than 50 percent stenosis.[178,179] It has been postulated that this paradox may be explained by the different response to stress of mild stenoses associated with stable and unstable plaque. Thus, beyond the ability to define anatomic stenosis, nuclear tests (by virtue of their physiologic assessments) may be able to discern abnormalities of endothelial function associated with high risk, even in the absence of significant stenosis.

To maximally extract the information regarding these prognostic determinants in CAD, it is necessary to consider the full extent and severity of abnormality, either quantitatively[180,181] or semiquantitatively,[56] rather than simply determining that the nuclear study is normal or abnormal. Furthermore, there appears to be incremental value in measuring both perfusion and function for the purposes of risk stratification, thus leading to increased prognostic utility of gated cardiac SPECT over standard myocardial perfusion SPECT.

Chapter 16: NUCLEAR CARDIOLOGY

ASSESSMENT OF STABLE OUTPATIENT POPULATIONS

Suspected Chronic Coronary Artery Disease

The most frequent reason for referral to the nuclear laboratory is the evaluation of known or suspected CAD. In outpatient populations, this often includes the evaluation of the presence and extent of cardiac ischemia. Stress nuclear imaging is an integral part of the evaluation of symptomatic patients for CAD. An imaging modality is commonly used in intermediate-risk patients or those with resting ECG abnormalities that preclude evaluation with the routine treadmill test. In this patient population, nuclear imaging most commonly includes myocardial perfusion SPECT performed to evaluate stress-induced defects and, more recently, gated SPECT to also allow assessment of ventricular function. If the ECG could not be interpreted for purposes of stress testing (e.g., LBBB, LV hypertrophy, digoxin therapy, Wolff-Parkinson-White syndrome), direct nuclear testing is highly effective in prognostic stratification (Chap. 14).

A synthesis of available data reveals that a normal scan is uniformly associated with a <1% annual risk of cardiac death or MI.[8,67,182183-183a] Abnormal scans are associated with an increased risk of cardiac events.[8,67,182] Characteristics of low-, intermediate-, and high-risk scans are listed in Table 40-4.

Normal Perfusion Scan

The event rate associated with a normal or low-risk perfusion scan has been shown by numerous investigators to be <1 percent per year of follow-up and to be isotope-independent-similar to the data from exercise and pharmacologic stress SPECT.[65-67,182] A recent meta-analysis of the prognostic value of a normal stress perfusion scan reveals that the annual risk of MI or cardiac death after a normal perfusion scan is 0.7 percent (95 percent CI 0.5 to 0.9 percent).[183] This uniformly low event rate is critical when applying nuclear test information to risk stratification. In the absence of limiting symptoms in patients who are at low risk of major cardiac events with normal perfusion scans, a conservative approach to posttest patient management would be appropriate. This conservative approach includes medical follow-up for signs of clinical worsening and treatment of cardiac risk factors and related cardiac symptoms (see Chap. 40).

Mild-Risk Perfusion Scans

Multiple randomized trials have demonstrated that revascularization can reduce the risk of cardiac death in selected high-risk subsets. However, since the annual mortality rate of patients undergoing revascularization is at least 1 percent,[177] patients predicted to have a rate of cardiac death of less than 1 percent per year do not warrant revascularization for purposes of improving survival. Recently, Hachamovitch et al. analyzed 5183 patients undergoing stress perfusion SPECT testing.[67] A total of 158 nonfatal MIs and 119 cardiac deaths were observed during follow-up of 646 ± 226 days. The nonfatal MI and cardiac death rates as a function of the summed stress perfusion scores are illustrated in Fig. 16-10. Patients with moderately and severely abnormal scans were at intermediate risk for both cardiac death and MI. Importantly, however, patients with mildly abnormal summed stress scores were at intermediate risk for MI (2.7 percent risk of MI per year of follow-up), but at low risk for subsequent mortality (0.8 percent annual cardiac death rate). Based on the results of this study, patients with a mildly abnormal scan (summed stress score between 4 and 8) could be considered as having "flow-limiting" CAD and intermediate risk of MI but to be at low risk of cardiac death. These patients would be candidates for aggressive risk-factor modification using secondary prevention guidelines. Medical therapy known to reduce a patient's risk of acute ischemic syndromes or cardiac hospitalizations [e.g., statins, acetylsalicylic acid, angiotensin converting enzyme (ACE) inhibitors, etc.] would then be indicated.[184-193]

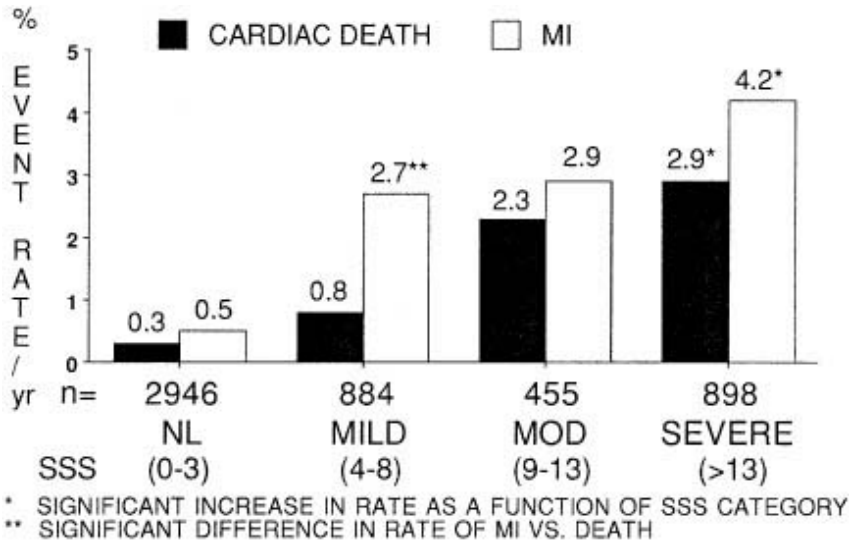

Figure 16-10: Rates of cardiac death (*solid bars*) and myocardial infarction (*open bars*) per year as a function of scan result. The numbers of patients within each scan category are shown underneath each pair of columns. *Statistically significant increase as a function of scan result. **Statistically significant increase in rate of MI versus cardiac death with scan category. NL = normal, MILD = mildly abnormal, MOD = moderately abnormal, SEVERE = severely abnormal. (Reproduced with permission from Hachamovitch et al.[67])

Moderately to Severely Abnormal Perfusion Scans

The relationship of varying extent and severity of perfusion abnormalities with cardiac outcomes has been reported in a variety of patient subsets.[66,67] Although both reversible and fixed stress perfusion defects are predictors of prognosis, those at highest risk of cardiac events include patients with extensive multizone abnormalities. Prognosis is also dependent on both the severity of perfusion defects (a correlate of the magnitude of stenosis) and their extent (a correlate of the amount of myocardium supplied by vessels with significant disease).[67] The combination of both of these factors is predictive of cardiac event rates. That is, as the severity and extent of defects worsens, there is an increase in the rate of major cardiac outcomes (Fig. 16-9). Annual cardiac event rates have been reported to range from 0.3 to 4.2 percent for patients with a normal, mild, moderate, and severely abnormal perfusion scans.[67]

Evidence Supporting Nuclear Imaging for Patients with an Intermediate/Indeterminate Treadmill Test

Several recent reports support nuclear testing in patients with uninterpretable or intermediate exercise ECG response.[66,195] An initial report from Cedars-Sinai (Fig. 16-11) demonstrated that myocardial perfusion SPECT was most effective in risk stratification and governing management of patients with intermediate treadmill test result (i.e., Duke treadmill score, a composite score integrating ST-segment changes, chest pain, and exercise time).[66] Patients with a low Duke treadmill score had a hard event rate of less than 1 percent, perhaps not needing nuclear testing.[194] Those with a high Duke treadmill score (representing less than 5 percent of the population) overall had a high event rate of 7.7 percent over the 18-month follow-up, and could have been directly catheterized. The majority of the patients in the study, however, fell into the category of an intermediate Duke treadmill score with an intermediate event rate of 2.5 percent. Within this category, those patients with a normal scan had a very low event rate and were infrequently catheterized; those with moderately abnormal scans had intermediate event rates and an intermediate rate of catheterization; and those with moderately to severely abnormal scans had higher event rates with higher rates of catheterization. Thus, the nuclear tests were able to stratify patients who could not be differentiated according to risk by Duke treadmill score alone. Similar results were shown by Shaw et al. in a large multicenter publication reporting event rates in 2498 patients with intermediate Duke treadmill scores undergoing stress myocardial perfusion SPECT (Fig. 16-12).[195]

Guidelines for Management of Patients with Stable Chest Pain by SPECT Results

Thus, patients with mildly abnormal scans (summed stress score between 4 and 8) could be considered as having CAD and intermediate risk of MI, but low risk of cardiac death[67] (Fig. 16-13). In the absence of refractory symptoms, these patients would be candidates for aggressive risk-factor modification without catheterization, using secondary prevention guidelines. Unlike the case with revascularization, a variety of medical therapies have been shown by randomized trials to reduce the risk of MI.[184-193] For patients with very abnormal summed stress scores, early revascularization resulted in a favorable survival benefit when compared with medical therapy from a recent observational assessment.[67] O'Keefe et al. reported similar results with medical versus invasive strategy.[196] As noted below, these recommendations for guiding patient management may now be further influenced by combining perfusion and poststress ventricular function variables from gated SPECT (LVEF and systolic volume). It is noteworthy that the above-described application of nuclear testing for risk stratification and prognosis in patients with an intermediate or high probability of CAD has been given class I recommendations in the ACC/AHA/ACP-ASIM guidelines.[8]

It appears that for patients who are appropriately referred to testing in the first place (patients with intermediate to high likelihood of CAD), a normal scan result is associated with a very low risk for approximately 2 years. After that time the risk rises, suggesting that repeat testing after 2 years should be considered in most patients for prognostic purposes.[197]

Current Data May Underestimate the True Prognostic Value of SPECT

The foregoing information provides compelling evidence that ^{99m}Tc sestamibi or ^{201}Tl myocardial perfusion SPECT is effective in the prognostic stratification of patients. Preliminary data have also been reported suggesting that ^{99m}Tc tetrofosmin is effective in risk stratification in chronic CAD.[198] It would appear, however, that current data on risk stratification by myocardial perfusion SPECT may actually underestimate the strength of this modality. In all the data quoted above, patients referred for early revascularization following nuclear testing were excluded (censored) from consideration in the prognostic studies. Although there is a reason for this censorship-namely, that the event rate may have been altered by the revascularization procedure-the exclusion results in the published data's inability to reflect the prognostic information derived from scans performed in the highest risk patient subset. A similar effect occurs to the extent that physicians and patients alter therapy and modify risk factors on the basis of the scan information, thereby probably reducing the event rate that might be observed for a given abnormal scan pattern in a natural history study. In other words, if patients with high-risk abnormalities are treated medically, they are likely to be treated aggressively in a manner that would lower their observed event rates.

Additionally, recent technical advances in the field of myocardial perfusion SPECT have typically not been included in the prognostic assessments. For example, the impact of quantitative analysis on prognosis has not been studied in any detail, although it has been reported to be equal to that of semiquantitative analysis, potentially improving the ability to generalize the findings to less experienced laboratories.[199]

ADDED VALUE OF GATED SPECT

The potent information contained in the ejection fraction assessed from gated SPECT is likely to enhance the prognostic content of myocardial perfusion SPECT. Since gated SPECT has become routine only recently, there are few reports of its incremental value over perfusion in assessing prognosis. Evidence that gated SPECT is likely to add to prognostic assessment is provided by prior ejection fraction data. LV ejection fraction has been shown to risk-stratify suspected disease patients according to their risk of subsequent cardiac death. In a series of reports from the Duke databank using rest and exercise first-pass radionuclide angiography, patients with suspected disease could be risk-stratified using a diagnostic threshold of 50 percent EF.[200-205]

In a preliminary communication, Hachamovitch et al. demonstrated that after risk adjustment for pretest likelihood of CAD and results of perfusion SPECT, EF provided significant incremental value in prediction

of cardiac death or nonfatal myocardial infarction in patients with known or suspected chronic CAD.[206] Sharir et al.,[207] studying 1680 patients, demonstrated that poststress LVEF, as measured by gated SPECT, provided significant information over the extent and severity of perfusion defect as measured by the summed stress score (Fig. 16-14). Furthermore, these authors demonstrated that LV end-systolic volume provided added information over poststress LVEF in prediction of cardiac death (Fig. 16-15). The relatively low cardiac death rate in patients with abnormal perfusion and normal LV function in this study is probably explained by a referral bias in which patients with greatest ischemia by SSS were preferentially sent for early revascularization and thus censored from assessment of the prognostic value of the test. In a subsequent preliminary report of 2600 patients, Sharir et al. have shown that while poststress EF provides incremental information over prescan and perfusion variables in prediction of cardiac death, the perfusion variables are stronger predictors of nonfatal MI. Once prescan and perfusion variables were known, poststress EF did not provide incremental information with respect to the risk of nonfatal MI.[208]

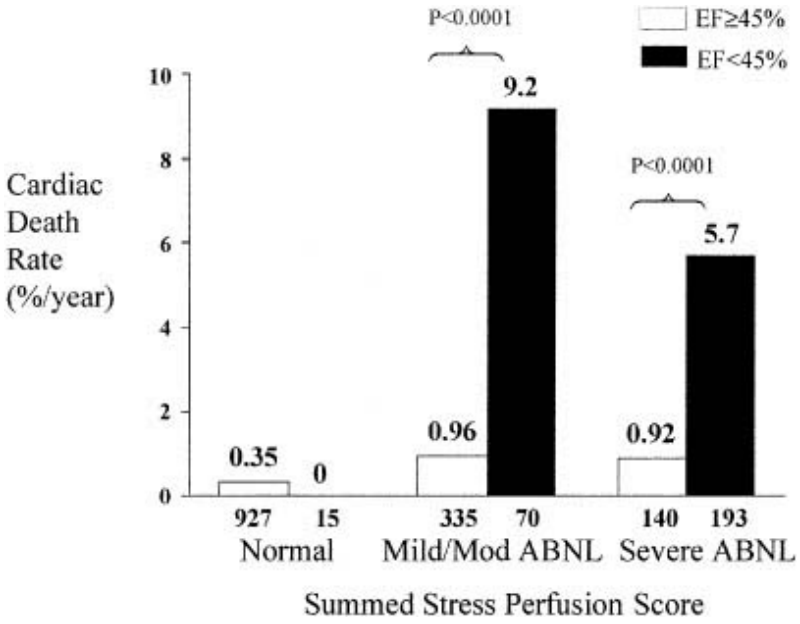

Figure 16-14: Cardiac death (percent per year) as a function of perfusion abnormality and poststress EF by gated SPECT. The number of patients within each category is indicated below ech column. MOD = moderate; ABNL = abnormality. The categories for summed stress score are normal (0-3), mild/moderate (4-13), severe (greater than 13). (Adapted with permission from Sharir et al.[207])

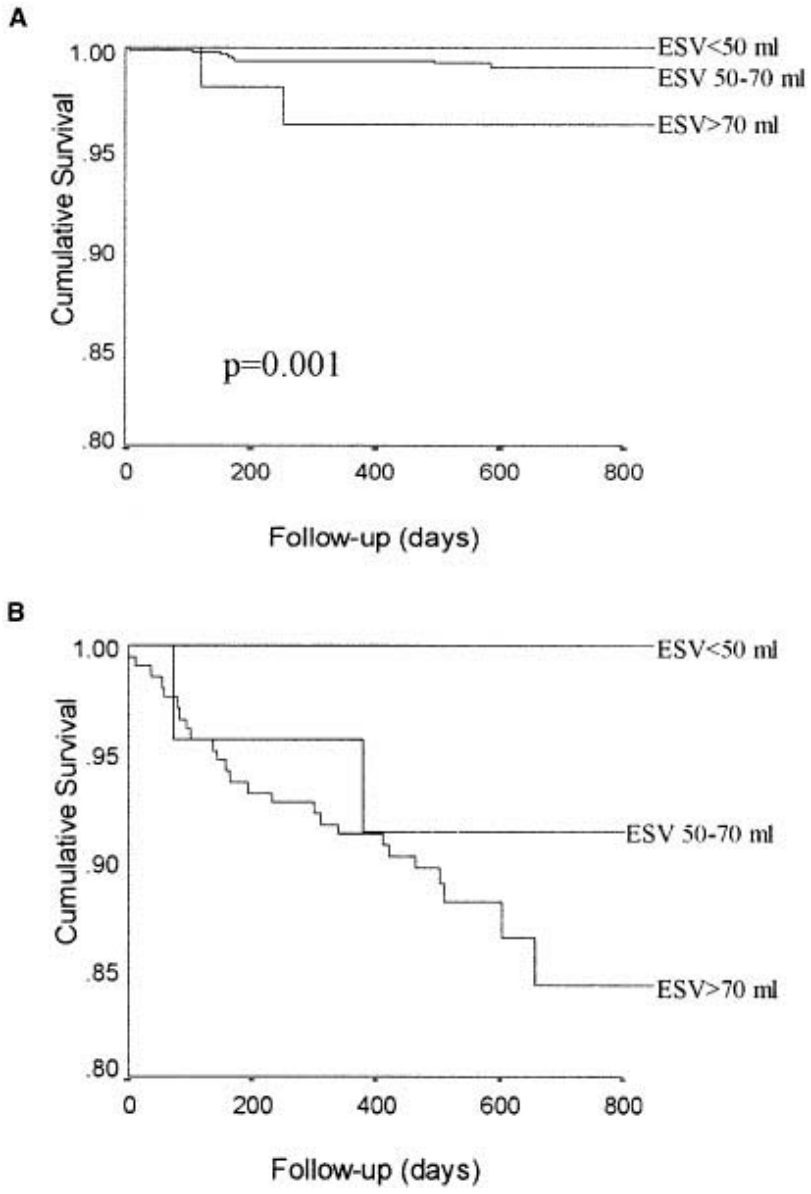

Figure 16-15: Cumulative survival of patients with poststress EF by quantitative gated SPECT greater than or equal to 45 percent (*left*) and less than 45 percent (*right*) stratified by end-systolic volume (ESV), also measured by gated SPECT. (Adapted with permission from Sharir et al.[207])

In the future, complex algorithms will need to be developed that incorporate all of the information from gated SPECT for purposes of guiding patient management. In this regard, it is likely that poststress EF (related predominately to the size of MI) and summed difference score (an expression of the amount of stress-induced ischemia) will provide the greatest complementary information. As an initial approach, Sharir et al. have reported the combination of the ejection fraction and reversible ischemia in the prediction of cardiac events. If poststress EF is less than 30 percent, cardiac death or nonfatal MI rates appear to be high regardless of the amount of ischemia as assessed by the summed difference score. In patients with poststress EF from 30 to 50 percent, mild amounts of ischemia were associated with relatively high cardiac event rates. In patients with ejection fractions of greater than 50 percent, only patients with moderately extensive ischemia were at high risk of cardiac events.

Other important information that can be derived from myocardial perfusion scintigraphy and may be related to risk has not been widely included in the prognostic assessment. Such information includes the assessment of poststress wall motion abnormalities on gated SPECT, a sign of exercise-induced stunning and a marker of severe CAD.[209,210] Additionally, transient ischemic dilation of the LV[89,90] and pulmonary uptake of radioactivity as determined by the measurement of lung/heart ratios of radioactivity[95,211,212] have been shown to be of prognostic importance[96,212,213] but are not yet part of most analyses of myocardial

perfusion SPECT for purposes of risk stratification. Extensive resting defect reversibility rest ^{201}Tl/stress ^{99m}Tc sestamibi, evaluated by 24-h ^{201}Tl imaging, has been shown to be predictive of a higher mortality rate than would be predicted by rest or stress perfusion defect abnormalities alone.[213]

NUCLEAR TESTING AS THE GATEKEEPER TO CARDIAC CATHETERIZATION

The major clinical decisions after nuclear testing include the decision to initiate new medical therapy, to refer a patient to cardiac catheterization, or to provide a conservative, watchful waiting approach to care. Among patients with normal scans, only a small proportion will require cardiac catheterization as a result of clinical symptomatology.[65] In a population of 2203 patients[66] (follow-up, 18 months), by multivariate analysis, the nuclear result was the dominant factor determining the referral to catheterization. This relationship between the results of myocardial perfusion SPECT and catheterization rates have also been reported by Bateman et al.[214] and Nallamothu et al.[215] (Fig. 16-16). Hachamovitch et al.[67] reported that when catheterization was limited to patients with moderate to severe perfusion abnormalities (i.e., summed stress score >8), significant cost savings (17 percent reduction in cardiac catheterization rate) could be achieved for 5183 patients undergoing dual isotope stress SPECT imaging.

In the era of cost containment, it becomes increasingly important to determine whether noninvasive testing can result in substantial cost savings in the diagnosis of CAD. Shaw et al.[216] evaluated a total of 11,249 consecutive stable angina patients, including our own, in a large multicenter study. In a matched cohort study of patients with chronic stable angina comparing direct catherization to myocardial perfusion SPECT with selective catheterization, there was a substantial reduction (31 to 50 percent) in costs for all levels of pretest clinical risk using the myocardial perfusion SPECT plus selective catheterization approach. This cost reduction was seen in both the diagnostic (early) and follow-up (late) costs, which included costs of revascularization (Fig. 16-17). The rates of subsequent nonfatal MI and cardiac death were virtually identical in comparisons of direct catheterization and myocardial perfusion imaging with selective catheterization approaches in all patient risk subsets of stable chestpain patients (Fig. 16-18). What was significantly different was the rate of revascularization, which was reduced by nearly 50 percent in the cohort receiving myocardial perfusion imaging with selective catheterization. In fact, patients with normal perfusion results had a reduced rate of cardiac catheterization as well as a reduced frequency of normal coronary angiographic findings at the time of catheterization.

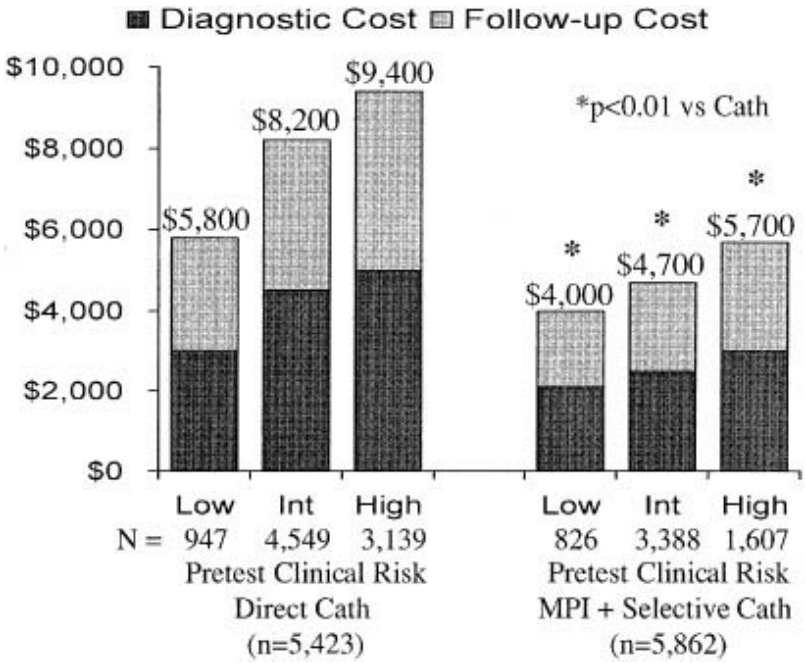

Figure 16-17: Comparative cost between screening strategies employing direct catheterization (Cath) and myocardial perfusion imaging (MPI) with selective Cath. Low, Int, and High represent low-, intermediate-,

and high-risk subsets of the patients with stable angina. Shown are the initial diagnostic costs (*solid bars*) and follow-up costs including costs of revascularization (*gray bars*). A 30 to 41 percent reduction in costs was noted in each category. (Adapted with permission from Shaw et al.[216])

The Role of RNA in Chronic CAD

In chronic CAD, the principal applications of RNA at the present time are at rest. Resting RNA using either equilibrium or first-pass techniques can be effective in defining the presence of a reduced LVEF, and thereby a patient population for whom ACE inhibitors can be effective. Following initial observations in patients with MI,[217] subsequent randomized trials in patients with chronic CAD demonstrated that patients who have reduced LVEF obtain a distinct beneficial effect from the long-term administration of ACE inhibitors. Thus, the available evidence would suggest that patients with suspected acute or chronic CAD are candidates for ACE inhibitor therapy if LVEF is low.[5,8,218,219] The other manner in which patients with CAD can benefit from RNA is with serial assessment of ventricular function. This is important in assessing the efficacy of treatments such as ACE inhibitor therapy and has been used in many trials of a variety of approaches to patients with severe reductions of LVEF. Commonly, a measurement of LVEF by equilibrium RNA is required as a method of documenting severe reduction of LVEF prior to admission into heart failure trials.

For the detection of CAD and management of patients with this condition, exercise RNA continues to play a role in some centers. The most commonly utilized measurement derived from RNA for these decisions is the peak exercise LVEF, whether from first-pass or equilibrium techniques. Many studies have reported the prognostic power of exercise EF as measured by the first-pass technique for subsequent cardiovascular death or nonfatal MI.[200-205,220] Similar reports have emerged from equilibrium RNA.[221-226] In a recent report by Shaw et al., the prognostic value of LV function during exercise was examined in 863 consecutive patients undergoing exercise gated equilibrium RNA within 90 days of catheterization who were followed up for subsequent events, with 99 percent of survivors completing five years of follow-up.[222] In a multivariable analysis, the resting or exercise EF contained significant predictive information ($p < 0.0001$). The rest or exercise EF contained similarly predictive information (exercise EF provided 63 percent of the information of the exercise model and resting EF provided 60 percent). When considering the addtion of the presence and extent of CAD observed at catheterization rest and exercise RNA data still provided significant improvement in the prediction of cardiac death.[222] There was aninverse relationship between peak exercise LVEF and survival.[219,222]

Bonow et al., using equilibrium RNA, documented the complementary role of exercise RNA and coronary angiography.[224] In this study, patients with triple-vessel disease and preserved LVEF at rest could be divided into a group in which mortality was negligible when exercise ejection fraction was normal and a high-risk group with an annual mortality of 7 percent when exercise ejection fraction was <50 percent.[224] Similarly, among patients with one- or two-vessel disease and reduced resting LVEF, those with normal EF responses did not exhibit any mortality over a 5-year follow-up, whereas 26 percent of patients with an abnormal EF response at exercise died in this time frame. Recently, Supino et al.[228] reported a 9-year follow-up of 167 stable patients with triple-vessel disease who had undergone rest and exercise RNA. Change in the LVEF from rest to exercise was the strongest predictor of major cardiac events and also predicted which patients would benefit from CABS. Patients whose LV ejection fraction decreased 8 percent or more with exercise had survival-prolonging benefit from bypass surgery performed less than 1 month after testing. Thus, data from several studies indicate that patients with chronic CAD can be accurately assessed with respect to prognosis by exercise RNA and that such assessment contains information that is complementary to that provided by standard clinical assessment as well as by coronary angiography.

Postcatheterization Patients

Although coronary angiography provides detail of coronary anatomy, the functional implications of coronary stenoses are not always evident from the angiographic data. High-grade stenoses in the absence of collaterals are appropriately considered lesions of clinical significance; frequently, however, lesions of

lesser grade are observed, or the implications of higher-grade lesions may be unclear due to presence of excellent collateral vessels. In these cases, the application of stress nuclear testing can supplement risk assessment for patients on the basis of the extent of stress-induced ischemia. Legrand et al. used exercise planar nuclear procedures to demonstrate that coronary flow reserve was normal in patients with 0 to 25 percent lesions and abnormal in patients with stenoses greater than 75 percent.[229] For patients in those extreme ranges, the data from nuclear testing were concordant with the angiographic results, supporting the concept that when angiographic results are clear, nuclear testing is not needed for functional assessment. In the range of 25 to 75 percent stenosis, however, there was an intermediate coronary flow reserve, unpredictable on the basis of coronary stenosis alone. In those patients, nuclear tests effectively separated the patients with low coronary flow reserve from those with normal coronary flow reserve. Therefore, the data on these patients with intermediate stenoses support the concept that nuclear testing can be useful with respect to functional significance in further assessment of such lesions. Similar data have been observed using sestamibi by Miller et al.[230]

Assessment of Therapy

With the broadening of the application of aggressive medical therapy (as an alternative to revascularization) to various subgroups of patients with CAD, methods for evaluation of the efficacy of medical therapy become of increasing importance. In this regard, it is likely that nuclear cardiology techniques will find an additional area of growth in serial patient assessment. After a patient is defined as being an appropriate candidate for medical therapy, nuclear techniques can be effectively employed to determine whether therapy has been successful or whether the patient's risk status has worsened, thereby requiring a change in therapeutic regimen. A requirement for serial applications is that the nuclear techniques being utilized be highly reproducible and that the degree of change in the assessed variables associated with measurement error be known. In an initial report on 16 patients with stable CAD and reversible perfusion defects, evaluated with quantitative ^{201}Tl myocardial perfusion SPECT following exercise performed on two separate occasions, the quantitative extent of stress perfusion defect showed a concordance coefficient of 0.94 and a mean absolute deviation of 5.1 percent.[231] Very similar findings were reported with serial exercise ^{201}Tl SPECT by Mahmarian et al.,[232] also using a quantitative analysis approach. These investigators demonstrated that a 10 percent change in total perfusion defect size in an individual patient defined the 95 percent confidence interval for exceeding the variability of the method. Although the statistical analyses were different between these studies, the results are very similar. More recently, high repeatability of exercise ^{99m}Tc sestamibi SPECT has been demonstrated using quantitative analysis approaches.[233] The summed stress score has also been shown to be highly reproducible.[233] These data provide the initial validation for the clinical application of nuclear methods for sequential assessment of therapy. In this regard, Mahmarian et al. had previously documented that transdermal nitroglycerin patch therapy reduces the extent of exercise-induced myocardial ischemia.[234] Lewin et al. have demonstrated that a sustained improvement in myocardial perfusion can be achieved with isosorbide mononitrate.[235] Most recently, Dakik and associates have demonstrated that SPECT imaging can be utilized to demonstrate a reduction in perfusion defect size in patients undergoing intensive medical therapy versus coronary angioplasty following acute MI.[236] Sequential assessment of perfusion and function with gated SPECT is also being applied in large randomized trials comparing medical therapy with angioplasty (COURAGE: *C*linical *O*utcomes *U*tilizing *R*evascularization and *A*ggressive *D*rug *E*valuation, see Chap. 10) and in evaluating the response of stress myocardial perfusion to therapy with vascular endothelial growth factor.[237]

Evidence Supporting Nuclear Testing for Patients after Percutaneous Coronary Intervention (PCI)

Nuclear testing is useful following PCI owing to the frequent occurrence of significant restenosis. Although recurrent symptoms often herald the presence of restenosis, clinically significant restenosis is frequently silent.[238] Exercise ^{201}Tl SPECT data obtained by Hecht et al.[239] have demonstrated that nuclear testing is accurate in defining the presence of restenosis. Subsequent work by Hecht et al. demonstrated this accurate detection of restenosis in asymptomatic as well as symptomatic patients.[240] Recent data suggest that nuclear testing remains effective in detecting restenosis for patients undergoing angioplasty with coronary stenting.[241,242] Pfisterer et al., using planar ^{201}Tl scintigraphy, demonstrated that silent and symptomatic ischemia in patients undergoing exercise scintigraphy 6 months following PCI, predicted an increased risk

of recurrent ischemic events.[238] In the angioplasty compared to medical therapy study (ACME), exercise planar ^{201}Tl scintigraphy was performed before and 6 months after randomization to medical therapy or PCI.[243] There was a significantly lower mortality rate in patients with either therapy in whom exercise-induced ischemia by scintigraphy was no longer present in the 6-month study (6 versus 18 percent, normalizing versus those nonnormalizing, $p = 0.02$). A preliminary report by Lewin et al. from our institution[244] has demonstrated that event rates are strongly related to the summed stress score following PCI, with a pattern very similar to that observed in patients with no known CAD; i.e., patients with mildly abnormal scans appeared to have increased rates of nonfatal MI but low rates of cardiac death, whereas the rates of both of these events were in the intermediate to high range in patients with more abnormal scans. This preliminary report also documented that there was an appropriate use of nuclear scan in guiding decisions for catheterization, with low early catheterization rates following nuclear scanning in patients with little evidence of ischemia.[244] A review of the use of nuclear testing after PCI has been published.[245,246]

The general recommended approach of nuclear testing in the post-PCI patient would therefore be as follows: in patients with single vessel CAD and angina or interpretable ST segment depression pre-PCI, post-PCI assessment could be performed on a clinical or standard exercise testing basis. In other patients, when symptoms develop, nuclear testing can be helpful in defining the culprit vessel and assessing the extent of ischemic abnormality. For patients with no symptoms, nuclear testing between 3 and 6 months after angioplasty has been recommended. Whenever moderate to severe ischemia is found by nuclear testing, consideration should be given to repeat catheterization.

Evidence Supporting Nuclear Testing after Coronary Bypass Surgery

Nuclear testing has become central in the assessment of the post-CABS patient. It is known that 75 percent of vein grafts can be expected to be occluded or severely stenosed by 10 years after surgery, particularly in patients undergoing saphenous vein CABS.[247,248] Due to an increased incidence of graft closure, a 5-year cutoff point to evaluate the postbypass patient may be considered appropriate.[246,249-251] Kaplan-Meier survival and MI-free survival for post-CABS patients undergoing exercise ^{201}Tl imaging from a recent study is depicted in Fig. 16-19.[250] This study also demonstrated that exercise ^{201}Tl SPECT is predictive of hard cardiac events even in the asymptomatic postbypass patient.[250] Moreover, we have reported findings using ^{99m}Tc sestamibi, illustrating that nuclear stress testing is effective in predicting subsequent events and determining need for catheterization in the post-CABS population.[251] In general, the recommendations for the post-CABS patient are that when symptoms develop, SPECT imaging is useful in determining the presence and extent of CAD. In the asymptomatic patient, SPECT perfusion imaging should be considered in the 5 to 7 years postoperative time frame. Whenever moderate to severe ischemia is present, consideration of repeat catheterization arises.[246,251]

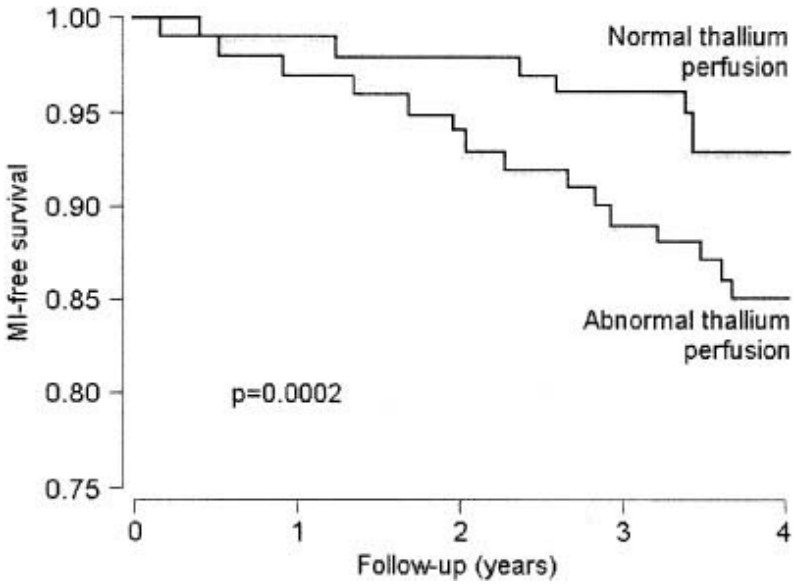

Figure 16-19: Kaplan-Meier plot for post-CABS patients associates reversible thallium defects with MI-free survival. Patients with reversible thallium perfusion defects had higher event rates. (From Lauer et al.,[250] with permission.)

Nuclear Testing for Risk Stratification in Special Populations

One of the principal strengths of nuclear cardiology is that a very large database has been accumulated, far larger than for any other noninvasive modality, documenting clear effectiveness of myocardial perfusion SPECT in risk stratification of appropriately selected patients with suspected chronic CAD. These large databases have now made it possible to evaluate risk in subsets of chronic CAD. Several of these applications are separately described below.

DIABETES

Myocardial perfusion SPECT has now been reported to be highly effective in risk stratification of patients with diabetes.[252,253] For example, in a study of 1271 patients with diabetes and 5862 without, Kang et al. demonstrated that a normal scan was similarly predictive of low cardiac event rates in both groups. Risk-adjusted event-free survival in patients with mildly and moderately abnormal scans, as defined by the SSS, was worse in patients with diabetes than in those without[252] (Fig. 16-20). A recent multicenter series reported that the extent of perfusion deficits and cardiac symptoms is more predictive of cardiac mortality in diabetics.[254] In a preliminary report, Lewin et al. have shown that in patients without diabetes, those with a moderately abnormal SSS had a cardiac mortality rate similar to that of patients with a mildly abnormal or normal SSS, whereas diabetics with moderately abnormal SSS had increased mortality rates. These findings suggest that in nondiabetic patients with known or suspected chronic CAD, the group with relatively low risk for cardiac death may be extended beyond that observed in general populations, potentially increasing the group of patients appropriately defined for noninvasive strategies (see also Chap. 78).[253]

LEFT BUNDLE-BRANCH BLOCK

Myocardial perfusion SPECT is highly useful for risk stratification in patients with LBBB. In a long-term follow-up of 245 patients with LBBB, Wagdy et al.[255] demonstrated that myocardial perfusion SPECT with vasodilator stress was an excellent predictor of cardiac events, with high risk being defined by a large, severe, fixed defect, a large reversible defect, cardiac enlargement and increased pulmonary uptake, or low resting EF. The 3-year survival was 57 percent in the high-risk group, versus 87 percent in the low-risk group ($p < 0.0001$). Similar findings have been reported by Nallamothu et al. in 293 medically treated patients with LBBB followed for 33 months.[256]

GENDER-BASED DIFFERENCES IN THE PROGNOSTIC VALUE OF PERFUSION IMAGING

For women, CAD incidence lags 10 years behind that of men. With the onset of menopause, the prevalence of CAD increases, achieving equivalence in disease prevalence at age 70 years.[257] In nondiabetic women before the age of 45 years, the likelihood of CAD is exceedingly low. In addition to differences in disease prevalence, a number of studies of small series of female patients have reported technical limitations and diminished accuracy in exercise treadmill testing, ^{201}Tl imaging, and in echocardiography.[174,258,259] With a perception on the part of clinicians of diminished accuracy of test results, reports have described sex-related bias in referral to cardiac catheterization after noninvasive testing.[260,261] When ^{201}Tl is used as the radiopharmaceutical in women, false-positive test results may be due to soft-tissue (breast) attenuation in the anterior and anterolateral segments.[174,262] In a small randomized trial comparing the diagnostic accuracy of ^{201}Tl with that of ^{99m}Tc sestamibi, test specificity was 67 versus 92 percent, respectively,[174] suggesting that gated SPECT with a ^{99m}Tc perfusion agent may be the preferred form of SPECT in women. Reports from large female populations indicate that for both ^{99m}Tc sestamibi (rest and exercise) and dual-isotope myocardial perfusion SPECT, there is an added incremental prognostic value of myocardial perfusion data as compared to clinical and exercise variables in women.[66,263,264] From a recent multicenter registry of 3402 women with stable chest pain symptoms, risk stratification was similar by gender (84 percent underwent ^{99m}Tc sestamibi SPECT).[264] By the number of vascular territories with ischemia, 3-year survival ranged from 98.5 to 85 percent for none to three vascular territories abnormal by SPECT.[264] Amanullah and colleagues reported on 130 women undergoing adenosine ^{99m}Tc sestamibi SPECT, revealing that a moderately to severely abnormal perfusion scan (i.e., SSS >8) was associated with a sensitivity and specificity of 91 and 70 percent for the detection of multivessel CAD.[265]

PROGNOSTIC VALUE OF PERFUSION IMAGING IN THE ELDERLY

Patients over age 65 years have a higher disease prevalence and risk of major cardiac events as well as more frequent comorbid diseases. Exercise duration, heart rate, and total workload decrease with increasing age of our screened population. The prognostic value of perfusion scintigraphy has been reported in several recent series.[266,267] In an ambulatory population over age 70 years, abnormal exercise thallium imaging was accurate in identifying a high-risk population.[266] In a consecutive series of elderly patients, those with evidence of reversibility and a fixed defect were at highest risk of 3-year cardiac death or MI.[266] Cardiac death or MI at 2 years after testing occurred in almost half of elderly patients with a high-risk perfusion scan. Similarly, Hachamovitch et al. found that exercise dual-isotope SPECT was able to risk-stratify patients aged 65 and older successfully-patients with normal scans had less than a 1 percent event rate over the first year of follow-up.[266a] In addition, the perfusion scan added incremental prognostic information over nonnuclear variables, and the addition of myocardial perfusion imaging to test strategies reduced the overall cost of testing per patient. In an elderly cohort of patients 80 years of age and older, Amanullah et al. found that dual-isotope adenosine myocardial perfusion SPECT was able to risk-stratify patients and yield incremental prognostic value over clinical variables.[267] In general, for the elderly as well as for those patients with functional limitations, similar risk assessment is possible with exercise and pharmacologic stress SPECT.[267a] Owing to the higher mortality rate of the general population in this age group, upward adjustment of the "intermediate-risk" group to levels higher than the 1 to 3 percent used for general populations may be appropriate. In this regard, Hayes et al. evaluated 1848 consecutive patients ≥80 years of age undergoing rest ^{201}Tl/stress ^{99m}Tc sestamibi dual isotope myocardial perfusion SPECT. Annualized cardiac death rates ranged from 1.9 percent in 722 patients with normal summed stress score to 9.3 percent in 401 patients with severely abnormal summed stress score (SSS ≥13).[267b]

PREOPERATIVE RISK ASSESSMENT IN NONCARDIAC SURGERY PATIENTS

Preoperative risk assessment is a common reason for cardiology consultation. Although clinical history, physical examination, and the resting ECG are highly useful, in many clinical settings these tools are inadequate. In contrast, assessment of LV function and/or jeopardized myocardium provides an accurate method to complement clinical assessment. Patients with peripheral vascular disease are at increased risk of having CAD. A large coronary angiographic study of asymptomatic patients revealed that 44 percent of patients undergoing peripheral vascular surgery have angiographically significant CAD.[268] It has furthermore been shown that peripheral vascular surgery, with its associated marked hemodynamic stresses,

carries at least a moderate risk of perioperative events for patients with known CAD. Since these patients frequently cannot exercise, they are ideal candidates for the utilization of vasodilator stress in conjunction with myocardial perfusion imaging, and a large body of literature exists documenting the effectiveness of nuclear stress testing in this context. Although some have advocated the routine application of stress nuclear testing in this patient group, recent guidelines have been developed suggesting that nuclear testing is best reserved for patients with an intermediate risk of a cardiac event at the time of the procedure. Data supporting this approach were first presented by Eagle et al.[269] and then expanded in 1996 to include 3368 operations.[270] A metanalysis of the comparative value of the vasodilator myocardial perfusion scintigraphy and dobutamine echocardiography in risk stratification before vascular surgery has been published.[271] Together with other data sets, these data led to the guidelines for perioperative cardiovascular evaluation, published by the ACC/AHA task force (see Chap. 74). From these guidelines, candidates for vasodilator myocardial perfusion SPECT (or dobutamine echo) include patients with two of three high-risk factors (Table 16-4). In general, this includes patients who are at intermediate risk for cardiac events.

Table 16-4: Shortcut to Noninvasive Testing Based on Guidelines*†

- Intermediate clinical predictors are present (Canadian class 1 or 2 angina, prior myocardial infarction based on history or pathologic Q waves, compensated or prior CHF, or diabetes)
- Poor functional capacity (<4 METS)
- High surgical risk procedure (emergency major operations; aortic repair or peripheral vascular; prolonged surgical procedures with large fluid shifts and or blood loss)

---

*Based on Leppo JA, American Society of Nuclear Cardiology, Tutorial in Nuclear Cardiology, Sept. 30-Oct. 3, Washington, D.C., 1999.†Noninvasive testing is useful in preoperative patients if any two factors are present.

Assessment of Myocardial Viability

Mortality associated with LV dysfunction in the setting of severe CAD is quite high.[272-275] Patients with LV dysfunction who undergo CABS receive a greater proportional risk reduction compared to patients with preserved function.[8] The clinical setting in which viability assessment is most commonly used is the evaluation of patients with poor LV function, when the likelihood of improvement after revascularization is being considered. This information can be useful in determining the appropriateness of medical management, revascularization, or cardiac transplantation. Excellent reviews of radionuclide techniques for assessment of myocardial viability have recently been provided by Bonow[272,273] and Dilsizian.[274]

As early as 1989, positron emission tomographic (PET) imaging was studied to examine the differential benefit of identifying viable from nonviable myocardium (see Chap. 19). Improved regional function postsurgery would occur more often in the setting of some modicum of myocardial viability. In addition to PET imaging, various protocols utilizing combinations of rest, redistribution, and reinjection thallium imaging have been devised, validated, and compared to assess the presence of hibernating myocardium optimally. When reversibility of defects is noted on stress/rest or stress/redistribution studies, the likelihood of postrevascularization improvement of regions with abnormal ventricular function is high. The likelihood of improvement is also high for patients in whom reversibility is noted on rest/redistribution myocardial perfusion scintigraphy. Improvement would also be expected in patients with very severe angiographic CAD (virtually certain to cause severe flow restriction with stress) if normal, mildly reduced, or even moderately reduced tracer uptake is noted on rest or redistribution scintigraphy, since it could be predicted that such patients would show clear reversibility if stress-rest or stress-redistribution imaging were feasible. This inference is commonly made for patients with known coronary anatomy, unstable angina, and physician reluctance to perform stress imaging. When severe reduction in uptake of radioactivity is noted on redistribution ^{201}Tl imaging, the likelihood of improvement in regional ventricular function is low.

When a moderate defect is noted at rest (or redistribution), the likelihood of improvement is intermediate.

Many studies have demonstrated thallium protocols using either rest-redistribution or stress-redistribution-reinjection to be nearly as accurate as PET in assessing myocardial viability.[274] Recent studies have also examined the predictive value of ^{99m}Tc sestamibi for functional recovery post-CABS. Summary data of the positive and negative predictive value of ^{201}Tl and ^{99m}Tc sestamibi in estimating functional recovery following CABS (using 2- to 3-month post-RNA or echocardiographic imaging) have shown that the positive predictive value (either weighted average or pooled) ranged from 69 to 79 percent and was similar by radioisotope. The negative predictive value (either by pooled or weighted average) ranged from 72 to 85 percent and was also similar by radioisotope. These accuracy statistics are dependent upon underlying risk (with higher predictive values noted for higher-risk populations); average patient samples were 25 to 30 for ^{201}Tl and ^{99m}Tc sestamibi.[272-275]

Currently there is controversy as to whether resting myocardial perfusion scintigraphy with ^{99m}Tc sestamibi (particularly if augmented by preinjection administration of nitroglycerin)[85,86] is as effective as redistribution ^{201}Tl scintigraphy in assessing myocardial viability. Without nitroglycerin, however, in principle it would be expected that rest/redistribution ^{201}Tl myocardial perfusion scintigraphy would be a more accurate approach than ^{99m}Tc sestamibi imaging for detection of viability in patients with severe hibernation (severe reduction in resting blood flood, downregulation of ventricular function, but preservation of the ability to improve ventricular function with restoration of blood flow).[277,278] Of note, it has been suggested for both ^{99m}Tc sestamibi[88] and ^{99m}Tc tetrofosmin[24] that an increase in extraction fraction at low flow may make the resting study with the ^{99m}Tc agent more like a redistribution thallium than a resting thallium study, potentially explaining the observed excellent ability of these tracers, even without nitroglycerin administration, to predict postrevascularization improvement in ventricular function.

Several technical improvements could improve the use of myocardial perfusion SPECT in the assessment of myocardial viability. As mentioned above for ^{99m}Tc sestamibi and tetrofosmin, the possibility of further enhancing the viability information of reinjection ^{201}Tl through the administration of nitroglycerin has been described.[38,276] Furthermore, in many of the studies assessing viability, a single cutoff point for myocardial counts in the region in question compared to the maximal observed value is employed: e.g., 50 or 60 percent of the maximal counts.[87,88] Of note, however, is the fact that the inferior wall in non-attenuation-corrected SPECT studies has far fewer counts than the other myocardial regions. This observation would suggest that the ability to predict viability for myocardial perfusion SPECT would be enhanced by approaches that take into account the number of standard deviations below normal in a given region rather than a single percentage of maximal count uptake. Finally, the use of combined rest-redistributioned ^{201}Tl/stress ^{99m}Tc sestamibi or tetrofosmin dual isotope SPECT may be particularly effective in assessing myocardial viability, since the protocol can combine what may be the optimal rest SPECT protocol (rest and redistribution ^{201}Tl) with a stress imaging assessment.[56,213]

Table 16-5 illustrates conceptually the relationship between several different myocardial states associated with chronic CAD and the patterns that might be observed on myocardial perfusion SPECT. In the presence of myocardial hibernation, resting blood flow would be expected to be mildly to even severely reduced, with corresponding reductions in resting ^{201}Tl or ^{99m}Tc perfusion agent uptake.[277,278] With ^{201}Tl, the equilibrium uptake of radioactivity would also be expected to be normal or potentially slightly reduced if true equilibrium was not achieved or if prolonged hibernation had resulted in cellular degeneration.[278] Thus these patients often demonstrate resting reversibility of perfusion defects.[213] For the ^{99m}Tc agents, resting perfusion (and thus viability assessment) can be enhanced by nitroglycerin administration prior to the resting injection of the tracer.[85,86] If patients with hibernation are subjected to stress, an even greater degree of reduction in flow would be expected, causing a greater degree of defect reversibility in most cases. The likelihood of improvement with revascularization is great in these patients.

Table 16-5: Scintigraphic and Clinical Characteristics of Hypocontractile Regions According to Their Viability Status

Viability Status	Rest	Redistribution (Tl-201)	Rest Reversibility	Stress/Rest/RI Reversibility	Likelihood of Improvement with Revasc
Q MI	↓↓↓	↓↓↓	-	-	-
Non Q MI	↓-↓↓	↓-↓↓	-	±*	±*
Hibernation	↓ to ↓↓↓	→ to ↓	+	+++	+++
Stunning (with exercise)	→	→	→	+++	+++
Remodeled	→	→	→	→	→
Nonischemic CM with incidental CAD	→	→	→	→	→

*Depends on stenosis of IRA.
ABBREVIATIONS: Q = Q wave; MI = myocardial infarction; CM = cardiomyopathy; RI = reinjection; Revasc = revascularization.

Stunning occurs in the setting of a prolonged episode of severe ischemia[279] with subsequent restoration of flow. It is usually associated with acute CAD and is most often seen in the setting of aborted MI (either by thrombolytic therapy, direct revascularization, or spontaneous thrombolysis). Stunning can also occur in the setting of chronic CAD, such as following prolonged exercise in patients with high-grade coronary lesions.[209,280] In these circumstances, resting myocardial perfusion scintigraphy is generally normal or minimally reduced, reflecting the return of normal or nearly normal perfusion. Equilibrium ^{201}Tl concentration would be normal, and there would be no evidence of resting reversibility. However, patients with exercise-induced stunning would be expected to demonstrate marked perfusion defects on the stress study.[209] In these patients, the likelihood of improvement in exercise flow and function, as well as postexercise function following revascularization, would be high. It should be noted that stunning observed in conjunction with stress is not generally associated with an abnormality of true resting ventricular function but is discovered as a consequence of measuring ventricular function early after using stress testing.[209,280] For this type of stunning abnormality to improve, revascularization is usually necessary; in contrast, improvement in ventricular function occurs spontaneously over time with the stunning associated with an aborted acute coronary syndrome.

A great deal of attention has recently been placed on the remodeled LV, usually occurring as a consequence of extensive prior MI.[281,282] In this circumstance, LV function can become diffusely abnormal, even in areas remote from the infarct zone. The area of abnormal contraction associated with remodeling in these patients would be expected to have normal resting ^{99m}Tc perfusion tracer or ^{201}Tl uptake, normal equilibrium ^{201}Tl uptake, no evidence of reversibility on either stress or rest imaging, and little likelihood of improvement following revascularization. Patients with remodeled LVs may have very profoundly reduced ventricular function. Given the differential response to revascularization of the remodeled LV and the hibernating LV, this ability of nuclear scanning to differentiate between them becomes important.

Nuclear Cardiology Applications Unique to RNA

ASSESSMENT OF ANTHRACYCLINE CARDIOTOXICITY

RNA, using either the equilibrium or first-pass approach has become the method of choice for evaluating the effects of doxorubicin and other anthracyclines on LV function in patients with suspected

cardiotoxicity. In an early report, Alexander and colleagues demonstrated that patients with normal LVEF that had not fallen by more than 15 points did not develop cardiotoxicity with continued doxorubicin therapy; however, once EF fell below 45 percent or by more than 15 percent, continued doxorubicin therapy was commonly associated with irreversible cardiac failure.[283] In a subsequent report of a large high-risk population from the same group, guidelines were established for the use of continued doxorubicin therapy.[284] These recommendations are summarized in Table 16-6. In a group of 70 high-risk patients in whom these guidelines were strictly followed, 2.9 percent developed subsequent congestive heart failure (CHF) that responded to therapy. Of 212 high-risk patients in whom the recommendations were not closely followed, 21 percent developed CHF ($p < .001$ versus the strict-guideline group). The CHF in the majority of these patients was considered moderate to severe. Similar findings have been reported by other groups.[285,286]

Table 16-6: Guidelines for Monitoring Patients Receiving Doxorubicin*

Perform baseline radionuclide angiocardiography at rest for calculation of left ventricular ejection fraction (LVEF) prior to administration of 100 mg/m^2 doxorubicin. Subsequent studies are performed at least three weeks after the indicated total cumulative doses have been given, before consideration of the next dose.
PATIENTS WITH NORMAL BASELINE LVEF (≥50%)
Perform the second study after 250 to 300 mg/m^2
Repeat study after 400 mg/m^2 in patients with known heart disease, radiation exposure, abnormal electrocardiographic results, or cyclophosphamide therapy; or after 450 mg/m^2 in the absence of any of these risk factors.
Perform sequential studies thereafter prior to each dose.
Discontinue doxorubicin therapy once functional criteria for cardiotoxicity develop, i.e., absolute decrease in LVEF ≥10% (EF units)
PATIENTS WITH ABNORMAL BASELINE LVEF (≤50%)
Doxorubicin therapy should not be initiated with baseline LVEF ≤30%.
In patients with LVEF >30% and <50%, sequential studies should be obtained prior to each dose.
Discontinue doxorubicin with cardiotoxicity: absolute decrease in LVEF ≥10% (EF units) and/or final LVEF ≥30%.

*From Ref. [284].

DETERMINING THE TIME FOR VALVE REPLACEMENT IN AORTIC REGURGITATION

It has been demonstrated that resting LVEF, as measured by equilibrium RVA, provides an excellent method for the sequential follow-up of asymptomatic patients with aortic regurgitation. For patients with chronic aortic regurgitation, a fall in LVEF has been shown to be strongly predictive of the development of subsequent progressive severe deterioration in LV function.[287,288] These investigators have suggested that asymptomatic patients with severe aortic regurgitation whose EFs at rest fall below normal should be considered for elective valve replacement. Using a combination of rest/exercise RNA and rest/echo, a recent study by Borer et al.[289] demonstrated in asymptomatic patients with severe aortic insufficiency that if a change in LVEF from rest to exercise, normalized for the change in end-systolic stress from rest to exercise, is abnormal, even patients with normal resting LVEF and no symptoms were likely to develop future complications. Cheitlin[290] suggested, however, that the more commonly available, less complex periodic assessment of rest LVEF or end-systolic volume may be as good an approach for determining the time for operative intervention in this condition.

Chapter 16: NUCLEAR CARDIOLOGY

ACUTE CORONARY ISCHEMIC SYNDROMES

Acute coronary ischemic syndromes have been categorized as acute transmural (Q) MI, nontransmural (non-Q) MI, and unstable angina pectoris. More recently, unstable angina and non-ST-segment elevation MI have been linked since flow preservation strategies and treatment are similar in these conditions (see Chap. 41). In general, all of these syndromes have the underlying pathophysiology of the presence of severe obstruction or closure of a coronary artery secondary to acute thrombus formation or spasm in a segment of an artery. Because of this relationship to closure of a vessel, myocardial perfusion/function scintigraphy is an effective means of detecting patients with acute ischemic syndromes. Acute coronary syndromes represent a wide array of clinical presentations from worsening chest pain in patients seen in the outpatient clinic to acute MI. Annually, there are a total of 1.5 million admissions to coronary care units in the United States, with half of these patients ruling in for ischemia or MI (Chaps. 41 and 42). A number of guidelines have described the advantages of postinfarction stratification afforded by nuclear testing.[218,219,291] While less dramatic than with chronic CAD, there has been continued growth in the application of nuclear cardiology to the assessment of patients with acute ischemic syndromes.

Evaluation of Acute Chest Pain

Although the diagnosis of acute MI is frequently straightforward, in many patients it is not. For example, the ECG is diagnostic in only two-thirds of patients with MI at the time of their initial presentation to the emergency department (ED). In non-Q-wave MI, and particularly in left circumflex MI, the ECG is frequently normal.[292,293] Furthermore, the ECG is frequently nondiagnostic even when abnormal (e.g., with LBBB, nonspecific ST- or T-wave changes, pacemakers).[294] From the emergency physician's standpoint, the problem of missed MIs in the ED is of particular importance. It is has been estimated that up to 50,000 patients per year in the United States have MIs that are missed, representing approximately 4 percent of all patients with MIs who present to the ED.[218,219,291,295] Approximately 25 to 40 percent of malpractice claims against emergency physicians arise from patients with missed MI.[295] It has also been demonstrated that patients discharged from the ED with missed MIs have a substantially higher mortality rate than patients in whom MI is appropriately detected and results in admission.[294,296] Therefore, with respect to patients with normal or nondiagnostic initial ECGs on presentation to the ED, an important clinical problem is how to distinguish those with acute coronary syndromes, who may benefit from early intervention, from those who may require less intensive care, can be discharged, or undergo immediate stress testing (see Chaps. 41 and 42).

For patients without ST-segment elevation, clinical management is not defined. The reasons are multifold, including the fact that only a small portion of patients presenting with an acute onset of chest pain symptoms are eligible for thrombolysis (i.e., 9 to 39 percent).[218,291] Of the remaining cohort of chest pain patients presenting to the ED, the outcome of patients with only minor ST-T-wave changes is variable. Evidence from the recent GUSTO IIa trial revealed that the outcome of patients with presenting ST-segment depression was 6.8 percent for 30-day mortality and 12.4 percent for death or MI at 1 year. Of the non-ST-segment elevation candidates, 28 percent have three-vessel CAD and half have an MI during the index hospitalization. As such, in nonthrombolytic candidates the risk of CAD and major cardiac complications varies and may be

high in a large proportion of patients.[297]

Because many of these patients are subsequently ruled out for MI, chest pain units have been instituted for the acute evaluation of chest pain patients presenting to the ED.[298,299] The chest pain units provide an integrated approach to the diagnosis and treatment of patients at risk for CAD. This includes laboratory tests, cardiac imaging, and early and aggressive treatment vis-à-vis a dedicated staff of nurses and physicians. A number of reports have documented the economic savings that have been realized by the introduction of these dedicated facilities.[298,299] The ROMIO study randomized 100 low-risk patients to an ED-based rapid-rule-out protocol or to routine hospital care.[299] The results revealed that the hospital stay was shorter and charges were lower with the rapid protocol than with routine care ($p = 0.001$). Among patients in whom ischemia was ruled out, those assigned to the rapid protocol had a shorter hospital stay (median 11.9 versus 22.8 h, $p = 0.0001$) and lower initial ($893 versus $1349, $p = 0.0001$) and 30-day ($898 versus $1522, $p = 0.0001$) hospital charges than did patients given routine care.

^{99m}Tc sestamibi or tetrofosmin SPECT, with injection during chest pain, provides an excellent opportunity to reduce clinical indecision in the acute evaluation of chest pain[300-302] (Fig. 16-21). Investigations have demonstrated a role for myocardial perfusion imaging in the initial evaluation of these patients. Hilton and colleagues performed acute sestamibi imaging for patients presenting to their ED with typical angina and normal or nondiagnostic ECGS.[300] Only one patient of 70 in this cohort with a normal scan experienced a subsequent cardiac event on follow-up (cardiac death, MI, PCI, CABS, thrombolysis). Patients with equivocal or abnormal scans had event rates of 13 and 71 percent, respectively. The nuclear scan provided incremental risk stratification over clinical and ECG data. Based on these data, nuclear imaging can be used to assist in the risk stratification of patients with ongoing symptoms whose diagnosis cannot be clearly determined in an ED setting. In patients with ongoing symptoms, a normal perfusion scan can identify patients who can either be discharged early or admitted to non-intensive-care beds.

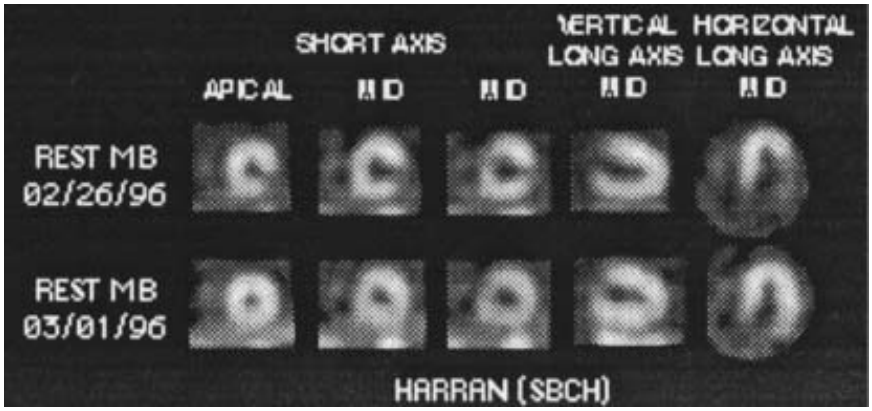

Figure 16-21: Resting sestamibi (MB) injected during chest pain in emergency department (*top*) and 3 days post-PCI of the left circumflex coronary artery (LCX) (*bottom*) in patient with no EGG or enzyme abnormalities. Clear evidence of extensive myocardial salvage in LCX territory is shown.

A number of larger series have been reported.[303-307] Tatum et al.[303] developed a triage evaluation strategy in which patients with a very high, high, or very low probability of an acute ischemic syndrome did not undergo nuclear testing, but those with a moderate to low probability of an acute ischemic syndrome did. It was found that 338 of 438 patients had normal studies and 100 patients had abnormal studies. Subsequent deaths and MIs over the following year were found to

occur only in the patients with abnormal ^{99m}Tc sestamibi studies, while none of the 338 patients with normal ^{99m}Tc sestamibi studies developed subsequent MI (these studies included assessment of perfusion as well as myocardial function using gated SPECT). This group subsequently demonstrated, in a study of 620 patients with acute chest pain, that early myocardial perfusion SPECT and serial cardiac troponin I measurements have comparable sensitivies for identifying MI. This study also demonstrated that the two tests provide complementary information for identifying patients at risk for acute coronary syndromes.[304] In another report of 218 patients, this group demonstrated that myocardial perfusion scintigraphy is useful in assessing chest pain associated with cocaine use, with abnormal studies being very infrequent in this population.[305] A multicenter series employing ^{99m}Tc tetrofosmin of 357 patients presenting to six centers with symptoms suggestive of myocardial ischemia was recently published.[306] This study examined the predictive value of rest ^{99m}Tc tetrofosmin SPECT at the time of ED admission for patients with a nondiagnostic ECG upon presentation. Of this study cohort, 20 patients had an acute MI, with a test sensitivity of 90 percent and a specificity of 60 percent. Most of the missed MIs were small inferior wall MIs mistaken as attenuation artifacts. The slightly lower sensitivity for acute MI in this series might be attributed to not using gated SPECT, which helps distinguish true resting perfusion defect from attentuation artifacts in these patients. In the analysis of these authors, using a normal SPECT image to decide not to admit a patient to the hospital would result in a 57 percent reduction in hospital admissions with a mean cost savings per patient of $4258.

A synthesis of published reports on acute use of myocardial perfusion imaging reveals an average sensitivity and specificity of 98 and 69 percent, respectively, for patients who are admitted with an abnormal perfusion scan.[302,303,306-308] A predictive model of index MI or revascularization based on multivariable risk-adjusted logistic regression has been reported in a cohort of 532 patients with acute chest pain revealed the following predictors: abnormal ^{99m}Tc sestamibi scan [odds ratio (OR) = 14-fold], diabetes (OR = 2.8-fold), typical angina (OR = 2.1-fold), and male gender (OR = twofold).[307] A very recent randomized clinical trial in 2300 patients tested the incremental value of historical, ECG, and sestamibi parameters in the decision to admit a patient presenting with acute chest pain (multicenter trial sponsored by the Agency for Healthcare Policy Research).[309] This trial randomized patients without a prior CAD history but with symptoms suggestive of acute ischemia, and a nondiagnostic ECG, to a nuclear scan versus no scan strategy. This study compared the ability of the scan to correctly classify patients who should be admitted as well as the costs associated with each comparative management strategy and demonstrated a 20 percent reduction in hospital admissions of patients subsequently shown not to have acute ischemic syndromes, no change in admission rates of patients with acute ischemic syndromes, and modest cost savings associated with nuclear scanning. Among 2127 patients whose final confirmed diagnosis was not acute cardiac ischemia, 52 percent of the patients randomized to the usual-care strategy were admitted to hospital or observation in what could be classified in retrospect as unnecessary admissions. Among the patients randomized to have a sestamibi scan as part of their evaluation strategy, however, the unnecessary admission rate was reduced to 42 percent. These data suggest that incorporating perfusion imaging into an ED strategy for patients with chest pain and a nondiagnostic ECG can improve the effectiveness of ED triage. Furthermore, projecting data on total direct costs from one site to the entire trial, we estimate that the added cost of the perfusion scan was more than overridden by the savings accrued from the reduction in unnecessary admissions in patients without acute ischemia.

Guidelines for SPECT Imaging in the ED

Several considerations are important for the most effective application of acute nuclear imaging. If the patient has had prior MI, the studies are generally not useful. The principal exception to this rule occurs in patients who had previously undergone myocardial perfusion scintigraphy, the results of which are immediately available to compare with the results of the new study performed

during acute chest pain. Also, combined assessment of perfusion and function should be routinely performed in order to minimize the false negative rate. Of note, ^{99m}Tc-based myocardial perfusion imaging agents (^{99m}Tc sestamibi or tetrofosmin) are preferable in this acute ischemic syndrome application, since they may be injected during chest pain in the emergency department and imaged 30 min to 4 h later. Thus, the absence of redistribution with these myocardial perfusion imaging agents provides an advantage for acute imaging applications.

The accuracy of this approach for detecting an acute ischemic syndrome is probably related to the timing of injection with respect to the patient's chest pain. Ideally, the agent would be administered during chest pain or the first hour after chest pain; however, the importance of this timing has not been widely studied. In this regard, patients with unstable angina could conceivably have intermittent coronary occlusion, with normalization of myocardial perfusion at the time the vessel is open.

Because of this consideration, a protocol suggested by Ziffer et al.[310] is recommended for the assessment of those patients in whom chest pain has been relieved prior to injection (Fig. 16-22). In this protocol, patients with ongoing chest pain and resolved chest pain are managed differently. The former are injected with ^{99m}Tc sestamibi, as noted above; a normal study in this cohort may result in either discharge or referral for immediate stress testing, depending on the clinical likelihood of an acute ischemic syndrome. On the other hand, patients with abnormal initial studies are admitted with a presumptive acute ischemic syndrome.

Unique to the protocol described by Ziffer is the handling of a patient with resolved chest pain in the ED. In this case, a resting ^{201}Tl injection would be performed instead of resting ^{99m}Tc sestamibi or ^{99m}Tc tetrofosmin. If the resting ^{201}Tl SPECT is abnormal, the patient would be admitted and therapy for an acute ischemic syndrome begun, including consideration of early coronary angiography. Redistribution imaging may be useful for the assessment of myocardial viability. If the resting ^{201}Tl study is normal, the patient would not be discharged, since the possibility of resolved chest pain secondary to unstable angina would not yet have been evaluated. The patient would instead be submitted to a stress ^{99m}Tc sestamibi study (after a series of negative enzyme studies) employing the resting ^{201}Tl/stress ^{99m}Tc sestamibi protocol described at the beginning of Chap. 56. Based on these combined assessments, patient management would range from discharge (with a normal scan or mildly abnormal scan) to admission (with a clearly abnormal scan). In this latter case, the presumptive diagnosis would be that unstable angina caused the resting chest pain that had led to the emergency room presentation.

Ziffer et al. have recently published preliminary data on 2737 patients undergoing this protocol.[310] In 32 percent of the patients only resting imaging was performed, while in the remaining 68 percent rest and subsequent stress imaging were performed. Overall, 77 percent of all patients imaged were discharged without admission, and 23 percent were admitted. When the success of this protocol was evaluated, two aspects were of particular importance. The investigators compared the event rates for patients who were discharged from the hospital following imaging to the event rates that had previously been observed for patients discharged from the emergency room before the myocardial perfusion imaging protocol had been instituted. With the chest pain center and the myocardial perfusion imaging protocol, the annualized event rate for patients discharged from the emergency room was 0.17 percent. In the patients discharged in the period immediately prior to the opening of the chest pain center, the annualized cardiac event rate was 2.7 percent. Thus, use of myocardial perfusion scintigraphy in the chest pain center was associated with a 16-fold reduction in the event rate (death or nonfatal MI) for patients discharged. In a subsequent preliminary communication, Ziffer et al. demonstrated clear cost savings by applying myocardial perfusion scintigraphy to appropriately selected patients.[311] Application of this modified protocol to patients in whom acute chest pain has resolved is illustrated in Fig. 16-23, in which a patient with unstable angina was correctly classified by the combination of rest and stress

scintigraphy but would have been misclassified by the use of resting scintigraphy alone.

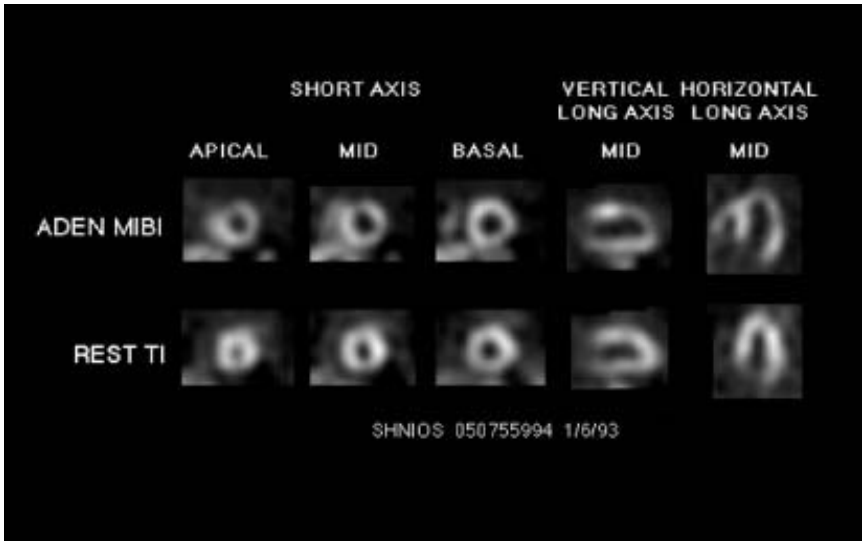

Figure 16-23: Normal rest 201Tl SPECT (*bottom*) followed by adenosine 99mTc sestamibi (ADEN MIBI) (*top*) in a patient with intermittent chest pain which had resolved prior to injection with 201Tl at rest. Reversible defects are seen in the left arterior descending and left circumflex territories. Angiography revealed 50 percent left main, 100 percent left anterior descending, 90 percent left circumflex, and 50 percent right coronary artery stenoses.

Assessment during Early Hospitalization for Acute Coronary Syndromes

Early (i.e., within 24 h) risk assessment has included perfusion or ventricular function imaging. Miller et al.[312] have documented that there is a strong relationship between the size of a very early myocardial perfusion defect (an indicator of infarct size) and subsequent mortality in the setting of acute MI. Overall a 3 percent mortality rate was observed in patients following acute MI. However, 7 percent of patients with myocardial perfusion defects (infarct size) greater than 12 percent of the myocardium had died at the end of a 2-year follow-up, compared to zero percent of the patients with infarct size less than 12 percent.[312] Christian et al.[313] have shown that rest myocardial perfusion SPECT, when combined with resting LV function, can provide information on myocardial stunning. In patients with acute MI, when there was a mismatch (with LVEF lower than would be expected from admission myocardial perfusion SPECT defect size), late improvement in LV function could be predicted.[313]

Radionuclide angiography has also been applied in the coronary care unit setting for assessing prognosis in patients with acute MI,[314,315] establishing the diagnosis of RV infarction,[314,315] and differentiating causes of cardiogenic shock.[314,315] A strong inverse relationship between resting EF and 1-year cardiac mortality has been demonstrated in large multicenter trials[316] (Fig. 16-24). At the other end of the clinical spectrum, resting RNA can aid in the assessment of the cause of low cardiac output in the acute setting. The approach can accurately distinguish patients with LV dysfunction, RV dysfunction, mitral regurgitation, cardiac tamponade, and ventricular septal defect. Those with LV dysfunction would have substantially reduced LVEF and concomitant severe wall motion abnormalities. The syndrome with predominant RV dysfunction is easily recognized by RV enlargement and a greater reduction in RVEF than LVEF.[314,315] Mitral regurgitation severe enough to allow low cardiac output in the setting of acute MI would be detectable through the LV/RV stroke-count ratio which can be derived from the regions of interest utilized to calculate RVEF and LVEF. Similarly, if a pericardial effusion, with or without

bleeding, is large enough to cause hemodynamic compromise, it would easily be detected by equilibrium RNA as a halo surrounding the left cardiac chambers. Furthermore, in the postoperative setting, RNA allows identification of pericardial bleeding.[317,318] By combining a first-pass and equilibrium acquisition (with acquisition of one to two frames per cardiac cycle), one can also assess the presence of a ventricular septal defect through analyzing the pulmonary time-activity curve.

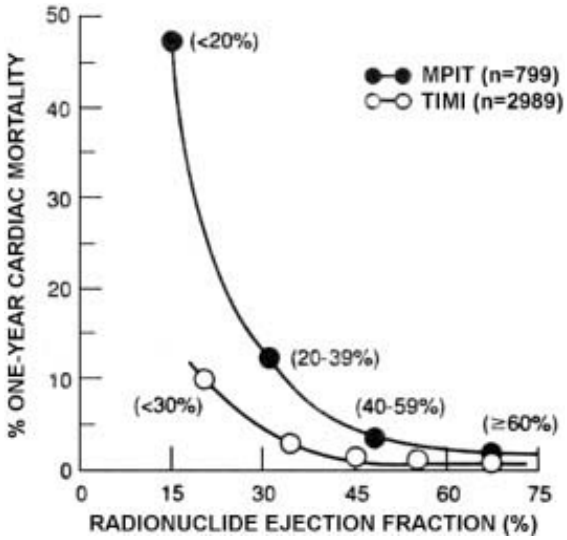

Figure 16-24: One-year mortality rates after acute myocardial infarction as function of left ventricular ejection fraction at rest. Data are shown from Multicenter Postinfarction Trial (MPIT) a decade ago and compared with more recent Thrombolysis in Myocardial Infarction (TIMI) II Trial. (From the Multicenter Postinfarction Research Group,[316] with permission.)

SELECTION OF INITIAL THERAPY

An important application of myocardial perfusion scintigraphy in acute ischemic syndromes is the selection of the appropriate therapy for patients with a known ischemic syndrome. For example, in patients presenting late (greater than 12 h) after onset of symptoms and acute MI, Christian et al. have suggested that not all patients will benefit from reperfusion therapy but that the benefit might be predictable based on the myocardial perfusion imaging pattern at the time of admission.[318] In this regard, thrombolytic therapy or angioplasty may not be beneficial in patients with severely reduced or absent myocardial perfusion late following symptoms, but these therapies may be successful for patients with preserved myocardial perfusion (and therefore preserved myocardial viability).

It has been suggested that considerations as to whether thrombolytic therapy or PCI should be performed can be elucidated by resting myocardial perfusion scintigraphy in the following conditions: (1) patients presenting late after chest pain, as noted above, (2) patients with ST-segment depression in whom injection can be made during chest pain (those with severe reduction in flow would be candidates for thrombolytic therapy or PCI, whereas those without decrease in flow would not be good candidates). Additionally, (3) patients with LBBB, in whom thrombolytic therapy or PCI are generally recommended, could most likely be better classified for therapy on the basis of resting myocardial perfusion scintigraphy rather than through the use of clinical criteria alone. None of these applications have been well studied by randomized trials, but they remain interesting potential clinical applications.

EVALUATION OF THERAPY

It has by now been well demonstrated that myocardial perfusion scintigraphy is useful in the assessment of therapeutic efficacy for patients undergoing thrombolytic therapy or percutaneous transluminal coronary angioplasty (PTCA). Maddahi et al. first demonstrated this application using ^{201}Tl planar scintigraphy in the early 1980s.[319,320] Subsequently, Gibbons et al.[321] reported similar findings using ^{99m}Tc sestamibi. On the basis of extensive work by that group of investigators, myocardial perfusion scintigraphy can be used in patients with acute MI before and after therapy (or even simply after therapy) and represents an efficient, less expensive endpoint for examining the efficacy of a variety of therapies compared to conventional mortality endpoints.

ASSESSMENT OF MYOCARDIAL VIABILITY

In the setting of acute MI, at times it becomes clinically important to assess the viability of abnormally contracting segments. In this regard, it has become important to recognize the high frequency of myocardial stunning that occurs in the setting of an aborted acute MI. Since the earliest thrombolytic trials, it has been clear that severe and extensive wall motion abnormalities and severe reduction of LV function can be associated with the stunned myocardium when thrombolytic therapy or PTCA is applied early enough to abort the development of myocardial necrosis. Although the return of ventricular function may be delayed by up to several months, the degree of improvement in ventricular function can be dramatic. In this regard, the finding of normal or nearly normal perfusion after initial therapy (thrombolytic therapy or PTCA) can be used to accurately predict the return of ventricular function in a patient with an acute ischemic syndrome, whereas ongoing resting ischemia might indicate the need for urgent revascularization.[321a]

Discharge Planning Post-Unstable Angina

Guidelines developed under the sponsorship of the Agency for Health Care Policy Research (AHCPR) have indicated a clear role for the use of nuclear testing in patients admitted with unstable angina.[291] Although at the present time most patients admitted with unstable angina are referred to catheterization, the guidelines suggest that a significant number of these patients should be medically treated after appropriate risk stratification. This strategy is applicable to patients who respond quickly to medical therapy, particularly in the presence of concomitant conditions that increase the risk of or decrease the likelihood of using an invasive strategy (e.g., very advanced age or debilitation). In these medically stabilized patients, either exercise or pharmacologic stress testing with perfusion imaging can effectively stratify patients into low- and high-risk subsets, as demonstrated by a number of studies.[291] Failure of medical treatment to control ischemia or the presence of hemodynamic instability would result in referral to catheterization. Hemodynamically stable patients with medically controlled ischemia would be candidates for a noninvasive management approach. Within this approach, those patients at low risk by clinical factors (patients who probably did not have unstable angina initially) can be managed as outpatients and referred to stress testing within 72 h of initial admission. Patients at intermediate to high risk who have been pain-free for 48 h and have no recurrent angina, LV dysfunction, or significant ventricular dysrhythmias are also candidates for in-hospital noninvasive risk stratification. The initial test on these patients could be treadmill ECG testing in those individuals with normal resting ECGs who are not on digoxin and are able to perform exercise. Patients with abnormal rest ECGs or on digoxin would undergo exercise or pharmacologic stress imaging; those patients unable to exercise would undergo pharmacological stress imaging. Either of these latter two groups are also potential candidates for stress echocardiographic studies. The decision between stress echocardiography and stress perfusion imaging would be guided by test availability and local expertise. For hospitalized patients with acute unstable angina, the 1994 AHCPR guidelines reported annual rates of cardiac death or MI of

3 percent for patients with normal test results as compared with 18 percent event rates for patients with high-risk nuclear scan results.[291]

Discharge Planning after Uncomplicated Acute MI

Practice guidelines in the United States have indicated that stress testing (with or without imaging) can be effective in risk stratification and guiding subsequent management of hospitalized patients without acute MI in whom the clinical indications of high risk are not present.[291] This suggestion is based on the results of several clinical trials. For example, in the TIMI-IIB study of 1681 patients assigned to early catheterization and 1658 patients assigned to "watchful waiting" strategies following acute MI with thrombolysis, there was no significant difference with respect to cardiac death, MI, or anginal status. Of importance, these excellent outcomes with "watchful waiting" were obtained without any standardized approach to the use of noninvasive testing.[218] Recently, the results of the Veterans Affairs non Q-Wave Infarction Strategies in Hospital (VANQWISH) trial provided similar data for patients with non Q-wave MI.[322] Common clinical thought had been that patients with non-Q-wave MIs were more likely to have a subsequent acute event and should require more aggressive management when compared to patients with Q-wave MIs. Nonetheless, this supposition was not borne out by the VANQWISH study. A total of 920 patients were randomly assigned to "invasive" (462 patients) versus "conservative" (458 patients) management. The invasive management included early catheterization performed a median of 2 days following MI (see Chap. 41). The conservative management included the use of RNA and predischarge symptom-limited exercise ^{201}Tl study or dipyridamole ^{201}Tl study. Catheterization was recommended if recurrent angina developed with ECG changes (>2-mm ST-segment depression on exercise testing), if there were two or more reversible defects on the ^{201}Tl study, or if increased ^{201}Tl uptake was observed.[355] The probability of event-free survival was higher in patients undergoing conservative therapy than in patients undergoing the invasive therapy approach.

Despite these findings, there is discordance between the practice guidelines and the actual practice in the United States. Mark et al. reported that 72 percent of patients following acute MI underwent early catheterization in the United States, compared to only 25 percent of patients in Canada. Interestingly, there was no significant difference in 1-year mortality rates between the two countries.[323] Topol et al. have noted that only 9 percent of patients undergoing PTCA after a recent MI had stress testing prior to their angioplasty.[324a]

Both exercise[324a] and pharmacologic stress testing postmyocardial infarction has also shown to effectively identify patients at low and high risk of subsequent events.[325,326] With respect to perfusion scintigraphy, it should be noted here that the post-MI application is one in which the use of pharmacologic stress over low-level nuclear stress testing may be particularly advantageous. Although either type of stress would be recommended by the guidelines, our preference is to use pharmacologic stress. The reasons are as follows: (1) pharmacologic stress does not require that the patient be able to exercise; (2) it can be easily and safely employed as early as 2 days following MI[327,328]; (3) it lowers rather than raises blood pressure, avoiding the potential problem of myocardial rupture; and (4) it produces a maximal hyperemic stimulus, thereby obviating the need for maximal stress testing after recovery.

In studies performed in the postthrombolytic era by Mahmarian and colleagues suggested that adenosine thallium SPECT is effective in stratifying patients in the post-MI period.[325,329] In the most recent study, they also showed that there is incremental value in knowing the LVEF as well as the extent of jeopardized myocardium, as determined by equilibrium radionuclide angiography and adenosine ^{201}Tl myocardial perfusion SPECT.[329] These same investigators have demonstrated the value of adding LVEF to exercise myocardial perfusion SPECT.[325] As

described above, these assessments can now be made with a single study using gated myocardial perfusion SPECT. Assessment of increased lung uptake of radioactivity during myocardial perfusion scintigraphy has also been shown to be of prognostic significance in patients with acute syndromes of unstable angina and non-Q-wave MI.[330] Overall, myocardial perfusion test results which have been demonstrated to indicate high risk (and thus the need for angiography) in the predischarge patient include reversible defects in the MI zone, a multivessel defect pattern, large nonreversible defects, transient left ventricular dilation, increased lung uptake, and reduced left ventricular ejection fraction.[330a]

A recent landmark multicenter randomized trial has been reported comparing submaximal ^{99m}Tc sestamibi SPECT at discharge to early dipyridamole ^{99m}Tc sestamibi SPECT performed 2 to 4 days after acute MI.[331] A total of 451 patients presenting with first acute MI were randomized in a 3:1 ratio to either (1) an early (days 2 to 4) dipyridamole ^{99m}Tc sestamibi SPECT and a predischarge (days 6 to 12) submaximal exercise ^{99m}Tc sestamibi SPECT or (2) only the predischarge study. The very early use of dipyridamole testing was associated with no adverse events, indicating the safety of this approach in appropriately selected post-MI patients. Multivariate predictors of in-hospital events included the summed stress score and summed reversibility scores, derived using a 17-segment model with the same 0-to-4 scale described above,[56,66] as well as peak creatine kinase levels. For postdischarge cardiac events, the multivariate predictors in patients undergoing dipyridamole sestamibi SPECT were the SSS, the summed reversibility score, the summed rest score, and anterior MI. Dipyridamole sestamibi imaging showed better risk stratification than submaximal exercise myocardial perfusion imaging (Fig. 16-25). Importantly, the submaximal exercise ECG had no significant predictive value for cardiac events. Interestingly, the ability to separate low- and high-risk subsets by use the of the SSS in early dipyridamole sestamibi SPECT was significantly better for patients who received thrombolysis than for those who did not (Fig. 16-26).

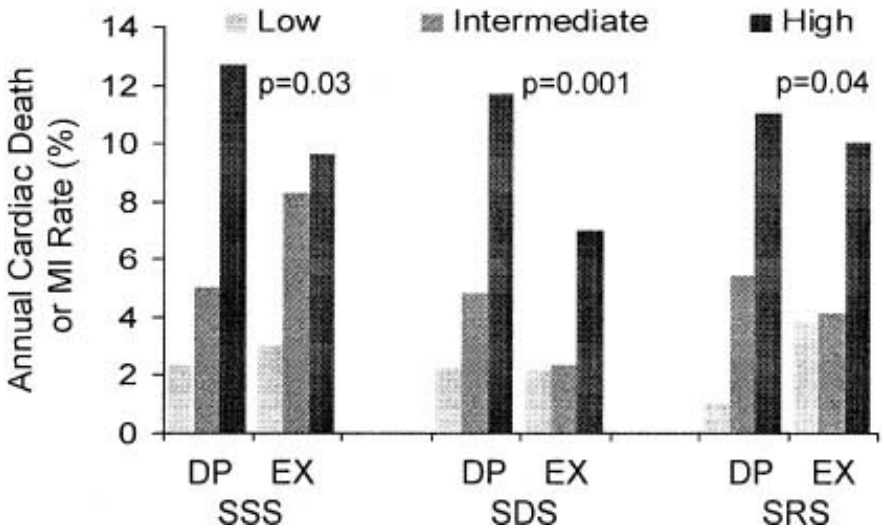

Figure 16-25: Annual cardiac death rate or recurrent MI rate as a function of SSS, SDS, and SRS for dipyridamole (DP) and submaximal exercise (EX) 99mTc sestamibi SPECT imaging. Event rate increased as scores increased. The ability to predict cardiac events was better for dipyridamole studies than for exercise studies for each summed score (*p* value depicted). All event rates are derived from risk-adjusted Cox survival curves. Intermed indicates intermediate. (From Brown et al.,[321] with permission.)

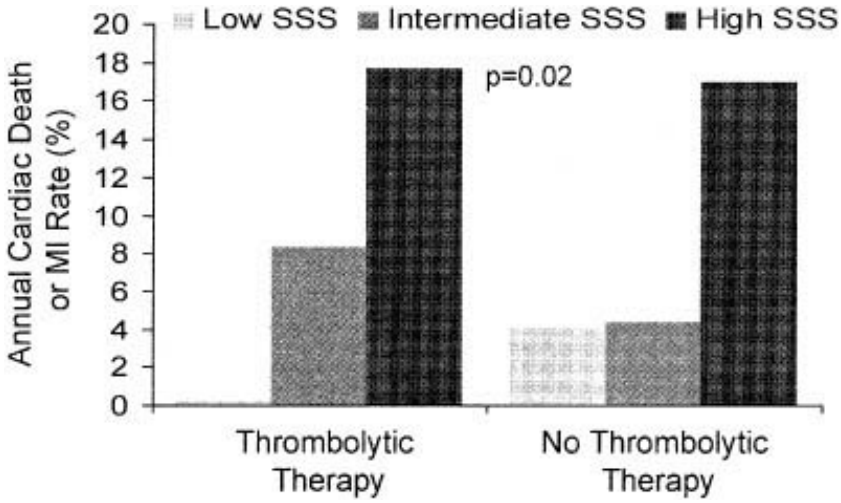

Figure 16-26: Annual cardiac death or MI rate as a function of SSS and thrombolytic therapy. The predictive value of SSS was greater for patients receiving thrombolysis (p = 0.02). (From Brown et al.,[331] with permission.)

The investigators found a significant interaction between the degree of reversibility on dipyridamole sestamibi imaging (SDS) and the overall stress perfusion defect size (SSS) (Fig. 16-27). In the low and intermediate summed stress score groups, the annual cardiac death or nonfatal infarction rate was low when the SDS was low (0 to 2). The event rate in patients with intermediate SSS (5 to 8) increased to 6 percent in patients with intermediate SDS (3 to 7) and to 17 percent in patients with high SDS (greater than 7). In patients with high SSS (greater than 8), the cardiac event rate was high regardless of the extent of defect reversibility by SDS. The authors concluded that the dipyridamole sestamibi scanning very early after MI predicts early and late cardiac events, with superior prognostic value compared with submaximal exercise testing. They suggested that the technique can allow management decisions to be made earlier in patients with acute MI, with potentially significant cost implications associated with earlier discharge of low-risk patients.[331]

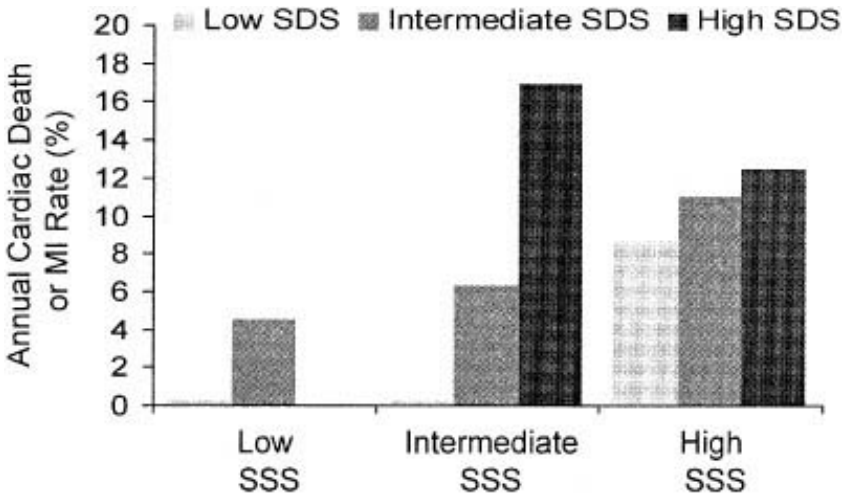

Figure 16-27: Annual cardiac death or MI rate as a function of SDS for a given SSS. For each SSS subgroup, cardiac event risk increased as SDS increased. The effect of SDS was greatest in the intermediate (intermed) SSS group. (From Brown et al.,[331] with permission.)

The potential of this early hospital discharge summary was discussed in an accompanying editorial.[332] The editorial points out that intervenous adenosine may be preferable to dipyramole in the very early post-MI patient owing to its very brief half-life; it also suggests that if a management strategy based on the results of this study were widely adopted, substantial cost savings could be realized in appropriate patients populations. Recent work of Dakik et al.[236] suggests that the approach to medical therapy might safely be extended to patients considered to be at moderate to even high risk following acute MI, with serial nuclear studies providing the basis for initial selection of therapy as well as for subsequent assessment of its effectiveness and consideration for therapeutic change.

It is anticipated that these results will be integrated into the future guidelines for the management of patients with acute MI.

One of the major dilemmas in post-MI patient management is the timing and use of cardiac catheterization. Conceptually, a conservative patient management approach of "watchful waiting" for provocative ischemia or recurrent symptoms could result in worse outcomes, while at the same time an aggressive approach to care (i.e., early and direct catheterization) might result in more expensive care without an improvement in outcomes.[218] In fact, the challenge for clinicians caring for acute MI patients is to identify the balance between extra clinical benefits and extra costs. Currently, routine catheterization is performed in the vast majority of patients with acute MI.[218] An alternate strategy that has been advocated in several recent national guidelines is to refer to catheterization (with consideration of early revascularization) only when clinically necessary and to use noninvasive testing to selectively identify patients for catheterization.[219] From the recent American College of Physicians (ACP) guidelines for risk stratification after MI, a 3 to 5 day assessment of ventricular function for patients with an uncomplicated hospital course is recommended.[219] For patients with preserved systolic function, a vasodilator stress myocardial perfusion SPECT early (i.e., days 2 to 4)[331] in the course of care of the uncomplicated MI patient may provide important information regarding residual risk as well as reassurance to the patient and family regarding their risk of cardiac events during the year following discharge.[219] This approach may also allow for the early discharge of appropriate low-risk patients with acute myocardial infarction, potentially as early as three to five days following admission (Fig. 16-28).

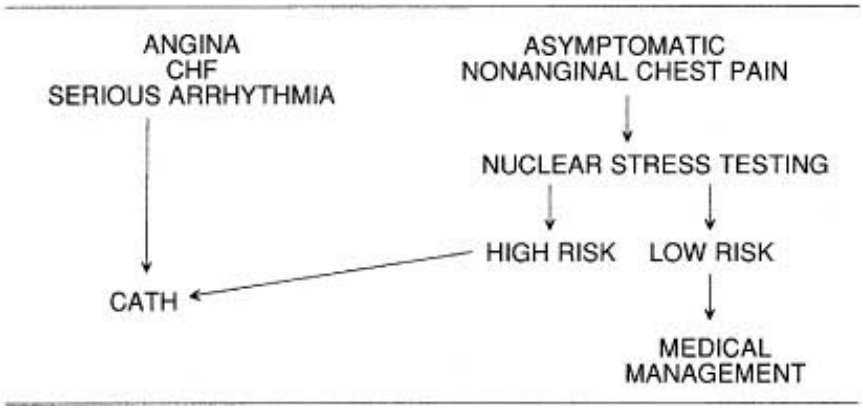

Figure 16-28: Management strategy for the use of nuclear stress testing in patients recovering from acute MI. Cath = catheterization; CHF = congestive heart failure.

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 17:

COMPUTED TOMOGRAPHY OF THE HEART

Author: John J. Mahmarian

Computed tomography has emerged as a technique that can fully evaluate both cardiac structure and function. Recent advances in imaging speed have allowed for more complete evaluation of relatively stationary structures, such as the thoracic aorta, and rapidly moving structures, such as the myocardium. When combined with electrocardiographic (ECG) gating, literally "freeze frame" images of the heart can be obtained, obviating most of the blur caused by motion artifact during systole and diastole. This is particularly important when obtaining contrast-enhanced images of the coronary arteries or quantifying coronary artery calcium.

Two types of computed tomographic (CT) scanners are currently available for performing cardiac evaluations. Continuously rotating spiral CT scanners can acquire images within 500 ms, whereas exposure times have been markedly reduced to 50 ms with the advent of electron-beam computed tomography (EBCT).

TECHNICAL CONSIDERATIONS

Spiral Computed Tomography

Traditional CT scanners produce images by rotating an x-ray tube around a circular gantry through which the patient passes on a table. With spiral CT scanners, the x-ray tube rotates continuously as the table moves through the gantry without the need for incremental stops. The x-ray tube can make one revolution around the patient in less than 1 s, and the table can advance through the gantry to acquire up to two slices per second. Further improvements in spiral CT technology have increased the number of images that can be obtained through each revolution of the x-ray beam, thus shortening total acquisition times at any given slice thickness.

The actual rotation of the x-ray tube is limited, however, by its mechanical movement around the patient. Therefore, imaging time is still currently limited to at best 500 ms. When imaging the constantly moving myocardium and coronary arteries, faster acquisition times are required to avoid image blur, even when ECG gating is employed.

EBCT

EBCT uses an electron beam of 130 kV that is deflected via a magnetic coil and focused to strike a series of four tungsten targets located beneath the patient (Fig. 17-1). The electron beam is magnetically swept along the tungsten targets at a 210° arc. Each target ring is separated by a distance of 4 mm. The resulting x-rays generated beneath the patient are then attenuated as they pass through the thorax and recorded by a series of two twin fixed detector arrays arranged in a semicircle above the patient. Imaging is complete within 50 ms, which is the time required for the electron beam to sweep along the tungsten targets. With a 100-ms acquisition time, a "freeze frame" image of the myocardium and coronary arteries in end-diastole can be achieved with little, if any, motion blur.

EBCT is commonly operated using three different acquisition modes. The *cine mode* creates real-time cross-sectional views of the beating heart and is commonly used to assess both global and regional right ventricular (RV) and left ventricular (LV) function (Fig. 17-2). The *volume mode* allows acquisition of a single image with each preselected movement of the patient couch. Up to 40 continuous slices can be obtained scanning 12 to 32 cm of anatomy (Fig. 17-3). This imaging mode is commonly gated to the electrocardiogram to obtain high-resolution static images for detailed evaluation of cardiovascular anatomy, such as coronary artery calcification (see also Chap. 40). The *triggered (flow) mode* is used to assess blood flow through specific cardiac chambers and the myocardium itself. This mode allows acquisition of some 20 to 40 consecutive scans, where imaging occurs at a designated time during each cardiac cycle. From these consecutive scans, time-density curves can be constructed that can estimate blood flow through specific cardiac chambers and within the myocardium.

Chapter 17: COMPUTED TOMOGRAPHY OF THE HEART

EVALUATION OF MYOCARDIAL STRUCTURE AND FUNCTION

Both the left and right ventricles are well visualized by spiral computed tomography and EBCT, allowing excellent spatial separation between the two structures. Delineation of the epicardial and endocardial surfaces allows accurate and reproducible measurement of LV and RV wall thickness and myocardial mass.[1-3] LV hypertrophy can be quantified and serially assessed. RV dysplasia is accurately diagnosed based on the characteristic EBCT findings of an enlarged right ventricle with a scalloped appearance, trabeculations with low attenuation characteristics, and abundant epicardial adipose tissue.[4]

EBCT can assess LV and RV hemodynamics[5] as well as regional myocardial wall motion and thickening.[6-8] The cine mode is used to acquire multiple gated images of the right and left ventricles during maximal contrast enhancement of the cavities.[7,8] This affords accurate and reproducible quantification of LV and RV end-diastolic and end-systolic volumes and ejection fraction.[5,7] EBCT is comparable with first-pass radionuclide angiography for calculation of left ventricular ejection fraction (LVEF) in patients with myocardial infarction[9] (Fig. 17-4). Serial changes in RV and LV volumes and diastolic parameters are well defined in patients following acute myocardial infarction.[10-12] Ventricular remodeling can be assessed by using EBCT in a similar fashion to gated blood pool radionuclide angiography[13,14] and echocardiography.[15] Cine EBCT can identify wall thinning and impaired LV thickening in an area of previous myocardial infarction[16] and delineate the presence of anterior and posterior LV aneurysms and associated mural thrombus[17,18] (Fig. 17-5).

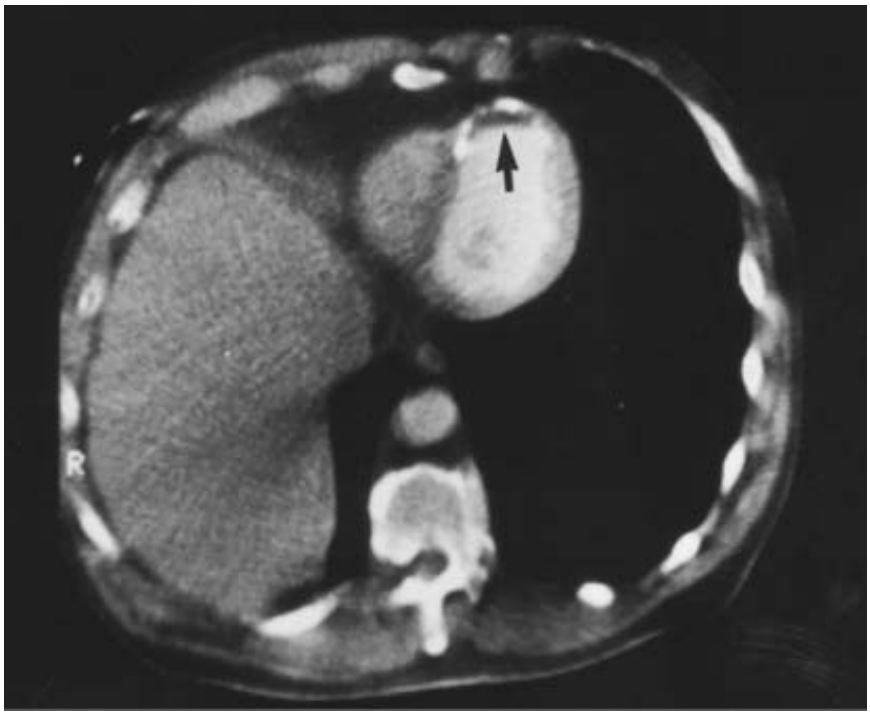

Figure 17-5: A single frame from a contrast-enhanced cine CT scan demonstrates thrombus in a LV aneurysm. Also note that the wall of the aneurysm is calcified.

Stress-rest EBCT imaging has been used to detect underlying ischemic heart disease based on changes in global LVEF and regional wall motion. One *small* study compared semisupine bicycle exercise contrast-enhanced EBCT with ^{99m}Tc myocardial perfusion single-photon-emission computed tomography (SPECT) in patients with suspected coronary artery disease (CAD), all of whom underwent angiography.[7] An abnormal EBCT study was defined as a less than 5 percent increase in LVEF during exercise. The sensitivity and specificity of exercise EBCT for detecting CAD were 81 and 76 percent, respectively, when using the global LVEF criteria for abnormalcy but improved to 88 and 100 percent when regional wall motion abnormalities were considered. EBCT was as accurate as ^{99m}Tc SPECT in the diagnosis of CAD.

Although echocardiography generally is used to assess valvular heart disease, EBCT is an alternative modality in patients with poor acoustic windows. In patients with mitral or aortic regurgitation, EBCT can accurately determine LV and RV stroke volumes and thereby calculate valvular regurgitant fractions.[5,19] When contemplating possible need for valvular surgery, EBCT can delineate the important parameters of LV chamber size, wall thickness, and LVEF. As with gated blood pool radionuclide angiography, EBCT cannot distinguish mitral from aortic regurgitation and cannot calculate the regurgitant fraction if significant right-sided valvular regurgitation is present. One of the complications of mitral valve disease is the development of left atrial thrombi. *One study* showed greater accuracy of EBCT as compared with transthoracic echocardiography in demonstrating left atrial thrombi.[20] Whether EBCT can detect thrombi as well as transesophageal echocardiography remains to be determined.

Chapter 17: COMPUTED TOMOGRAPHY OF THE HEART

EVALUATION OF CAD

Detection of Coronary Artery Calcification

For the detection of coronary artery calcium with EBCT, typically 40 consecutive 3-mm-thick images are acquired at a rate of 100 ms per image from the base of the heart to just below the carina. Images are obtained at end-inspiration with ECG triggering at 80 percent of the RR interval (end-diastole). A calcified lesion generally is defined as either two or three adjacent pixels (0.68-1.02 mm^2 for a 512^2 reconstruction matrix and a camera field size of 30 cm) of greater than 130 Hounsfield units (HU). Each calcified lesion is multiplied by a density factor as follows: 1 for lesions with a maximal density between 130 and 199 HU, 2 for lesions between 200 and 299 HU, 3 for lesions between 300 and 399 HU, and 4 for lesions greater than 400 HU. The total coronary artery calcium score (CACS) is calculated as the sum of each calcified lesion in the four main coronary arteries over all the consecutive tomographic slices (Fig. 17-6).

With spiral computed tomography, consecutive 3-mm-thick images are acquired at a rate of two contiguous 2.5-mm slices per second. ECG gating generally is not employed. Calcified lesions are defined as those with a tomographic density greater than 90 HU (2 standard deviations above blood density) with an area greater than 0.5 mm^2. A modified density factor is used: 1 for lesions of 90 to 199 HU, 2 for lesions of 200 to 299 HU, 3 for lesions of 300 to 399 HU, and 4 for lesions greater than 400 HU. As with EBCT scoring, the total CACS is calculated as the sum of each calcified plaque over all the tomographic slices.

To date, only 1 small study has directly compared EBCT with conventional CT scanning in patients referred for coronary angiography.[21] Thirty-seven of 42 patients had significant (>50 percent) stenosis in at least one coronary artery. A close linear correlation was observed between the CACS derived from EBCT versus conventional CT scanning ($r = 0.98$; $p < 0.0001$). There are no other published studies comparing EBCT with either conventional or spiral CT. The EBCT-derived CACS correlates with calcified areas found in individual coronary arteries as determined by histomorphometric measurements[22] (Fig. 17-7). No such data are available using conventional or spiral CT.

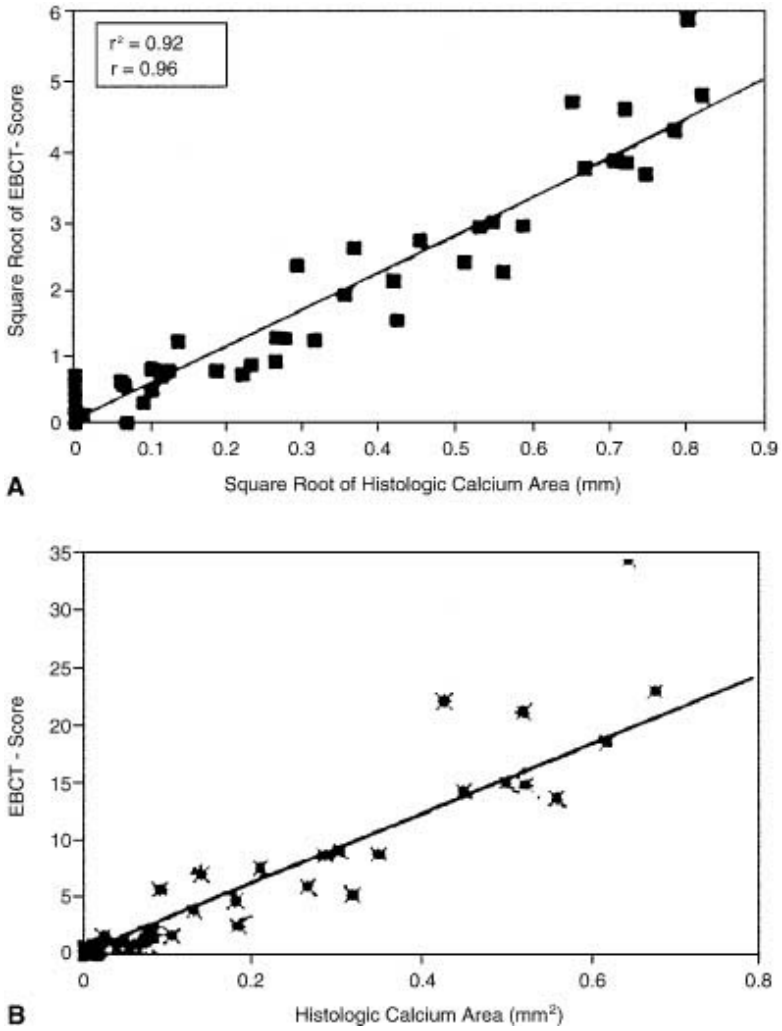

Figure 17-7: Linear regression comparing the EBCT CACS [square root transformation (*A*) and actual data (*B*)] versus the calcium area measured at histomorphometric examination. There is an apparent high positive correlation between the EBCT calcium score and histomorphometric calcium area ($r2 = 0.92$, $r = 0.96$; $p < 0.0001$). (From Mautner et al.[22] Reproduced with permission from the publisher and authors.)

Coronary Artery Calcification and Atherosclerotic Plaque Burden

The presence of coronary artery calcification is clearly indicative of coronary atherosclerosis.[23,24] Furthermore, the CACS severity, as assessed by EBCT, is directly related to the total atherosclerotic plaque burden present in the epicardial coronary arteries.[23,24] Coronary calcification begins early in life but progresses more rapidly in older individuals who have further advanced atherosclerotic lesions.[25] Calcification is an active, organized, and regulated process occurring during atherosclerotic plaque development, where calcium phosphate in the form of hydroxyapatite precipitates in atherosclerotic coronary arteries in a similar fashion as observed in bone mineralization.[26-28] Although lack of calcification does not categorically exclude the presence of atherosclerotic plaque, calcification occurs exclusively in atherosclerotic arteries and is not found in normal coronary arteries. However, it does not necessarily correlate with the presence or extent of coronary artery luminal stenosis (Chap. 40).

The presence and extent of histologically determined plaque area have been compared with the total calcium area as assessed by EBCT in individual coronary arteries derived from autopsied hearts.[23] A strong linear correlation exists between total coronary artery plaque area and the extent of coronary artery calcification as found in individual hearts ($r = 0.93$; $p < 0.001$) and in individual coronary arteries ($r = 0.90$; $p < 0.001$) (Fig. 17-8). However, the total calcium area underestimates total plaque area, with approximately five times as many noncalcified as calcified plaques.[23]

Coronary Artery Calcification and Stenosis Severity

Significant (>50 percent) coronary artery stenosis by angiography is associated with the presence of coronary artery calcium as assessed by EBCT. *Stenosis severity is not directly related to the total CACS, however*. A recent study compared calcium extent with coronary artery luminal diameter stenosis determined by morphologic examination of 723 coronary artery segments.[24] Although coronary stenosis severity increased with increasing coronary artery calcification, this relationship was poor and could not be used to estimate angiographic stenosis severity on a segment-by-segment basis (Fig. 17-9). One explanation is that coronary artery diameter increases with increasing plaque burden so as to maintain luminal patency.[29,30] Noncalcified plaques are usually associated with less than 50 percent diameter stenosis and typically less than 20 percent stenosis.[24] These data indicate that lack of coronary calcification predicts a very low likelihood of obstructive CAD.

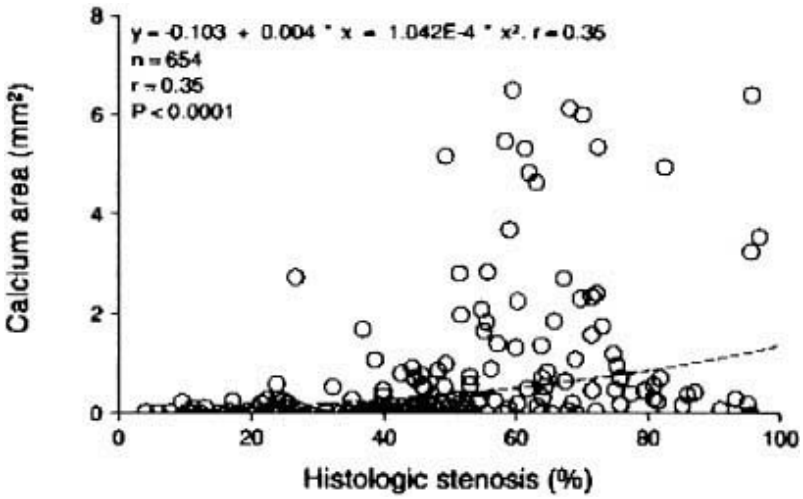

Figure 17-9: Graph showing the polynomial regression analysis of coronary calcium area (mm2) versus percent histologic stenosis for 654 coronary artery segments with calcium greater than 0 mm2. (From Sangiorgi et al.[24] Reproduced with permission from the publisher and authors.)

Clinical angiographic trials confirm the relationship between CACS severity and the presence of significant (≥50 percent) CAD.[31-42] Although the diagnostic accuracy of EBCT improves with age, most younger patients (<50 years) with obstructive CAD also have coronary calcification (85 percent).[37,39] To date, there are 12 studies evaluating EBCT with coronary angiography where obstructive CAD was defined as greater than 50 percent luminal diameter stenosis[31-42] (Table 17-1). In these studies, the overall sensitivity and specificity for detecting obstructive CAD are 95 and 43 percent, respectively. *The poor specificity* of EBCT can be reconciled by the fact that the presence of coronary artery calcification confirms the presence of atherosclerotic plaque that may not necessarily be obstructive in nature. The CACS severity may be a better barometer of obstructive CAD than the mere presence of calcium. Budoff et al.[37] observed that specificity increased with the number of calcified coronary arteries (i.e., high calcium scores). Two separate reports in patients referred for coronary angiography found that a CACS of more than 100 best predicted obstructive CAD with an equally high sensitivity and specificity of 80 percent.[43,44] There appears to be a threshold CACS above which most patients will have significant coronary artery stenosis. However, despite the relationship between obstructive CAD and CACS severity, *the latter is still too imprecise in itself to be used as a definitive criterion for proceeding directly to coronary angiography*. The current ACC/AHA guidelines on coronary angiography do not recommend coronary angiography on the basis of a positive EBCT.

Distinguishing Ischemic from Nonischemic Conditions with Computed Tomography

The presence or absence of coronary artery calcification by EBCT may help to distinguish patients with ischemic versus nonischemic dilated cardiomyopathy.[45,46] In one study, 44 of 53 patients without significant (>50 percent stenosis) CAD (83 percent) had a CACS of 0, whereas 71 of 72 (99 percent) with CAD had an abnormal EBCT study. Importantly, 44 of 45 patients with a normal EBCT had nonischemic dilated cardiomyopathy (98 percent negative predictive value). The total CACS increased with the extent and severity of underlying CAD (Fig. 17-10). Differentiating ischemic from non-ischemic dilated cardiomyopathy also has been demonstrated with spiral computed tomography.[46]

EBCT may be able to distinguish ischemic versus nonischemic chest pain in patients presenting to the emergency room with nondiagnostic electrocardiograms.[47] In one series, none of 47 patients with a normal EBCT had a subsequent cardiac event over a 1-month period. Conversely, 7 of 86 patients (8 percent) who had coronary calcification had a subsequent myocardial infarction ($n = 4$) or revascularization procedure ($n = 3$). The high negative predictive value of EBCT, despite its low positive predictive value, may improve triage of patients with questionable ischemic symptoms.

In two recent reports, most asymptomatic patients who had a subsequent first acute myocardial infarction had coronary calcification by EBCT (96 percent).[41,48] Since many acute myocardial infarctions occur following rupture of nonobstructive plaques, it is not surprising that the CACS will be mild (<100) in a large percentage (34 percent) of patients and severe (>400) in relatively few (27 percent).[48] In one study evaluating survivors of a first myocardial infarction with spiral CT, 19 percent lacked coronary artery calcification.[49] This higher percentage of normal studies may reflect the lower sensitivity of spiral CT as compared to EBCT for detecting calcium. Patients without calcium generally are younger in age and tend to be active smokers.[48,50] With the exception of young smokers, a normal EBCT defines a population at low

likelihood for significant CAD and subsequent acute cardiac events. *Larger prospective trials in patients with acute coronary syndromes are needed to further delineate the role of EBCT in this population*.

Coronary Artery Calcification: Prognostic Implications

The likelihood of plaque rupture and the development of acute cardiovascular events is related to the total atherosclerotic plaque burden.[51,52] Since there is a direct relationship between the CACS severity and the extent of atherosclerotic plaque, the calcium score should predict risk for subsequent cardiovascular events among otherwise heterogeneous patient populations with cardiac risk factors even though most plaques vulnerable to erosion or fissure resulting in plaque rupture contain minimal calcium.[52a] In a study by He et al.,[53] the CACS severity identified a high-risk group of asymptomatic subjects who had silent myocardial ischemia. In fact, the total CACS was the best single predictor of an abnormal stress SPECT study. Many studies have now demonstrated an increased risk for cardiac events in asymptomatic patients who have extensive silent myocardial ischemia.[54-58] Since the total CACS severity predicts the presence of significant anatomic CAD and myocardial ischemia, it could be useful for risk assessment of asymptomatic individuals and potentially guide therapeutics.

Several recent trials have studied whether the extent of coronary artery calcification as assessed by EBCT can predict subsequent patient outcome. In an early series by Secci et al.,[59] 324 initially asymptomatic subjects were followed for 32 ± 4 months. Eleven patients died or had a nonfatal myocardial infarction (3.3 percent), and an additional 12 patients (3.7 percent) underwent coronary revascularization. A threefold higher event rate was observed in patients in the highest quartile of CACS (>506). In another report from the same group, 1196 asymptomatic patients were followed for 41 ± 5 months after undergoing EBCT.[60] Subjects with a CACS of greater than 44 (median value in this trial) were 2.3 times more likely to suffer myocardial infarction or cardiovascular death as compared with subjects with lower scores. Patients were enrolled only if they had greater than 10 percent risk for developing cardiovascular events over an 8-year period, as determined by the Framingham risk model. In this group at relatively high pretest clinical risk for cardiovascular events, the CACS results did not add to the Framingham risk model for predicting patient outcome.

Arad et al.[61] followed 1173 asymptomatic patients for 19 months after an initial screening EBCT. During follow-up, 18 patients (1.53 percent) had 26 cardiac events, including *1 death, 7 nonfatal myocardial infarctions,* and 17 coronary revascularization procedures. No events occurred in patients with a normal study, and the negative predictive value was 99.8 percent in patients with a CACS of less than 100. The positive predictive accuracy for cardiac events increased as the CACS increased from greater than 100 (5.5 percent) to 160 (7.1 percent) to greater than 680 (14 percent). Callister et al.[48] also reported similar data on 632 asymptomatic patients who were *referred* for a screening EBCT and then followed for 32 ± 7 months. In this study, both the absolute CACS and the age- and gender-adjusted relative CACS percentiles predicted subsequent hard cardiac events of death and nonfatal myocardial infarction. Hard cardiac events occurred in only 0.3 percent of subjects with a normal EBCT, but this increased to 13 percent in those with a CACS of greater than 400. Likewise, in patients in the lower 50th percentile for CACS severity based on age and gender, the total cardiac event rate was only 1.1 percent compared with 8.2 percent for patients with a CACS greater than the 50th percentile (Table 17-2). In the studies of both Arad et al. and Callister et al., there were no adjusted estimates of outcome.[52,61a]

Table 17-2: Cardiac Event Rates in Asymptomatic Subjects Based on Absolute and Relative Coronary Artery Calcium Scores

Absolute Calcium Score	Event Rate, Death/NFMI
0	0.3% (1/292)
1-99	5.5% (12/219)
100-400	10.8% (8/74)
>400	12.8% (6/47)
Calcium Score Percentile	
<50th	1.1% (4/351)
>50th	8.2% (23/281)
>75th	10.5% (19/181)
>90th	11.8% (11/93)

ABBREVIATIONS: NFMI = nonfatal myocardial infarction.
SOURCE: From Callister et al.[48] Adapted with permission of the publisher and authors.

The exceedingly low cardiac event rate in subjects with a CACS of less than 100 is consistent with angiographic studies indicating a comparably low likelihood of significant CAD and an extremely low incidence of stress-induced myocardial ischemia (1.5 percent) in such individuals.[53] The increasing number of cardiac events with an ever-increasing CACS is also consistent with the dramatic increase in the incidence of stress-induced myocardial ischemia when scores are greater than 100 and particularly greater than 400.[53] All these data in asymptomatic patients indicate a potential role of EBCT in screening subjects for subclinical CAD. However, enrollment in prognostic studies primarily has been limited to Caucasian men. Whether the CACS severity has similar prognostic value in other patient populations remains unclear.[62] Since cardiac event rates are known to be very low in asymptomatic individuals with cardiac risk factors[57,61,63-66] (Table 17-3), large prospective trials in patients of greater ethnic diversity, followed for a longer period of time, will be needed to further clarify the value of EBCT in risk stratification.[67]

Screening for CAD Using EBCT

One of the most novel applications of EBCT may be as a screening test for identifying subjects with subclinical CAD based on the presence and severity of coronary artery calcification (for contrary view see Chap. 40). This is particularly true in view of recent primary prevention trials demonstrating that aggressive risk factor modification, including treatment of hyperlipidemia, reduces the incidence of subsequent cardiac events.[64,68]

RISK FACTOR ANALYSIS

Traditional risk factor analysis is commonly used to identify individuals who are at increased risk for developing cardiovascular disease based on standard clinical criteria.[69,70] Implicit to this risk model is the assumption that a certain combination of risk factors will promote atherosclerosis, which, in turn, will result in cardiovascular events. However, among individuals with a similar risk factor profile, the presence and severity of atherosclerosis will vary enormously; thereby overestimating risk in certain subjects and underestimating risk in others. This discrepancy will be most apparent among individuals with several risk factors who are members of a more heterogeneous population at risk compared with those without risk factors (a more uniformly low-risk group) or those with multiple risk factors (a more uniformly high-risk group). The imprecision of risk factor analysis for identifying patients with significant atherosclerosis is probably related to the fact that traditional risk factor analysis fails to incorporate presently unknown biochemical, environmental, and genetic factors that promote the development of CAD.

Since the development of symptomatic cardiovascular disease occurs almost exclusively in patients with atherosclerosis, it would seem advantageous in risk assessment to use a technique that directly measures the presence and severity of atherosclerotic burden rather than estimate its presence through indirect measures. For example, although there is a clear relationship between the number of cardiac risk factors and the

presence of coronary artery calcification by EBCT, in one recent series, 40 percent of men and 30 percent of women without risk factors had coronary artery calcification, whereas 26 percent of men and 36 percent of women with greater than three traditional risk factors did not.[71] Similarly, in the Healthy Women Study, risk factor analysis was imprecise at predicting coronary calcification in postmenopausal women.[72] Although the combination of a high low-density lipoprotein (LDL) cholesterol level, a low high-density lipoprotein (HDL) cholesterol level, and a history of cigarette smoking was a strong predictor of coronary artery calcification, this risk factor profile was observed in only 6 percent of all women studied. Furthermore, only 6 of 21 women with the highest calcium scores (>101) had this risk factor profile. Conversely, 20 percent of women in the lowest risk profile (i.e., nonsmokers, LDL cholesterol < 130 mg/dL, and HDL cholesterol > 60 mg/dL) had calcium by EBCT. The incorporation of EBCT calcium results into traditional risk factor analysis may improve accuracy for identifying significant obstructive CAD in symptomatic patients[44,73] and also may be helpful in excluding extensive three-vessel or left main CAD in others.[74]

SUBCLINICAL CAD DETECTION AND STRESS TESTING

Noninvasive techniques, such as exercise treadmill testing and myocardial perfusion imaging, can identify patients with coronary atherosclerosis. However, unlike EBCT, which can detect coronary atherosclerosis at its earliest stages, these techniques can only identify patients with advanced CAD who manifest myocardial ischemia. Although the presence and extent of ischemia can accurately identify asymptomatic individuals at high risk for cardiac events[55-57] (Fig. 17-11), the very low prevalence of a positive test result (<5 percent) precludes their use as primary screening tests for the early detection and treatment of CAD. In fact, both exercise treadmill testing and myocardial perfusion imaging have received a class III indication (no justification for their use) for screening asymptomatic individuals (see Chap. 40).[75,76]

EBCT AND MYOCARDIAL PERFUSION IMAGING

A recent trial explored the complementary role of EBCT and myocardial perfusion SPECT for identifying both subclinical CAD and silent myocardial ischemia in a generally asymptomatic population who had risk factors for CAD development.[53] The purpose of this study was to identify (1) patients with subclinical CAD who might benefit from aggressive risk factor modification and (2) those who are at relatively higher short-term risk for cardiac events based on the presence of silent myocardial ischemia. Among the 3895 subjects who had EBCT, 411 also underwent stress SPECT within a close temporal period (median 17 days). The mean CACS was significantly higher in the 81 subjects (20 percent) who had an abnormal (1065 ± 983) as compared with a normal (286 ± 394; $p < 0.00001$) SPECT. The likelihood of an abnormal SPECT increased dramatically with the total CACS. Whereas only 1 percent of subjects with a total CACS of less than 100 had an abnormal SPECT, this was observed in 46 percent of those with scores of 400 or higher. Only 10 percent of all 3895 subjects scanned with EBCT had a CACS of 400 or higher. Large ischemic perfusion defects were virtually confined to subjects who had a CACS of 400 or higher. Patients with large ischemic perfusion defects by SPECT are known to be at high risk for subsequent cardiac events, whereas patients with small perfusion defects or those with normal scans have an exceedingly low cardiac event rate.[55,56,77-79] Although a similar percentage of subjects had an abnormal SPECT (16.1 percent) or stress electrocardiogram (17.5 percent; p = NS), only the former was related to the total CACS (Fig. 17-12), further illustrating the poor predictive accuracy of treadmill testing for detecting CAD in asymptomatic subjects (see also Chap. 14).

In the author's opinion, the results of this study support the role of EBCT as an initial screening test for identifying subjects with varying degrees of coronary atherosclerosis and emphasize the effectiveness of selectively combining SPECT with EBCT in the anticipated small percentage of subjects who will have a high (>400) CACS so as to specifically identify those with silent myocardial ischemia (Fig. 17-13). *These results need further confirmation.* Although the cost-effectiveness of using EBCT as a screening test requires further clinical investigation, it has been proposed that the CACS may be used to guide therapeutics and recommend the need for additional diagnostic testing.[80] This approach has not been sanctioned by the ACC/AHA expert consensus document on EBCT for the diagnosis and prognosis of

CAD[81] or by the AHA Prevention V Conference[82] (see Chap. 40).

Tracking Changes in Coronary Artery Calcification

Sequential testing with EBCT may be useful in determining the rate of progression of coronary atherosclerosis[83] or in identifying treatment effects based on regression of coronary artery calcification.[84] In order for sequential testing to have any clinical relevance, the biologic changes being studied need to be greater than the intrinsic variability of the test result. Thus, if a CACS increased from 300 to 400, only by knowing the variability inherent to the test result could one determine whether this was a true patient change.

EBCT REPRODUCIBILITY

The reproducibility of EBCT has been evaluated using both the traditional Agatston scoring system[33,85-87] and a more recent volumetric calcium scoring system.[88] With the Agatston method, good inter- and intraobserver reproducibility is reported for recalculating the CACS on a single scan.[31,86] However, significant variability exists when comparing the results of two separate studies on the same patient. Devries et al.[85] studied 91 subjects who had two EBCT scans performed 24 h apart using an identical acquisition protocol. The variability in CACS observed in the 42 subjects who were abnormal on both scans was 49 ± 45 percent. Variability was inversely related to the absolute value of the CACS, being particularly great when the initial score was less than 10 (72 ± 54 percent). In a report by Bielak et al.,[33] 256 patients had two EBCT studies performed minutes apart. The mean CACS was 73 ± 233 (scan 1) versus 75 ± 242 (scan 2). Linear regression analysis showed that the two scores were highly correlated ($r = 0.962$; $p = 0.0001$). However, CACS variability was greatest particularly in patients with low scores. These studies indicate that large changes in initial CACS may be needed to be confident that a real change has occurred beyond chance alone. If one considers that the rate of progression of CACS in patients with known CAD may be less than the observed variability of the test,[83] EBCT assessments using the Agatston scoring system may not be able to track changes in atherosclerotic plaque burden.

The volumetric calcium scoring method proposed by Callister et al.[88] calculates the volume of calcified plaque area rather than generating a CACS based on an arbitrary plaque attenuation coefficient (i.e., Agatston method). This method has been shown in one study to be more reproducible than the Agatston method, with an approximately 40 percent reduction in overall variability.[88]

TRACKING CALCIUM PROGRESSION/REGRESSION

If the reproducibility of EBCT using the volumetric method is adequate, an important question is whether EBCT can be used to track the effects of pharmacologic therapy on plaque progression.[84] In a recent *retrospective* analysis with all of its limitations, Callister et al.[84] studied 149 asymptomatic hyperlipidemic patients who had no history of prior CAD or treatment of hyperlipidemia and who underwent a baseline screening EBCT. Following EBCT, treatment with a statin drug was begun at the discretion of the referring physician. Serial measurements of LDL cholesterol were obtained and correlated with the change in calcified plaque volume. Sixty-five treated patients achieved an LDL cholesterol level of less than 120 mg/dL (mean 100 ± 17 mg/dL), whereas 40 did not (mean 139 ± 18 mg/dL). In the 44 untreated patients, the mean LDL cholesterol level was 147 ± 22 mg/dL. Importantly, in the 44 untreated patients and in the 40 treated patients with an LDL cholesterol level of greater than 120 mg/dL, the calcium score increased by 52 ± 36 and 25 ± 22 percent, respectively. However, in the treated patients who achieved an LDL cholesterol level of less than 120 mg/dL, the calcium score decreased by 7 ± 23 percent. Sixty-three percent of the patients in this group had a net decrease in their calcium volume score, whereas none of the other patients had a reduction in calcium score.

These data suggest that aggressive treatment with cholesterol-lowering medication can reduce *calcified plaque burden* as assessed by EBCT. The reduction in calcified plaque burden presumably indicates a reduction in total atherosclerotic plaque, which is consistent with prior angiographic studies showing a

small, albeit significant, reduction in coronary artery stenosis severity with long-term statin therapy.[89,90]

Contrast Angiography of Bypass Grafts and Native Coronary Arteries

BYPASS GRAFTS

Contrast-enhanced EBCT can visualize both coronary artery bypass grafts[91-93] and native coronary arteries.[94-97] Initial studies using conventional CT angiography reported a sensitivity and specificity of 93 and 95 percent, respectively, for detecting graft patency when compared with coronary angiography.[98] More recently, spiral CT also has been studied for identifying bypass graft patency.[99] The sensitivity, specificity, and diagnostic accuracy for detecting graft patency were 92, 97, and 93 percent, respectively.[99] Positive predictive accuracy for graft closure was 78 percent, and the negative predictive accuracy for graft patency was 99 percent. The accurate detection of internal mammary artery grafts was somewhat lower than that for vein grafts, as was the detection of distal anastomotic sites. Studies using EBCT have likewise reported high sensitivity (89 percent), specificity (93 percent), and overall diagnostic accuracy (92 percent) for detecting bypass graft patency.[91] However, as with spiral computed tomography, EBCT cannot distinguish partially obstructive versus nonobstructed grafts, and the accuracy for assessing graft patency is worse for the right and circumflex arteries as compared with the left anterior descending coronary artery.

NATIVE CORONARY ARTERIES

EBCT also has been established as a noninvasive method for visualizing the epicardial coronary arteries.[94-97] The imaging technique is similar to that used for scanning for coronary artery calcification but requires intravenous contrast material injection. A scout scan is first performed to localize the position of the heart in the chest. The time from contrast material injection to peak contrast enhancement of the aortic root is then determined. The amount of dye administered is based on the heart rate and the number of slices desired. Forty contrast-enhanced cross-sectional images of the heart of 3-mm thickness are then obtained during full inspiration at an acquisition rate of 100 ms per image (one image per cardiac cycle). Image acquisition is gated to the electrocardiogram in a standard fashion. Using the preceding parameters and depending on the heart rate, the total imaging time is between 30 and 50 s (Fig. 17-14).

Several small series have compared EBCT with standard coronary angiography for detecting CAD[94-97] (Table 17-4). The overall sensitivity of EBCT for detecting significant (>50 percent) stenosis is 83 percent and increases to 92 percent for detecting high-grade (>75 percent) stenosis (Fig. 17-15). Specificity is also comparably high at 92 percent.

Table 17-4: Diagnostic Accuracy of Contrast Enhanced EBCT as Defined by Coronary Angiography

Study	No. of Pts	CAD Definition	ARI	Sensitivity	Specificity	Positive PA	Negative PA	Overall Accuracy
Achenbach et al.[94]	125	>75%	376/500 (75%)	69/75 (92%)	282/301 (94%)	69/88 (78%)	282/288 (98%)	351/376 (93%)
Schmermund et al.[95]	28	>50%	237/330* (72%)	31/38 (82%)	176/199 (88%)	31/54 (57%)	176/183 (96%)	207/237 (87%)
Rensing et al.[96]	37	>50%	211/259* (81%)	25/33 (76%)	168/178 (94%)	25/35 (71%)	168/176 (95%)	193/211 (91%)

Budoff et al.[97]	52	>50%	185/208 (89%)	43/55 (78%)	118/130 (91%)	43/55 (78%)	118/130 (91%)	161/185 (87%)
TOTAL	242		1009/1297 (78%)	168/201 (83%)	744/808 (92%)	168/232 (72%)	741/777 (96%)	912/1009 (90%)

ABBREVIATIONS: ARI = arteries (segments*) interpretable by EBCT; PA = predictive accuracy.

EBCT can detect high-grade restenosis after previous coronary artery angioplasty with high sensitivity (94 percent) and specificity (82 percent).[100] Most patients (96 percent) without restenosis by EBCT have comparable normal angiographic findings (Fig. 17-16).

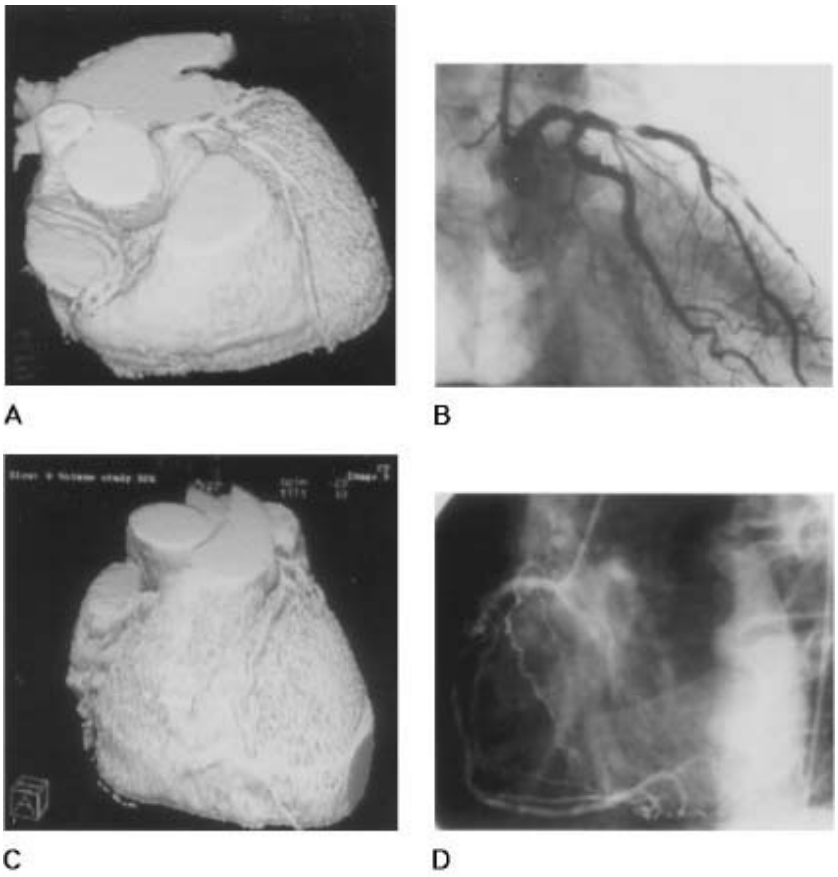

Figure 17-16: Three-dimensional EBCT reconstruction and coronary angiography depicting high-grade restenosis after coronary angioplasty of the proximal left anterior descending coronary artery (*A*, *B*) and right coronary artery (*C*, *D*). (From Achenbach et al.[100] Reproduced with permission from the publisher and authors.)

These reports are encouraging, but several points must be emphasized. EBCT *cannot* assess approximately 20 to 25 percent of all coronary arteries due to technical factors, such as respiration artifact, the presence of severe coronary calcification, and motion artifacts. Respiration artifacts can be avoided by instructing patients about proper breath-holding techniques. *Motion artifacts* are observed most commonly with the right and circumflex coronary arteries because they lie in close proximity to the atria, which contract at end-diastole. The right and circumflex arteries also lie perpendicular to the imaging plane, limiting spatial resolution. Imaging at a different time in diastole (to avoid atrial contraction), shortening acquisition time,

and imaging in different cardiac planes may obviate these problems.

Chapter 17: COMPUTED TOMOGRAPHY OF THE HEART

EVALUATION OF PERICARDIAL DISEASE

Computed tomography provides excellent visualization of the pericardium and associated mediastinal structures[101-104] (Fig. 17-17). Although echocardiography remains the primary diagnostic technique for assessing pericardial abnormalities, CT scanning can be useful, particularly when visualization of the pericardium is suboptimal with echocardiography. CT scanning can readily detect pericardial effusion and can help determine the characteristics of the fluid based on CT density.[105]

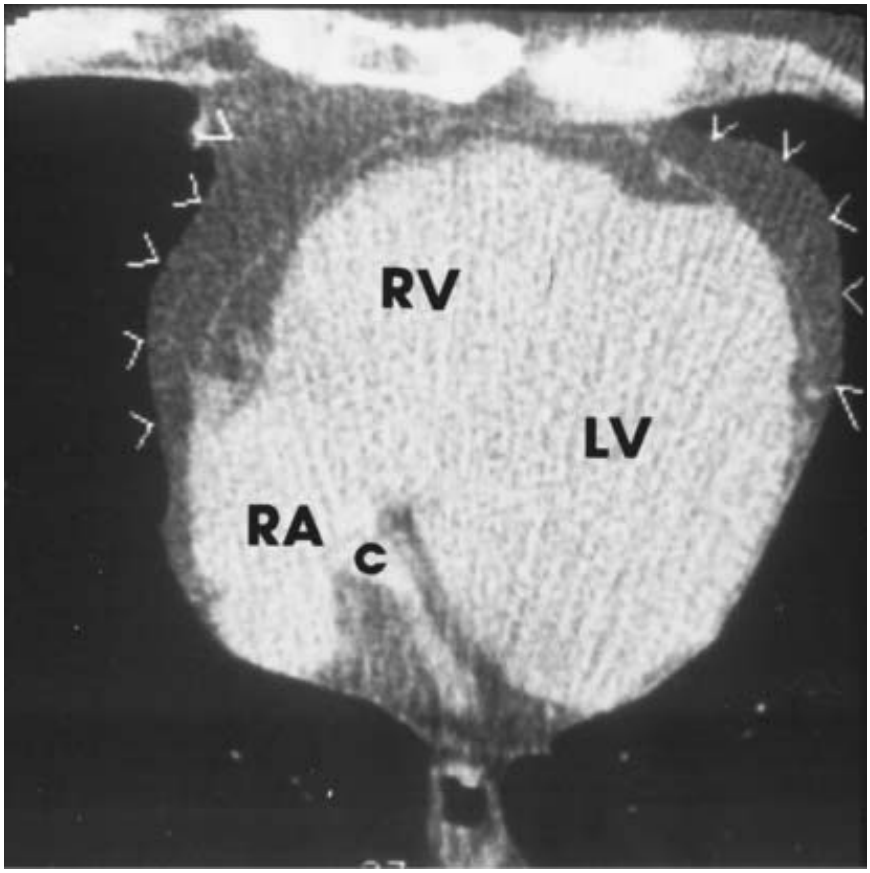

Figure 17-17: The fat that resides both inside and outside (*arrowheads*) the pericardium provides sufficient contrast to outline the normal pericardium, which is only 1- to 2-mm thick. Contrast enhancement with iodine agents is unnecessary. C, coronary sinus; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Brundage BH, Mao SS. In: Schlant RC et al., eds. *Diagnostic Atlas of the Heart*. New York: McGraw-Hill; 1996:243. Reproduced with permission from the publisher and authors.)

CT scanning is useful in accurately diagnosing constrictive pericarditis and distinguishing it from similar conditions, such as restrictive myopathy.[102] Based on the presence of pericardial thickening (Fig. 17-18) or calcification (Fig. 17-19), cine EBCT can assess both the

anatomic and functional abnormalities associated with pericardial constriction.[103] A pericardial thickness of more than 4 mm in a patient with typical abnormal rapid early LV diastolic filling is diagnostic of pericardial constriction.

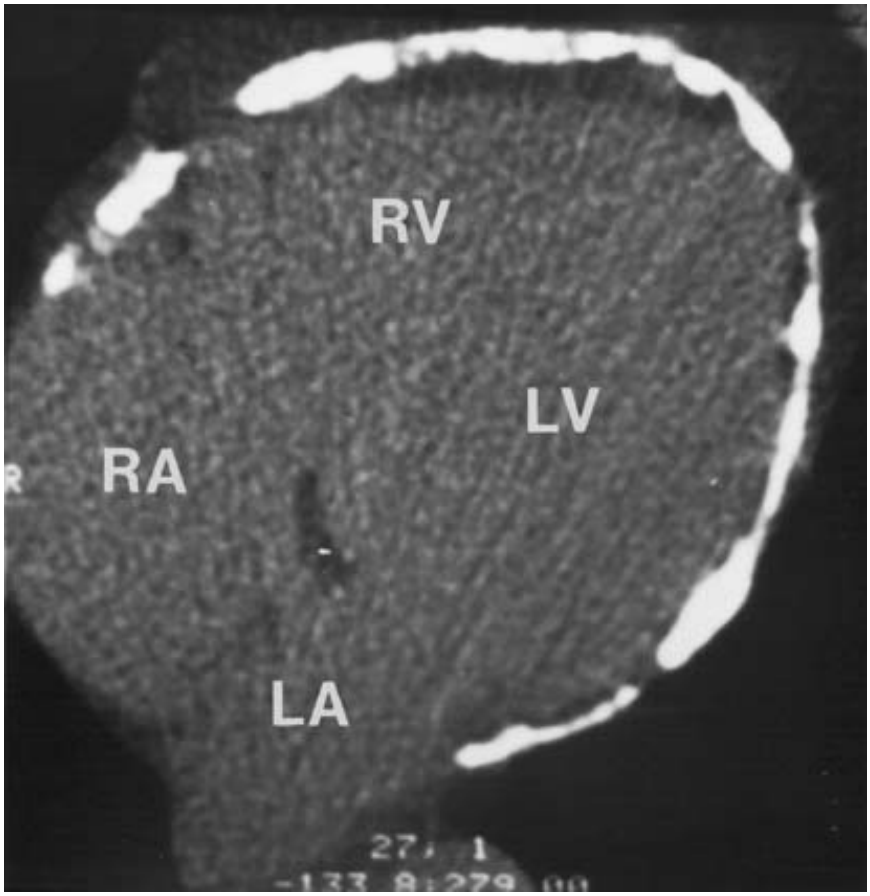

Figure 17-19: Densely calcified pericardium is easily identified in this scan of the midheart. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Brundage BH, Mao SS. In: Schlant RC et al., eds. *Diagnostic Atlas of the Heart*. New York: McGraw-Hill; 1996:243. Reproduced with permission from the publisher and authors.)

CT scanning can assess congenital abnormalities such as absence of the pericardium[106] or pericardial cyst.[107] CT scanning is currently one of the best techniques for defining the location and extent of mediastinal tumors and in diagnosing metastatic involvement of the pericardium.[107,108]

Chapter 17: COMPUTED TOMOGRAPHY OF THE HEART

EVALUATION OF CONGENITAL HEART DISEASE

Standard CT scanning and EBCT are both useful techniques in the evaluation of patients with congenital heart disease. Anomalies of the aortic arch, septal defects, tetralogy of Fallot, Ebstein's anomaly, and abnormal arteriovenous connections can all be carefully evaluated with CT techniques[109,110] (Fig. 17-20). EBCT, due to its high spatial resolution, also can evaluate the atrioventricular valves in conditions such as tricuspid and mitral valve atresia,[111,112] and detect congenital abnormalities of the coronary arteries.[113] Beyond identifying structural abnormalities, EBCT can be used to accurately quantify intracardiac shunts,[114,115] assess RV and LV function,[5,7] measure myocardial mass,[1-3] and evaluate valvular function. Despite the applications of CT scanning in evaluating congenital heart disease, magnetic resonance imaging is the modality of choice because it does not require x-ray exposure or the need for intravenous contrast material for both structural and functional delineation.

Chapter 17: COMPUTED TOMOGRAPHY OF THE HEART

EVALUATION OF CARDIAC TUMORS

The presence and extent of intracardiac tumors (Chap. 77) can be well defined with either conventional CT scanning or EBCT. CT scanning also can delineate metastatic tumor within the myocardial wall. Intracardiac tumors are readily detected by noninvasive two-dimensional echocardiography. Tumors such as myxomas, however, are also well visualized by EBCT, particularly when imaging is performed following intravenous contrast enhancement[116] (Fig. 17-21).

Chapter 17: COMPUTED TOMOGRAPHY OF THE HEART

DISEASES OF THE GREAT VESSELS

Conventional CT scanning is widely used for diagnosing thoracic aortic aneurysms and dissections.[117-119] With the introduction of spiral CT scanners, up to 60 images of approximately 2- to 3-mm thickness can be acquired within a single 30-s breathhold. A complete study of the thoracic aorta can be completed in only several minutes. Following scan acquisition, three-dimensional reconstructions are readily produced that can be rotated and viewed from multiple angulations to facilitate diagnosis. EBCT also can acquire rapid CT images with elimination of aortic pulsation as a cause for potential artifact.[120]

Aortic dissection is readily diagnosed with CT angiography with greater than 90 percent accuracy. In a recent study comparing spiral computed tomography, magnetic resonance imaging, and two-dimensional echocardiography, CT and magnetic resonance imaging were shown to be superior to echocardiography in their diagnostic accuracy.[119] Similar comparisons with EBCT are not available, but the increased imaging speed with EBCT over spiral CT would appear to be an advantage. Excellent definition of the intimal flap, false and true lumens, and the amount of intraaneurysmal thrombus can be determined.

CT scanning is also an effective method for diagnosing aortic aneurysm, defining its maximal diameter, and monitoring its expansion over time[120] (Fig. 17-22). CT scanning can diagnose traumatic aneurysms of the thoracic aorta,[118] sinus of Valsalva aneurysms, and coarctation of the aorta (Fig. 17-23). In patients undergoing redo coronary artery bypass surgery, CT scanning may guide the surgical approach by defining the position of the sternum to the right ventricle and aorta and thereby avoid unnecessary bleeding.[121]

Both spiral CT[122,123] and EBCT[124] can diagnose acute and chronic pulmonary thromboembolism (Fig. 17-24). CT scanning may be particularly useful in confirming the diagnosis of acute pulmonary embolism in patients with an intermediate nuclear ventilation-perfusion scan.[123]

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 18A:

MAGNETIC RESONANCE IMAGING OF THE HEART

Authors: Mark Doyle, Gerald M. Pohost

INTRODUCTION

The phenomenon of nuclear magnetic resonance (NMR) was discovered more than 60 years ago, and NMR spectroscopic methods were initially applied by physicists and chemists to explore molecular structure and composition.[1,2] Although NMR spectroscopy has proved invaluable in providing metabolic information in a variety of different myocardial physiologic and pathologic states, it is still used primarily as a research tool. The concept of using NMR to obtain images was propounded by Lauterbur[3] and was introduced independently by Mansfield in the early 1970s, when it was discovered that an inhomogeneous magnetic field can localize nuclei in space and thus produce an image. Advances in computer technology and superconducting magnets now allow routine clinical NMR imaging. Images are obtained with exquisite morphologic detail, in any tomographic orientation, in a nondestructive and noninvasive manner. As NMR entered mainstream clinical practice, the potential for public concern about "nuclear"technology was avoided by using the less descriptive term *magnetic resonance imaging* (MRI). It is important to note that there are types of magnetic resonance in addition to NMR, including electron spin resonance and Mossbauer spectroscopy.

Physicians and patients have become aware of the great versatility of MRI, and that knowledge has allowed the modality to become the "gold standard" of noninvasive imaging for many diagnostic and management areas in noncardiac diseases. Similarly, MRI has the potential to become an invaluable tool for evaluating cardiovascular morphology, function, perfusion, and viability. Even diagnostic imaging of the coronary arteries promises to become a reality in the near future. In addition, investigations of the clinical characteristics of plaque promise an exciting future in this area of MRI.

This chapter focuses on the basic principles and practices of applying MRI for the evaluation of normal cardiovascular structures and the diagnosis of diseases that affect the heart.

Chapter 18A: MAGNETIC RESONANCE IMAGING OF THE HEART

PRINCIPLES OF NMR

Magnetism and Vectors

To fully understand NMR, one must have extensive knowledge of quantum and nuclear physics; fortunately, the basic theory of NMR can be explained by using concepts drawn mostly from classical physics. An intrinsic property of atomic nuclei is that of *spin*. The combination of nuclear spin and electric charge is analogous to an electric current circulating in a small wire loop, producing a small magnetic field (Fig. 18A-1). The strength of the magnetic field produced by the nucleus is expressed in terms of a magnetic moment.

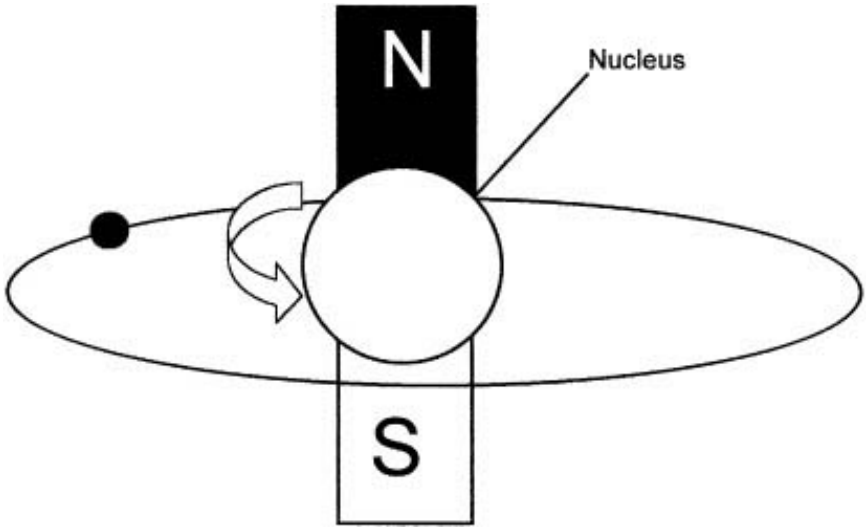

Figure 18a-1: The positively charged nucleus of a hydrogen atom spins and creates a magnetic field.

Within the body, nuclei orient randomly in space and do not produce any net magnetization; however, positioning the body within a strong magnetic field produces a net magnetic moment within the body. Intuitively, one might expect all nuclei to align parallel to the magnetic field (B_0), however, two energy states are created: parallel and antiparallel to B_0. Since the parallel alignment is at a lower energy level, slightly more nuclei become aligned parallel to B_0, causing the body to become weakly magnetized (Fig. 18A-2). The strength of the magnetization vector is proportional to the strength of B_0, the energy difference between spin states, and temperature. The fractional excess in the lower-energy state is extremely small [i.e., about 3 per million for hydrogen nuclei in at a field of strength 1.5 tesla (T) at body temperature].

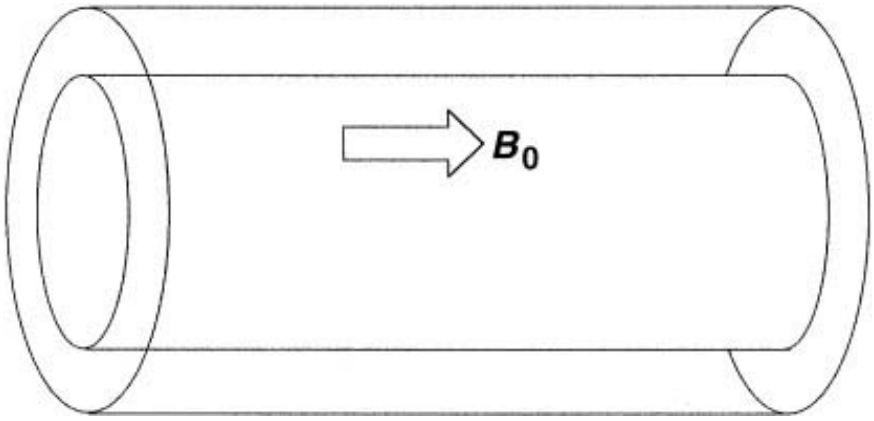

Figure 18a-2: The nuclei of the hydrogen atoms within the body (represented by the black and white bar magnets) align with the magnetic field (B_0), both parallel and antiparallel. Slightly more nuclei align parallel to the B_0, creating a net magnetization vector (*open arrow*).

In equilibrium, the magnetic moment does not yield a detectable signal. Signal can be generated by perturbing the system, causing its net magnetization to deviate from alignment with B_0. When tilted from alignment, the magnetization vector experiences a torque that causes it to precess. The phenomenon of nuclear precession is analogous to the precession exhibited by a spinning gyroscope tilted from alignment with the earth's gravitational field. Importantly, the precession frequency (ω_0) is much lower than the spinning frequency and is proportional to the field strength B_0. The frequency ω_0 is related to B_0 by a constant (γ) termed the *gyromagnetic ratio*, and these valves are related by the Larmor equation: $\omega_0 = \gamma B_0$ The gyromagnetic ratio (γ) is unique for each nuclear isotope.

The Resonance Phenomenon

To displace spins from alignment with B_0, a magnetic field of much lower strength (B_1) is applied so that B_1 rotates in a plane perpendicular to B_0. If the B_1 field rotates at the Larmor frequency, it will maximally affect the net magnetization of the body by virtue of being on resonance (Fig. 18A-3). The resonance frequency of the B_1 field is in the radiofrequency (RF) range and contributes the term *resonance* to NMR and MRI. The angle (θ) of rotation from B_0 is proportional to the time *(t)* of application of the rotating field and the strength, $|B_1|$: $\theta = \gamma |B_1| t$ When B_1 is turned off, the spins are free to precess under the influence of the extrinsic static magnetic field. It is during this time of free precession that the spins give off a detectable electromagnetic signal, again in the RF frequency range. The spin signal decays over a matter of tens of milliseconds and is known as *a free induction decay* (FID) (Fig. 18A-4).

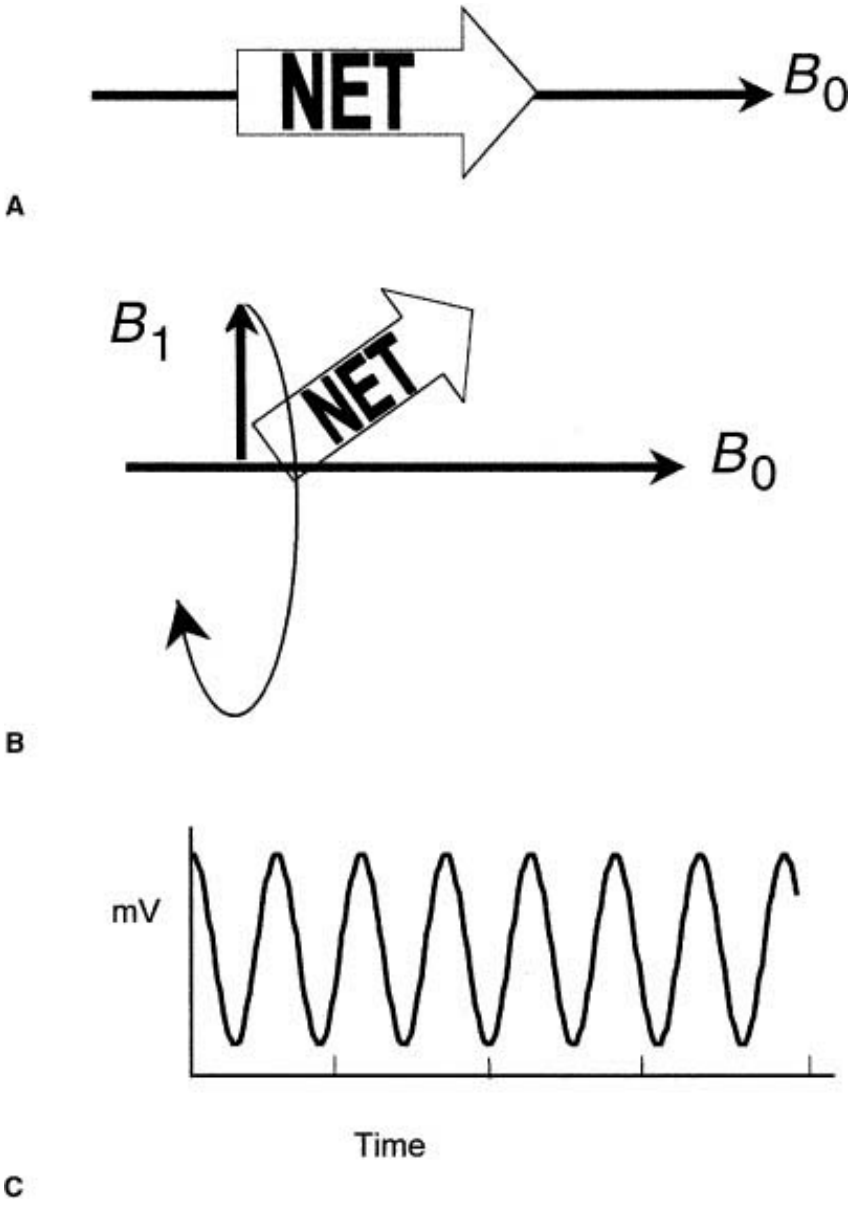

Figure 18a-3: The net magnetization vector (NET) aligns with B_0 (*A*). A rotating magnetic field (B_1) applied as a radiofrequency (RF) pulse causes the vector to precess out of B_0 alignment (*B*). The RF pulse is then discontinued, and the vector precesses, producing a signal (*C*) with a characteristic frequency, which depends on the field strength (B_0) of the magnet and the atomic species producing the signal (usually hydrogen).

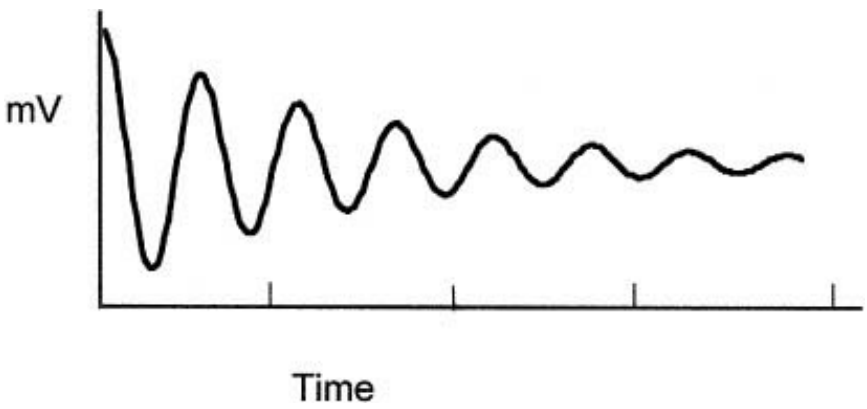

Figure 18a-4: The signal detected from the freely precessing nuclei decay, typically in a matter of milliseconds.

Relaxation

The spin signal gradually decays as a result of "relaxation" phenomena, that is, the gradual return of nuclei to their equilibrium energy states. Two distinct relaxation parameters are used frequently: T1 and T2; these parameters can be exploited to enhance image contrast.

T1 RELAXATION

Nuclei in the body are surrounded by a network of structures collectively known as the *lattice*. The lattice and the spin system constantly exchange energy; hence, nuclei lose the energy initially imparted by the RF pulse, resulting in a decrease in the net magnetic moment as spins realign along the B_0 axis. The realignment occurs in an exponential manner, and T1 relates to the time constant of this exponential decay. The time constant, T1, for a particular sample is the time needed for 63 percent of the nuclei to return to their equilibrium value. T1 frequently is referred to as the spin-lattice relaxation time. After a perturbation of the spin system, a time period of 5 T1 is regarded as necessary for the spins to return to equilibrium. Since spin-lattice relaxation requires an exchange of energy, the process is field-strength-dependent. The T1 of myocardium is approximately 900 ms at a field strength of 1.5 T and is less at lower fields.

T2 RELAXATION

Aside from the lattice, the interaction of neighboring spins contributes to the relaxation process. These interactions are referred to as *spin-spin relaxation* or *T2 relaxation*. Spin-spin relaxation occurs in the so-called transverse plane, i.e., the plane orthogonal to the B_0 direction in which the spins precess. The spin-spin interaction does not require any net energy exchange but instead can be envisioned as a loss of coherence of the precessing spins. As the spins gradually lose phase coherence, their net signal diminishes exponentially. The T2 for a sample is the time interval for the transverse magnetization to decay to 37 percent of its initial value. Additionally, in practice, B_0 fields are not perfectly homogeneous. Thus, nuclei within a sample are exposed to slightly different magnetic fields and, as a result, precess at slightly different frequencies. The free induction decay in such a field occurs more rapidly than is indicated by purely T2 considerations. This more rapid rate of decay is termed $T2^*$ ("T2 star"). The T2 process does not involve an exchange of energy with the lattice and is essentially independent of field strength. The T2 of myocardium is approximately 80 ms.

Each type of tissue has characteristic T1 and T2 relaxation properties that are influenced by a variety of conditions, including the proximity and mobility of molecules in the surrounding environment, the hydrogen concentration of the tissue, and exposure to the local magnetic fields at the molecular level. MR image contrast can be made sensitive to these conditions through the use of specialized pulse sequences that can be implemented by using the computer in the MR system. Image contrast generally is described in terms of the level of T1 or T2 "weighting" (described later in this chapter). Additionally, image contrast can be sensitive to motion of either the blood or the myocardium. These different contrast mechanisms can be understood in terms of the image-forming process of MRI techniques used clinically to image cardiovascular structures

Magnetic Resonance Image Formation

MRI is the most complex of all the medical imaging modalities, and it is important in regard to optimal image interpretation to have an understanding of the technical aspects of image formation. While scanner technology is constantly improving, certain basic system features remain constant.

The following paragraphs describe the basic elements of an MR system.

A general misconception exists that clinical MR systems, which are used commonly for brain and musculoskeletal imaging, cannot perform cardiovascular imaging and thus a dedicated cardiovascular system is needed. In fact, specialized software can produce a means for cardiovascular imaging in most clinical systems. Typically, the only additional hardware requirements are cardiac and respiratory gating devices, which are available for most systems. However, optimal cardiovascular magnetic resonance (CMR) requires a specialized system dedicated to cardiovascular applications. Clinical MR systems use superconducting magnets with field strengths typically ranging from 0.5 to 1.5 T. A tesla is the equivalent of 10,000 gauss (G). To put this into perspective, the earth's magnetic field is between 0.3 and 0.7 G, and a household magnet is about 100 G (0.01 T). Higher-field-strength magnets result in an increased signal-to-noise ratio and, as a consequence, clearer images; however, these higher field strengths often exaggerate artifacts because of cardiac, respiratory, and blood flow motion. Most clinical systems operate at 1.5 T, but clinical magnets with field strengths as high as 8 T are being used for research.

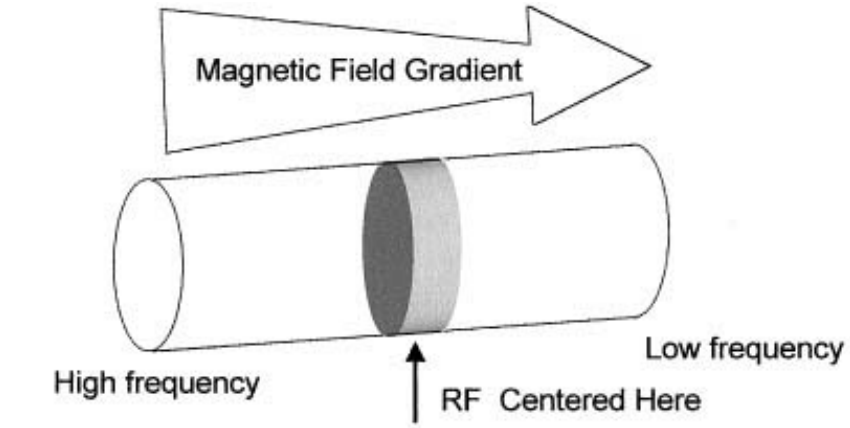
Systems tailored for cardiac applications generally acquire data rapidly to "freeze" cardiac motion and produce images with minimal blur. In an attempt to decrease scan times, the signal-to-noise ratio generally is reduced. Thus, of particular importance to cardiac systems is the requirement to obtain data with a high signal-to-noise ratio. Thus, cardiac systems typically are supplied with specialized receiver coils. Signal reception is optimal when the coil is closest to the heart. Typically, a cardiac coil comes in two parts: one positioned posteriorly and one positioned anteriorly over the heart. These coils are usually of the efficient phased-array design.[4]

As a result of its lesser regularity, respiratory motion is more difficult to compensate for than is normal cardiac motion. Cardiac motion is accommodated by synchronizing the acquisitions with the electrocardiogram. However, for general cardiac imaging, simultaneous triggering with the respiratory cycle is generally time-prohibitive. To accommodate the requirements for respiratory compensation, a number of rapid cardiac scan approaches have been developed that can be applied in combination with respiratory compensation. One method of respiratory compensation is to have the patient voluntarily suspend breathing temporarily (typically for 15 to 30 s). During this interval, the scan is performed. Other methods involve tracking the respiratory excursion of the heart by means of a belt and bellows apparatus secured around the patient's waist. Alternatively, an MRI-derived "navigator" signal (analogous to an M-mode echocardiogram) can be used to track the position of the diaphragm and allow synchronization with the respiratory cycle.[5,6]

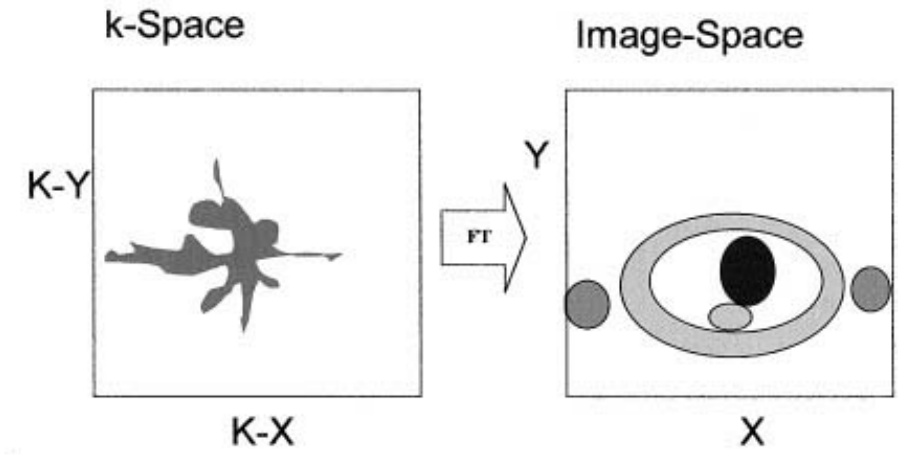
GRADIENTS

To produce an image, spatial discrimination must be encoded in the NMR signal. Within a homogeneous B_0 field, all nuclei resonate at the same frequency; thus, after the application of an RF pulse, a single frequency signal is produced with no spatial information. To generate an image, the magnetic field must vary over the field of interest. This is best accomplished by applying a linear magnetic field gradient over the sample. Three orthogonal gradients are incorporated into the scanner system: in the craniocaudal direction (z), in the right-to-left direction (x), and in the anterior-posterior direction (y). These gradients are controlled by the scanner's computer system. The first step in spatial resolution is to select a slice at a specified location. Slice selection is accomplished by the application of a linear gradient orthogonal to the desired slice direction. This gradient generates a range of resonant frequencies along the direction of the gradient. When the B_1 RF pulse is applied at a specific frequency (corresponding to the resonance frequency of the desired slice position), only spins in a narrow frequency range experience the effect of the RF pulse (Fig. 18A-5*A*). In this way, a slice can be selected with programmable orientation and thickness. To generate an image of the slice, it is necessary to apply gradients in two dimensions. Unfortunately, the application of two such gradients simultaneously results in a single gradient

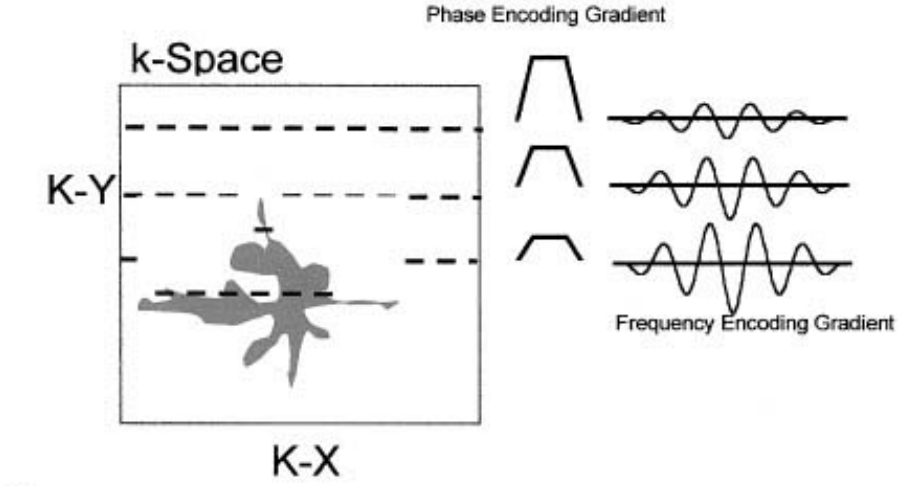
vector. Hence, image generation in two dimensions requires that the two gradients be applied at separate times. This feature is responsible for the relatively long acquisition times associated with cardiovascular MRI. It is important to realize that the MRI signal does not directly relate to an image. Instead, an image is formed by the mathematical process known as a Fourier transform (Fig. 18A-5*B*). The MRI signal is acquired and assembled into a matrix that is termed k-space, and an image is produced when the Fourier transform is applied. In Fig. 18A-5*C*, the process of acquiring lines in k-space is illustrated. The data are read in the presence of one imaging gradient termed the *frequency encoding* or *measurement* gradient. To step between lines of k-space, a "phase-encoding" gradient is applied as indicated in Fig. 18A-5*C*.



A



B



C

C

Figure 18a-5: A combination of gradient and RF energy is used to select a slice in the sample (*A*). The gradient imposes a range of frequencies over the sample, and the B_1 field is applied at the frequency needed to select the slice. The data sampled by MRI are in the so-called k-space of the frequency domain (*B*). Images in this domain are converted into images in the spatial domain by performing a Fourier transform (FT). Each line of k-space is sampled by application of a "frequency-encoding" gradient (typically for 2-3 ms) (*C*). To step between each line of k-space, a "phase-encoding" gradient is applied (typically in 1 ms).

PULSE SEQUENCES

A pulse sequence is a set of RF and gradient waveforms that are required for image generation. Different pulse sequences highlight different features in an MR image.

Gated Spin Echo

On slice selection using the gradient and RF pulse combination, the signal is maximal immediately at the end of the RF pulse. However, relatively few sequences can use the signal at this time, since the signal generally requires some form of preparation before it can be useful. However, as time from the RF pulse elapses, the signal loses coherence because of the combined effects of T2 and magnet inhomogeneities.

The application of a second pulse of 180° causes the spins to reverse direction and realign (or refocus), resulting in a so-called spin echo. This refocused echo signal is corrected for the effects of field inhomogeneity (but not for the effects of T2 relaxation). The time from the RF pulse to the maximal signal is called the *echo time* (TE). The time interval between each "phase-encoding" step in the image-generating process is called the *repetition time* (TR). The imaging computer can vary TE and TR to affect the degree of T1 and T2 "weighting" in the images; i.e., for a short TE and TR the image becomes T1-weighted, and for a long TE and TR the image becomes T2-weighted. However, much of the contrast in such spin-echo images occurs as a result of rapidly flowing blood. Since blood moves between applications of the two RF pulses, the signal emanating from the region with flowing blood is related to the blood flow. In the presence of rapid blood flow that is directed out of the imaging plane, there is no signal, since the blood does not experience the refocusing pulse. As blood flow decreases, its signal increases. Thus, within vascular lumens and cardiac chambers, signal voids generally are seen in spin-echo images (also termed dark blood images). This sequence highlights cardiovascular wall morphology (Fig. 18A-6).

Gated Gradient Echo

Another widely used method for generating clinical images involves applying a magnetic gradient to recall a signal echo. After the RF pulse used in slice selection, an additional gradient is applied and then reversed after several milliseconds. This refocuses the spins into an echo. The major difference between this "gradient-echo" approach and the "spin-echo" approach is that with gradient-echo approach, only one RF pulse is applied. Thus, gradient-echo images can be made sensitive to flowing blood (since even moving blood experiences the signal-refocusing properties of the gradient echo sequence). This method typically uses rapidly repeated RF pulses and causes partial "saturation" (i.e., heavy T1 weighting) of spins. Thus, decreased signal from static tissues results from the rapid repetition rates of the RF pulse. However, blood flowing into the imaging plane will not have been exposed to the slice-selective train of RF pulses and thus will not be "saturated," resulting in an intense blood signal relative to the static tissue signal with low intensity (Fig. 18A-6). Consequently, flowing blood appears bright. Thus, the gradient-echo-

type sequence also is known as the *bright blood sequence*. This imaging approach is quite useful, since the resultant images may be displayed in a cine/movie to allow visualization of cardiac and blood pool motion. One should note that turbulent flow causes dephasing of spins as a result of chaotic motion, resulting in signal loss. Therefore, this technique is useful for visualizing regurgitant, stenotic, and shunt lesions.

Rapid Imaging

Of particular importance to cardiovascular imaging are rapid imaging sequences, since the gated approaches result in a prolongation of the basic scan time. A two-dimensional (2D) image of a stationary object can be generated in a matter of seconds (e.g., with a TR of 7 ms, an image with 128 lines can be generated in less than 1 s). With the requirement of cardiac triggering, the scan time will be extended to the time of 128 cardiac cycles. Thus, methods for producing cardiac images in shorter times have been an active area of research.[7-9] One such rapid sequence is echo-planar imaging (EPI).[10-13] EPI is based on the gradient-echo approach, but instead of just one echo being recalled, a number of echoes are recalled, speeding up the sequence. The main disadvantage of the EPI approach is that the echo train can be quite long (i.e., greater than 50 ms) and thus the images are heavily T2-weighted. An approach that avoids the T2 weighting of EPI is the segmented or turbo imaging approach. This involves the acquisition of a series of single gradient echoes that are acquired rapidly in a group and assigned to one cardiac phase.[14-17] Further modification and variants continue to be developed to allow the production of cardiac images in ever shorter scan times.

One rapid technique that merits special mention is spiral imaging. This approach does not encode data in an orthogonal matrix (as is done in the techniques described above) but acquires data in a curved matrix. This approach exploits the fact that it is physically easier to drive the imaging gradients by using a waveform with gradually increasing amplitude as opposed to abruptly switching the polarity of the gradients (as is required for the gradient-echo and spin-echo approaches). Spiral approaches have been used to produce high-resolution images of the coronary arteries. The disadvantage of this technique is that high system performance is required.[18]

SPECIALIZED PULSE SEQUENCES

An imaging sequence that can be used in conjunction with many of the approaches described above is that of tagging[19-22] (Fig. 18A-7). Typically, tagging involves applying a set of parallel lines or a grid of orthogonal lines at the time of the electrocardiogram (ECG)R wave. Once they are applied, these lines or grids then move with the heart to highlight motion. Naturally, since the lines or grids are composed of tagged signal regions, they cannot interfere with cardiac function. Such RF tagging allows quantification of cardiac function on a regional basis.

Specialized sequence known as phase-velocity mapping (PVM) is used to determine blood flow and myocardial motion. PVM uses NMR signal phase (as opposed to signal amplitude) that is made sensitive to motion.[23-27] With PVM, two image sets are required to generate a velocity map, and this doubles the scan time compared with conventional MRI. However, the advantage of generating such "phase-velocity maps" is that the velocity in any selectable direction can be encoded.

It can be appreciated that many creative pulse sequences can be used to highlight morphology, function, blood flow, perfusion, and even diffusion. These include techniques applied to MR angiography (MRA), quantification of cardiac function, quantification and visualization of blood flow velocity, and cardiac perfusion imaging. Clinical application of these techniques will be discussed in detail later in this chapter.

Patient Considerations

PATIENT COMFORT

Most patients tolerate the MRI procedure without the need for sedation. However, claustrophobia limits scan completion in approximately 5 percent of patients. Although rarely necessary, gentle sedation may be required so that the patient can relax and then remain motionless during the scan acquisition. Methods more commonly used to decrease anxiety include removing the patient from the magnet bore between scans and allowing a friend or family member to be positioned at the head of the bore to talk to the patient during scanning. Earphones are placed on the patient to minimize the acoustic noise, allowing many patients to sleep during the scan. However, for protocols that require the patient to perform breath holds, it is necessary for the patient to remain conscious throughout the examination. For these scans, some systems allow the patient to view movies through special MRI-compatible virtual reality systems. Newer magnets are shorter and may reduce the incidence of claustrophobia. Scan preparation and imaging time vary with the complexity of the clinical question to be answered. For example, if only ventricular function is assessed, the study can be performed in approximately 20 min; however, if the patient is being assessed for complex congenital heart disease, imaging times of 1 h or more may be required. As scanner technology and software have improved, imaging times have decreased. However, as the capabilities of MRI have increased, the amount of clinical data that can be acquired during an MRI session has increased. Thus, typically an MRI scan session can last 30 to 45 min. However, during this time a great deal of clinical information can be acquired.

PATIENT SAFETY

As with any diagnostic medical technique, safety is a critical issue, and safety procedures and rules should be familiar to the physicians ordering the scan and the technicians performing the scan. MR techniques can be contraindicated in a patient because of (1) the potential of the magnetic field to move or dislodge an object or device, (2) the possibility that the RF field will heat a conductor such as a pacemaker electrode, (3) the potential for inducing electric currents in a conductor such as a pacing electrode, and (4) the generation of artifacts by metallic objects that can confound diagnoses. The most common implanted devices that exclude a patient from having an MRI study are pacemakers (permanent or temporary) and automated implantable cardiovascular defibrillators. At least six deaths have occurred in patients with pacemakers, and those deaths were thought to be related to an MRI procedure.[28] Prosthetic heart valves are generally MR-compatible, with the possible exception of the pre-6000 series Starr-Edwards valve, a caged ball device used clinically several decades ago. To the authors' knowledge, there has never been a report of an untoward incident with a heart valve prosthesis. The presence of sternal wires and bypass graft clips is not hazardous to the patient but results in MR signal artifact. Properly installed intravascular coils, stents, and filters are unlikely to dislodge but result in MR signal loss in the region of the metallic device.[29] Commonly encountered implanted devices that are potentially MR-hazardous include intracranial aneurysm clips and certain metallic ocular, cochlear, and penile prostheses. Technicians also must be aware of the potential danger associated with metallic devices that may accompany the patient, such as wheelchairs, intravenous (IV) poles, oxygen tanks, and iron-shot-filled hemostatic "sandbags." These devices may become dangerous projectiles in the vicinity of an MR system. A useful resource is the Web site that lists current devices and their degree of MR compatibility: http://MRIsafety.com/index.html.

A static magnetic field is not the only potential source of hazard. The rapidly changing magnetic gradients required for imaging can induce strong currents in conducting objects such as wires and cables. Further, the RF fields also can induce electric currents to flow. External devices that may cause harm to a patient by causing skin burns include pulse oximetry and ECG cables. MR-compatible cables, i.e., those designed to reduce the incidence of heating or induced currents, are

available and must be used in an MR facility. In addition, all non-MRI-compatible metal cables and detection devices must be removed from the patient before the scan is performed.

Chapter 18A: MAGNETIC RESONANCE IMAGING OF THE HEART

CLINICAL APPLICATIONS

There are many applications of MR to the cardiovascular system, both clinical and research.[30] The current clinical indications are for assessment of function and morphology of the heart and great vessels. However, MR methods also have the potentialability to image perfusion (using the first transit of a paramagnetic contrast agent), assess viability after a myocardial infarction (MI), image the coronary arteries, and image and characterize atherosclerotic plaque.

Since MRI can generate images in any tomographic orientation, it can provide information for comprehensive assessment of the heart with excellent spatial resolution. The three-dimensional imaging ability of MRI allows accurate assessment of global and regional function. Such assessment in theory should be more accurate than methods that are predominantly two-dimensional, such as echocardiography and x-ray angiography, and methods with lower resolution, such as radionuclide approaches.

Assessment of Cardiac Morphology and Ventricular Function

The standard cardiac MRI exam begins with spin-echo images in the orthogonal planes of the body: transverse, coronal, and sagittal. To evaluate ventricular function, image planes should be oriented in relation to the intrinsic axes of the heart. Accordingly, cine cardiac MR images are obtained in the two-chamber (right anterior oblique), four-chamber, and short-axis views (Fig. 18A-8). Consequently, the resultant image orientation is comparable to that of other imaging modalities. Both static spin-echo (dark blood) and dynamic cine MR (bright blood) imaging allow comprehensive assessment of a wide variety of cardiac dimensions and volumes.

Measurements

"Computer calipers" are a standard feature of the software available on clinical MR systems. Linear point-to-point measurements of distances similar to that used on echocardiographic equipment provide a means to report standard dimensions. Since spin-echo images highlight morphologic detail, these images are used to evaluate the diameter of the great vessels and the cardiac chambers,[31-33] ventricular wall thickness,[34] left ventricular (LV) mass, pericardial thickness, cardiac and paracardiac masses, and congenital anomalies.

MRI generally provides images with excellent definition of endocardial surfaces, allowing ready measurement of left and right ventricular end-diastolic and end-systolic size within each myocardial slice. When area-length calculations are used for orthogonal long- and short-axis slices or for summing serial short-axis slices (Simpson's rule), end-systolic, end-diastolic, and stroke volumes of the left and right ventricles can be determined accurately. From these volumes, one can calculate cardiac output and ejection fraction. These volumetric parameters correlate well with other imaging techniques.[35-43] MRI allows routine quantitative assessment of regional ventricular function with visualization of all myocardial segments. In a similar fashion, the epicardial contour also may be outlined, and thus the volume of the myocardium, i.e., the volume between the epicardial and endocardial surfaces, can be calculated. Myocardial mass can be determined without geometric assumptions by multiplying the myocardial volume by the assumed value for the density of myocardial tissue.[44-48]

When the technique of phase-contrast imaging (phase-velocity mapping, velocity-flow mapping, or velocity-encoded cine MR is used), blood flow velocity can be determined (Fig. 18A-9). This method has been validated in a variety of in vivo models.[49-53] With this technique, blood flow in both the ascending aorta and the pulmonary artery can be determined simultaneously, allowing calculation of the ratio of pulmonary to systemic flow (Q_p/Q_s) for assessment of shunt size[54] or regurgitant volumes. Myocardial contractile velocity also has been determined by using PVM.

Ischemic Heart Disease

Several MR approaches are useful for detecting various aspects of ischemic heart disease. These include myocardial tissue characterization, postinfarct imaging of the intensity of contrast agents (e.g., hyperenchancement), stress-induced segmental dysfunction, perfusion imaging, and ischemia-induced changes in high-energy phosphate metabolism using spectroscopic methods (Table 18A-1). This section is divided into two main components: evaluation of stable and acute ischemic syndromes.

Table 18A-1: Ischemic Heart Disease Assessment by MR

Method	Established for Clinical Application	Ready for Clinical Application	Under Development (Emerging)	Research
Regional wall motion at rest	Cine, tagging			
Global ventricular function	Cine, tagging			
Regional and global stress		Cine, tagging		
Myocardial perfusion			Contrast agent	
Myocardial viability			Contrast agentDelayed hyperenhancement	
Myocardial metabolism				Spectroscopy (e.g., ^{31}P, ^{1}H)
Coronary artery disease			AngiographyPlaque characterization	

STABLE ISCHEMIC HEART DISEASE

A number of MR methods are useful for detecting and evaluating the severity of stable ischemic heart disease. Some of these methods have been applied widely and should be considered as the standard of care, some are promising but still under development, and some are still considered research (Table 18A-1).

Stress-Induced Segmental Dysfunction

Stress-induced impairment of regional LV function is an early and reliable sign of ischemia associated with significant coronary artery stenosis, preceding ST-segment depression, and angina pectoris.[55,56] Dobutamine can be used as a pharmacologic means of inducing stress and provides a way to induce ischemia-related wall motion abnormalities. Dobutamine infusion generally begins at 10 μg/min and is increased 5 μg every 2 min until angina occurs. ECGs are distorted in MR systems by the magnetic and RF fields. Thus, reliable ECG monitoring is not possible during MRI. Nevertheless, with symptoms, blood pressure, and pulse closely monitored, the test has been performed without life-threatening complications. Regional abnormalities of wall motion can be observed by using radionuclide cineangiography[57] and echocardiography.[58-61] MRI offers a noninvasive imaging approach with high spatial resolution and three-dimensional imaging for optimally accurate evaluation of regional LV function.[62,63] Van Rugge and colleagues used graded dobutamine infusion in conjunction with MRI in 45 patients with chest pain. Thirty-seven patients had angiographically significant coronary artery disease[64]; with peak dobutamine infusion, segmental dysfunction was observed in 30 patients, yielding an overall sensitivity for detection or coronary artery disease of 81 percent. None of the eight patients without significant coronary artery stenoses had abnormal wall motion; i.e., the specificity in this very small series was 100 percent. Furthermore, the sensitivity for detecting single-, double-, and triple-vessel disease was 75 percent, 80 percent, and 100 percent, respectively. The total duration of the examination is approximately 1 h.

Myocardial Perfusion Imaging Using MR Contrast Agents

Myocardial perfusion imaging (MPI) is used widely with radionuclides. However, it is now clear that MPI with MR methods can provide higher-resolution imaging without ionizing radiation. Although a substantial body of data has been acquired using MR MPI, this procedure should be considered developmental until a larger-scale multi center study is done.

Paramagnetic substances such as gadolinium and dysprosium cause a reduction in both T1 and T2. The magnitude of the decrease is related to the magnetic field strength and the concentration of the paramagenetic agent.[65] When a paramagnetic agent (e.g., gadolinium DTPA or gadoteridol) is given intravenously as a bolus, generally using a power injector, regional myocardial perfusion can be assessed. Currently, there are three classes of paramagnetic agents: extracellular, blood pool, and intracellular. The most commonly used is extracellular gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA), which actually distributes in the blood pool and extracellular space.

MRI records the first pass of the paramagnetic agent through the myocardium. A pulse sequence that markedly diminishes (or "nulls") the signal intensity of the myocardium is used. Thus, myocardium with the greatest concentration of contrast agent is assumed to be normally perfused. The portion of the myocardium with reduced signal is presumed to be underperfused or ischemic (Fig. 18A-10). The authors' initial experience in over 200 patients compared MR and radionuclide perfusion imaging using acquisitions at rest with thallium-201 or low dose ^{99m}Tc sestamibi and then with the first bolus injection of the gadolinium-based agent. A dipyridamole infusion was then initiated using this standard dose of 0.56 mg/kg over a 4-min interval. Two minutes after the infusion, practically simultaneous infusion of ^{99m}Tc sestamibi and gadoteridol was given. In the first 50 patients, sensitivity and specificity were significantly better with radionuclides. In the second 50 patients, radionuclides and MR showed equivalent sensitivity and specificity (probably related to a "learning curve").

Reading MR perfusion images requires some experience, since the approach is dynamic rather than static as it is with radionuclides.[66] One must evaluate the homogeneity with which the myocardium enhances as the paramagnetic agent enters the myocardium. One pitfall that it is

essential to know about is that the lower portion of the interventricular septum frequently demonstrates reduced signal in patients without significant coronary artery disease. Accordingly, if this territory is the only one with a "defect", one should not assume abnormal perfusion but instead an artifact of the MR method. Manning and associates[67] used GD-DTPA to assess myocardial perfusion at rest in patients with severe coronary artery disease. As was anticipated, the time to peak signal intensity was delayed, and peak signal intensity was reduced in regions of the myocardium perfused by a severely stenotic coronary artery. An alternative approach to detecting regions of compromised myocardium has been developed by Hundley and Wlleagues,[68] utilizing the ability of MRI to measure flow.

Using dipyridamole, Matheijssen and Coworkers[69] compared perfusion MRI with sestamibi single photon emission computed tomography (SPECT). Agreement in localization of the artery with significant occlusive disease was 80 percent between angiography and SPECT, 70 percent between angiography and MRI, and 90 percent between SPECT and MRI. MR perfusion studies have been limited by the need to use first-pass acquisition, resulting in the depiction of only one or two slices at the level of the mid-left ventricle. Walsh and associates have developed a method called the block regional interpolation scheme for k-space (BRISK) to acquire up to four tomographic slices through the ventricle by using a conventional MR scanner. This approach represents a great step forward, allowing a more extensive evaluation of perfusion within the short duration of the first pass of the paramagnetic bolus.[70-72] New contrast agents are under development. One strategy includes blood pool agents such as iron particles and a gadolinium agent that binds to albumin. Contrast agents that remain within the blood pool are less complex to analyze since they involve only one compartment. Iron particles have been under investigation, since they remain within the blood pool.[73] Another, more long-range approach for perfusion imaging was reported by Simor and Coworkers.[74] This group described an agent that appears to enter and remain within the myocardium, as thallium-201 or sestamibido.[74] Such agents, when clinically available, should allow myocardial perfusion imaging over many cardiac cycles rather than only one, as is the case with the "first-pass" approach. The use of such myocardial localizing agents should provide the highest-resolution perfusion images available by any technology.

MR Spectroscopy

MR spectroscopy provides another perspective for evaluating the myocardium and defining ischemia. This approach should still be considered research. Cardiac metabolism and energy reserve can be assessed by using spectroscopic methods to assess baseline and changes in the high-energy phosphates within the myocardium (Fig. 18A-11).[75-78] Studies in laboratory animals have demonstrated a rapid decrease in phosphocreatine (PCr) after coronary occlusion. The PCr-to-adenosinetriphosphate (ATP) ratio is used frequently to express changes in bioenergetics, particularly with myocardial ischemia.[79-81] Typically, a surface coil is placed on the anterior chest wall and ^{31}P spectroscopic imaging is performed before, during, and after hand-grip exercise stress. The patient is asked to grip as hard as possible. This is said to be the maximal level. Then, during the study, the grip is maintained at 30 percent of maximum.[82,83] Localized spectroscopic methods then examine PCr/ ATP in the anterior myocardium. Using isometric hand-grip stress, Weiss and coinvestigators[84] and Yabe and associates[85] reported significant decreases in PCr/ ATP ratios in patients with angiographically documented left anterior descending (LAD) coronary artery disease. In the NHLBI-supported WISE (Women with Ischemia Syndrome Evaluation), study to 20 to 30 percent of women with no significant coronary artery disease (CAD) but chest pain had a significant reduction in PCr/ ATP compared with age-matched controls. Such data suggest the importance of the PCr/ ATP stress test in detecting ischemia.

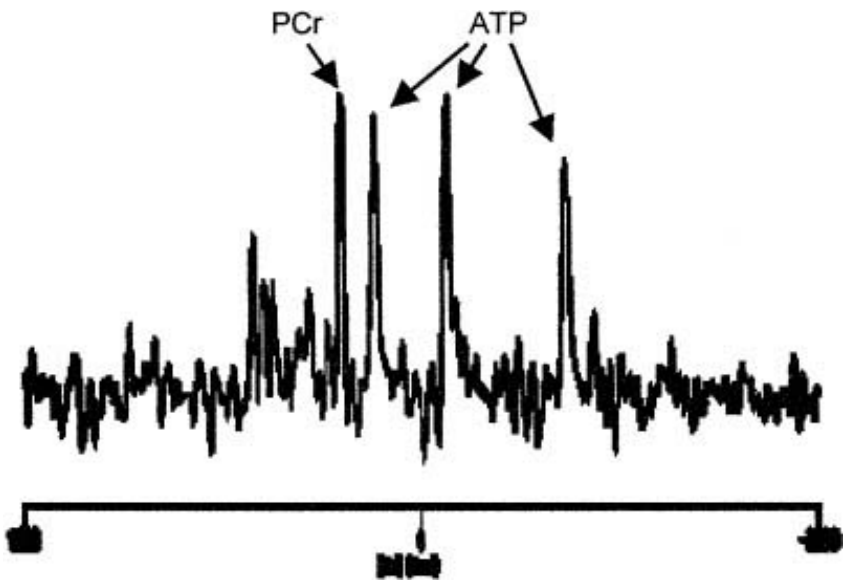

Figure 18a-11: Myocardial spectrum acquired from a healthy person, indicating the phosphocreatine (PCr) and ATP peaks.

ACUTE ISCHEMIC SYNDROMES

MR imaging can be used to differentiate between angina and acute MI. Morphology, function, perfusion, and coronary angiography may all be useful to differentiate reversible ischemia syndromes from MI. Infarct size, regional and global function, and viability can be evaluated. Further, the sequelae of myocardial infarction can be assessed.

Global and Regional Function

Wall motion and thickening can be readily assessed using a cine technique or a real-time approach[86-89] (Fig. 18A-12). Regional wall motion abnormalities and wall thickening by MRI correlate well with sites of dysfunction by x-ray cineventriculography.[90] End-diastolic wall thickness and the degree of systolic wall thickening demonstrated by MRI may be used as markers for predicting myocardial viability (Fig. 18A-13). Hofman and coworkers proposed employing cardiac pacing in combination with MR imaging.[91] Using ^{99m}Tc sestamibi SPECT imaging, Sechtem and coworkers[92] demonstrated that an end-diastolic wall thickness greater than 6 mm or a systolic wall thickening greater than 1 mm correlated with viable myocardium. This was supported by positron emission tomography (PET) imaging with ^{18}F-fluorodeoxyglucose and cine MR imaging of wall thickness and wall thickening to define viability.[93,94] Normal MR values of left ventricular dimensions have been reported by Lorenz and Wlleagues.[95] Wall function can be assessed quantitatively by using MR cine tagging approaches.[96,97]

Infarct Size

Within an hour of the onset of an MI, T1 and T2 relaxation times generally increase within infarcted myocardium; such prolongation of relaxation times provide a means to determine the location and extent of the infarction.[98-100] Whereas some investigators have claimed that infarct imaging with T1 and T2 is not specific,[101] others have demonstrated a good correlation between thallium-201 scintigraphy and T1 and T2 MR imaging in examining infarct size and location.[102,103] Using spin-echo imaging to emphasize T2 has demonstrated increased signal intensity in regions of infarcted tissue and provides a means to determine infarct size.[104,105] Furthermore, wall thinning and asynergy may be of value in assessing the extent of myocardial

tissue infarction.[106]

Paramagnetic contrast agents such as a chelate of gadolinium have been reported to be of value in differentiating between infarcted and noninfarcted myocardium. A phenomenon termed *delayed hyperenhancement* has been observed 3 to 15 min after contrast administration and has been found to correlate with zones of irreversible myocardial damage, whereas the absence of delayed hyperenhancement indicated reversible damage.[107] However, this observation may be controversial in view of the recent study of Rogers and coinvestigators.[108] In that study, delayed enhancement occurred in regions in which myocardial injury was reversible, while hypoenhancement occurred in regions with irreversible myocardial injury. The hyperenhancement phenomenon most likely is related to a delay in the uptake of the paramagnetic agent within the injured territory as a result of reduced blood flow and edema (Fig. 18A-14).[109] The ultimate significance of this finding awaits further study.

Myocardial Tissue Characterization

Changes in the biophysical properties of ischemic myocardium during an ischemic insult can be detected readily by using MR imaging. The relaxation times, T1 and T2, increase with several ischemic insults and are related largely to an increase in water content.[110-113] In animal models, the largest increase in relaxation times occurs in ischemic zones with moderate to severely reduced blood flow, whereas in zones in which the ischemia is total, there is little, if any, increase in myocardial T1 and T2. Other factors of less importance than edema that contribute to such changes in relaxation times include the presence of free radicals, the change in magnetic susceptibility related to the paramagnetic effects of deoxyhemoglobin as a result of hemorrhage, and lipid accumulation.[114,115] Spin-echo images with long echo times will emphasize T1 increases, depicting them as zones of increased intensity.

Complications of Myocardial Infarction

MR imaging provides exquisite morphologic and functional detail. Thus, it can be used to sensitively detect short- and long-term complications of myocardial infarction, including ventricular aneurysm, mitral regurgitation caused by papillary muscle necrosis, perforation of the interventricular septum, LV thrombus, and pericardial effusion. In addition to the regional wall thinning of infarcted myocardium, compensatory hypertrophy and LV chamber enlargement (remodeling) also may be demonstrated. Furthermore, pericardial effusions after infarction are readily demonstrated and quantified.

Coronary Artery Disease

It is possible, using MR angiography methods, to perform coronary artery imaging. In addition, several investigators have demonstrated the feasibility of characterizing the stability of atherosclerotic plaque by using MR methods. These topics are described in detail in Chap. 00.

Valvular Heart Disease

The ideal approach for evaluating patients with valvular heart disease must include an accurate assessment of the valve morphology and function and a means to assess myocardial structure and function and potentially energetics (e.g., using ^{31}P spectroscopy). Structural and functional changes related to valve dysfunction include atrial and/or ventricular chamber enlargement, ventricular wall thickening, poststenotic dilatation of the aorta and/or pulmonary artery, and atrial and/or ventricular thrombus.

MORPHOLOGY

Normal valve leaflets are 1 to 2 mm in thickness and are highly mobile throughout the cardiac cycle. Echocardiography provides high spatial and temporal resolution of the valve leaflets (see Chap. XX). Since the slice thickness of clinical MR images ranges from 5 to 10 mm, the spatial resolution is not adequate to assess the valve leaflets accurately and reproducibly. Nevertheless, spin-echo and gradient-echo images provide a reasonable approach for determining the number of leaflets, the degree of excursion, and approximate leaflet thickness.

With MRI, because of dimensional accuracy, high resolution, and three-dimensional aspects, the ventricular and atrial morphology and function can be assessed accurately without employing geometric assumptions. When the resultant information is used, MR imaging can be helpful in determining the approximate time for surgical intervention by defining chamber volumes and function. It has been demonstrated that preoperative LV size and ejection fraction are good predictors of LV function after surgical intervention for aortic and mitral regurgitation.

VALVE FUNCTION

The severity of valvular dysfunction can be assessed by two MR methods: cine gradient-echo imaging and phase-velocity imaging. In the former method, the chaotic motion of turbulent flow results in dephasing and consequently in a reduction of MR signal. Thus, a signal void is present within a normally signal-intense blood pool. The territory of MR signal void corresponds to the area of color Doppler signal by echocardiography[116-119] (Fig. 18A-15). The reduction in signal can be altered by changing acquisition parameters such as TE, TR, sampling size of the imaged volume element (voxel), and/or orientation of the imaging plane relative to the flow jet.[120,121] Thus, consistency of these factors must be maintained to assure appropriate interpretation. Similar to echocardiography, the volume of proximal flow convergence, which appears as a small cone-shaped MR signal void on the side of the valve opposite to the direction of regurgitant flow, is predictive of the severity of regurgitation.[122,123] MR has been used to measure regurgitant volumes and regurgitant fraction by measuring right ventricular (RV) and LV stroke volumes and thus determining the severity of regurgitation, assuming that regurgitant lesions involve only one side (RV or LV).[124-126]

In addition, gradient-echo imaging can be used to approximate the degree of aortic stenosis by observing the extent of turbulent flow (signal loss) in the ascending aorta.[127] However, it is possible to use phase-velocity imaging to assess flow velocities to 5 m/s.[128] In this way, the severity of aortic stenosis can be assessed more reliably.

In summary, MRI represents a reliable noninvasive means for assessing valvular and ventricular function to assist in determining the appropriate timing for valve replacement. PVM may be useful for the quantification of valve dysfunction.

Pericardial Disease

Normal pericardium on multislice spin-echo MR images appears as a thin, low-intensity signal (< 3 mm) between the high-intensity signal of mediastinal and epicardial fat and the medium-intensity signal of myocardium.[129,130] The lower signal intensity of the normal pericardium results from the amount of fibrous tissue (with long T1 and short T2 relaxation times). Sechtem and associates reported that the pericardium adjacent to the right ventricle could be visualized by MR in 100 percent of the subjects studied, whereas the pericardium along the lateral wall of the left ventricle could be visualized in only 61 percent of the subjects.[131]

PERICARDIAL EFFUSION

Normal pericardial fluid has a low signal intensity on spin-echo images. Such fluid leads to a zone of reduced signal intensity separating the pericardium from the myocardium and the epicardial fat. It has been postulated that the appearance is dark because of the nonlaminar flow of fluid within the pericardial sac as a consequence of cardiac motion. Such nonlaminar flow changes the spin phase and causes MR signal loss.[132] In gradient-echo images, the pericardial fluid appears bright as a result of this flow, clearly separating the parietal pericardium from the myocardium (Fig. 18A-16).

The ability of MRI to detect moderate or large pericardial effusions is comparable to that of echocardiography. However, MRI is able to detect small fluid collections better than echocardiography can. This is especially noteworthy in areas at the medial border of the right atrium or posterior to the LV apex.[133] Because of its lower cost and portability, echocardiography should be used as the first-line approach in assessing patients for pericardial effusion; however, MRI should be performed when a clinically suspected pericardial effusion is not detected on echocardiography. MRI is also useful for demonstrating loculated pericardial effusions.

PERICARDIAL THICKENING

In both MRI and computed x-ray tomography, a pericardial thickness of more than 4 mm is considered abnormal.[134] Pericardium visualized by MRI varies in thickness in different regions of the heart; thus, a standard imaging plane must be established. For this reason, transverse imaging at the levels of the right atrium and the right and left ventricles is recommended.

By demonstrating the presence or absence of a thickened pericardium, MRI can help distinguish between constrictive pericarditis and restrictive cardiomyopathy. Patients examined by MRI who had proven constrictive pericarditis had a pericardial thickening greater than 5 mm.[135] In addition, calcification of the pericardium, which demonstrates reduced signal intensity, also aids in the diagnosis of a pericardial rather than cardiomyopathic restrictive disease.

Cardiomyopathy

Evaluation of global and regional wall thickness and thickening, wall excursion, and chamber size is helpful in diagnosis and prognostication in cardiomyopathy. For example, a dilated cardiomyopathic ventricle with substantial regional wall motion abnormalities suggests an "ischemic" process. Further, valve dysfunction, ventricular outflow tract obstruction, and vena caval dilatation are readily detectable signs of cardiomyopathy. As was stated above MRI is an optimal means for detecting these conditions with excellent reproducibility.

HYPERTROPHIC CARDIOMYOPATHY

The diagnosis of hypertrophic cardiomyopathy is most sensitively made by visualizing the entire myocardium in view of its wide phenotypic variability. The most common pattern is associated with asymmetric hypertrophy. Nevertheless, a wide variety of patterns of wall thickening can be seen, from extensive and diffuse to limited and segmental, with no single morphologic expression considered typical.[136] Serial short-axis MR images systematically slice the ventricles from base to apex, allowing comprehensive evaluation of wall thickness (Fig. 18A-17). Cardiac MRI using this approach correlates well with echocardiography and x-ray cineventriculography in delineating the precise site and extent of hypertrophy.[137-139] Hypertrophy confined to the apex is a variant of hypertrophic cardiomyopathy that may be difficult to visualize by conventional echocardiography but is readily distinguished by MRI.[140-142] When the extent of turbulent flow (signal loss) in the LV outflow tract is defined, a semiquantitative assessment of the degree of dynamic LV outflow tract obstruction can be made with gradient-echo MRI.

DILATED CARDIOMYOPATHY

Typically, dilated cardiomyopathy is characterized by biventricular enlargement with depressed systolic function. MRI provides a noninvasive method for accurately determining RV and/or LV end-systolic and end-diastolic volumes, stroke volume, ejection fraction, thrombus, and/or valve dysfunction. Segmental wall thinning and regional dysfunction suggest a coronary artery disease etiology. However, one must be cautious in evaluating regional LV function, since the apex is frequently akinetic in dilated cardiomyopathy.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy is characterized by myocardial thickening with normal to reduced chamber volumes and frequently depressed LV systolic function. In addition, because of restricted diastolic ventricular filling, the atria and vena cavae commonly are dilated.[143] In patients with restrictive/constrictive hemodynamics, MRI frequently can distinguish between restrictive cardiomyopathy, which is managed medically, and constrictive pericarditis, which is managed surgically. The pericardium is thickened in constrictive pericarditis but usually is not thickened in restrictive cardiomyopathy. Occasionally, restrictive cardiomyopathy is caused by hemochromatosis. This condition frequently is characterized by a reduced or absent signal from the liver and spleen, since the reticuloendothelial system is laden with iron.

ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA

Because of the geometric shape of the right ventricle, segmental analysis is exceedingly difficult using current imaging technologies. The segmental morphology and function of the right ventricle can be evaluated extensively by using serial contiguous tomographic slices through the heart from base to apex, for example, by spin-echo and gradient-echo imaging. The hallmark of arrhythmogenic RV dysplasia is fatty infiltration with extreme thinning and akinesis of the RV free wall. Fat is identified readily by its increased intensity on T1-weighted MR images. The RV free wall is normally 3 mm in thickness, and thinning is more difficult to detect because of limitations of spatial resolution on traditionally gated cine MR studies. Also, it can be difficult to distinguish between the intramyocardial fat and the epicardial fat adjacent to the TV wall.[144] Analysis of RV function using gradient-echo or echo-planar MRI provides a means of observing focal RV free wall aneurysms and segmental dyskinesis[145] (Fig. 18A-18). Nevertheless, the resolution afforded by MRI allows other characteristics of arrhythmogenic RV dysplasia, such as conspicuous trabeculations and scalloping of the RV free wall, to be visualized.

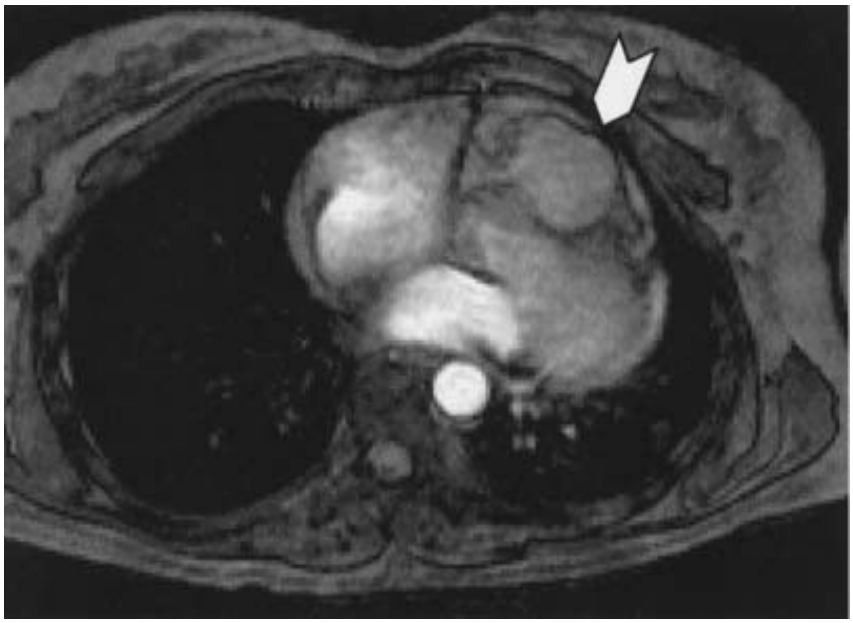

Figure 18a-18: Gradient-echo image of a patient with arryhythmogenic RV dysplasia (ARVD). Note the focal region of thinning of the right ventricular free wall (*arrow*). Another sign of ARVD is the appearance of lipid infiltrating the involved segment. However, this is not the case here.

Congenital Heart Disease

Transthoracic echocardiography is an ideal approach for noninvasive assessment of congenital cardiovascular anomalies in infants and young children, since this technique often requires no sedation and the ultrasound beam is not obstructed by calcified bone and has a nearer target than it does in older children, adolescents, and adults. As a child approaches adolescence or has a surgical repair, the echo assessment may become more difficult and sometimes incomplete. More often, invasive techniques must be performed to assess cardiac, vascular, conduit, or baffle structures adequately. Because of the morphologic detail afforded by MRI and MRA, virtually all common congenital anomalies have been reported in the literature.[146-149] Hence, many patients do not require cardiac catheterization to identify complex congenital anatomy accurately.

MR approaches can image the five necessary anatomic parameters for the initial evaluation of a patient with complex congenital heart disease: situs, ventricular loop, atrioventricular connection, location of the apex, and ventriculoarterial connections. Since MR methods are not influenced by body habitus or scar tissue, deep vascular structures such as the central pulmonary arteries and the ductus arteriosus are well visualized even in a postoperative patient. Baffles and conduit size and function can be evaluated fully by MR provided that no metallic (conductor or ferromagnetic) materials were used at the sites, which would interfere with image integrity because of substantial signal loss.[150] As was described previously, RV size and function are determined more accurately by MRI, which is most relevant in the management of patients with disorders such as transposition of the great vessels and interventricular and interatrial shunts or after repair of tetralogy of Fallot. In patients with coarctation of the aorta with or without aortic hypoplasia, angiography is no longer required unless knowledge of coronary anatomy also is desired.[151-154] Measurements of flow and velocity across shunts and within baffles and conduits also can be made by using PVM. By using such phase-velocity measurements, one can determine the magnitude of the shunt severity or the severity of stenosis noninvasively.[155,156] Furthermore, when phase-contrast cine MR is used, the size of an atrial septal defect can be defined accurately, thus assisting in determining the timing for optimal operative intervention.[157]

Intracardiac Masses and Thrombi

Masses within a heart chamber can be identified with either spin-echo (dark blood) or gradient-echo (bright blood) imaging. The MR intensity of the mass in the spin-echo image also may help characterize its pathology on the basis of T1 relaxation time. For example, cysts and lipomas have very high signal intensity, whereas lymphomas and myxomas have less intensity[158-162] (Fig. 18A-19). Thrombus is more difficult to identify since it is usually present in a dysfunctional ventricular segment or in the atrial appendages.[163] Within a cardiac chamber, slow-moving blood within the area of the akinesis or dyskinesis will contain signal and sometimes artificially appear as a mass. Gradient-echo and/or phase-velocity imaging can be used to differentiate clot from blood stasis. The contents of the atrial appendages, especially in patients with atrial fibrillation, also may resemble thrombus since the blood movement is typically sluggish. The most definitive assessment of atrial thrombi continues to be transesophageal echocardiography (TEE).

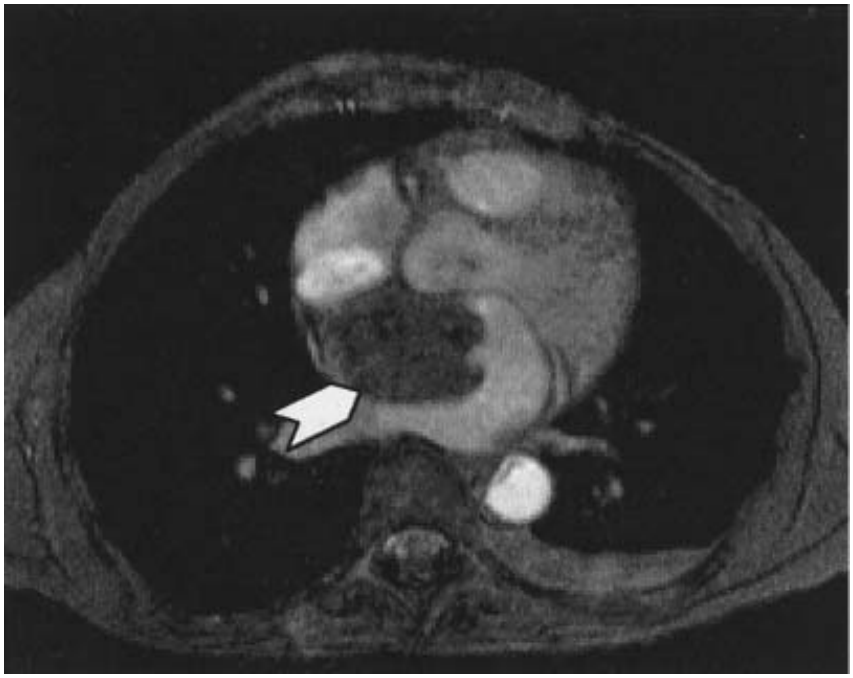

Figure 18a-19: A two-chamber gradient-echo images of a patient with a large left atrial mass (region with reduced signal). Note that the mass in fills about half the left atrial cavity.

Chapter 18A: MAGNETIC RESONANCE IMAGING OF THE HEART

SUMMARY

Cardiovascular MR methods have gone beyond the status of a research tool to become the diagnostic method of choice for many conditions involving the cardiovascular system. This is a noninvasive modality that can generate unlimited tomographic planes, and operator interaction is not necessary. Further, there is no exposure to ionizing radiation. Resolution is high and real-time imaging is normally possible with new-generation MR systems. Also, it can generate spectra showing important metabolites such as ATP within the myocardium. Weaknesses include the lack of portability, the maintenance expense of the instrument, and the risk of the magnetic and RF fields that can displace or heat implanted devices. Despite its technical superiority, reimbursement for cardiac MRI is only somewhat higher than that for a two-dimensional echo/Doppler transthoracic echocardiographic study. Currently, MRI and MRA are most cost-effective when they replace an invasive procedure (e.g., aortography or TEE) or are performed when multiple diagnostic techniques would otherwise be required. For complex congenital heart disease in adults, aortic pathology, and cardiac or paracardiac masses, MRI is the imaging modality of choice. As physicians become more conversant with MRI in clinical practice, they will discover a diagnostic technology capable of answering questions that previously were unanswerable and improving the information provided by other technologies. If one generates images depicting ventricular and valve function, myocardial perfusion, viability, and coronary anatomy within a single time period, there is no better way to evaluate a patient with suspected cardiovascular pathology. This goal is imminently achievable.

Chapter 18a: MAGNETIC RESONANCE IMAGING OF THE HEART

List of Figures

Figure 18a-11: Myocardial spectrum acquired from a healthy person, indicating the phosphocreatine (PCr) and ATP peaks.

Figure 18a-12: Regional left ventricular dysfunction. Midventricular long-axis tomographic gradient-echo sections in end diastole (*A*) and end systole (*B*). Note some thickening of the intervernricular septum but akinesis and marked thinning of the posterior and posterolateral segments (*arrows*).

Figure 18a-13: Long-axis (*A*) and short-axis (*B*) views of the heart. Note the generalized myocardial thinning of the dilated left ventricle and dilation of the right ventricle (*B*). The mid-left ventricular anterilateral wall and the interventricular septum are particularly thin.

Figure 18a-14: A patient with an occluded left circumflex coronary artery that was opened by PTCA and stented. The MRI was performed 2 weeks after an acute MI. Images are seen in the short-axis (*A*) and long-axis views (*B*), and the regions of delayed hyperenhancement are arrowed. (Images provided courtesy of Robert M. Judd.)

Figure 18a-15: Transverse gradient-echo images are shown depicting mitral (*A*) and aortic regurgitation (*B*). In each case, turbulent flow caused by the regurgitant lesion results in loss of MR signal (*arrow*). Note reduced signal on the side of the valve opposite the direction of regurgitation (*white arrow*). This in part is consistent with proximal flow convergence.

Figure 18a-16: *A.* A coronal spin-echo image depicting a large pericardial effusion (*arrow*) *B.* A gradient-echo image depicting bright signal from a pericardial effusion (*white arrow*). Also note the circular region of reduced signal intensity related to postoperative sternal wire.

Figure 18a-17: End-diastolic (*A*) and end-systolic (*B*) gradient-echo frames from a patient with hypertrophic cardiomyopathy (HCM). Note the marked thickening of the left ventricular myocardium, particularly the interventricular septum (*arrow*). In late systole, the left ventricular cavity becomes very small.

Figure 18a-18: Gradient-echo image of a patient with arryhythmogenic RV dysplasia (ARVD). Note the focal region of thinning of the right ventricular free wall (*arrow*). Another sign of ARVD is the appearance of lipid infiltrating the involved segment. However, this is not the case here.

Figure 18a-19: A two-chamber gradient-echo images of a patient with a large left atrial mass (region with reduced signal). Note that the mass in fills about half the left atrial cavity.

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 18B:

MAGNETIC RESONANCE IMAGING OF THE VASCULAR SYSTEM

Authors: Valentin Fuster, Zahi A. Fayad, Stephen G. Worthley, Gerard Helft, Thomas K. F. Foo

INTRODUCTION

Over the last decade, there has been substantial growth in the role of cardiovascular magnetic resonance (CMR) imaging in evaluating cardiovascular structure and function in both clinical practice and research. CMR is an excellent diagnostic tool because of its noninvasive nature, lack of ionizing radiation, high spatial resolution, tomographic acquisition in any plane, and unique tissue contrast. This chapter reviews technical considerations in CMR, describes the established clinical CMR applications, and describes novel and promising approaches for the diagnosis of cardiovascular disease.

CMR relies on the same principles as do other MR techniques.[1-4] Since hydrogen (^{1}H) is the simplest and most abundant element in the human body, most MR studies are of hydrogen nuclei (protons) in water. During the examination, the patient is subjected to a strong local magnetic field, usually 1.5 tesla, that aligns the protons in the patient's body. These protons or spins are excited by a radiofrequency (RF) pulse and subsequently are detected with receiver coils. The detected signals are influenced by relaxation times (T1 and T2), proton density, motion and flow, molecular diffusion, magnetization transfer, changes in susceptibility, and so forth. Three additional magnetic fields (gradient fields) are applied during MR imaging: one to select the slice and two to encode spatial information. The timing of the excitation pulses and the successive magnetic field gradients determine the image contrast.

Chapter 18B: MAGNETIC RESONANCE IMAGING OF THE VASCULAR SYSTEM

TECHNICAL CONSIDERATIONS

Introduction

In MR imaging, an image is encoded into its constituent spatial frequency components. To generate an image of a specific spatial resolution and image field of view (FOV), data for a minimal set of spatial frequencies, or k-space lines, must be sampled so that the object's spatial frequency distribution can be determined. With a single k-space line sampled after a single RF excitation pulse, the number of k-space lines in an image directly determines the total image acquisition time.

In CMR, cardiac motion and respiratory motion present unique challenges in obtaining images of the heart at specific time points in the cardiac cycle. To freeze the motion of the heart, image acquisition time must be shorter than 50 to 100 ms. Longer data acquisition periods lead to increased cardiac motion artifacts. If all the data (k-space data) needed to reconstruct an image cannot be acquired with a single R-R interval, data acquisition must be partitioned across several cardiac cycles, with each data segment being acquired at the same cardiac phase. This synchronization of data acquisition to the cardiac cycle [electrocardiogram (ECG)-gating] ensures that the heart is in the same spatial position or cardiac state for each data acquisition (k-space phase encoding) segment.

Similar to cardiac gating, acquisitions can be triggered by the respiratory cycle, hence the use of a device (e.g., respiratory bellows or belt) or method (e.g., navigator echoes[5]) that indicates expiration and inspiration. Therefore, data acquisition is performed only during a certain phase of the respiratory cycle. Cardiac and respiratory gating may be combined, but image acquisition is therefore increased.

Cardiac MR images can depict the anatomy of the vasculature at a single phase of the cardiac cycle and at multiple spatial locations (multislice imaging) or can be acquired at the same spatial location but at different temporal cardiac phases (multiphase imaging or cine). The multislice techniques can generate projectional angiograms similar to those of conventional x-ray angiography and provide structural anatomic information. Images acquired at multiple phases of the cardiac cycle then can be played back in a movie loop to provide a dynamic representation of the flowing blood[6] (see also Chap. 18A).

Black Blood Imaging Techniques

CONVENTIONAL ECG-GATED SPIN ECHO

The conventional single-phase, multiple-slice ECG-gated spin echo (SE) is the most common imaging sequence traditionally used for CMR. The SE technique generates images in which the blood signal appears dark ("black blood" images) because of the requirement that any spins excited by the initial 90° RF pulse dephase and are rephased by the subsequent 180° RF pulse. Flowing spins (such as blood) transiting through the imaged slice are affected by one but not both of the RF pulses. Hence, the spins flowing through the slice will not refocus and return a signal; i.e., the signal appears dark in the image. However, slow-flowing blood will not appear dark in SE

images as it may remain within the imaged slice and thus see both the 90° and 180° RF pulses. Saturation RF pulses usually are placed above and below the image planes to ensure that the blood signal is dark.

Long scan times make gated SE images extremely sensitive to respiratory motion and dependent on consistent ECG gating. To minimize the image artifacts from respiratory motion, respiratory view ordering (respiratory compensation) often is used.[7] However, this further extends the total scan time (10 to 20 min) and is sometimes ineffective.

ECG-GATED FAST SPIN ECHO

Conventional SE, with its acquisition of a single line of k-space data per slice excitation, is susceptible to respiratory artifacts, but this can be overcome by using techniques that provide shorter imaging times. When multiple k-space lines are encoded after a single 90° RF excitation pulse with a train of refocusing 180° RF pulses, the fast spin-echo (FSE), or turbo spin echo, sequence provides shorter imaging with reduced respiratory motion artifacts. The number of echoes acquired after the 90° excitation is called *echo train length* (ETL), or turbo factor. With an ETL of 8, the scan time for a T2-weighted sequence [repetition time (TR) = 2 R-R] is reduced to 32 heartbeats for a 128-phase-encoding image.

To ensure that signal from blood is suppressed adequately, a double-inversion recovery magnetization preparation pulse ("velocity-selective" inversion) is used.[8] As shown in Fig. 18B-1, a nonselective inversion pulse inverts all spins in the body. This is followed quickly by a slice-selective inversion pulse that restores the magnetization within the imaged slice. An inversion time (TI = ~600 ms) is selected to null signal from blood when the 90° RF excitation pulse is applied. To minimize image-blurring artifacts from T2 decay in a long echo train, the acquisition is segmented over to several heartbeats and the spacing between echoes [echo spacing (ESP)] is minimized. With an ETL of 32, a gated T2-weighted FSE image can be acquired in 16 heartbeats for 256 k-space lines. This allows fast data acquisition during suspended respiration and provides artifact-free images of the cardiovascular anatomy (Fig. 18B-2). One of the disadvantages of the current double-inversion recovery FSE sequence is that images are acquired a single slice at a time to avoid affecting the effectiveness of the inversion pulses used to null signal from blood.

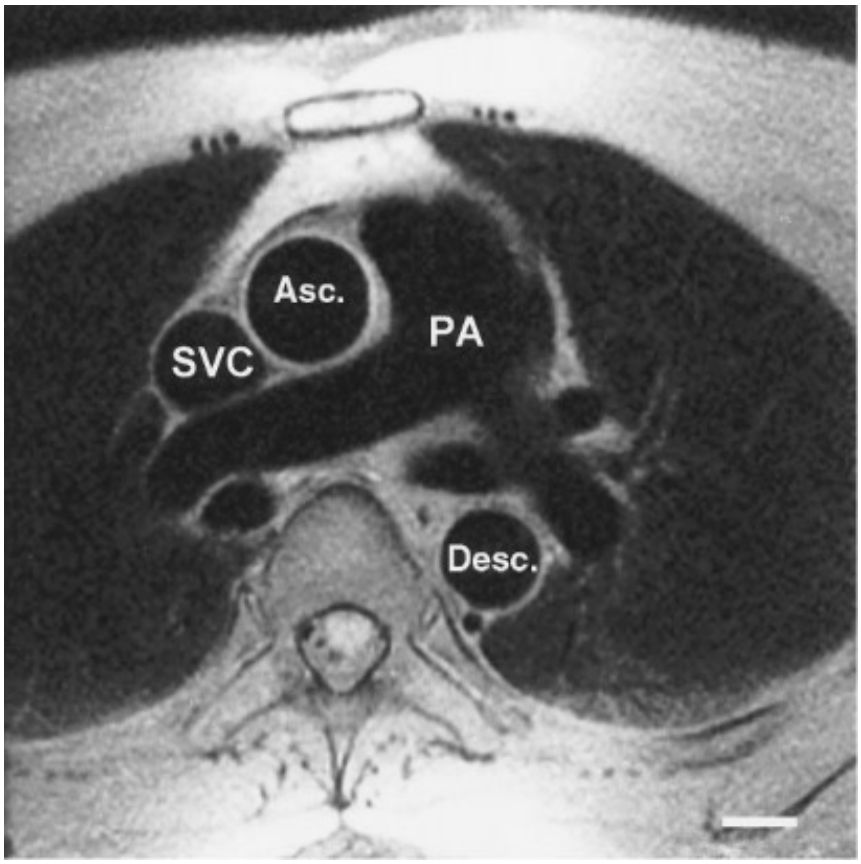

Figure 18b-2: Double-inversion recovery, fast spin-echo, proton-density-weighted magnetic resonance image from a normal subject. The signal from blood is suppressed, and therefore, the lumen is dark. The aortic wall of the ascending (Asc.) and descending (Desc.) aorta is clearly seen. PA = pulmonary artery; SVC = superior vena cava.

A recent extension of the FSE sequence is the single- or segmented-shot (half Fourier turbo spin-echo (HASTE) technique.[9,10] Image acquisition can be acquired in as a short a time as a single heartbeat.

White Blood Imaging Techniques

INTRODUCTION

So-called white blood imaging techniques refer primarily to gradient-recalled echo pulse sequences, which provide images that are T1-weighted. These techniques are characterized by short sequence TRs, flip angles less than 90°, and substantially greater signal intensity of the ventricular blood pool compared with that of the myocardium. The latter effect is due to the in-flow refreshment phenomenon, in which fresh unsaturated blood continues to course through the imaged slice and experience fewer RF pulses than does stationary tissue that remains in the imaged slice throughout the data acquisition period. Bright blood techniques can be subcategorized into time-of-flight (TOF) and phase-contrast techniques.

TIME OF FLIGHT

Conventional Gradient Echo (Cine)

Short TR-gated gradient echo-pulse sequence are used to generate cine images at multiple time frames in the cardiac cycle. Conventional cine pulse sequences run asynchronously to the cardiac

cycle, with the spatial frequency (phase)-encoding value updated on detection of the R-wave trigger. Each RF excitation pulse is applied at the same spatial location and is repeated at intervals of TR in the cardiac cycle. Since the sequence runs asynchronously, the RF excitation pulses may occur at varying time delays from the R wave from one cardiac cycle to the next. On detection of the next cardiac R wave, the k-space encoding value is updated and the acquired temporal data from the previous R-R interval are resorted and interpolated into evenly distributed time frames within each cardiac cycle. This method of gating also is known as retrospective gating because data from the current R-R interval are resorted only after the next R-wave trigger is detected.

As was noted earlier, conventional gradient-echo cine pulse sequences acquire only one k-space encoding view per heartbeat. The total image acquisition time is then of the order of 128 heartbeats. As this time is beyond the ability of patients to maintain an effective breath hold, conventional cine scans are subject to respiratory motion artifacts and require some form of respiratory gating or an intelligent k-space acquisition view reordering to maintain an artifact-free image. These measures, however, are only marginally effective and cannot substitute for a breath-held acquisition.

Segmented K-Space Techniques

Faster CMR techniques have been able to dramatically reduce the image acquisition time to as little as 10 to 15 heartbeats, making breath holding a feasible option to reduce respiratory motion artifacts. Faster scan times have been achieved by segmenting k-space and acquiring multiple k-space lines per R-R interval.[11] The scan time is speeded up by a factor equal to that of the number of k-space lines acquired per image per R-R interval. In this manner, a typical cine acquisition with a matrix size of 128 pixels in the phase-encoding direction can be completed in as little as 16 heartbeats, with eight k-space lines per segment (or views per segment). K-space is divided into several segments, with each k-space line in a segment acquired in a single R-R interval.

Because of the need to acquire data rapidly for several k-space lines to minimize motion-blurring artifacts, segmented k-space techniques are used almost exclusively with fast gradient-echo pulse sequences that have very short TR. Fast gradient-recalled echo acquisition also can be RF-phase spoiled to achieve better tissue-blood pool contrast. However, shorter TRs require smaller flip angles, and as a consequence, image signal-to-noise ratio is lower than that in conventional gradient-echo cine acquisitions.

Multiple phases of the cardiac cycle can be visualized by means of repeated acquisition of the same k-space segment within an R-R interval but assigning the data acquired at different time points in the cardiac cycle to different temporal phases.

In segmented k-space scans, the total scan time is inversely proportional to the number of views per segment (vps). The larger the number of views acquired per segment, the shorter the scan time. However, the reduction in scan time is obtained at the expense of reducing the image's temporal resolution. Significant motion of the heart during data segment acquisition time will result in a loss of spatial resolution from cardiac motion-related blurring. Minimizing artifacts from cardiac motion by decreasing the number of views per segment, conversely, would lead to an increase in the total scan time, reducing the ability to breath hold and reintroducing respiratory-related motion artifacts.

Fortunately, the minimum temporal resolution needed to sample cardiac motion, especially during systole, is about 40 ms. With fast gradient-echo pulse sequences, TR can be reduced to about 5 to 8 ms, permitting the collection of at least 5 to 8 k-space lines per segment. Similar to conventional cine acquisition, a higher effective temporal resolution can be obtained by means a simple interpolation or nearest neighbor viewsharing process.[12]

Each temporal phase image represents the cardiac motion at specific delays from the cardiac R-wave trigger, averaged over the acquisition time per segment. In Fig. 18B-3, it is clear that intermediate cardiac phases can be synthesized or interpolated by sharing k-space views between adjacent time segments to generate images averaged over different time points. The true image temporal resolution is unchanged, but the effective temporal resolution is doubled. View sharing thus can increase the number of phases reconstructed without affecting the manner in which the k-space data are acquired (Fig. 18B-3).

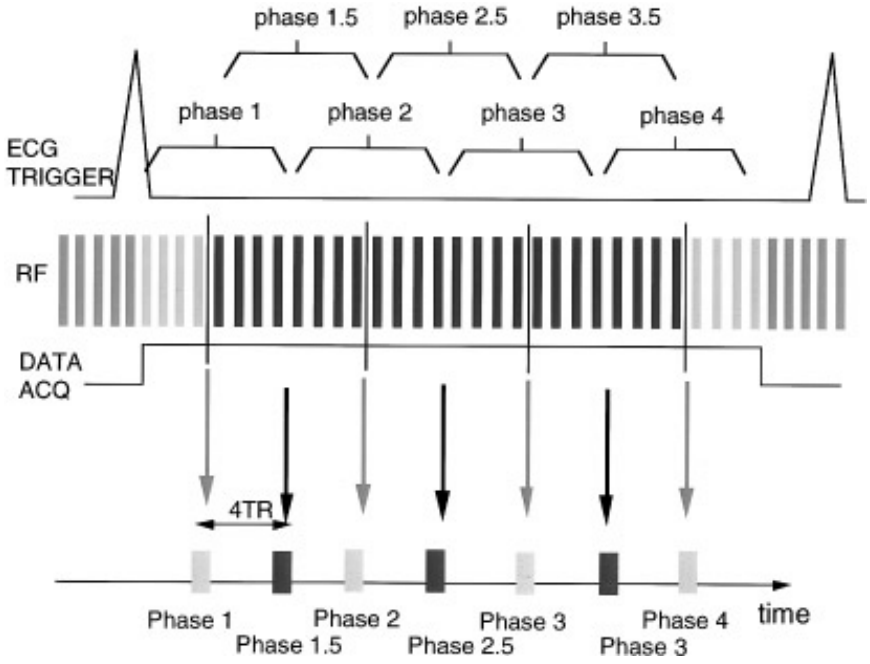

Figure 18b-3: Segmented k-space acquisition and view sharing. View sharing increases the effective temporal resolution by reconstructing images at different time points in the cardiac cycle, similar to the linear interpolation scheme applied to conventional cine scans. The true temporal resolution remains unchanged even though the effective (reconstructed) temporal resolution is doubled.

In addition to the acquisition of images at the same spatial location at different time points in the cardiac cycle (cine), a single-phase multislice acquisition can be performed. A segmented k-space gradient-echo multiplanar acquisition would then acquire images at different spatial locations, each at a different phase of the cardiac cycle. Although the image quality is somewhat limited, a wide range of pathologies can be detected on these images. Major structures such as the aorta, main pulmonary arteries, liver, spleen, and spine are viewed. Another application of this technique is the imaging of uncooperative and sedated patients for whom breath holding is not possible.

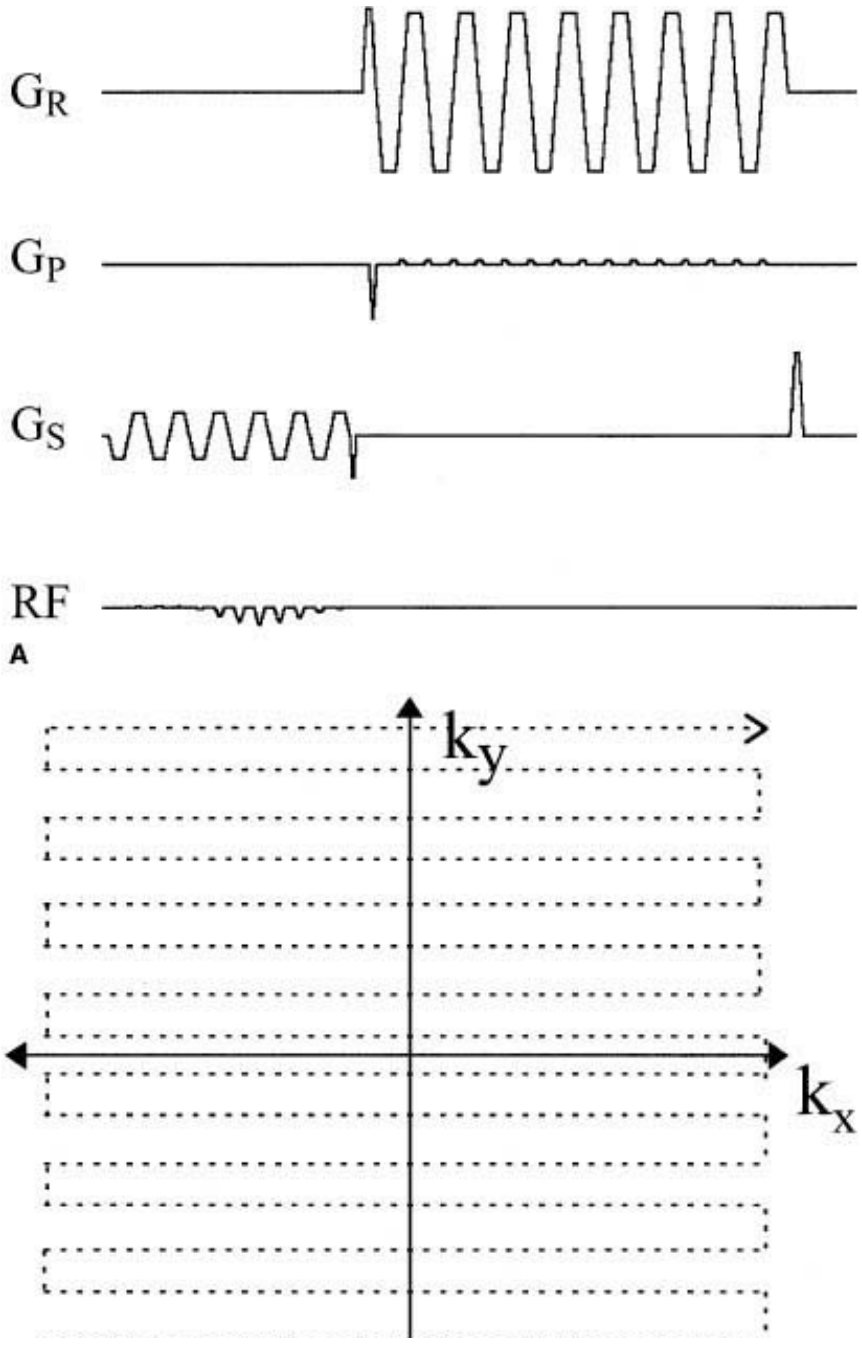
Fast Hybrid Imaging

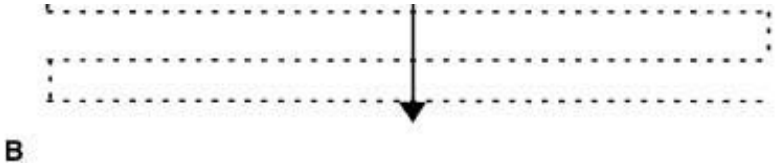
Very fast imaging techniques such as echo-planar imaging (EPI) and spiral imaging (see below) can achieve short scan times by acquiring a larger portion of k-space in each TR compared with conventional imaging. As will be discussed in this section, these techniques are prone to image artifacts. When multishot hybrid EPI and interleaved spiral techniques with relatively short echo train length and short echo spacing and sampling times are used, image artifacts are reduced while significant fast scan times are achieved compared with conventional imaging techniques. New gradient and receiver MR subsystems have substantially improved the performance of EPI and spiral imaging. Several CMR applications, such as real-time interactive scanning, coronary

imaging, first-pass myocardial perfusion, and fast functional cardiac imaging, are now possible with these techniques.

Conventional, Interleaved, and Hybrid EPI

In fast segmented k-space cardiac acquisitions, only one k-space line or view is acquired per RF excitation pulse. EPI is an acquisition technique that collects all lines (single-shot imaging) or several k-space lines (multishot imaging) per RF excitation.[13] As is shown in Fig. 18B-4, this is accomplished by effecting rapid gradient reversals of the readout gradient, generating a series of gradient echoes with each readout echo acquiring data for a single k-space line or view.[14] The number of gradient echoes after a single RF pulse is known as an ETL. As segmented k-space acquisitions reduced the scan time corresponding to a factor equal to the number of k-space lines acquired per R-R interval, interleaved EPI scans further reduce the scan time by a factor equal to ETL. The most significant benefit from using interleaved EPI sequences is that breath-holding times can be further reduced from 16s to 4s with comparable image spatial resolution.





B

Figure 18b-4: *A.* Pulse sequence timing diagram for multishot echo-planar imaging. Note the spectral-spatial RF pulse used for fat suppression. *B.* K-space trajectory traversed by one repetition of the pulse sequence shown in (*A*).

Unlike conventional EPI scans, not all the k-space lines necessary to reconstruct an image are acquired after a single RF excitation pulse. The data acquisition is interleaved between several RF excitation pulses, with between four and eight echoes acquired per RF excitation pulse.[15] The result is a hybrid EPI sequence that is inherently more efficient than conventional segmented k-space fast-gradient echo because multiple phase-encode lines are acquired in each TR. The smaller number of ETLs in a cardiac interleaved EPI acquisition significantly improves image quality, as there is less image blurring from changes in signal intensity across the multiple gradient echoes from T2* relaxation.

Different versions of EPI have been proposed for CMR applications. Single-shot EPI and dual-shot EPI have been used to multislice first-pass myocardial perfusion imaging.[14,16] Similarly, single-shot and multishot EPI and hybrid EPI have been used for faster functional cardiac imaging (multislice and phase imaging)[15,17] and for fast flow quantification.[18] Finally, three-dimensional (3D) multishot EPI also has been used for coronary imaging.[19]

Spiral Imaging

A different approach to cardiac imaging involves the use of spiral rather than rectilinear sampling of k-space.[20] In spiral imaging, the k-space trajectory usually starts at the center of k-space for each RF excitation pulse and proceeds to the higher k-space spatial frequency values in a spiral fashion. This imaging technique has the advantage of acquiring a greater number of data points than are acquired in a conventional rectilinear two-dimensional (2D) Fourier transform acquisition per RF excitation. A complete k-space matrix can be filled by using a single spiral (single-shot) or by using multiple interleaved spiral arms (interleaved spiral). Typically, 2048 and 4096 data points are acquired after each RF excitation pulse per spiral arm or interleave. Complete sampling of k-space is attained by interleaving several spiral arms (usually 16 to 24) in different acquisitions (Fig. 18B-5). Therefore, multiple slice locations (12 to 18) usually are obtained during a short breath hold. The fact that the k-space sampling always starts at the center of k-space for each spiral trajectory makes spiral scans less sensitive to motion- and flow-related artifacts. Longer TRs and larger flip angles usually are used in spiral acquisitions, providing an SNR advantage over small flip-angle fast gradient-echo imaging. The RF excitation pulse used with spiral imaging is usually a spectral-spatial pulse that provides excellent suppression of pericardial fat (Fig. 18B-5).[21]

To reconstruct spiral scans using 2D direct inverse Fourier transform (2DIFT), a uniformly sampled rectilinear grid must be calculated from the acquired k-space data before the 2DIFT operation. Calculating the rectilinear grid is referred to as *regridding*.[20] In practice, one disadvantage of spiral imaging is that the regridding process increases the time required for image reconstruction.

The primary and distinctive image artifact for spiral imaging is spatially localized blurring caused by off-resonance effects (e.g., the chemical shift of fat and magnetic field inhomogeneities). These artifacts are minimized by using the spectral-spatial RF excitation pulse, short sampling times, and

deblurring postprocessing methods.[22] The sampling time can be kept short by increasing the number of interleaves and using a high sampling bandwidth (64 to 125 kHz).

Studies have shown that spiral imaging can provide excellent high-resolution depiction of the coronary arteries[20] (see the section on coronary artery imaging, below) and cardiac cine imaging.[23]

Real-Time Imaging

The short scan times afforded by spiral trajectories and EPI imaging have enabled fast real-time imaging of cardiac motion. The images are acquired with no ECG gating and during free breathing at a frame rate of about 12 to 24 images per second at an in-plane resolution of ~2 mm.[24,25] The combination of higher-performance gradient subsystems and fast compute engines permits fast data acquisition and image reconstruction with minimal lag time.

This real-time imaging capability allows the user to change and localize scan planes of the heart and coronary arteries rapidly (Fig. 18B-6).

Phase-Contrast Cardiac Imaging

PRINCIPLES

Phase-contrast (PC) MR angiography[26] offers a different contrast mechanism to discriminate between flowing spins and stationary tissue. Rather than depending on the relative saturation of flowing blood and tissue, PC angiography derives image contrast from the differences in the phase accumulated by stationary and moving spins in a magnetic field gradient. The amount of phase accumulated is directly proportional to the flow velocity, allowing quantitative measurement of flow velocities, with stationary tissue having zero value for the phase. In addition, PC angiography allows discrimination of flow direction. Spins moving in the direction of a magnetic field gradient accumulate positive phase, while spins moving in the opposite direction accumulate negative phase. Hence, the magnitude of the phase determines the velocity, while the sign of the accumulated phase determines flow direction.

TIME-RESOLVED QUANTITATIVE FLOW MEASUREMENT

Time-resolved flow information can be obtained by using an ECG-gated fast gradient-echo acquisition and linear interpolation, similar to conventional cine pulse sequences. The difference here is that a pair of flow-encoding acquisitions must be acquired for each k-space view to quantify flow in a single direction (Fig. 18B-7). In a PC acquisition, two images are generated. The phase image contains information about the direction and magnitude of the velocity, and the magnitude image provides T1-weighted image contrast (Fig. 18B-8). When played in a cine loop, the multiple temporal PC images can provide visualization of changes in the flow (direction and velocity) as a function of the cardiac cycle (Fig. 18B-9).

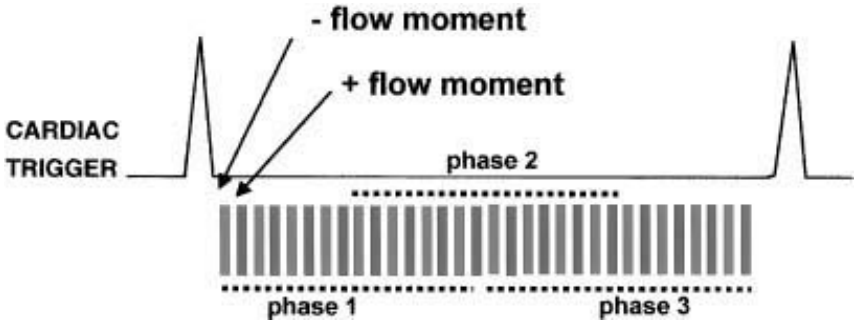


Figure 18b-7: Schematic showing the acquisition of a multiphase (cine) phase-contrast image data set. In this example, flow in one direction is encoded by the toggled flow-encoding gradients (positive flow moment and negative flow moment). As in a fast segmented gradient-echo cardiac acquisition, the R-R interval time is divided into segments, with each segment representing a cardiac temporal phase image (phases 1 and 3). View sharing can be used to generate intermediate phases (phase 2) by using data from each acquired segment.

Plots of the phase velocity as a function of time also can be made across a cross-sectional area of the vessel. If the cross-sectional area of the vessel is known and the flow-velocity time profile is integrated, an average measure of flow in milliliters per minute can be calculated. However, in these measurements, care must be taken to ensure that there are sufficient pixels across the target vessel to minimize errors in the flow measurement from partial volume inclusion of stationary spins.[27]

As in conventional cine acquisitions, the acquisition time for a gated cine phase-contrast scan (cine-PC) is a function of the patient's heart rate and the spatial resolution. A typical cine-PC scan can be completed in about 2 min. The respiratory deficiencies encountered in conventional cine scans are also present in cine-PC acquisitions.

Aortic flow and pulmonary arterial flow also can be measured and assessed against left and right ventricular function, respectively. The assessment of flow across valve leaflets in patients with valvular abnormalities also has been proposed. PC imaging has been shown to provide discriminate flow between the true lumen and the false lumen in aortic dissections and to separate thrombus and flow.

FAST CARDIAC PHASE CONTRAST

Segmented fast gradient-echo techniques also can be applied to PC (Fastcard-PC) scans to reduce the total scan time substantially.[12] Rather than acquiring one flow-encoded k-space view per cardiac cycle, several k-space views can be acquired with flow-encoding gradients, generating a series of flow-sensitized images at different temporal phases with substantially reduced total scan time.

Fastcard-PC scans have been used to evaluate flow in the great vessels and also in the measurement of coronary flow reserve.[28-30] With shorter scan times, PC-cine images can be acquired during a single breath hold. However, care must be taken to avoid using too large of a number of vps, as this may lead to low pass filtering or blunting of the temporal response of the PC measurements.[31]

Contrast-Enhanced 3D Imaging

Conventional and breath-hold SE and gradient-echo techniques define most vessel abnormalities; these are situations in which vessel anatomy is not seen with sufficient clarity because of artifacts. Contrast (e.g., gadolinium-chelates)-enhanced (CE) imaging is advantageous in displaying

detailed vessel anatomy and reducing artifacts.[32] The high signal provided by vascular contrast enhancement makes 3D image processing easier than it is with unenhanced images. CE MR angiography requires very short TR and echo time (TE) times and timing imaging to coincide with the arterial or venous phase of the contrast bolus. The resulting MR images can be rendered in multiple projections. If the patient is incapable of performing breath holding, a slower acquisition can be done over several minutes with a longer and/or slower infusion of contrast agent. However, the vessels may be degraded by respiratory motion.

Coil Selection

Early on, CMR was performed using a body coil, which has the primary advantage of a large FOV and uniform signal intensity. Conventional surface or phased-array coils that were not specifically optimized for cardiac imaging also have been used because of the lack of a cardiac-specific coil. These conventional receiver coils are optimized for general body-imaging purposes (spine, pelvis, etc.); therefore, they have poor sensitivity at larger depths and do not address the specific geometry of the heart within the chest. For example, a standard quatradure surface coil for spine imaging provides adequate images at depths of penetration of only up to 7 cm from the surface of the coil. When such a coil is placed on the anterior chest wall, the deep structures, such as the posterior wall of the left ventricle (located approximately 10 to 15 cm from the anterior chest wall) or the distal coronary arteries, can be well visualized.

Dedicated cardiac coils[33] are becoming commercially available. The FOV is somewhat smaller, and the signal intensity is not uniform. However, the cardiac coils are necessary for improved SNR and for good coverage of the heart and coronaries. Coil placement is very important for adequate SNR, and care must be taken to center the coil around the heart.

Chapter 18B: MAGNETIC RESONANCE IMAGING OF THE VASCULAR SYSTEM

CLINICAL APPLICATIONS

Coronary Artery Imaging

INTRODUCTION

Coronary artery magnetic resonance imaging (MRI) is considered a very challenging area and often is referred to as one of the "holy grails" of CMR. Coronary arteries are small structures (3 to 4 mm in diameter), follow a tortuous course, and are intimate with many surrounding structures, making them difficult to visualize. Motion artifacts from cardiac and respiratory motion provide a further challenge to image quality. Existing coronary MR angiography (MRA) techniques[34-36] can visualize the proximal and middle portions of most coronary artery segments and some branches. Clinical applications include determining patency and direction of flow in native coronary arteries, evaluating the patency of coronary artery bypass grafts and native vessels after intervention, evaluating anomalous coronary arteries, and following up after surgical or medical therapy. The blind prospective detection of coronary artery lesions with coronary MRA is being evaluated with several MRI techniques. No single technique has emerged that can provide the sensitivity and specificity of catheter-based x-ray contrast angiography, although preliminary clinical studies appear promising. At this stage of development, coronary MRA can be used to exclude or confirm suspected clinically important coronary stenoses in patients referred for diagnostic contrast x-ray angiography. As techniques continue to improve, coronary MRA may become an integral part of the clinical evaluation and screening of patients with ischemic heart disease.

CORONARY MR IMAGING TECHNIQUES

Early Imaging

Early attempts at coronary MRA using conventional SE were inadequate. Reports by Lieberman and associates[37] and Paulin and coworkers[38] demonstrated the difficulty of visualizing long portions of artery as well as any stenosis that existed. Since that time, advances in MR technology have allowed more reliable visualization of the proximal epicardial vessels. In an attempt to improve image quality, current techniques combine ECG gating, suppression of respiratory motion (e.g., respiratory gating and compensation), fast image acquisition, and the suppression of signal from surrounding tissues.

2D SEGMENTED K-SPACE BREATH-HOLD METHODS

The most widely studied modality uses 2D segmented k-space gradient-echo imaging.[39] This method allows image acquisition (100 to 150 ms) during middiastole, a period of bulk cardiac diastasis and high coronary blood flow. Each cardiac cycle typically contains eight interleaved phase-encoding steps (vp = 8) and generates a single 2D image on a 128 × 256 matrix in a breath hold of 16 heartbeats (~15 to 20 s, depending on the heart rate) to minimize interference from respiratory motion. Typical parameters are a slice thickness of 3 to 5 mm, an FOV of 240 mm, and in-plane spatial resolution of 1.9 × 0.9 mm. To complete a study, 40 or more breath holds may be required. In this white blood technique, laminar blood flow appears "bright" (inflow of unsaturated spins) in normal regions and turbulent blood flow appears "dark" (dephasing of

signal) in areas of possible stenosis.[39-41] Coronary arteries usually are embedded in fat, which has high signal intensity on T1-weighted images. Suppression of the high signal from fat offers improved coronary visualization. This technique is called *fat suppression* and suppresses the signal from the pericardial and epicardial fat.

OTHER METHODS

Segmented k-space methods require repetitive excitation of the same slice of slab within each cardiac cycle. The result is (1) suboptimal intravascular blood signal caused by saturation effects resulting from the use of low flip angles and short TRs and (2) motion-induced artifacts caused by long acquisition times per cardiac cycle. Multishot echo-planar breath-hold imaging for coronary imaging has been used to alleviate these problems.[42]

Interleaved spiral imaging provides high temporal and spatial resolution with relative insensitivity to flow and motion artifacts.[20] This technique has shown great promise for coronary imaging (Fig. 18B-10).

A 2D breath-hold multislice segmented k-space gradient-echo technique that automatically tracks coronary artery motion by adjusting the slice offset to prospectively follow the coronary artery throughout the cardiac cycle has been proposed. This method increases the number of images in which portions of the coronary arteries are visible (Fig. 18B-11).[43]

Using the black blood fast spin-echo sequence with "velocityselective" inversion preparatory pulses[8] to null the signal from flowing blood high-resolution imaging of the coronary arteries also can be performed in a breath hold (Fig. 18B-12). The advantage of this sequence versus bright blood imaging techniques is being investigated.

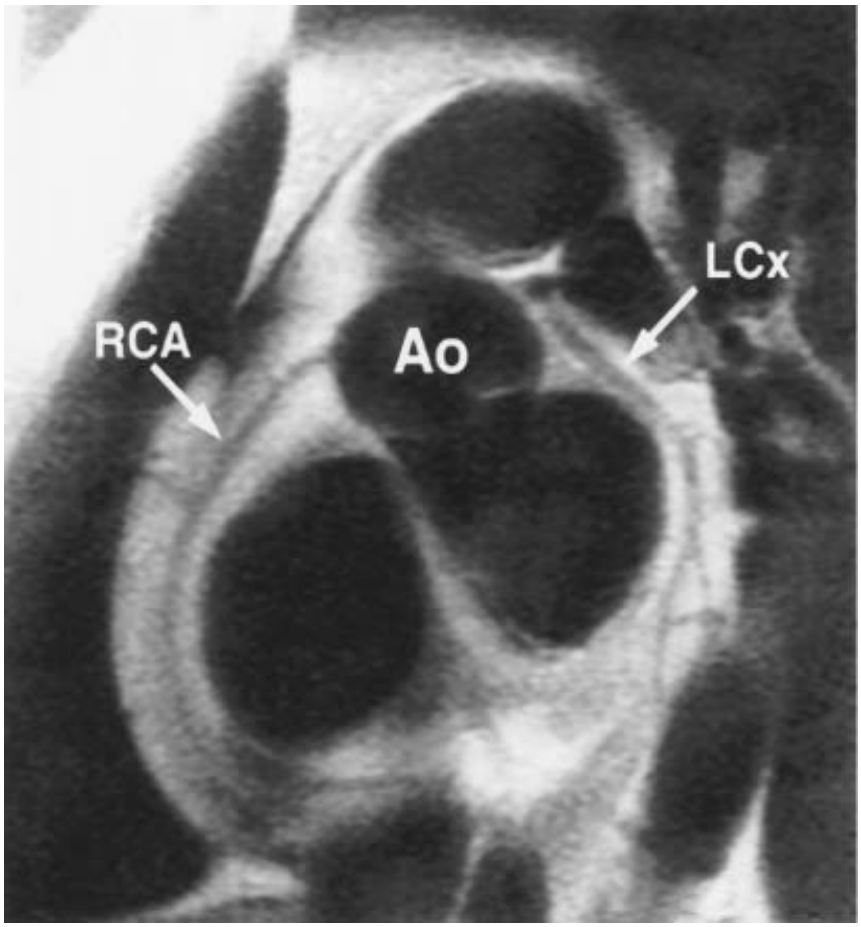

Figure 18b-12: Black blood imaging of the coronary arteries using a 2D double-inversion recovery fast spin-echo sequence. This image was obtained in a breath hold of 16 heartbeats. Long-echo train imaging (ETL = 32) and short echo spacing (ESP = 4 ms) were used. No fat saturation was necessary. The in-plane resolution was 0.5 mm, and the slice thickness was 3 mm. Ao = aorta; RCA = right coronary artery; LCx = circumflex.

Contrast preparation mechanisms such as magnetization transfer,[44] inversion recovery,[45] and T2 preparation[46] also can be employed to improve the delineation between the coronary artery and the surrounding myocardial tissue, especially for the left coronary artery distribution. These contrast preparation techniques are important because they improve vessel visualization by reducing partial volume effects.

3D IMAGING

Three-dimensional imaging offers enhanced signal reception[47] with reconstruction capabilities used for visualizing tortuous vessels.[48] 3D imaging is prone to blurring and requires scan times that far exceed that of a breath hold.[49]

Attempts have been made to improve the free breathing 3D acquisition methods. Signal averaging,[50] respiratory feedback,[51] a respiratory monitoring belt,[52] and coached breathing[53] have all been used. New thin 3D slab acquisition is allowing imaging of the coronary arteries in a breath hold.[19]

NAVIGATOR ECHO IMAGING

Techniques used to suppress motion artifact may eliminate the difficult task of breath holding. Real-time navigator echo[5] has been successful in limiting respiratory motion artifacts. When the

lung-heart or lung-diaphragm interface is interrogated (Fig. 18B-13*A*), positional changes can be monitored through the respiratory cycle (Fig. 18B-13*B*) and image acquisition can be gated to respiratory motion according to the superoinferior position of the diaphragm (Fig. 18B-14).[54] The navigator data then are used to perform image correction prospectively[55,56] or retrospectively.[44,57] The navigator data also can be used to prospectively correct the slice position, allowing the use of wider gating windows with improved time efficiency.[45,46,58] Irregular breathing patterns may be problematic, and the accuracy with which the diaphragm is tracked determines to a great extent whether the coronary arteries are imaged at a constant position.[54]

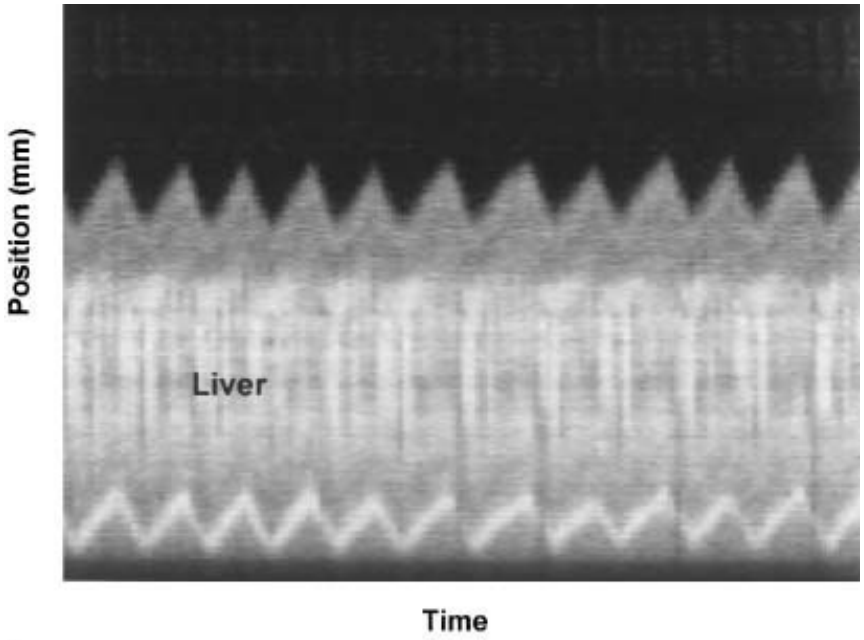

Figure 18b-13: *A.* A sagittal scout image in the region of the right hemidiaphragm showing the placement of a rectangular or cylindrical two-dimensional navigator echo column. The one-dimensional profile of the signal from this column is used to determine the displacement of the edge of the diaphragm from a specified reference position. *B.* An image composed of stacked one-dimensional navigator profiles as a function of time. The vertical axis has units of distance, and the horizontal axis is a function of time. The region of bright signal is the dome of the liver, and the lung field is indicated by the noise.

Typically, the acquisition parameters for a coronary MR study have an image FOV of 20 to 24 cm, with 1- to 1.5-mm sections. Since the volume acquisition is targeted over a specific vessel, the use of 16 to 20 partitions allows a 15- to 30-mm-thick region to be imaged, with the coronary artery approximately in the plane of acquisition. Scan times may range from 5 to 10 min for visualizing a single coronary artery distribution. The scan planes can be targeted for the different coronary artery structures (Fig. 18B-15).

CONTRAST-ENHANCED CORONARY ANGIOGRAPHY

Contrast-enhanced MRA has dramatically affected aortic, renal, and peripheral MRA through the use of both conventional extravascular (e.g., gadolinium-chelates) and new intravascular contrast agents. The latter include iron particle-based (e.g., iron particle-based AMI-227, Advanced Magnetics; iron particle and NC100150, Nycomed-Amersham; gadolinium-chelate, which binds to plasma albumin IS325, EPIX, and gadomer-17, Shering) contrast agents. Intravascular agents have several advantages over extravascular contrast agents: (1) higher T1 relaxivity, (2) higher concentration within the blood, (3) reduction of extravasation into the myocardium, and (4) blood signal remaining enhanced for a relatively long time. Early studies suggest that CE coronary MRA may play a role in improving coronary imaging (Fig. 18B-11).[59-61] The potential clinical applications of these agents awaits the results of large-scale multicenter clinical trials.

ANOMALOUS CORONARY ARTERIES

Not only is coronary MRA a noninvasive method, conventional x-ray angiography often may not be able to determine the exact pathway of an anomalous vessel. Both 2D and 3D coronary MR methods are proving to be well suited for the characterization of anomalous coronary arteries. Although rare, coronary anomalies must be defined accurately, as certain varieties carry the risk of

sudden cardiac death (Fig. 18B-16). MRA is an excellent way to identify anomalies and in some cases is superior to coronary angiography.[62,63] Coronary MRA should be considered a diagnostic tool in any suspected case.

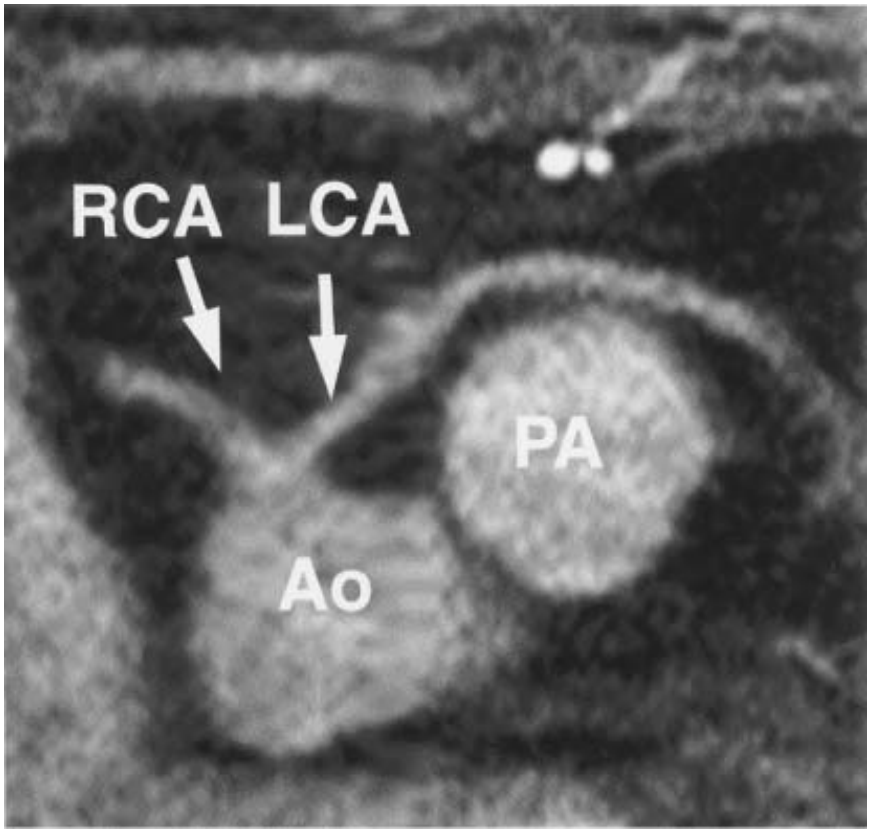

Figure 18b-16: A 53-year-old woman with multiple cardiac risk factors and recent onset of chest discomfort suggestive of angina. Thallium stress test was suggestive of reversible ischemia. 3-D navigator triggered MR angiogram (curved reformat) shows anomalous left coronary artery (LCA) originating from right cusp and passing anterior to pulmonary artery (PA). Ao = aorta; RCA = right coronary artery. (Courtesy Dr. Christine H. Lorenz, Barnes-Jewish Hospital at Washington University Medical Center, St. Louis, MO.)

CORONARY BYPASS GRAFTS

Conventional ECG-gated spin echo and gradient echo have been used to evaluate coronary bypass grafts. The more stationary position and the straight path of internal mammary and saphenous vein grafts contribute to the relative ease at which these vessels may be visualized by MRA. Routinely, contiguous transverse images are obtained through the area expected to contain each graft. The graft is deemed patent if laminar flow is detected by signal void (spin echo) or bright signal (gradient echo) in at least two contiguous anatomic levels. Laminar flow on only one level is considered indeterminate. The absence of laminar signal means the vessel is occluded. SE and gradient-echo methods have demonstrated equal accuracy.[64-66] Contrast-enhanced MRA has demonstrated improved accuracy in bypass graft evaluation.[67,68]

As with intravascular stents (see below), a major obstacle for bypass graft imaging is the local signal loss and artifact associated with implanted metallic objects such as ostial graft rings and homeostatic clips. These artifacts may make signal voids related to blood flow through a stenosis in the bypass graft indistinguishable. In addition, grafts with tight stenoses may result in insufficient contrast penetration to characterize graft patency. Therefore, identification of focal

stenoses within a graft may be extremely difficult and limited. The possible use of more MR-"friendly" materials may help alleviate this problem in the future.

STENTS

Since the introduction of coronary stents,[69] coronary stenting has been used commonly to treat obstructive coronary artery disease. Coronary stents typically are made of stainless steel or tantalum.[70] After implantation, they are endothelialized and incorporated into the vessel wall. Because of the strong magnetic field required by current MRI systems, there has been concern about the possible heating or even dislocation of previously implanted coronary stents in patients undergoing MRI. The current recommendation is to wait several weeks (~6 weeks) after stent placement before doing an MRI.[71] Additionally, the implanted stent may cause imaging artifacts and signal loss[72] because of its metallic nature[73] at the implantation site, prohibiting the visualization of the underlying structures (Fig. 18B-17).

Despite these challenges and limitations, coronary MRA after stent placement has been found to be safe[74] and possible for the assessment of coronary artery patency.[75] The use of more MR-"friendly" and artifact-free stents may provide a way to minimize this problem in the future.[76]

CORONARY BLOOD FLOW ASSESSMENT

Assessment of coronary blood flow with MR at rest and under pharmacologic stress offers the potential to identify noninvasively areas of the myocardium that merit revascularization in coronary artery disease (CAD) patients. MR flow measurement is based on modification of the MR signal of the flowing blood as it traverses the imaging plane. The use of phase-contrast MR imaging (velocity-encoded cine) is based on the principle that protons in the bloodstream experience a net change in the phase of precession proportionally to their velocity as they travel in a magnetic field gradient. The region of interest around the vessel perimeter is defined, and flow-velocity values are analyzed.

The main technical challenge for coronary flow determinations is the small diameter of the coronary arteries. Partial volume averaging results in overestimation of the flow velocity. Furthermore, cardiac motion and the currently limited spatial resolution of MR imaging introduce potential error in the measurement of coronary artery cross-sectional area and quantification of absolute coronary blood flow. Measurement of flow in the coronary sinus[29] and proximal aorta[77] can overcome the problems of partial volume averaging, motion, and low resolution. However, such global assessment of the coronary circulation is of little help in the study of focal coronary stenoses.

Various modifications of the phase-contrast approach[30,78,79] have been used to measure coronary flow at rest and after intravenous injection of adenosine or dipyridamole and after isometric exercise in patients with CAD.[80,81] A threefold to fivefold increase over resting blood flow and velocity can be measured after pharmacologic vasodilatation.[78,79] In patients with significant stenoses, the impaired coronary flow reserve has less than a twofold increase.

Similarly, MR coronary blood flow measurement has been used in native and grafted internal mammary arteries and saphenous vein grafts.[65,66,82]

CORONARY WALL IMAGING AND PLAQUE CHARACTERIZATION

The ability to define the components of a complex coronary atherosclerotic lesion (i.e., fibrous cap, lipid core, calcium, and hemorrhage) accurately could potentially allow risk stratification of patients for future acute coronary syndromes.[83] Given the excellent soft tissue contrast provided

by CMR imaging techniques, the ability of MR to differentiate between these plaque components has been investigated.[84-87] Experimental data have shown that MR is effective in identifying both the normal vessel wall components and atherosclerotic plaque in research conditions, often using high-field MR systems and performing imaging ex vivo to improve the spatial resolution.[88,89] In animal models, MR has been shown to be able to characterize the components of atherosclerotic lesions in transgenic mice and rabbits.[90-92] However, the ability to translate these techniques to the human coronary arteries in vivo has the same limitations that initially faced MR coronary angiography: motion (cardiac and respiratory), small vessel size, and tortuousity of the vessels. However, to visualize the components of a coronary atherosclerotic lesion, submillimeter resolution will be required.[93]

Experience with long-echo-train fast spin-echo imaging to null the signal from flowing blood and an optimized chemical shift pulse to null signal from perivascular and epicardial fat have shown great promise (Fig. 18B-18).[94,95] A cardiac phased-array surface coil for high-resolution coronary imaging (up to 460-μm in-plane spatial resolution) is used.[33] Normal and atherosclerotic human coronary wall imaging can be performed with high-resolution black blood methods. This may allow the identification of atherosclerotic disease before it becomes symptomatic. Further studies are necessary to identify the different plaque components and assess lesions in asymptomatic patients and their outcomes.

Aortic Imaging

CMR has been shown to be useful in both acquired and congenital abnormalities of the aorta. The noninvasive and high-resolution nature of MR makes it an ideal tool for imaging the deep structures of the thorax.

AORTIC DISSECTION

Among all the imaging modalities currently clinically available for the detection of aortic dissection, CMR appears to have the highest accuracy.[96,97] Furthermore, because of its noninvasive nature, it permits sequential imaging over time and thus allows patients at risk of and those who already have had an aortic dissection to be monitored. Using CMR, one can assess not only the intimal flap and site of tear with contrast-enhanced 3D MRA (Fig. 18B-19) but other important associated abnormalities, such as aortic wall thrombus/hematoma, aortic regurgitation, pericardial effusion, and branch vessel involvement.[98,99] It is the investigation of choice in hemodynamically stable patients. However, because of potential delays in patient access, transesophageal echocardiography (TEE) is indicated for unstable patients. Despite a high sensitivity for aortic dissection detection with TEE, it has a reduced specificity compared with MRI.[96]

The ability to detect aortic wall thrombus/hematoma has clinical implications, as it is considered a precursor for dissection.[100] MRI can accurately identify aortic wall thrombus/hematoma, as determined by aortic wall thickening (>7 mm), with a smooth surface and often areas of high signal intensity on T1-weighted images because of the presence of methemoglobin.[101]

AORTIC ANEURYSM

When contrast-enhanced three-dimensional MRA is used, high-quality imaging of the thoracic aorta can be performed (Fig. 18B-20), allowing not only detection of aortic dissection, as described above, but also visualization of aneurysms irrespective of the site or etiology; thus, it can assist in determining the appropriate timing for surgery.[102] CMR appears to be better able to accurately define complex aneurysm anatomy and branch vessel involvement than ultrasound for

abdominal aortic aneurysms.[103] Furthermore, CMR is able to detect mural thrombus (gradient- and spin-echo sequences) complicating an aortic aneurysm.[104,105] However, the advantage of CMR over simpler techniques (ultrasound and computed topography) in determining the timing of surgery in patients with aortic aneurysms is unclear.

Figure 18b-20: Dynamic 3D imaging after the administration of Gd-DTPA. This MR image shows a severe aortic aneurysm in the ascending aorta (*asterisk*).

CONGENITAL ANOMALIES

In adults with congenital vascular anomalies, CMR is the diagnostic approach of choice because of its large field of view and the lack of the need for hyperosmolar contrast medium such as the radiopaque contrast medium used for x-ray angiography. MR angiography is useful for assessing the presence and severity of aortic coarctation, the effectiveness of balloon aortic angioplasty, and the etiology of postoperative complications, e.g., aneurysms or dissections.[106-108] The luminal dimensions of the aorta can be reproduced serially to assess the risk for aortic aneurysm rupture, as in patients with Marfan syndrome.[109,110] Frequently, concurrent problems such as pectus excavatum and scoliosis limit echocardiographic windows but do not limit imaging with MR. In fact, CMR and MRA provide more complete anatomic detail than does echocardiography and are optimal for assessing and following virtually all these patients. Anomalous aortic configurations such as vascular rings, right-sided aortas, and anomalous origins of branch vessels may be delineated by MRA not only to generate morphologic information but also to determine blood flow.

AORTIC ATHEROSCLEROSIS

Evidence is emerging confirming an association between ascending aortic and aortic arch plaque and atheroembolic cerebrovascular disease.[111] Pathologic and TEE studies have shown that aortic atheroma in these regions is an important cause of embolic cerebral infarction.[111] The risk of atherosclerotic plaque rupture and subsequent thrombogenicity appears to be modulated by the composition of aortic atheroma.[83] The ability to document noninvasively the size and composition (i.e., lipidic versus fibrotic components) of aortic atheroma could permit stratification of risk and allow monitoring of therapeutic approaches such as lipid lowering on the aortic atheroma. However, TEE is semi-invasive, and ultrasound techniques may be limited in their ability to differentiate the various components of complex atherosclerotic lesions.[112]

MR has been shown to accurately differentiate atherosclerotic plaque components in experimental and human models.[84,85,88-90,92] Furthermore, with black blood double-inversion recovery fast spin-echo sequences, there is the potential to visualize the aortic wall with submillimeter resolution, providing noninvasive data about atheroma size and composition (Fig. 18B-21).[86,87] This use for CMR remains under investigation and is an area of ongoing research.

Chapter 18b: MAGNETIC RESONANCE IMAGING OF THE VASCULAR SYSTEM

List of Figures

Figure 18b-11: A 2D multislice segmented k-space gradient-echo image of the right coronary artery (RCA). The imaging was performed using automated vessel tracking and increased the number of images in which portions of the right coronary artery were visible. Imaging was performed after the injection of gadolinium (0.10 mmol/kg).

Figure 18b-12: Black blood imaging of the coronary arteries using a 2D double-inversion recovery fast spin-echo sequence. This image was obtained in a breath hold of 16 heartbeats. Long-echo train imaging (ETL = 32) and short echo spacing (ESP = 4 ms) were used. No fat saturation was necessary. The in-plane resolution was 0.5 mm, and the slice thickness was 3 mm. Ao = aorta; RCA = right coronary artery; LCx = circumflex.

Figure 18b-13: *A.* A sagittal scout image in the region of the right hemidiaphragm showing the placement of a rectangular or cylindrical two-dimensional navigator echo column. The one-dimensional profile of the signal from this column is used to determine the displacement of the edge of the diaphragm from a specified reference position. *B.* An image composed of stacked one-dimensional navigator profiles as a function of time. The vertical axis has units of distance, and the horizontal axis is a function of time. The region of bright signal is the dome of the liver, and the lung field is indicated by the noise.

Figure 18b-14: Diagram showing the timing of the 3D navigator echo pulse sequence for imaging the coronary arteries. As shown in this figure, the navigator echo segment precedes the fat suppression segment and the image data acquisition segments. Each data acquisition segment consists of an RF excitation pulse to encode for one value of the k-space view in the slice or phase-encoding direction. A magnetization preparation segment also can be implemented into the sequence without affecting the navigator echo acquisition. In this scheme, prospective determination to enable or disable data acquisition for the current R-R interval depends on the ability of the MR imaging system to calculate the diaphragm displacement and arrive at an accept-reject decision within the time period of the navigator echo segment.

Figure 18b-15: Prospective navigator echo three-dimensional coronary artery images in double oblique planes after planar reformation in a healthy volunteer. In two separate acquisitions, the right coronary artery (RCA) (*A*) and the left main coronary artery/left anterior descending (LAD) artery (*B* and *C*) can be visualized clearly. Acquisition parameters were 24-cm field of view, 20 1.5-mm sections, and 256 × 224 matrix with partial Fourier reconstruction

Figure 18b-16: A 53-year-old woman with multiple cardiac risk factors and recent onset of chest discomfort suggestive of angina. Thallium stress test was suggestive of reversible ischemia. 3-D navigator triggered MR angiogram (curved reformat) shows anomalous left coronary artery (LCA) originating from right cusp and passing anterior to pulmonary artery (PA). Ao = aorta; RCA = right coronary artery. (Courtesy Dr. Christine H. Lorenz, Barnes-Jewish Hospital at Washington University Medical Center, St. Louis, MO.)

Figure 18b-17: A 55-year-old man with a single stent in the proximal left anterior descending artery (LAD). *A.* Oblique transaxial images with fat suppression. An area of signal void caused by the susceptibility artifact of the stent is visualized (*arrow*). *B.* Oblique transaxial images without fat suppression. The area of signal void caused by the susceptibility artifact of the stent is better visualized. The mid-LAD is seen only faintly (*arrow*). (From Duerinckx AJ, with permission. Duerinckx AJ, et al.[75])

Figure 18b-18: X-ray angiogram from a 76-year-old male patient showing high-grade stenosis in the proximal left anterior descending coronary artery (LAD) (*arrows, panel A*). The in vivo cross-sectional black blood MR image of the LAD lumen (obtained without fat saturation) (*panel B*) shows an obstructed lumen (elliptical lumen shape), while the wall image (obtained with fat saturation) (*panel C*) shows a large eccentric plaque with heterogeneous signal intensity (maximum thickness ~6 mm). LV = left ventricle; RV = right ventricle; RVOT = right ventricular outflow tract.

Figure 18b-19: Maximum intensity projection images. Dynamic 3D imaging after the administration of gadolinium. Patient had a history of ascending aortic dissection repair. Images show a residual aortic dissection (*arrow*) extending from near the origin of the right subclavian artery through the thoracic (*A*) and abdominal aorta into the right common iliac arrows (*B*). (Courtesy of Dr. Steven D. Wolff, Integrated Cardiovascular Therapeutics, Woodbury, NY.)

Figure 18b-20: Dynamic 3D imaging after the administration of Gd-DTPA. This MR image shows a severe aortic aneurysm in the ascending aorta (*asterisk*).

Figure 18b-21: T2-weighted CMR images from a patient with severe diffuse disease in the descending thoracic aorta. The plaques are different in appearance and characteristics from one location to another. Plaque characterization was based on the information obtained from T1-, proton-density-, and T2-weighted MR images. The inserts in each panel represent a magnified view of the descending thoracic aorta. Panel A shows a type Vc (fibrocellular) plaque. Panel B shows a lipid-rich plaque (type Va). MR images are 5 mm thick, were acquired with no interslice gap, and are displayed cephalad (*panel A*) to caudal (*panel B*). The origin of the right coronary artery (RCA) is clearly seen taking off from the aortic root (Ao).

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 19:

PET FOR THE NONINVASIVE STUDY AND QUANTIFICATION OF BLOOD FLOW AND METABOLISM IN HUMAN CARDIAC DISEASE

Author: Heinrich R. Schelbert

The study of the human heart with conventional radionuclide techniques remains confined to primarily ventricular function and relative distributions of regional myocardial blood flow (MBF). Positron emission tomography (PET) exceeds these capabilities. It offers the probing and defining regional functional processes in absolute units in the human heart spanning from MBF to biochemical reaction rates, substrate fluxes, and neuronal activity. The many positron-emitting, biologically active tracers, the quantitative imaging capability, and the in vivo application of tracer kinetic principles are unique to PET and account for this capability. The human heart's physiology and pathophysiology thus can be characterized more comprehensively. Also, novel insights into the function of the human heart can be gained, while, at the same time, PET can have a decisive impact on patient diagnosis and management. This chapter describes the key ingredients of PET and the tools for the evaluation and/or quantification of local functional processes in the human heart. It then examines how these tools can be applied to the diagnosis and characterization of coronary artery disease (CAD) and its consequences on regional myocardial function and discusses the impact of PET findings on patient management.

TOOLS FOR PROBING MYOCARDIAL TISSUE FUNCTION

Fundamental to the uniqueness of PET are (1) the quantitative imaging and high temporal resolution capability, (2) the in vivo application of tracer kinetic principles, and (3) the large number of physiologically active radiotracers.

Imaging with Positron-Emitting Radiopharmaceuticals

DEDICATED PET SYSTEMS

The quantitative imaging capability results from the physical properties unique to positrons. After losing their kinetic energy, they combine with an electron and "annihilate." The annihilation represents a conversion of mass into energy; i.e., the combined mass of the positron and the electron converts into two 511-keV photons that leave the site of the annihilation in diametrically opposed directions. If both strike two scintillation detectors connected by a coincidence circuitry at the same time, an annihilation event is registered. Its location in space can be defined by circular arrays of scintillation detectors. The near-simultaneous arrival of two 511-keV photons at the two scintillation detectors positioned in opposite directions allows the use of tomographic reconstruction algorithms analogous to those used with x-ray computed tomography. Accordingly, the spatial resolution throughout the image plane is rather homogeneous, unlike that obtainable with single-photon-emission computed tomography (SPECT), where the spatial resolution declines as a function of the distance between the imaged object and the scintillation detectors. Further, by acquiring "transmission" images with external rotating or circular sources of positronemitting isotopes, the images of the tracer tissue concentrations ("emission" images) can be corrected for photon attenuation so that the resulting tomographic images represent accurately the true regional radioactivity concentrations (mCi or MBq/cm^3). Current PET systems offer

spatial resolutions of as high as 4 to 5 mm full-width half-maximum (FWHM). Further, because modern tomographs are stationary circular devices, images can be acquired at sampling rates in the range of seconds. It is therefore possible with PET to rapidly measure changing radiotracer concentrations in tissues.

COMBINED SPECT AND PET

Several institutions use SPECT and PET for the evaluation of cardiovascular disease. For example, the distribution of MBF is determined with ^{201}Tl- or ^{99m}Tc-labeled tracers of MBF and SPECT and then compared with the distribution of myocardial glucose use by imaging [^{18}F]deoxyglucose with dedicated PET systems.[1-3] While this approach yields a diagnostic accuracy comparable with that achieved with dedicated PET systems, diagnostic difficulties can arise due to differences in the geometry of the heart and spatial resolution on SPECT and PET images, as well as artifacts on the SPECT images due to photon attenuation, especially of the inferior wall and the interventricular septum.[4,5]

MULTIPURPOSE IMAGING SYSTEMS

Most clinical applications of PET do not require assessment of functional processes in absolute units. This is particularly true for the identification of myocardial viability and, to some extent, for the detection of CAD. In view of the high cost of dedicated PET systems, lower-cost "hybrid" or "multipurpose" imaging systems are now available. Generally, two types of systems have emerged (Fig. 19-1). One is a SPECT-like system equipped with ultra-high-energy general-purpose collimators to accommodate the 511-keV photons of positrons instead of the 70- to 160-keV photon energies of conventional radiotracers. When used together with ^{201}Tl- or ^{99m}Tc-labeled flow tracers, the [^{18}F]deoxyglucose images provide diagnostic information comparable with that available with dedicated PET systems.[6-11] The second type of system entails a SPECT-like dual-head device with coincidence detection. While highly promising because of its superior spatial resolution, its use is still evolving, and clinical studies are scarce.[12] Initial studies demonstrate a spatial and contrast resolution that is superior to the high-energy-collimator SPECT system and approaches that of dedicated PET systems. Critical, however, is appropriate correction for photon attenuation that now seems feasible with 511-keV photon sources.[13] Both camera types also can be used for conventional single-photon-emitting tracers, hence the name *hybrid* or *multipurpose* systems.

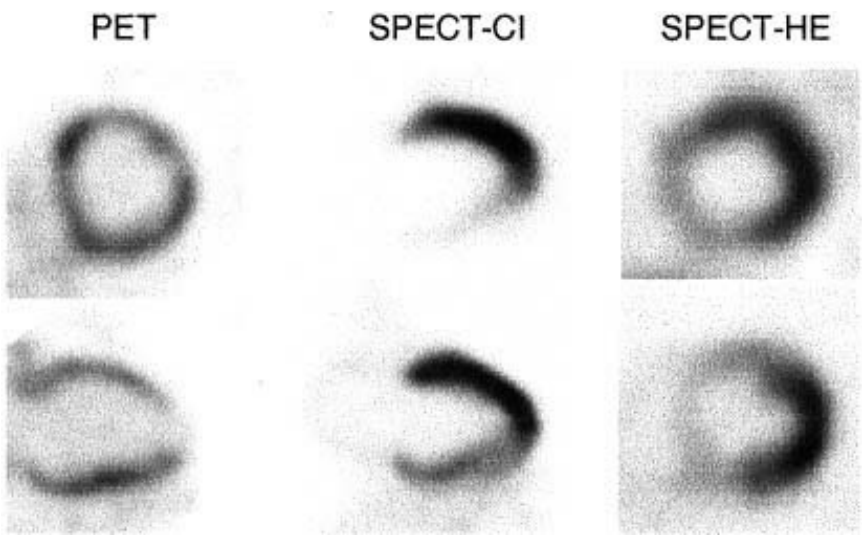

Figure 19-1: Examples of myocardial [18F]deoxyglucose images obtained with PET (*left*), a SPECT-like system with coincidence detection (CI, *middle panel*) (courtesy Dr. R. Henkins, Chicago, IL), and a SPECT system equipped with an ultra-high-energy-photon general-purpose collimator (HE). For the SPECT-CI images, the non-attenuation-corrected image is shown on top and the corrected image at the bottom.

Tracer Kinetic Principles

Positron-emitting isotopes of elements that constitute major parts of living matter such as carbon-11 (^{11}C), nitrogen-13 (^{13}N), and oxygen-15 (^{15}O) are inserted into biomolecules without disturbing their very physiologic properties. Their high specific activity (radioactivity per mass) permits administration of true tracer quantities without exerting a mass effect and perturbing the very process to be studied. Since their physical half-life is short, functional processes can be measured repeatedly or different aspects of the myocardial tissue function can be explored within the same study session. The radioactivity concentrations of these tracers in tissues such as arterial blood and myocardium and their changes over time can be determined noninvasively. The time-activity curves derived from serially acquired tomographic images at sampling rates of 1 to 10 s are fitted with operational equations that are derived from tracer kinetic models and yield quantitative estimates of regional functional processes. Tracer compartment models describe the distribution of the tracer radiolabel in tissue and its time-dependent changes. Because only the activity concentration of the tracer radiolabel can be measured externally, these models relate the externally derived signal to the metabolic fate of the tracer label and its relationship to the functional process under study. Such tracer kinetic models typically consist of functional rather than anatomic pools or compartments that contain the radiotracer or its metabolites. Exchange of radiotracers between compartments is described typically by first-order rate constants. Flux of a radiotracer through a given compartment depends on the flux rate of tracer or of its metabolite and on the size of the compartment. Tracer compartment models provide the basis for developing operational equations; applied to the externally derived radioactivity signal as, for example, tissue time-activity curves, estimates of regional functional processes are derived in absolute units.

Positron-Emitting Tracers of Myocardial Tissue Function

BLOOD VOLUME AND TISSUE CHARACTERIZATION

Blood can readily be radiolabeled with minute quantities of ^{15}O or ^{11}C carbon monoxide (CO). Once inhaled, the radiolabeled CO binds to hemoglobin, thereby tagging red blood cells. The latter serve to define the components of the myocardium in terms of vascular space, viable and normal myocytes, and scar tissue. One such characterization assumes that only living myocytes exchange water rapidly.[14] Transmission images represent the densities of the various tissues in the chest. They resemble low-spatial-resolution x-ray computed tomographic (CT) images and delineate the volume of the myocardium together with the blood in its cavities. The true extravascular volume is obtained by subtracting blood pool images from the transmission images. The fraction of the extravascular volume that exchanges water rapidly is then estimated with ^{15}O-labeled water and is referred to as the *water perfusable tissue index* (PTI). If all the extravascular volume does indeed rapidly exchange water, then the PTI approaches unity.[14] If a portion of the myocardium is injured irreversibly and scar tissue has formed, this fraction becomes less than unity.[15,16] Further, the PTI also will be reduced in diffuse interstitial fibrosis. Initial clinical investigations demonstrated that the fraction of irreversibly injured myocardium or of regional scar tissue formation does indeed indicate whether an impairment in contractile function is irreversible or whether a postrevascularization improvement is likely.[15] If functionally compromised but viable myocardium exchanges water as rapidly as normal myocardium, this may limit the predictive value of the PTI. In recent observations, a reduced PTI had a high negative predictive value, but a near-normal PTI predicted less accurately than [^{18}F]deoxyglucose an improvement in contractile dysfunction.[17] Moreover, the sum of viable and normal myocytes in a

given myocardial segment also serves as a reference to which transmural estimates of MBF or substrate metabolism can be related.[18]

MYOCARDIAL BLOOD FLOW

Several approaches exist for measurements of regional MBF in absolute units. Tracers such as ^{82}Rb or [^{13}N]ammonia are retained in myocardium in proportion to MBF.[19,20] Images of their regional activity concentrations in the myocardium depict the relative distribution of MBF at the time of tracer injection. Each tracer offers advantages and disadvantages. For example, ^{82}Rb is available through a generator based pushbuttonoperated infusion system and hence is easy to use clinically.[21] Its physical half-life of only 75 s affords repeat studies at only 10-min time intervals, enabling evaluation of changes in regional MBF in response to physiologic or pharmacologic interventions. The short physical half-life, however, can result in low-count and, thus, statistically noisy images. The longer physical half-life of [^{13}N]ammonia (10 min), by contrast, produces images of higher count rates and higher diagnostic quality but requires 40- to 50-min time intervals between studies.[20]

The various approaches yield comparable estimates of MBF in the human myocardium during rest and during pharmacologically induced hyperemia.[22-27] Some variability between studies probably derives from methodologic differences but also from intergroup differences in the hemodynamic state. Importantly, MBF in the normal myocardium depends largely on oxygen demand and thus on cardiac work as estimated from the rate pressure product.[28] Thus individual flow measurements should be interpreted within the context of the rate-pressure product.[29] Finally, gender-related differences in MBF have been reported. Compared with an age-matched group of males, women demonstrated higher MBFs both at rest and during hyperemia, which the authors attributed to higher high-density lipoprotein (HDL) cholesterol and lower triglyceride plasma levels in females.[30]

Repeat studies in the same normal volunteers report a 10 ± 11 percent *reproducibility* (average percentage difference of flows normalized to the rate pressure product) for rest MBF and a 12 ± 9 percent reproducibility for hyperemic MBFs.[31] Other studies report similar values for both, [^{13}N]ammonia and for [^{15}O]water.[32,33] Furthermore, the validity of the noninvasive measurements of MBF has been extensively established in animal experiments,[22,27,34-36] as well as in humans, using intracoronary flow velocity probes.[37]

MYOCARDIAL SUBSTRATE METABOLISM

Figure 19-2 depicts the major aspects of the myocardial substrate metabolism. According to this simplified depiction, the myocardium chooses between various substrates; foremost are free fatty acid (FFA), glucose, lactate, and ketone bodies. Selection of a given fuel substrate depends largely on its concentration in plasma and the overall hormonal milieu.[38,39] These in turn are governed by the dietary state, the level of physical activity, and the plasma concentrations of catecholamines, insulin, and glucagon. In the fasting state, circulating FFA levels are high and insulin levels are low so that as much as 70 to 80 percent of the myocardium's oxygen consumption can be accounted for by oxidation of FFA.[40] Conversely, oral glucose intake elevates the plasma glucose level and thus insulin levels while lowering FFA levels so that myocardium shifts its fuel selection to glucose.[39] Strenuous physical exercise increases plasma levels of lactate, which then becomes the major fuel substrate.[41,42] In fact, as much as 60 percent of the O_2 consumption can be accounted for by oxidation of lactate. On the other hand, catecholamines accelerate lipolysis so that circulating FFA levels increase, shifting the heart's substrate selection to FFA.

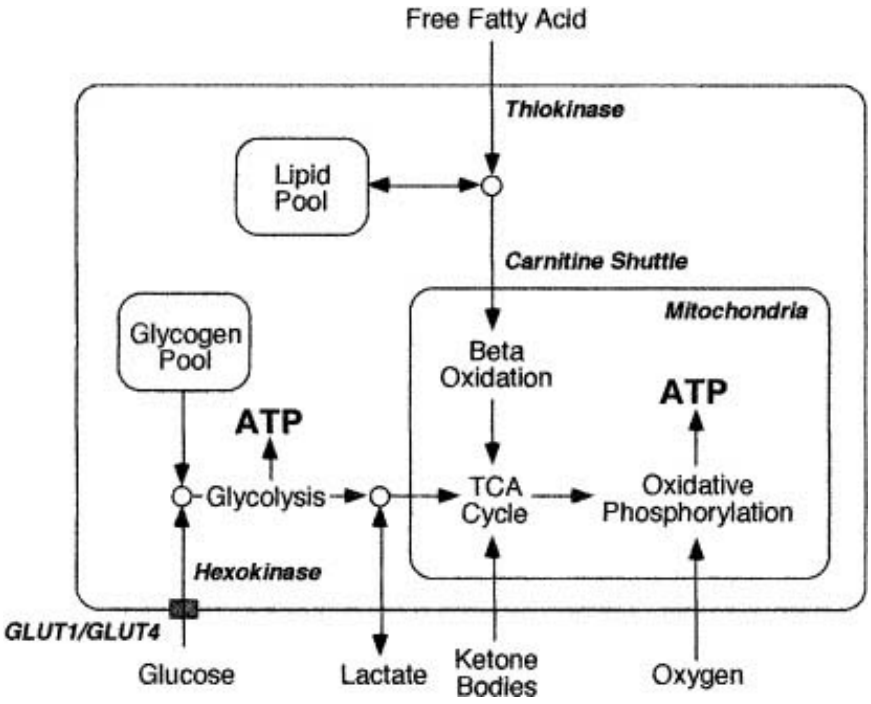

Figure 19-2: Highly simplified depiction of the myocardium's substrate metabolism (TCA, tricarboxylic acid; ATP, adenosine triphosphate; GLUT1 and GLUT4, glucose transporters 1 and 4).

Glucose enters the cell via facilitated transport systems, the largely insulin-independent glucose transporter GLUT1 and the largely insulin-dependent glucose transporter GLUT4. The hexokinase reaction phosphorylates glucose to glucose-6-phosphate. This compound then may be synthesized to glycogen or, alternatively, enter glycolysis with pyruvate as its end product. Converted to lactate, it may leave the myocardium or, if activated to acetyl-CoA, enters the tricarboxylic acid (TCA) cycle as the final oxidative pathway shared by most fuel substrates. Exogenous lactate can be converted via NAD^+ to pyruvate, which then again after esterification to acyl-CoA enters the TCA cycle. FFA also may enter two different metabolic pathways. On entering the cells, it is esterified by the thiokinase reaction to acetyl-CoA. This compound then enters an endogenous lipid pool, consisting mostly of glycerides and phospholipids, and/or proceeds via the carnitine shuttle to the inner mitochondrial membrane. It is there where β-oxidation cleaves of the long-chain acyl-CoA units' two-carbon fragments, which then engage in the TCA cycle. The TCA cycle metabolizes the two-carbon units into CO_2 and H_2O. The rate of flux through the TCA cycle is coupled closely with oxidative phosphorylation, where the energy resulting from the synthesis of oxygen and hydrogen ions is stored in the high-energy phosphate bonds of adenosine triphosphate (ATP). The latter is shuttled into the cytosol with transfer of energy to the high-energy phosphate bond of creatine phosphate. Other sites of high-energy production include glycolysis. The energy yields relative to oxygen differ between the various substrates; e.g., for 1 mol of oxygen, glucose yields 6.3, lactate 6, and FFA 5.7 mol ATP.[43]

Myocardial Glucose Utilization

The initial metabolic step of exogenous glucose metabolism can be evaluated and quantitated with [^{18}F]deoxyglucose (see Fig. 19-2). This radiolabeled glucose analog exchanges across the capillary and sarcolemmal membranes in proportion to glucose with which it then competes for hexokinase for phosphorylation to [^{18}F]deoxyglucose-6-phosphate.[44,45] The phosphorylated glucose analog is a poor substrate for glycogen formation, glycolysis, and the fructose-pentose

shunt; its rate of dephosphorylation is low in myocardium, and it is relatively impermeable to the cell membrane. The phosphorylated tracer thus becomes trapped in the cell so that images of the myocardial ^{18}F concentrations at 40 to 60 min after tracer injection reflect the relative distribution of glucose utilization rates. Because the compound traces only the initial steps of glucose utilization (up to the branch point between glycogen synthesis and glycolysis; see Fig. 19-2), it offers no direct information on glycolytic rates, glucose oxidation, or glycogen synthesis. Yet, in states of glycogen depletion, such as, for example, during ischemia, exogenous glucose serves as the major source of glycolytic flux so that [^{18}F]deoxyglucose may offer an estimate of the rate of glycolysis.

Myocardial Fatty Acid Metabolism

This aspect of the substrate metabolism can be evaluated with 1-[^{11}C]palmitate. The labeled long-chain FFA participates fully in the metabolic fate of its natural counterpart (see Fig. 19-2). Once esterified to acyl-CoA, a fraction of tracer label proceeds via the carnitine shuttle into mitochondria, where β-oxidation catabolizes the long-chain fatty acid into two-carbon fragments that are oxidized via the TCA cycle. The label is released from the myocardium in the form of $^{11}CO_2$. The remaining fraction of the initially extracted and activated tracer enters intracellular lipid pools, mostly those of di- and triglycerides and phospholipids. The biexponential morphology of the myocardial time-activity curve reflects the metabolic fate of the tracer. The slow turnover rate of the intracellular lipid pools accounts for the slow clearance phase, whereas the rapid clearance curve component corresponds to the fraction of tracer that enters β-oxidation and its rate of oxidation. Ischemia reduces the rate of FFA oxidation and of TCA cycle activity. The relative size and rate of the rapid clearance curve component on the ^{11}C myocardial time-activity curve typically decline during acute myocardial ischemia.[46,47] A disproportionately greater fraction of tracer label then enters the slower-turnover endogenous lipid pool. Used mostly as a tracer for the qualitative evaluation of regional myocardial fatty acid metabolism, recent studies suggest the possibility of quantitating myocardial fatty acid oxidation in milliequivalents of FFA per gram of myocardium per minute.[48]

Preferential use of a given fuel substrate (e.g., glucose, lactate, or FFA) depends on its concentration in arterial blood, which, in turn, depends on dietary state, serum levels or insulin resistance, and physical stress.[49] A change in the myocardium's preferential substrate use can be demonstrated with either [^{11}C]palmitate and [^{18}F]deoxyglucose or both.[49-51] In the presence of high FFA and low glucose and insulin levels, use of FFA as the preferred substrate is reflected on the [^{11}C]palmitate curve by the large relative size of the rapid clearance phase and its steep slope (both corresponding to increased fatty acid oxidation) and the low or even undetectable [^{18}F]deoxyglucose uptake. Ingestion of carbohydrates raises plasma glucose levels, stimulates insulin secretion, and depresses FFA levels. The shift to glucose use is reflected by a decline in the size and slope of the rapid-clearance phase of [^{11}C]palmitate and by an increase in myocardial [^{18}F]deoxyglucose uptake.

Myocardial Oxygen Consumption (MVO2)

While molecular ^{15}O oxygen is available for measurements of the (MVO_2,[52,53] the more widely applied approach entails rapid serial imaging with [^{11}C]acetate. The radiotracer clears rapidly from blood into the myocardium and produces high signal-to-background images.[54-57] It directly traces the rate of substrate flux through the TCA cycle as the final oxidative pathway common to most fuel substrates. The rate of clearance of ^{11}C activity from the myocardium on serially acquired images corresponds to the TCA cycle activity and, because of its close coupling to oxidative phosphorylation, to oxidative metabolism and MVO_2. Of note, the tracer yields rate

constants only, which can be converted into units of O_2 per minute per gram. Unlike [^{11}C]palmitate or [^{18}F]deoxyglucose, the clearance rate of [^{11}C]acetate from myocardium is relatively insensitive to changes in myocardial substrate utilization.[54] A tracer compartment model, based on biochemical assays of the tracer tissue kinetics of [^{14}C]acetate in isolated rat hearts[58] forms the base for estimating MVO_2 in absolute units in the human heart and, at the same time, of regional MBFs.[59,60]

Chapter 19: PET FOR THE NONINVASIVE STUDY AND QUANTIFICATION OF BLOOD FLOW AND METABOLISM IN HUMAN CARDIAC DISEASE

CLINICAL APPLICATIONS

Clinical imaging of positron-emitting radionuclides with PET or PET-like devices is gaining momentum because of research showing the considerable potential for contributing to diagnosis, characterization, treatment, and monitoring of disease. New, lower-cost positron imaging devices and the availability of positron-emitting tracers through regional distribution centers have accelerated the pace of dissemination. Foremost in cardiology have been (1) the identification and characterization of CAD and (2) the detection of myocardial viability.

Identification and Characterization of CAD

GENERAL CONSIDERATIONS

Most studies with PET, such as, for example, those performed with [^{13}N]ammonia or ^{82}Rb, evaluate the relative distribution of MBF from the retention of tracer in the myocardium. More recent investigations use PET's quantitative capability for estimating regional MBF in milliliters of blood per minute per gram of myocardium in order to demonstrate abnormalities in vasomotion of the human coronary circulation during the early stages of coronary atherosclerosis.

Unlike other radionuclide approaches, PET employs almost exclusively pharmacologic stress for the detection of CAD and determination of its extent and functional significance. The transmission images, essential for correction of photon attenuation, must be acquired with the patient in exactly the same position as during the emission images. Both dipyridamole and adenosine afford the determination of the myocardial flow reserve as the ratio of hyperemic to rest MBFs. The now classic studies by Gould et al.[61] demonstrated a curvilinear, inverse correlation between stenosis severity and hyperemic flows or flow reserve. Thus the attenuation of the MBF response to dipyridamole induced hyperemia depends on the functional stenosis severity. As demonstrated by flow measurements with either [^{15}O]water or [^{13}N]ammonia, dipyridamole and adenosine as direct vascular smooth muscle dilators evoke interindividually variable hyperemic responses but induce on average four- to fivefold increases in MBF.[22,23,25,62] The magnitude of the hyperemic flow response is similar for dipyridamole (at a dose of 0.56 mg/kg over 4 min) and for adenosine (140 μg/kg/min).[26] Increases in the dipyridamole dose by 50 percent do not produce higher flows, nor do they reduce the interpatient variability in flow responses.[63] Additionally, the values of the normal flow reserve were derived from studies in young normal volunteers with an average age of 34 ± 16 years. This is important as evidence accumulates that flow reserve declines progressively with age[64-66] (Fig. 19-3). Contributing factors include an age-dependent *decline* in the vasodilator capacity and an agedependent *increase* in baseline MBF due to higher rate-pressure products as a major determinant of MBF. A progressive decline in vascular compliance is another possible explanation. Surprisingly, increases in the mean arterial blood pressure due to either isometric handgrip exercise or supine bicycle exercise attenuated the maximum flow response, most likely because of increased vascular resistance due to greater extravascular resistive forces.[63,67] These factors also may contribute to lesser flow increases during physical exercise when flow increases in proportion to MVO_2. Thus pharmacologically induced hyperemia may not necessarily prove to be more accurate in identifying functionally significant coronary stenoses. Even though flows in

remote myocardium may rise less with exercise depending on the level of cardiac work, higher intracavitary left ventricular (LV) pressures and regional wall stresses in ischemic or dysfunctional myocardium may enhance extravascular resistive forces so that flow responses in stenosis-dependent myocardium in fact may be even more attenuated. Because of differences between pharmacologically and physically stressed-induced ischemia, the vasodilator reserve as determined pharmacologically may not necessarily reflect truly the myocardium's ability to raise flow during physical exercise. An example is hypertrophic cardiomyopathy, where MBF during exercise failed to increase despite some residual flow reserve demonstrated with dipyridamole.[68]

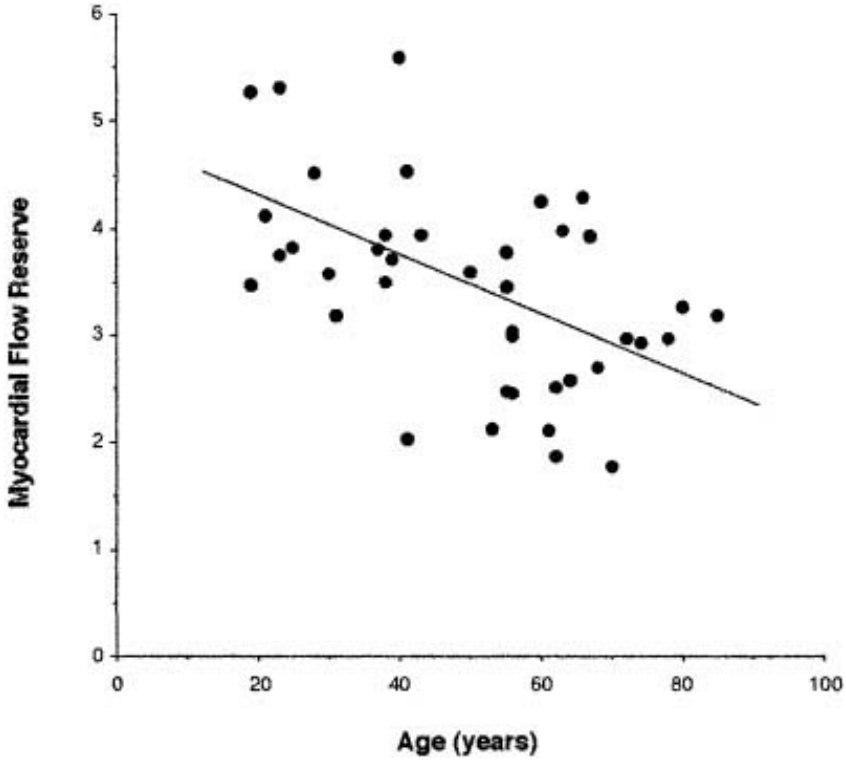

Figure 19-3: Progressive decline in myocardial perfusion reserve as a function of age in 40 normal volunteers. (Reproduced with permission of the American Heart Association from Czernin et al.[29])

Another important consideration with regard to pharmacologic stress is the variability of the hyperemic response. In normal individuals, responses range from about two- to sixfold increases in MBF. Several factors may account for this variability. Among these are (1) the coronary driving pressure, best reflected by the mean arterial blood pressure, (2) extravascular resistive forces as a function of wall tension and tension development, which in turn depend on the diastolic volume and the myocardium's contractile state, (3) β- and especially α-adrenergic control of the basic vasomotor tone,[69] (4) endothelial-dependent vasomotion, and (5) pharmacologic effects on vascular smooth muscle relaxation. The latter may be altered by antagonists of dipyridamole and adenosine, such as, for example, caffeine or theophylline-containing agents.[70] It thus is imperative that patients refrain from these substances for at least 24 h prior to a pharmacologic stress study.

Positive inotropic agents also are used for stress interventions. Dobutamine raises MBF in proportion to increases in cardiac work, as evidenced by increases in the rate pressure product.[71] In one study, intravenous infusion of dobutamine in normal volunteers at a rate of 40 μg/kg of body weight per minute increased the rate-pressure product by about 200 percent, which was

paralleled by a 225 percent increase in MBF.[71] Lower infusion rates produced lesser increases in the ratepressure product and thus in MBF.[72]

ASSESSMENT OF HEMODYNAMICALLY SIGNIFICANT CAD

For the detection of CAD, the relative distribution of MBF is examined at rest and during pharmacologic vasodilation. Either ^{82}Rb or [^{13}N]ammonia is used. Both are retained in myocardium in proportion to MBF so that the resulting images depict the distribution of MBF at rest and during hyperemia. The approach identifies flow defects at rest as well as attenuated responses of regional MBF to hyperemia as a consequence of a coronary stenosis (Fig. 19-4). The baseline and hyperemia flow images are analyzed by visual inspection combined with circumferential activity profile techniques or polar map approaches. While most studies rely on visual analysis, several laboratories employ quantitative image analysis. The regional tracer activity concentrations in a patient are compared with databases of normal displayed graphically in various cartographic forms, such as polar (or azimuthal) or cylindrical (Mercator-like) projections or surface rendered three-dimensional displays of the LV myocardium.[73-76]

Clinical investigations confirmed PET's high diagnostic performance for the detection of CAD.[77-83] Sensitivities range from 87 to 97 percent; and specificities from 78 to 100 percent. Most studies compared rest or stress-induced flow defects to arteriographic findings by visual analysis, and most defined a 50 to 70 percent diameter luminal narrowing as significant stenosis. Given the well-known limitation of visual analysis, Gould et al.[84] and, subsequently, Demer et al.[79] graded stenosis severity by estimates of coronary flow reserve by quantitative arteriography. Coronary arteries were classified as moderately to severely stenosed if the predicted coronary flow reserve was less than 3, as intermediate if the coronary flow reserve ranged from 3 to 4, and as minimal for coronary flow reserve values of greater than 4. According to this classification, 94 percent of vessels with moderate to severe, 49 percent of vessels with intermediate, and 5 percent of vessels with minimal stenosis were accurately identified with PET and pharmacologic vasodilator stress.

COMPARISON OF PET WITH CONVENTIONAL TECHNIQUES

The diagnostic accuracy of PET must be directly compared with that of more conventional approaches in order to define the diagnostic gain. (See also Chap. 16.) Demer et al.[79] indirectly compared their findings with those by another laboratory using ^{201}Tl SPECT but an identical angiographic approach for defining stenosis severity.[85] In this comparison, PET outperformed SPECT. Both studies defined stenosis severity by the angiographically predicted coronary flow reserve. Moderate to severe coronary stenoses were detected with a 95 percent sensitivity by PET and a 72 percent sensitivity by ^{201}Tl SPECT; intermediate stenoses were detected with a 49 percent sensitivity by PET, whereas none were detected by SPECT.

Other studies compared the PET with the SPECT approach in the same patients. An early study used supine bicycle stress and [^{13}N]ammonia in 48 patients with CAD and reported comparable diagnostic performances for PET and SPECT.[78] In another investigation of 202 patients, MBF was evaluated with ^{82}Rb at rest and again 4 min after the dipyridamole infusion.[80] About 8 to 9 min later, or a total of 12 to 13 min after the end of the dipyridamole infusion, ^{201}Tl was injected and SPECT imaging performed within 10 min. PET and SPECT exhibited comparable specificities, while PET demonstrated a significantly higher sensitivity than SPECT. The results were similar when only 132 of the 202 patients without prior cardiac events were analyzed. A third study reported somewhat different findings in 81 patients.[81] Again, all patients underwent rest and dipyridamole stress imaging with ^{82}Rb and PET; for the ^{201}Tl SPECT study, 38 (or 47

percent) of the patients underwent treadmill testing, and the remaining 43 (or 53 percent) underwent pharmacologic stress with dipyridamole. In that study, PET and SPECT exhibited comparable sensitivities; however, the specificity was higher for PET than for SPECT. The diagnostic accuracies were similar for patients submitted to treadmill stress testing and patients with pharmacologically induced hyperemia for SPECT imaging with ^{201}Tl.

Thus both studies demonstrate the high diagnostic accuracy for PET but differ in terms of higher sensitivities and specificities. The average decay half-time of 33 min for the hyperemic response amounts to an only 10 percent decline in the hyperemic response over a 4-min period[86] that is unlikely to fully explain the lower sensitivity of ^{201}Tl SPECT. The gain in specificity in the study by Stewart et al.[81] most likely resulted from the adequate correction of photon attenuation and thus a reduction of falsely positive findings. Although the reasons for the observed differences between both studies remain unclear, image analysis at different points of the receiver operating curve may be one possible explanation.

On balance, the reported studies demonstrate a statistically significant gain in diagnostic accuracy for the detection of CAD by PET. Although larger clinical trials are needed, especially in previously undiagnosed patients with normal MBF and normal wall motion at baseline, current information indicates an improved diagnostic accuracy that may eliminate additional diagnostic procedures. A recent report compared the effect of PET and of SPECT on the subsequent referral to coronary angiography in 1490 and 102 patients, respectively.[87] Pretest likelihoods for CAD were similar for both patient groups. However, the rate of angiography was significantly less (16.7 percent) after PET than after SPECT (31.4 percent), which produced an approximately 23 percent cost saving per patient.

EFFECT OF CORONARY STENOSES ON REGIONAL MBF

Recent investigations took advantage of PET's ability for measurements of regional MBF with [^{15}O]water or [^{13}N]ammonia in order to define the relationships between the angiographic stenosis severity, hyperemic flow responses, and vasodilator capacity.[88-90] These studies noted significant correlations between the anatomic stenosis severity and an attenuation of the hyperemic response to pharmacologic vasodilation. A similar correlation between MBF and coronary stenosis severity was observed when MBF was increased with dobutamine[41] (Fig. 19-5).[91] One study describes an inverse, nonlinear correlation between the cross-sectional area reduction of the stenosis and the flow reserve in the stenosis-dependent myocardium[84] (Fig. 19-6) that resembles the nonlinear correlation observed in animals.[61] In exploring the existence of such correlation in human CAD, the latter study excluded confounding factors such as stenoses in series or collateral vessels to stenosis-dependent myocardium.[89] While such correlation had in fact been expected in human CAD, the considerable scatter of the data about the regression line was not. Factors accounting for this scatter include possible inaccuracies in regional MBF measurements, the variability of the hyperemic response to pharmacologic vasodilation, age differences, and different baseline hemodynamic states. The scatter of the data may further point to a disparity between the anatomic and functional properties of human coronary artery stenoses. Different from the controlled and idealized coronary artery stenoses in the experimental setting, human coronary artery stenoses are of remarkably greater morphologic complexity, including eccentricity, variable stenosis inflow and outflow angles, and different lengths and irregular surfaces, that may not be fully appreciated by angiography nor be adequately accounted for by assumptions underlying model-based estimates of stenosis severity. It thus seems probable that the evaluation of flow, either semiquantitatively or quantitatively, renders more accurate functional information on the stenosis severity and, more broadly, on CAD. Moreover, estimates of an attenuated flow reserve obtained from static images of the relative distribution of MBF during

hyperemic stress clearly offer invaluable information on the functional significance of coronary artery stenosis. Yet, in view of the nonlinear response in flow tracer uptake to increases in blood flow, such "semiquantitative" estimates would tend to be less accurate than those available through true measurements of MBF.

ASSESSMENT OF CORONARY VASOMOTION AND PRECLINICAL CAD

Noninvasive measurements of regional MBF offer the intriguing possibility to uncover vasomotor abnormalities of the human coronary circulation. If such abnormalities exist already during the early stages of CAD, it then may become possible to detect the disease during its evolutionary and preclinical stages. Such measurements further offer the prospect of monitoring disease progression as well as the responses to interventions aiming at regression of disease or slowing or halting its progression. Several lines of evidence support such possibility.

The now well-established beneficial effects of cholesterol lowering and especially of HMG-CoA reductase inhibitors have shifted the emphasis to the assessment of function rather than to the morphology of the human coronary circulation. Dietary and/or pharmacologic cholesterol lowering affect the anatomic stenosis severity only little, if at all, at least over the time periods studied, but strikingly reduced cardiac morbidity and mortality.[92] Hence the beneficial effects are attributed to plaque stabilization and improvements in endothelial function.[93]

Invasive studies of the human coronary circulation, performed during cardiac catheterization with intracoronary administration of direct vascular smooth muscle dilator agents such as adenosine or papavarine and of acetylcholine as a pharmacologic probe of predominantly endothelial-mediated coronary vasomotion, emphasize the importance of endothelial dysfunction early during the development of atherosclerosis (see Chaps. 36 and 37). For example, human coronary arteries with minimal atherosclerotic changes but no flow-limiting stenoses or even without any structural changes but in the presence of coronary risk factors alone revealed normal, predominantly vascular smooth muscle-mediated vasodilator capacities but attenuated or even highly abnormal endothelial-mediated flow responses.[94-96] These invasive studies test endothelial function at two sites of the coronary circulation, the large epicardial conduit and the coronary resistance vessel.[94-96] Measurements of regional MBF by PET offer the opportunity to probe the function of the human coronary circulation entirely noninvasively and mostly at the level of the resistance vessels.

PET-based measurements of MBF in asymptomatic patients with hypercholesteremia revealed an approximately 32 percent reduction in myocardial flow reserve or an approximately 18 percent reduction in hyperemic flow during adenosine administration.[97-102] In fact, the myocardial flow reserve was correlated with the ratio of plasma total cholesterol over HDL cholesterol.[97] Subsequent investigations confirmed these observations but also noted that elevated plasma triglycerides or, in young individuals, a family history of CAD alone or of hypertension was associated with diminished vasodilator capacities and myocardial flow reserves.[103-105] Other studies again observed diminished hyperemic responses in patients with diabetes,[104,106-108] and one study found a correlation between the hyperemic MBF response and the therapeutic control of the diabetic state.[109]

To some extent, these observations differ from those made by invasive techniques, where frequently the predominantly vascular smooth muscle-mediated vasodilator response to, for example, intracoronary papavarine or adenosine was preserved despite the presence of coronary risk factors, while primarily endothelial-mediated responses were markedly abnormal.[110] As Bache suggests,[111] however, the major resistance to flow through the coronary circulation resides at vessels in the diameter range of 100 to 400 μm. If increases in flow exert shear stresses on the

endothelium of the 400-μm vessels, then primarily endothelial-dependent mechanisms augment the flow response to predominantly vascular smooth muscle vasodilators. Conversely, as forearm blood flow measurements have shown, pharmacologic impairments of endothelial function reduce the maximal flow response to intravascular adenosine by about 25 to 35 percent.[112] Consequently, coronary risk factors such as low-density lipoprotein (LDL) cholesterol, triglycerides, and diabetes interfere with endothelial function and account for the diminished hyperemic response to adenosine or dipyridamole.

Another potentially important new concept for identifying diffuse coronary artery narrowing without discrete stenoses has been introduced recently.[113,114] Diffuse luminal narrowing causes a greater decline in pressure along the coronary artery. This then is associated with a progressive decrease in myocardial perfusion from the proximal to the distal portion of the coronary arterial system and hence in a longitudinal base-to-apex perfusion gradient. A similar longitudinal perfusion gradient likely exists during hyperemia in patients without CAD but with coronary risk factors.[115]

The predominantly endothelial-mediated coronary vasomotion can be assessed by the cold pressor test. In invasive studies, cold pressor testing evoked paradoxical changes in the diameter of the conduit vessels comparable with those evoked by intracoronary acetylcholine and, further, alterations at the level of the resistance vessels that correlated with those produced by intracoronary acetylcholine.[116-118] Observations with PET-based measurements of MBF in long-term smokers support the use of the cold pressor test for this purpose.[119] In these young smokers, vascular smooth muscle-mediated hyperemic flow responses to intravenous dipyridamole were normal, but cold pressor testing produced only modest, nonsignificant increases in MBF as compared with nonsmokers, where MBF rose in direct proportion to the cold-induced increase in cardiac work, as estimated by the rate-pressure product (Fig. 19-7). Similarly, abnormal flow responses to cold also were noted in postmenopausal women with and without CAD risk factors.[120]

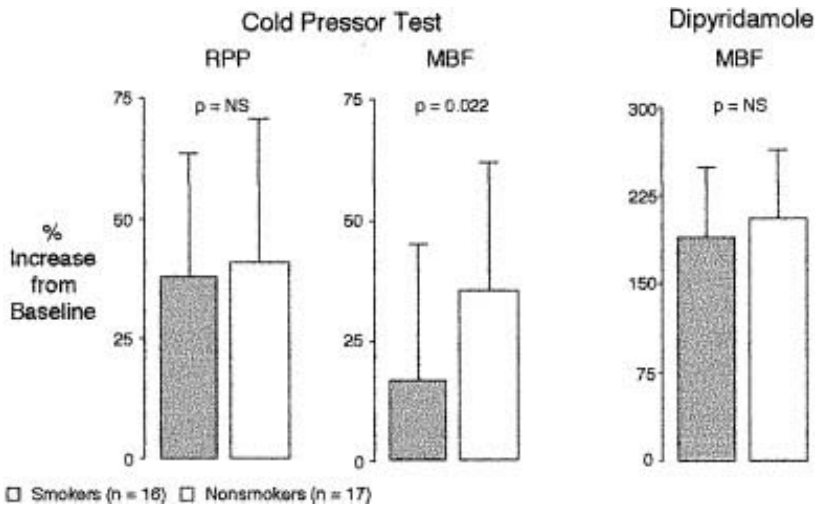

Figure 19-7: Increases in MBF in response to cold pressor testing and to intravenous dipyridamole in nonsmokers and long-term smokers (*shaded bars*). Note the comparable increases in MBF in response to dipyridamole in both groups. Also, cold pressor testing produced comparable increases in the rate pressure product (RPP), while the increase in MBF in long-term smokers was markedly attenuated as compared with normal individuals. (Data taken from Campisi et al.[119])

MONITORING RESPONSES TO RISK FACTOR MODIFICATION

Given their high degree of reproducibility, PET-based measurements of MBF are equally suited for monitoring responses in coronary vasomotion to pharmacologic interventions and risk factor modification. Early studies in only 13 participants in a 6-week cardiovascular conditioning program demonstrated this capability.[121] Dietary changes, regular exercise, and lifestyle modifications were associated with weight loss, decreases in heart rate and blood pressure at rest, and significant decreases in plasma total and LDL cholesterol. A 12 percent decline in MBF at rest was proportionate to the decrease in resting cardiac work. Cardiovascular conditioning also produced a 9 percent increase in hyperemic flow, and MBF reserve increased by a total of 20 percent. Rigorous lifestyle and risk factor modification had been shown previously with PET to result in smaller and less severe stress-induced perfusion defects.[122,123] More recent studies with PET-based measurements of MBF have demonstrated beneficial effects of cholesterol lowering by HMG-CoA reductase inhibitors.[124,125] In one study, a 6-month course of fluvastatin treatment produced a 26 percent increase in hyperemic MBFs (at 6 months but not at 2 months) and thus in vasodilator capacity.[124] Of interest was the delayed improvement in vasodilator capacity (Fig. 19-8). In these patients with CAD, the cumulative coronary function improved in myocardial territories subtended by both diseased and nondiseased coronary arteries. These observations differ with those of another study that demonstrated a significant improvement in vasodilator capacity only in territories with stress-induced perfusion defects but not in apparently normal myocardium,[126] whereas a third study demonstrated again a 20 percent improvement of hyperemic flows in remote myocardium.[125] Another study reported immediate (within 24 h) improvements in hyperemic MBFs following LDL cholesterol plasma apheresis.[127] In the latter study, however, plasma LDL cholesterol apheresis reduced total cholesterol by 42 percent and LDL cholesterol by 58 percent, which was greater than in the fluvastatin study with total and LDL cholesterol reductions of 29 and of 37 percent, respectively.[124]

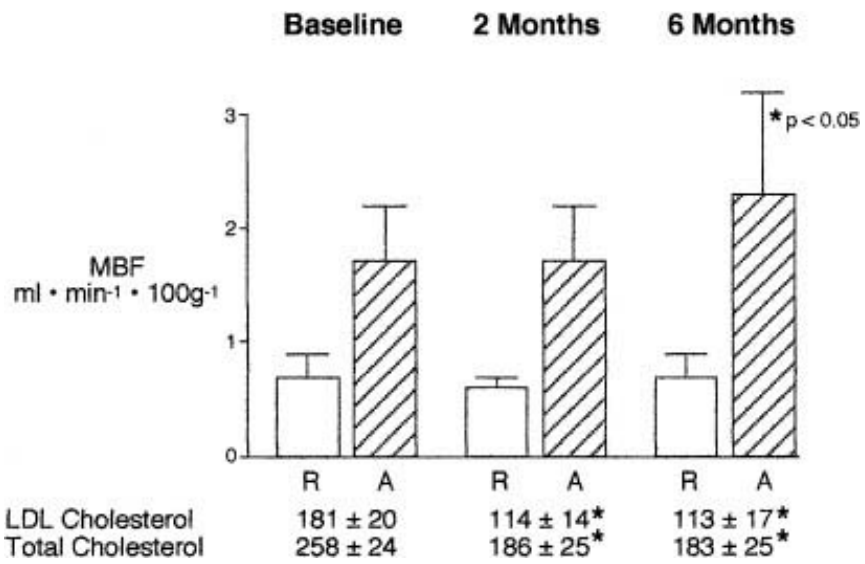

Figure 19-8: Changes in coronary artery vasodilator function in patients with CAD on a 6-month course of fluvastatin. The upper panel shows the MBF at rest and during adenosine hyperemia (A, *shaded bars*); the lower panel, the plasma levels for cholesterol in milligrams per deciliter. Note the delayed improvement of hyperemic MBF despite the significant decline in plasma total and LDL cholesterol at 2 months (*$p < 0.05$ versus baseline). (Data after Guethlin et al.[124])

Other investigations explored pharmacologic effects on predominantly endothelial-dependent

coronary vasomotion. For example, intravenous L-arginine (30 g) as the substrate of nitric oxide synthase (NOS) in long-term smokers normalized the MBF response to cold pressor testing, suggesting that endothelial function or, at least, the bioactivity of nitric oxide had normalized.[128] Whether increases in the substrate for NOS accelerate production of nitric oxide remains uncertain, especially in view of the low K_m, which renders the reaction relatively substrate-independent.[129] One possibility could be a nonspecific effect, perhaps on the oxidative stress, as recently demonstrated with cold pressor testing in response to acute administration of vitamin C.[130] Other possible mechanisms include competitive displacement of asymmetric dimethylarginine, an inhibitor of NOS with elevated plasma levels in hypercholesteremic patients.[131] An insulin-dependent mechanism is also possible, especially because L-arginine infusions prompted three- to fourfold increases in plasma insulin concentrations.[128] Similarly, hormone-replacement therapy in postmenopausal women without coronary risk factors can normalize the MBF response to cold, while the responses remain abnormal in postmenopausal women with coronary risk factors despite hormone-replacement therapy.[120]

Assessment of Myocardial Viability

Myocardial viability pertains to an impairment of myocardial contractile function that is potentially reversible. Distinction of such potentially reversible from irreversible impairment of contractile function often is of considerable clinical importance but remains diagnostically challenging. Both types of tissue injury share several features, including similar degrees of abnormal systolic wall motion, of reduced MBF, and of electrocardiographic abnormalities. Persistence of metabolic activity for sustaining vital, energy-requiring processes, however, including cellular homeostasis, depends on some residual MBF for removal of inhibitory metabolites as well as for supply of fuel substrates. Hence key features of viable myocardium include

- Impairment of systolic wall motion at rest
- Normal or reduced, but not absent, blood flow
- Preservation of cellular homeostasis
- Persistent metabolic activity for high-energy phosphate production
- Recruitable contractile reserve

GENERAL CONSIDERATIONS

Research studies in animals provided the base for the detection of myocardial viability. Known alterations in substrate metabolism during acute myocardial ischemia were demonstrated noninvasively with positron-emitting tracers of myocardial substrate metabolism.[132] Consistent with an impaired FFA oxidation was the diminished initial uptake of [^{11}C]palmitate and its delayed clearance from the myocardium.[46,47] Additionally, the known increase in glucose extraction and use was reflected by a regional increase in [^{18}F]deoxyglucose uptake.[133] Initial studies in patients with acute myocardial ischemia revealed blood flow and glucose metabolism patterns that were virtually identical to those in animals, e.g., enhanced [^{18}F]deoxyglucose uptake in hypoperfused dysfunctional myocardial regions. Unexpectedly, the same pattern existed in patients with chronic CAD but no signs of acute ischemia (Fig. 19-9). This raised the question of whether the observed blood flow-metabolism pattern was unique to acute ischemia or represented a more general metabolic pattern in chronically dysfunctional and hypoperfused myocardium. Also intriguing were observations in other CAD patients with regionally reduced [^{18}F]deoxyglucose uptake that paralleled the reduction in regional MBF[134] (see Fig. 19-9). A more systematic study in patients scheduled for surgical revascularization confirmed the hypothesis that the regionally enhanced [^{18}F]deoxyglucose uptake, in contrast to a reduction, reflected metabolic activity as evidence of viability in myocardium with complete or partial loss

of contractile function.[135] Restoration of tissue perfusion was followed by improved contractile function in myocardium with but not in myocardium without persistent glucose metabolic activity.

Possible Mechanisms of the Blood Flow Metabolism Pattern

The preceding observations established the clinical utility of these PET findings, but the underlying mechanisms remained uncertain. Patients with CAD revealed after supine bicycle exercise in stress-induced flow defects an augmented [^{18}F]deoxyglucose uptake when the radiotracer was administered 20 to 30 min after exercise and after the stress-induced flow defect had already resolved.[136] This implicated *myocardial stunning* as one possibility, subsequently supported by observations in animal experiments and in patients with either collaterized myocardium or unstable angina.[137-139] These studies demonstrated the evolution of a blood flow-metabolism pattern in chronically reperfused myocardium: An immediate postreperfusion decrease in glucose uptake was followed by an increase that subsequently declined to normal as contractile function returned.[137] The enhanced [^{18}F]deoxyglucose uptake was attributed to increased lactate release and thus anaerobic glycolysis that persisted even after blood flow had been restored.[140] The evolution of such metabolic pattern also may pertain to early postinfarction patients[141] but does not fully explain all observations in patients with chronic CAD. Another possibility includes *repetitive stunning*[142] as the reason for the persistent increase in [^{18}F]deoxyglucose uptake in dysfunctional myocardium. An impairment in contractile function associated with enhanced glucose use was noted in collateral-dependent myocardium only if the flow reserve was markedly restricted.[138] It limits the coronary circulation's ability to respond appropriately to transient and frequent increases in oxygen demand during daily life, leading to transient ischemic episodes, each followed by stunning and preventing recovery of contractile function.

Myocardial hibernation serves as another explanation.[143] The postulated downregulation of contractile function in response to diminished rest MBF is thought to be associated with an alteration of the myocardium's substrate metabolism with a dominant role for the more oxygen-efficient glucose. Hibernation in its truest sense then implies that the downregulated energy requirements match the available energy supply. A new supply-demand imbalance is established, but at a lower level. Such a new balance, however, will be a precarious one because even moderate increases in demand or decreases in supply disturb the steady state and cause ischemia. It is thus possible and likely that both *hibernation* and *stunning* coexist to varying extents in many patients. Observations in experimental animals suggest that sustained reductions in both blood flow and contractile function can be maintained for some time without significant necrosis, but development of structural alterations resembling those in patients with chronic CAD[144-148] supports the concept of hibernation.

Both concepts, repetitive stunning and hibernation, may, in their purest form, represent the two ends of a spectrum. As Fig. 19-10 illustrates, the spectrum begins with a reduction in myocardial flow reserve, where increased demand can no longer be matched by an appropriate increase in supply and which ends with a loss of the flow reserve and a decline in regional MBF at rest, associated with a downregulation of contractile function and adaptation of substrate metabolism. Such a spectrum could represent a temporal progression in coronary artery stenosis severity. Recent findings in chronically instrumented animals with a progressive decline in and ultimately loss of regional flow reserve associated with a decrease in rest blood flow support such a scenario.[148-151] Reductions in flow or flow reserve also may occur suddenly in view of the high incidence of blood flow metabolism mismatches in early postinfarction patients.[134,141,152] In acute animal studies, sudden moderate reductions in regional MBF are associated initially with evidence of acute ischemia (e.g., release of lactate and enhanced glucose uptake). An apparent resetting or adjustment of demand follows, and lactate release converts to uptake, high-energy phosphate stores are replenished, and a new supply-demand balance seems to have

returned.[144,153,154] Some debate focused on the issue of whether MBF at rest can indeed be chronically reduced.[155] Nevertheless, findings in chronic animal experiments, as well as substantial improvements in resting MBF following surgical revascularization, argue in favor of the possibility of a true chronic regional hypoperfusion.[148,150,151,156,157]

Ultrastructural and Histochemical Observations

Other attempts to gain mechanistic insights into the enhanced [^{18}F]deoxyglucose uptake include morphometric and histochemical analyses of biopsy specimens harvested from dysfunctional human myocardium during surgical revascularization. Prior autopsy studies indicated a general correlation between the degree of regional myocardial fibrosis and the severity of the impairment of regional contractile function. Yet there were exceptions.[158] In some instances, dyskinetic myocardium was free of fibrosis at autopsy, or conversely, some normally contracting myocardium contained as much as 40 percent fibrosis.[159] It also was known that "abnormal" myocytes (Fig. 19-11) existed in chronically dysfunctional myocardium.[160] More recent investigations noted correlations between the externally determined relative blood flows and relative [^{18}F]deoxyglucose concentrations with the morphometrically determined fractions of fibrosis, abnormal myocytes, and normal myocardium.[138,161,162] The various studies agree on a general correlation between relative blood flow and the percentage of tissue fibrosis (Fig. 19-12) but differ on the fraction of abnormal myocytes. In one study, this fraction is the same in reversibly and irreversibly dysfunctional myocardium,[161] whereas a second study notes a significantly greater fraction in reversibly than in irreversibly dysfunctional myocardium.[162] Because the centrally located glycogen granules are key features of such abnormal myocytes and a significant correlation exists between the fraction of such abnormal myocytes and the relative [^{18}F]deoxyglucose uptake, these abnormal myocytes have been considered the ultrastructural correlate of enhanced [^{18}F]deoxyglucose uptake in chronically dysfunctional myocardium. Other observations argue against this notion. Again, electron microscopy and histochemistry of biopsy samples from the center of the dysfunctional myocardial wall demonstrate highly different degrees of severity of morphologic alterations in myocardial regions with blood flow-metabolism mismatches.[163] Despite identical flow and glucose metabolism findings on PET, nearly half the patients in this study revealed only minimal, if any, morphologic changes, whereas the other half demonstrated severe structural abnormalities. Such variability in morphologic alterations argues against the structurally abnormal myocyte and especially the glycogen granules as an explanation of the enhanced [^{18}F]deoxyglucose uptake. More likely explanations include translocation and possibly upregulation of GLUT1[164] as a flux-generating step, uncoupling of glycolysis from glucose oxidation, regulated probably by malonyl-CoA and carnitine palmitate transferase I,[165,166] and possibly an ischemia-related loss of adrenergic innervation or function[167] associated with increased exogenous glucose use. In cardiac allografts, glucose use was about 70 percent higher in denervated than in reinnervated myocardium.[168]

Myocytes in Chronically Dysfunctional Myocardium

Whether abnormal myocytes as described initially by Flameng et al.[160] and subsequently observed in biopsy material from mismatched myocardium point specifically in the direction of or are ingredients unique to any particular pathophysiologic mechanism underlying the chronic, though potentially reversible, impairment of contractile function remains uncertain. Two schools of thought exist. One holds that the morphologic alterations result from (1) contractile unloading, (2) increased wall stress (stretch), and (3) a metabolic substrate switch to preferential glucose use.[169] In fact, contractile unloading recently has been demonstrated to result in virtually identical structural changes.[170,171] The expression and distribution patterns of other features such as of α-smooth muscle actin, cardiotin, and titin,[169] as well as an increased expression of glucose transporter 1 (GLUT1) mRNA,[164] features that resemble those in embryonic and/or neonatal myocytes, suggested that the changes of abnormal myocytes may represent "dedifferentiation."[169] Histochemical analysis further uncovered alterations in the extracellular matrix, with increased amounts of collagen and fibronectin surrounding the abnormal myocytes.[169] Finally, similar to neonatal myocytes, these abnormal myocytes have been found to be relatively tolerant of ischemia.[172] The absence of true degenerative changes further has been claimed to support this possibility.

The other school of thought emphasizes a progressive deterioration rather than a stable state of the cell's morphology and therefore referred to *hibernation* as "incomplete adaptation to ischemia."[173] The process begins with few structural changes but a switch in substrate selection to glucose, either because of its greater oxygen efficiency or, alternatively, because of loss of enzymes essential for fatty acid oxidation, followed by loss of contractile protein and accumulation of glycogen and mitochondrial and nuclear alterations, ultimately leading to cell death and scar tissue formation (Fig. 19-13).[163] Other studies again report reduced expression of contractile and cytoskeletal proteins associated with increased expression of extracellular matrix proteins,[173] implying a progressive loss of contractile protein and of the cell structure that is paralleled by accelerated formation of tissue fibrosis and hence a progressive loss of viability that was further found to be associated with apoptosis and replacement fibrosis. Biopsies from patients with preoperatively viable myocardium but without a postrevascularization improvement in contractile dysfunction demonstrated an about threefold increase in mRNA of caspase-3, a promoter of apoptosis, together with an about 50 percent reduction in the expression of the antideath genes *Bcl-2* and *p53*, again consistent with continued cell death and replacement fibrosis.[174] Chronic animal experimental studies similarly have demonstrated significant increases in apoptotic myocytes in hibernating myocardium with reduced rest MBF and critically reduced or absent flow reserve.[151] The fact that myocyte apoptosis in these studies occurred scattered and not in clusters raises the question of whether apoptosis is indeed the end point of the progressively deteriorating abnormal myocyte or such apoptosis represents a process that occurs in parallel. To some extent this may depend on the duration and severity of the ischemic compromise. For instance, other animal studies with more sudden reductions in flow and shorter time periods report higher rates of myocyte apoptosis occurring in clusters.[175]

A progressive deterioration of reversibly dysfunctional myocardium is also consistent with clinical observations that point to the high prevalence of mismatch patterns in patients with prior myocardial infarctions[134,176] but note a declining incidence of blood flow-metabolism mismatches as a function of time after an acute myocardial infarction.[152] Moreover, the loss of the capability to improve global LV function if revascularization was delayed by more than 6 months[177] or an increase in fibrosis and loss of functional recovery after revascularization as a function of the duration of clinical symptoms[178] seem to support such progression. The blood flow-metabolism mismatch may represent a transient rather than a permanent state of reversibly dysfunctional myocardium. It is possible that reversibility can be maintained up to a certain point. Once this critical point has been reached, myocytes become committed to irreversibility and cell death.

In the clinical setting, prompt restoration of adequate tissue perfusion through interventional revascularization therefore will be essential, regardless of whether abnormal myocytes represent dedifferentiation or degeneration. It would seem that ultimately the return of contractile function will depend on the amount of connective tissue. Once fibrosis and scar tissue occupy more than 35 to 40 percent of the myocardium, dysfunction has been shown to be irreversible.[15,16] Also, the presence of structural changes in viable myocardium, as demonstrated with blood flow-metabolism imaging, implies that if the contractile machinery in abnormal or dedifferentiated myocytes can be reconstructed, the recovery of contractile function will not be immediate but slow, as animal experimental[179] and clinical investigations have indeed demonstrated.[180] The delay in cell repair also may explain the persistence of increased [^{18}F]deoxyglucose uptake after successful revascularization.[181]

Viability Assessment in the Clinical Setting

The classic and now most widely applied approach entails evaluation of the relative distribution of blood flow and exogenous glucose use with [^{18}F]deoxyglucose. Initial studies uncovered three distinct patterns:

- Normal blood flow and normal or enhanced glucose uptake
- Reduced blood flow but normal glucose uptake in excess of blood flow (mismatch)
- Reduced blood flow and proportionately reduced glucose uptake (match)

While these terms are purely operational, they infer, at least to some extent, the underlying pathophysiology accounting for the contractile dysfunction. Normal flow and/or metabolism may represent *stunned* myocardium, whereas the classic mismatch may be consistent with *hibernating* myocardium. Both patterns predict a postrevascularization improvement in contractile function, whereas the concordant reduction in blood flow and metabolism predicts that function will not improve.[135,182,183] It should be emphasized that the reduction in regional flow for both matches and mismatches may vary considerably between patients.

Because of the observed correlation between tissue fibrosis and relative flow tracer uptake, the evaluation of regional MBF alone can provide information on the presence of reversible contractile dysfunction (Fig. 19-12). [162] Severe reductions to less than 25 percent of normal or complete absence of blood flow reflects complete or nearly complete transmural scar tissue formation and hence nonreversiblity.[184] In another study, flow reductions of more than 60 percent were highly accurate in predicting nonreversiblity of contractile dysfunction.[185] Conversely, completely normal or only mild reductions (<20 percent) of MBF in dysfunctional myocardium argue against the presence of significant amounts of tissue fibrosis; it possibly reflects myocardial stunning and thus indicates functional reversibility. Mild to moderate flow reductions are less reliable discriminators. If combined with a metabolic study, the [^{18}F]deoxyglucose uptake in the case of a small nontransmural/infarction with otherwise normal myocardium would be reduced in proportion to blood flow.[186] Conversely, an increase in glucose uptake would indicate the coexistence of reversibly dysfunctional myocardium with scar tissue and predict an improvement in contractile function.

Another, again limited approach for identifying reversible contractile dysfunction is the use of [^{18}F]deoxyglucose alone. This approach assumes that regional reductions in [^{18}F]deoxyglucose greater than 50 percent relative to remote myocardium represent irreversible contractile function, whereas mildly reduced or normal uptake indicates the presence of reversible dysfunction.[187,188] While used for some time as a benchmark for defining the accuracy of ^{201}T1-based techniques for assessing myocardial viability,[187] only recently has the validity of this particular approach been tested against the postrevascularization outcome in regional contractile function.[189] Electrocardiographic gated image acquisition affords simultaneous evaluation of regional function

and metabolism and thus can further augment the predictive accuracy of the [^{18}F]deoxyglucose stand-alone approach.[190,191] A more recent report emphasizes the utility of measurements of exogenous glucose use in absolute units. Using a threshold value of 0.25 μmol/g per minute offered a 93 percent positive and a 95 percent negative predictive accuracy for the improvement of contractile dysfunction.[192] Nevertheless, this approach is severely limited when glucose use and hence [^{18}F]deoxyglucose uptake cannot be controlled sufficiently. In such instances, it may be difficult to distinguish between scar tissue, normal myocardium, and reversibly contractile dysfunction, which then could be readily clarified by evaluating the distribution of regional MBF.[193]

The pattern of normal blood flow and glucose metabolism in mildly to severely hypokinetic myocardium of severely depressed left ventricles is a difficult clinical problem. One study reports that of 32 such myocardial regions, only 8 regions (or 25 percent) improved following surgical revascularization.[194] Such regions therefore may represent remodeled LV myocardium. Conversely, an improvement in wall motion may be consistent with myocardial stunning. If suspected, careful evaluation of the coronary anatomy or, if unavailable, the addition of a pharmacologic stress study can aid in distinguishing between stunned and remodeled LV myocardium (Fig. 19-14).

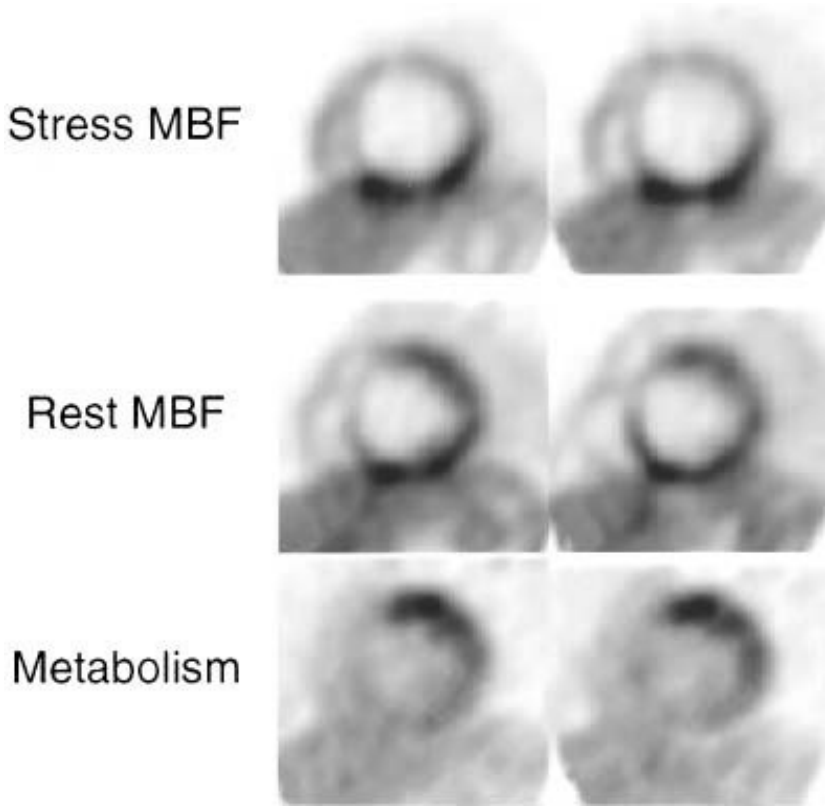

Figure 19-14: Two contiguous short-axis images through the mid-left ventricle in a patient with ischemic cardiomyopathy. The MBF images at rest (*middle panel*) reveal in the interventricular septum reduced but relatively well preserved flow in the anterior and anterolateral wall associated with regionally increased [18F]deoxyglucose uptake in the same portion of the left ventricle as seen in the lower panel (metabolism). The stress induced flow defect in the anterior and anterolateral wall (as seen in the upper panel) implicates stunning as the cause of the enhanced [18F]deoxyglucose uptake.

Alternate Approaches to Blood Flow and Glucose Metabolism Imaging

Several institutions use SPECT myocardial perfusion imaging with either ^{201}Tl or ^{99m}Tc-sestamibi and metabolic imaging with [^{18}F]deoxyglucose with dedicated PET systems. The reported predictive accuracies for segmental and global LV function approach those obtained with dedicated PET systems.[1] Nevertheless, such combined PET/SPECT approaches present at times with diagnostic limitations, especially because of considerable differences in contrast and spatial resolutions as well as artifactual reductions in tracer concentrations due to photon attenuation.[4,5] This can limit the ability to accurately estimate the extent of a blood flow-metabolism mismatch.

More recent approaches rely solely on the use of multipurpose SPECT-like systems, either equipped with ultrahigh-photon-energy general-purpose collimators or with coincidence-detection systems (see also Fig. 19-1). Little information thus far has become available on the clinical performance of coincidence-detection systems, whereas systematic studies with ultra-high-photon-energy general-purpose collimator SPECT systems using ^{201}T1- or ^{99m}Tc-labeled flow tracers and [^{18}F]deoxyglucose report predictive accuracies that are comparable with those reported with dedicated PET systems.[195,196]

Further, ^{201}Tl rest-redistribution imaging has been useful for identifying myocardial viability and for predicting the postoperative outcome of ischemic cardiomyopathy, although with a somewhat lower predictive accuracy (see Chap. 17). This approach suffers from instrumentation-related shortcomings, especially in patients with poor LV function, and consequently, poor signal-to-noise ratios. Thallium-201 offers a negative signal (reduced tracer uptake) as compared with [^{18}F]deoxyglucose, with a positive signal (enhanced tracer uptake) that is more readily accessible to visual analysis.[193] One study reporting that [^{18}F]deoxyglucose and PET identified myocardial viability in 18 of 20 patients with an average LV ejection fraction of 23 percent and only fixed ^{201}Tl defects on SPECT[197] is consistent with a more recent report of viability by [^{18}F]deoxyglucose in 17 of 33 patients (LV ejection fraction <35 percent) with fixed or minimally redistributing ^{201}Tl defects.[198] Further, a comparison study of ^{201}Tl and [^{18}F]deoxyglucose SPECT reports a generally excellent agreement between both approaches but observed disparities in patients with severely depressed LV ejection fractions, where [^{18}F]deoxyglucose revealed more viable myocardial segments than ^{201}Tl SPECT.[11]

In synthesizing the currently available information, it appears that ultimately the total fraction of scar tissue in a given myocardial segment determines largely whether or not contractile function will improve. Because of the linear correlation between scar tissue and relative MBF,[138,161,162] evaluation or even quantitation of regional MBF offers information on potential reversibility. On the other hand, if in viable though functionally compromised myocardium MBF is also reduced, then the augmented glucose use, as evidenced by the enhanced [^{18}F]deoxyglucose uptake, offers additional and critical information. This has prompted most investigators to predict the ultimate functional outcome from a combined assessment of blood flow and [^{18}F]deoxyglucose uptake.[199,200] Further, the temporal recovery of contractile function after revascularization appears to depend on the degree of ultrastructural changes of myocytes as well as the fractional distribution between myocytes with only mild and those with severe ultrastructural changes.[199] If, as postulated, only mild structural changes are associated with a full functional recovery within 3 months, more severe structural changes may require substantially longer time periods and, further, may account for the persistence of increased [^{18}F]deoxyglucose uptake even for many months following revascularization.[181]

CLINICAL ROLE OF PET VIABILITY ASSESSMENT

Among the various PET approaches, the blood flow and glucose metabolism approach has gained the greatest clinical acceptance. Viability assessments with PET can decisively affect therapeutic strategies in patients with advanced CAD and ischemic cardiomyopathy. The therapeutic options in these patients range from aggressive medical management to surgical revascularization and cardiac transplantation. While conservative pharmacologic approaches to the management of such patients has improved markedly over the past decade, the long-term survival of medically treated patients remains relatively poor.[201] Cardiac transplantation as another approach offers a better long-term survival and an improvement in the quality of life, but the supply of donor hearts has not kept pace with the increasing demand, so this therapeutic option remains limited (see Chap. 22). At present, the prevalence of ischemic cardiomyopathy in the United States alone amounts to about 2.5 million cases, thus affecting roughly 1 percent of the U.S. population. The decision to revascularize frequently depends on the answers to several questions. First, what is the leading cause of poor LV function? Second, if CAD has been identified as the culprit, is there enough viable myocardium so that surgical revascularization produces an improvement in LV performance and/or congestive heart failure symptoms? Third, will revascularization avert future catastrophic cardiac events and prolong survival? And finally, can the surgical risk be predicted, since this will influence the preoperative risk-benefit ratio?

Ischemic versus Idiopathic Dilated Cardiomyopathy

In addition to heart failure symptoms, ischemic cardiomyopathy shares several other features with idiopathic dilated cardiomyopathy, such as, for example, the LV enlargement, the often diffuse hypokinesis, the markedly depressed LV ejection fraction, and frequently, mitral regurgitation. Biventricular enlargement has been thought of as a feature characteristic of idiopathic dilated cardiomyopathy but also can be present in ischemic cardiomyopathy. Conduction abnormalities often limit the accuracy of electrocardiographic criteria to distinguish between both entities. Additionally, an intrinsic myopathic process including LV remodeling also may exist in a number of patients with CAD so that the major cause of the poor LV function may remain unknown or difficult to elucidate. Importantly, however, the therapeutic approach to both disease entities will differ strikingly (see Chap. 66).

Both disease entities, however, reveal remarkably different patterns of blood flow and substrate metabolism on PET. A comparative study in patients with ischemic cardiomyopathy and idiopathic dilated cardiomyopathy found the distribution of MBF to be characteristically homogeneous in idiopathic cardiomyopathy as compared with distinct flow reductions clearly corresponding in ischemic cardiomyopathy to the coronary vascular territories.[202] Similarly, uptake of [^{18}F]deoxyglucose was noted to be homogeneous in dilated cardiomyopathy, whereas matches and/or mismatches between blood flow and [^{18}F]deoxuglucose uptake were present in ischemic cardiomyopathy (Fig. 19-15). Combined imaging of blood flow and glucose metabolism distinguished with an overall accuracy of 85 percent between both disease entities.

Prediction of the Outcome in Global LV Function

Numerous clinical investigations have reported the high accuracy of [^{18}F]deoxyglucose imaging with PET in predicting the postrevascularization outcome in regional LV wall motion.[1,135,182,183,188,189,203-205] Even though some of these investigations employed permutations of the initially described blood flow-metabolism approach or relied only on the evaluation of regional [^{18}F]deoxyglucose uptake in dysfunctional myocardium,[188,189] the predictive accuracy, both positive and negative, continued to be high. Such studies have been important because they prove the concept of blood flow-metabolism patterns as accurate predictors of the outcome of regional wall motion after restoration of MBF. More relevant in the clinical setting is whether blood flow-metabolism patterns can predict the postrevascularization

outcome in global LV function.

Initial semiquantitative studies demonstrated some correlation between the extent of the blood flow-metabolism mismatch and the postrevascularization gain in LV ejection fraction.[135] Patients with blood flow-metabolism mismatches that occupied at least two or more of seven total myocardial segments revealed a statistically significant increase in the LV ejection fraction following coronary bypass grafting.[135] No such improvement was observed in patients with only one mismatch segment or with only matches. Subsequent studies reported significant gains in LV function in patients with blood flow-metabolism mismatches as compared with no improvement in those patients without metabolic evidence of viability. Fig. 19-16 summarizes the findings in 19 investigations including a total of 570 patients.[1,3,156,161-163,177,183,194,195,198,205-211] The gain in global LV function is most striking in patients with an LV ejection fraction of less than 35 percent, who had a 34 percent postoperative increase in the LV ejection fraction as compared with a 19 percent ($p < 0.02$) improvement in patients with an LV ejection fraction of more than 35 percent. Additionally, recent studies reported significant correlations between the percentage of the left ventricle with a blood flow-metabolism mismatch and the postrevascularization increase in the LV ejection fraction.[212,213] Thus the extent of a blood flow-metabolism mismatch has some predictive value on the postoperative gain in global LV performance[194,211] (Fig. 19-17). The absence of such improvement in one specific laboratory may be attributable to differences in the imaging and analysis approach used.[181,205] MBF is evaluated with ^{82}Rb at rest and during pharmacologic stress, and the distribution of MBF during stress is compared with the myocardial glucose uptake at rest. This approach identifies both stress induced ischemia and "viable myocardium" at rest. Hence blood flow and possibly wall motion at rest may be normal in some patients so that revascularization predominately improves the capacity of the left ventricle to respond to exercise.[205,214]

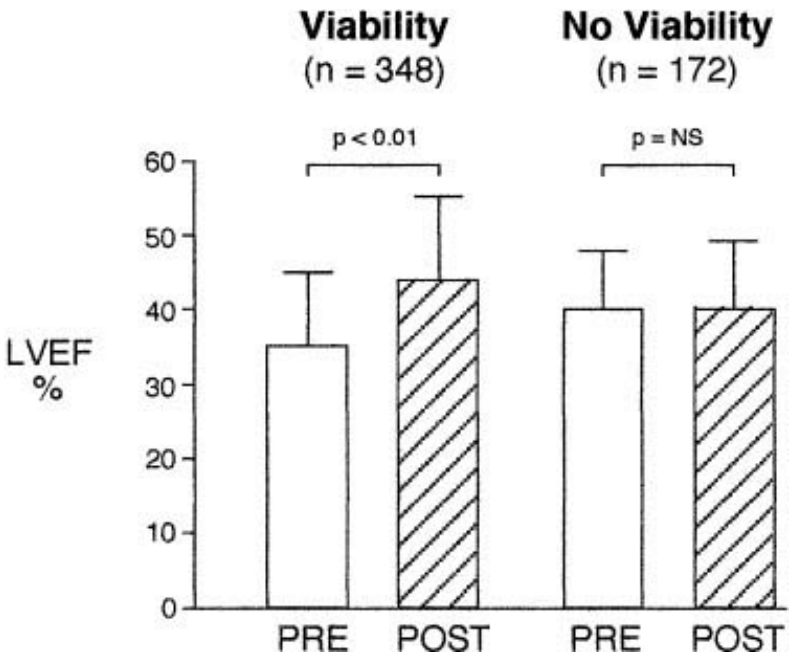

Figure 19-16: Summary of changes in LV ejection fraction from baseline (PRE) to following revascularization (POST) as reported for a total of 570 patients in 19 clinical investigations.[1,3,135,156,161-163,177,183,194,195,198,205,-211] Patients with metabolic evidence of reversible contractile dysfunction are shown on the left and those without on the right. The average LV ejection fractions are shown at baseline (PRE) and following surgical revascularization (POST).

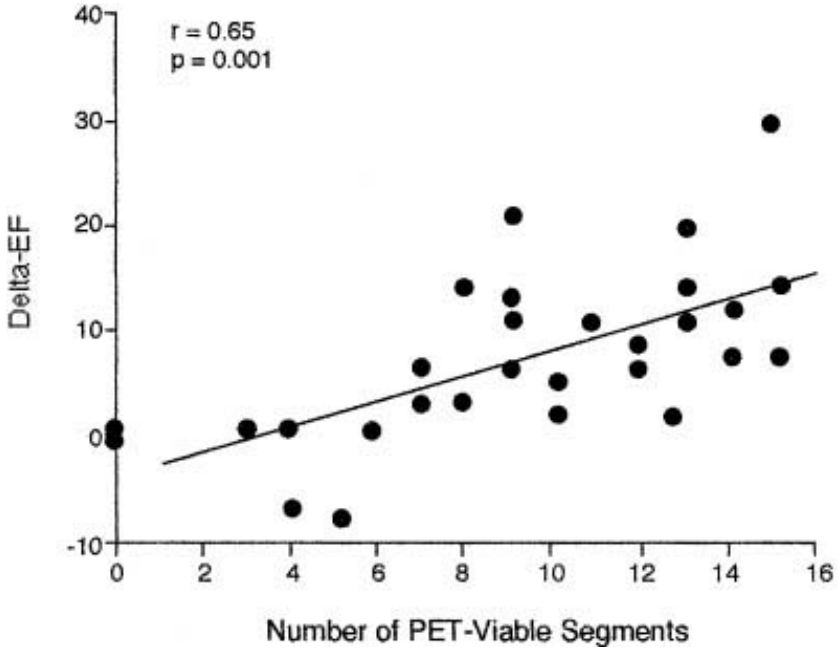

Figure 19-17: Postrevascularization improvement in LV ejection fraction as a function of the number of viable myocardial segments as determined by PET. (Reproduced with permission Pagano et al.[211])

The improvement in regional and especially global LV function may not occur immediately but slowly though progressively following revascularization. In a highly selected patient group, blood flow had been shown to recover promptly following revascularization by angioplasty, whereas contractile function remained initially unchanged.[180] On reexamination 67 ± 19 days later, no further improvements in regional MBF had occurred, but systolic wall motion had now significantly improved. The disparity between recovery of MBF and contractile function may be attributed to stunning and/or to rebuilding of the contractile machinery that had been lost in abnormal myocytes. Preliminary observations suggest a correlation between severity of the mismatch and the rate of recovery of contractile function. The rate of recovery appears to be faster when flow is relatively well preserved as compared with segments with more severe flow reductions and possibly more severe ultrastructural changes. Segments with largely preserved flows recovered faster than segments with more severe flow reductions.[215] The contractile function appears to recover or improve more promptly in myocardial regions without marked ultrastructural abnormalities or a lesser fraction of abnormal myocytes.[199] Finally, in addition to a slow recovery of contractile function in reversibly dysfunctional myocardium, other studies describe an associated decline in end-diastolic and end-systolic volumes, suggesting the possibility of a reversal of LV remodeling.[216]

Effect on Congestive Heart Failure-Related Symptoms

A related clinical question is whether such improvement is also associated with relief or amelioration of congestive heart failure symptoms. Several retrospective studies indicate such possible symptomatic improvement. Two investigations concluded that patients with blood flow-metabolism mismatches undergoing surgical revascularization demonstrated a significantly higher incidence of improvement in NYHA functional class than patients without mismatches or patients with matches but not submitted to regional revascularization.[217,218] Among the 52 patients with mismatches and congestive heart failure class III or IV, 81 percent of the 26 patients undergoing

revascularization revealed a significant improvement in congestive heart failure class as compared with only 23 percent of 26 patients treated conservatively.[218]

The amount of viable myocardium on blood flow and [^{18}F]deoxyglucose imaging contains information on the magnitude of the postrevascularization improvement in congestive heart failure symptoms.[219] The level of physical activity patients were able to perform prior to and 24 ± 14 months following coronary artery bypass grafting was graded on a specific activity scale and expressed in metabolic equivalents.[220] Among the 36 patients in this study with an average LV ejection fraction of only 28 ± 6 percent prior to revascularization, the extent of the blood flow-metabolism mismatch ranged from 0 to 74 percent (mean 23 ± 22 percent) on polar map analysis. When patients were grouped according to the extent of the mismatch, 11 patients with a mismatch occupying less than 5 percent of the LV myocardium revealed a statistically significant but only mild improvement in functional status (34 percent increase in metabolic equivalents) (see Chap. 17). Intermediate-sized mismatches (5 to 17 percent) in 8 patients were associated with a 42 percent increase in metabolic equivalents, whereas large mismatches, i.e., greater than 18 percent, in 17 patients were followed after revascularization by an average increase of 107 percent in metabolic equivalents. Furthermore, the improvement in functional status was linearly correlated with the anatomic extent of the blood flow-metabolism mismatch. Lastly, blood flow-metabolism mismatches of 18 percent or more were 70 percent sensitive and 78 percent specific in predicting an improvement in physical activity or functional status following successful surgical revascularization.

Impact on Long-Term Survival

Several studies examined the long-term fate of patients after being evaluated for MBF and metabolism with PET.[217,218,221,222] These studies presented compelling evidence for an increased prevalence of cardiac events in patients with blood flow-metabolism mismatches not submitted to interventional revascularization. They also implied that revascularization of blood flow-metabolism mismatches may avert future cardiac events.

Despite this general agreement, important differences emerged from these studies. One study in 129 chronic CAD patients followed for a time period of 17 ± 19 months found the presence of mismatches in the absence of revascularization to be independent predictors of the 17 nonfatal ischemic events.[221] Nevertheless, the LV ejection fraction and the patient's age contained the highest predictive values for the 13 cardiac deaths in this patient group. In patient series with more homogeneously depressed LV function, the predictive value of a low LV ejection fraction applied equally to all groups. As shown in Fig. 19-18, the cumulative long-term survival was lowest in the patient subgroup with blood flow-metabolism mismatches who were on medical treatment. Of note, all four subgroups were similar with regard to age and clinical and hemodynamic findings. There were no significant intergroup differences in the LV ejection fraction, which for the whole patient group averaged only 25 ± 7 percent. Of note, patients with mismatches who underwent revascularization revealed a significantly better cumulative survival that no longer differed significantly from that of the groups without mismatches (Fig. 19-18). In this study, the LV ejection fraction was without significant predictive value, whereas by Cox model analysis the extent of a mismatch had a significant negative effect on survival ($p < 0.02$), and revascularization of mismatch patients had a significant positive effect on survival ($p < 0.04$).[218] A second study in patients with similar uniform depression of LV ejection fraction reached similar conclusions.[217]

Assessment of Perioperative Risk

Surgical revascularization of patients with ischemic cardiomyopathy is associated with high

perioperative mortality and morbidity. Two investigations have explored the contribution of PET to the surgical risk assessment.[208,223] Both studies together include a total of 317 patients with ischemic cardiomyopathy and LV ejection fractions of less than 35 percent. The patients were categorized into two groups. Group one (35 and 88 patients, respectively, in each study) underwent coronary artery bypass grafting based on standard clinical criteria including LV size or ejection fraction, the suitability of the coronary anatomy for surgical revascularization, and the presence of comorbidities. The same criteria also were applied to the second group (41 and 153 patients per study), which, however, underwent blood flow metabolism imaging with PET in addition. Thirty-four of 41 patients (83 percent) in one and 110 of 153 patients (72 percent) in the other group demonstrated evidence of reversibly dysfunctional myocardium involving at least 20 to 30 percent of the left ventricle and subsequently underwent bypass grafting. Both studies consistently demonstrated lower perioperative mortalities in those patients who had undergone PET imaging (30-day mortalities of 0 and 0.9 percent) as compared with mortalities of 11.4 and 19.8 percent in the patients not evaluated by PET. Additionally, 1-year cardiac mortalities were lower for the PET-selected patients (3 and 10 percent, respectively) than for those not evaluated with PET (21 and 30 percent, respectively). PET-selected patients required less inotropic support or intraaortic balloon pumping and had better cardiac output and shorter stays in the intensive care unit. If further confirmation of such short-term benefits is established, PET evaluations of patients with ischemic cardiomyopathies would then offer important and possibly critical prognostic information on the immediate and long-term risks of cardiovascular surgery in patients with severe ischemic cardiomyopathy.

Lastly, the prevalence of reversibly dysfunctional myocardium is high. A survey of 283 patients with ischemic cardiomyopathy revealed a 55 percent prevalence of blood flow and glucose metabolism mismatches.[224] Half these mismatches involved 25 percent or more of the LV myocardium and thus would lead to significant gains in LV function and clinical symptoms after revascularization. The remainder of mismatches were smaller but, if not revascularized, may be associated with an increased long-term cardiac morbidity and mortality. Indeed, in the setting of ischemic cardiomyopathy, inclusion of PET in the diagnostic algorithm can be cost-effective and, at the same time, cost saving.[225,226] Clinical criteria for deciding on coronary artery bypass grafting in patients with ischemic cardiomyopathy have already been developed.[227] In addition to the diastolic dimension, the LV ejection fraction, and suitable target vessels, the criteria include the presence of viable myocardium affecting at least 15 to 20 percent of the LV myocardium.

Part 3: HEART FAILURE
Chapter 20:

PATHOPHYSIOLOGY AND DIAGNOSIS OF HEART FAILURE

Authors: Gary S. Francis, John P. Gassler, Edmund H. Sonnenblick

DEFINITION OF TERMS AND CLASSIFICATION

Heart failure is a broad term that encompasses multiple etiologies, pathophysiologic mechanisms, and clinical presentations. There has been and continues to be much confusion regarding the definition and classification of heart failure. The definition of heart failure has changed remarkably throughout the years,[1] undoubtedly related to the difficulties integrating many simple bedside observations (water retention, scant and concentrated urine, distended neck veins, and enlarged heart) with intellectual elaborations of the laboratory. For the practitioner, heart failure is a clinical syndrome in which structural or functional alterations of the heart lead to secondary phenomena such as exertional dyspnea and circulatory congestion. The diseased heart is the centerpiece of the syndrome. It is perhaps useful to think of heart failure as a continuum that begins with structural or functional abnormalities of the heart that have few or no clinical manifestations. This is followed by an often slow progression, with changes such as chamber enlargement, hypertrophy, or in some cases impairment of ejection phase indices, leading eventually to the clinical manifestations that are apparent by history and physical examination. There is often an important time element between the very beginnings of impaired cardiac structure or function and the clinical manifestations of heart failure that are observed weeks, months, or years later. In some cases, such as in severe hypertrophic cardiomyopathy or mitral stenosis, left ventricular (LV) systolic function may be intact, and there may be no LV chamber enlargement. In acute myocardial infarction, structural and functional changes occur swiftly, and symptoms of heart failure may appear suddenly. Such patients may then recover and have a long latency period of few symptoms, only to manifest substantial chamber enlargement, impaired LV function, and clinical heart failure many months or even years after the index event. There is an important time domain that spans the onset of cardiac structural and functional changes (often asymptomatic) to the clinical syndrome that the physician recognizes at the bedside or in the office as "heart failure." Although it is the clinical manifestations such as cardiomegaly, exertional dyspnea, and circulatory congestion that define the syndrome to the clinician, the student of heart failure knows that the disorder often has its roots in more fundamental structural and functional impairment that begins long before the patient experiences signs and symptoms of dyspnea and circulatory congestion.

The clinical syndrome of heart failure must be distinguished from other causes of circulatory congestion where the heart is not the culprit. It is worth considering the definition of heart failure put forth by Professor Ludwig W. Eichna in his George E. Brown Memorial Lecture at the American Heart Association meeting in Philadelphia in 1959.[2] This definition makes the important distinction between *circulatory congestion* (which can be due to noncardiac causes such as renal failure) and *congestive heart failure* (CHF), where the myocardium is at fault. Eichna opined that "circulatory (venous) congestion is the hemodynamic disturbance responsible for the symptoms usually associated with congestive heart failure; removal of the congestion, regardless of how accomplished, relieves the symptoms. Circulatory congestion is a nonspecific hemodynamic disturbance and may arise when the heart does not fail as a pump. This is noncardiac circulatory congestion. The term *congestive heart failure* should be reserved for those states of circulatory congestion in which there is myocardial failure." Basically, Eichna is making

the important distinction between circulatory congestion of noncardiac cause (e.g., acute renal failure) and circulatory congestion due to "myocardial failure." The implication is that in *heart failure* there must be something structurally or functionally abnormal with the heart.

Heart failure remains largely a clinical or bedside diagnosis. There is no "gold standard" laboratory test. The combination of a careful history (breathlessness, fatigue, fluid retention) and physical examination (congested lungs, distended neck veins, tachypnea, gallop rhythm, and fluid retention) is how one makes the diagnosis. There should be some direct evidence of structural heart disease, and the echocardiogram is most useful in this regard. However, it remains a clinical, bedside diagnosis. One makes the diagnosis by a careful bedside or office examination and confirms the diagnosis by chest x-ray and/or echocardiography.

The bedside diagnosis of heart failure has been made somewhat more subtle in the past 20 years by the widespread contemporary use of potent loop diuretics. Some of the cardinal clinical features of heart failure may be unimpressive or even lacking.[3,4] Patients may present with a history of breathlessness and fatigue who have clear lungs, no venous distention, and no edema. The "congestion" may be lacking in some patients with "congestive heart failure," thus rendering the term *heart failure* more appropriate than *congestive heart failure*. Moreover, with the gradual erosion of bedside skills and more reliance placed recently on echocardiography, we have allowed the less sophisticated physician to equate the clinical syndrome of heart failure with the finding of a low ejection fraction. A low ejection fraction is *not* heart failure. No single laboratory test fulfills all diagnostic purposes. The heart may be small on chest x-ray. Echocardiography and cardiac catheterization may indicate normal systolic function. Impaired relaxation of the left ventricle may be the primary mechanism, emphasizing the need to perform echocardiography. Heart failure is a clinical syndrome with multiple etiologies, heterogeneity, and great plasticity. This is why it has been difficult to clearly define. The following definitions, though imperfect, have been used in the past by various authors.

Circulatory Failure

Circulatory failure is a nonspecific older term that is sometimes used to describe heart failure and includes the condition of *circulatory shock*. The basic concept of circulatory failure implies that there is inadequacy of the cardiovascular system in providing nutrition and blood flow to the cells of the body and inadequacy in removing metabolic products from cells. Circulatory failure can be due to cardiac and noncardiac causes. *Myocardial failure*, from acute or chronic injury, would be a cardiac cause of circulatory failure. Examples of cardiac circulatory failure would include acute myocardial infarction, acute inflammatory conditions such as lymphocytic myocarditis, chronic cardiomyopathy, and severe valvular heart disease. Noncardiac circulatory failure would include inadequate blood volume and insufficient oxyhemoglobin.

Circulatory overload or *congestion* is also an older general term referring to excess blood volume from either cardiac or noncardiac causes,[2] but it still carries some important conceptual considerations. *Noncardiac circulatory overload* may be divided into two categories: (1) conditions where the primary defect appears to be an increase in blood volume, as may occur with the accumulation of excess salt and water due to salt-retaining steroids, excess blood or fluid administration, acute glomerulonephritis, oliguria, or anuria, and (2) conditions where the primary defect appears to be an increased venous return and/or decreased peripheral resistance, as may occur with arteriovenous fistulas, beriberi, cirrhosis, or severe anemia, in which the increase in blood volume is secondary. Many patients with noncardiac circulatory overload eventually develop secondary "high output" heart failure.

Heart Failure

Heart failure also has been defined as a complex clinical syndrome that arises from a process of

ventricular dysfunction (acute or chronic) where the heart is unable to pump sufficient blood to meet the metabolic needs of the body at normal filling pressures, provided the venous return to the heart is normal. Ventricular systolic dysfunction is characterized by a loss of contractile strength of the myocardium accompanied by the compensations of ventricular hypertrophy and/or dilatation (ventricular remodeling). This syndrome, however, involves more than a circulatory disorder caused by impaired pump function. As ventricular dysfunction proceeds, there is activation of numerous neuroendocrine systems that, although "designed" to protect blood pressure, are directly toxic to the heart and contribute to progressive cardiomegaly and sodium retention. Heart failure is also generally associated with a very poor prognosis, even when symptoms are mild.[5,6] *Systolic LV dysfunction* or *failure* reflects a decrease in normal emptying capacity [usually with an ejection fraction (EF) of 45 percent or less] that is usually associated with a compensatory increase in diastolic volume. *Isolated diastolic ventricular dysfunction* or *failure* is present when the filling of one or both ventricles is impaired, while the emptying capacity is normal. It may be due to a thickened (hypertrophied) ventricular wall, infiltrative cardiomyopathies, and/or tachycardia, which limits the time for diastolic filling, resulting in increased ventricular filling pressures and eventually pulmonary edema.

Congestive heart failure denotes a clinical syndrome with complex and variable signs and symptoms, including dyspnea and increased fatigability, tachypnea, tachycardia, pulmonary rales, cardiomegaly, ventricular gallop sounds, and peripheral edema. In most patients, CHF and abnormal circulatory congestion occur as a result of both heart failure and subsequent changes in the peripheral circulation, accompanied by activation of the sympathetic nervous system and the renin-angiotensin system. In most patients with clinical CHF due to mechanical or myocardial abnormalities, the heart (pump) failure is preceded by a substantial period of *myocardial* dysfunction during which cardiac *pump* function and cardiac output (at least while at rest) may be maintained by compensatory mechanisms that include myocardial hypertrophy and ventricular dilatation. For this reason, in the early stages the patient may have little or no limitations or symptoms. Initially, the cardiac output may be within the range of normal at rest but fails to increase or may even decline during exercise or stress. Ultimately, the cardiac output is decreased even at rest. Associated changes include an increase in systemic vascular resistance (SVR) at rest and a failure of the SVR to decrease with increased metabolic needs.

When the intravascular circulatory congestion is present for any length of time with elevation of LV diastolic and pulmonary venous pressures, fluid transudation from the capillaries into the interstitial spaces increases. In the pulmonary circulation, pulmonary edema develops if the rate of transudation exceeds the rate of lymphatic drainage. Pulmonary edema is often detected initially by x-ray examination, and only later are audible rales detected on physical examination. In the systemic venous system, elevated jugular venous pressure is often visible and may be accompanied by dependent peripheral edema and hepatomegaly. In the majority of patients, CHF develops chronically and is associated with the retention of sodium and water by the kidneys.

Acute heart failure can develop during acute ischemia of the ventricle (i.e., a myocardial infarction), secondary tachycardia, or due to the rupture of a cardiac valve or structure. An acute shift of blood from the systemic to the pulmonary circulation can occur before the retention of significant sodium or water. The term *congestive heart failure* should not be used unless there is congestion of cardiac origin. When the cause of the pulmonary or peripheral congestion is not clear, however, it is usually preferable to describe the symptoms or signs, which are nonspecific, and to avoid improperly diagnosing heart failure.

CLASSIFICATION AND STAGES OF HEART FAILURE

Numerous classification schemes and definitions have evolved over the years (Table 20-1), including the antiquated "forward heart failure" and "backward heart failure" concepts that are no longer very useful. Even the New York Heart Association classification system, though widely

used, lacks precision.

Table 20-1: Classifications and Definitions of Some Common Types of Heart Failure

Heart failure A clinical syndrome with classic symptoms of breathlessness, fatigue, and exercise intolerance that are attributable to impaired myocardial function.
Congestive heart failure Similar to the preceding but with features of circulatory congestion such as jugular venous distention, rales, peripheral edema, and ascites.
Noncardiac circulatory congestion A syndrome that is clinically indistinguishable from congestive heart failure where there is no reason to ascribe the condition to structural heart disease. There must be a noncardiac cause such as acute renal failure.
Systolic heart failure A clinical syndrome with classic symptoms of breathlessness, fatigue, and exercise intolerance whereby the dominant cardiac feature is a large, dilated heart and impaired systolic performance. There may or may not be concomitant valvular disease.
Heart failure with normal systolic function Sometimes referred to as *diastolic heart failure,* this is a clinical syndrome characterized by breathlessness, fatigue, and exercise intolerance whereby the dominant cardiac feature is impaired diastolic function (usually diagnosed by echo) and normal or near-normal ejection phase indices. There is often LV hypertrophy and impaired filling of the heart due to altered LV stiffness or other evidence of diastolic dysfunction. Often, severe systemic hypertension is present. There may or may not be concomitant valvular disease, such as mitral insufficiency. This form of heart failure may coexist with systolic heart failure.
Right-sided heart failure A clinical syndrome characterized by tissue congestion including jugular venous distention, peripheral edema, ascites, and abdominal organ engorgement. There is marked impairment of right ventricular systolic performance, usually with right ventricular dilatation and severe tricuspid regurgitation. There are multiple causes of this syndrome, including severe left-sided heart failure, severe lung disease with chronic hypoxemia and pulmonary hypertension (so-called cor pulmonale), right ventricular myocardial infarction, and primary pulmonary hypertension.

New York Heart Association Functional Classification

I. *Patients with cardiac disease but without resulting limitations of physical activity*. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.
II. *Patients with cardiac disease resulting in slight limitation of physical activity.* These patients are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
III. *Patients with cardiac disease resulting in marked limitation of physical activity*. These patients are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.
IV. *Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort*. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

A more recent and useful "staging" scheme of heart failure is now being used more commonly by guideline committees and regulatory agencies and is more closely intertwined with prevention and therapy:

Stages of Heart Failure

Stage A. Patients at risk of developing heart failure because of comorbid conditions that are strongly associated with the development of HF. Such patients have no signs or symptoms of HF and have never manifested signs or symptoms of HF. There are no structural or functional abnormalities of the valves or ventricles. Examples: systemic hypertension, coronary artery disese, diabetes mellitus.

Stage B. Patients who have developed structural heart disease that is strongly associated with the development of HF, but have no symptoms of HF and have never manifested signs or symptoms of HF. Examples: left ventricular hypertrophy (LVH); enlarged, dilated ventricles asymptomatic valvular heart disease; previous myocardial infarction.

Stage C. Patients who have current or prior symptoms of HF associated with underlying structural heart disease.

Stage D. Patients with marked symptoms of heart failure at rest despite maximal medical therapy and who require specialized interventions. Examples include patients who cannot be safely discharged from the hospital; recurrently hospitalized; are in the hospital awaiting heart transplantation; are in a hospice setting; at home receiving continuous intravenous support for symptom relief; are being supported with a mechanical circulator assist device.

This newer staging scheme is very clinically oriented and allows physicians to target therapy in a more focused manner toward specific subsets of patients. In general, patients only progress forward in this schema, although occasionally patients may go from D to C.

Systolic and Diastolic Dysfunction

A useful distinction in ventricular failure is that between systolic and diastolic dysfunction (Table 20-2 and Fig. 20-1). These terms, however, are most appropriately defined in terms of altered ventricular architecture rather than systemic hemodynamics. *Systolic dysfunction* describes a large, dilated ventricle whose output is limited by impaired ejection, whereas *diastolic dysfunction* refers to a thickened, small cavity ventricle in which filling is limited. It is appropriate to reserve the term *systolic dysfunction* for a dilated, often eccentrically hypertrophied ventricle and *diastolic dysfunction* for a thick-walled, concentrically hypertrophied ventricle with a normal or small cavity, highlighting the important architectural differences between these two entities.

Table 20-2: The Differential Diagnosis of Systolic Heart Failure and Heart Failure with Normal Systolic Function (Diastolic Heart Failure)

Systolic Heart Failure	Diastolic Heart Failure
Large, dilated heart	Small LV cavity, concentric LV hypertrophy
Normal or low blood pressure	Systemic hypertension
Broad age group; more common in men	Elderly women more common
Low ejection fraction	Normal or increased ejection fraction
S_3 gallop	S_4 gallop
Systolic and diastolic impairment by echo	Diastolic impairment by various echo measurements

Treatment well established	Treatment not well established
Poor prognosis	Prognosis not as poor
Role of myocardial ischemia important in selected cases	Myocardial ischemia common

Diastolic heart failure (or heart failure with preserved LV systolic function) is increasingly recognized as a major and growing epidemiologic clinical problem.[7,8] As many as 40 percent of patients presenting with heart failure have preserved LV systolic function, and it may be an even higher proportion in hospitals caring for more elderly and inner-city patients. Diastolic heart failure often coexists with poorly controlled systemic hypertension. Factors contributing to altered LV diastolic function include myocardial fibrosis, hypertrophy, ischemia, and increased afterload.[9] Myocardial ischemia is an especially important mechanism to identify[10] because, like hypertension, it is usually treatable.

It is important to recognize that systolic and diastolic dysfunction frequently coexist in patients with heart failure and that systolic events can influence diastolic function.[11,12] The diagnosis of diastolic dysfunction can be challenging, but advancing echocardiographic techniques for this purpose have improved substantially. Limitations imparted by loading conditions, heart rate, and age to some extent have been overcome by new applications of continuous-wave Doppler, color Doppler M-mode, and Doppler tissue imaging.[13-15]

Women seem to be overrepresented in the group of patients with diastolic heart failure,[16] especially elderly women with hypertension, diabetes mellitus, and LV hypertrophy. For any given afterload stress, women seem to develop more hypertrophy than men. Patients with heart failure and normal systolic function have a lower mortality risk than patients with a reduced EF,[17] but they still have a fourfold mortality risk compared with control subjects who are free of heart failure.[18] Assessing LV architecture and function by echocardiography is important before initiating therapy in a patient with heart failure, since treatment for systolic dysfunction may be ineffective or even counterproductive if symptoms are due to abnormal diastolic properties with preserved systolic function. Knowledge of renal function and renal vasculature also may be important, especially in patients with severe hypertension. For example, many elderly patients with heart failure and severe hypertension have associated renal vascular stenosis.[19] Institution of an angiotensin-converting enzyme inhibitor in such a patient could lead to severe renal insufficiency. Likewise, prolonged aggressive use of diuretics in patients with severe LV hypertrophy and a small LV cavity may lead to a reduced stroke volume and hypotension. It is important, therefore, to have knowledge of myocardial architecture, anatomy, and function when planning therapy and in determining prognosis.

Generally, systolic ventricular dysfunction is characterized by an increase in end-diastolic volume (EDV) and a normal or somewhat reduced stroke volume (SV), resulting in a decrease in EF. This relationship of SV to EDV is normally described by the Frank-Starling relationship (Fig. 20-2). The increase in EDV is associated with an increase in ventricular end-diastolic pressure (EDP) in consonance with the resting pressure-volume curve. The filling pressures may be further elevated for a given EDV by concentric hypertrophy or a fibrotic wall. Conversely, they actually may be decreased by chronic overdistention (eccentric hypertrophy). The relation between LV wall force and fiber length is depicted in Fig. 20-3.

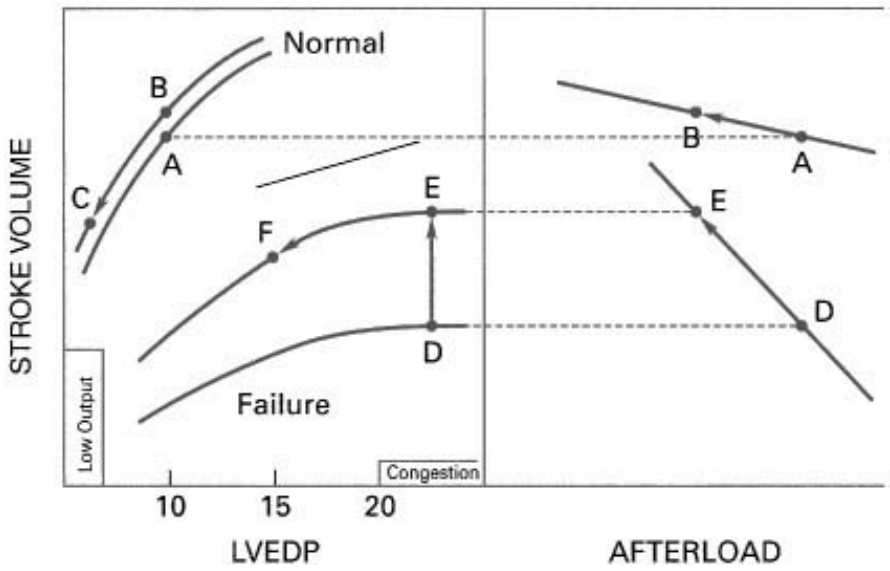

Figure 20-2: Relationship between stroke volume and left ventricular end-diastolic pressure (LVEDP) (*left*) and afterload (*right*). Normally, the ventricle operates on a sharply rising Frank-Starling curve with an LVEDP less than 12 mmHg (point *A*), where small changes in filling pressure yield large changes in stroke volume. Further, stroke volume is largely independent of the afterload. When failure occurs, ventricular function is characterized by a shift of the curve relating stroke volume to LVEDP to the right and downward. Low output may ensue if the curve is sufficiently depressed, while pulmonary congestion occurs as the LVEDP is increased. At the same time, this failing ventricle is now highly afterload-dependent, in that small changes in afterload produce large changes in stroke volume. When afterload is reduced in the normal heart (point *A* to point *B, right*), stroke volume rises very slightly. If, at the same time, venodilation reduces filling pressure, stroke volume falls to point *C* (*left*). The net result is a decrease in cardiac output. On the contrary, when afterload is reduced in the presence of severe ventricular failure, stroke volume is increased (point *D* to point *E, right*). Since the Frank-Starling curve is relatively flattened, a simultaneous decrease in filling pressure leads to a decrease in LVEDP with only a small decrease in stroke volume (point *E* to point *F, left*). The net reult of these opposing consequences can increase stroke volume. These results are observed clinically when a vasodilator is administered along with a diuretic in treating the failing ventricle.

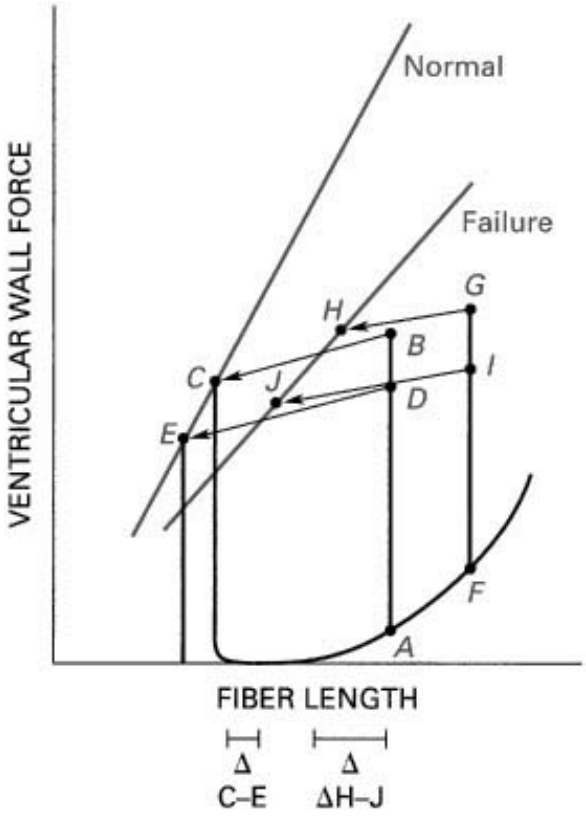

Figure 20-3: Relationship between LV wall force and fiber length. Hypothetical contractile cycles have been portrayed for the normal and failing ventricle. In the normal heart, contraction starts at point *A*, LV pressure rises until the aortic valve is opened (point *B*), the ventricle empties (point *B* to *C*), and relaxation ensues. When arterial pressure (afterload) is reduced (e.g., to point *D*), ejection starts at point *D* and proceeds to point *E*, which increases stroke volume. When the ventricle fails, the fiber length in diastole is increased, and ventricular contraction starts at point *F*. With systolic contraction, ventricular pressure rises to point *G*, and with ventricular emptying, fiber length decreases to point *H*. With a similar decrease in the afterload, wall force only needs to reach point *I* when ventricular emptying occurs to point *J*. As a result, for the same relative change in afterload, the increase in shortening is greater in the failing ventricle (Δ*H-J*) than in the normal heart (Δ*C-E*).

In patients with mild heart failure, the ventricular EDP and the cardiac output may be normal at rest, but the former may become elevated to abnormal levels during stress such as exercise or an increase in afterload. The ability to increase the cardiac output in response to the increase in oxygen consumption is also reduced (see below and Chap 3). In patients with more severe systolic dysfunction, both the early pressure and the EDP may be elevated even at rest. The elevated LV diastolic pressure increases pulmonary venous and capillary pressures and contributes to increased dyspnea as a result of changes in pulmonary compliance due to pulmonary congestion and edema. It is also apparent that before one reaches this stage of clinical heart failure, the body has used many compensatory mechanisms after the onset of the initial abnormality or stress and that these compensatory mechanisms eventually have failed to maintain the needs for cardiac output (see below).

Low-Output Heart Failure

The causes of overall heart pump failure may be classified in four main categories: (1) failure primarily related to work overloads or mechanical abnormalities, (2) failure mostly related to primary myocardial abnormalities, (3) failure related to abnormal cardiac rhythm or conduction disturbances, and (4) myocardial ischemia/infarction. Myocardial infarction resulting in a

quantitative loss of myocardium creates a special type of work overload. During the acute infarction, the EF falls as the EDV is increased to sustain a reduced SV, and the fall in EF is approximately proportional to the amount of myocardium lost. With time, the EF tends to remain at this reduced level. With healing of the infarction, the akinetic infarcted region becomes a scar that not only cannot contribute to ventricular emptying but may even contribute to the load. Thus the entire load falls on the remaining nonischemic myocardium. This load is further increased by the increased diastolic volume, which causes wall tension to be increased for any given pressure, even though the nonischemic myocardium hypertrophies in proportion to the amount of myocardium that is lost. Heart failure may ensue months or years later as a so-called ischemic cardiomyopathy resulting from progressive ventricular dilatation and reactive hypertrophy, termed *ventricular remodeling*, in the remaining nonischemic myocardium.

Cardiomyopathy

Virtually any form of heart disease eventually can lead to heart failure, and there are many causes of both "primary" and "secondary" heart failure. However, these distinctions are quite arbitrary and of little clinical value. *Primary heart failure* usually refers to "cardiomyopathy," a vague term that can include idiopathic dilated cardiomyopathy, familial dilated cardiomyopathy (an increasingly recognized cause of dilated cardiomyopathy), and hypertrophic cardiomyopathy. It simply depends on how one defines the term *cardiomyopathy*. Familial dilated cardiomyopathy is more common than previously believed.[20] It cannot be predicted by clinical or phenotypic techniques and requires family screening for identification. It is important to always consider familial dilated cardiomyopathy when evaluating patients with "idiopathic dilated cardiomyopathy" because it has a more unpredictable natural history and can present with a very rapid downhill course necessitating early referral to a heart transplant center.[21] Cardiac abnormalities are common in asymptomatic relatives of patients with dilated cardiomyopathy.[22] As many as 30 percent or more of patients with dilated cardiomyopathy may have an inherited disorder.[23] Single-gene defects may be important in the disease pathogenesis.[24]

Hypertrophic obstructive cardiomyopathy (HOCM) and nonobstructive hypertrophic cardiomyopathy are also often familial, affecting about 1 in 500 people in the general population. Most cases are inherited in an autosomal dominant manner with variable clinical penetrance and expression. Many different mutations have been described for at least seven abnormal sarcomeric proteins. Late-onset expression of HOCM may be a distinct clinical entity. Unfortunately, the genetic heterogeneity of this disease has made routine genetic testing impractical. Clinical screening may be warranted for members of families characterized by hypertrophic cardiomyopathy.

Unlike familial dilated or hypertrophic cardiomyopathy, alcoholic cardiomyopathy and "viral" cardiomyopathy (e.g., secondary to inflammatory myocarditis) may be overdiagnosed by clinicians. There are no specific clinical markers for so-called alcoholic cardiomyopathy, and there is no good evidence indicating an alcohol dose-response relationship. Apparently, a broad segment of the alcoholic population remains somehow immune to this complication. Nevertheless, patients believed to be "heavy" users of alcohol who present with dilated cardiomyopathy in whom heart failure resolves on cessation of alcohol use probably have "alcoholic cardiomyopathy." This observation should be a strong reason to encourage abstinence in patients with dilated cardiomyopathy of uncertain or possibly alcoholic origin.

Viral myocarditis can only be diagnosed by examining myocardial tissue (e.g., myocardial biopsy), since we now know that the "clinical" diagnosis of viral myocarditis is notoriously inaccurate. Only 5 to 10 percent of biopsies taken from the hearts of patients suspected clinically of having inflammatory myocarditis are actually "positive." Physicians should refrain from telling patients that their heart failure was due to a virus unless there is tissue verification. There are, of course, patients with mild or subclinical acute myocarditis who progress to heart failure and

present with "dilated cardiomyopathy." The prognosis of patients with proven inflammatory myocarditis may be somewhat better than that of patients with idiopathic dilated cardiomyopathy, since spontaneous improvement in LV ejection fraction is not uncommon.[25] However, others have found no difference in the 5-year survival between patients with myocarditis and idiopathic dilated cardiomyopathy (56 versus 54 percent, respectively).[26] Patients with active inflammatory myocarditis may suffer severe rejection earlier and more commonly after heart transplantation. Idiopathic giant-cell myocarditis is important to distinguish from inflammatory lymphocytic myocarditis because it has a worse survival rate and may respond better to heart transplantation.[27]

Anthracycline-induced heart failure is now increasingly recognized as a form of "toxic" heart failure.[28] It is clearly a dose-related phenomenon and may present as a "cardiomyopathy." A rapidly growing number of persons, including a fraction of the 150,000 adults in the United States who have survived childhood cancers, will develop anthracycline-induced cardiomyopathy.[29,30] There may be a long latency period (years) between treatment and onset of symptoms. Recently, Herceptin (recombinant humanized anti-HER2 antibody) has been approved for the treatment of breast cancer. About 27 percent of patients receiving both Herceptin and doxorubicin or Paclitaxel experience cardiac dysfunction,[31] which is a far greater percentage than those receiving anthracycline or Paclitaxel alone. Cardiac toxicity should be a major concern for patients receiving Herceptin, which is often used in conjunction with an anthracycline. Heart failure induced by these drugs is not a simple complication that can be "managed" by drug therapy but is a potentially lethal complication that requires skillful care. Other causes of toxic cardiomyopathy include cocaine, other cytostatic agents, interferons, interleukin-2, anabolic steroids, and a host of miscellaneous agents.[31]

The cause of LV systolic dysfunction in patients with chronic obstructive lung disease is unknown, although the combination of hypoxia and hypercapnia may be important. LV diastolic dysfunction in such patients is, in part, secondary to the pronounced right ventricular hypertrophy and dilatation with secondary elevation of LV diastolic pressure due to ventricular interdependence. The latter phenomenon is also important in the pathophysiology of acute pulmonary edema occasionally encountered in patients with acute pulmonary embolus.

Myocardial "Overload"

Myocardial failure may develop from many causes of "overload." It may evolve from pressure overloads in which myocytes hypertrophy to meet the load. Hypertrophied cells contract and relax more slowly[32] and may be subject to metabolic limitations. In addition, hypertrophied myocardial cells may have a shortened life span.[33,34] This is of considerable prognostic importance because cardiac myocytes appear to have little or no capacity to proliferate. When age-related myocyte loss is added to the picture, particularly in association with a late decrease in myocyte contractile activity, failure may ensue with ventricular dilatation. Loss of myocytes-whether segmental, as in acute myocardial infarction, or diffuse, as in myocarditis-sets up a vicious cycle that leads to reactive hypertrophy in remaining myocytes. As compensatory hypertrophy becomes more marked in some disease states, the unit contractility of the myocardium often declines because of molecular changes in the heart's contractile proteins and activation system. This is especially likely to occur in response to pressure overload, as in systemic arterial hypertension or aortic stenosis, but also ensues when myocytes are lost.

Ultimately, the myocardial failure (plus mechanical abnormalities that may be present) often leads to a decrease in systolic pump function that is sufficient to produce overall pump or heart failure. In most patients, significant dysfunction and failure of the myocardium occur before the clinical syndrome of CHF becomes apparent.

High-Output Failure

Some patients with high-output states or primary noncardiac circulatory overload may develop pulmonary congestion and edema secondary to an abnormal elevation of ventricular diastolic pressure at a time when the total cardiac output (systolic, or pump, function) and EF of the left ventricle are normal or even increased. The latter syndrome also can occur in conditions associated with an increase in blood volume from the accumulation of excess salt and water due to salt-retaining steroids, excess blood or fluid administration, acute glomerulonephritis, oliguria, or anuria. In other patients, it may occur with an abnormally increased venous return and/or decreased peripheral resistance, as might occur in patients with arteriovenous fistulas, beriberi, hyperthyroidism, cirrhosis, severe anemia, and large vascular tumors. Under such conditions, the chronic volume and/or pressure overload on the ventricle eventually may produce myocardial and ventricular systolic (pump) dysfunction or failure. Ultimately, this can both increase diastolic pressures and reduce cardiac output to abnormally low levels. When symptoms of pulmonary congestion or pulmonary edema secondary to elevated diastolic pressure occur while the cardiac output is still normal or elevated, the syndrome is sometimes referred to as *high-output failure*.

High-output heart failure is rare in the United States. For example, to have high-output heart failure from chronic anemia, a hematocrit of about 13 percent (9-16 percent) typically would be necessary.[35] This is an uncommon presentation in North America. However, this condition may be found in areas of the world where chronic parasite infestation can lead to severe, chronic anemia. As with low-output heart failure, patients with high-output heart failure have salt and water retention, reduced renal blood flow, and neuroendocrine activation.[35] Low concentration of hemoglobin in patients with anemia may lead to a relative inability to degrade nitric oxide (NO), leading to the vasodilation that is so typical of high-output heart failure. Low blood pressure may in turn activate neuroendocrine activity. Various conditions that increase cardiac output are depicted in Table 20-3.

Table 20-3: Conditions That Increase Cardiac Output

Bacteremia/sepsis	Fibrous dysplasia (Albright's syndrome)
Anemia (acquired or congenital)	Renal disease (acute or chronic)
Hyperthyroidism	Hepatic disease
Beriberi	Environmental temperature extremes
Arteriovenous fistulas (acquired or congenital)	Polycythemia vera
Pregnancy	Carcinoid syndrome
Paget's disease	Dermatologic abnormalities
Hyperdynamic heart syndrome	Erythroderma syndrome
Arterial hypertension	Kaposi's sarcoma

Left and Right Heart Failure

Left heart (*left-sided*) *failure* and *right heart* (*right-sided*) *failure* are clinical terms for conditions in which the primary impairment is of the left side of the heart or of the right side of the heart, respectively. Since both sides of the heart are in a circuit, it is apparent that one side cannot pump significantly more blood than the other side for any length of time in the absence of abnormal shunts, communications, or regurgitation. Furthermore, experimentally produced failure of one ventricle may produce significant hemodynamic and biochemical abnormalities of the other

ventricle, even without the usual hemodynamic manifestations of ventricular failure. Abnormal function of the left ventricle not only overloads the right ventricle from augmented pulmonary pressures but also may affect the right ventricle via the shared septum and the phenomenon of ventricular interdependence or interaction (see below). Altered elastic recoil of the left ventricle in diastole also may affect the right ventricle. Accordingly, when the pumping ability of one ventricle is primarily impaired, the output of the contralateral ventricle can be secondarily decreased; the biochemistry and hemodynamics of the contralateral ventricle also can be abnormal even in "pure" one-sided failure.

Right-sided heart failure commonly follows left-sided heart failure. In most situations, the expression *left-sided heart failure* is used clinically in reference to symptoms and signs of elevated pressure and congestion in the pulmonary veins and capillaries, whereas the term *right-sided heart failure* is used clinically in reference to symptoms and signs of elevated pressure and congestion in the systemic veins and capillaries. Actually, significant amounts of sodium and water retention, with subsequent peripheral edema formation, may occur with pure left-sided heart failure without hemodynamic evidence of right-sided heart failure. As noted previously, an increase in the diastolic pressure in either ventricle can increase the diastolic pressure or decrease the distensibility of the contralateral ventricle, especially if the pericardium is intact.

Compensated Heart Failure

Compensated heart failure is that condition in which the symptoms of heart failure are relieved, usually by therapy or compensatory mechanisms, although the EDV and EDP often remain elevated, and the EF remains reduced. As noted below and in Table 20-4, the usual "compensatory" mechanisms include increased sympathetic adrenergic stimulation of the heart, activation of the renal renin-angiotensin system, increased vasoconstriction, fluid retention by the kidney, increased venous return, increased ventricular preload, and cardiac dilatation and hypertrophy. Clinically, myocardial compensation and a decrease in congestion may be produced by improved ventricular performance. The term *compensated heart failure* frequently is used in reference to patients with CHF whose symptoms and signs of pulmonary or peripheral congestion have been relieved by therapy. In many such patients, reduced myocardial function and low cardiac output persist, although symptoms are relieved by an improvement in peripheral circulation and the reduction in edema and congestion.

Chapter 20: PATHOPHYSIOLOGY AND DIAGNOSIS OF HEART FAILURE

MECHANISMS OF HEART FAILURE

Since virtually any form of heart disease can lead to heart failure, there can be no single causative mechanism. At the organ and the cellular level, there is likewise no single mechanism that is consistently operative. Identification of fundamental mechanisms remains an area of very active investigation (Table 20-5). Multiple alterations in organ and cellular physiology contribute to heart failure under various circumstances and at different points in time. Adaptive processes occur that affect the myocardium, kidneys, smooth and skeletal muscles, endothelium, peripheral vasculature, and multiple reflex control mechanisms, adding to the complexity of the syndrome (Tables 20-6 and 20-7). The schema of the sequence of events in heart failure is daunting (Fig. 20-4). Distinguishing primary etiologic forces from secondary epiphenomena has been very difficult. Identification of the precise mechanisms whereby heart failure evolves and quantifying the contributions of individual components (e.g., apoptosis) have remained elusive. Major gaps in our knowledge, such as what triggers the early activation of the sympathetic nervous system and withdrawal of vagal tone or how spontaneous resolution of heart failure occurs, have persisted despite intense investigation. Nevertheless, enough information has accrued to construct a reasonably coherent working hypothesis.

Table 20-5: Possible Mechanisms of Myocardial Failure

Loss of myocytes
Hypertrophy of remaining myocytes
Energy production and utilization
Oxygen and energy supply
Substrate utilization and energy storage
Inadequate mitochondria mass and function
Ventricular remodeling
Contractile proteins
Abnormal myofibrillar or myosin ATPase
Abnormal myocardial proteins
Defective protein synthesis
Nonuniformity of contraction and function
Activation of contractile elements
Membrane Na^+,K^+-ATPase defects
Abnormal sarcoplasmic reticulum function
Abnormal Ca^{2+} release
Abnormal Ca^{2+} uptake

Abnormal myocardial receptor function
Downregulation of beta adrenoreceptors
Decreased β_1 receptors
Decreased G_s protein
Increased G_1 protein
Autonomic nervous system
Abnormal myocardial norepinephrine function or kinetics
Abnormal baroreceptor function
Increased myocardial fibroblast growth and collagen
synthesis
Aging changes, presbycardia
Sustained tachycardia
Miscellaneous

Table 20-6: Compensatory Mechanisms in Heart Failure

Autonomic nervous system
Heart
Increased heart rate
Increased myocardial contractile stimulation
Increased rate of relaxation
Peripheral circulation
Arterial vasoconstriction (increased afterload)
Venous vasoconstriction (increased preload)
Kidney (renin-angiotensin-aldosterone)
Arterial vasoconstriction (increased afterload)
Venous vasconstriction (increased preload)
Sodium and water retention (increased preload and afterload)
Increased myocardial contractile stimulation
Endothelin-1 (increased preload and afterload)
Arginine vasopressin (increased preload and afterload)
Atrial and brain natriuretic peptides (decreased afterload)

Prostaglandins
Peptides
Frank-Starling law of the heart
Increased end-diastolic fiber length, volume, and pressure (increased preload)
Hypertrophy
Peripheral oxygen delivery
Redistribution of cardiac output
Altered oxygen-hemoglobin dissociation
Increased oxygen extraction by tissues
Anaerobic metabolism

Table 20-7: Neurohumoral Changes in Heart Failure

Increased sympathetic nervous system activity (increased norepinephrine, epinephrine)
Increased endothelin
Increased arginine vasopressin
Increased renin and angiotensin II
Increased aldosterone
Increased neuropeptide Y
Increased atrial and brain natriuretic peptides
Increased
Insulin
Cortisol
Growth hormone
Tumor necrosis factor-α
Interleukin 6
Vasoactive intestinal peptide
Adrenomedullin
Urodilatin
Increased dopamine
Increased prostaglandins (PGI_2, PGE_2)
Increased vasodilator peptides, (e.g., bradykinin)

NOTE: Measurements in individual patients vary significantly, and changes may not always be present.

To understand heart failure, it is useful to think in terms of evolutionary theory.[36] The cell, the organ, and the organism each has evolved adaptive responses to offset hostile environments, thus allowing a survival advantage. In many cases, heart failure may begin as an acute injury to the heart, such as an acute myocardial infarction or severe inflammatory myocarditis. In other cases, there may be a phenotypically silent mutation that is finally expressed (for unknown reasons), leading to structural and functional perturbations of such magnitude that the heart eventually fails. Valvular heart disease may lead to unusual loading conditions, forcing the myocytes to adapt by increasing their size (hypertrophy). In essence, there is an *index event* that in many cases is not clinically visible or may occur secondary to unknown toxins or an unusual mechanical load on the heart. The heart and its circulary physiology must somehow "adapt" to this "hostile" new environment.

In response to increased load, whether created by increased pressure or loss of myocytes, hypertrophy occurs that tends to normalize the load per cell. With an increased volume load, myocytes elongate and in rare cases may undergo division.[37,38] It is believed that hyperplasia and apoptosis involves less than 1 percent of the cardiac myocytes. Reprogramming of the cardiac myocytes occurs, resulting in a more fetal-like response leading to an increase in the size of the cardiac myocyte,[39,40] presumably rendering the surviving myocytes a short-term structural and functional advantage. The reprogramming requires altered signals, both mechanical and "chemical," to reach the nucleus of the cardiac myocyte in order to set into motion "new" gene transcription.[41] Ultimately, there is a transition from hypertrophy to heart failure,[42] which has been recognized for more than 100 years but is still not well understood.[34] In a sense, this "unnatural growth response" of myocyte hypertrophy leads to the obvious structural changes of LV remodeling, thus creating a large, dilated, and poorly functioning heart. The processes of cellular remodeling and subsequent architectural changes in cell and chamber size and shape are highly complex[41] and include many components other than myocardial cell hypertrophy. There is myocardial fibrosis, cell dropout, and myocyte slippage. As cardiac output falls, multiple neurohormones including renin and norepinephrine are "released" in an attempt to protect blood pressure and organ perfusion,[43] while atavistic counterregulatory natriuretic peptides are "released" in an attempt to offset vasoconstriction, hypertrophy, and volume conservation.[44] The story is undoubtedly much more complex than this[45] and includes a cornucopia of molecular mechanisms,[41,46] some of which primarily affect the cardiac interstitium and others the cardiac myocytes. The pathophysiologic changes observed in heart failure are partially depicted in Table 20-6 and Fig. 20-5.

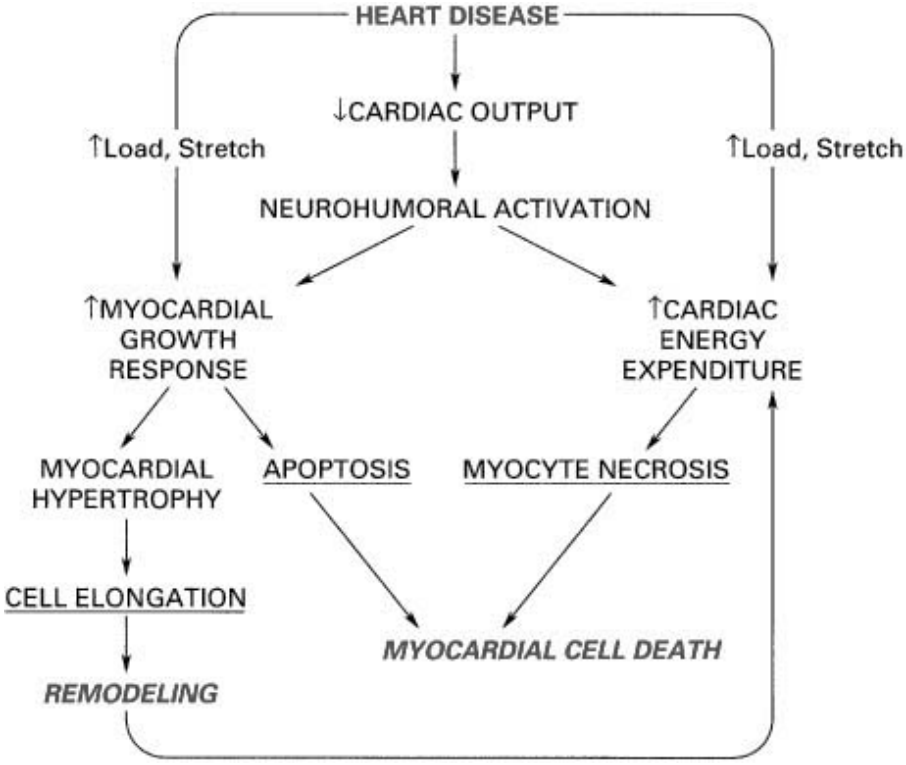

Figure 20-5: Possible mechanisms by which overloading can cause progressive deterioration of the heart ("cardiomyopathy of overload"). Several mechanisms, including myocyte stretch, activate a growth response that initiates myocardial hypertrophy in the overloaded heart (*left*). The same growth response may also activate signal transduction systems that cause programmed cell death (apoptosis). The hypertrophic response to overload, by causing sarcomeres to be added in series, can also lead to cell elongation and so accelerate remodeling; the resulting increase in wall tension, along with the overload itself (*right*), increases cardiac energy expenditure that, in the overloaded heart, can accelerate myocyte necrosis. Reduced cardiac output activates neurohumoral responses (*center*), which, by increasing afterload and β-adrenergic stimulation of the heart, also increase cardiac energy expenditure. Because many mediators of the neurohumoral response to a fall in cardiac output promote myocardial cell growth, neurohumoral activation can also accelerate both apoptosis and remodeling.

Maladaptive remodeling of cardiac myocyte size and shape begins long before clinical heart failure begins.[47-50] Alterations in myocyte proteins and mitochondria size and number and changes in myocardial interstitium and collagen content/architecture are seen in response to a variety of "injuries" including pressure overload,[51-53] volume overload,[54] and myocardial ischemia.[55,56] Additional phenotypic changes in heart failure include apoptosis[57,58] and side-to-side slippage of myocytes.[59] It is important to recognize that much of the neuroendocrine activation that occurs in a primordial attempt to conserve organ perfusion appears to facilitate this myriad of phenotypic change in the heart at the cellular level,[45] thereby possibly accounting for the success of neuroendocrine blockers as therapy for heart failure. Lastly, there is no single phenotypic change, protein expression, or signal-transduction pathway that is dominant. Rather, there is extraordinary redundancy in these mechanisms. This observation has important implications for therapy. For example, blocking one neuroendocrine system may lead to enhanced overactivity of other neuroendocrine systems. Blocking one signal-transduction pathway may lead the cell to hypertrophy through alternative pathways. Thus it is likely that polypharmacy will always be necessary in the treatment of heart failure.

In summary, heart failure often begins with an index event that results in loss of myocardium (e.g., acute myocardial infarction) or excessive overload (e.g., valvular heart disease, acute myocardial infarction, mutation leading to dilated or hypertrophic cardiomyopathy, etc.). Where hypertrophy cannot sustain the increased load, ventricular dilatation occurs, and the ventricle assumes a more globular shape (i.e., eccentric hypertrophy), thus allowing for maintenance of stroke volume despite a reduced EF. This provides short-term benefit. Absence of some dilatation probably would lead to shock and early death. Neuroendocrine activation presumably occurs in response to a perceived need to protect perfusion pressure, but

neurohormones also facilitate the LV remodeling process, thus contributing importantly to the pathogenesis and progression of heart failure. Despite the presumed coherency of this oversimplified working hypothesis, many gaps in our knowledge remain to be filled in, particularly with regard to the quantitative contribution that each phenotypic change makes toward the progression of heart failure. We still have much to learn.

Molecular, Physiologic, and Biochemical Alterations Occurring with Hypertrophyand the Progression to Heart Failure

Alterations are found in the failing heart in numerous contractile proteins, especially in heredity-based idiopathic dilated cardiomyopathies. In the latter situation, these alterations can be the sole cause of heart failure. Such alterations have been found in myosin, troponin T, and actin. These alterations in protein structure likely contribute to diminished myocardial performance. Alterations in gross cardiac structure and cellular components in heart failure resulting from systolic overloads are much more complex. Findings in animal models of overload-produced heart failure may vary from model to model, and observations made in human failing hearts may be different from those made in animal models. In the human failing heart, many changes in gene expression at the mRNA or protein level have been found in hearts harvested at the time of cardiac transplantation. These are hearts with end-stage myocardial disease in which many factors (such as receiving multiple inotropic drugs) may obscure actual pathogenesis. Despite these caveats, we have learned much from these studies, only some of which will be discussed here.

β-MYOSIN HEAVY CHAIN

Two myosin heavy chain (MHC) isoforms are present in mammalian heart, α- and β-MHC. The α-MHC is cardiac-specific and is more enzymatically active. The less active β-MHC is present in heart and also in slow-twitch skeletal muscle. The distribution of α- and β-MHC is developmentally and hormonally regulated. Mechanical stress, such as pressure overload, induces an α- to β-MHC transition in the ventricles of experimental animals, thus imparting a slower but more economical type of work for the overloaded heart. Either way, myosin remains the principal structural and contractile unit of muscle fiber. Lowes et al.[60] recently have demonstrated downregulation of α-MHC and upregulation of β-MHC using mRNA measurements from right ventricular endomyocardial biopsies from nonfailing hearts and failing human hearts. This alteration, if translated into protein expression, would decrease myosin ATPase enzyme velocity and slow the speed of contraction. Although such adaptive changes could be viewed to have an "economical" survival advantage in the face of increased load, slower contraction and relaxation may contribute to diastolic dysfunction.

SARCOPLASMIC RETICULUM FUNCTION

There is substantial evidence that defects in sarcolemma Ca^{2+} uptake (sarcolemmal transport via Na^{+},K^{+}-ATPase) and release by the sarcoplasmic reticulum (SR) are present in heart failure, especially at later stages.[61-63] Alternatively, uptake of Ca^{2+} by the SR may remain intact.[64] These alterations in Ca^{2+} transport may be secondary to quantitative alterations of gene expression of SR Ca^{2+} transport proteins, especially the sarco(endo)plasmic reticulum Ca^{2+}-ATPase (SERCA)[65] and phospholamban,[66] a reversible inhibitor of cardiac SR Ca^{2+}-ATPase activity. Other Ca^{2+} cycling proteins such as Na^{+}-Ca^{2+} exchanger proteins[67] and ryanodine receptors[68] also may be altered in heart failure. Unfortunately, these observations are not always consistent from model to model and may not always be relative to failing human hearts. Nevertheless, it is likely that heart failure is characterized by reduced myofilament activation and decreased Ca^{2+} available for activation as well as heightened cytosolar Ca^{2+} levels in diastole. Some studies have shown increased myofibrillar Ca^{2+} sensitivity[69] and altered Ca^{2+} kinetics.[70] These abnormalities of calcium metabolism may be of primary importance in some types of heart failure, and they may be secondary or epiphenomena in other types. Most abnormalities of myocardial contractile activation have been demonstrated only in the late stages of heart failure and therefore may be the result of maladaptive hypertrophy rather than a primary cause of ventricular dysfunction.

FORCE-FREQUENCY RESPONSE IN HEART FAILURE

The failing human myocardium is characterized by an abnormal force-frequency response that parallels the

severity of heart failure. Normally, increase in frequency of stimulation is accompanied by an enhanced force of contraction (Bowditch effect). In heart failure, an increase in heart rate by pacing an additional 50 beats per minute is accompanied by about a 30 percent decrease in myocardial performance as measured by dP/dt_{max}. It is likely that some impairment of systolic function in response to increased heart rate may be related to impaired LV filling, although a negative inotropic effect, as shown in isolated muscle to be due to alterations in intracellular Ca^{2+} handling, cannot be excluded. This feature of heart failure may help explain some impairment of cardiac function during exercise.[71,72]

ENERGY PRODUCTION AND USE

Oxygen deprivation, which is most often due to coronary artery disease, results in impaired relaxation and weakened contraction, as may be seen in angina pectoris. When transient, these are readily reversible. With prolonged ischemia, decreased contraction (dyskinesis) may persist for hours beyond return of blood flow and is termed stunning. If coronary blood flow is chronically reduced, myocardium may fail to contract normally (*hibernation*), even if necrosis does not ensue. With more serious loss of flow, infarction can occur. All these stages may produce substantial dyskinesia for which the remaining myocardium must sustain this load. The result is hypertrophy of the nonischemic portion of the ventricle; if this is inadequate, an increase in ventricular volume occurs using the Frank-Starling mechanism to sustain stroke volume.

In patients with heart failure, the total amount of oxygen consumed by the heart may be increased significantly because of the increased total mass, the increase in myocardial systolic wall tension due to the Laplace relationship, and perhaps some wasted contractile energy. This increase may result in the extraction of a greater amount of oxygen from each unit of coronary blood flow and a widening of the coronary arteriovenous oxygen difference. Many patients with heart failure are able to increase coronary blood flow during exercise; however, some patients with a dilated ventricle that increases in diameter during exercise may have a further widening of the coronary arteriovenous oxygen difference during exercise and a decrease in coronary blood flow reserve (see Chaps. 3 and 37). In the presence of severe LV hypertrophy, coronary blood flow per unit mass of myocardium is usually normal at rest. On the other hand, the capacity of the coronary vascular bed to dilate during reactive hyperemia, which is normally four- to fivefold, is reduced. In the presence of severe hypertrophy where filling pressures are elevated, tachycardia such as may occur with atrial fibrillation may reduce diastolic coronary perfusion, producing ischemic ventricular failure. While reduced perfusion is probably common in end-stage heart failure, a deficit in coronary blood flow or oxygen delivery has not been clearly demonstrated to be a primary cause of heart failure associated with hypertrophy, except in the presence of obstructive coronary disease (see below).

SUBSTRATE USE AND ENERGY STORAGE

Although the myocardial uptake of fatty acids and glucose per 100 g of myocardium is normal in heart failure,[73] there is conflicting evidence on whether or not there is a primary decrease in energy liberation by mitochondrial oxidative phosphorylation.[33,34,73-77] The reductions in stores of myocardial high-energy phosphate, creatine phosphate, and/or adenosine triphosphate (ATP) generally found in heart failure usually are thought to be secondary and to be the consequence of the failure rather than the primary cause of the failure.[73-82] There also may be reduced levels of creatine kinase and changes in the isoenzymes of creatine kinase in heart failure.[82]

The major consequences of the state of energy starvation that is probably seen in many, if not most, failing hearts are due to attenuation of important allosteric (regulatory) effects of ATP rather than reduction in the supply of substrate for the many energy-consuming reactions involved in contraction, relaxation, and excitation-contraction coupling. Because the normal systolic ATP concentration is around 5 to 10 m*M*, whereas the substrate-binding sites of most ATP-hydrolzing systems are saturated at ATP concentrations less than 1 m*M*, it is unlikely that ATP concentrations fall to levels below those needed to saturate known energy-consuming reactions except in the dying heart. These allosteric effects of high ATP concentrations, which do not require that the nucleotide be hydrolyzed, resemble those of a "lubricant" in that ATP accelerates ion pumps, ion exchangers, and passive ion fluxes through membrane channels. By facilitating the many calcium fluxes involved in excitation-contraction coupling and relaxation, these allosteric effects of ATP exert both inotropic and lusitropic effects.[76]

MITOCHONDRIAL MASS AND FUNCTION

There are conflicting data on whether or not there is a significant decrease in the mass of mitochondria relative to the mass of myofibrils that occurs in experimental cardiac hypertrophy.[80-82] It is possible that this is one of the limitations of severe hypertrophy. Defects in mitochondrial oxidative phosphorylation and in mitochondrial calcium metabolism also may be associated with myocardial failure.[83] Except in circumstances where coronary flow is limited, such as with large vessel obstructive disease (see Chap. 40) or purported microvascular obstructive or vasospastic disease, a primary role of energy limitation in the evolution of heart failure has yet to be demonstrated.[74] It is possible that it may play a role during periods of higher metabolic demand, such as tachycardia,[77] as noted previously.[84,85]

VENTRICULAR REMODELING (HYPERTROPHY AND DILATATION)

When one portion of the ventricle is disabled, an increase in intraventricular volume slowly occurs, presumably in response to a sustained venous return. This involves increased myocyte length, with the limit being at the level of the sarcomere at 2.2 μm. With systolic overloads, compensatory hypertrophy occurs with the addition of sarcomeres in parallel, leading to a lateral thickening of the myocyte while sarcomere length does not change.

Acute dilatation is also limited by the sarcomere, which at 2.2 μm attains maximum force. Beyond this point, stiffness of the sarcomere and the myocardium becomes very large, and resting tension rises to high levels. Such acute dilatation may lead to relative "side to side" slippage of myocytes. When distending forces become chronic, addition of new sarcomeres occurs in series. Dilatation of the ventricle also adds to the load by the Laplace relation, whereby tension in the wall rises with increased volume at the same pressure. This results in some lateral growth of myocytes, although elongation is the major alteration. In addition, functional mitral regurgitation may occur from excessive ventricular volume that adds to the volume overload. When increased systolic tension occurs, myocyte hypertrophy that occurs by laying down of sarcomeres in parallel is accomplished by biochemical alterations in both the contractile proteins and activating membrane systems (see Chap. 5).

In addition to the synthesis of sarcomeres in series with preexisting sarcomeres, "slippage" of myofibrils and myocardial fibers and rearrangement of myocardial fibers along cleavage planes of the left ventricle occur.[59] Thus, although overstretch of sarcomeres rarely may be present very transiently, it does not appear to be an important primary mechanism of chronic heart failure. There is evidence, however, that excessive stretch of myocytes can lead to myocyte death, apparently by the process of apoptosis (programmed cell death), which may lead to further heart failure. The effects of the law of Laplace with ventricular dilatation were noted earlier. Nonuniformity of myocardial contraction and functional mitral regurgitation also contribute to heart failure.

MYOCARDIAL RECEPTOR FUNCTION

One of the hallmarks of heart failure is decreased myocardial inotropic function. Although it is clear that no single mechanism accounts for the depressed inotropic state, reduction in myocardial β-adrenergic receptors and its subsequent second messenger cAMP may play an important role in this regard.[86] β-Adrenergic stimulation contributes importantly to the cardiac response to exercise,[87] and β-adrenergic desensitization and uncoupling may be at least partially responsible for the reduced chronotropic and inotropic response to peak exercise commonly found in patients with heart failure.[87] The β-adrenergic receptor abnormalities in heart failure appear to be due to desensitization and uncoupling of the β_1 receptor produced by local and not systemic alterations in catecholamines.[88] In severe heart failure, the norepinephrine (NE) stores in sympathetic nerve endings are well known to be depleted. In a sense, the failing myocardium becomes functionally denervated. cAMP responses are reduced by about 30 to 35 percent, leading to further contractile dysfunction.[79] It is possible that with rather selective downregulation of the β_1 receptor, there remains a relatively high proportion of β_2 receptors to mediate chronotropic and inotropic responses.[89] However, there is mild uncoupling of the β_2 receptor from its G protein and a mild upregulation of the $G\alpha_i$ subunit, further contributing to a depressed response to chronotropic and inotropic stimuli.[90-92] There is

also a profound decrease in cardiac β-adrenergic responsiveness with aging,[93] which has clinical implications because heart failure is heavily concentrated in the aging population.

The desensitization and uncoupling of β-adrenergic receptors occurs early with mild to moderate ventricular dysfunction. It is related to the degree of heart failure and is associated with a very reduced response to β-adrenergic stimulation with drugs such as dobutamine.[94] Long-term stimulation of β-adrenergic receptors may enhance myocardial β-adrenergic receptor kinase (β-ARK) activity,[95] leading to further desensitization and uncoupling of the β-adrenergic receptor. These observations generally support the previously counterintuitive concept of using β-adrenergic blocking drugs to treat patients with heart failure. Of some interest, β-adrenergic blockade with metoprolol, a relatively cardioselective β_1 blocker, upregulates the β_1 receptor, whereas carvedilol, a nonselective β_1 and β_2 blocker with additional α_1 blocking activity, does not increase β_1 receptor density.[96] Both drugs can improve LV function. This suggests that the improvement in cardiac function seen with chronic β blocker use is not simply due to upregulation of β-adrenergic receptors. Moreover, high plasma norepinephrine levels do not predict benefit from carvedilol,[97] suggesting that there is not a simple relation between activation of the sympathetic nervous system and β-adrenergic receptor function in heart failure.

AUTONOMIC NERVOUS SYSTEM DYSFUNCTION

Heart failure is characterized by many abnormal reflex control mechanisms. Peripheral vascular resistance is increased, there is defective cardiac parasympathetic control,[98] an abnormal response to upright tilt,[99] altered baroreceptor function,[100-103] and reduced cardiac sympathetic activity in response to a variety of stimuli.[104-106] Indeed, an early sign of heart failure is increased sympathetic tone accompanied by reduced vagal tone resulting in an increased heart rate even at rest.

The increase in systemic vascular resistance observed in well-established heart failure, a therapeutic target for short-term hemodynamic treatment with nitroprusside, is likely due to a combination of locally active heightened vasoconstrictors (norepinephrine, angiotensin II, endothelin, vasopressin, neuropeptide Y) and to structural changes in blood vessels related to fluid retention and reduced endothelial-dependent vasodilation. Early in heart failure there may be a fall in cardiac output, arterial pressure, and baroreceptor activity, leading to an "adaptive" increase in excessive neuroendocrine drive. The sympathetic nervous system and the renin-angiotensin-aldosterone axis are activated. Arginine vasopressin is released. Sodium and water retention occur, hypervolemia restores cardiac output and arterial pressure, and neuroendocrine activity may reach a steady state. However, as heart failure progresses, there is impaired cardiosensory activity that fails to reduce neuroendocrine drive. Cardiac afferent activity to the central nervous system, for unclear reasons, is reduced, leading to unhindered, efferent excitatory responses from the brain to the periphery. Reflex vasoconstrictor responses to unloading the heart are paradoxically blunted.[99,106] There are abnormal vascular responses to postural change.[107] Some of these changes lead to alterations in regional blood flow that accompany heart failure.[108] Heart rate variability is markedly reduced and is a hallmark in defining congestive failure. Further, decreased heart rate variability may provide independent prognostic value in the identification of patients at risk for premature death.[109]

Although the genesis of these abnormal reflex control mechanisms is still not clearly understood, the changes may be more functional than structural in origin. Heart transplantation reverses cardiopulmonary baroreflex control mechanisms to some extent,[110,111] but the improvement may be absent[112] or delayed[113] in some cases. The role that abnormal reflex control mechanisms plays in the progression of heart failure, like other neuroendocrine alterations, has been difficult to quantitate. Nevertheless, it is now increasingly clear that the sympathetic nervous system and the renin-angiotensin-aldosterone system greatly influence the progression and natural history of heart failure. The therapeutic implications derived from these observations have proven to be very important.[114,115]

Chapter 20: PATHOPHYSIOLOGY AND DIAGNOSIS OF HEART FAILURE

MECHANICAL AND HEMODYNAMIC FEATURES OF HEART FAILURE

The term *heart failure* implies structural heart disease. The central problem of heart failure remains impaired cardiac performance, although many of the secondary "adaptive" responses become maladaptive and contribute substantially to progression of heart failure. An understanding of how these changes occur can provide insight into the pathophysiology of the syndrome.

As ventricular function becomes impaired, the Frank-Starling law of the heart becomes operative (see Fig. 20-2). Inadequate emptying of the ventricle leads to increased EDVs. This is referred to as *increased preload,* and it produces an increase in SV during the next contraction. The Frank-Starling law simply states that the increase in contractile force (i.e., contractility) is related to sarcomere lengthening (up to 2.2 μm). For any given amount of Ca^{2+} released into the myocyte, there is increased crossbridge formation and enhanced sensitivity of the myofilament to Ca^{2+} as the sarcomeres lengthen.

In the failing ventricle, the extent of shortening for a given diastolic fiber length and load (afterload) is reduced. The ventricle can maintain a normal or near-normal SV with an increased EDV and thus maintain end-diastolic fiber length for a period of time. Eventually, the filling pressure rises inordinately, limiting this compensation (see Fig. 20-1). Further, the clinically dilated ventricle tends to "give" like an overstretched elastic band, and end-diastolic volume may increase somewhat with no increase in LV end-diastolic pressure, reflecting a shift in the passive pressure-volume curve to the right. An obligatory reduction in ejection fraction occurs when SV is maintained in the face of a large EDV (EF = SV/EDV; normal EF = 0.62 ± 0.12). Eventually, further increases in EDP produce little change in EDV, thus flattening the SV-EDP curve (see Fig. 20-1). There is no true descending limb to Starling curve because increasing preload indefinitely ultimately will lead to mitral regurgitation.[116,117] As the heart dilates, the increase in wall stress according to the Laplace relationship also will increase afterload, which may account for any observed reduction in SV as the heart dilates further (i.e., the perception of a descending limb). It is important to keep in mind that LV performance depends not only on systolic pump function but also on active relaxation, passive diastolic properties, and vascular loading conditions. It is likely that at high LV end-diastolic pressure, valvular incompetence (mitral regurgitation) is a major cause of a decrease in cardiac output. Thus, in end-stage heart failure in the intact circulation, the Starling curve flattens out. It is possible under certain experimental conditions that the severely failing heart is able to utilize the Frank-Starling mechanism,[118] but a hallmark of heart failure is the inability of the chamber to respond robustly to an increase in preload.

Afterload and the Concept of the Laplace Relation

A characteristic feature of the dilated, failing heart is that it gradually becomes less sensitive to preload (EDV and fiber length) and more sensitive to afterload stress. At very high LV filling pressures (>30 mmHg) when the sarcomeres are fully extended and the preload reserve is exhausted, the SV becomes exquisitely sensitive to alterations in the afterload.[119] The impedance to ejection includes blood viscosity, vascular resistance, vascular distensibility, and myocardial wall tension. The afterload is the total load that the heart must work against during contraction. Much of the afterload is made up of ventricular myocardial wall tension. In the ventricle, the

tension on the walls increases as ventricular chamber volume increases, even if intraventricular pressure remains constant. Calculations of myocardial wall tension are defined by the Laplace equation and are expressed in terms of tension *T* per unit of cross-sectional area (dynes per centimeter).

Within a cylinder, the law of Laplace states that wall tension is equal to the pressure within the cylinder times the radius of curvature of the wall: $T = P \times R$ where *T* is wall tension (dyn/cm), *P* is pressure (dyn/cm^2), and *R* is the radius (cm). Basically, wall tension is proportional to radius. Because the heart has thick ventricular walls, wall tension is distributed over a large number of muscle fibers, thereby reducing tension on each. The equation for a thick-walled cylinder such as the heart is: $T = \frac{P \times R}{h}$ where *h* is wall thickness. The equation is sometimes stated as: $T = \frac{P \times R}{2h}$

Since the geometry of the ventricles is more complex than a cylinder, ventricular wall tension cannot be measured with precision. Wall stress, the force distributed across an area, is actually more correct but is seldom measured.

There are two fundamental principles that stem from the relationship between the geometry of the ventricular cavity and the tension on its muscular walls:

1. *Dilation of the ventricles leads directly to an increase in tension on each muscle fiber.*
2. *An increase in wall thickness reduces the tension on any individual muscle fiber. Therefore, ventricular hypertrophy reduces afterload by distributing tension among more muscle fibers.*

The wall tension is highest in the inner surface of the heart. The endocardial surfaces must do more work and therefore are also more vulnerable to reductions in coronary blood flow. Dilatation of the heart decreases cardiac efficiency, unless hypertrophy is sufficient to normalize wall stress. In heart failure, wall tension (or stress) is high, and thus afterload is increased. The energetic consequences of the law of Laplace may have some role in progressive deterioration of energy-starved cardiac myocytes in the failing heart.

Another major disadvantage of the dilated ventricle is the inability to decrease the average radius during contraction. In the normal heart, wall tension falls during ventricular ejection as the volume decreases, even though pressure is rising. In heart failure, given the dilated heart with reduced ejection, the average tension in the myocardial fibers actually may continue to increase from the beginning of the ejection until peak systolic pressure is reached,[120-122] adding additional afterload during ejection. The rate of myocardial fiber shortening is reduced, further contributing to diminished myocardial performance. It is difficult to overstate the importance of the law of Laplace when considering the syndrome of heart failure. This contrast is apparent in mitral insufficiency. With preserved contractility and a relatively small EDV, mitral insufficiency leads to rapid unloading of volume and reduced tension. When ventricular dilatation occurs with decreased ventricular contractility, ejection is reduced, and tension remains high during systole, leading to an unsteady state that cannot be maintained for long.

Ventricular dilatation, though initially adaptive as an attempt to sustain SV, eventually becomes a substantial disadvantage and contributes importantly to impaired myocardial performance. As the left and right ventricles dilate, functional mitral and tricuspid regurgitation can occur, adding to circulatory congestion. Stretched myocardial cells can induce programmed cell death (apoptosis), thereby contributing to further disease progression.[123] Any treatment that slows progressive

dilatation of the heart, such as angiotensin-converting enzyme inhibitors or β-adrenergic blockers, will likely have a powerful role in the treatment of heart failure. The plasticity of the process of progressive dilatation is now more apparent, with remarkable reversal of dilatation observed under specific circumstances such as cessation of alcohol use in patients with alcoholic cardiomyopathy and spontaneous improvement in patients with inflammatory myocarditis.

Myocardial Hypertrophy

Hypertrophy of myocardial myocytes occurs to meet the demand of increased rate of use of mechanical energy. It is basically a response to sustained hemodynamic overloading of the heart, be it a volume or pressure overload or a combination of the two. Ischemic heart disease leads to a reduction of contractile tissue, ventricular dilatation, and a volume overload on the remaining viable myocytes. In this sense, it is a form of volume overload hypertrophy. Up to a point, the increased mass of cardiac muscle is beneficial in that it tends to normalize wall stress and provides for a larger number of contractile elements (sarcomeres).

Experimentally, evidence of hypertrophy (e.g., synthesis of new mRNA) occurs within hours of imparting a new load on the heart.[124,125] Pressure- and volume-induced hypertrophy are associated with distinct myocyte phenotypes and differential induction of peptide growth factors.[126] The heart demonstrates remarkable plasticity in response to a variety of growth factors and hemodynamic loads.[41] Isolated cell deformation is a sufficient stimulus for induction of hypertrophic growth, but the modulating role of angiotensin II, norepinephrine, altered membrane ion channels, and numerous growth factors is of obvious importance. The changing mechanical loading conditions appear to be the primary driving force behind myocardial hypertrophy in heart failure, and other factors likely act more as important modulators or facilitators of the process. Hyperplasia, or an increase in new myocardial cells, may occur to some extent under conditions of excessive loading or myocyte loss.[127,128] However, the capacity for new cardiac myocytes to form is limited, and whether they are functionally useful is unknown. Rather, the primary response to altered load is the assembly of new working units or sarcomeres per myocardial cell. In general, pressure overload results in replication of sarcomeres in parallel, whereas volume overload leads to new sarcomeres both in parallel and in series.[129] There is, however, significant hyperplasia of fibroblasts,[130-136] which outnumber cardiac myocytes by 3:1 to 4:1. It is the fibroblasts that are the major source of the reparative and replacement collagen when myocytes are lost in the evolution of heart failure.

Classically, pressure overload induces a form of *concentric hypertrophy*, whereas volume overload causes a form of *eccentric hypertrophy*. Concentric hypertrophy typically occurs with aortic stenosis or severe hypertension and causes a thickened ventricular wall, usually with no increase in chamber diameter. Myocytes primarily are increased in diameter. Capillary growth to these thickened myocytes may be diminished.[137,138] In eccentric hypertrophy, usually a consequence of volume overload, there is a proportional increase in wall thickness and chamber diameter. Myocytes primarily elongate from new sarcomeres assembled in series.

There also may be *reactive hypertrophy* of remaining myocytes in response to myocardial infarction.[139] In actuality, such myocardial hypertrophy is often hybrid, with both myocyte elongation and increased thickness of individual cardiac myocytes being observed. Local activation of autocrine/paracrine angiotensin II may play a role in the regulation of the hypertrophic process[140] but may not be an essential component of this complex system.[141]

There is now evidence from animal experiments that cell elongation may contribute importantly to chamber dilatation.[142,143] However, other factors such as myocyte slippage and increased interstitial tissue also may help to explain the increase in heart size frequently encountered in patients with heart failure. It should be pointed out that the original increase in heart size is geared to maintain stroke volume and normal wall tension. When decompensated heart failure occurs, it

is apparent that the increase in wall thickness is insufficient to normalize wall tension. Afterload rises and performance worsens, contributing to decompensation.

Of course, other changes in the myocardium are occurring simultaneously, and hypertrophy is only one factor, albeit an important one. Biochemical changes, phenotypic changes in protein synthesis, altered excitation-contraction, slower velocity of shortening due to a slower acting myosin heavy chain, and reduced β-adrenergic receptor density are all occurring simultaneously. Mechanically, reduced velocity of contraction, delayed time to peak tension, and slower relaxation are observed in the myocardium of failing hearts. All these factors likely converge to produce clinical decompensation. Delayed ventricular relaxation may limit filling, leading to heightened filling pressure, pulmonary congestion, and shortness of breath. Force development and shortening capacity remain intact in the face of hypertrophy, and only in very late failure does contractility or contractile force decline. What ultimately happens to the patient may depend on the acuteness or chronicity of the load, the extent of hypertrophy and fibrosis, the amount of myocyte loss, the heart rate and synchrony of atrioventricular contraction, and a host of invisible perturbations occurring at the level of the cell (Fig. 20-6).

Diastolic Heart Failure

Diastolic heart failure is often present when there is limitation of exercise tolerance and dyspnea that cannot be explained by lung disease or the extent of underlying LV systolic dysfunction. Diastole is usually divided into several mechanical phases (Fig. 20-7). Investigation of patients with heart failure and normal systolic function, usually by echo, often indicates LV hypertrophy and abnormal diastolic function. Unfortunately, there is no agreement as to what constitutes abnormal diastolic function. Disturbances include alterations in relaxation (reduced rate of decline in wall tension), an upward shift of the LV diastolic pressure-volume relationship (a decrease in LV diastolic distensibility) (see Fig. 20-1), incoordinate wall motion during isovolumic relaxation, and altered ventricular inflow velocity. These measurements are influenced by loading conditions, ischemia, heart rate, and age, making it difficult to determine the actual contribution of diastolic dysfunction to heart failure. This is why some prefer the phrase "heart failure with intact or normal systolic function." Nevertheless, disturbances in diastolic function are common in patients with heart failure and are multifactorial. Diastolic impairment is frequently symptomatic in patients with LV hypertrophy, coronary artery disease, and diabetes mellitus. There also may be impairment of diastolic function due to an infiltrative process such as amyloid. For any given EDV, there is often a higher LV end-diastolic pressure, indicating increased chamber stiffness and a smaller cavity size.

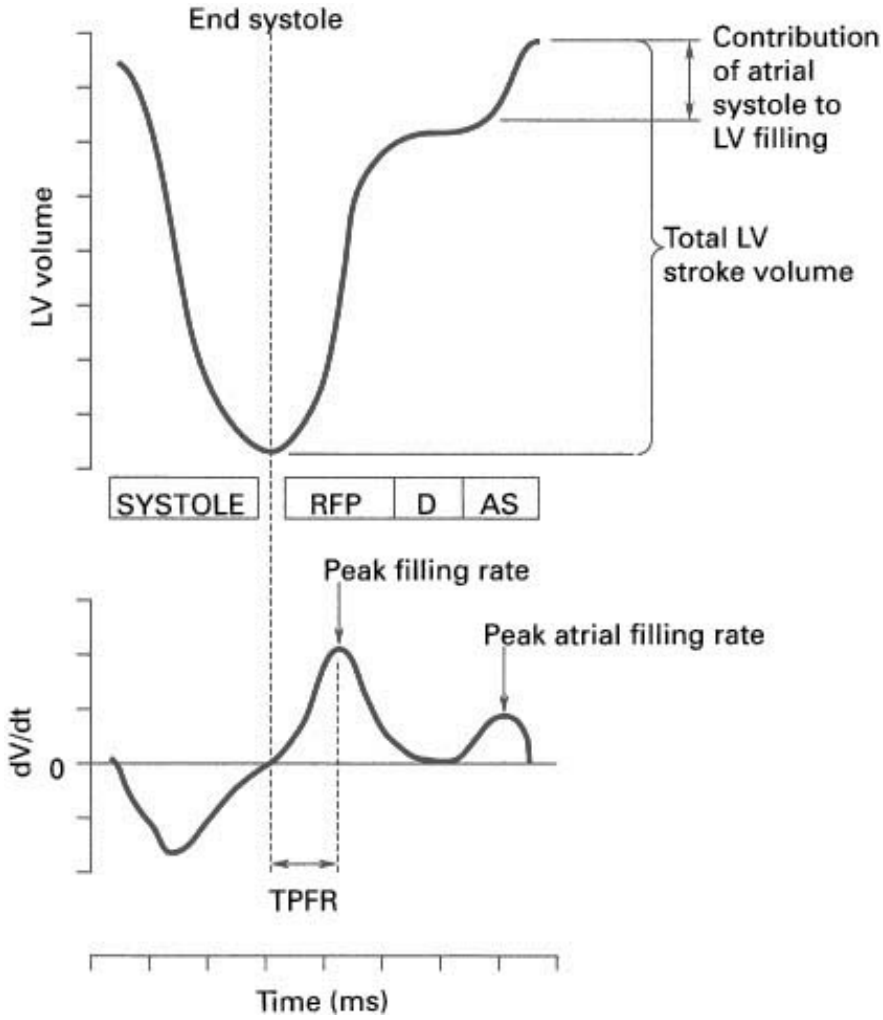

Figure 20-7: Idealized plot of left ventricular volume versus time (*top*) and the rate of change of volume (*dV/dt*) versus time (*bottom*), such as might be obtained from contrast or radionuclide ventriculographic studies. The representative cardiac cycle begins at end diastole. Subsequent events as depicted by the bars in the center of the figure are (1) systole, during which left ventricular volume decreases to a minimum and *-dV/dt* reaches its maximum; and (2) diastole, the beginning of which is signaled by the opening of the mitral valve and the onset of left ventricular filling. Diastole has three distinct phases in normal individuals: (1) the rapid filling phase (RFP), during which the left ventricle fills rapidly but passively and the peak filling rate occurs; (2) diastasis (D), during which relatively little left ventricular volume change occurs; and (3) atrial systole (AS), in which active atrial contraction fills the left ventricle to its end-diastolic volume. The diastolic parameters that have been derived from such analysis are the peak filling rate, the time to peak filling rate (TPFR), the percent contribution of atrial systole, and the first third filling fraction. (From Labovitz AJ, Pearson AC. Evaluation of left ventricular diastolic function: Clinical relevance and recent Doppler echocardiographic insights. *Am Heart J* 1987; 114:836-849. Reproduced with permission from the publisher and authors.)

As the population ages, one can expect to see more diastolic heart failure.[144] The development of atrial fibrillation with resulting reduced diastolic ventricular filling time commonly produces pulmonary edema in such patients. Although not as lethal as heart failure with a reduced ejection fraction, the prognosis of diastolic heart failure is poor. Diastolic abnormalities usually coexist with alterations in systolic function in patients with dilated cardiomyopathy.[145] The recognition, evaluation, and treatment of diastolic heart failure remain an obvious challenge,[146,147] but diastolic heart failure is an important component of the syndrome of heart failure and must be considered by all who care for patients with heart failure.

Hibernating and Stunned Myocardium

There is now a considerable body of evidence indicating that the myocardium can adapt its activity successfully to prevailing energetic circumstances.[148,149] *Hibernating* myocardium is a condition of reduced myocardial blood flow and impaired myocardial function that improves with revascularization. Myocardial *stunning* is the mechanical dysfunction that persists after reperfusion despite the absence of irreversible damage. Hibernation is particularly important to recognize, diagnose, and treat because revascularization may be associated with a lower cardiovascular event rate.[150] The most commonly used tests for diagnosing hibernating myocardium are dobutamine echocardiography, thallium and sestamibi single-photon-emission computed tomographic (SPECT) myocardial perfusion imaging, positron-emission tomography, and magnetic resonance imaging (MRI) with gadolinium (see Chaps. 16, 18, and 19). Essentially, these imaging techniques are used to define myocardial viability.[151] Many large referral centers have developed their preferred method of assessment. LV function often improves or normalizes with revascularization when there is a "significant" amount of hibernating, but viable, myocardium as the major cause of LV dysfunction. When hibernating myocardium is documented, revascularization rather than heart transplantation is the appropriate therapy, provided the coronary arteries are suitable for revascularization.

Although the precise mechanism of hibernating myocardium has not been determined, the concept is very attractive to clinicians. It is as though the heart downgrades its myocardial function to the extent that blood flow and function are once again in equilibrium. There is no myocardial necrosis or symptoms of ischemia. These observations suggest that the heart can adapt to chronically low myocardial blood flow and that a new steady state between perfusion and contraction can be achieved and maintained. The pathophysiology is undoubtedly highly complex and is accompanied by phenotypic changes and morphologic alterations.[152] It is likely that hibernating myocardium represents a precarious though reversible state, and failure to revascularize it may lead to an increased rate of adverse events and a poor prognosis. Hibernating myocardium may be the end result of repetitive myocardial stunning, perpetuated by renewed episodes of ischemia.

The Cardiac Interstitium

Collagen and the interstitium are normally in a steady state but increase during hypertrophy and following loss of myocytes due to myocardial injury. In heart failure the interstitial space includes reparative and interstitial fibrosis. Contrary to previous concepts, the interstitium is a very dynamic structure, with both matrix removal and synthesis occurring simultaneously at all times. Connective tissue remodeling, either physiologic or pathologic, is in most cases a homeostasis between collagen synthesis and collagen degradation by matrix metalloproteases (MMPs). The matrix of the heart is a very complex scaffolding composed of fibrillar and ground substance proteins (collagen) that pattern around and between myocytes in a very precise and organized pattern. The matrix likely plays a very important role in maintaining an ideal ventricular shape.[153] Changes in the cardiac "skeleton" can contribute to impairment of both diastolic and systolic function.[154] In the failing human heart with advanced coronary disease (so-called ischemic cardiomyopathy), fibrosis is the major force of LV remodeling. Infarct scars may account for 30 percent of fibrosis, whereas microscopic fibrosis remote from the infarct may account for 70 percent of the total fibrous tissue found in the ventricles.[155] In general, interstitial loci of fibrosis are the "tombstones" of lost myocytes. It is likely that increased MMPs contribute to ventricular dilatation in heart failure.[156] Tissue inhibitors of MMPs (TIMPS) exist in the myocardium and are regulated independently of MMPs,[156] an observation with potentially important therapeutic implications. Enhanced protease activity in heart failure contributes to fibrillar collagen degradation, setting the stage for weakened connective tissue and disrupted organ integrity, myocyte slippage, and ventricular remodeling.

The growth of the interstitium in response to pressure and volume overload is highly complex and

involves fibroblasts and their ability to sense altered mechanical forces. Hormones, including the renin-angiotensin-aldosterone system[157] and endothelin,[158] also facilitate the production of collagen via their interaction with fibroblasts. Once abnormal loading conditions are removed, connective tissue hypertrophy regresses more slowly than myocyte hypertrophy. It is rather striking how the importance of this once considered inert ground substance has emerged over the past 15 years, previously hidden to investigators largely because it was essentially invisible by the usual techniques of light microscopy. It is now clear that the cardiac interstitium is very important in the syndrome of heart failure and contributes in many ways to the structural and functional alterations.

Chapter 20: PATHOPHYSIOLOGY AND DIAGNOSIS OF HEART FAILURE

NONCARDIAC "ADAPTATIONS" IN HEART FAILURE

The Neurohumoral Hypothesis

A large number of neurohormones have been found to circulate in abnormal quantities in heart failure (Table 20-7). The natriuretic peptides [atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and clearance natriuretic peptide (CNP)] are considered counterregulatory because they tend to reduce right atrial pressure, systemic vascular resistance, aldosterone secretion, sympathetic nerve stimulation, and hypertrophy of cells and can enhance sodium excretion.[159] The predominant consequence of most neurohormone "release" in heart failure, however, is vasoconstriction coupled with salt and water retention. The regulation of body fluid volume is very complex but has a primitive relation to many of the neurohormones and their propensity to facilitate retention of sodium and water while at the same time protecting perfusion pressure. The integrity of the arterial circulation as a function of cardiac output and SVR is also determined by flexibility in renal sodium and water excretion.[160] Underfilling of the arterial bed by low cardiac output or vasodilation activates neuroendocrine reflexes that stimulate sodium and water retention. Sodium and water retention cease to be major problems after heart transplantation, indicating that there is no intrinsic renal dysfunction in heart failure. The kidney responds to a perceived reduction in arterial filling in an appropriate manner by retaining volume.

Decreases in blood pressure, stroke volume (pulse pressure), and perfusion (flow) in heart failure are sensed by mechanoreceptors in the left ventricle, carotid sinus, aortic arch, and renal afferent arterioles. When there is diminished activation of these receptors, as in heart failure, there is augmentation of sympathetic outflow, activation of the renin-angiotensin-aldosterone system, and nonosmotic release of arginine vasopressin (AVP).[160] Heightened peripheral vasoconstriction occurs along with increased blood volume, thereby "restoring" circulatory integrity and perfusion pressure. Of course, neuroendocrine activation has many important consequences at the cellular level, including facilitation of myocyte hypertrophy[41] and collagen synthesis.[136] Activation of the sympathetic nervous system contributes to tachycardia and arrhythmias and can be directly toxic to the myocardium.[161,162] Cardiac myocyte necrosis also occurs in response to low levels of angiotensin II.[163] Although neuroendocrine responses are not the primary cause of heart failure under most circumstances, they clearly contribute to the pathogenesis of the syndrome[164] (Fig. 20-8). The overly simplistic view that neurohormones in heart failure are a response to perceived "hypovolemia" is clearly incorrect.[165] Neuroendocrine mechanisms are now the targets of several important and successful therapeutic interventions in heart failure and hypertension[166] and have a key role in determining prognosis.[167] Angiotensin-converting enzyme inhibitors, β-adrenergic blockers, and aldosterone antagonists now have a prominent role in the treatment of heart failure, and new, more innovative neuroendocrine-blocking agents are being developed rapidly, adding strong support to the neurohumoral hypothesis.[164]

Norepinephrine

It has been recognized since the time of Starling that patients with heart failure manifest signs of a hyperadrenergic state. Vascular constriction, tachycardia, diaphoresis, and oliguria are clear signs of increased sympathetic drive. Starling's observations in 1897[168] were amplified in the early 1960s by the group from the National Institutes of Health (NIH), who verified increased plasma

norepinephrine (NE) levels in patients with heart failure.[169] Myocardial stores of NE were found to be depleted.[170] Later studies by various investigators using the more sensitive radioenzymatic technique measured plasma NE levels in patients with heart failure and described a correlation with functional class[171] and extent of hemodynamic dysfunction.[172]

NE synthesis begins in the body of the neuron with the synthesis of enzymes necessary to go from tyrosine to NE. The enzymes are transported down the neuron to the dendrites of the cell, where the actual synthetic steps take place. Dopamine is synthesized and transported into storage vesicles, where the final synthetic steps occur. These storage vesicles are both large and small, the large vesicles containing additional peptides such as neuropeptide Y. Following discharge of an axonal action potential, exocytosis occurs, allowing the vesicle contents to be released into the synaptic cleft. The vast majority of the NE is then taken back up into the cell for storage and rerelease (uptake 1). Some NE is taken up by effector organs and metabolized (uptake 2), and only a small quantity is released into the plasma (≈5 percent), where it circulates as plasma NE. There are now microneurographic techniques than can be used to directly measure sympathetic traffic direction[173] and "spillover" techniques that can measure specific organ sympathetic activity.[174] It now seems clear that increased cardiac sympathetic traffic precedes more generalized sympathetic activation in the course of heart failure.[175] However, the plasma NE level has served as a useful research and prognostic guide for the study of patients with heart failure.[176]

It is overly simplistic to consider NE to be "good" or "bad" for patients with heart failure. Those with severe New York Heart Association (NYHA) class IV heart failure may be quite dependent on catecholamine support[177] and often require a continuous dobutamine infusion to maintain suitable organ perfusion prior to heart transplantation. However, there is no question that NE is toxic to the myocardium and is responsible in part for progressive LV remodeling.[178,179] The favorable and detrimental effects of sympathetic drive are depicted in Table 20-8. These observations imply that blocking the sympathetic nervous system effects are most likely to benefit NYHA class I-III patients, whereas such action potentially could worsen the condition of class IV patients who manifest congestion.

UNDEFINED: TITLEUNDEFINED: HTML

The Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system (RAAS) plays an important role in the pathogenesis of heart failure (Fig. 20-8), and consistent benefit has been derived from angiotensin-converting enzyme inhibitor therapy in patients with heart failure. The mechanisms responsible for the release of renin from the renal cortex have been studied exhaustively[180] and include sympathetic drive to the kidneys, hyponatremic perfusate to the macula densa of the kidney, and the use of diuretics and a low Na^+ diet, which tends to promote a relative volume contraction. Renin proteolytic enzyme has little biologic activity, but it interacts with angiotensinogen to split off two amino acids to form angiotensin I, which is then cleaved by the angiotensin-converting enzyme found locally and widely in the vascular system, especially the lungs, to produce angiotensin II, a peptide with a vast range of biologic activities. Angiotensin II in turn stimulates release of aldosterone from the adrenal cortex, which also has an array of biologic effects, including Na^+ and H_2O retention and kaliuresis.

There now are at least four recognized angiotensin II (AT) receptors, but much of the activity is subserved by the AT_1 receptor. The AT_1 actions include arterial vasoconstriction, cell growth (hypertrophy), apoptosis in myocytes, polydypsia, NE release, sensitization of blood vessels to NE, AVP release, and aldosterone release. The AT_2 receptor appears to subserve somewhat counterregulatory effects, including antigrowth/antiremodeling, apoptosis in vasculature,

vasodilation, and activation of the kinin-nitric oxide-cGMP system.[181] Since AT_1 receptor-blocking drugs (so-called ARBs) increase angiotensin II levels, they may enhance unoccupied AT_2 receptor activity. Angiotensin II levels tend to "escape" the pharmacologic effects of chronic angiotensin-converting enzyme inhibition and may stimulate AT_2 and AT_2 receptor activity. It is also now clear that the RAAS is not solely a classic endocrine system but has autocrine and paracrine activity that may be particularly important in cardiovascular, brain, and renal tissue. With our current knowledge that angiotensin-converting enzyme inhibitors remarkably reduce all cardiovascular events and the onset of new diabetes mellitus in patients with cardiovascular disease, it is difficult to overstate the role of the RAAS in the pathogenesis of heart and vascular disease, including progressive heart failure.[182-184]

Arginine Vasopressin

Patients with heart failure sometimes may have water retention in excess of Na^+ retention, which leads to hyponatremia. The hyponatremia is due in part to nonosmotic release of AVP, which acts on the kidney to reduce clearance of free water.[185] Release of AVP in heart failure probably occurs via activation of carotid baroreceptors.[160] Plasma AVP levels are often but not always increased in patients with LV dysfunction[186] and heart failure.[187] AVP acts on the V_2 receptors in the collecting duct of the kidney via adenylate cyclase to translocate aquaporin-2 water channels from cytoplasmic vesicles to the apical surface of the collecting duct. AVP also increases aquaporin channel-2 synthesis. Activation of V_1 receptors in vascular tissue contributes to heightened vascular resistance and myocardial dysfunction in heart failure.[188] Recognition of the role of AVP in the pathogenesis of heart failure has led to the development and investigation of selective and dual V_1-V_2 receptor blockers as potential adjunctive treatment.

Natriuretic Peptides

A family of natriuretic peptides including atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and clearance natriuretic peptide (CNP) have evolved over time, encoded by separate genes, each with a tissue-specific distribution, regulation, and biologic activity.[159] These natriuretic peptides are often increased in patients with heart failure, and BNP may even be a marker for asymptomatic LV dysfunction or early heart failure.[189,190] ANP is a 28-amino-acid peptide that is normally synthesized and stored in the atria and to some extent in the ventricles. It is released into the circulation during atrial distention. BNP is synthesized mainly by the ventricles and is released in LV dysfunction or early heart failure. For the most part, these peptides act via guanylate cyclase receptors to promote vasodilation (ANP, BNP, CNP) and natriuresis (ANP, BNP). They also may attenuate NE release, RAAS activity, and the growth/hypertrophy of target cells-hence the term *counterregulatory hormones*.

Patients with heart failure are relatively resistant to the natriuretic effects of these peptides when they are administered exogenously, perhaps due to decreased Na^+ delivery to the collecting duct as a result of diminished glomerular filtration or increased Na^+ reabsorption in the proximal tubule.[160] Nevertheless, BNP infusion has a remarkable positive hemodynamic effect in patients with heart failure,[191] and drugs designed to inhibit degradation of natriuretic peptides (so-called neutral endopeptidase inhibitors) have been combined with angiotensin-converting enzyme inhibitor activity as potential therapy for hypertension and heart failure. The role of natriuretic peptides as potential therapy continues to evolve.

Endothelin

Endothelins are a family of vasoconstrictor peptides produced by vascular endothelial cells[192,193] whose normal function is as yet unclear. Although blood levels are increased in patients with heart failure,[194,195] endothelin-1 (ET-1) is more of a paracrine than an endocrine hormone. In heart failure, myocardial tissue ET-1 levels are increased, possibly more due to decreased clearance by the lungs than to increased synthesis.[196] Endothelial cells synthesize ET-1 rapidly and convert so-called big endothelin-1 into endothelin by an endothelin-converting enzyme. The synthesis of ET-1 is enhanced by angiotensin II, NE, growth factors, insulin, hypoxia, oxidized low-density lipoproteins (LDLs), shear stress, and thrombin.[193] Its synthesis is antagonized by ANP and prostaglandins.

Endothelin acts on at least two types of G protein-coupled receptors, A and B. The ET-A receptor subserves smooth muscle vasoconstriction and cell proliferation/hypertrophy and mainly resides on vascular smooth muscle cells. The ET-B receptor, which is mainly endothelial, subserves vasodilation that is probably mediated by a variety of mechanisms including increased production of nitric oxide and prostaglandins and activation of potassium channels. ET-1 also can act on the heart to cause hypertrophy, on the adrenal gland to release aldosterone, and on the kidney to promote Na^+ and H_2O retention.[193] The importance of ET-1 in the pathogenesis of heart failure is highlighted by the development and clinical testing of several new endothelin antagonists.[197] Endothelin-blocking agents are believed to hold promising vasodilator, natriuretic, and antiremodeling effects.

Additional Neurohormones

Many other neurohormones are believed to be important in the pathogenesis of heart failure, including neuropeptide Y, vasointestinal peptide, bradykinin, prostaglandins, adrenomedullin, and urodilatin. As we grow to better understand heart failure, some of them may emerge as "systems" to block or enhance, depending on their primary function.

Cytokines

In 1990 it was reported by Levine et al.[198] that circulating tumor necrosis factor alpha (TNF-α), a proinflammatory cytokine, was increased in cachectic patients with chronic heart failure. Since then, a large body of work has emerged indicating that proinflammatory cytokines such as TNF-α may play a fundamentally important role in modulating abnormal myocardial structure and function in late stages of heart failure.[199-201] This group of proinflammatory cytokines also includes interleukin 1 (IL-1) and interleukin 6 (IL-6). These proteins, largely products of macrophages and lymphocytes, are also expressed under some circumstances by myocardial tissue. Each of these cytokines can influence the expression of the other two, and each can modulate cardiovascular performance when expressed at sufficiently high levels. Experimentally, a continuous infusion of TNF-α leads to time-dependent depression in LV function[202] and provokes a hypertrophic growth response in adult cardiac myocytes.[203] When there are large quantities being produced, TNF-α spills over into the circulation and acts as an endocrine "hormone" leading to metabolic wasting and cachexia.[204,205] Overexpression of TNF-α in a transgenic mouse model leads to a phenotype consistent with cardiomyopathy.[206] TNF-α acts via two different membrane receptors. The transduction signal pathways are not fully understood, but in the heart they may mediate cell growth, negative inotropy, and apoptosis. The emergence of these important observations has lead to the launching of a clinical trial with etanercept (a fusion molecule that binds circulating TNF-α) for the treatment of patients with late-stage heart failure.

Renal Retention of Salt and Water

Since its earliest clinical descriptions, a hallmark of heart failure has been renal retention of Na^+ and H_2O, resulting in signs and symptoms of fluid retention. The precise mechanism whereby the

heart signals the kidney in the early stages of heart failure to retain Na^+ and H_2O is still unknown, although in the late stages reduced cardiac output and impaired renal blood flow likely play a major role. In early heart failure, when normal cardiac output is maintained via compensatory mechanisms and renal blood flow is not reduced, there is still some Na^+ retention. Curiously, some patients with advanced heart failure rarely demonstrate peripheral edema or ascites. This suggests that in some cases counterregulatory natriuretic peptides may be acting to maintain natriuresis. Perhaps release of ANP and BNP in the early stages of heart failure offsets the tendency to retain Na^+, thereby maintaining Na^+ balance. Salt and water retention usually becomes evident in the syndrome of heart failure as adequate perfusion and protection of blood pressure become more imperative.[207] The RAAS is dominant in this regard.[208] Angiotensin II preserves glomerular filtration rate in patients with heart failure even when renal perfusion is severely compromised, and this effect is achieved independently of this hormonal system's propensity to support systemic blood pressure.[209] Intraglomerular hydraulic pressure and therefore glomerular filtration are preserved by the constriction of glomerular efferent arterioles via angiotensin II.[210] Increased intrarenal formation of angiotensin II during a reduction in renal artery pressure maintains efferent arteriolar tone and, consequently, the effective filtration pressure.[211] The resulting high level of filtration fraction favors changes in the postglomerular circulation that promote avid proximal fluid reabsorption via elevated peritubular capillary oncotic pressure.[212] Increased aldosterone acts principally on the cortical collecting tubules to conserve Na^+. Because the plasma volume and blood pressure vary considerably from day to day, there is no consistent relation between the RAAS and fluid retention.

The mechanisms of Na^+ and H_2O retention in heart failure are complex and determined by multiple other factors. Sympathetic nervous system traffic to the kidney favors sodium retention. Increased AVP activity diminishes free water clearance. The prostaglandins normally dilate afferent glomerular arterioles to enhance intraglomerular flow and pressure, and their inhibition by nonsteroidal anti-inflammatory agents may lead to a marked reduction in filtration and sodium retention. Enhanced Na^+ reabsorption of heart failure also occurs in the ascending loop of Henle, as well as in the cortical and medullary collecting ducts. Eventually, the "goal" of plasma volume expansion is met, but at the expense of circulatory and tissue congestion.

Endothelial Dysfunction, Nitric Oxide, Exercise Intolerance, and Sleep Disorders

Data from many animal and human studies indicate that endothelium-dependent vasodilation is abnormal in a number of disease states, including atherosclerosis, hypertension, heart failure, hyperhomocysteinemia, insulin resistance, and hypercholesterolemia. Treasure et al.[213] observed abnormal endothelial-dependent dilatation of the coronary arteries in patients with dilated cardiomyopathy. Peripheral resistance vessels in both experimental animals[214] and patients with heart failure[215] demonstrate endothelial dysfunction. Data collected to date would suggest that the endothelial dysfunction in heart failure (i.e., failure to vasodilate in response to a specific endothelial-dependent vasodilator) may be due to a reduced release of nitric oxide during stimulation.[216] The basal release of nitric oxide may be preserved or even enhanced in heart failure[217] and may be compensatory by antagonizing neuroendocrine vasoconstrictor forces. However, impairment of endothelium-dependent peripheral vasodilation may be a factor contributing to exercise intolerance in patients with chronic heart failure, perhaps by limiting nutritive skeletal muscle flow during exercise.[218] This dysfunction of the endothelium may be related to deconditioning in later stages of heart failure, and with training, it is largely reversible. Further, abnormal endothelium-dependent responses in heart failure are reversible following heart transplantation.[219]

The roles of nitric oxide and nitric oxide synthase in the failing heart are much more complex.[220,221] Nitric oxide inhibits the positive inotropic response to β-adrenergic stimulation in

the failing heart. While smaller physiologic amounts of constitutive nitric oxide (cNOS) are necessary for normal function and have an antioxidant effect to protect cells, high levels of nitric oxide in the heart may exert proapoptotic and cytotoxic effects. The inducible isoform of nitric oxide synthase (iNOS) is overexpressed in human heart failure[222] and therefore may contribute to worsening heart failure. On the other hand, there is decreased myocardial nitric oxide synthesis during decompensation of experimental heart failure.[223] The relative roles of nitric oxide also may differ at different stages in the evolution of heart failure.

In addition to a reduced myocardial force-frequency response, inability to fully use the Starling effect, chronotropic incompetence and diminished myocardial β-receptor density, endothelial dysfunction, reduced nutritive blood flow, and disuse atrophy of skeletal muscles limits exercise tolerance in patients with heart failure. The latter effects appear to be excessively dependent on a glycolytic metabolism,[224] in part due to reduced metabolic efficiency in performing external work. Possible mechanisms include changes in muscle fiber recruitment, selective atrophy of oxidative fibers, and physical deconditioning. The mitochondrial content of skeletal muscle is reduced[225] in heart failure. Increased expression of the inducible isoform of nitric oxide synthase in skeletal muscle is correlated with reduced mitochondrial creatine kinase expression and exercise intolerance.[226] Apoptosis is frequently found in skeletal muscle of patients with heart failure and is associated with exercise impairment.[227] Exercise capacity and EF are very poorly correlated in heart failure, suggesting that impairment in nutritive blood flow is not the dominant reason for exercise intolerance.

Pulmonary dysfunction is common in patients with heart failure and also may contribute to exercise intolerance. The amount of intrathoracic space available for ventilation may be decreased by alveolar and interstitial edema, by pleural effusions, or by an increase in blood volume. Increased pulmonary vascular congestion decreases lung compliance and increases the work of breathing. Excessive ventilation during exercise is a hallmark of heart failure. Acute reduction in pulmonary capillary wedge pressure has no effect on the augmented ventilatory response, and the extent of excessive ventilation does not relate to either resting or exercise pulmonary capillary wedge pressure.

The potential mechanisms resonsible for exercise intolerance, a uniform feature of heart failure, are numerous (Table 20-9). Exercise intolerance is clearly multifactorial and is a potent prognostic indicator used the to help determine the optimal timing of heart transplantation (e.g., $V(r)_{O_{2,max}}$ of less than 50 percent predicted for size and age). Exertional symptoms generally correlate with maximal exercise capacity,[228] although exertional symptoms frequently underestimate the severity of functional disability. Although EF does not correlate with exercise performance ($V(r)_{O_2}$), if the latter is markedly reduced (e.g., $V(r)_{O_2}$ <12 mL/kg/min) along with a low EF, the prognosis is especially grave. Cardiopulmonary exercise testing should be done in patients with heart failure to assess functional capacity. Importantly, exercise tolerance can improve with training, which should be encouraged in patients with classes I to III heart failure symptoms.

Table 20-9: Mechanisms of Exercise Intolerance in Heart Failure

Inability of endothelium to respond to vasodilator stimulus
Reduced nutritive blood flow to skeletal muscle
Inability to increase stroke volume in response to exercise
Chronotropic incompetence
Reduced myocardial force-frequency response
Diminished myocardial β-adrenergic receptor density
Skeletal muscle atrophy
Shift from slow- to fast-twitch fiber types
Atrophy of fast-twitch type II fibers
Reduced level of skeletal muscle mitochondrial enzymes
Reduced skeletal muscle mitochondrial size
Increased skeletal muscle apoptosis
Reduced lung compliance
Excessive ventilatory response to exercise
Generalized deconditioning

Periodic breathing (Cheyne-Stokes) is common in patients with heart failure. It can be caused by lung edema, which can excite carbon dioxide responses through vagal reflexes. Enhanced sensitivity to carbon dioxide may predispose some patients with heart failure to the development of central sleep apnea.[229] Cheyne-Stokes respiration in heart failure is associated with a poor prognosis.[230] Successful treatment of Cheyne-Stokes respiration with nocturnal nasal oxygen improves sleep, exercise tolerance, and cognitive function in patients with heart failure.[231] Severe untreated sleep-disordered breathing can further impair LV function, leading to arterial oxyhemoglobin desaturation and arrhythmias.[232] Central sleep apnea may occur in as many as 40 percent of patients with heart failure, and 10 percent suffer from obstructive sleep apnea.[233] Obstructive sleep apnea increases afterload and heart rate during sleep but is responsive to continuous positive airway pressure.[234]

Chapter 20: PATHOPHYSIOLOGY AND DIAGNOSIS OF HEART FAILURE

DIAGNOSIS AND EVALUATION OF PATIENTS WITH HEART FAILURE

History

The dominant and most recognizable symptom of congestive heart failure is "shortness of breath." The clinical term for this shortness of breath is *dyspnea*, and it is described by patients as the sensation of being unable to get enough air with each inspiration. Frequently, dyspnea is first noted by the patient on exertion and often dismissed by the patient as part of aging. As the heart failure progresses, the sensation of dyspnea occurs with less and less exertion, until the patient experiences symptoms at rest.

Despite all the advances in the field of cardiology, the mechanism of dyspnea remains poorly understood. When patients develop acute heart failure, they are often hypoxemic secondary to pulmonary edema and a resulting decrease in oxygen diffusing capacity. Patients with chronic stable heart failure, even if clinically compensated, still experience dyspnea, despite a lack of overt pulmonary edema. The explanation for the dyspnea in this latter group of patients is likely multifactorial, including increased physiologic dead space, increased airway resistance, reduced lung compliance, and fatigue of the respiratory muscles. Additionally, there may be some as yet undefined signals from the pulmonary J-receptors and respiratory muscles that contribute centrally to the sensation of dyspnea.[235,236]

The classic respiratory symptom triad of heart failure includes dyspnea, orthopnea and paroxysmal nocturnal dyspnea (PND). Orthopnea is the sensation of shortness of breath in the supine position. Patients may describe the need for more pillows under their head to sleep or even needing to prop the head of the bed up. PND relates to sudden, nocturnal dyspnea, often awakening the patient from sleep and requiring the patient to sit or stand up and ambulate to improve breathing. Onset of these symptoms indicates progression of the underlying heart failure and may culminate in a Cheyne-Stokes respiratory pattern.

The other typical complaint of patients with heart failure is fatigue. Since everyone feels fatigued at some time, this a vague, subjective complaint that does not easily lend itself to measurement. Often, the interviewer must inquire about specific tasks or ask the patient to provide examples of how the fatigue occurs. The patient often will describe being physically exhausted by activities that presented no difficulty weeks or months prior to the interview. Some may be able to separate fatigue from dyspnea, but the two complaints frequently coexist. Like dyspnea, the underlying mechanism of fatigue remains unclear. It is likely multifactorial and may be in part due to a reduced cardiac output with resulting poor tissue perfusion, excessive activity of the neuroendocrine system, elevated cytokine levels, or deconditioning of skeletal muscles.

Wheezing and cough are additional common complaints of patients with heart failure. Symptoms of circulatory and organ congestion also can occur and include nausea, vomiting, and discomfort from hepatic and bowel edema. Right upper quadrant abdominal pain can be severe in acute heart failure and is due to distention of the hepatic capsule. Peripheral edema is also a frequent complaint of patients with heart failure, though, curiously, some patients never manifest it. Along with dyspnea, ankle swelling is a common early symptom that often brings the patient for treatment. This is generally more prominent at day's end; with sleeping, fluid reabsorption with redistribution into the chest may lead to orthopnea.

The initial evaluation of the patient suspected of having heart failure should include a thorough past medical history and review of systems. This can be beneficial in defining the etiology of the patient's cardiac dysfunction. Since ischemic heart disease is the most frequent cause of heart failure in the United States, coronary risk factors such as diabetes mellitus, hypertension, cigarette smoking, hyperlipidemia, and family history need to be assessed and vigorously treated. Poorly controlled hypertension can cause heart failure that is unrelated to coronary artery disease. Relatively mild hypertension in the diabetic may result in a specific cardiomyopathy. Excessive alcohol or illicit drug use also can lead to cardiomyopathy. A

comprehensive list of cardiomyopathies, though far from exhaustive, is found in Table 20-10. Dietary needs and therapeutic compliance need to be assessed in all patients. They must know that excessive salt intake can lead to diuretic resistance and acute decompensation. Patient education regarding signs, symptoms, treatment, and prognosis is critical for the well-being of the patient. End-of-life wishes regarding resuscitation and intubation also should be discussed at a time when the patient is stable and can participate in meaningful dialogue.

Table 20-10: Classification of Cardiomyopathies

Dilated cardiomyopathy (idiopathic)
Hypertrophic, cardiomyopathy
Restrictive cardiomyopathy
Arrhythmogenic right ventricular cardiomyopathy
Unclassified cardiomyopathy
Ischemic cardiomyopathy
Valvular cardiomyopathy
Hypertensive cardiomyopathy
Inflammatory cardiomyopathy
Metabolic cardiomyopathy
Infiltrative cardiomyopathy
Muscular dystrophy-associated cardiomyopathy
Neuromuscular disorder-associated cardiomyopathy
Toxic cardiomyopathy
Peripartum cardiomyopathy

SOURCE: Adapted from Richardson P, McKenna W, Bristow M, et al. Report of the 1995 World Health Organization/International Society and Federation of Cardiology Task Force on the Definition and Classification of Cardiomyopathies *Circulation* 1996; 93:841-842.

Physical Examination

The physical examination in heart failure is not relegated solely to the cardiovascular examination. A complete examination is necessary because peripheral findings can provide additional insight into the extent and chronicity of the disease process. The patient's overall appearance can be very enlightening. A generalized wasting with skeletal muscle loss, referred to as *cardiac cachexia*, is usually indicative of severe and late-stage heart failure.

A complete cardiovascular examination encompasses both peripheral and cardiac findings (see Chap. 10). On palpation of the heart, the point of maximal impulse is often laterally displaced and diffuse. An LV heave often can be appreciated, as can a right ventricular heave if the pulmonary artery pressures are elevated or if right-sided heart failure has begun. In the case of severe valvular aortic stenosis, a palpable thrill, LV heave, and radiation of the murmur into the carotids is often present. On cardiac auscultation of the apex, an S_3 gallop rhythm is indicative of decompensated heart failure. An S_4 gallop in a patient with coronary artery disease, hypertension, or aortic valve stenosis makes the examiner consider a stiff ventricle due to cardiac hypertrophy. A pericardial knock can be found in constrictive pericarditis, an unusual cause

of circulatory congestion. The systolic murmur of mitral regurgitation can be found in either primary (organic valve disease) or secondary (due to LV dilatation) mitral valve incompetence. Severe mitral regurgitation can occur with no or little audible murmur. Additionally, the murmurs of aortic stenosis, aortic insufficiency, tricuspid regurgitation, and less commonly, a ventricular septal defect can provide further evidence of the etiology and extent of CHF. A loud P_2 (i.e., audible at the apex of the heart) can indicate elevated pulmonary artery pressures in either the acute or chronic setting.

The vascular examination provides important information. An increased resting heart rate is common. An new irregular pulse in a previously compensated patient can implicate new-onset atrial fibrillation as the source of an unexplained decompensation. Bilateral carotid "bruits" radiating from the heart with a decreased and delayed (*parvus et tardus*) pulse can indicate severe aortic stenosis. However, in the absence of the bruit and any aortic stenosis murmur, a decreased pulse waveform may indicate a poor stroke volume and therefore low cardiac output. This is also usually reflected by a narrow pulse pressure. Poor capillary refill and cool extremities can indicate a severely restricted cardiac output. An elevated jugular venous pressure is an indicator of high right-sided pressure and volume overload. Careful examination of the jugular venous pressure is most useful when determining diuretic dosage. A prominent *v* wave can be seen in severe tricuspid regurgitation, which is often accompanied by a pulsatile liver. Pedal edema is often observed in heart failure, and scaly, discolored, and ulcerated lower legs denote a chronic edematous state (*stasis dermatitis and ulceration*).

The pulmonary examination can be relatively normal in chronic compensated heart failure. However, rales due to alveolar fluid accumulation accompanied by hypoxemia often are found in acute or decompensated heart failure. Decreased breath sounds at the bases and dullness to percussion are found with pleural effusions. On occasion, wheezing rather than rales will be heard, which is termed *cardiac asthma*.

Diagnostic Studies

Routine blood work sometimes can provide some insight into the etiology of heart failure and the extent of decompensation. Noncardiac factors may increase failure or make it initially evident. Fever or anemia may help to explain decompensation in a previously stable patient with severe coronary disease. A low serum sodium level (hyponatremia) often is observed in patients with advanced heart failure and can be a poor prognostic sign. Prerenal azotemia is found in patients with poor cardiac output and resulting renal hypoperfusion, whereas a rise in the creatinine level may indicate renal dysfunction that can be primary or secondary to heart failure. Other laboratory values of import are noted in Table 20-11.

Table 20-11: Recommended Tests for Patients with Signs or Symptoms of Heart Failure

Test Recommendation	Findings	Suspected Diagnosis
Electrocardiogram	Acute ST-T-wave changes	Myocardial ischemia
	Atrial fibrillation, other tachyarrhythmia	Thyroid disease or heart failure due to rapid ventricular rate
	Bradyarrhythmias rate	Heart failure due to low heart
	Previous myocardial infarction (e.g., Q waves), left ventricular performance	Heart failure due to reduced contractile tissue
	Low voltage	Pericardial effusion
	Left ventricular hypertrophy	Diastolic dysfunction
Complete blood count	Anemia	Heart failure due to or aggravated by decreased oxygen-carrying capacity
Urinalysis	Proteinuria	Nephrotic syndrome

	Red blood cells or cellular casts	Glomerulonephritis
Serum creatinine	Elevated in renal failure	Volume overload due to renal dysfunction
Serum albumin	Decreased	Increased extravascular volume due to hypoalbuminemia
T_4 and TSH (obtain only if atrial fibrillation, evidence of thyroid disease, or patient age >65)	Abnormal T_4 or TSH	Heart failure due to or aggravated by hypo/hyperthyroidism

SOURCE: From Konstam M, Dracup K, Baker D, et al. *Heart Failure: Management of Patients with Left-Ventricular Systolic Dysfunction. Quick Reference Guide for Clinicians No. 11.* AHCPR Publication No. 94-0613. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Human Services; June 1994.

The standard 12-lead electrocardiogram should be part of the routine evaluation. Pathologic Q waves can indicate previous myocardial infarction. Evidence of LV hypertrophy can be found in patients with aortic stenosis or chronic systemic hypertension. New atrial fibrillation in a patient with previously compensated heart failure may explain recent decompensation. The chest x-ray also provides information beyond radiographic pulmonary edema and pleural effusions. An enlarged cardiac silhouette is usually found in dilated cardiomyopathy or can be due to a large pericardial effusion. Taking note of the various chambers can provide insight into valvular involvement and can indicate the presence of right-sided heart failure.

The echocardiogram is the most important imaging tool for evaluating patients with symptoms of heart failure. The overall systolic function and chamber size can be evaluated quickly. Global LV dysfunction can be differentiated from the regional abnormalities more commonly found in ischemic cardiomyopathy. Valvular stenosis and incompetence can be defined and graded. Furthermore, mitral regurgitation can be evaluated to determine if it is a primary valvular problem or secondary to the LV dilatation and related to LV chamber enlargement. This information may provide insight into the potential benefit of mitral valve repair or replacement, as well as the type of surgical technique required. Importantly, diastolic function of the heart can be evaluated by echocardiography. Abnormalities of diastolic function are a component of all cardiomyopathies but are particularly important in patients with normal *systolic* function. Finally, dobutamine stress echocardiography can help to define ischemic and hibernating myocardium, which may be necessary when considering coronary revascularization. The use of coronary angiography in patients with heart failure, however, is still somewhat controversial. It should be strongly considered when there is angina.

Radionuclide imaging is sometimes preferred when evaluating patients with heart failure. It is perhaps more quantitative than echocardiography. Additionally, positron-emission tomographic (PET) scanning is useful in distinguishing nonviable myocardial scar from dysfunctional but viable myocardium (Table 20-12) when considering coronary revascularization.

METABOLIC EXERCISE TESTING

The addition of gas-exchange measurements to exercise stress testing creates a noninvasive test that provides a wealth of information and can be performed safely in a symptom-limited fashion in patients with heart failure.[235] In addition to the evaluation of potential ischemia and objective assessment of functional capacity, the patient's maximal oxygen consumption at peak exercise ($V(r)_{O_{2,max}}$) and anaerobic threshold can be evaluated.[236-239] As an initial evaluation, metabolic exercise testing can provide insight into the patient's functional disability and allow the physician to council the individual patient on physical limitations and rehabilitation. When a patient's maximal oxygen consumption is less than 50 percent of expected for age and body size and/or if the $V(r)_{O_{2,max}}$ is below 14 mL/kg per minute, the patient may be a candidate for heart transplant evaluation.[240,241]

CARDIAC CATHETERIZATION

Swan-Ganz (right-sided heart) catheterization is performed frequently in patients with heart failure. Even so, its use in this patient population remains a point of contention among experts in the field. In general, the diagnosis of heart failure can be made on physical examination. Prognosis also can be estimated reasonably by noninvasive means.[242] The major benefit of right-sided heart catheterization (RHC) resides in the ability of the physician to demonstrate hemodynamic changes in response to pharmacologic treatment. The primary use of RHC should be in patients with worsening heart failure requiring intravenous agents in an intensive care unit setting. Sometimes it is necessary to use RHC when LV filling pressure is uncertain and the patient is clearly deteriorating.

The need for coronary angiography in patients with heart failure is controversial. It should be strongly considered if angina is present. In a country where ischemic heart disease is rampant and post-myocardial infarction patients are surviving more frequently to develop ischemic cardiomyopathy, diagnostic coronary angiography is performed frequently. It may not be possible to distinguish clinically ischemic cardiomyopathy from nonischemic dilated cardiomyopathy. The prognosis of patients with heart failure is worse when there is underlying coronary artery disease and is related to the extent of coronary artery disease.[243]

Chapter 20: PATHOPHYSIOLOGY AND DIAGNOSIS OF HEART FAILURE

CONCLUSIONS

Heart failure is a complex clinical syndrome that is growing in magnitude as the population ages. It is difficult to define but relatively straightforward to diagnose. Heart failure implies underlying structural and functional changes in the heart that contribute importantly to the clinical syndrome. Although the molecular underpinnings of heart failure are still incompletely understood, the importance of pathophysiologic principles such as reduced preload reserve and enhanced sensitivity to afterload is now well recognized. Neuroendocrine and inflammatory responses are common in patients with heart failure and serve as important therapeutic targets. There is no single cause or unifying mechanism of heart failure. There can be a diversity of signs and symptoms, most of which can be evaluated at the bedside. The echocardiogram in conjunction with a careful history and physical examination remains the primary diagnostic test. Ancillary evaluation includes use of the chest x-ray, electrocardiogram, exercise test, and in some cases, cardiac catheterization with coronary angiography.

Chapter 20: PATHOPHYSIOLOGY AND DIAGNOSIS OF HEART FAILURE

List of Figures

Figure 20-3: Relationship between LV wall force and fiber length. Hypothetical contractile cycles have been portrayed for the normal and failing ventricle. In the normal heart, contraction starts at point *A*, LV pressure rises until the aortic valve is opened (point *B*), the ventricle empties (point *B* to *C*), and relaxation ensues. When arterial pressure (afterload) is reduced (e.g., to point *D*), ejection starts at point *D* and proceeds to point *E*, which increases stroke volume. When the ventricle fails, the fiber length in diastole is increased, and ventricular contraction starts at point *F*. With systolic contraction, ventricular pressure rises to point *G*, and with ventricular emptying, fiber length decreases to point *H*. With a similar decrease in the afterload, wall force only needs to reach point *I* when ventricular emptying occurs to point *J*. As a result, for the same relative change in afterload, the increase in shortening is greater in the failing ventricle (ΔH-J) than in the normal heart (ΔC-E).

Figure 20-4: Schema of the sequence of events in heart failure. An increased load or myocardial abnormality leads to myocardial failure and eventually to heart failure. This results in increased sympathetic activity, increased levels of renin-angiotensin-aldosterone, pulmonary and peripheral congestion and edema, and decreased cardiac output reserve. Endothelial dysfunction also occurs, with decreased endothelial-dependent vasodilatation and with increased plasma levels of endothelin-1, a very strong vasoconstrictor. See text for details.

Figure 20-5: Possible mechanisms by which overloading can cause progressive deterioration of the heart ("cardiomyopathy of overload"). Several mechanisms, including myocyte stretch, activate a growth response that initiates myocardial hypertrophy in the overloaded heart (*left*). The same growth response may also activate signal transduction systems that cause programmed cell death (apoptosis). The hypertrophic response to overload, by causing sarcomeres to be added in series, can also lead to cell elongation and so accelerate remodeling; the resulting increase in wall tension, along with the overload itself (*right*), increases cardiac energy expenditure that, in the overloaded heart, can accelerate myocyte necrosis. Reduced cardiac output activates neurohumoral responses (*center*), which, by increasing afterload and β-adrenergic stimulation of the heart, also increase cardiac energy expenditure. Because many mediators of the neurohumoral response to a fall in cardiac output promote myocardial cell growth, neurohumoral activation can also accelerate both apoptosis and remodeling.

Figure 20-6: Evolution of myocardial damage to left ventricular function and ultimate congestive heart failure. The syndrome of congestive heart failure is the end result of processes that evolve in response to initial myocardial damage and/or cardiac overloads. The initiating event may be myocyte loss, either segmental, as with acute myocardial infarction, or diffuse, as with idiopathic cardiomyopathies and myocarditis; systolic overload, such as hypertension or aortic stenosis; or diastolic overload, such as mitral regurgitation or aortic regurgitation. Major loss of myocytes may also stimulate the renin-angiotensin and adrenergic systems, which may contribute to ventricular and vascular remodeling. All of these overloads create an increased workload for the heart, as characterized by Laplace relationship, where tension (T) is equal to the product of pressure (P) and ventricular radius (r) divided by twice the wall of thickness (h). The initial adaptations to these overloads, termed *ventricular remodeling*, are an increase in both myocyte length and diameter as well as an increase in ventricular volume to maintain adequate stroke volume and hence cardiac output. If hypertrophy is adequate to normalize the tension load, a relatively steady state may be maintained. Myocytes continue to be lost as a function of aging per se, however, and this tends to lead to further myocyte hypertrophy and cardiac dilatation. Moreover, the aging process may be amplified by hypertrophy. Should there be a sudden increase in end-diastolic pressure within the ventricle, an added factor of relative myocyte slippage within the wall tends to occur, which may lead to a further decrease in myocytes across the ventricular wall, further increasing ventricular wall tension. This may create a downward spiral in which progressive cell loss leads to further ventricular remodeling and continued ventricular dilation. As noted above, the entire process of ventricular remodeling may occur

asymptomatically, and myocardial damage progresses to left ventricular dysfunction, which is characterized by an increasing diastolic volume and thus a reduced ventricular ejection fraction. Symptoms associated with congestive heart failure occur when decreased left ventricular reserve limits cardiac output response to exercise. As the process of heart failure evolves, abnormalities of endothelial function in the peripheral arterioles lead to reduced ability of the peripheral vasculature to dilate in response to metabolic need. As these abnormalities occur, abnormal skeletal muscle blood flow occurs in response to exercise and decreased exercise tolerance. In addition decreased renal perfusion leads to further activation of the renin-angiotensin-aldosterone system (RAAS), with increased aldosterone secretion and sodium retention. The combination of these two events leads to decreased exercise capacity and peripheral edema, important components of the symptom complex of congestive heart failure. Decreased cardiac performance promotes neurohumoral responses characterized by activation of the sympathetic nervous system and the renin-angiotensin-aldosterone system, leading to peripheral vaso-constriction and sodium accumulation. These factors feed back to increase the ventricular remodeling process and to amplify cardiac damage. Thus, initial myocardial damage progresses to ventricular dysfunction and ultimately to congestive heart failure. It is important to note that the myocardial damage and left ventricular dysfunction are often asymptomatic, and by the time symptomatic heart failure ensues, the disease process is far advanced. [Revised from LeJemtel TH, Sonnenblick EH. Heart failure and maladaptive processes: Introduction. *Circulation* 1993; 87(suppl VII):VII1-VII4. Reproduced with permission from the American Heart Association and the authors.]

Figure 20-7: Idealized plot of left ventricular volume versus time (*top*) and the rate of change of volume (*dV/dt*) versus time (*bottom*), such as might be obtained from contrast or radionuclide ventriculographic studies. The representative cardiac cycle begins at end diastole. Subsequent events as depicted by the bars in the center of the figure are (1) systole, during which left ventricular volume decreases to a minimum and *-dV/dt* reaches its maximum; and (2) diastole, the beginning of which is signaled by the opening of the mitral valve and the onset of left ventricular filling. Diastole has three distinct phases in normal individuals: (1) the rapid filling phase (RFP), during which the left ventricle fills rapidly but passively and the peak filling rate occurs; (2) diastasis (D), during which relatively little left ventricular volume change occurs; and (3) atrial systole (AS), in which active atrial contraction fills the left ventricle to its end-diastolic volume. The diastolic parameters that have been derived from such analysis are the peak filling rate, the time to peak filling rate (TPFR), the percent contribution of atrial systole, and the first third filling fraction. (From Labovitz AJ, Pearson AC. Evaluation of left ventricular diastolic function: Clinical relevance and recent Doppler echocardiographic insights. *Am Heart J* 1987; 114:836-849. Reproduced with permission from the publisher and authors.)

Figure 20-8: Schema of events in congestive heart failure leading to symptoms. Note that fatigue and other symptoms of limited cardiac output are primarily related to decreased ejection, whereas peripheral and pulmonary edema are related to Na+ and water retention from increased sympathetic tone and increased renin-angiotensin-aldosterone. See text for details.

Part 3: HEART FAILURE
Chapter 21:

DIAGNOSIS AND MANAGEMENT OF HEART FAILURE

Authors: Thierry H. LeJemtel, Edmund H. Sonnenblick, William H. Frishman

The management of patients with chronic heart failure is increasingly complex, since congestive heart failure (CHF) represents the end result of many cardiovascular, pulmonary, and systemic diseases that require specific and aggressive therapy.[1-3] Moreover, ventricular dysfunction generally precedes clinical symptoms by months or years.[4] Thus, the initial aim of therapy is to treat the primary etiology and prevent or slow the progression of or even reverse left ventricular (LV) systolic dysfunction independent of symptoms. This goal most often is achieved on an outpatient basis. Once symptoms of CHF occur, their control becomes a primary focus. Ultimately, the severity of symptoms may require hospitalization with parenteral therapy. Overall, successful management of patients with CHF rests on in-depth knowledge and treatment of the processes responsible for ventricular dysfunction and ultimately the symptoms that evolve. Despite the diversity of the initial processes, three guiding principles remain central.

The first guiding principle in CHF management is the concomitant, continuous, and aggressive pursuit and treatment of the underlying disease or diseases that led to the development of CHF. For example, hypertension requires vigorous and adequate therapy. When CHF is due to obstruction of the coronary arteries, a demonstration of reversible myocardial ischemia, even in the absence of angina, can lead to a coronary revascularization procedure that in turn can lead to an improvement in myocardial function. Similarly, slowing the progression of coronary artery disease through the use of both antithrombotic and lipid-lowering therapies along with cessation of cigarette smoking is as important as is the treatment of the clinical symptoms of ischemic CHF.

The second guiding principle in managing patients with CHF is to define precisely the stage of the disease when therapy begins. The syndrome of CHF is a dynamic process, and the therapeutic goals and end points vary as the process evolves. Symptoms, even as judged by exercise testing,[5] do not correlate with the severity of ventricular dysfunction as judged by measurement of the ejection fraction.[6] Thus, symptoms should not be used to guide therapy in the early stages of the disease. Minimal serial measurement of the ejection fraction remains the guide to advancement of the primary diseases, and symptoms and their relief may not predict survival. Prevention of sudden death is an important therapeutic outcome in patients with asymptomatic or mildly asymptomatic LV systolic dysfunction. It may be a limited therapeutic goal in extremely symptomatic patients who are not candidates for cardiac transplantation or LV assist devices, in whom symptom relief becomes a primary concern.

The third guiding principle in managing patients with severe CHF is the recognition that a key determinant of successful therapy is the intensity of care; this requires frequent visits, in-home monitoring, and meticulous attention to management details such as diet, daily activity level, daily weight, and the doses of the medications being used, with an appreciation of their adverse effects.[7,8] The importance of this principle is illustrated by the careful approach that is required to both successfully initiate and increase the dosage of beta-adrenergic blockade therapy in patients with symptomatic LV systolic dysfunction.

To plan an appropriate therapy, an accurate clinical diagnosis is necessary, with an understanding of the pathophysiology involved. Details of diagnostic approaches are presented elsewhere (see

Chap. 20).

PREVENTION OR REVERSAL OF LV DILATATION AND HYPERTROPHY

Besides primary prevention of the processes that are associated with LV systolic dysfunction and the development of CHF (coronary artery atherosclerosis, hyperlipidemias, hypertension, diabetes), secondary prevention of LV dilatation has been achieved most successfully over the past decade by modulating heightened activity of the neurohumoral activity of the sympathetic and renin-angiotensin-aldosterone systems. As will be discussed, below deactivation of both systems has led to attenuation or reversal of the remodeling process that accompanies the syndrome of CHF. However, the extent to which these systems should be deactivated is still poorly understood, especially late in the syndrome of CHF. Of interest, the dissociation between LV systolic performance and functional capacity that is present at baseline in patients with CHF seems also to be observed during therapeutic interventions. Further, the substantial improvement in LV ejection fraction that frequently occurs during long-term beta-adrenergic blockade does not necessarily translate into improved functional capacity. Current therapeutic investigations regarding the progression of LV dilatation and hypertrophy are focusing on cytokine receptor antagonists and endothelin receptor antagonists.[9,10]

Chapter 21: DIAGNOSIS AND MANAGEMENT OF HEART FAILURE

PATHOPHYSIOLOGY AND DIAGNOSIS OF CONGESTIVE HEART FAILURE

The dynamic process by which ventricular dysfunction evolves into CHF can be conveniently described in three phases[11] (Fig. 21-1). The clinical characteristics of each phase and its duration depend heavily on the specific primary etiology involved. Myocardial damage with massive myocyte loss and fibrotic repair may be rapid, as occurs with an acute transmural myocardial infarction or a viral myocarditis, or may evolve over years, as occurs with overloads resulting from systemic hypertension or valvular disease.[12,13] In the absence of overt clinical symptoms, such as chest pain with a myocardial infarction or sudden (flash) pulmonary edema, the initial damage may go undiagnosed. In this situation, a two-dimensional echocardiogram can be helpful in documenting the presence and extent of LV dysfunction and segmental wall motion abnormalities. Ventricular dilatation is not uncommon in largely asymptomatic patients.

The second stage in the evolution of heart failure involves an adaptation to myocardial damage termed *ventricular remodeling*. This involves myocardial hypertrophy in response to myocardium that is lost or overloaded and ventricular dilatation, which helps sustain cardiac output (Fig. 21-1). In general, heart failure begins with increased loading of the ventricle with pressure or volume or with loss of myocardium leading to ventricular dysfunction. In a sense, loss of myocardium, whether segmental as occurs with myocardial infarction or diffuse as occurs with cardiomyopathies, creates an overload for the myocardium in that less myocardium must maintain the work of the heart. Once an overload is created, the myocardium responds with changes in growth and architecture that constitute ventricular remodeling. This includes increases in myocyte length as well as lateral dimension. With an increased pressure load, myocytes respond by laying down more contractile units in parallel, thus increasing the lateral dimensions of the myocyte and its force potential. This form of hypertrophy tends to normalize the tension in the ventricular wall. When volume is increased, whether because of increased flow from an insufficient valve or increased diastolic filling pressure that results as a compensation for lost myocardium, myocytes elongate in order to maintain force and shortening. Acutely, this occurs within the limits created by the physiological lengthening of the sarcomere, i.e., the Frank-Starling length-tension curve. With a sustained diastolic load, sarcomeres are added in series, resulting in increased myocyte length. Since augmented diastolic volume itself results in increased ventricular wall tension [wall tension (T) = pressure (P) × dimension (r)/wall thickness (h)], lateral growth (hypertrophy) of myocytes commonly accompanies myocyte lengthening. In addition to hypertrophy of myocytes, other dynamic events occur in the myocardium.

Myocytes may be lost diffusely when excessive overloads occur through the process of apoptosis and focal necrosis with replacement fibrosis. With sustained diastolic loads, ventricular dilatation proceeds with not only marked myocyte lengthening but also with apparent displacement of myocytes or groups of myocytes one to the other, a process labeled *myocyte slippage*. While hypertrophy of myocytes is readily demonstrable, hyperplasia of myocytes also may be observed.[14,15] Taken together, hypertrophy, myocyte hypertrophy, further myocyte loss, and hyperplasia, along with ventricular wall restructuring, constitute ventricular remodeling. With systolic overloads, this generally is characterized by increased ventricular wall thickness with normal intraventricular volumes (e.g., normal ejection fraction). When the hypertrophy cannot sustain required systolic tension, whether because of a primary decrease in force production by a given myocyte[16] or because of loss of myocytes, ventricular dilatation occurs and a fall in the ejection fraction is observed. Generally, it proceeds silently unless it is heralded by an acute

myocardial infarction. Thus, except for clinical symptoms, such as dyspnea and exertion, that may reflect an increased diastolic filling pressure resulting from a thickened ventricular wall, ventricular remodeling generally progresses unobserved.

The factors that mediate progressive ventricular remodeling (hypertrophy) are both physical forces and hormonal factors (e.g., angiotensin). During this evolution of ventricular remodeling, neurohumoral activation occurs.[17] Activation of the sympathetic nervous system with parasympathetic withdrawal leads to tachycardia and peripheral vasoconstriction. Activation of the renin-angiotensin system causes further vasoconstriction and salt accumulation through stimulated aldosterone secretion. Both of these latter factors, along with excessive stretch of the myocardium, can lead to further myocyte loss, with fibrosis along with further myocyte hypertrophy, while ventricular dilatation may induce functional mitral and/or tricuspid insufficiency, creating an additional hemodynamic load (Fig. 21-2).[18]

The third phase in the evolution of heart failure evolves from these adaptive changes, with development of symptoms of CHF, characterized by decreased exercise tolerance, pulmonary and systemic congestion, and central and peripheral edema. The interval between the initiation of ventricular dysfunction and the onset of symptoms, during which ventricular remodeling occurs, may extend over a long period, but if the damage is related to an acute myocardial infarction, this period can be very short. With more chronic processes, such as those which occur with hypertension or idiopathic cardiomyopathies, this period may extend over months or years. Indeed, when patients were first identified with asymptomatic LV dysfunction in the Studies of Left Ventricular Dysfunction (SOLVD) trial (discussed below), their average ejection fraction was already reduced to 28 percent, indicating that extensive ventricular damage had already occurred (Fig. 21-3). At this point, exercise performance, as represented by peak oxygen consumption, was moderately reduced, but not to an extent that limited exercise performance or produced symptoms. Circulating norepinephrine was increased slightly, while plasma renin levels (slashed lines) were not, except when diureties had been administered (open bars). Once symptoms occurred, there was a progressive increase in circulating norepinephrine and plasma renin. A progressive decline in exercise capacity was documented as patients progressed from New York Heart Association (NYHA) class I to class IV. The reduction in exercise performance was relatively greater than the decrease in the ejection fraction. This relates to the finding that with inactivity, the capacity for peripheral vasodilatation is reduced, limiting skeletal muscle performance. Ventricular dysfunction may involve the left ventricle, the right ventricle, or both. In addition, such abnormalities may be amplified by overloads created by valvular insufficiency (e.g., mitral or tricuspid) or systolic overloads (e.g., aortic stenosis, arterial or pulmonary hypertension). Separating the effects of myocardial dysfunction from such imposed overloads is difficult. Moreover, functional mitral and/or tricuspid insufficiency resulting from ventricular dilatation imposes a further volume load on an already damaged myocardium.

Abnormalities of ventricular function can be usefully divided into problems of ventricular filling (diastole) and problems of ventricular emptying (systole). Even in the presence of normal systolic ventricular performance, abnormalities of ventricular filling, termed *diastolic ventricular dysfunction*, may be observed, and these abnormalities require specific diagnostic consideration (Fig. 21-4). This is characterized by an increased ventricular filling pressure for any end-diastolic volume (EDV) resulting from reduced compliance of the ventricle. Thus, with normal EDV and stroke volume (SV), filling pressures may be markedly increased, leading to signs of pulmonary congestion despite a normal ejection fraction. Such a situation may occur with LV hypertrophy, especially when associated with a rapid heart rate, which further limits the time for ventricular filling. It also can occur with an aging heart, where diffuse myocyte loss can occur with replacement fibrosis and reactive myocyte hypertrophy.[19]

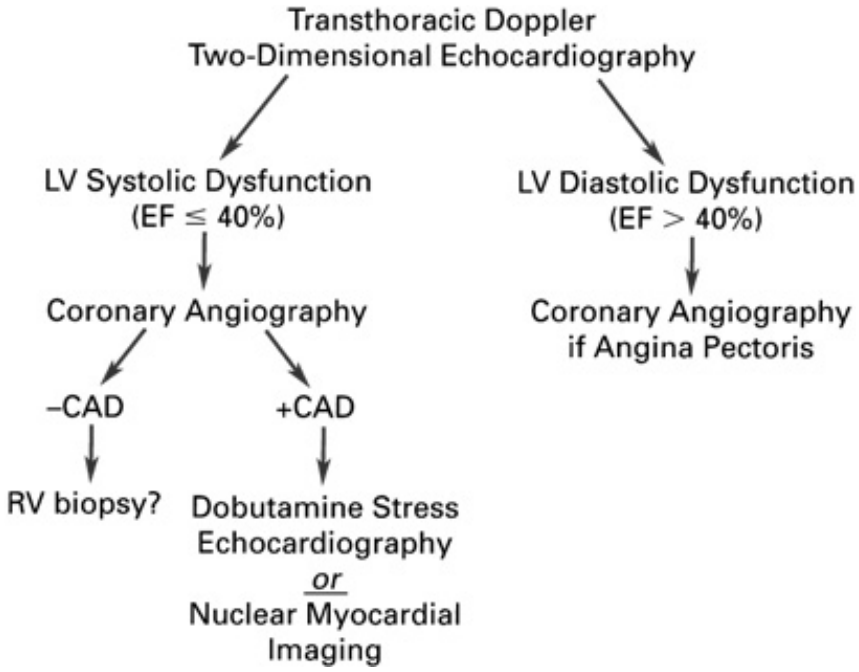

Figure 21-4: Evaluation of patients with congestive heart failure. Transthoracic Doppler and two-dimensional echocardiography provide a central modality to evaluate ventricular function and valvular abnormalities. Ventricular wall thickness and both end-diastolic and end-systolic volumes can be determined. With an ejection fraction (EF) more than 40 percent, coronary angiography is indicated in the presence of angina pectoris or evidence of significant ischemia. With an EF less than 40 percent, coronary arteriography is indicated since the underlying ischemic depression may be amenable to reperfusion by angioplasty or coronary bypass surgery. Nuclear imaging techniques are used to define viable ischemic myocardium, while stimulation of such myocardium with dobutamine or extrasystolic potentiation may indicate recoverable hibernating myocardium. Right ventricular biopsy may be indicated in the absence of coronary artery disease to rule out processes such as amyloid or sarcoid.

Systolic ventricular dysfunction is characterized by a reduced ability to generate pressure isovolumically and a decreased capacity to eject blood in systole. As is known from classic physiology, the SV depends on the diastolic volume as well as the afterload, which is directly related to the arterial pressure. If the afterload is reasonably normal, there is a linear relation between SV and EDV, and the resultant slope (SV/EDV) is termed the *ejection fraction*. If the slope of the relation linking end-systolic pressure and LV volume is reduced, as occurs when the ventricle is depressed, the SV at any EDV is reduced, resulting in a decreased ejection fraction. If the afterload is approximately normal, this reduced ejection fraction can serve as a measure of *reduced systolic ventricular performance*. Since the extent of shortening of myocardium is reduced as afterload is increased, an increased systolic ventricular pressure can by itself reduce SV and hence tend to decrease EF, as can occur in severe aortic stenosis. Similarly, with severe mitral insufficiency, which decreases afterload through a low-impedance pathway into the left atrium, an increased SV tends to occur, yielding an artificially increased ejection fraction. Thus, with these considerations in mind, the ejection fraction can provide a useful indicator of systolic ventricular performance.

Although complex indices of systolic ventricular function have been described on the basis of myocardial muscle function,[20] the measurement of the ejection fraction has served as the clinical standard, whether determined noninvasively by echocardiography and nuclear imaging techniques or invasively with angiography. In addition to an overall depression of myocardial function, focal abnormalities of ventricular wall motion, described in terms of hypokinesis and akinesis, may produce major alterations in overall LV function, as seen in coronary artery disease. While a segment of the LV wall may be replaced by fibrotic scar, focal abnormalities of contraction may

occur in viable myocardium when coronary perfusion is transiently reduced, leading to a prolonged decrease in contraction; this is termed *stunning*. Alternatively, with a sustained reduction in coronary blood flow that is still adequate to sustain viability, contraction can be persistently reduced or absent; this is termed *hibernation*.[21,22] These important alterations can occur simultaneously in a given patient and are hard to separate.[22] Defining these abnormalities in coronary heart disease with heart failure is extremely important, since reversal of transient or persistent ischemia with vascular reperfusion may be vital for restoring segmental contraction and improving overall ventricular function.[21,23] Various techniques have been employed to identify such tissue, including echocardiographic studies using a catecholamine stress[24-28] and angiographic studies using nitroglycerin[29] or extrasystolic potentiation after a premature ventricular contraction.[21,30,31]

Once ventricular dysfunction is manifest, abnormalities of reflex control of the circulation ensue. As CHF progresses, decreased baroreceptor sensitivity occurs with augmented sympathetic tone and reduced parasympathetic tone (Fig. 21-2).[32] This results in an increase in heart rate along with reduced beat-to-beat heart rate variability and loss of the Valsalva overshoot. These changes also help establish the diagnosis of heart failure.

With reduced ventricular function, exercise performance tends to be reduced as measured by a reduced maximum O_2 uptake on a treadmill (VO_2). However, this reduction in exercise performance does not always correlate with a reduced ejection fraction,[5] since it also reflects the *training* state of the peripheral circulation.

Clinical Assessment in Directing Therapy

Clinically, the initial diagnosis of heart failure is made by the patient's history, physical findings on clinical examination, and data obtained from routine chest x-rays and electrocardiography (ECG). The history obtained from patients tends to reflect pulmonary or systemic congestion or both, with complaints of shortness of breath, initially with effort and on lying down, generally associated with easy fatigability and, commonly, peripheral edema. Common factors in the history often include diabetes mellitus, ischemic events, and hypertension. On physical examination, peripheral vasoconstriction and tachycardia are common, along with the presence of pulmonary rales and physical signs of pleural effusion. Cardiac findings may include a fourth heart sound (S_4), reflecting a stiffened or hypertrophied ventricle, and a third heart sound (S_3), reflecting more profound LV failure. Murmurs can be auscultated that may relate to valvular organic abnormalities, although functional mitral and tricuspid insufficiency can occur as a function of LV and/or right ventricular (RV) dilatation per se. Peripheral venous engorgement and an enlarged liver, along with peripheral edema, are detected as RV failure ensues. If RV failure is severe, clinical symptoms associated with LV failure, such as severe shortness of breath, actually may be lessened.

Precipitating factors for developing CHF should be looked for, such as anemia, infection, dietary indiscretion, acute arrhythmias (especially atrial fibrillation), poor compliance with treatment, pulmonary embolism, and occult myocardial infarction.

Nuclear imaging techniques, computed tomography, and magnetic resonance imaging have been useful in assessing ventricular volume, shapes, and motion and have provided an excellent assessment of ventricular function. However, two-dimensional echocardiography provides much of the necessary information in a practical and cost-effective manner and remains the clinical standard. Its accuracy and usefulness depend on the care expended in performing the procedure and the professional oversight utilized in both detecting and interpreting the findings that are obtained. Echo-Doppler examination not only provides information about systolic and diastolic volumes, and thus ejection fraction, but also allows for the evaluation of valve structure and function, including regurgitation and stenosis. Reasonably accurate measurements of gradients,

and thus valvular orifices, can be made, and this can help direct therapy.

In defining the etiology of heart failure, segmental wall motion abnormalities with hypokinetic and contralateral hyperkinetic segments suggest an ischemic etiology. Indeed, after an acute myocardial infarction, a two-dimensional echocardiogram obtained within a few days is essential. The finding of ventricular dilatation within a few days of an acute anterior wall infarction tends to predict progressive LV dilatation with a falling ejection fraction. Among patients sustaining an anterior wall infarction without initial ventricular dilatation, approximately one-third will show ventricular dilatation at 3 months. In contrast, ventricular dilatation rarely occurs after inferior wall infarctions, except when the region involved is large, extending from the base of the heart to the apex. After an acute myocardial infarction,[33] LV enlargement, as measured by two-dimensional echocardiography, is associated with an increased incidence of adverse cardiovascular events. When LV diastolic volumes of patients with an infarction are divided into quartiles, patients in the fourth quartile have a mortality rate of 45.5 percent, while patients in the third quartile have a mortality rate of 21.1 percent and those in the first and second quartiles both have a mortality rate of 16.7 percent.[34] If LV dilatation occurs much later, however, two-dimensional echocardiography will not differentiate between the causes of heart failure, i.e., coronary artery disease or other etiologies. Moreover, patients with a primary cardiomyopathy also may exhibit segmental wall motion abnormalities. As was noted above, stimuli that elicit latent contraction, such as low-dose dobutamine, stress, and premature ventricular contractions, may help identify patients with dilated left ventricles and severe coronary artery disease who also have *hibernating* or *stunned* myocardium.[22,35,36]

Chapter 21: DIAGNOSIS AND MANAGEMENT OF HEART FAILURE

THE TREATMENT OF CONGESTIVE HEART FAILURE

As was noted initially, the treatment of heart failure requires close attention to both the primary etiology and the relief of symptoms while attempting to reduce the risk of death from the process. This includes vigorous control of hypertension, if present, and an evaluation for treatment of myocardial ischemia. As was noted above and discussed further relative to surgical approaches to heart failure, noncontractile but viable myocardium, whether resulting from stunning or from hibernation, requires definition with consideration of coronary reperfusion.[22,37] Valvular disease that imposes an excessive volume or pressure overload must be considered relative to the need for surgical correction. For example, critical aortic stenosis with heart failure is an urgent indication for aortic valve replacement, when possible, not medical therapy. To those ends, there is a multifactorial approach to therapy[38] that varies with the etiology and stage of the heart failure process (Fig. 21-5).

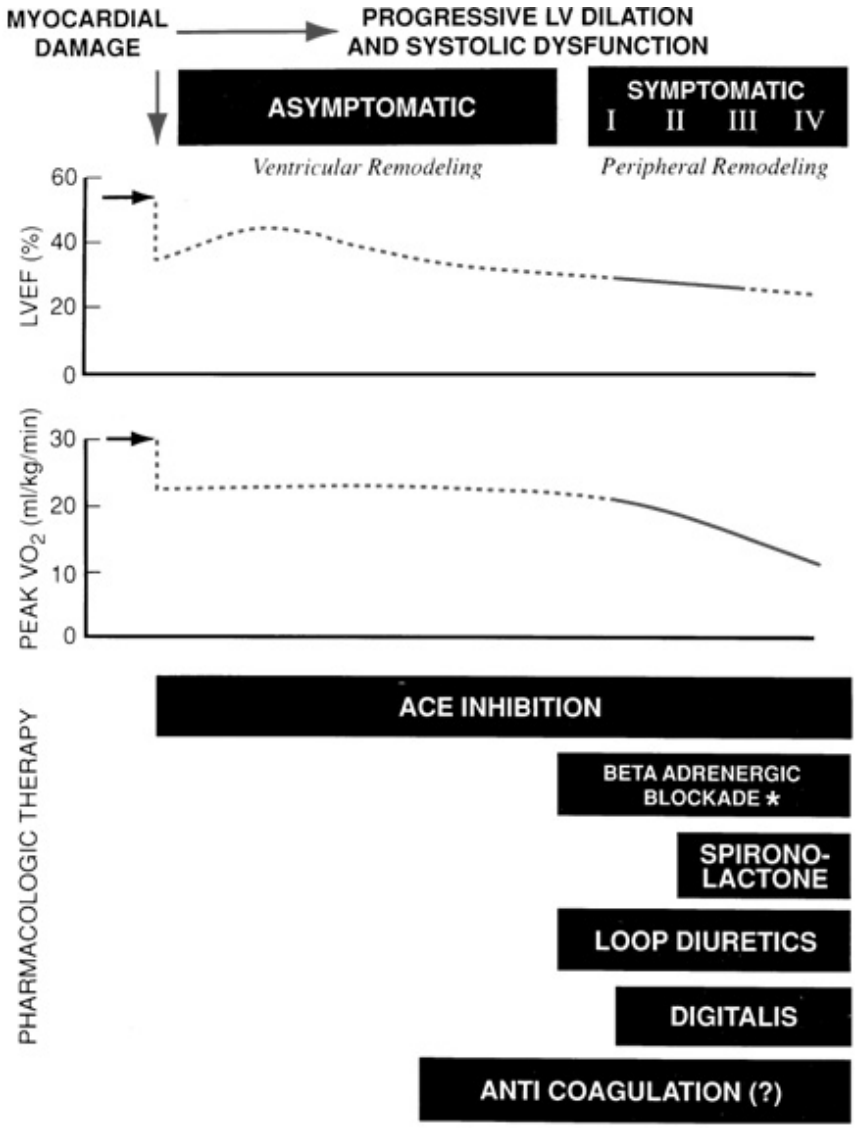

Figure 21-5: figuremeasure taged use of therapeutic agents in heart failure. Initial approaches include control of factors that may cause progression of heart failure and/or augment its manifestations.

Hypertension requires control. Unanticipated tachycardia may augment oxygen needs while reducing the time in diastole for coronary flow to take place. The reduction in the diastolic time can lead to marked elevations of left ventricular (LV) diastolic pressure as well as increased ischemia. Moreover, atrial fibrillation will deprive ventricular filling of the "atrial kick" and lead to further elimination of diastolic pressures. These considerations are of special importance with ventricular hypertrophy and resultant diastolic dysfunction. During the "remodeling" phase of ventricular failure, the patient may be asymptomatic. Nevertheless, inhibition of the renin-angiotensin system is indicated to reduce the rate of ventricular remodeling and slow ventricular dilation. Beta-adrenergic blockade reverses ventricular remodeling and improves survival in patients with class II to III symptoms. * Reflects the inconsistent effects of beta-adrenergic blockade in patients with class IV symptoms. In the Copernicus trial, carvedilol was beneficial, while in the BEST trial, bucindolol appears to be detrimental. Once symptoms ensue, loop diuretics generally are needed for fluid control. Digitalis glycosides also are indicated for neurohumoral benefits in reducing sympathetic tone and enhancing parasympathetic tone while providing modest inotropic support. These actions appear to improve morbidity without necessarily altering mortality.

General Principles in the Pharmacologic Treatment of CHF

Therapy is tailored to the phase of heart failure. In the initial phase, where ventricular damage is a primary concern, identification of etiology is essential with appropriate therapy. Thismight be termed treatment of ventricular dysfunction and its causes. Hypertension must be controlled aggressively. Even mild hypertension should be treated in the presence of the diabetic state to attempt to prevent large- and small-vessel coronary disease. Overt or silent ischemia should be identified and treated. Early inhibition of the neurohumoral responses to initial cardiac damage with both beta-adrenergic blockade and inhibition of the activated renin-angiotensin-aldosterone system (RAAS) requires consideration. This is particularly the case as one moves into the phase of ventricular remodeling in which inhibition of progressive ventricular damage is essential. It is important to remember that what bothers the patient, such as edema and shortness of breath, is generally not life-threatening, while therapy that may reduce mortality, such as beta blockers, may do nothing to alleviate symptoms. Thus, both agendas must be addressed. In general, mortality has been used to measure efficacy. Improvement in symptoms has been difficult to assess, and a combined end point of mortality and the need for hospitalization has been useful. As the syndrome of CHF ensues, pharmacologic treatment is directed to three demonstrable hemodynamic end points: (1) reducing volume overloads and maintaining a stable volume state, (2) reducing preload and afterload to enhance ventricular performance, and (3) improving ventricular contractility when necessary. An additional pharmacologic aim is to reduce heightened neurohumoral activity, which is seen in patients with heart failure, with the hope of limiting abnormal loading created by these systems and preventing the progression of the heart failure process. The ultimate aim is to reduce morbidity and perhaps extend life.

INACTIVATION OF THE RENIN-ANGIOTENSIN SYSTEM AND ALTERNATIVE THERAPIES

Neurohumoral activation plays an important role in the progression of the syndrome of chronic LV systolic dysfunction/heart failure. After initial increases in sympathetic tone and decreases in parasympathetic tone, the renin-angiotensin system is activated.[39] This generally occurs when diuretics are initiated or, in their absence, with the onset of the clinical symptoms of CHF. With release of renin from the kidneys, angiotensinogen, which is circulating in the blood, is converted to inactive angiotensin I, which in turn is converted to the highly active angiotensin II by a converting enzyme that is ubiquitously located along vascular walls. Angiotensin II in turn stimulates aldosterone secretion by the adrenals, which results in sodium accumulation and also produces marked arteriolar constriction, which augments peripheral vascular resistance. Both phenomena, which increase ventricular preload (filling pressure) and afterload (systolic pressure), contribute to the clinical picture of CHF. In addition to these actions, angiotensin II serves as a growth factor, adding to myocardial hypertrophy and apparently fostering fibrosis. It also may contribute to subtle myocyte loss by enhancing apoptosis.[40]

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The initial impetus toward the use of angiotensin-converting enzyme (ACE) inhibitors for the treatment of patients with CHF was the desire to duplicate with one agent the hemodynamic effects produced by the combination of nitrate and hydralazine.[41] In the late 1970s, combined administration of nitrate and hydralazine was shown to enhance LV systolic performance and alleviate symptoms in patients with

CHF.[42] In severe heart failure, this resulted from the combined action of nitrates to reduce diastolic filling pressures (preload) and hydralazine to reduce peripheral arterial resistance (afterload). The result was reduced filling pressures accompanied by an increased cardiac output. Initial hemodynamic studies with captopril (Table 21-1) demonstrated substantial lowering of ventricular filling pressures, a modest increase in cardiac output, and a reduction in systemic arterial pressure without tachycardia.[41] In a landmark randomized, placebo-controlled study, the administration of captopril for 3 months produced sustained improvement in LV performance, improvement in the functional class, and increased duration of maximal exercise,[43] resulting in U.S. Food and Drug Administration (FDA) approval of captopril for the treatment of CHF. In the first weeks of the study, exercise duration also improved in patients on placebo. This initial improvement in exercise duration on placebo probably is due to familiarization with exercise equipment and increased patient motivation.

Several aspects of long-term therapy with ACE inhibitors in patients with CHF are worthy of mention:

1. The magnitude of the initial hemodynamic change does not predict the long-term clinical response. Some of the beneficial effects of lower ventricular filling and systemic arterial pressures may relate to increased levels of kinins, resulting from decreased enzymatic destruction that also is mediated by ACE inhibitors.[44] Whether sustained elevation in kinin levels exerts long-term clinical benefits is uncertain. The dissociation between acute hemodynamic effects and long-term clinical benefit suggests that the mechanisms underlying the benefits of ACE inhibitors may be related to structural and functional changes in the peripheral vasculature. Improvement in peak aerobic capacity (VO_2) has been directly related to enhanced perfusion of skeletal muscle at maximal exercise.[45] The exact mechanisms that mediate the benefits of ACE inhibitors on the vasculature are poorly understood. The time differential between the acute, immediate hemodynamic and the more delayed functional benefits suggests that the cellular alterations produced by ACE inhibitors, rather than just the relief from heightened vasoconstriction, may mediate the clinical benefits. Improvement of vascular endothelial function, which is reversibly depressed in CHF, as through the response to local administration of acetylcholine, is so far the best documented vascular effect of ACE inhibitors in patients with CHF.[46,47] Improved vascular endothelial function during long-term ACE inhibition may be mediated in part via the kinins pathway. Whether lowering tissue levels of angiotensin II (AII) affects vascular smooth muscle structure and function is unknown. However, AII is a smooth muscle growth factor, and its reduction may reduce smooth muscle mass and thus affect vascular tone and compliance.[48]
2. The impact of long-term ACE inhibition on LV systolic function appears to be modest. Thus, the absolute increase in LV ejection fraction observed in large multicenter randomized trials ranged from 1 to 3 absolute units.[49] With long-term use of ACE inhibitors, LV end-diastolic and systolic volumes are only modestly altered and somewhat disparate in patients with CHF. Initial reduction in LV end-diastolic volume during long-term ACE inhibition appears to be related largely to decreased loading of the failing ventricle rather than structural cardiac alterations, since LV volume increases within a few days after the withdrawal of ACE inhibition.[50] More recently, LV end-diastolic volume was noted to increase steadily during long-term ACE inhibition in patients with CHF while remaining unchanged in patients treated with AII type 1 receptor blockade (ARB) in addition to ACE inhibition.[51] However, persistent diastolic unloading with these agents may reduce the progression of dilatation.
3. Long-term use of ACE inhibitors has significant natriuretic effects. From a hormonal point of view, a decrease in AII tends to reduce aldosterone secretion, with a resultant lessening of sodium accumulation and a reduced potassium loss. However, aldosterone synthesis is modulated by factors other than AII, such as potassium levels, corticotropin, and endothelin, among others.[52] During long-term treatment with ACE inhibitors, levels of aldosterone remain elevated in up to 38 percent of patients of with CHF.[53] Thus, one cannot assume that long-term ACE inhibition alone can reliably lower plasma aldosterone levels. Increased diuresis with the consequent reduction in the dose of loop diuretics has been reported during long-term therapy with captopril.[54] This natriuretic effect of captopril may be related to the increase in renal blood flow demonstrated after the administration of captopril, despite the concomitant reduction in systemic arterial pressure.[55]

A major impetus for an increasing use of ACE inhibitors in patients with LV systolic dysfunction and CHF derives from the experimental work of Pfeffer and associates.[56] Ligation of the left anterior descending

coronary artery in rats resulted in a large infarction and progressive ventricular dilatation. Long-term therapy with captopril reduced LV dilatation and shifted the pressure-volume curve favorably to the left. The process of LV enlargement in those experiments was largely dependent on the size and location of the myocardial infarct as well as the patency of the infarct-related artery. It was theorized that by lowering LV diastolic wall stress, long-term therapy with ACE inhibitors could favorably alter the loading conditions of the left ventricle and reduce LV enlargement, thus enhancing the survival of patients after a myocardial infarction.[57] A short-term trial in humans with acute myocardial infarction suggested that ventricular dilation could be attenuated with ACE inhibition (captopril).[58] A subsequent study with postinfarction patients with an ejection fraction less than 40 percent demonstrated a 21 percent reduction in mortality after 4 years.[58a] Of note, a similar reduction in reinfarction was observed.

In addition to the work of Pfeffer and associates,[56] several large survival trials were launched and completed exploring the effects of ACE inhibitors in patients with heart failure.[59] Beneficial effects of an ACE inhibitor on mortality in patients with CHF was first demonstrated with enalapril. The results of the Cooperative North Scandinavian Enalapril Study (CONSENSUS) involving 253 patients with symptoms compatible with NYHA functional class IV showed that after an average follow-up of 188 days, 68 of the 126 patients randomized to placebo died, while only 50 of 127 patients randomized to enalapril died, a reduction in mortality of 27 percent ($p = .003$).[60] The entire reduction in total mortality was found to occur among patients with progressive heart failure, whereas no difference was observed in the incidence of sudden death. After the initial dose of enalapril was reduced from 10 to 2.5 mg, only 3.2 percent of the patients could not tolerate enalapril because of symptomatic hypotension.

The second Veterans Administration Cooperative Vasodilator Heart Failure Trial (V-HeFT II) randomized 804 men with peak aerobic capacity <25 mL/kg per minute to enalapril or to hydralazine plus isosorbide dinitrate. At 2 years, the mortality was lower in the enalapril group than it was in the hydralazine plus isosorbide dinitrate group (18 percent versus 25 percent, $p = .016$; reduction in mortality, 28 percent).[61] The reduction in mortality, particularly in patients with less severe symptoms (NYHA classes I and II), was attributable to a reduction in sudden death. V-HeFT II also confirmed previous findings that treatment with long-term ACE inhibitor was associated with a minimal absolute increase in the LV ejection fraction, i.e., 2 percent with enalapril and 45 percent with hydralazine plus nitrate.

The SOLVD Study assessed the effect of ACE inhibition with enalapril in patients with symptomatic and asymptomatic LV systolic dysfunction as evidenced by an ejection fraction <35 percent.[62,63] Two thousand five hundred sixty-nine patients who had CHF as defined by the need for therapy and a mean ejection fraction of 24.8 percent were enrolled in the treatment arm of SOLVD and randomized to placebo or enalapril. Over a period of 48 months, 510 of the 1284 patients randomized to placebo died, while only 452 of the 1285 patients randomized to enalapril died [risk reduction, 10 percent; 95 percent confidence interval (CI), 5 to 26 percent; $p = .0036$]. The chief difference in mortality was due mostly to progressive heart failure, as the number of deaths classified as arrhythmogenic without worsening CHF was similar in the placedo and enalapril arms. Four thousand two hundred twenty-eight patients who were not treated for CHF and thus were considered asymptomatic had a mean ejection fraction of 28 percent and were enrolled in the prevention arm of SOLVD. Over a period of 37.4 months, 334 of the 2117 patients randomized to placebo and 313 of the 2111 patients randomized to enalapril died (risk reduction, 8 percent; 95 percent CI, 8 to 21 percent; $p = .030$). In the placebo group, 818 patients developed heart failure or died compared with only 630 patients in the enalapril group, i.e., 38.1 versus 29.8 percent (risk reduction, 29 percent; 95 percent CI, 21 to 30 percent; $p < .001$).

Of great note was a common effect of enalapril in both the treatment and prevention arms of the SOLVD trials to reduce the incidence of recurrent myocardial infarction, i.e., 288 in the enalapril group versus 362 in the placebo group (risk reduction, 23 percent; 95 percent CI, 11 to 34 percent; $p < .001$).[64] Similarly, 499 patients in the enalapril group and 595 in the placebo group developed unstable angina (risk reduction, 20 percent; 95 percent CI, 9 to 29 percent; $p < .001$). Whether this reduction in the incidence of acute coronary events in patients with coronary artery disease is associated with long-term ACE inhibition with enalapril or is related to the improvement in endothelium vasomotor dysfunction, which was subsequently demonstrated with quinapril, another ACE inhibitor, is not known.[46,65] It is also possible that ACE inhibition plays a role in stabilizing atherosclerotic plaques, perhaps by reducing smooth muscle growth. Importantly, as is noted below, the same considerations have been raised by the Survival and Ventricular Enlargement (SAVE) trial of ACE inhibition in the depressed heart after myocardial infarction.

The impetus for an earlier use of an ACE inhibitor in patients with LV dysfunction and heart failure also has been provided by the results of the Heart Outcomes Prevention Evaluation (HOPE) study.[66] Therapy with ACE inhibitors traditionally has been recommended in patients with CHF related to LV systolic dysfunction, as defined by an LV ejection fraction <40 percent (to 35 percent) in most clinical trials. By demonstrating that long-term administration of ramipril, a tissue-specific ACE inhibitor, improved life expectancy in patients with vascular disease or diabetes and one cardiovascular factor who did not have any evidence of LV systolic dysfunction, the findings of the HOPE trial indirectly but strongly argued for the use of ACE inhibitors at a pre-LV dysfunction stage in patients with clinical conditions known to be associated with the development of chronic heart failure.[67] These results also emphasize the vascular benefits of ACE inhibitors, since other morbid vascular events, such as stroke, were reduced significantly. Since the conditions that lead to LV systolic and diastolic dysfunction are similar, the early use of ACE inhibitors is warranted in patients with both LV systolic and diastolic dysfunction. Besides the already mentioned effects of ACE inhibitors on skeletal muscle vasculature and the prevention of subsequent acute coronary events by ACE inhibitors in patients enrolled in the SOLVD and SAVE trials, the results of the HOPE trial point out the importance of the vascular effects of ACE inhibitors in mediating their clinical benefits. To a large extent, in the majority of patients with CHF, deterioration of LV function is related to progressive systemic and coronary vascular processes that now can be altered favorably by ACE inhibitors. The vascular benefits of ACE inhibitors appear to be additional to those provided by aspirin, beta-adrenergic blockers, and lipid-lowering agents.[66]

The fact that ramipril exerted vascular benefits in patients who were receiving aspirin is of particular importance, as the attenuations of the hemodynamic effects of ACE inhibitors have been reported in patients receiving aspirin.[68] The negative interaction between ACE inhibitors and aspirin presumably is due to interference with kinin-mediated synthesis of prostaglandin. The loss of benefit from ACE inhibitors noted in patients treated with aspirin in some large trials contrasts with the findings of the HOPE trials and others.[69] In view of the importance of the kinin pathway in vascular biology, one would expect that if a negative interaction exists between ACE inhibitors and aspirin, it would have been observed in patients enrolled in the HOPE trial. Whether the use of ticlopidine or clopidogrel is preferable in a subset of patients with LV dysfunction, CHF, and renal insufficiency who are treated with ACE inhibitors is unknown.

By preventing events related to myocardial ischemia and the progression of atherosclerosis, ACE inhibitors are becoming the cornerstone of both treatment and prevention in patients with LV dysfunction, independent of the presence or absence of symptoms. Whether patients should be treated for vascular protection with ACE inhibitors other than those specifically approved for the treatment of LV systolic dysfunction and CHF is unclear. So far no study has included clinical end points to show an advantage of one ACE inhibitor over another. Tissue-specific ACE inhibitors appear more apt to exert vascular benefits than do ACE inhibitors with low tissue specificity.[47] Tissue specificity is probably most relevant at low doses of ACE inhibitors; at maximally recommended doses of ACE inhibition, tissue specificity is less likely to be relevant. Overall, in several clinical trials and in daily practice the dose of ACE inhibitors is strikingly low.[62,63] The patients randomized to ACE inhibition in the SOLVD trial received only 11 mg of enalapril daily.[62] Several small studies and one large study [Assessment of Treatment with Lisinopril and Survival (ATLAS)] randomized patients to 2.5 to 3.5 mg or to 32.5 to 35 mg of lisinopril and showed that high doses of ACE inhibitors produce greater hemodynamic and clinical benefits.[70] Moreover, recent data suggest that even what is currently considered a maximal dose of ACE inhibitors may in fact be insufficient to completely block formation of AII via the ACE pathway, independent of the possible contribution of enzymatic pathways other than ACE to the generation of AII.[71] Thus, every effort should be made to increase the dose of ACE inhibitors to the maximally recommended or tolerated dose in every patient with LV systolic dysfunction and CHF. Unfortunately, this practice is not followed routinely.

In view of the clear benefits observed, all patients with documented LV dilatation should be treated with ACE inhibitors. The only patients with LV dysfunction who should not be treated with ACE inhibitors are pregnant women, patients with documented angioedema or anuria during earlier exposure to ACE inhibitors, and patients with severe bilateral artery stenosis. The benefits of ACE inhibitors have not been looked for in patients with serum creatinine levels >2.5 mg/dL, since those patients have been excluded from clinical trials. The important effects of ACE inhibitors on cardiovascular protection that are independent of any renal effects argue in favor of a trial of ACE inhibitors in patients with CHF with severe chronic renal insufficiency as defined by a serum creatinine level >3.0 mg/dL. However, patients with

serum levels of creatinine >3.0 mg/dL require careful follow-up, including daily monitoring of renal function after the initiation of ACE inhibitors at the lowest possible dose. Since inhibition of AII production leads to dilatation of the efferent artery of the glomerulus, a decrease in glomerular perfusion pressure occurs and a modest rise in serum creatinine (0.5 to 1.9 mg/L) is anticipated. This poses no problem unless the creatinine continues to rise, in which case ACE inhibition needs to be reduced. Indeed, in the presence of diabetes, renal protection is afforded by ACE inhibition, and the rise in creatinine, which is reversible, does not reflect ACE inhibitor-induced renal damage.[72] Moreover, ACE inhibitors that are in part excreted by the liver are preferable in this clinical situation. Overall, it is always recommended to avoid prescribing nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with CHF, but this is particularly important in patients with decreased renal function. Renal function is likely to deteriorate further after the initiation of ACE inhibitor therapy in patients treated with NSAIDs. Patients with plasma levels of potassium >5.0 mmol/L at baseline, particularly if they are diabetic with renal tubular acidosis, require daily measurement of electrolytes and renal function at the initiation of ACE inhibitor therapy.

A potential drug-drug interaction with aspirin and ACE inhibitors has been described, with a potential loss of the protective effects of ACE inhibition on patient survival in heart failure. However, this finding has not been substantiated in recent analyses of large clinical data bases.[69]

ALTERNATIVES TO ACE INHIBITORS

Angiotensin II Receptor Antagonists

Several ARBs are approved by the FDA for the treatment of hypertension (losartan, valsartan, irbesartan, candesartan, telmisartan and eprosartan) (Fig. 21-6). Although trials are in progress involving the use of ARBs alone or in combination with ACE inhibitors in heart failure, none have been approved for this purpose. The first comparison of ACE inhibition with captopril (150 mg daily) and ARB (losartan 50 mg daily) was undertaken in 722 patients with CHF who were over 65 years old. The results suggested that losartan may be preferable to captopril.[73] The rate of death and hospitalization for heart failure was 9.4 percent in patients randomized to losartan and 13.2 percent in patients randomized to captopril (risk reduction 32 percent; 95 percent CI, 4 to 55 percent, $p = .075$). The results of ELITE I were not confirmed by a subsequent study of identical design that included over 3000 patients, ELITE II.[74] In fact, while the number of deaths or hospitalizations was similar during the first 12 months of the study, thereafter fewer patients randomized to captopril died or were hospitalized for heart failure compared with patients randomized to losartan. Thus, the results of ELITE II failed to confirm the hypothesis derived from ELITE I, suggesting that ARBs may be superior to ACE inhibition for the treatment of patients with CHF. Of note, the design of ELITE II and the number of patients studied do not allow one to conclude that the two interventions are equal, based on a lack of statistical difference between the number of events noted in patients randomized to captopril and that in patients randomized to losartan. The ELITE II trial also must be viewed as inconclusive since there remains a question of adequate dosage and, as noted below, the potential for the concomitant use of ACE inhibition and ARBs.

The present use of ARBs for the treatment of CHF is limited to patients who experience intolerable cough or angioedema while receiving ACE inhibitors. Patients who cannot tolerate ACE inhibitors because of worsening renal function or hyperkalemia are likely to experience similar side effects with ARBs.

Another potential use of ARBs for the management of CHF is to counteract the attenuation of the benefits of ACE inhibition that may occur with time, a phenomenon often referred to as *ACE escape*. After long-term (1 year) ACE inhibition, plasma AII levels rise above initial values and LV antiremodeling and the decrease in norepinephrine levels effects attenuate.[75-77] Whether this is due to ACE inhibition becoming partial with time or whether AII is generated via pathways other than the converting enzyme is controversial.[78] Independent of the underlying mechanisms that mediate ACE escape, the addition of ARB to ACE inhibition negates the detrimental effects of elevated levels of tissue and circulating angiotensin.[79]

Several experimental and small studies have clearly demonstrated the added benefits of combined ARB and ACE inhibition on LV performance, functional capacity, and safety.[80-84] The safety of combining ARB and ACE inhibition has been well documented in the Valsartan Heart Failure Trial (Val-HeFT), which has safely randomized 4000 patients treated with adequate doses of ACE inhibitors to 320 mg daily of valsartan or to placebo. The results of Val-HeFT are not yet known, but enrollment and maintenance into the trial

were uneventful. The addition of ARBs to ACE inhibitors is extremely well tolerated even in patients who do not tolerate high doses of ACE inhibitors because of symptomatic hypotension.[82] This may be explained by the fact that ARBs are specific vasodilators that lower vascular resistance primarily to essential organs such as the heart, brain, and kidneys. In contrast, as a result of the concomitant increases in kinin levels, ACE inhibitors are also nonspecific vasodilators that lower vascular resistance to cutaneous tissues and splanchnic beds.[85] In addition, ARBs are associated with a greater improvement in plasma fibrinolytic parameters than that achieved by ACE inhibitors.[86] Whether the beneficial effects of combined ARB and ACE inhibition on functional capacity and LV performance and dimensions will translate into added benefits in life expectancy over those provided by ACE inhibition alone is being evaluated in the Val-HeFT trial with valsartan and the CHARM trial with candesartan.

Other Vasodilators

Vasodilator agents may be used as adjunctive therapy in the management of heart failure. The combination of hydralazine and isosorbide dinitrate is an alternative therapy when ACE inhibitors are contraindicated or cannot be tolerated. Daily doses of hydralazine up to 300 mg in combination with isosorbide dinitrate 160 mg in the presence of cardiac glycosides and diuretics probably have some effect in reducing mortality in patients with chronic heart failure but not in reducing hospitalization for heart failure.[87] At these doses, the combination increased exercise performance more than enalapril did.[61] The effects of hydralazine and nitrates, alone or in combination, when added to ACE inhibitors are unknown. There is no evidence of proven benefit when either nitrates or hydralazine is used alone, but nitrates often are prescribed without hydralazine. Nitrates also may be used effectively for the treatment of concomitant angina. Early development of hemodynamic tolerance (tachyphylaxis) to nitrates may occur with frequent dosing (every 4 to 6 h) but is less with intervals of 8 to 12 h[88] or in conjunction with ACE inhibition. Also, hemodynamic tolerance may be less during coadministration with hydralazine.[89]

Prostacyclin, which is a potent systemic vasodilator used in the treatment of primary pulmonary hypertension, has not been shown to improve mortality outcomes in patients with heart failure despite improvements in hemodynamics. Similarly, alpha blockers, despite their potent vasodilatory activity, have not shown benefit in patients with chronic heart failure; this probably is related to hemodynamic tolerance with prolonged drug treatment.

Calcium Antagonists

Calcium antagonists are not recommended for the treatment of CHF because of their negative inotropic effects. However, second-generation dihydropyridine-type calcium antagonists such as amlodipine and felodipine may be considered for the treatment of concomitant arterial hypertension or angina. Some second-generation calcium antagonists are still under investigation with respect to their long-term effect on mortality in chronic heart failure, in addition to baseline therapy including ACE inhibition. Preliminary data indicate either no effect[90] or a positive outcome in restricted patient populations, i.e., in patients with idiopathic dilated cardiomyopathy.[91] Although in these studies the second-generation dihydropyridine agents evaluated appeared to be safe and seemed not to increase mortality, there are no reasons to recommend these agents for the treatment of heart failure caused by systolic dysfunction; rather, they can be recommended as adjunctive medication for ischemia. As a result of the potential benefits noted below, however, beta blockers should be preferable to calcium blockers for patients with CHF and ischemia.

A study is in progress evaluating the dihydropyridine agent amlodipine as an adjunctive therapy for patients with congestive cardiomyopathy. Similarly, the selective T-channel calcium antagonist mibefradil, a drug that has no apparent effect on myocardial function,[92] has been studied. No beneficial effects of mibefradil on survival were demonstrated in patients with heart failure, and unfavorable drug-drug interactions, especially with amiodarone, led to the withdrawal of mibefradil from the market.[93] The use of calcium blockers in patients with diastolic dysfunction (e.g., verapamil) has been reported, but there are no long-term outcome studies with this form of treatment. The use of verapamil in the treatment of patients with hypertrophic cardiomyopathy has been well defined.[92]

BETA-ADRENERGIC BLOCKADE

In view of the marked benefits afforded by beta-adrenergic blockade in patients with heart failure after a myocardial infarction, beta-adrenergic blockade was advocated 25 years ago by Waagstein and colleagues for the treatment of patients with dilated cardiomyopathies.[94] In the BHAT trial, in which propranolol was begun 7 to 21 days after an acute MI and continued for 24 months, 5 lives per 100 were saved when heart failure was present, and only 2 lives when heart failure was absent.[95] Just as the use of ACE inhibitors in patients with CHF did not become widely accepted until the positive results of large survival trials such as CONSENSUS I, SOLVD, and V-HeFT II were known, the use of beta-blocking agents did not gain broad acceptance until large survival trials demonstrated the benefits of beta-adrenergic blockade on survival in patients with CHF.[96,97] The Cardiac Insufficiency Bisoprolol Study II (CIBIS II) evaluated the effects of bisoprolol, a $beta_1$ -selective adrenergic blocker, on mortality from all causes in patients with CHF treated with standard medical regimens, including ACE inhibitors.[98] This multicenter placebo-controlled trial was conducted in Europe and enrolled 2647 patients with CHF characterized by functional class III-IV according to the NYHA and an LV ejection fraction <40 percent. Treated patients received up to 10 mg of bisoprolol. The trial was discontinued prematurely because mortality from all causes was significantly lower in the bisoprolol group than it was in the placebo group. Of the 1320 patients receiving bisoprolol, 156 died; of the 1327 patients randomized to placebo, 228 died. The estimated annual mortality rate was 8.8 percent in the bisoprolol group and 13.2 percent in the placebo group (hazard ratio, 0.66; 95 percent CI, 0.54-0.81 percent). The most common dose of bisoprolol was 10 mg in 564 patients, followed by 5 mg in 176 patients and 7.5 mg in 152 patients. Sudden death and hospitalization for worsening CHF were 42 percent and 32 percent lower in patients randomized to bisoprolol, respectively. In summary, in a trial that did not include a run-in period and thus did not select patients who tolerated beta-adrenergic blockade, bisoprolol lowered the risk of mortality from all causes by 32 percent. Bisoprolol was equally efficacious in patients with ischemic cardiomyopathy and patients in functional classes II and IV. However, in view of the overall low mortality rate of patients randomized to placebo, one may question how many patients were really in functional class IV before prerandomization.

In the Metoprolol CR/XL Randomised Intervention Trial (MERIT-HF), the effects of a controlled-release/extendedrelease formulation of metoprolol (CR/XL) on mortality was studied in patients with CHF treated with a standard medical regimen, including ACE inhibitors.[99] The 3991 patients with LV ejection fractions <40 and functional class II-IV were randomized to metoprolol (target dose 200 mg) for 2 months or to placebo after a 2-week single-blind placebo period. The study was terminated prematurely on the recommendation of the safety committee after a mean follow-up of 12 months. One hundred forty-five of the 1990 patients randomized to metoprolol died, and 217 of the 2001 patients randomized to placebo died ($p = .0062$). The mortality rates were 7.2 percent and 22 percent per patient-year of follow-up, respectively, with a relative risk of 0.66 (95 percent CI, 0.53-0.81 percent). Sudden death and death from aggravated heart failure were less frequent among treated patients: 79 versus 132, 0.59 (0.45-0.78), $p < .0002$, and 30 versus 58, 0.51 (0.33-0.79), $p = .0023$. The mean daily dose of metoprolol was 159 mg, with 87 percent of patients receiving more than 100 mg and 64 percent receiving the target dose of 200 mg. In summary, as demonstrated with bisoprolol, metoprolol CR/XL lowered mortality from all causes by 34 percent in patients with CHF already treated with ACE inhibitors and diuretics. As was noted in the CIBIS II trial, most of the patients enrolled in the MERIT-HF trial had moderate CHF, as evidenced by the low mortality of patients in the placebo group. Few patients in functional class IV participated in MERIT-HF. Thus, too few patients in functional class IV were randomized to active therapy in both the CIBIS II and MERIT-HF trials to assess the safety and efficacy of bisoprolol and metoprolol in this population. Both the CIBIS II and MERIT-HF trials demonstrated that mortality from all causes can be reduced by a selective $beta_1$-adrenergic agent in patients with mild to moderate CHF. Metoprolol is about 80-fold more selective for the human $beta_1$ than for the $beta_2$ receptor, and bisoprolol is approximately 120-fold more selective.[100]

While both $beta_1$ and $beta_2$ receptors are present in the normal human myocardium, $beta_2$ receptors predominate in the human failing myocardium, since $beta_1$ receptors are downregulated.[101] Thus, selection of a nonselective beta-blocking agent may seem preferable when the therapeutic aim is to protect the heart from beta-adrenergic stimulation. In the United States, most of the experience in treating patients with beta-adrenergic blockers has been gained with nonselective agents such as carvedilol and bucindolol. In addition to being a nonselective beta-adrenergic blocker, carvedilol has alpha-blocking and antioxidant properties, while bucindolol has direct vasodilating properties.[102]

Carvedilol is the only beta blocker currently approved by the FDA for the treatment of patients with

CHF.[102] Since a long-term survival trial has not been conducted with carvedilol, its approved use is for delaying the progression of myocardial disease and heart failure. The U.S. Carvedilol Program was composed of four trials and was stopped prematurely by the safety committee because of a highly significant reduction in mortality in treated patients (65 percent, $p < .0001$) compared with placebo.[102-107] The four trials were the Multicenter Oral Carvedilol in Heart Failure Assessment (MOCHA), the Prospective Randomized Evaluation of Carvedilol in Symptoms and Exercise (PRECISE), and the "mild" and "severe" heart failure trials.[103-106] The intended duration of these trials was 6 months. The primary end points were submaximal exercise for the MOCHA and PRECISE trials; a composite end point of death, reduction in cardiovascular hospitalizations, and a need to increase heart failure medications for the "mild" heart failure trial; and quality-of-life evaluation for the "severe" heart failure trial. The MOCHA and PRECISE trials had completed enrollment by the time the program was interrupted. Whereas primary end points were not reached expect in the "mild" heart failure trial, the average LV ejection fraction increased substantially in patients randomized to carvedilol in all the trials, while LV ejection fraction remained unaltered in patients randomized to placebo.[103-106] The improvement in LV ejection fraction was noted in patients who were already receiving optimal standard therapy, including ACE inhibitors. A dose-related reduction in mortality and enhancement of LV ejection fraction was noted in the MOCHA trial.[103] Cardiovascular hospitalizations were fewer and symptoms were alleviated in patients randomized to carvedilol in the PRECISE trials.[104] Lastly, global heart failure assessments were improved in patients randomized to carvedilol in the "severe" heart failure trial.[106] Thus, although the primary end points were different, the carvedilol trials demonstrated substantial reduction in mortality and dose-dependent improvement in the ejection fraction. This improvement was present in both ischemic and nonischemic cardiomyopathies, although it was greater in the latter group.

The Australia-New Zealand (ANZ) trial included an initial phase of 6 months and a longer phase with an average follow-up of 19 months.[108] Submaximal exercise, the end point of the initial phase, remained unchanged in patients randomized to carvedilol. During the second phase of the ANZ trial, fewer patients randomized to carvedilol died or were hospitalized.

The effects of beta-adrenergic blockade on LV function and dimensions are unique. No other pharmacologic intervention has been shown to reverse LV remodeling and improve LV ejection fraction so consistently in patients with CHF caused by LV systolic dysfunction. In all clinical trials in which patients received beta-blocking agents for at least 3 months, LV ejection fraction increased.[102] Long-term administration of selective and nonselective beta-blocking agents increases LV ejection fraction consistently to a much greater extent than is achieved by vasodilator therapy. The long-term benefits of beta-adrenergic blockade on LV performance are in contrast with the deterioration that may be observed initially. The time course of the effects of beta-adrenergic blockade includes an initial reduction in LV ejection fraction during the first weeks of treatment, a return to the initial ejection fraction at 4 weeks, and a substantial increase ranging from 5 to 10 absolute units at 3 months.[109] Thereafter, from 4 to 12 months, LV end-systolic and end-diastolic volumes and mass steadily decrease, a phenomenon often referred to as *reversed remodeling*.[110] Reversal of LV remodeling has been documented with carvedilol at 12 months in a substudy of the ANZ trial.[111] At 1 year, LV ejection fraction was greater and LV end-diastolic volume index was 14 mL/m^2 smaller in patients randomized to carvedilol than was the case in patients randomized to placebo.[111]

Not every patient benefits from long-term adrenergic blockade. In those who benefit, the rise in ejection fraction averages 10 percent. Increases in LV ejection fraction up to 15 to 20 percent with a normalization of LV volumes have been observed in individual patients. Systolic blood pressure and myocardial contractility, as evaluated by LV maximal rate of rise of pressure (dp/dt), are predictors of the response to long-term beta-adrenergic blockade in terms of LV ejection fraction.[112] The higher systolic blood pressure and LV dp/dt are, the more likely the ejection fraction is to increase during long-term beta-adrenergic blockade. Thus, patients with mild to moderate CHF and LV systolic dysfunction are the optimal candidates for beta-adrenergic blockade. Conversely, beta-adrenergic blockade is unlikely to benefit, and at present is not recommended for, patients in functional class IV with extremely reduced ejection fractions. Despite the fact that patients in functional class IV are the least likely to benefit from long-term beta-adrenergic blockade, they are the most likely to decompensate at the initiation of therapy as a result of their lack of cardiac reserve. Exacerbation of LV dysfunction at the initiation of therapy often leads to worsening CHF and hospitalization. The Beta Blocker Estimation of Survival Trial (BEST), a large randomized, placebo-controlled study of the effect of bucindolol, a third-generation beta-adrenergic blocking agent with

direct vasodilating properties, on the survival of 2708 patients with NYHA functional class III and IV, was stopped because of the lack of benefit seen. A preliminary report indicates that whereas bucindolol reduced mortality in patients in functional class III, it did not do so in patients in functional class IV.

The long-term and acute effects of beta-adrenergic blockade on LV performance have important therapeutic and pathophysiologic implications. First, the deterioration in LV performance that is observed routinely during the first weeks of therapy mandates that beta-adrenergic blockade be initiated at the lowest dose possible of a given agent in stable patients with CHF. Since beta-adrenergic blockade is aimed at altering the progression of the syndrome of CHF and not at providing acute relief of symptoms, effective beta blockade can be reached progressively by increasing doses of beta blocker agents every 2 to 3 weeks. When CHF is associated with angina or excessive tachycardia and effective beta blockade is needed for control of symptoms, the doses of beta blockers can be increased every few days under close in-hospital monitoring. An important unresolved issue concerning beta-adrenergic blockade in CHF is the treatment of patients whose symptoms worsen to functional class IV while they are being treated with beta-blocking agents. No data are available to provide guidelines to manage these patients. A pragmatic approach is to hospitalize patients who decompensate while receiving beta blockade and treat them with temporary inotropic support with a specific phosphodiesterase inhibitor, such as milrinone, which does not require beta receptors for its activity. Patients who improve are kept on a beta-adrenergic blocker, and inotropic support is discontinued after a few days. Beta-adrenergic blockade should be tapered off and withdrawn in patients who fail to improve. The pathophysiologic implication of successful beta-adrenergic blockade is that the process of LV dysfunction can be reversed by pharmacologic means even in patients with markedly reduced LV function. Thus, a certain amount of plasticity that was previously unrecognized remains in dilated fibrotic left ventricles. The cellular and molecular mechanisms that reverse myocyte dysfunction, thereby enhancing global LV performance, are poorly understood (Table 21-2). Since patients with both ischemic and nonischemic cardiomyopathy benefit from long-term beta-adrenergic blockade, dysfunction of surviving myocytes is a common characteristic of CHF independent of its etiology.[113] Patients with nonischemic cardiomyopathy were initially thought to experience greater benefit from long-term beta blockade compared with patients with ischemic cardiomyopathy. Since it is practically impossible to compare patients with different etiologies of CHF at a similar stage of their disease process, definite conclusions concerning the effects of long-term beta-adrenergic blockade as a function of the etiology probably should not be drawn.

Table 21-2: Possible Mechanisms by Which Beta-Adrenergic Blockers Improve Ventricular Function in Chronic Congestive Heart Failure

1. Upregulation of beta receptors
2. Direct myocardial protective action against catecholamine toxicity
3. Improved ability of noradrenergic sympathetic nerves to synthesize norepinephrine
4. Decreased release of norepinephrine from sympathetic nerve endings
5. Decreased stimulation of other vasoconstrictive systems, including renin-angiotensin-aldosterone, vasopression, and endothelin
6. Potentiation of kalikrein-kinin system and natural vasodilatation (increase in bradykinin)
7. Antiarrhythmic effects raising ventricular fibrillation threshold
8. Protection against catecholamine-induced hypokalemia
9. Increase in coronary blood flow by reducing heart rate and improving diastolic perfusion time; possible coronary dilation with vasodilator-beta blocker
10. Restoration of abnormal baroreflex function
11. Prevention of ventricular muscle hypertrophy and vascular remodeling
12. Antioxidant effects (carvedilol?)
13. Shift from free fatty acid to carbohydrate metabolism (improved metabolic efficiency)
14. Vasodilation (e.g., bucindolol, carvedilol)
15. Antiapoptosis effect
16. Improved left atrial contribution to left ventricular filling

---

The selection of a beta-adrenergic blocker for the treatment of CHF is at the present time somewhat academic, since carvedilol is the only beta blocker approved by the FDA for this indication in the United

States. The rationale for selecting a nonselective agent over a selective beta$_1$ antagonist has been mentioned previously. Studies comparing a selective versus a nonselective agent are few and have enrolled small numbers of patients. Their results are controversial. In a 6-month study of 67 patients randomized to carvedilol or metoprolol, Kukin and associates demonstrated no significant difference between these agents.[114] In contrast, carvedilol was reported to enhance LV function and reverse LVE remodeling in patients with dilated cardiomyopathy who were failing metoprolol therapy.[115] Similarly, compared with metoprolol, carvedilol was found by Gilbert and colleagues to produce greater improvement in functional class and LV performance in patients with idiopathic dilated cardiomyopathy.[116] Lastly, the antioxidant properties of carvedilol were recently documented in vivo by demonstrating an inhibition of reactive oxygen species generation by leukocytes.[117] The clinical relevance of the antioxidant action of carvedilol remains to be determined in patients with CHF. A large trial comparing the respective benefits of carvedilol and metoprolol in patients with CHF is under way [Carvedilol or Metoprolol Evaluation Trial (COMET)]. Whether enough events will occur in the patients enrolled in the COMET trial to detect a meaningful difference between these agents is uncertain. In addition, a trial is in place [Carvedilol Prospective Randomized Cumulative Survival Trial (COPERNICUS)] that is examining the effects of carvedilol in class IV patients.

In summary, in the absence of an indication such as reversible airways obstructive disease, advanced heart block, or episodic decompensation, all symptomatic patients with CHF, except those in functional class IV, should be treated with long-term beta-adrenergic blockade.[3,101,102] Treatment should be initiated at the lowest possible dose and advanced to full beta blockade over 1 to 2 months as tolerated. Patients who do not tolerate the full dose should be kept on intermediate doses that still result in substantial improvement in LV function and a reduction in mortality.[102] Beta-adrenergic blockade is the only pharmacologic intervention that reverses LV remodeling, whereas ACE inhibition is the only intervention that improves the vascular processes. Thus, beta-adrenergic blockade is not an exclusive intervention but a complementary intervention. Both ACE inhibition and beta-adrenergic blockade are essential interventions for the treatment of CHF.

DIURETICS

Sodium accumulation tends to occur in the early stages of CHF, with peripheral edema accompanied by weight gain. Diuretics, along with salt restriction, remain the best therapeutic tool for treating the edematous state in heart failure. Despite the advent of new agents for treating symptomatic CHF, diuretics continue to be among the most commonly prescribed drugs in the world.

The mechanism for edema is generally multifactorial and includes renal vasoconstriction, increased aldosterone and vasopressin activity, and/or increased venous pressures. Increased sympathetic nervous system activity (tone) tends to occur early in the course of heart failure. Activation of the renin-angiotensin axis tends to occur somewhat later, commonly when diuretics are begun.[39] This leads to increased aldosterone, leading to sodium accumulation and potassium loss. Even with asymptomatic LV dysfunction, avidity of the kidneys for sodium and water is enhanced greatly, and peripheral edema constitutes an early physical sign that brings the problem of CHF to the physician's attention. Salt and water retention leads to an expanded intravascular volume, with an increase in LV filling pressures to maintain cardiac output.[118] With continued worsening of LV function, progressive volume expansion continues and LV end-diastolic pressure rises along with venous hydrostatic pressure in both the systemic and pulmonary beds. This alteration in Starling forces favors transudation of intravascular fluid into the interstitial compartment, culminating in edema formation.[119] Eventually a point is reached at which additional increases in LV filling pressure fail to augment cardiac output, and with progressive increases in peripheral arterial vasoconstriction, renal perfusion is reduced. By this time, overt heart failure is established, and the kidney's ability to excrete a salt load is severely impaired.[118] Important mediators in this process are (1) activation of the renin-angiotensin-aldosterone axis, (2) stimulation of the sympathetic nervous system, (3) increased levels of antidiuretic hormone leading to water retention and hyponatremia, and (4) resistance to atrial natriuretic peptide (ANP), which is an endogenous hormonal vasodilator and diuretic.

The appropriate use of diuretics depends on the stage of disease and severity. With mild fluid accumulation characterized by peripheral edema, pulmonary rales, and weight gain, oral diuretics are indicated. Long-acting but less potent diuretics, such as hydrochlorothiazide and chlorthalidone, may be adequate. Intermittent use of more potent loop diuretics, such as furosemide, bumetanide, and torsemide, may allow

one to regain dry weight more rapidly. Efficacy can be assessed by daily weights, and diuretic regimens can be adjusted appropriately.

Loop Diuretics

The most potent diuretics are those whose action occurs in the medullary thick ascending limb of Henle because of the percentage of filtrate reabsorption that occurs at this segment of the nephron. In the euvolemic state, about 20 percent of filtered sodium load is reabsorbed in the thick ascending limb, compared with only 7 percent in the distal tubule and 5 percent in the collecting duct.[120] Drugs in this diuretic class include furosemide, bumetanide, torsemide, and ethacrynic acid. The loop diuretics are more than 98 percent protein-bound and therefore are not freely filtered by the glomerulus. Rather, they access the tubular lumen, where they act by secretion via an organic anion transporter.[121] This secretion of loop diuretic may be impaired and their action may be limited by the presence of elevated levels of endogenous organic acids, as occurs in renal failure, and by probenecid, salicylates, and NSAIDs. Once in the lumen of the tubule, the loop diuretics compete with chloride for binding to the $Na^+/K^+/2Cl$ contransporter situated on the apical membrane of cells of the medullary thick ascending limb, thus inhibiting the reabsorption of both sodium and chloride.[122] The urinary diuretic concentration best represents the fraction of drug delivered to the thick ascending limb and significantly correlates with the natriuretic response after diuretic administration.[123]

Furosemide is the most widely used loop diuretic. In normal patients, the oral bioavailability of furosemide is 50 percent. After an oral dose, the onset of action occurs within 30 to 60 min, peaks at 1 to 2 h, and has a duration of action of 6 h, with a half-life of 50 min.[121,124] Furosemide may be given intravenously over 1 to 2 min; after intravenous administration, diuresis begins within 15 min and peaks at 30 to 60 min. The duration of action is up to 2 h when the drug is given intravenously. Sixty percent of furosemide is excreted unchanged in the urine; the rest is conjugated with glucuronic acid in the kidney.[121,124] In renal insufficiency [glomerular filtration rate (GFR) >30 mL/min)], the elimination half-life is prolonged, although the diuretic response is impaired, largely owing to reduced drug delivery to its site of action within the tubule.[125]

In CHF, the pharmacokinetics of oral furosemide are also altered; furosemide absorption is delayed, which leads to a delay in the time at which peak concentration occurs.[123] Altered pharmacodynamic properties of furosemide occur independent of the route of administration, resulting from adaptations within the glomerular microcirculation and renal tubule that are present during chronic diuretic administration.[123] Bumetanide is 40 times more potent than furosemide and is available in both oral and intravenous formulations. In normal patients, the bioavailability is 80 percent after an oral dose, and the onset of diuretic effect occurs within 30 min and peaks within 1 h. The duration of action of oral bumetanide is between 3 and 6 h, with a half-life between 1 and 3.5 h.[124,126] Similar to furosemide, the delayed absorption of oral bumetanide in heart failure results in lower peak concentrations as well as a delayed time to peak concentration.

Torsemide is a newer loop diuretic that differs from others in its class in that 80 percent of a dose undergoes hepatic metabolism. Because only 20 percent of the drug is excreted unchanged in the urine, its half-life is altered minimally in renal failure.[127] Torsemide is absorbed rapidly and is 80 to 90 percent bioavailable. In patients with chronic renal insufficiency or with cirrhosis, the natriuretic response after torsemide is unaffected by the route of administration.[128] Maximal sodium excretion occurs within the first 2 h after either routine. In healthy individuals, the half-life of torsemide is 3.3 h, but it is prolonged to 8 h in cirrhosis.[127,129] When selecting an oral agent in patients with heart failure, the physician may find oral torsemide to be advantageous since its absorption is unimpaired and is less variable than that of oral furosemide.[130] In fact, the pharmacokinetics of torsemide in CHF patients are comparable to those in normal persons. As is the case with all loop diuretics, however, dose-response curves for torsemide in patients with CHF are shifted downward and to the right, suggesting altered drug pharmacodynamics and a diminished diuretic response. The efficacy of loop diuretics often is reduced significantly in patients with decompensated heart failure. Impaired drug absorption has been implicated as one cause of variable efficacy. Reduced gastric and intestinal motility, an edematous bowel wall, and decreased splanchnic blood flow may delay absorption. The total amount of furosemide absorbed over 24 h, however, is similar to that found in normal individuals.[131-133]

In patients with stable, compensated heart failure who are given oral furosemide, the time to peak urinary excretion is prolonged to about 190 min (normal, 90 min) and peak urinary excretion rate is reduced by 50 percent.[123] Furosemide and bumetanide, when given in doses of equivalent potency, induce a similar natriuretic response in patients with heart failure.[123] The pharmacokinetic properties of intravenous furosemide are unaltered in heart failure patients compared with normal individuals.[134]

The effectiveness of loop diuretics is limited by two phenomena in patients with chronic heart failure and normal renal function. The *rebound phenomenon* consists of a decrease in sodium excretion below baseline after the effect of the loop diuretic has worn off. The *braking phenomenon* refers to an increase in tubular sodium reabsorption by the distal tubule that occurs during long-term administration of loop diuretics.

In decompensated heart failure, the intravenous route of administration is preferable when possible, since the onset of diuresis is shorter and more predictable (Fig. 21-7). In patients with CHF that is refractory to standard doses of intravenous furosemide, higher doses may be efficacious. In 20 patients with severe CHF that was previously resistant to lower intravenous doses of furosemide,[135] intravenous furosemide was administered at doses of 500 to 2000 mg daily for a mean of 10 days, with increased diuresis, weight reduction, and symptomatic improvement. Other investigators observed a similar clinical improvement, as assessed by NYHA classification criteria, in 17 of 21 patients using high-dose oral furosemide (>500 mg daily) for 1 month.[136]

Continuous intravenous rather than intermittent administration of loop diuretics is an effective method of overcoming diuretic resistance in heart failure. In a randomized crossover study comparing continuous versus bolus bumetanide in patients with chronic renal failure (mean GFR, 17 mL/min), a greater net sodium excretion was observed during continuous infusion despite comparable drug excretion.[137] In CHF, continuous infusion of furosemide produces a similar natriuresis at serum concentrations 20 times lower than those after a comparable effective bolus dose.[138] Only one prospective, randomized crossover study is available that compares the continuous infusion of furosemide (loading dose 30 to 40 mg followed by infusion at a rate of 2.5 to 3.3 mg/h for 48 h) with intermittent intravenous bolus administration (30 to 40 mg every 8 h for 48 h) in NYHA class III and IV heart failure.[139] When it was infused continuously, furosemide's pattern of delivery produced more effective drug utilization, that is, sodium excretion relative to total furosemide excretion, whereas with intermittent bolus furosemide, wide fluctuations in urine output and sodium excretion were observed. Theoretically, an infusion of furosemide at a constant rate may be safe than using intermittent intravenous dosing, although a larger study is needed to confirm this.[140]

In summary, loop diuretics with salt restriction monitored by weight measurement by scale remain the basis for the treatment of edema. As CHF progresses, increasing oral doses of loop diuretics tend to be needed. In severe CHF with hospitalization, intravenous loop diuretics, commonly at higher doses, become essential. As will be discussed below, other agents, such as metolazone, may be required as well to increase and sustain sodium loss. Limitations to diuretic use remain hyponatremia and a progressive increase in serum creatinine, which may require careful dose reductions (Table 21-3).

Table 21-3: Stepwise Approach to Loop Diuretic Resistance

1. Enforcement of strict low-sodium diet
2. Use of effective doses of loop diuretics
3. Combination administration of long-acting thiazide with loop diuretic to offset the antinatriuretic rebound effect observed after administration of short-acting loop diuretics
4. Constant intravenous infusion of loop diuretic

Thiazides

The thiazide diuretics may be reasonable first-line natriuretic agents in early LV dysfunction when renal perfusion is not yet significantly compromised. In overt ventricular failure, however, thiazides are usually ineffective or inadequate. Thiazides are 50 percent protein-bound, and more than 95 percent of the dose is

excreted unchanged in the urine.[124] They gain access into the tubular lumen through both glomerular filtration and tubular secretion. In the kidney, they inhibit sodium chloride reabsorption in the early distal tubule, where they compete for the chloride site on the apically located Na^+/Cl cotransporter.[141,142]

Hydrochlorothiazide is the most widely prescribed drug in this class of diuretics. Seventy-one percent of an oral dose is absorbed. The onset of diuresis occurs within 2 h, peaks between 3 and 6 h, and continues for up to 12 h.[124] Hydrochlorothiazide's pharmacokinetics follow a two-compartment model of elimination (α phase, 5 h; β phase, 6 to 15 h), and the half-life is prolonged in patients with decompensated heart failure and those with renal insufficiency.

Metolazone is a quinazoline diuretic and is similar to the thiazides in structure and mechanism of action.[124,143] Although its major effect occurs in the cortical diluting segment, metolazone has a minor inhibitory effect on proximal tubular sodium reabsorption. Metolazone is lipid-soluble and easily accesses the tubular lumen during states of renal insufficiency, unlike the thiazides.[144] Another advantage of metolazone is its longer duration of action (12 to 24 h).[124,143]

Potassium-Sparing Diuretics

Aldosterone, an endogenous adrenal hormone, normally increases sodium reabsorption with the simultaneous excretion of potassium. Aldosterone levels are increased in heart failure, to some degree because of its augmented secretion induced by angiotensin II. In heart failure, an increase in aldosterone activity may cause significant sodium retention, potassium depletion, and magnesium depletion. Increased aldosterone activity also can be harmful by causing an augmentation of sympathetic stimulation and a decreased activity of the parasympathetic nervous system, thus contributing to baroreflex dysfunction, a poor prognostic finding in patients with heart failure. Aldosterone also may promote the formation of patchy myocardial fibrosis, leading to arrhythmias and further depression of LV dysfunction.

Spironolactone, a lipid-soluble potassium-sparing diuretic, competes with aldosterone for binding to its receptor in the principal cell of the collecting duct and thus leads to diuresis.[124] Spironolactone is particularly advantageous during states of reduced renal perfusion because its delivery to its site of action is not dependent on GFR. Spironolactone may be a useful adjunct to hydrochlorothiazide in offsetting its effect of producing hypokalemia resulting from sodium-potassium exchange. Since the exchange of sodium for potassium is reduced, potassium loss is reduced and hypokalemia may be corrected. Indeed, potassium supplements given for hypokalemia generally should be stopped to avoid hyperkalemia. If the use of spironolactone is warranted in a severe heart failure patient receiving an ACE inhibitor, therapy may be initiated at a dose of 25 mg a day. Because of the risk of hyperkalemia, serum potassium concentration should be monitored closely not only during concomitant therapy with ACE inhibitors or AII receptor blockers but also during periods of declining renal function. If the serum potassium concentration exceeds 5.5 meq/L, the spironolactone dose should be reduced to 25 mg every other day. Alternatively, after 8 weeks, the spironolactone dose may be increased to 50 mg a day in patients with stable serum potassium concentrations who are experiencing worsening heart failure symptoms. Maintenance doses of 50 mg a day or greater should be limited to patients with refractory or severe heart failure who have evidence of pulmonary or peripheral edema caused by an increased incidence of hyperkalemia. In this particular patient population, however, doses as high as 200 mg a day may be necessary. However, once a patient's condition has stabilized, the dose of spironolactone should be decreased to the maintenance level (25 to 50 mg a day) used before the heart failure exacerbation.[145]

The use of spironolactone also has been associated with reduced mortality in CHF, perhaps by helping to maintain potassium levels, thus reducing the risk of arrhythmic death in patients with heart failure,[146] or by inhibiting other pathologic processes influenced by aldosterone.[147] Spironolactone also has been shown to improve endothelial dysfunction, increase nitric oxide bioactivity, and inhibit the conversion of angiotensin I to angiotensin II, providing additional mechanisms for its beneficial effects on cardiovascular mortality.[148]

Amiloride and triamterene are similar to spironolactone in that they are potassium-sparing and act on the principal cell; however, they must be delivered intralumenally to be effective. More specifically, they reduce sodium flux into principal cells by blocking the apically located sodium channel.[124] When used

alone, the potassium-sparing diuretics are relatively weak. In heart failure, they are useful when used in combination with a loop diuretic to overcome diuretic resistance and reduce potassium wasting.[149]

Combined Use of Diuretics

Numerous reports have demonstrated a rapid, profound diuresis (1 to 2 L daily within 24 to 48 h), accompanied by clinical improvement, after the addition of metolazone to furosemide in patients with CHF (Fig. 21-7) who were previously resistant to furosemide alone.[150-157] Metolazone, a thiazide-like diuretic, is particularly advantageous since it has a prolonged duration of action, is lipophilic, and remains effective in states of renal impairment. In a study comparing metolazone with a thiazide, however, when either was used in combination with a loop diuretic, no significant difference in sodium excretion or urine output was observed between the two drugs.[157] Spironolactone, when used in combination with a loop diuretic (Fig. 21-7), also has been associated with an improvement in diuretic response in patients with CHF previously resistant to loop diuretics.[149]

In summary, thiazides, potassium-sparing diuretics, and aldosterone inhibitors (e.g., spironolactone), along with loop diuretics, provide potent tools to reduce salt accumulation in CHF. Early in CHF, their use is mainly to reduce or eliminate peripheral edema and help relieve pulmonary congestion. Once dry weight is approximated, intermittent and reduced diuretic use is advisable to avoid electrolyte problems. Daily weights are the best guide to the adequacy of this therapy. Early in CHF, thiazides with potassium-sparing diuretics may be all that is necessary, although loop diuretics provide increased diuresis. Indeed, loop diuretics can be used intermittently on top of thiazides when needed. It is possible that the early use of diuretics can hasten the evolution of CHF by increasing reflex neurohumoral responses that may have adverse consequences, such as activation of the renin-angiotensin system.[39] As CHF progresses, the loop diuretics in increasing amounts are generally required. Here again, a scale for weight provides guidance for the dose. With excessive diuresis in very severe CHF, increasing renal insufficiency may be induced by hypovolemia, and this in itself may increase loop diuretic dose, its used intravenously, and the need for the concomitant use of thiazides (metolazone) or spironolactone.

INOTROPIC AGENTS

The use of inotropic agents in the treatment of CHF is predicated on the finding that a major contributing factor in reducing ventricular performance results from depression of myocardial contractility and that this can be reversed, or at least improved, by inotropic drugs. The fact that there is reduced myocardial contractility in failing heart muscle, whether from a sustained work overload of pressure or in response to losing myocardium, has been well demonstrated and appears to be due largely to inadequate Ca^{2+} availability for activation. All currently available inotropic agents act to increase Ca^{2+} for activation in both normal and failing myocardium. This is the case whether the mechanism of action is via cyclic AMP system excitation (e.g., catecholamines) or occurs by sarcolemmal Na^{+}-K^{+}-ATPase inhibition (e.g., digitalis glycosides). The problem remains whether this increase in intracellular Ca^{2+} can benefit pump function while doing no harm, such as enhancing the propensity for arrhythmia or theoretically producing further myocyte loss. Moreover, agents that reduce afterload may enhance ventricular emptying without these potential hazards. In end-stage, severely decompensated CHF, inotropic agents (e.g., dobutamine) may be temporarily lifesaving (Fig. 21-7), and at somewhat earlier stages, they may reduce morbidity (e.g., digitalis glycosides). In earlier stages of CHF, the benefits of inotropic agents may not outweigh the risk, and their use is relegated to later stages in the disease process (Figs. 21-5 and 21-7).

Digitalis Glycosides

Digitalis glycosides have had a long and venerable history in the treatment of CHF and are the only oral inotropic agents available currently for this purpose (Fig. 21-8). In 1785, William Withering[158] reported on his use of the digitalis leaf as a purported diuretic agent to treat anasarca, presumably caused by CHF. Indeed, the major effects of digitalis initially were thought to be on the kidneys, although important effects on heart rate were noted. Only during the latter part of the nineteenth century did it become apparent that there was a direct action of digitalis glycosides to increase cardiac contractility,[159] while in the earlier part of the twentieth century the effects of digitalis on the peripheral circulation and the autonomic nervous system were noted.[160] Despite this long history, the risks and benefits of digitalis administration in patients

with sinus rhythm have remained controversial. The controversy was partially addressed in a large randomized, placebo-controlled clinical trial of digoxin use in CHF.[161] Overall, digoxin was shown to be safe with a significant reduction in morbidity, expressed in terms of less need for hospitalization, but not in mortality. The benefit in terms of hospitalization for heart failure appears greatest in those with lower ejection fractions. As will be discussed later, with serum digoxin levels below 1 μg/mL, the neurohumoral and autocrine effects of digoxin predominate over the inotropic effects.

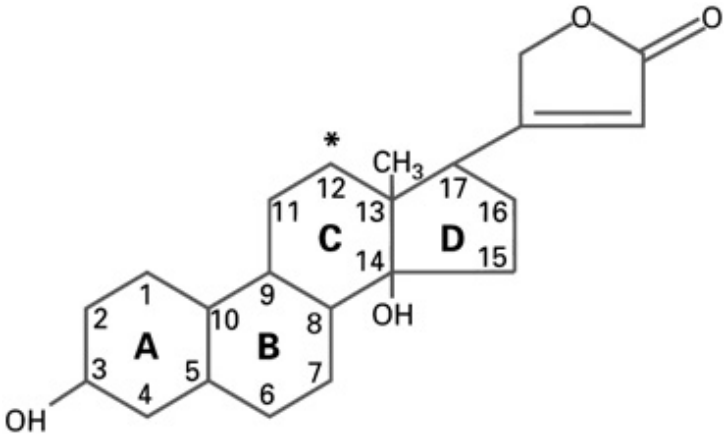

Figure 21-8: Structure of digitalis molecule. * Digitoxin becomes digoxin with OH placement at C_{12}. (From Sonnenblick EH, LeJemtel TH, Frishman WH. Digitalis preparations and other inotropic agents. In: Frishman WH, Sonnenblick EH, eds. *Cardiovascular Pharmacotherapeutics*. New York, McGraw-Hill; 1997:241. Reproduced with permission from the publisher and authors.)

Digitalis glycosides have important effects on multiple systems in addition to augmenting the contractility of the myocardium.[162,163] Electrophysiologically, digitalis glycosides speed conduction in the atrium while inhibiting conduction at the atrioventricular node. This has made them useful for rate control in atrial fibrillation. In the normal circulation, digitalis glycosides also produce generalized arteriolar vasoconstriction while affecting the central nervous system to enhance parasympathetic tone and reduce sympathetic nervous system activation. Digitalis glycosides sensitize baroreflexes to decrease efferent sympathetic activity, which acts to reduce sinus node activity and thus reduce heart rate. The precise mechanism for these effects is unclear. The increase in baroreflex sensitization also increases parasympathetic tone, even in mild heart failure, while central vagal nuclei also are stimulated. The broad enhancement of parasympathetic activity with digitalis glycosides helps explain the sinus heart rate slowing observed after digitalis glycosides even with sinus rhythm as well as their therapeutic efficacy in controlling supraventricular arrhythmias. As is discussed below, in the failing state, the effects of sympathetic withdrawal may be dominant, leading to reduced arterial vascular resistance, while in the normal circulation, arterial vasoconstriction may be dominant. Integration of these various actions adds to the inotropic activity and the therapeutic usefulness of digitalis glycosides.

The positive inotropic action of digitalis glycosides to increase the contractility and alter the electrophysiology of heart muscle occurs through binding to and inhibition of the enzyme Na^+-K^+-ATPase on the surface membrane of myocardial cells, which results in an increase in the cytocyclic Ca^{2+} concentration.[164,165] Na^+-K^+-ATPase is an energy-requiring "sodium pump" that extrudes three Na^+ ions, which enter the cell during depolarization in exchange for two K^+ ions, thus creating an electric current and a negative resting potential.[166] Contraction is initiated with an action potential that depolarizes the surface membrane of the cell. This is created by a rapid inward current of Na^+ into the cell that opens sarcolemmal Ca^{2+} channels, permitting Ca^{2+} to enter the cell. This Ca^{2+} releases substantially more Ca^{2+} from stores in the sarcoplasmic reticulum within the cell, which in turn activates the contractile mechanism by binding to a component of the troponin-tropomyosin system that had been maintaining the resting state. With Ca^{2+} bound to troponin, actin and myosin can interact to produce force and shortening. The greater the amount of activating Ca^{2+}, the greater the force and the shortening.[165,166] When Ca^{2+} is released from troponin and taken up by the sarcoplasmic reticulum, relaxation occurs.[165] The relatively small amount of Ca^{2+} that

enters the cell with activation ultimately is removed by an electrogenic Na^+/Ca^{2+} exchange that extrudes one Ca^{2+} for three Na^+ ions. When intracellular Na^+ is increased, less exchange occurs and the net amount of intracellular Ca^{2+} is increased. Thus, by inhibiting the Na^+-K^+-ATPase, digitalis glycosides produce a decrease in intracellular K^+ and an increase in intracellular Na^+ that increases intracellular Ca^{2+} (Fig. 21-9).[165,166] In general, the main way in which all inotropic agents, including digitalis glycosides, increase contractility is by increasing the amount of Ca^{2+} available for activation.[167] This is the case in both normal and failing myocardium. In the failing heart, there is also a decrease in the Ca^{2+} released into the cytosol with activation.[168,169] Digitalis glycosides increase this intracellular Ca^{2+} that augments Ca^{2+} stores in the sarcoplasmic reticulum, resulting in a subsequent increase in previously reduced myocyte contraction.

Digoxin

Although there are numerous digitalis glycosides with varying durations of action and metabolic fates, digoxin has a relatively rapid onset and an intermediate duration of action. Digoxin has its most beneficial hemodynamic actions when substantial ventricular depression is evident along with CHF. In this circumstance, it augments myocardial performance while reflexly reducing peripheral resistance.[170] Acutely, digoxin also reduces cardiac norepinephrine spillover and reduces efferent sympathetic nerve activity in skeletal muscles in patients with CHF.[170] Slowing of the heart rate, whether via enhanced parasympathetic tone and reduced sympathetic activity to reduce sinus rate or via control of heart rate in atrial fibrillation (as discussed below), greatly benefits ventricular filling and reduces pulmonary congestion.[171] In the treatment of CHF, digoxin generally is employed along with diuretics and vasodilator agents. Thus, by reducing peripheral resistance, digoxin and peripheral vasodilators act in a complementary manner.

In acute heart failure, either caused by massive sudden loss of myocardium, as may occur with a myocardial infarction, or with increasing decompensation in severe chronic CHF, characterized by acute pulmonary edema, severe limitations of cardiac output, and perhaps hypotension, more rapidly acting inotropic agents such as intravenous dobutamine and milrinone (discussed below) may be required (Fig. 21-7), together with loop diuretics and vasodilators. This situation may occur in the setting of rapid deterioration of a patient with more chronic heart failure or after a large myocardial infarction.[172] In this circumstance, the main aim is to increase cardiac output and reduce filling pressures as a setting for longer-term stabilization. While rapidly acting inotropic agents are being used, digitalis may be administered cautiously for its longer-term effects. In the setting of myocardial infarction, the situation is more complex. Because of a fear that arrhythmias may be induced or oxygen consumption may be increased, which might be detrimental, digoxin generally is avoided in the first few days after infarction,[172] although in a longer-term treatment of CHF, digitalis, especially if dosing is carefully controlled, may be of value along with other agents, especially ACE inhibitors.

For chronic CHF, digoxin is of use over the long term when administered in association with loop diuretics and ACE inhibitors. Benefits are most evident in patients with NYHA class III or IV CHF. In this circumstance, the response of the circulation is characterized by a decrease in venous pressures and ventricular filling pressures and an increase in cardiac output. Heart rate is slowed, and the ejection fraction tends to rise, while peripheral resistance falls with little or no change in arterial pressure. These salutary effects are attributed to a combination of augmented myocardial contractility and restoration of baroreceptor sensitivity, which results in enhanced parasympathetic and decreased sympathetic tone. Whereas myocardial oxygen consumption may increase in the normal heart from the increased contractility, in heart failure it tends to be reduced as a result of a decrease in heart size, and thus ventricular wall tension, and a slowing of heart rate. Earlier concepts supported the view that digoxin is of greatest benefit when atrial fibrillation is present and controlled. It is now clear that efficacy is also present when a patient with heart failure is in sinus rhythm.[173] Withdrawal of digoxin from such patients led to rapid deterioration even when both diuretics and ACE inhibitors were used.[174,175] While digoxin has been associated with an increase in the ejection fraction, vasodilators have been shown to cause more significant increments in exercise performance.[176] These considerations would justify the combined use of these agents. Whereas the use of ACE inhibitors may be indicated when the ejection fraction is reduced and symptoms are limited (class I, II), digoxin probably should be reserved for use with more overt symptoms (class III, IV).

While digoxin can be given once a day without tolerance or tachyphylaxis, the dose is a matter at issue.[177]

In general, a serum level of 0.5 to 1.5 mg/L is felt to be therapeutic.[178] This level may vary from patient to patient, and a clear dose-response relation has not been established. Indeed, some of the greatest benefits may be gained from lower doses (e.g., 0.125 mg/day), which may induce the neurohumoral benefits of lower sympathetic and higher parasympathetic tone while reducing the incidence of possible toxic side effects,[177] as is discussed below. There appear to be no adverse effects from digoxin usage in terms of mortality in patients with CHF,[161] and the substantially increased morbidity noted when the drug is withdrawn[174,179,180] suggests such a result. Effects on mortality with digoxin are complicated by the fact that the nature and progression of the underlying process, which led to failure in the first place, may be the ultimate determinant of mortality. If morbidity is reduced substantially with digoxin, as has been demonstrated,[161] a neutral effect on ultimate mortality would be acceptable. This was demonstrated in the Digitalis Investigation Group (DIG) Study (sponsored by the National Institutes of Health), a controlled trial in patients with CHF that showed no effect on survival compared to placebo, a reduction in hospitalizations, and a low incidence of digoxin toxicity.[161]

Digoxin has been shown to be of limited value in the treatment of right-sided heart failure, which can occur in cor pulmonale or with left-to-right shunts. Digoxin also has limited value in acute LV failure caused by acute myocardial infarction, although it is useful in the subsequent treatment of ischemia-related CHF. Nevertheless, since mortality may be increased after infarction by digoxin, especially when clear evidence of heart failure is absent, its use is best reserved for patients with overt CHF.

Toxicities from digitalis glycosides can be numerous and are somewhat dependent on the serum level. Central nervous symptoms include loss of appetite and nausea, and visual changes may be seen. Cardiac limitations include atrioventricular block, premature ventricular extra systoles, and ultimately ventricular tachycardia and fibrillation. Monitoring serum levels may be useful in a patient with sinus rhythm, while the ventricular rate provides an adequate guide to dosing in the presence of atrial fibrillation. Except in dire circumstances, such as a suicide attempt, cessation of therapy is adequate. In the former circumstances, antibodies to digoxin may be indicated.

Catecholamines

As was noted above, positive inotropism is based on enhancing the delivery of Ca^{2+} to the contractile system to increase force and shortening. Increasing Ca^{2+} in the serum effects this transiently, while digitalis glycosides increase Ca^{2+} for activation by inhibiting sarcolemmal Na^{+}-K^{+}-ATPase. Catecholamines increase activating Ca^{2+} via beta-adrenergic receptors and the adenyl cyclase system (Fig. 21-9).

Beta receptors are located in the sarcolemma and constitute a complex structure that spans the membrane.[181] The beta receptor is connected with G proteins (Fig. 21-9) that either activate (G_s) or inhibit (G_i) a secondary enzyme system, adenylate cyclase, which, when activated by G_s, induces the formation of 3′-5′ cyclic adenosine-monophosphate (cyclic AMP). Cyclic AMP in turn activates certain protein kinases, which lead to intracellular phosphorylation of proteins that enhance both the entry and the removal of intracellular Ca^{2+}.[182] When more Ca^{2+} is provided to the troponin-tropomyosin system, a greater interaction between actin and myosin occurs, increasing force and shortening. Increasing the rate of Ca^{2+} removal from the cytoplasm speeds the rate of relaxation.

In a normal heart, norepinephrine is synthesized and stored in the sympathetic nerve endings that invest the entire heart, including the atria, conduction system, and ventricle.[183] When these nerve endings are depolarized, norepinephrine is released from granules in nerve endings into myocardial clefts containing beta-adrenergic receptors, which, when activated, turn on the sequence of events noted above. Not only does this enhance Ca^{2+} entry into the myocyte to augment contraction, it also phosphorylates phospholamban, which enhances relaxation.[182] Subsequently, most of the released norepinephrine is taken back up and restored in the sympathetic nerve endings. Released norepinephrine also is inactivated by two enzymes, catechol *O*-methyltransferase (COMT) and monoamine oxidase (MAO), and the products are excreted largely by the kidneys.[182]

In very severe heart failure, stores of norepinephrine in the ventricle are largely depleted and the sympathetic nerve endings fail to take up norepinephrine normally.[184] Rapid turnover of whatever

norepinephrine stores remain is suggested by increased cardiac norepinephrine spillover in CHF. At the same time, circulating norepinephrine released from peripheral sympathetic nerve endings may be increased, especially in severe failure.[185] In less severe heart failure, the serum norepinephrine levels tend to be normal despite increased sympathetic nerve activity.[186]

In both normal and failing myocardium, activation of the adenyl cyclase system can augment contractility. Agents that do this may be divided into two categories. The first category consists of the catecholamines (e.g., norepinephrine, epinephrine) and their synthetic derivatives (e.g., dobutamine, isoproterenol), which act via cell-surface adrenergic receptors (Fig. 21-9).[182] The second includes agents that inhibit the breakdown of cyclic AMP by inhibiting phosphodiesterase type III (e.g., amrinone, milrinone, and pimobendan), resulting in an increase in cyclic AMP.[186] Some of these agents, such as pimobendan, also may increase myofibril sensitivity to calcium and then further augment contraction.[187]

Catecholamines constitute an endogenous hormonal system that exerts reflex control of the heart and circulation. Their effects depend on localized, controlled neural release and receptor specificity in terms of action. Dopamine is the naturally occurring precursor of both norepinephrine and epinephrine (Fig. 21-10).[188] While epinephrine is released from the adrenal medulla, norepinephrine is the primary mediator in the heart and the peripheral circulation.[182]

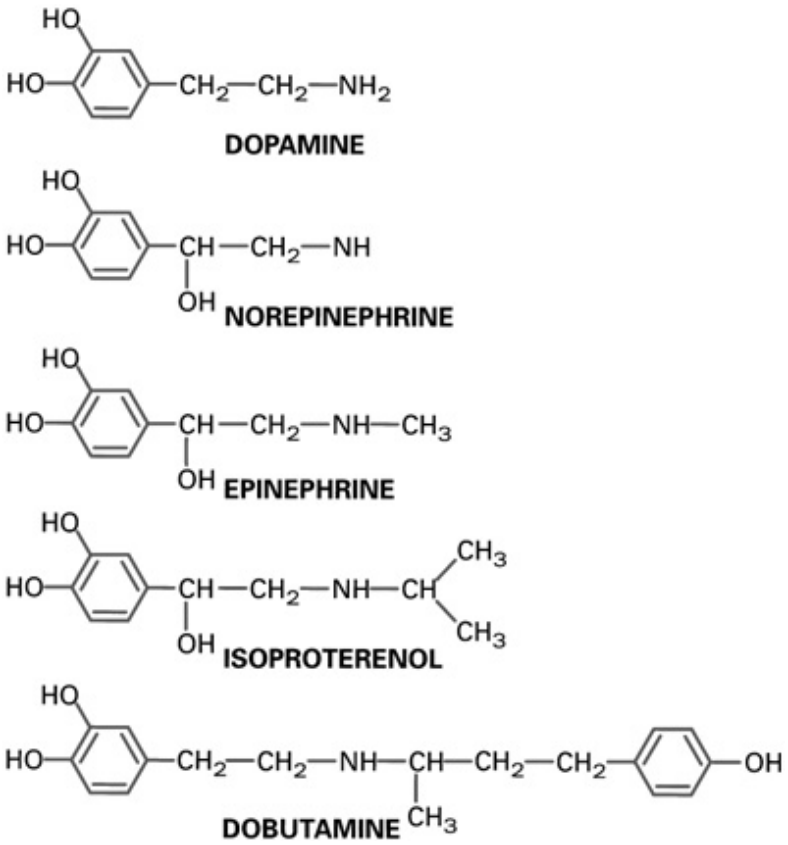

Figure 21-10: Structure of catecholamines.

The actions of both endogenous and exogenous catecholamines depend on their activation of specific alpha- and beta-adrenergic receptors (Tables 21-4 and 21-5).[182] Alpha receptors include alpha$_1$ receptors, which are postsynaptic and are located in vascular smooth muscle and in the myocardium. In smooth muscle, they mediate vasoconstriction; in the heart, weak positive inotropic and negative chronotropic effects. Alpha$_2$ receptors are presynaptic and, when stimulated, decrease norepinephrine release from peripheral nerve endings as well as sympathetic outflow from the central nervous system. Alpha$_2$ receptors also may mediate vasoconstriction in specific peripheral vascular beds.

Table 21-4: Adrenergic Receptor Activity of Sympathomimetic Amines

	$Alpha_1$	$Beta_1$	$Beta_2$	Dopaminergic	Dose
Dopamine	+++	++	+	++++	<2 (μg/kg)/min: vasodilation effects on peripheral dopaminergic receptors2-10 (μg/kg)/min: inotropic effects, $beta_1$ receptor activation;5-20 (μg/kg)/min: peripheral vasoconstriction, alpha effects
Norepinephrine	++++	++++	0	0	Initiate with 8-12 μg/min; maintain 2-4 μg/min
Epinephrine	+++	++++	++	0	
Isoproterenol	0	++++	++++	0	0.5-5 μg/min
Dobutamine	+++	++++	++	0	Start at 2-3 (μg/kg)/min and titrate upward

Table 21-5: Physiologic and Pharmacologic Actions of Catecholamine Receptors

Receptor	Receptor Activity	Primary Location
$Beta_1$	Positive inotropic and chronotropic action; increased AV conduction	Heart (atria, ventricle, AV node)
$Beta_2$	Peripheral vasodilation	Arterioles, arteries, veins, bronchioles
$Alpha_1$	Arteriolar vasoconstriction	Arterioles
$Alpha_2$	Presynaptic inhibition of norepinephrine release	Sympathetic nerve endings, CNS
Dopaminergic-1	Renal and mesenteric vasodilation, natriuresis, diuresis	Kidneys

NOTE: AV = atrioventricular; CNS = central nervous system.

Beta-adrenergic receptors can be divided into $beta_1$ and $beta_2$ subtypes. $Beta_1$ receptors are located in the myocardium, where they mediate positive inotropic, chronotropic, and dromotropic effects.[186] Their activation occurs primarily through norepinephrine released from neurons in the heart. $Beta_2$ receptors are located in vascular smooth muscle, where they mediate vasodilatation, and in the sinoatrial node, where they are chronotropic. In general, $beta_2$ receptors are activated by circulating catecholamines released from peripheral sites such as the adrenal medulla.

Another type of receptor, which has been termed the *dopaminergic receptor,* is localized to the mesenteric and renal circulation and mediates arterial vasodilatation. The physiologic and pharmacologic actions of various catecholamines depend on which receptor they activate, both in the heart and in the periphery (Tables 21-4 and 21-5).

Norepinephrine has potent alpha$_1$ and beta$_1$ activity. When norepinephrine is released from cardiac nerve endings, as occurs in normal exercise, myocardial contractility and heart rate are augmented. When norepinephrine is administered exogenously, its major action is to stimulate alpha$_1$ receptors, leading to marked peripheral arterial vasoconstriction. Thus, norepinephrine has been used to increase arterial blood pressure in the presence of severe hypotension to maintain blood flow to vital organs. Long-term renal vasoconstriction from continued norepinephrine administration may produce ischemic renal damage, including acute tubular necrosis, so that prolonged use, i.e., for more than 24 to 48 h, is usually untenable. For a failing heart, this peripheral vasoconstriction also provides an undesirable added pressure load (afterload), which tends to vitiate the potential benefits of beta$_1$ stimulation.

Dopamine[188] has both alpha$_1$ and beta$_1$ activity but also stimulates dopaminergic receptors in the renal vasculature to produce arterial dilation and increased renal blood flow. Its beta$_1$ effects in the heart occur largely through the release of endogenous norepinephrine, which may be largely depleted in a failing heart. As doses of dopamine are increased, conversion to norepinephrine also occurs, which tends to produce relatively more pressor effects than myocardial inotropic stimulation (Table 21-4). As such, the benefits of dopamine administration, if any, occur at low doses (e.g., 0.02 mg/kg per minute), where it may induce renal arterial vasodilatation. In general, it is employed in association with more potent inotropic agents (e.g., dobutamine).

Dobutamine[189,190] is a synthetic variant of the catecholamines whose structure has been altered to optimize the hemodynamic response in the dog, characterized by an increase in cardiac output and a decrease in ventricular filling pressure with little change in heart rate. Since arterial pressure also rises modestly, peripheral vascular resistance must of necessity fall. The positive inotropic activity of dobutamine is mediated by direct stimulation of beta$_1$-adrenergic receptors in the myocardium (Table 21-4). It is unclear why a concomitant increase in heart rate does not always occur. One possibility is that an increase in cardiac output that increases arterial pressure serves to buffer any increase in heart rate reflexly. Given its capacity to increase cardiac output and reduce filling pressures without substantial changes in heart rate, dobutamine has been used widely to treat severe acute LV failure in the absence of profound hypotension, which is poorly responsive to diuretics and vasodilators (Fig. 21-7). This may be seen after a very large myocardial infarction or in acute decompensation in the course of chronic CHF. In the presence of severe hypotension, the beta$_2$ stimulation of dobutamine may be harmful, and the administration of an alpha$_1$-stimulating vasoconstrictor such as norepinephrine or higher-dose dopamine also may be necessary to increase arterial peripheral resistance.

Dobutamine infusion generally is begun at 2 μg/kg per minute and titrated to optimize cardiac output while reducing LV filling pressure. Tachycardia is avoided carefully to avoid increasing myocardial oxygen demands and inducing ischemia. The effects on myocardial oxygenconsumption (MVO_2) are complex.[190] While the increase in contractility will increase MVO_2, a decrease in heart size will tend to reduce it. The end result is generally a modest increase in MVO_2 induced by dobutamine. With a better maintained arterial pressure and reduced LV diastolic pressure in the absence of tachycardia, coronary perfusion pressure also may be increased. The major side effects of dobutamine are an excessive increase in heart rate with high doses and ventricular arrhythmias, both of which may mandate dose reduction and even drug discontinuation. Tachyphylaxis also may occur to a variable degree. In general, once hemodynamic benefits are attained, dobutamine is withdrawn slowly. In some cases this has not been possible, and sustained administration becomes necessary, which may require portable pumps for administration at home. The outcome in this circumstance is generally dire.

In chronic CHF, the patient commonly is maintained on vasodilators such as ACE inhibitors, loop diuretics, and digoxin. Nevertheless, episodes of acute decompensation may intervene, characterized by increased pulmonary congestion and edema and reduced renal function with increasing fluid accumulation (Fig. 21-7). The in-hospital addition of dobutamine, with or without milrinone (see below), using a Swan-Ganz catheter to monitor hemodynamics, provides for an increase in cardiac output with a decrease in filling pressures, which, with added diuretics, may help restore a steady state for a variable period. Dopamine, at a low dose, commonly is used concomitantly to augment renal blood. This generally requires a short hospitalization and temporary hemodynamic monitoring. In CHF, norepinephrine is used only for a

limited time to treat severe hypotension and shock unresponsive to dopamine and dobutamine, and then the outcome is generally very poor.

Phosphodiesterase Inhibitors and Other Agents

The adenyl cyclase-cyclic AMP system also can be activated beyond the beta receptor. Hormones such as glucagon activate the system and can increase myocardial contractility acutely despite $beta_1$ blockade.[191] While intravenous glucagon administration is useful in overcoming beta-adrenergic blockade when necessary, glucagon may induce gastric atony and nausea, and this has limited its more generalized use.

Amrinone and milrinone are prototypes of cardiotonic agents that activate the adenyl cyclase system through inhibition of the enzyme that breaks down cyclic AMP, phosphodiesterase (PDE) III.[192,193] Type III PDE inhibitors decrease the breakdown of cyclic AMP in the myocardium and increase cyclic guanidine monophosphate (cyclic GMP) in vascular smooth muscle, resulting in an increase in myocardial contractility as well as arterial and venous vasodilatation. Other members of this class of drugs include enoximone and pimobendan, although only intravenous amrinone and milrinone have been approved by the FDA for the treatment of acute heart failure. The mechanisms by which vasodilatation occurs are not completely understood. Increased cyclic GMP induces phosphorylation of myosin light-chain kinase, which decreases sensitivity to calcium and calmodulin. In the heart, inotropism may relate not only to increased cyclic AMP-mediated calcium availability for contraction and increased rates of its removal for relaxation but also to increased sensitivity of the contractile system for calcium.[194] Both amrinone and milrinone,[193] which are available as intravenous agents, have substantial ability to augment cardiac output while reducing both RV and LV filling pressures. The lowering of filling pressures is greater than that seen with dobutamine. Dilatation of the pulmonary arterial vasculature is also a very useful therapeutic effect. Arterial pressure tends to be reduced, while an increase in heart rate may occur. Since dobutamine increases cyclic AMP and milrinone reduces its breakdown, the combination of these agents is substantially more potent than is either agent alone.[193] When either dobutamine or milrinone is utilized, ectopic activity may be increased; this requires careful supervision in their use. PDE III inhibitors are also orally active and produce the same hemodynamic improvement seen with intravenous use. In longer-term oral use, however, increased mortality was seen with the use of milrinone, especially in the presence of class IV heart failure.[195] This increased mortality might have been due to the relatively short action of this agent (90-min half-life), which leads to large peaks and valleys in dosing and concomitant arrhythmias. For the time being, this has vitiated clinical study of these agents in oral formulations, but more stringent control of the use of this class of agents as adjuncts to other agents ultimately may increase their value, especially in improving quality of life in the terminal and short-term outcome of very severe CHF.

NEWER INOTROPIC AGENTS

Agents under investigation include the inodilatory benzimidazoline PDE inhibitors, such as levosimendan, which acutely increase cardiac output and reduce filling pressure while improving exercise tolerance in patients with CHF.[196] Levosimendan and other drugs in this class (MCI-154, EMD 53998, EMD 57033) may have additional effects to enhance calcium binding to troponin-C, a calcium-sensitizing action (Fig. 21-9).[196-198] Theoretically, this could enhance the contractile response for a given amount of cytolytic Ca^{2+}, which could lead to less arrhythmogenicity. This may be an important consideration since the activation of the cyclic AMP system may be detrimental in inducing tachycardia and arrhythmias. Clinical trials evaluating the efficacy and safety of levosimendan are in progress. Preliminary results from one study that compared levosimendan to dobutamine [Levosimendan versus Dobutamine (LIDO)] demonstrated comparable hemodynamic activities with less chest pain and arrhythmia with levosimendan. The critical issues to be addressed, now that acute efficacy is apparent, are whether these agents will improve symptoms, i.e., reduce morbidity, and/or improve mortality.

ADJUNCTIVE THERAPIES

As was mentioned earlier, patients with heart failure require treatment of underlying disease processes that may be aggravating the myopathic process. Systemic hypertension should be treated vigorously. In diabetes, hyperglycemia should be controlled. Aspirin prophylaxis and cholesterol-lowering drugs should be used in patients with coronary artery disease. It is not known whether estrogen replacement therapy in

postmenopausal women can modify the course of heart failure.[199]

Heart failure patients with mental depression have an increased mortality risk. The tricyclic antidepressant drugs have been associated with myocardial depression and probably are contraindicated in heart failure patients. However, the selective serotonin reuptake inhibitors have a favorable risk profile in cardiac patients and could be considered an adjunctive treatment for relieving mental depression. However, many of these drugs interfere with the hepatic cytochrome P450 system, and that might affect the metabolism of drugs being used to treat heart failure (see Chap. 81).

Beta blockers should be considered in all patients who survive a myocardial infarction with or without ventricular dysfunction. As was described earlier, carvedilol, metoprolol, and bisoprolol should probably be the beta blockers of choice in patients with symptomatic mild to moderate CHF of ischemic or nonischemic origin. Propranolol, metoprolol, atenolol, or timolol should be used in myocardial infarction survivors who are asymptomatic with and without LV dysfunction.

Patients with CHF are liable to develop venoembolic disease and systemic emboli from intracardiac mural thrombi. These embolic events are major causes of morbidity and mortality in CHF. In patients with atrial fibrillation and CHF, with and without mitral stenosis, anticoagulation is indicated. In patients with normal sinus rhythm and cardiomyopathy, the role of prophylactic anticoagulation with warfarin is not well defined.[3] A cohort analysis of the SOLVD population focused on the relation between warfarin use and the risk of all-cause mortality and found a beneficial effect with an anticoagulant.[200] Most of this benefit appeared to relate to reduced ischemic events. It is more difficult to anticoagulate patients with CHF because of drug-drug interactions, malabsorption of medications, varying perfusion of the liver, and malnutrition.[201] Patients with CHF who have developed a phlebothrombotic process or who have definite evidence of ventricular mural thrombi and systemic embolism should receive warfarin despite the potential problems with the regulation of anticoagulation in these patients.

Patients with heart failure have a markedly increased prevalence of ventricular ectopy and incidence of sudden death. These patients should be assessed for hypokalemia, hypomagnesemia, hypoxia, infection, and the use of antidepressant drugs. Many antiarrhythmic drug regimens have negative inotropic actions and may aggravate the heart failure process. Amiodarone and beta blockers have been used in patients with LV dysfunction with less risk involved and are probably the drugs of choice when treatment of ventricular ectopy is considered.[202,203] There is little evidence to show that antiarrhythmic drug therapy changes the natural history of advanced CHF.[203] Amiodarone also can be used to treat atrial arrhythmias with and without digoxin and calcium channel blockers.

DIASTOLIC DYSFUNCTION

Diastolic dysfunction of the left and right ventricles often leads to all the signs and symptoms of systolic dysfunction, but the therapeutic approach varies for these two conditions. Often, there is significant LV hypertrophy present, and aggressive management of systemic hypertension is required.[202,204] These patients develop significant congestion, and so diuretics are often necessary. With hypovolemia from other diseases, however, patients are prone to develop hypotension. The effects of diuretics in these patients should be monitored carefully. Digoxin is probably of no use unless the patient is in atrial fibrillation, and vasodilating drugs with peripheral venodilator actions may cause hypotension. The role of ACE inhibitors, angiotensin II receptor blockers, and other vasodilator drugs are not well defined in this condition, and they may cause hypotension. Large clinical trials have begun to include patients who have diastolic dysfunction as the primary cause for clinical heart failure. Studies with the ACE inhibitor perindopril and the angiotensin receptor blocker candesartan are in progress.

Tachycardia must be avoided. Rate-lowering calcium blockers (verapamil, diltiazem) are useful drugs of choice for reducing elevated blood pressure, keeping the heart rate under control, and improving ventricular compliance.[205] Beta-adrenergic blockers are first-line therapy for maintaining relative bradycardia to maintain time for diastolic ventricular filling. However, their effects on ventricular compliance are not as well defined. Both verapamil and beta blockers can be used with caution in patients with heart failure caused by hypertrophic cardiomyopathy.

DRUG THERAPIES UNDER INVESTIGATION

Natriuretic Peptides and Their Enhancers

Conventional diuretics are associated with undesirable stimulation of the renin-angiotensin axis, sympathetic nervous system, and vasopressin. ANP and brain natriuretic peptide (BNP), by contrast, induce diuresis and natriuresis while concomitantly suppressing the renin-angiotensin axis with dilation of peripheral vascular beds.[206-210] In heart failure, despite high endogenous ANP and BNP levels, a state of intense sodium avidity prevails.[206,207,210,211] Attempts at restoring the efficacy of ANP in heart failure include infusing ANP intravenously and administering a neutral endopeptidase inhibitor. Prolonged infusion of ANP in patients with moderate CHF (NYHA class II to III) has been associated with doubling of the urine flow rate and a three- to fourfold increase in sodium excretion.[212] When ANP is infused in patients with moderate to severe CHF (NYHA class II to IV), however, the natriuretic and diuretic response is attenuated.[207,208]

Favorable hemodynamic responses have been observed after ANP infusion, including a fall in pulmonary capillary wedge pressure (PCWP), plasma renin activity, and systemic vascular resistance and an increase in cardiac output.[207,208,213] When ANP and furosemide are administered concomitantly, urine volume and sodium excretion are not augmented, although in this setting ANP does maintain its inhibitory effect on the renin-angiotensin axis and on sympathetic discharge.[214]

Neutral endopeptidase (NEP) inhibitor administration is associated with a rise in endogenous ANP levels resulting from the inhibition of ANP metabolism.[210,215-219] In a canine model of CHF, Cavero and coworkers reported that at similar ANP levels, NEP inhibitor treatment was associated with a better diuretic and natriuretic effect than was an ANP infusion.[215] In human studies, however, the two modalities appear to have similar natriuretic and diuretic effects. In 1989, Northridge and colleagues were the first to report diuresis after NEP inhibitor infusion in six patients with mild CHF (mean ejection fraction, 37 percent).[218] A 60 percent increase in the 4-h urine sodium excretion was observed, associated with a three- to fivefold rise in ANP levels.[218] The same investigators compared the renal and hemodynamic effects of NEP inhibitor administration to low-dose furosemide in mild CHF.[220] Eighteen patients were randomized to receive an NEP inhibitor, candoxatrilat 200 mg twice daily, candoxatrilat 400 mg twice daily, or furosemide 20 mg twice daily. The administration of a NEP inhibitor was associated with diuresis; however, the change in urine flow rate and sodium excretion from baseline was greater in the low-dose furosemide group. Although its diuretic effect was modest, the NEP inhibitor was associated with desirable hemodynamic effects, including marked preload reduction (PCWP decreased 40 percent), and with no stimulation of plasma renin activity. In comparison, the group given furosemide experienced only a 15 percent reduction in PCWP and a threefold rise in plasma renin activity.

The natriuretic properties of NEP inhibitors are mediated by inhibition of sodium reabsorption within the renal tubule, since they do not alter renal hemodynamics (GFR or renal plasma flow) significantly. This is supported by their association with an increased fractional excretion of lithium, a marker of proximal tubular reabsorption.[215,217] In addition to inhibiting ANP degradation, the NEP inhibitors inhibit the breakdown of bradykinin and BNP. They also have been shown to enhance prostacyclin synthesis, another mechanism by which they may exert a natriuretic effect.[221,222] In the most severe stages of CHF (NYHA class III to IV; ejection fraction, 22 percent), an impaired renal response to NEP inhibitor treatment can be expected. Munzel and colleagues[209] reported an unpredictable natriuretic response to candoxatrilat in nine patients with severe CHF. Three patients had no diuresis, five had a minimal response, and one (cardiac index > 2.5 L/min) had a good diuresis. The natriuretic response correlated closely with the cardiac output, which theoretically was most likely related to renal perfusion status.

In contrast to ANP, the natriuretic effect of BNP infusion is surprisingly and significantly more pronounced in patients with CHF than in normal patients, even when similar BNP levels are infused.[210] Yoshimura and colleagues infused BNP in normal patients and in those with NYHA class II to IV CHF and observed a fivefold rise in urine flow rate and a tenfold increase in sodium excretion in the CHF group.[210] In normal patients, diuresis and natriuresis were only three- to fourfold that of baseline, respectively. BNP infusion also was associated with a reduction in PCWP, systemic vascular resistance, and aldosterone levels as well as a rise in ANP levels.

It is unclear why high-dose BNP infusion is not associated with an attenuated natriuretic response in CHF, as is seen with ANP infusion. Like the process in ANP, inhibition of NEP 24.11 with candoxatril prevents the metabolism of BNP, increasing BNP levels by about 50 percent.[222] Because of its enhanced natriuretic effect at high infusion rates and prolonged duration of action compared with ANP, BNP appears to be the most promising natriuretic peptide candidate for future investigation and potential clinical therapeutic use.

When the BNP nesiritide is infused in patients with CHF, it reduces pulmonary capillary wedge pressure and systemic vascular resistance while increasing stroke volume and cardiac index. It suppresses plasma aldosterone but does not change plasma renin, norepinephrine, or epinephrine. It increases renal plasma flow and GFR as well as insulin excretion without affecting blood pressure and heart rate.[223] Nesiritide was recently considered by the FDA for intravenous clinical use in the treatment of acute heart failure, but excessive hypotension caused by treatment in studies has delayed its approval.[224] A recent study demonstrated that twice-daily subcutaneous injections of nesiritide can improve hemodynamics in patients with CHF, and this may provide a new therapeutic approach to chronic therapy.[225]

It is believed that the attenuation of responsiveness to endogenous ANPs with endopeptidase inhibition is due to activation of the RAAS. This has prompted the development of agents that both augment the action of ANP and block the RAAS, the dual NEP-ACE inhibitor drugs (e.g., omapatrilat, sampatrilat), which are now being examined in patients with systemic hypertension and CHF.[226]

In patients with heart failure, omapatrilat has been shown to be more effective in improving symptoms and reducing the combined risk of death and hospitalization than is the ACE inhibitor lisinopril (IMPRESS trial). In addition, fewer omapatrilat-treated patients exhibited signs of renal dysfunction. Results from a substudy showed that omapatrilat caused a greater improvement in arterial compliance.[227] Omapatrilat is being compared to enalapril in a long-term survival study (OVERTURE Study).

Another naturally occurring natriuretic peptide being evaluated for the treatment of patients with heart failure is adrenomedullin,[223,228] a hypotensive peptide originally isolated from human pheochromocytoma.

Endothelin Inhibitors

Endothelin-1 exhibits potent inotropic activity in isolated hearts, cardiac muscle strips, isolated cells, and instrumented intact animals.[229] High-affinity receptors for endothelin have been demonstrated in both the atria and the ventricles.[230,232] Intravenous endothelin-1 produces a delayed prolonged augmentation of LV performance in addition to its biphasic vasoactive effects of transient vasodilation followed by sustained vasoconstriction.[229]

Endothelin is also a potent secretagogue of atrial natriuretic factor, which is a naturally occurring antagonist of endothelin that acts by inhibiting its release.[233] The endothelin-A receptor appears to mediate endothelin's actions of vasoconstriction and the stimulation of the ANP secretion, and the endothelin-B receptor mediates endothelin-induced vasodilatation and activation of the RAAS. Urinary water excretion is mediated through both receptors, but sodium excretion is mediated through the endothelin-A receptor.

Increased endothelin levels have been described in patients with CHF[234-239] that are predictive of increased mortality risk.[235] It also has been suggested that increased endothelin levels may play an important role in the increased systemic vascular resistance observed in CHF.[234,240,241] Endothelin-1 levels decrease with therapy and have been found to correlate significantly with symptomatic improvement. It therefore appears that endothelin-1 is an independent, noninvasive predictor of functional and hemodynamic response to therapy in patients with CHF.[242] Increased endothelin levels also have been observed in the plasma and hearts of cardiomyopathic Syrian hamsters[243] and in the cells of endothelial cells infected with *Trypanosoma cruzi* in experimental Chagas' cardiomyopathy.[244]

There is early clinical evidence that treatment with endothelin-A receptor antagonists and endothelin-converting enzyme inhibitors can influence the course of human heart failure favorably.[245] Some of these agents are being investigated in clinical heart failure trials (bosentan, BMS193884, LU135252).[246,247] ACE inhibitors also may benefit patients with heart failure because of their antiendothelin actions.[248,249]

Vasopressin Antagonists

Vasopressin, which usually is elevated in patients with heart failure, correlates with the severity of disease and the incidence of hyponatremia. In human beings, this aquaretic hormone is released in response to the level of plasma osmotic pressure or osmolality. Its release also is influenced by hemodynamics in the setting of heart failure, a decrease in mean arterial pressure, a decrease in cardiac output, a decrease in atrial pressure, hormones such as angiotensin II, increased sympathetic nervous system activation, and a variety of less common stimuli.[250]

Two physiologically important subtypes of vasopressin receptors are the V1 and V2 receptors. V1 is found primarily in vascular smooth muscle and promotes vasoconstriction. The V2 receptor is found in renal collecting duct cells and promotes reabsorption of free water in the kidney. Vasopressin elevations in heart failure could induce vasoconstriction and increase renal water retention and thirst.

The first peptide vasopressin antagonists (V2 receptor specific) were developed in the 1980s.[251] More recently, combined V1A/V2 receptor antagonists have become available. In human studies vasopressin antagonists have been shown to reverse the impaired urinary diluting capacity seen in chronic heart failure, increase sodium free water excretion, correct dilutional hyponatremia, decrease urinary aquaporin-2 (AQP-2) excretion, promote peripheral vasodilation, and improve cardiac output.

Two orally active V2 receptor antagonists (WAY-VPA985 and SR49-059) and a combined V1A/V2 receptor antagonist YM087 are being evaluated in clinical trials in patients with class III and IV heart failure who are currently on standard treatment that includes continuous inotropic drug infusion.

Adenosine Receptor Antagonism

Blockade of adenosine (A1) receptors in animals can induce a brisk natriuresis without a kaliuretic effect,[252] an observation that has been confirmed in humans in short-term studies using FK 4531, a selective A1 receptor antagonist.[253-255] The mechanism for this lack of kaliuretic action has not been elucidated; neither has the safety and efficacy of this drug class in long-term clinical trials.

Oral Dopamine Receptor Agonists

The unique, selective vasodilatory and inotropic actions of intravenous dopamine are limited by the lack of an oral formulation. This has led investigators to develop newer dopamine agonists that are orally effective. Unlike L-dopa, which has been used in heart failure, these new drugs do not cross the blood-brain barrier but maintain most of the pharmacologic activity of dopamine.[256]

Ibopamine, which is an orally active derivative of dopamine, has dopaminergic D_1 and D_2 activity with alpha- and beta-adrenergic actions. In therapeutic doses, it is a peripheral vasodilator and appears to have favorable cardiovascular and renovascular actions in patients with heart failure. The results of the Prospective Randomized Study of Ibopamine on Mortality and Efficacy in Heart Failure (PRIME-2), however, raised serious questions about the safety of ibopamine and agents of this class[257] in patients with heart failure. Fenoldopam is a selective D_1 agonist that has been used to treat patients with CHF and hypertension. Because of bioavailability problems with the oral formulation, only the intravenous form is used in patients with severe hypertension.[258] Dopexamine is an intravenous D_1 and $beta_2$-receptor agonist that is being studied in patients with CHF and low cardiac output states.

Inhibition of Immune Activation

Cytokines are a group of small pleiotropic endogenous peptides produced by a variety of cell types in response to a variety of different stimuli. Tumor necrosis factor-alpha (TNFα), interleukin-1α and -1β, and interleukin-6 are classified as "proinflammatory" cytokines. These substances are responsible for initiating the primary host response to bacterial infections as well as initiating the repair of injured tissues.[259]

Cytokines are involved in augmenting the expression of adhesion molecules and the enhanced cell-to-cell

interactions involved in inflammation. In addition, the proinflammatory cytokines are able to affect cardiovascular functioning by promoting LV remodeling, causing ventricular dysfunction, and uncoupling myocardial beta receptors.[259] They are elevated in the serum in various cardiovascular disorders and are often a marker of the severity of disease.[260]

TNFα was originally discovered in 1975 as a protein with necrotizing effects in certain transplantable mouse tumors.[261] More recently, this cytokine has been shown to exert a spectrum of pleiotropic effects in many different cell types.[262] The major biological role of TNFα is thought to be a host response to systemic infections, most notably gram-negative sepsis.[263] In fact, TNFα levels are elevated considerably in patients with septic shock, and TNFα has been implicated as an important mediator in the lethal effect of endotoxin, possibly causing the symptoms characteristic of the "shock state."

Many experimental and clinical studies have shown an association between depressed myocardial function and elevated levels of TNFα.[264] The basis of this association is not clear; however, there are studies suggesting that elevated levels of TNFα play a major role in causing myocardial depression, whereas other studies have concluded that TNFα is likely to play a role in the alleviation of this condition.[265] A third school of thought suggests that the elevated levels of TNFα are merely a marker that may indicate the stage of progression of the disease. Thus, although it is clear that there are elevated levels of TNFα in various cardiac diseases, the reasons for these increased levels and the mechanisms of their effects are not agreed on. Since there is a strong association and possibly a causative relationship between TNFα and CHF, various drug trials are looking at TNFα and its possible metabolic pathways as a therapeutic target in the treatment of heart disease.[266]

The drugs thalidomide and pentoxifylline have been shown in small studies to suppress the production of TNFα in patients with heart failure, with favorable effects on hemodynamics being reported.

A study is in progress evaluating the effects of a soluble recombinant human TNF-R fusion protein (etanercept) on the clinical course of patients with advanced heart failure.[267-269] Preliminary results suggest that etanercept will suppress the cardioinflammatory cytokines IL-1β and IL-6 while increasing the anti-inflammatory cytokine IL-10. These effects appeared to be associated with impaired clinical functioning and regression of ventricular remodeling. Other inflammatory cytokines may be therapeutic targets in the future.

A recent clinical trial evaluated the use of the intravenous immunoglobulin IgG in patients with a new onset of dilated cardiomyopathy, with no apparent benefit compared to placebo. In experimental studies, the cytokine interleukin-10 has been used successfully to treat viral myocarditis.[270]

Studies with prednisone and cyclosporine have shown no clinical benefit in the treatment of patients with dilated cardiomyopathy and myocarditis.[271-273]

Other approaches under consideration for attenuating the heightened inflammatory responses observed in patients with heart failure include monoclonal antibodies that interfere with complement activation and those which interfere with neutrophil adhesion and migration.

Nitric Oxide

Preliminary work is being done investigating inhaled nitric oxide, a vasodilator substance produced by the endothelium, as a possible treatment for CHF.[274-277] Arginine, a nitric oxide precursor, and agents that potentiate nitric oxide synthesis, are now potential directions for new heart failure therapies. To date, results with L-arginine use in patients with heart failure have been inconclusive. Nitric oxide donor substances are also being evaluated.[277]

Imidazoline Receptor Agonists

The drugs rilmenidine and moxonidine are centrally acting antihypertensive agents that decrease sympathetic outflow by stimulating nonadrenergic imidazole-l receptors in the brain. These drugs are similar to clonidine in their pharmacologic activities but cause less sedation. Modulation of the sympathetic

nervous system by decreasing central catecholamine release has been proposed as a therapeutic approach to prolonging life in patients with CHF. However, the results of a recent study using moxonidine in heart failure patients did not show any benefit on survival.[278]

Matrix Metalloproteinase Inhibitors

Matrix metalloproteinases and their inhibitors are biological proteins that are involved with the formation and breakdown of collagen and interstitial tissue. Matrix metalloproteinase activity is elevated in patients with heart failure, suggesting that these proteins may be contributors to myocardial remodeling and the worsening of symptoms. Matrix metalloproteinase inhibitors are being considered as treatments for heart failure.[279]

Supplementary Hormones and Antioxidants

Increasing experimental evidence and preliminary clinical data suggest that growth hormones may have beneficial effects in the treatment of heart failure. However, the mechanisms behind these favorable actions are not well understood.[280,281] Growth hormone exerts its effects either directly or indirectly through insulin growth factors.

In experimental studies, growth hormone has been shown to increase the force of contraction by increasing the number of myocardial cross-bridges and the amount of available calcium. Growth hormone also can enhance peripheral blood flow and increase skeletal muscle mass. Growth hormone has been shown to attenuate pathologic remodeling without inducing LV hypertrophy.

In patients with heart failure, growth hormone has been shown to improve LV systolic function and exercise tolerance while normalizing plasma levels of BNP. Long-term morbidity and mortality studies in patients with heart failure remain to be done.

Anabolic steroids have been evaluated in patients with heart failure. They have been shown to improve left myocardial performance, increase skeletal muscle, and improve the patient's sense of well being. However, there is little long-term morbidity and mortality experience with this treatment.

Metabolic Enhancers and Antimetabolites

Abnormalities of energy metabolism often are cited as key elements in the progression of the worsening LV dysfunction that characterizes heart failure. Ranolazine is one of a class of partial inhibitors of fatty oxidation (pFOX inhibitors). By shifting adenosine triphosphate production away from fatty acid oxidation and toward carbohydrate oxidation, ranolazine reduces oxygen demand without decreasing cardiac work and maintaining coupling of glycolysis to pyruvate oxidation, which minimizes lactate accumulation. Ranolazine may be useful as an antianginal drug, and in experimental heart failure studies it has been shown to improve LV performance.

Carnitine is a biological substance that plays an important role in the oxidation of long-chain fatty acids. It also allows for the removal of short- and medium-chain fatty acids from the cell. Carnitine also has been shown to facilitate the aerobic metabolism of carbohydrates.[282]

It has been demonstrated by investigators that myocardial carnitine levels are decreased in many pediatric and adult cardiomyopathies in which myocardial fatty acid metabolism is impaired. It has been proposed that the restoration of normal carnitine levels through the administration of exogenous L-carnitine would be of therapeutic value in heart failure through its ability to stimulate fatty acid metabolism.

The usefulness of oral L-carnitine for the treatment of pediatric cardiomyopathy is well established.[283] A few small studies in patients with heart failure have examined the effects of L-carnitine and have demonstrated improvements in hemodynamics, functional capacity, and survival.[282] A large randomized, placebo-controlled trial is still required to adequately assess the usefulness of L-carnitine in heart failure.

Coenzyme Q10(CoQ10), or ubiquinone, is an endogenous cellular membrane constituent that has been

shown to have antioxidant properties. Its central physiologic role is in mediating electron transport between nicotinamide adenine dinucleotide and succinate dehydrogenases and the cytochrome system.

CoQ10 has been suggested as a treatment for CHF in which low levels of the substance in the myocardium have been observed. Despite a theoretical benefit in patients with heart failure, trials with CoQ10 supplementation have not demonstrated any effectiveness.

Heart failure also has been associated with the accumulation of oxygen free radicals, which can cause cellular damage in the heart. At this juncture, treatments with various nutritive antioxidants (vitamins and minerals) and naturally occurring enzymatic free radical scavengers have not been associated with efficacy in patients with heart failure.

Antiapoptosis Therapy

An innovative approach to preserving myocardial function involves interventions that can interfere with programmed myocardial cell death (apoptosis), a natural process that is accelerated by aging, myocardial ischemia, hypertension, diabetes mellitus, and myocardial cell stretch (LV dilation). Utilization of AII receptor blockers and the infusion of insulin growth factor in rats can inhibit the amount of myocardial apoptosis by 50 percent and suggests future therapeutic approaches in human beings. Caspase, an enzyme essential to the apoptotic process, can be inhibited pharmacologically, with evidence of enhanced myocardial preservation in experimental animals.

Gene Therapy

In experimental studies, gene therapy has been shown to improve failing human cardiac myocyte function.[284,285] It was demonstrated that the abnormal contraction, relaxation, and contraction amplitude-frequency relationship of isolated myocytes obtained from patients with dilated cardiomyopathy could be normalized by transfection of the myocytes in vitro with an adenovirus expressing the sarcoplasmic reticulum Ca^{2+}-ATPase, SERCA2a; transfection increased Ca^{2+}-ATPase activity 80 percent. The enhanced function of the myocytes was associated with corresponding improvements in the kinetics of the Ca^{2+} transient. The isolated myocyte results confirm previous in vitro findings by Meyer and associates in normal rabbit myocytes that indicated that adenoviral transfection of SERCA2a can improve contraction and relaxation.[286]

Nonpharmacologic Aspects of Treatment

Nonpharmacologic factors contribute to the overall efficacy of care. Weight reduction by dieting is generally advisable when obesity is present. Often, however, nutritional status is compromised and cachexia is present.[287] Limitation of salt intake is important and may delay the time when diuretics may be necessary as well as reduce the amount required. In advanced heart failure, strict salt limitation is essential, although it is difficult to maintain. A diet containing less than 20 g/day of salt is desirable. Intake of fluids should be reduced to 1 to 1.5 L every 24 h in patients with advanced heart failure, with or without hyponatremia, except in warm climates. As will be stressed in relation to the use of diuretics, a readable weight scale is essential, and daily weights are of great value in judging therapy.

Smoking should be discouraged strongly in all patients, especially in the presence of obstructive vascular disease. Alcohol is a cardiac depressant in general and should be forbidden if an alcoholic cardiomyopathy is suspected. In all other cases, daily intake of alcohol probably should not exceed 40 g/day in men and 30 g/day in women, although there are insufficient data on the effects of alcohol in patients with mild heart failure to support these recommendations.[288]

Patients should routinely receive vaccinations against influenza and pneumococcal pneumonia.

Deconditioning related to muscular inactivity in association with muscular atrophy and decreased metabolic vascular dilatation is a major factor in reducing exercise performance as heart failure progresses.[289] The 6-min walk test is a semiquantitative assessment tool for assessing functional capacity before and after treatment.[290] Low-level exercise, such as walking, should be encouraged, whereas strenuous isometric

activities should be discouraged. Specific exercise training needs to be tailored to the appropriate level of the patient's disease and always should be performed under medical guidance. Isometric exercise should be avoided. In patients with stable heart failure, there is evidence that appropriate physical exercise and exercise training can lead to improvements in both exercise capacity and the quality of life of the patient, although the effect of this intervention on the prognosis is unknown.[291-293] Specific recommendations include dynamic aerobic exercise (walking) three to five times a week for 20 to 30 min and cycling for 20 min at 70 to 80 percent of the peak heart rate five times a week.[291,292]

In patients with acute heart failure and in those with exacerbations of chronic heart failure, rest is advisable. Prolonged rest, however, should not be encouraged in patients with stable chronic heart failure.

Surgical Treatment

BIVENTRICULAR CARDIAC PACING

The use of dual-chamber pacemaker technology to treat patients with chronic heart failure remains controversial.[294-300] It has been proposed that by altering the timing, sequence, and site of cardiac electrical activation in patients with heart failure, hemodynamic abnormalities may be favorably altered.

The subgroups of patients with heart failure who might benefit include (1) those with an atrial contraction too early in relation to the onset of ventricular contraction during native conduction, (2) patients with long atrioventricular (AV) conduction and significant shortening of the diastolic filling period because of presystolic mitral or tricuspid regurgitation or both, and (3) certain patients with ECG PR intervals >200 ms in whom dual-chamber pacing at an optimal AV delay eliminates diastolic mitral regurgitation and improves cardiac output.[294]

In patients with heart failure, it was shown that single-site pacing at the site of greatest intraventricular conduction delay was as beneficial in improving hemodynamics as was biventricular pacing[300]

A blinded randomized clinical trial is in progress [The Multicenter InSync Randomized Clinical Evaluation (MIRACLE)] evaluating a new biventricular myocardial conduction resynchronization device (InSync) in 300 patients with class III and IV heart failure. End points include measures of functional status, quality of life, and effects on peak oxygen consumption and echocardiographic indices of both systolic and diastolic function.

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

In patients with documented sustained ventricular tachycardia or ventricular fibrillation, an implantable cardioverter defibrillator is highly effective in treating recurrences of these arrhythmias by antitachycardia pacing or cardioversion-defibrillation, reducing morbidity and the need for rehospitalization. There is some evidence that the efficacy of this device in terminating ventricular tachycardia or ventricular fibrillation may translate into improved survival[3,301] in patients with heart failure, but no definite proof exists. Studies are in progress that are designed to address this issue.[302,303]

The benefit of implantable cardioverter defibrillation therapy may decrease with increasing degrees of heart failure.[304] Preliminary data suggest improved survival compared with conventional antiarrhythmic therapy, including amiodarone, in patients with asymptomatic LV dysfunction or mild to moderate heart failure.[305,306] For patients with severe heart failure and documented sustained ventricular tachyarrhythmias, implantable cardioverter defibrillators at present should be considered a bridge to transplantation, but their effectiveness in this setting has not been proved.

LEFT VENTRICULAR ASSIST DEVICES

In a patient who cannot be sustained with medical therapy and for whom ultimate cardiac transplantation is anticipated, an LV mechanical support device (LVAD) has been successful in serving to maintain ventricular function as a bridge to transplantation. With two portable devices now approved by the FDA, the question remains whether they eventually can be used as long-term destination therapy for patients with

end-stage heart disease. Preliminary results from randomized studies have demonstrated a 100 percent increase in survival at 2 years in patients with class IV heart failure who are ineligible for heart transplantation and are maintained on standard medical therapy. However, recent data have shown that LVAD implantation in heart failure patients is associated with activation-induced T-cell death and immune dysfunction, putting recipients at risk of serious infection.[307]

HEART TRANSPLANTATION

Heart transplantation is now an accepted mode of treatment for end-stage CHF. Transplantation significantly increases survival, exercise capacity, return to work, and quality of life compared with conventional treatment provided that proper selection criteria are applied. Recent results in patients on triple immunosuppressive therapy have shown a 5-year survival of approximately 70 to 80 percent[308] and a return to full- or part-time work or seeking employment after 1 year in about two-thirds of the patients in the best series.[309]

Patients who should be considered for transplantation are those with severe CHF with no alternative form of treatment. Predictors of poor survival are taken into account. The patient must be willing and able to undergo intensive medical treatment and be emotionally stable to withstand the many uncertainties that are likely to occur both before and after transplantation.

Besides a shortage of donor hearts, the main problem in heart transplantation is rejection of the allograft, which is responsible for a considerable percentage of deaths in the first postoperative year. The long-term outcome is limited predominantly by the consequences of immunosuppression (infection, hypertension, renal failure, malignancy, accelerated progression of atherosclerotic vascular disease) and by transplant coronary artery disease.

Experimental work is under way looking at xenotransplantation of myocardial cells and entire organs (pig hearts) as potential heart failure treatment. The humoral immune response of the recipient against the graft remains a preeminent hurdle. There is also limited information regarding the physiology of the pig heart as a replacement for the human heart.

CORONARY REVASCULARIZATION SURGERY

A major and important surgical approach to ischemic cardiomyopathies is reperfusion of ischemic tissue by coronary bypass surgery.[310] This is based on the concept that transiently ischemic myocardium (stunning) and myocardium with reduced flow (hibernating) have reduced contractility, which may return to normal with restoration of adequate coronary blood flow. Moreover, revascularization of ischemic regions of the ventricle may prevent recurrent infarction in this area and thus help prevent further deterioration of ventricular function. In such patients, it is necessary to establish that significant amounts of viable tissue remain in an akinetic or hypokinetic zone; this can be accomplished with nuclear techniques such as a 24-h thallium perfusion study and positron emission tomographic scanning.[311] If contractile activity also can be elicited, as shown in echo studies with low-dose dobutamine stimulation[22] or postextrasystolic potentiation, coronary bypass surgery provides a good chance to stabilize or improve ventricular function[310,312,313] and enhance survival.[314] In this era, every patient with ischemic cardiomyopathy should be evaluated for possible revascularization and assumed to be a candidate until proved otherwise.

OTHER PROCEDURES

Other surgical approaches to the dilated heart have included the recent concept of removing a segment of the left ventricular wall, the "Battista operation," to reduce LV volume and thus wall stress. The surgical risk is immense, and specific benefits have not been established.[315]

Enhanced external counterpulsation is a noninvasive therapy consisting of gated diastolic sequential leg compression, producing hemodynamic effects similar to those from an intraaortic balloon pump. The procedure has been shown to improve exercise capacity and LV failure in patients with heart failure who already are receiving medical therapy.[316]

Immunoabsorption procedures have been directed against $beta_1$-adrenergic receptor antibodies, with clinical improvement found in patients with heart failure.[317]

The General Approach to Therapy in Congestive Heart Failure

Appropriate therapy in CHF depends on the stage of the disease process (Table 21-6 and Figs. 21-11 and 21-12). While one seeks to define and treat the factors that initiated the process, one also attempts to reduce symptoms and prolong life. Thus, with initial damage, e.g., after a large myocardial infarction, ACE inhibition or angiotensin II receptor blockade is indicated. Beta-adrenergic receptor blockers also are indicated at this stage because of mortality reduction. As failure progresses to more symptomatic phases, beta blockers also appear to be indicated, along with ACE inhibition. Once symptoms increase and edema and central congestion occur, loop diuretics and spironolactone become useful to maintain dry weight. To prevent further ischemic tissue loss, other measures, such as cessation of smoking and appropriate lipid control, are essential. Digitalis glycosides, especially in modest doses, are indicated when class II to III symptoms occur.

Table 21-6: Chronic Heart Failure-Choice of Pharmacologic Therapy

	ACE Inhibitor	Diuretic	Potassium-Sparing Diuretic	Cardiac-glycosides	Vasodilator (Hydralazine/ISDN)	Beta Blocker
Systolic dysfunction						
Asymptomatic LV dysfunction	Indicated in some	Not indicated (unless ↑ BP)	Not indicated	Only with atrial fibrillation	Not indicated	After MI
Symptomatic HF (NYHA-II)	Indicated			(a) When atrial fibrillation is present or (b) when improved from more severe HF in sinus rhythm	If ACE inhibitors are not tolerated	Indicated (under specialist care)
- Fluid retention		Indicated in some	Not indicated			
+ Fluid retention		Indicated	Persisting hypokalemia			
Worsening/severe HF (NYHA III-IV)	Indicated	Indicated, combinations of diuretics	Persisting hypokalemia; spironolactone for efficacy	Indicated	If ACE inhibitors are not tolerated or insufficient	Indicated (under specialist care)
End-stage HF (persisting NHYA IV)	Indicated	Indicated, combinations of diuretics	Persisting hypokalemia; spironolactone for efficacy	Indicated	If ACE inhibitors are not tolerated or insufficient	Indicated (under specialist care)

[a]Preliminary data from the DIG (Digitalis Investigation Group) trial suggest that digoxin also may be indicated in NYHA II heart failure and sinus rhythm.
NOTE: ACE, angiotensin-converting enzyme; BP, blood pressure; HF, heart failure; ISDN, isosorbide dinitrate; LV, left ventricular; MI, myocardial infarction; NYHA, New York Heart Association.

In acute decompensation, as may occur after a massive myocardial infarction or intermittently in class III to IV chronic heart failure, more aggressive therapy may be required, along with hospitalization for Swan-Ganz catheter monitoring. In this circumstance, short-term stimulation of the myocardium with dobutamine and/or milrinone, along with increasing amounts of intravenous diuretics, may be required for short periods to regain a stable state. At present there are no oral agents of this nature available to extend this care to outpatients, and if dobutamine cannot be withdrawn, occasional administration by an external pump is required. Such therapy presents a short outcome of days or months.

In summary, therapy for heart failure seeks the reversal or attenuation of the processes that initiated the syndrome while treating the patient to relieve symptoms and prolong life. The latter end is best achieved early in the disease process through prevention of further loss of myocardium (e.g., reperfusion) or reduction of loading (e.g., appropriate valve surgery or treatment of hypertension). In very late stages of the disease, relief of symptoms can now be accomplished with modest gains in life expectancy.

Chapter 21: DIAGNOSIS AND MANAGEMENT OF HEART FAILURE

List of Figures

Figure 21-1: The pathophysiology of heart failure progressing with time from the initial event, related to a loss of myocardium and/or a persistent overload, to the adaptive responses, including myocardial hypertrophy, and ultimately ventricular dilatation. Left ventricular (LV) dilatation augments diastolic wall stress that produces deformations of the ventricular wall and functional mitral regurgitation (MR) as well as further myocyte loss (apoptosis). Neurohumoral responses become activated with increased sympathetic tone, reduced parasympathetic tone, and activation of the renin-angiotensin system. These structural alterations constitute what is termed *ventricular remodeling*. With progression of these latter processes and with decreased ventricular capacity to augment cardiac output as required along with renal retention of sodium, central and peripheral edema ensue, with limitation of exercise performance. Thus, the syndrome of congestive heart failure (CHF) finally becomes manifest. Shown at the bottom of the figure are various studies addressing these phases of heart failure in terms of morbidity and mortality. GISSI, Gruppo Italiano per lo Studio dell a Sopravivenza nell'Infarcto Miocardio; CONSENSUS, Cooperative North Scandinavian Enalapril Study; SMILE, Survival of Myocardial Infarction; ISIS, International Study of Infarct Survival; SAVE, Survival and Ventricular Enlargement Trial; SOLVD, Studies of Left Ventricular Dysfunction; TRACE, Trandolapril Cardiac Evaluation: V-HeFT, Veterans Administration Cooperative Vasodilator Heart Failure Trial; AIRE, Acute Infarction Ramipril Efficacy Study.

Figure 21-2: Ventricular remodeling and progression of ventricular dysfunction. Myocardial cell loss leads to ventricular remodeling, characterized by myocyte hypertrophy and elongation. An increase in ventricular volume (the Starling effect) helps maintain cardiac output (CO), but at the cost of increasing ventricular filling pressures. The increase in diastolic stretch and pressure produces further damage, including stretch-induced myocyte death (apoptosis), which amplifies the process of remodeling. With inadequate pump function, neurohumoral activation occurs with decreased vagal tone and enhanced sympathetic tone. With activation of the renin-angiotensin system and increased sympathetic tone, arterial vasoconstriction occurs with resultant maldistribution of blood flow. Decreased vagal and increased sympathetic stimulation induce tachycardia, and the latter system, along with the activated renin-angiotensin system, via angiotensin II can produce further myocyte death. In this manner, the process is self-perpetuating in that ventricular damage leads to remodeling, which in turn leads to further damage. These interrelated cycles thus provide therapeutic opportunities.

Figure 21-3: Progression of initial ventricular damage to sympathetic congestive heart failure. Data from the SOLVD trial of enalapril therapy, plotted in terms of LV ejection fraction and exercise capacity measured in terms of peak oxygen consumption (VO_2). Also shown are median plasma norepinephrine and plasma renin activity. The latter is shown in terms of patients who did or did not receive diuretics.

Figure 21-4: Evaluation of patients with congestive heart failure. Transthoracic Doppler and two-dimensional echocardiography provide a central modality to evaluate ventricular function and valvular abnormalities. Ventricular wall thickness and both end-diastolic and end-systolic volumes can be determined. With an ejection fraction (EF) more than 40 percent, coronary angiography is indicated in the presence of angina pectoris or evidence of significant ischemia. With an EF less than 40 percent, coronary arteriography is indicated since the underlying ischemic depression may be amenable to reperfusion by angioplasty or coronary bypass surgery. Nuclear imaging techniques are used to define viable ischemic myocardium, while stimulation of such myocardium with dobutamine or extrasystolic potentiation may indicate recoverable hibernating myocardium. Right ventricular biopsy may be indicated in the absence of coronary artery disease to rule out processes such as amyloid or sarcoid.

Figure 21-5: figuremeasure taged use of therapeutic agents in heart failure. Initial approaches include control of factors that may cause progression of heart failure and/or augment its manifestations. Hypertension requires control. Unanticipated tachycardia may augment oxygen needs while reducing the time in diastole for coronary flow to take place. The reduction in the diastolic time can lead to marked elevations of left ventricular (LV) diastolic pressure as well as increased ischemia. Moreover, atrial fibrillation will deprive ventricular filling of the "atrial kick" and lead to further elimination of diastolic pressures. These considerations are of special importance with ventricular hypertrophy and resultant diastolic dysfunction. During the "remodeling" phase of ventricular failure, the patient may be asymptomatic. Nevertheless, inhibition of the renin-angiotensin system is indicated to reduce the rate of ventricular remodeling and slow ventricular dilation. Beta-adrenergic blockade reverses ventricular remodeling and improves survival in patients with class II to III symptoms. * Reflects the inconsistent effects of beta-adrenergic blockade in patients with class IV symptoms. In the Copernicus trial, carvedilol was beneficial, while in the BEST trial, bucindolol appears to be detrimental. Once symptoms ensue, loop diuretics generally are needed for fluid control. Digitalis glycosides also are indicated for neurohumoral benefits in reducing sympathetic tone and enhancing parasympathetic tone while providing modest inotropic support. These actions appear to improve morbidity without necessarily altering mortality.

Figure 21-6: The classification and characteristics of angiotensin II receptors. DTT, dithiothreitol. (From Kang PM, Landau AJ, Eberhardt RT, Frishman WH. Angiotensin II receptor antagonists: A new approach to blockade of the renin-angiotensin system. *Am Heart J* 1994; 127:1388-1401.)

Figure 21-7: Treatment of congestive heart failure is directed toward controlling salt and water retention (central or peripheral edema) and/or relieving a low-flow state by increasing cardiac output while reducing very increased filling pressures. Dobutamine is useful to augment cardiac output except when $beta_1$-adrenergic blockade is present. Milrinone, which stimulates the adenyl cyclase system beyond the beta receptor, acts well in this circumstance to augment the effects of dobutamine while serving as an arterial and venous dilator. When inadequate cardiac output can no longer be maintained, surgical implantation of a left ventricular assist device (LVAD) may be used to pump blood from the left ventricle to the aorta as a temporary support or bridge to transplantation.

Figure 21-8: Structure of digitalis molecule. * Digitoxin becomes digoxin with OH placement at C_{12}. (From Sonnenblick EH, LeJemtel TH, Frishman WH. Digitalis preparations and other inotropic agents. In: Frishman WH, Sonnenblick EH, eds. *Cardiovascular Pharmacotherapeutics*. New York, McGraw-Hill; 1997:241. Part 3: HEART FAILURE
Chapter 22:

CARDIAC TRANSPLANTATION, MECHANICAL VENTRICULAR SUPPORT, AND ENDOMYOCARDIAL BIOPSY

Authors: Sharon A. Hunt, John S. Schroeder, Gerald J. Berry

HISTORY AND OVERVIEW

Although a number of advances in therapy for failing myocardium have saved or at least prolonged the lives of many patients with previously terminal myocardial dysfunction, a sizable number of young patients are fated to die or be severely disabled because of irreversible myocardial disease. In patients with such end-stage disease, biological replacement of the heart has come to be a standard therapy and is currently widely accepted as a modality for prolonging life and improving its quality in carefully selected patients. As technological and engineering advances occur, mechanical replacement of the heart and xenotransplantation (transplantation of animal organs) may become very competitive or complementary modalities for the treatment of such patients, but biological replacement with human donor hearts is the current standard of therapy.

Interest in developing surgical techniques to interpose a functioning heart into a recipient's circulation dates back at least to the early part of the 20th century. In 1905, Carrel and Guthrie[1] described the heterotopic transplantation of a functioning donor heart into the neck of a dog. The heart in that model functioned in sequence with the recipient's heart in the circulation and was not actually capable of supporting the circulation. Although the exact anatomic connections were not described in detail, this apparently nonworking model of heterotopic transplantation beat regularly for approximately 2 h before the blood clotted in all the chambers. Carrel's initial interest was in the concept of performing vascular anastomoses, an interest reportedly stimulated by his distress at the inability of the best French surgeons of that time to avert the death by exsanguination from a severed portal vein of the president of the French republic.[2] Carrel and his colleague Guthrie developed innovative surgical techniques for vascular anastomoses at the University of Chicago, and those advances set the stage for anastomoses leading to organ transplantation. This work was a major part of the body of work for which Carrel was awarded the Nobel Prize for Medicine and Physiology in 1912.

Work in the field lay dormant until Mann and coworkers from the Mayo Clinic published their seminal report in 1933 of a technique for heterotopic heart transplantation with circulatory loading of the right ventricle.[3] Presumably because this was a working model, the chambers did not clot immediately, and the hearts in their dogs beat for a mean of 4 days. Mann perceived several important surgical points, including the importance of avoiding ventricular distention and air embolism and the prevention of thrombosis by heparin, but his most incisive and critical observation was that failure of a transplanted heart was in fact due not always to faulty surgical technique "but to some biologic factor which is probably identical to that which prevents survival of other homotransplanted tissues and organs." In what was undoubtedly the first description of acute allograft rejection, Mann recounts: "When the heart was removed just before it became quiescent . . . the surface of the heart was covered with mottled areas of ecchymoses . . . histologically the heart was completely infiltrated by large mononuclears and polymorphonuclears." Although various other animal models for surgical techniques for heterotopic heart transplantation were described in subsequent years,[4-7] it took another 30 years to

better understand and manipulate the "biologic factor" Mann described as limiting the survival of allografted organs. In 1960, Shumway and Lower performed orthotopic heart transplants in dogs using cardiopulmonary bypass and topical hypothermia for donor heart preservation.[8] The dogs survived between 6 and 21 days and died of rejection. Shumway and Lower also recognized the limiting "biologic factor" and stated that "if the immunologic mechanisms of the host were prevented from destroying the graft, in all likelihood it would continue to function adequately for the normal lifespan of the animal." Their technique, involving anastomoses at the midatrial level and the supravalvular level in the great vessels, remained the basis of cardiac transplant technique in the 1990s.

In the early 1960s, the concept of pharmacologic immunosuppression was introduced; it ushered in the marriage of surgical and medical technology that is known today as the field of organ transplantation. Immunosuppression was, of course, seen as a means to mitigate the "biologic factor" that otherwise limited organ graft survival. The first clinical transplants were of the kidney, a logical choice since hemodialysis was then available as a backup system if the graft failed, and the field has flourished since the early 1960s.[9]

The first human heart allograft procedure was performed in South Africa in 1967,[10] followed shortly by the first U.S. transplant by Shumway at Stanford in 1968 and then by a flurry of transplant activity in many centers. This initial enthusiasm subsided as it became evident that postoperative survival was limited by a variety of complex medical problems, including opportunistic infections and graft rejection. Most major centers discontinued performing heart transplantation in the early 1970s, and it was not until the introduction of cyclosporine-based immunosuppression at Stanford in 1980 and the demonstration of the attendant improvement in survival rates[11] that the procedure reemerged as a widely accepted therapy for end-stage heart disease. In the 1990s, many tertiary care centers provided programs for heart transplantation, and most medical care payers in the United States, including the federal government, provided coverage for such care.

Cardiopulmonary transplantation was introduced at Stanford in 1981,[12] and subsequent experience with heart and lung and with both single- and double-lung transplantation in many centers has proved that these procedures are valid therapies for a wide variety of primary lung diseases and end-stage cardiopulmonary disorders.[13]

Current Status

The most accurate data on volume and outcomes of thoracic organ transplantation are provided by the Registry of the International Society for Heart and Lung Transplantation and are updated yearly and published in the journal of that society. Since 1994, the Registry has been administered by the U.S. donor allocation organization, the United Network for Organ Sharing (UNOS), but it includes data on the vast majority of non-U.S. programs as well as all U.S. programs. As of the most recent Registry report,[13] there has been a plateau of heart transplant operations at approximately 3500 procedures worldwide on an annual basis since the late 1980s, a level generally accepted to be due to limitations of donor availability (Fig. 22-1). This most recent report includes data on 48,541 transplant procedures reported since the Registry's inception in 1982 and documents overall patient survival rates of 79, 71, and 63 percent, at 1, 3, and 5 years, respectively (Fig. 22-2). After the first year, there is a linear attrition rate of 4 percent per year to a survival of about 40 percent at 10 years.

According to this Registry, there are currently 304 programs in clinical heart transplantation, of which 165 are in the United States. According to data published in 1994, a large number of these U.S. programs have very low volume, and low volume is associated with inferior survival rates.[14,15] Thus, the survival rates to be expected at major, high-volume programs should be somewhat in excess of the overall reported rates.

Chapter 22: CARDIAC TRANSPLANTATION, MECHANICAL VENTRICULAR SUPPORT, AND ENDOMYOCARDIAL BIOPSY

RECIPIENT SELECTION AND MANAGEMENT

As is the case with any surgical procedure, careful selection of patients for heart transplantation results in optimum postoperative survival rates. In contrast, however, to the quality-of-life or prolongation-of-life issues involved in decisions regarding more conventional heart surgery, decisions regarding candidacy for heart transplantation must take into consideration a limited donor supply and the necessity of following a highly complex medical regimen for the rest of the patient's posttransplant life. These considerations can make selecting recipients most difficult. Major guidelines for recipient selection have been developed and are intended to provide the maximum benefit from the limited resource of donor organs.[16] Selection criteria are in a state of change worldwide, and criteria for acceptance at one center may not match exactly those at another center. The criteria generally reflect experience with the selection of patients who are most likely to survive and benefit, with a return to a normal life after the transplant.

Some basic or general criteria can be described that are universally accepted; these criteria are summarized in Table 22-1. They include the most basic criterion: the existence of end-stage cardiac disease irremediable by other, more conventional forms of medical or surgical therapy. The term *end stage* is, of course, difficult to define exactly, but in general it refers to cardiac disease associated with New York Heart Association (NYHA) functional class IV symptomatic status despite optimum medical management. In the past, one criterion was an estimated life expectancy of 6 months or less; however, the increasingly long waiting times for a suitable donor caused by increased patient numbers on the transplant waiting list now require the much more difficult task of estimating 1- to 2-year mortality in potential candidates. *With the recent major advances in heart failure therapy has come the realization that many transplant operations in patients referred for transplantation can be avoided by utilizing aggressive medical therapies*. Many transplant centers have found that as many as 30 to 50 percent of patients referred for heart transplants can be stabilized or even have their heart failure reversed by an aggressive, well-organized medical approach using angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockade, combination diuretics, beta blockers, and meticulous monitoring of the patient's weight, general status, electrolytes, and renal function.[17,18] Thus, most heart transplant centers have evolved into centers for heart failure management as well as transplantation. Table 22-2 lists a typical drug regimen for a patient with advanced heart failure who is waiting for a donor. The frequency of clinic visits for monitoring ranges from every week to every 4 weeks, depending on the status of the patient. Furthermore, the introduction of transvenously placed antitachycardia/defibrillation devices and the increasing use of new beta blockers have contributed to this ability to stabilize patients in order to avoid or delay heart transplantation. It also has been realized that a small percentage of patients may have their left ventricular dysfunction reversed by high-risk percutaneous interventional procedures or coronary bypass surgery in order to restore blood flow to areas of "hibernating myocardium." Positron emission tomography (see Chap. 19) or 24-h thallium scanning (see Chap. 16) is utilized to identify potential candidates for such procedures. It is also important to identify potentially reversible causes of cardiomyopathy as summarized in Table 22-3 (see Chaps. 66 and 69). Cessation of excessive alcohol intake or slowing of the ventricular rate with drugs or atrioventricular (AV) nodal ablation in patients with rapid heart rates occasionally results in a dramatic reversal of the heart failure.[19] Although it is more controversial, some centers continue to treat biopsy-proven acute lymphocytic myocarditis with high-dose steroids. This approach also is used for sarcoid cardiomyopathy. Finally, the introduction of beta blockers has resulted in dramatic improvement in survival statistics. Their use is associated with improved left ventricular ejection fraction over time as well[20-25] (see Chap. 21).

Table 22-1: Criteria for Acceptance of Cardiac Transplant Recipients

- Unacceptable heart failure that has not responded to an aggressive medical or surgical regimen
- Unacceptable prognosis for survival of 1-2 years
- Biological age less than 55-60 years
- Absence of irreversible pulmonary hypertension
- Absence of other systemic diseases that would limit long-term survival
- Medically compliant, with the ability to follow a complex medical regimen
- Adequate psychosocial support to assure compliance with medical directions and office visits
- Absence of self-abusive behavior that would interfere with postoperative course

Table 22-2: Typical Pharmacologic Regimen for Advanced Heart Failure Patients

ACE inhibitor/angiotensin II blocker
Loop diuretic
Triamterene/hydrochlorothiazide
Digoxin (low dose)
Coumadin
Enteric-coated aspirin if CAD
HMG-CoA reductase inhibitor if CAD
Beta-blocker trial

ABBREVIATIONS: ACE = angiotensin-converting enzyme; CAD = coronary artery disease.

Ischemic left ventricular dysfunction reversible with interventional or surgical reperfusion
Cardiomyopathy secondary to
Lymphocytic myocarditis
Sarcoidosis
Tachycardia
Ethanol

Age limits for cardiac transplant recipients are a second criterion for acceptance, and those limits have been expanded considerably in both directions over the past several years. In the early years of experience with cardiac transplantation, older patients experienced very inferior survival rates and the upper limit of eligibility was set at age 50. Since the advent of cyclosporine-based immunosuppression in 1980, it has become apparent that survival rates are no longer inferior in older age groups.[24] In the most recent year in

which such data were analyzed in the Registry of the International Society for Heart Transplantation, the 30-day mortality rates according to age were identical (at 10 percent) for all ages between 10 and 69,[25] and in the current Registry data, 1- and 5-year mortality risk increases only slightly over age 65. Reports from several individual centers also have attested to the excellence of both early and late postoperative survival rates in older patients.[26-29] On the basis of those data, most centers have now advanced the official age of acceptability to 60 and may accept patients up to age 65 as well as highly selected patients over age 65. The lower age limits for transplantation eligibility also have been expanded recently, with a number of major centers embarking on programs involving neonates and young children.

Potential cardiac transplant recipients also are screened for the existence of any other systemic disease that independently is likely to limit their survival. The coexistence of an active malignancy and the potentially increased tendency for its advancement in the presence of immunosuppression are an obvious problem, and such patients are routinely excluded. How to deal with a patient with end-stage heart disease and a remote history of malignancy is a more difficult problem. Edwards and associates[30] reported a small group of patients with a prior history of malignancy who were considered to have been cured of their malignant disease and were otherwise candidates for cardiac transplantation. Seven such patients underwent transplantation; six had a remote history of lymphoproliferative disease, and one had had adenocarcinoma of the colon. Only the patient with colon cancer has had recurrence of malignancy during follow-up averaging over 2 years. Thus, cautious acceptance of such patients may be justified.

The coexistence of one other major systemic disease-insulin-requiring diabetes-had been considered a contraindication to cardiac transplantation in otherwise acceptable patients. The rationale for this was the well-known increase in the incidence of early peripheral and cerebrovascular disease and nephropathy in these patients as well as their generally poor ability for wound healing and the difficulty of diabetic control during the period of constantly varying steroid doses in the early postoperative period. As steroid requirements have become lower, this requirement generally has been relaxed to allow the inclusion of stable (as opposed to "brittle") insulin-requiring diabetic patients, and in recent years several reports have attested to the safety and efficacy of heart transplantation in very carefully selected diabetic patients.[31-33]

Human immunodeficiency virus (HIV) positivity generally is considered an absolute contraindication to heart transplantation. Other comorbid conditions must be considered on an individual basis, but irreversible organ dysfunction such as emphysema, severe peripheral vascular disease, and hepatic or renal dysfunction out of proportion to that predictable as a consequence of severe congestive heart failure are strong relative contraindications. The presence of an active infection is an often temporary absolute contraindication to transplantation because of the mandatory posttransplant institution of immunosuppression. Early in the years of clinical experience with heart transplantation, it was found that a normal donor right ventricle is unable to increase its external workload acutely to overcome elevated **pulmonary vascular resistance (PVR)**. Because of this, patients who have end-stage heart disease with an elevated **PVR** often experience acute right-sided heart failure and cardiogenic shock after the transplantation of a normal heart with a right ventricle that has not been conditioned to pump against high resistance. This problem was a major cause of intraoperative deaths in the early years of transplantation and led to the setting of an upper limit of 4 Wood units of **PVR** (approximately 320 dynes·s/cm^5) as the cutoff point or fourth criterion for suitability for cardiac transplantation. In recent years, the concept of reactivity of the pulmonary vasculature and the potential reversibility of elevated **PVR** has gained acceptance. Because of this, potential candidates with **PVR** greater than 4 Wood units (320 dynes·s/cm^5) at baseline usually are subjected to pharmacologic maneuvers during hemodynamic monitoring, using nitroprusside and/or prostaglandin E_1 or inhaled nitric oxide to determine whether the elevated **PVR** is reversible; such patients are accepted as candidates for transplantation if the **PVR** can be reduced to acceptable levels while systemic arterial pressure remains adequate.

The last criterion that is accepted by most centers is the absence of unresolved pulmonary infarction. In spite of systemic anticoagulation, pulmonary infarcts that are due to emboli from the dilated right ventricle or the leg or pelvic veins are common complications in patients with biventricular congestive heart failure who are awaiting transplantation. *Experience has shown that pulmonary infarcts have a high probability of becoming pulmonary abscesses after the institution of immunosuppression*. For this reason, waiting recipients who sustain a pulmonary infarction usually are removed temporarily from the waiting list until the infarct resolves radiographically. Unfortunately, such resolution can be quite slow in this severely ill group of patients, and many never survive to return to the waiting list.

On the basis of these criteria, a group of patients is selected who are believed to have the best chance of benefiting from the operation and the attendant substantial commitment of medical resources. The type of underlying heart disease in the adult population selected for the procedure is nearly evenly split between idiopathic cardiomyopathy and ischemic disease; in the pediatric population, predictably, there is a higher percentage with congenital heart disease.

DONOR SELECTION AND MANAGEMENT

Acceptance of the concept of brain death, both legally and medically, has been central to the emergence of organ transplantation (particularly transplantation of unpaired organs such as the heart) in the modern era. The mandatory warm ischemic time that would be involved if cardiopulmonary death were the only accepted criterion of death would make heart transplantation impossible. Acceptance of the concept of irreversible brain death has been a perhaps surprisingly recent phenomenon. In 1970, Kansas became the first state in the United States to pass legislation recognizing the legal concept of brain death. Several states followed suit, and the medical and legal criteria for brain death have been refined over the years. The most recent and widely accepted set of guidelines was set out in the President's Commission Report in 1980.[34] It has been estimated that only 15 to 20 percent of persons who qualify as brain-dead and have usable or transplantable organs become organ donors in the United States.[35] The reasons for this are complex and include a lack of public awareness of the potential to donate organs as well as reticence among medical staff to make a request for donation. Efforts are being made in many areas to improve the percentage of organs recovered for transplantation from potential donors, but even with much higher recovery rates, heart transplantation probably will be a donor-limited field for the foreseeable future.

To be considered suitable donors for cardiac transplantation, brain-dead individuals must meet certain minimum criteria. Age criteria vary in different programs, but most cardiac donors have been under age 40. The donor obviously should not have had any significant cardiac disease, malignant disease, or acute or chronic infection. Risk factors for cardiovascular disease such as diabetes and severe hypertension or hypercholesterolemia are relative exclusion factors. Donors routinely are screened serologically for HIV and hepatitis B and C. Baseline serology for a number of other infectious diseases, such as cytomegalovirus (CMV), is obtained in many programs but usually is not used prospectively in donor-recipient matching. If there is any suspicion of cardiac disease in the donor, appropriate diagnostic studies (including echocardiography, cardiac catheterization, and coronary angiography) to assure the normality of the potential cardiac graft are pursued.

Once a potential donor is identified, the procurement process is initiated by contacting and referring to the local organ procurement organization (OPO), which maintains a registry of waiting recipients and coordinates equitable distribution of donor organs within a geographic area. Donor-recipient matching is fairly straightforward and requires ABO blood group compatibility as well as overall body size comparability, with ±20 percent body weight considered an acceptable discrepancy. Human leukocyte antigen (HLA) matching is not attempted prospectively because of the difficulty of obtaining HLA typing promptly as well as the relatively small numbers of donors and recipients, which severely limits choices.

Most donor hearts currently are "harvested," or removed, from the donor by a transplant donor team from a transplantation center and transported back to the center for implantation. A cold ischemic time of 4 h in adults generally is considered safe; this requirement limits the distance from which hearts can be transported and leads to the rationale for geographic subdivision into OPOs for cardiac allografts despite the drive for a "national" list for other organs.

Chapter 22: CARDIAC TRANSPLANTATION, MECHANICAL VENTRICULAR SUPPORT, AND ENDOMYOCARDIAL BIOPSY

SURGICAL TECHNIQUE

As was noted above, the surgical technique used in most centers today differs little from that described by Lower and Shumway in 1960.[8] With this procedure, both the donor and recipient hearts are removed by transecting the atria at the midatrial level, leaving the multiple pulmonary venous connections to the left atrium intact in the posterior wall of the left atrium, and then transecting the aorta and pulmonary artery just above their respective semilunar valves (Fig. 22-3).

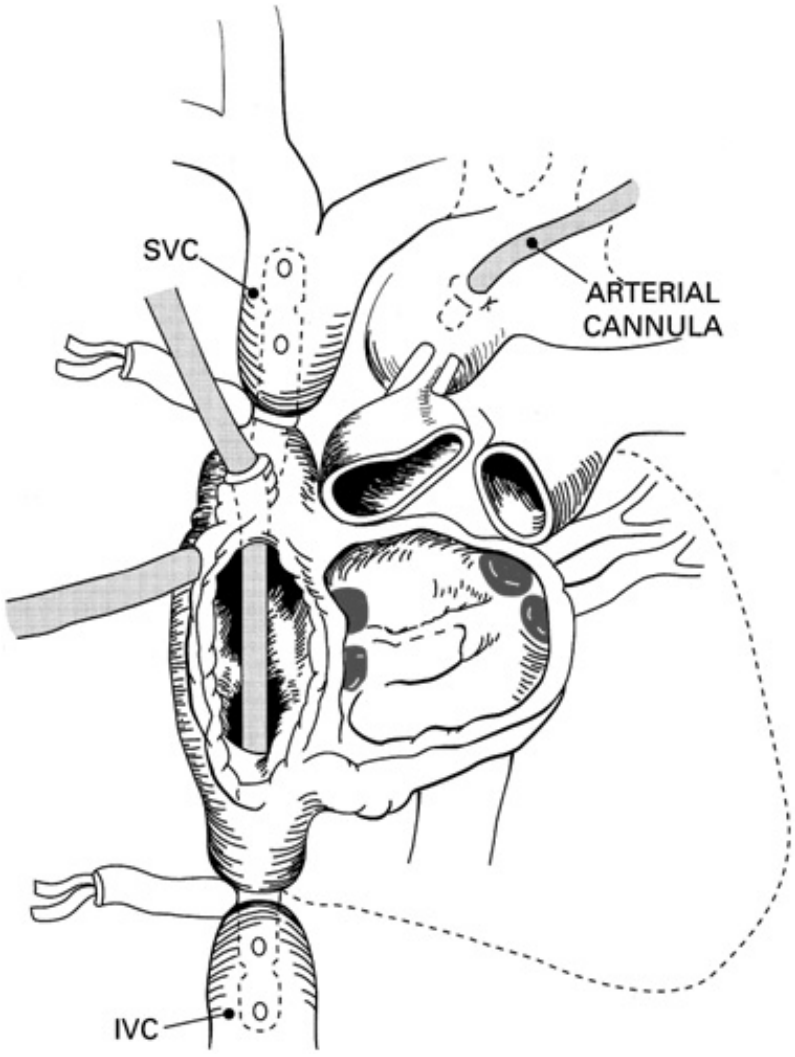

Figure 22-3: Diagram of recipient's mediastinum with heart resected and arterial and venous cannulas in place.

As was noted above, the donor heart usually is explanted, or harvested, by a surgical team at a hospital remote from the transplant center, and this surgery most often needs to be coordinated

with the requirements of other surgical teams procuring nonthoracic organs for transplantation at other centers. The donor heart is arrested with cold crystalloid or blood cardioplegic solution, and the explanted heart then is cooled topically by being placed in an iced preservation solution; it then is placed in a secure container and transported expeditiously to the transplant center. Ischemic times average 3 to 4 h. Implantation of the heart in the orthotopic position begins with reanastomosis at the midatrial level, beginning with the atrial septum (Fig. 22-4). Efforts are made to include a generous cuff of donor right atrium so that the sinoatrial node will be included. The great vessels are reanastomosed just above the semilunar valves.

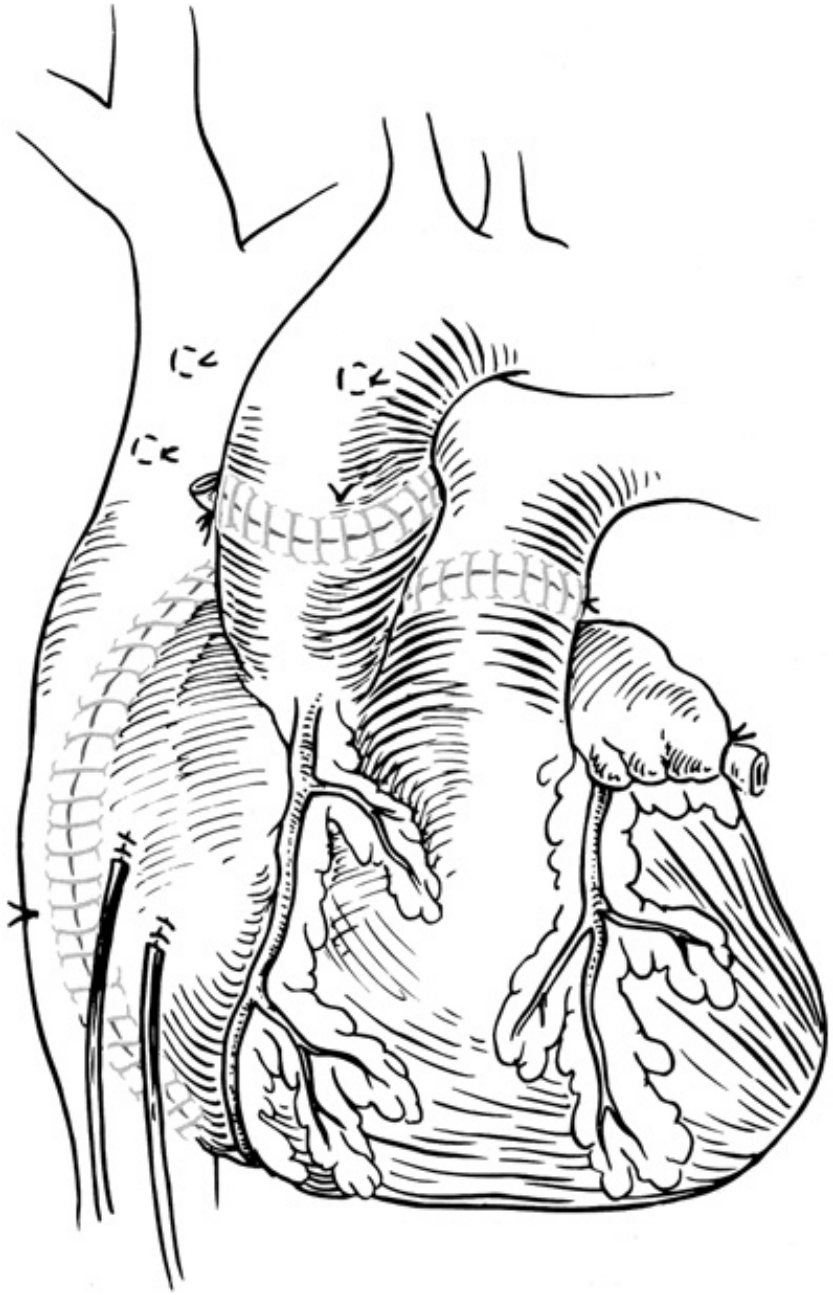

Figure 22-4: Diagram of donor heart anastomosed in the orthotopic position. Suture lines at the midatrial level and the aorta and pulmonary artery above semilunar valves.

In recent years, there has been a move to alter the surgical technique by leaving the donor atria intact and making anastomoses at the level of the superior and inferior venae cavae and pulmonary veins[36]; this is known as the *technique of bicaval anastomosis.*[37,38] There is evidence

that this modified technique is associated with a decreased requirement for pacemaker placement for donor sinus node malfunction and with less AV valve regurgitation,[39,40] most likely as a result of preservation of the geometric configuration and anatomic size of the atria and the preserved integrity of the sinoatrial node.

Immediate postoperative care differs little from that after more routine heart surgery except for the institution of immunosuppression (described below) and the need for chronotropic support of the donor sinoatrial node for the first 2 to 3 postoperative days, usually with temporary pacemaker support but occasionally with infusion of isoproterenol. Uncomplicated patients may be discharged from the hospital 7 to 10 days postoperatively.

POSTOPERATIVE MANAGEMENT

Immunosuppression

GENERAL

The need to suppress the normal immune response in the presence of a solid organ allograft begins immediately at the time of surgery and continues for the life of the graft, which is generally concurrent with the life of the patient in the field of cardiac transplantation. Historically, most clinically used immunosuppressive regimens have consisted of a combination of several agents used concurrently and sequentially. This multiple-drug approach continues to be considered the state of the art. The number of drugs and the timing of their administration vary from institution to institution, but several general principles are commonly adhered to.

The first general principle is that immune reactivity and the tendency toward graft rejection are highest early after graft implantation and decrease with time, although they probably never disappear entirely. Thus, most regimens employ the highest levels of immunosuppression immediately after surgery and decrease those levels later, eventually settling on the lowest maintenance levels of suppression that are compatible with preventing recurrent graft rejection. The second general principle is reminiscent of that originated in oncology chemotherapy regimens, using low doses of several drugs without overlapping toxicities in preference to higher (and more toxic) doses of fewer drugs whenever feasible. The third general principle is that too much or too intense immunosuppression is undesirable because it leads to myriad undesirable effects, such as susceptibility to infection and malignancy, but too little is equally undesirable because it permits graft rejection. Finding the right balance between over- and underimmunosuppression in an individual patient is truly an art that utilizes science. As newer immunosuppressive agents and modalities are developed, the possible array of drug regimens can be expected to multiply accordingly, but these principles probably will remain, and the process of tailoring an individual patient's immunosuppressive regimen probably will continue to be an art as well as a science.

There is currently a relatively limited repertoire of approved agents for immunosuppression after organ transplantation, but their numbers can be expected to increase. Most programs employ a long-term two- or three-drug regimen, and roughly half additionally use a brief early postoperative course of "induction" cytolytic therapy. Most programs employ glucocorticoids as one of the agents, usually in relatively high doses early postoperatively and then tapering to low doses or discontinuing the drug during the first postoperative year. The commonly used drugs and their toxicities are outlined in Table 22-4.

Table 22-4: Currently Available Immunosuppressive Agents

Agent	Toxicities	Avoid Toxicity
Cyclosporine	Renal dysfunction	Follow blood levels
	Hypertension	Antihypertensive medication
	Neurotoxicity	?
Tacrolimus (FK506)	Renal dysfunction	Follow blood levels
	Neurotoxicity	?
Mycophenolate mofetil	Gastrointestinal disturbances	Reduce dose

	Marrow toxicity (mild)	Follow CBC
Azathioprine	Marrow toxicity	Follow CBC
	Hepatotoxicity	Discontinue drug
Glucocorticoids	Cushingoid habitus	Minimize dose
	Glucose intolerance	
	Osteoporosis	
Methotrexate	Marrow toxicity	Follow CBC

ABBREVIATIONS: CBC = complete blood count.

In managing patients on these drugs, it is most important to be aware of the potential for drug interactions when other agents are added to or deleted from the patient's regimen. A list of the most common and clinically important drug interactions is shown in Table 22-5. It is also important to keep in mind the potential for changing drug concentrations in the face of intercurrent hepatic or renal dysfunction.

SURVEILLANCE AND THERAPY FOR REJECTION

There are rarely any striking physical signs or symptoms of rejection until it is far advanced. Cardiac allograft rejection is diagnosed almost exclusively by examining histologic findings in surveillance right ventricular endomyocardial biopsies. The technique used and the pathologic criteria for diagnosis are described below. A wide variety of noninvasive methods to diagnose rejection have been investigated, but none has been determined to have sufficient sensitivity and specificity to replace the biopsy. Protocols for the timing of surveillance endomyocardial biopsies generally are chosen to match the observed frequency of rejection episodes, which is clearly highest in the early postoperative period. Most programs perform surveillance biopsies on a weekly basis for the first 4 to 6 postoperative weeks and then with diminishing frequency in a stable patient but at a minimum every 3 months for the first postoperative year. The need for continued surveillance biopsies after the first year in clinically stable patients has been questioned,[41,42] but most centers continue to do them every 4 to 6 months.

Rejection episodes are treated with augmented immunosuppression, the intensity of which is matched to the histologic, or occasionally clinical, severity of the episode. Early or first rejection episodes usually are treated with methylprednisolone given intravenously in a dose of 1 g daily for 3 days followed by a repeat biopsy in 7 to 10 days. Episodes after 3 months that are not clinically severe can be treated safely with an increase in the oral steroid dose.[43] More severe rejection is treated with glucocorticoids and the addition of cytolytic therapy with either polyclonal antithymocyte globulin (commonly of rabbit or equine origin) or the murine monoclonal anti-CD3 preparation OKT3. Such treatment is highly effective,[44] but sensitization can limit its use.[45]

Several strategies are employed as adjunctive therapy for repetitive or recalcitrant rejection episodes. They include the use of two modalities with proven efficacy in therapy for autoimmune disease: total lymphoid irradiation[46] and low-dose methotrexate.[47] Both have been shown to be of benefit in patients with frequent or difficult-to-treat cardiac allograft rejection.[48-51] An analysis from 1997 suggests that the two modalities are both reasonably effective in this setting.[52] Tacrolimus (FK506), when substituted for cyclosporine, has been reported to benefit several heart transplant recipients with resistant rejection[53] as well as to be safe and effective as a primary agent in a cohort of patients[54]; there is a larger body of experience with its use in resistant renal graft rejection.[55] Similar success has been reported with the use of mycophenolate mofetil in therapy for recalcitrant rejection.[56] Studies are under way to evaluate several other drugs, modalities, and immunologic manipulations in the setting of resistant graft rejection.

If all these strategies fail and severe graft dysfunction supervenes, retransplantation is the only remaining

option and is offered in many centers. The results of retransplantation in this setting are, however, disappointing, with only 33 percent 1-year survival in one registry[57] and consistently inferior survival in the international registry.[13]

Infectious Complications

Although their incidence has decreased in the cyclosporine "era," infections, often with unusual and opportunistic organisms, are the major cause of death during the first postoperative year and remain a threat throughout the life of a chronically immunosuppressed patient. Effective therapy demands an extremely aggressive approach to obtaining a specific diagnosis and a background of experience in recognizing the more common clinical presentations of CMV, *Aspergillus*, and other opportunistic infectious agents. Transplant cardiologists generally have expertise in infectious disease management but usually require the availability of both infectious disease consultation for the more unusual problems and a high-quality infectious disease laboratory. Several well-proven regimens for infection prophylaxis are commonly used and are outlined in Table 22-6. Infection surveillance is mainly clinical, but routine chest radiography often detects infections, especially fungal and mycobacterial ones, at an early and asymptomatic stage.

Table 22-6: Infection Prophylaxis Regimens

Pathogen/Disease	Strategy
Aspergillus	? Air filtration
	? Prophylactic antifungals
Bacterial endocarditis	Standard subacute bacterial endocarditis prophylaxis
Cytomegalovirus	Blood product selection
	Prophylactic ganciclovir
	Prophylactic immunoglobulin
Influenza	None recommended
Pneumococcus	Preoperative vaccine
Pneumocystis	Sulfamethoxazole/trimethoprim
	Inhaled pentaminide
Toxoplasma	Pyrimethamine if donor seropositive

Posttransplant Malignancy

Any program of chronic immunosuppression is associated with a subsequent increased risk of lymphoproliferative malignancy; the earliest cases were noted after a period of immunosuppressive therapy for chronic hepatitis.[58] Organ transplantation has proved to be no exception, and the incidence of posttransplant lymphoproliferative disease (PTLD) has been documented in a registry based at the University of Cincinnati. The incidence of PTLD in heart transplant recipients is somewhat higher than that in kidney transplant recipients but not as high as that in liver recipients (Table 22-7); this probably is related to the intensity of immunosuppression required after the various allograft procedures.[59] According to the most recent registry report, malignancy accounts for 18.6 percent of deaths 4 years after heart transplantation.[13]

Table 22-7: Posttransplant Lymphoproliferative Disorder Incidence in Organ Transplantation

Organ	Incidence, %
Kidney	1.0
Heart	1.8
Liver	3.0
Heart/lung	4.6

SOURCE: Reproduced from Penn I. Roundtable report: Immunosuppression and lymphoproliferative disorders, 1992. (With permission of the author and Pro/Com International, Parsippany, NJ.)

There is convincing evidence that most PTLDs are related to infection (either primary or reactivation) with the Epstein-Barr virus (EBV).[60-62] They frequently occur in unusual, extranodal locations and may respond to reduction in immunosuppression,[63] although such reduction is clearly a "double-edged sword" with a cardiac allograft for which there is no alternative system, such as dialysis in renal transplantation, if the graft is rejected. PTLDs are usually quite radiosensitive, and both radiotherapy and surgical resection can play a major role in therapy when there is a single lesion.

There is anecdotal evidence that the use of the antiviral agent acyclovir may be useful in therapy for PTLD,[64] and most centers employ it as an adjunctive therapy. In recent years, there has been interest in the use of interferon for these malignancies,[65] and a multicenter oncology group protocol is under way to evaluate its efficacy. Recently, there has been interest in the use of infusions of donor leukocytes[66] and donor-derived EBV-specific cytotoxic lymphocytes for this disease in bone marrow transplant recipients.[67] The technology may well be transferred to organ transplant recipients but would require the maintenance of donor tissue lines prospectively.

Allograft Vasculopathy

INCIDENCE

When clinical heart transplantation was introduced, the complications discussed above were all anticipated problems in light of the nonspecific nature of available immunosuppression, but the frequent development of diffuse and often rapidly progressive obliterative coronary artery disease in young donor hearts was not expected. It occurs angiographically in approximately 10 percent of cardiac transplant recipients by the first postoperative year and in 50 percent by 5 years postoperatively,[68,69] and its incidence did not decrease after the introduction of cyclosporine-based immunosuppression in the early 1980s.[70] *The ischemic sequelae of this vasculopathy account for the vast majority of late posttransplant deaths, and it is currently the main factor limiting truly long-term survival*.[13]

MORPHOLOGY

The angiographic morphology of cardiac allograft vasculopathy has been well described,[71,72] and its main features are summarized in Table 22-8. The very diffuseness of the disease makes it easy to underestimate angiographically even when, as is usually recommended, similar angiographic views from serial angiograms are reviewed simultaneously with side-by-side projectors.

Table 22-8: Angiographic Features of Cardiac Allograft Coronary Artery Disease

Distribution: diffuse, distal, concentric, longitudinal obliterative lesions
May coexist with focal proximal lesions
Collateral vessel formation uncommon

In recent years, the use of intravascular ultrasound has gained acceptance as a sensitive and early detector of the intimal thickening that characterizes graft vasculopathy.[73-75] Intravascular ultrasound measurements of the extent of coronary intimal thickening currently serve as surrogate end points for the prevention of vasculopathy in several trials of new immunosuppressive agents that have shown promise of lessening the incidence of vasculopathy in animal models.

PATHOLOGY

The morphologic features of accelerated transplant vasculopathy and the principal differences from conventional atherosclerosis have been described.[76-78] In transplant arteriopathy, the major epicardial vessels, their branches, and often the intramyocardial divisions display uniform, diffuse involvement extending along their entire length. The arteries are cordlike in texture, and cross sections show uniform, concentric luminal narrowing (Fig. 22-5). The asymmetric and calcified plaques or lesions composed of cholesterol that are characteristic of conventional atherosclerosis are not found in uncomplicated lesions of vessels affected by transplant vasculopathy. Histopathologic sections show a thickened intimal layer composed of modified smooth muscle cells, foamy macrophages, and variable numbers of histiocytes and lymphocytes within a connective tissue matrix that ranges from loose, edematous, and myxoid in early lesions to densely hyalinized and fibrotic in older lesions (Fig. 22-6). The internal elastic membrane is usually preserved, with only focal interruptions and reduplications. The medial layer is generally intact but may show atrophy in advanced lesions. Intraluminal thrombosis is uncommon. While these changes rarely are seen on endomyocardial biopsy samples, signs of ischemia or infarction seen in the endomyocardial biopsy should alert the pathologist and the clinician to the possibility of the insidious presence of graft coronary disease.[79]

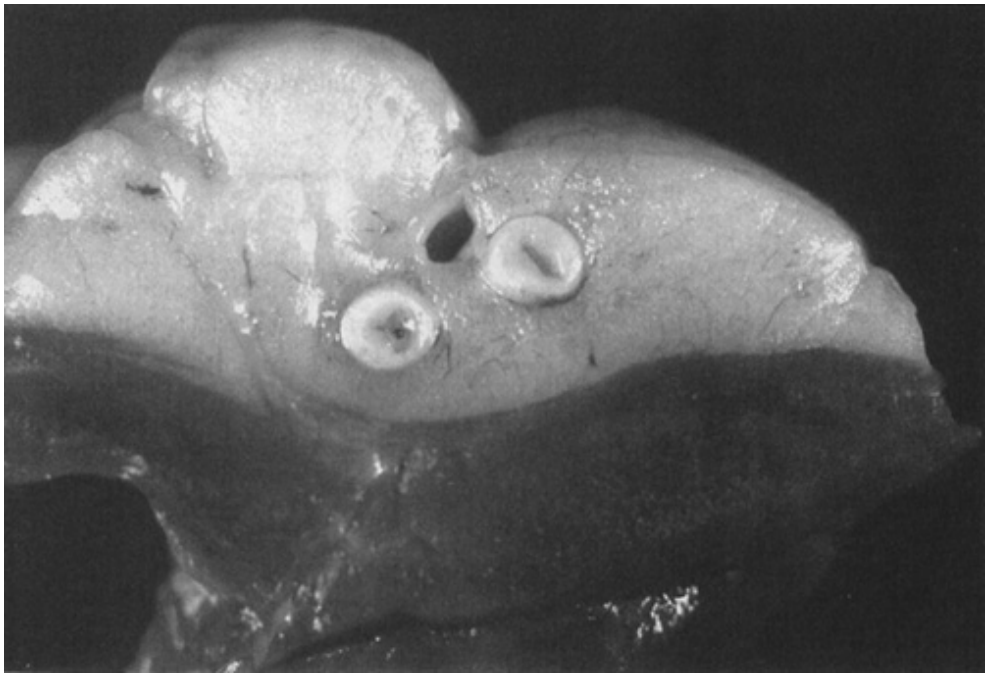

Figure 22-5: The mid-left anterior descending artery at autopsy in a 63-year-old man with advanced graft coronary disease.

Figure 22-6: A main epicardial artery and division vessel showing occlusive graft coronary disease. Note the concentric intimal proliferation with a slitlike lumen. The internal elastica of both vessels is intact. (EUG ×10)

CLINICAL PRESENTATION, SCREENING, AND PROGNOSIS

Because most cardiac transplant recipients have a persistent state of both afferent and efferent cardiac denervation, most are incapable of experiencing the subjective sensation of angina pectoris. Clinical presentations of ischemia in this patient population usually are related to sequelae of the ischemia, such as arrhythmias or left ventricular dysfunction. In recent years, it has been convincingly shown that some cardiac transplant recipients do have physiologic evidence of reinnervation[80-83] and may experience angina pectoris.[84]

The usual lack of angina and the diffuseness of the disease have made standard clinical and noninvasive screening for native coronary artery disease fairly insensitive in detecting this form of coronary vasculopathy.[85] Most of this technology is designed to detect uneven myocardial perfusion caused by focal lesions and is less effective in detecting the global ischemia of diffuse obliterative disease. Several reports have suggested that dobutamine stress echocardiography may in fact be the one noninvasive technique that offers reasonable sensitivity and specificity as well as prognostic value in screening for this disease,[86-88] and it offers an attractive alternative to the usual annual coronary angiography performed in these patients.

The prognosis for survival once significant graft vasculopathy is detected angiographically is generally poor. In one study, the 1- and 2-year survival rates after the detection of any 40 percent coronary artery stenosis were 67 and 44 percent, respectively.[89] After an ischemic event such as congestive heart failure or myocardial infarction, 1-year survival was only 18 to 20 percent in this study.

APPROACHES TO PREVENTION

A number of approaches to the prevention of allograft vasculopathy have been proposed, and several show promise. As was noted above, a decreased incidence of vasculopathy is one of the desired end points in all preclinical and clinical trials of new immunosuppressive agents, and several such trials are in progress. In addition, two studies have shown some decrease in the incidence and sequelae of vasculopathy with the use of other agents: one with a calcium channel blocker added to the patient regimen early after surgery and another with the lipid-lowering agent pravastatin added. In the former study, diltiazem was used in a

randomized study involving a total of 106 patients, and those taking diltiazem had little change in overall coronary diameter on quantitative angiography over a 3-year follow-up period and displayed a trend toward a decreased incidence of angiographic coronary stenosis and clinical events resulting from ischemia.[90] In the other study,[91] also randomized and involving a total of 97 patients, the use of pravastatin (regardless of lipid levels) was associated with improved survival and a markedly decreased incidence of allograft vasculopathy seen both at angiography and at autopsy. A more recent study[92] documented similar results with simvastatin, and this benefit is probably a class effect.

The mechanism of action for either of these agents remains speculative. It is to be hoped that since, as described below, the etiology of allograft vasculopathy is most likely immunologic, improved methods of inducing specific graft tolerance in the future may lead to the disappearance of this disease and permit truly long-term survival rates after heart and other organ transplantation.

APPROACHES TO THERAPY

The choice of treatment for established cardiac allograft vasculopathy is often difficult and controversial. No agent or modality has been shown to reverse the process. Its very diffuseness makes the disease only infrequently amenable to otherwise standard revascularization procedures such as angioplasty and surgical bypass grafting. A registry of revascularization procedures performed on heart transplant recipients in 13 large transplant centers in the United States documented 97 balloon angioplasty procedures in 66 patients before November 1991.[93] There was an angiographic 94 percent success rate and an acceptable complication rate. There was, however, a 55 percent restenosis rate at a mean of 8 months after angioplasty, and 19 patients underwent 31 repeat angioplasty procedures for 24 restenoses and 30 new lesions. Only 61 percent of these patients were alive without retransplantation at a mean of 19 months after coronary angioplasty. In the same registry, 12 surgical coronary bypass procedures were reported; 4 of these patients died in the hospital, a fifth died suddenly 2 months postoperatively, and a sixth has required further palliative angioplasty. Revascularization is clearly, at best, short-term palliation for this highly lethal disease.

The most definitive form of therapy for graft failure resulting from severe vasculopathy is obviously retransplantation, and this procedure has been offered in many centers to highly selected patients with advanced allograft vasculopathy. Survival rates after retransplantation, however, are clearly inferior to those after primary transplants, averaging only 52 percent at 1 year in the most recent registry data.[13] In data analyzed from a group of the highest-volume U.S. centers, even the most ideal retransplant candidates had only 68 percent 1-year postoperative survival.[57] While this clearly represents an improvement in the individual patient's prognosis, these lower survival rates, along with the increased costs involved,[94] have led some to question the ethics of performing retransplantation.[95] Nevertheless, most large programs continue to offer the option to highly selected patients.

Chapter 22: CARDIAC TRANSPLANTATION, MECHANICAL VENTRICULAR SUPPORT, AND ENDOMYOCARDIAL BIOPSY

ALTERNATIVES TO TRANSPLANTATION

Mechanical Support

TEMPORARY: PERCUTANEOUS INTRAAORTIC BALLOON PUMP

When aggressive medical therapy for severe heart failure no longer provides adequate organ perfusion in either the acute or the chronic setting, several mechanical devices are available to support the failing circulation on a temporary basis until myocardial recovery ensues or an appropriate cardiac donor for transplantation is procured. The intraaortic balloon pump (IABP), which first was described by Mouloupoulos in 1962,[96] is the most widely used device for such mechanical circulatory assistance. The device consists of a nonocclusive balloon catheter positioned in the descending aorta, with the balloon cyclically inflated during diastole (to provide diastolic pressure augmentation and increase coronary blood flow) and deflated during systole (to provide reduced arterial impedance or afterload reduction during ejection), a rhythmic sequence termed *counterpulsation.* These devices are widely used for circulatory support in acute situations, such as cardiogenic shock and refractory ischemia after myocardial infarction or cardiac surgery, as well as to support patients awaiting cardiac transplantation who become refractory to pharmacologic therapy.

Technique

A number of IABP systems are commercially available for surgical or percutaneous insertion. Most have a second lumen that permits balloon insertion over a guidewire and later provides monitoring of central aortic pressure. Percutaneous insertion systems generally require 9F femoral introducer sheaths. Retrograde insertion of the IABP system through a sheath in the femoral artery is the most commonly used method of insertion and can be accomplished under local anesthesia in the intensive care unit. When femoral pulses are absent or when percutaneous femoral cannulation is considered hazardous, surgical exposure of the common femoral artery enables the operator to cannulate the artery under direct vision. The existence of severe aortoiliac occlusive disease occasionally mandates insertion of the IABP from the upper extremities or from a graft attached to the ascending aorta.

Timing

Proper timing of inflation and deflation is necessary for IABP counterpulsation to provide effective ventricular assistance. Ideally, the balloon should inflate immediately after aortic valve closure and deflate at the onset of the subsequent systole. When initiating support, it is often helpful to begin with the balloon augmenting every other beat (the 2:1 mode) to be able to compare an unaugmented beat with an augmented beat as one adjusts the timing of the balloon. The aim here is to maximize the height of the augmented diastolic peak and minimize the height of the systolic peak after the augmented diastole.

Weaning

The balloon generally is used for augmentation of all beats (1:1 mode) until the patient's

ventricular function improves and allows stepwise reduction of the assist mode to the 2:1 and later the 3:1 mode over a period of 6 to 12 h.[97] When hemodynamic independence from the IABP is established, the balloon may be removed.

Complications

Complications have been reported to occur in 5 to 35 percent of IABP insertions.[98,99] Ischemia of the extremity distal to the femoral insertion site is the most common complication and may be more common when the percutaneous technique is used.[100] Severe ischemia requiring amputation of the toes, foot, or lower leg has been reported in 1 to 2 percent of cases.[97-99] Wound infection at the groin insertion site is the second most common complication, occurring in 3 to 4 percent of patients and usually presenting several days after catheter removal. Most of these complications resolve with topical care and systemic antibiotics. Other reported complications of IABP use include dissection or perforation of the distal aorta or its branches and peripheral or visceral embolization caused by thrombus formation. The incidence of the latter is decreased by the routine use of therapeutic doses of heparin.

TEMPORARY: VENTRICULAR ASSIST DEVICES

Mechanical support for a failing heart that becomes refractory even to IABP support is available in the form of ventricular assist devices (VADs) or replacement artificial ventricles. Since the first report of successful use of a VAD in 1965,[101] the technology has progressed a great deal. Most of these assist devices function by diverting blood out of the left ventricle through a large inflow conduit inserted into the left ventricular apex, into a pump-drive system, and back through a large outflow conduit into the ascending aorta. Figure 22-7 shows a typical VAD system in situ.

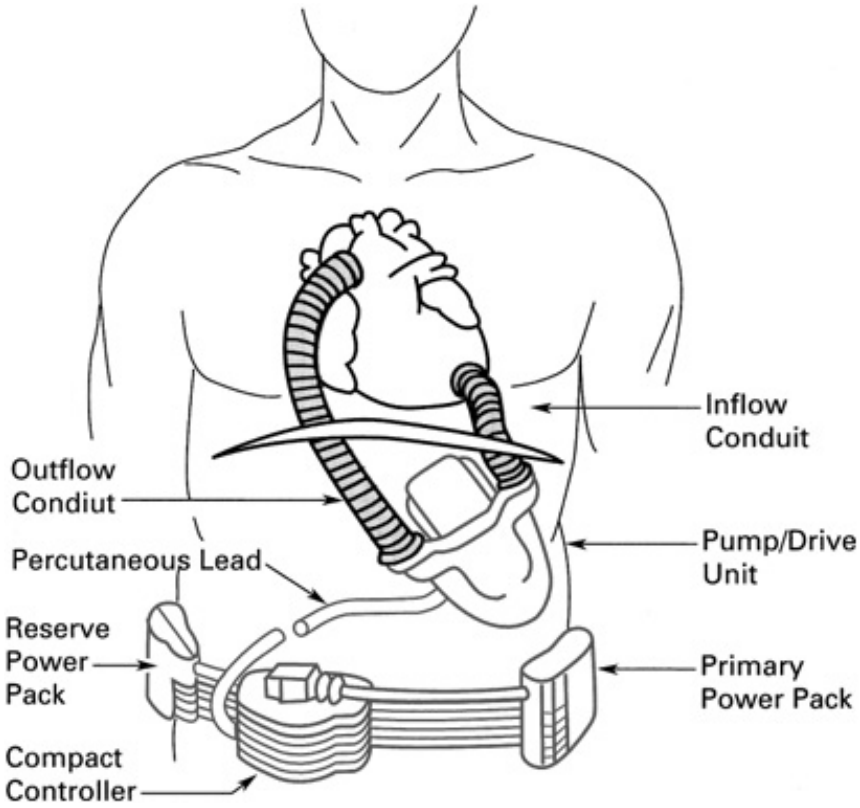

Figure 22-7: Diagram of a wearable Novacor left ventricular assist device in situ, showing inflow conduit inserted in apex of left ventricle leading to body of electrically driven pump, with outflow

conduit returning blood to the ascending aorta. (Courtesy of Novacor Division, Baxter Healthcare Corporation, Oakland, CA.)

In the United States, VADs are currently approved for two indications. The first is temporary support of potentially reversible cardiac dysfunction, and substantial myocardial salvage has been achieved in postcardiotomy[102,103] and, less frequently, postinfarction[104] cardiogenic shock. The second approved indication for VAD support is as a "bridge" to transplantation in waiting transplant recipients (who, by definition, have irreversible myocardial dysfunction) who deteriorate severely before a donor becomes available. Successful bridging with a VAD was first reported in 1984, using the Novacor implantable electrical VAD (Novacor Division, Baxter Healthcare Corporation, Oakland, CA) in a patient with end-stage ischemic heart disease.[105] Success with replacement artificial ventricles (an orthotopic artificial heart) was reported a year later in a patient with cardiomyopathy.[106] The artificial heart technology, however, was fraught with high complication rates and has not been used for a number of years. There has been some resurgence of interest in the use of total artificial hearts as bridges to transplantation[107] and their future is uncertain.

Because of the progressive "mismatch" between the increasing demand for donor hearts and the stable donor supply rate, increasing numbers of patients on transplant waiting lists are deteriorating and requiring the use of such bridge devices to survive until a donor becomes available. The use of mechanical technology in this situation is associated with excellent posttransplant survival rates for supported patients,[108,109] but it does add a substantial level of pretransplant expense and of course does not increase the overall size of the donor pool.

The Future: Permanent Ventricular Assist Devices

With the growing shortage of donor organs, there is an increasing need for a mechanical device as an alternative to the biological transplantation of a failing heart. The ultimate goal of the evolving technology first used for temporary ventricular assistance has been to develop a completely implantable electrical system with rechargeable batteries (allowing the patient freedom from tethering to a power supply) to serve as a permanent assist to left ventricular function. The first clinical trials of such devices have commenced and involve patients with end-stage heart disease who, for reasons of age or other comorbid conditions, are not considered transplant candidates.[110] If their safety and efficacy are established in this patient population, clinical trials comparing VAD support directly with transplantation can proceed and address many end points, such as quality of life, in addition to survival.

The Future: Xenotransplantation

Work on the development of a mechanical alternative to biological cardiac transplantation has proceeded simultaneously with immunologic research aimed at making it possible to use animal organs in humans, a field known as *xenotransplantation*. Formidable anatomic, physiologic, and immunologic barriers must be overcome before xenotransplantation can become a solution to the shortage of donor organs.[111] Anatomically, transplanted organs must be of the appropriate size and structure to replace the native organ. Physiologically, the transplanted organ must perform a complex set of tasks that require it to receive and often send appropriate hormonal and metabolic signals. Such needs require reasonable homology of both the involved hormones and the cell surface receptors between the human and donor species. Technically and biologically, primates are the obvious choice for a donor species. However, the supply of primates is much too small to fill the potential demand; ethical considerations also are a drawback to the use of primates as organ donors. The pig has emerged as the most likely species to provide the appropriate size, anatomic structure, and available numbers for human organ transplantation. Unfortunately, swine are quite phylogenetically distant from humans, and this distance is associated with a formidable

immunologic barrier. Humans universally possess so-called natural antibodies directed against swine antigens, primarily against carbohydrate moieties that are present on endothelial and other cells. These antibodies lead to hyperacute rejection of a swine organ through activation of the complement system initiated by the antibodies binding to donor endothelial cells, a process that occurs within an hour after implantation and leads to rapid destruction of the graft.[112,113]

Several means have been investigated to prevent hyperacute rejection. Depletion of xenogeneic natural antibodies against the donor organ as a way of modifying the host's humoral immunity is one approach.[114,115] Transient inhibition of complement activity with cobra venom factor or a soluble complement receptor delays hyperacute rejection and attests to the central role of the complement system in this process.[116] The activation and activity of complement are ordinarily regulated and limited by several endothelial cell-associated proteins. These proteins may function less effectively against heterologous than against native complement, making xenografts potentially more susceptible to complement-mediated injury. The production of transgenic swine bred to express human complement regulatory proteins to decrease the xenograft's susceptibility to complement-mediated injury has been an area of active research.[117,118] Such genetic alterations of the donor species hold some promise, at least for overcoming this first immunologic barrier to xenotransplantation. The later occurrences of acute and chronic rejection, however, are problems that remain to be solved. With current technology, the prevention of acute rejection of xenografts would require unacceptably intense regimens of immunosuppression, and prevention of chronic rejection, as was noted earlier, is inadequate with current technology, even in allografts.

The prospect of using animal tissues in transplantation has raised concern about the potential for the transmission of zoonotic pathogens from animal to human.[119] Since the likelihood of an organism causing disease in humans may be independent of its disease-causing potential in the donor species, the issue becomes a major one for the individual recipient and potentially has wide public health implications. When clinical trials begin, it will be extremely important to monitor recipients of xenogeneic tissue for the occurrence of unexplained illness; it has been suggested that the creation of a national or international registry of exposure to xenogeneic tissue would facilitate identification of clusters of events or illness.[119,120]

Chapter 22: CARDIAC TRANSPLANTATION, MECHANICAL VENTRICULAR SUPPORT, AND ENDOMYOCARDIAL BIOPSY

ENDOMYOCARDIAL BIOPSY

The Instrument

A percutaneous transvascular approach to biopsy of the beating heart was first described by Sakakibara and Konno in Japan in 1962,[121] and modifications of their instrument are still widely used. They generally are introduced from a femoral or brachial vein. This technology to permit nonsurgical biopsy of the myocardium was further developed in response to the need to obtain tissue from a transplanted heart to assess the presence and severity of graft rejection and monitor the response to antirejection therapy. Cardiac allograft rejection initially had been recognized by means of clinical observation of phenomena such as the emergence of heart failure, a gallop rhythm, or declining electrocardiographic voltage. Such phenomena often did not occur, however, until rejection was quite severe, and biopsy offered a means of early and objective assessment of rejection. In 1973, Caves and associates at Stanford introduced a new, shorter (and therefore more controllable) bioptome, which was introduced from the jugular rather than the femoral vein and allowed easy and repeated serial biopsy procedures under fluoroscopic guidance.[122] The Caves-Schultz-Scholten instrument was improved by Mason[123] and for years was the most commonly used bioptome in the United States. This bioptome is reusable, but its cleaning procedure is costly and labor-intensive, and several disposable instruments have been developed and have gained widespread use in recent years. An example of one of the most widely used is shown in Fig. 22-8 with the standard percutaneous approach from the right internal jugular vein. Longer bioptomes are also available for use from the femoral approach (usually through a long guiding sheath) in patients without internal jugular access.

The Technique

The right ventricle is usually the ventricle of choice for obtaining biopsy material because of the relative convenience and safety of approach to the right, as opposed to the left, ventricle as well as the usually homogeneous distribution of myocardial inflammatory and rejection processes. The procedure is performed with the patient supine, usually in a cardiac catheterization laboratory or in a procedure room or in the operating room if facilities are available. For the internal jugular approach, positioning with the feet elevated increases central venous pressure and facilitates cannulation of the vein. After the introduction of an intravascular sheath with the standard percutaneous technique, the bioptome can be advanced through it down to the right atrium, across the tricuspid valve, and into the right ventricle, pointed toward the septal wall. The stimulation of premature ventricular contractions by the instrument serves as confirmation of its presence in the ventricular chambers. Once it is safely within the ventricle and directed toward the septum, the jaws of the bioptome are opened, the instrument is advanced gently against the wall, and the jaws are closed, "biting off" a piece of septal myocardium 1 to 3 mm in diameter. The bioptome is then withdrawn, and the specimen is retrieved and placed in an appropriate medium for pathologic examination. The process is repeated until three to five adequate specimens are obtained.

Endomyocardial biopsy procedures generally are performed on an outpatient basis without the requirement for sedation or concomitant measurement of right-sided heart pressures unless they are clinically indicated. The procedure usually is done under fluoroscopic guidance,[124] but many centers perform it safely[125] and potentially with less cost[126] under echocardiographic guidance.

Complications

Large series have documented the low morbidity and mortality of endomyocardial biopsy, with major complications such as cardiac perforation and tamponade occurring in <0.5 percent of procedures.[127,128] More minor and generally transient complications include bundle branch block and arrhythmias. Fistulas between the coronary artery and the right ventricle have been described in a number of transplant patients

who have had multiple biopsy procedures but generally seem to have no hemodynamic consequence.[129,130] With increasing lengths of survival of cardiac transplant recipients and the continued use of surveillance myocardial biopsies, complications related to the sheer numbers of biopsies performed are becoming more apparent. Chief among these complications is damage to the tricuspid valve and its subvalvular structures. This complication was first reported in 1990,[131] when a series of five patients with tricuspid valve chordal rupture as a complication of endomyocardial biopsy was reported. None of those patients had hemodynamically significant tricuspid regurgitation. Subsequently, there have been reports suggesting that signs of right-sided heart failure eventually appear in some patients, and several patients are known to have required tricuspid valve replacement because of intractable right heart failure. The incidence of tricuspid valve injury may be decreased with the use of a sheath across the valve during biopsy.[132]

Role in the Evaluation and Diagnosis of Cardiac Disease

TISSUE HANDLING AND PROCESSING

Correct handling of retrieved biopsy specimens is essential for obtaining accurate histopathologic results and interpretability. To limit crush distortion of the tissue, the biopsy specimenshould be teased gently from the bioptome with a needle and immediately placed in an appropriate fixative. Neutral buffered 10% formalin is the standard fixative for light microscopy, and gluteraldehyde-based solutions are used for transmission electron microscopy (TEM). The specific clinical circumstances usually determine how the specimen will be fixed and processed and which histochemical stains will be selected. For the evaluation of myocarditis, cardiomyopathy, and specific heart muscle diseases, at least four biopsy pieces are recommended for light microscopy; one piece may be retained for TEM, and an unfixed piece may be frozen for immunofluorescence or immunohistochemical studies (optional). At least four pieces are required for light microscopy for adequate sampling in the grading of acute rejection; one piece may be frozen for immunofluorescence studies if acute vascular rejection is suspected. All the tissue samples (four to five pieces) should be placed in gluteraldehyde when grading of anthracycline cardiotoxicity is the clinical issue.

INDICATIONS FOR ENDOMYOCARDIAL BIOPSY

Since the successful application of an endomyocardial biopsy for the diagnosis and monitoring of acute rejection in the early 1970s, the indications for the procedure have expanded. The right ventricle usually is selected for technical reasons, including safety, although left ventricular biopsy occasionally is performed for the diagnosis of endomyocardial fibrosis, infantile fibroelastosis, left-sided irradiation effects, and cardiac involvement by scleroderma. The current indications for endomyocardial biopsy are listed in Table 22-9.

Table 22-9: Possible Indications for Endomyocardial Biopsy

Diagnosis and grading of acute rejection
Diagnosis of myocarditis
Evaluation of idiopathic cardiomyopathy
Diagnosis of specific heart muscle diseases
Distinguish restrictive versus constrictive heart disease
Evaluation and grading of anthracycline cardiotoxicity
Diagnosis of primary and secondary cardiac neoplasms
Evaluation of idiopathic arrhythmias
Evaluation of atypical chest pain

Myocarditis

As an inflammatory or immunologic process, myocarditis is defined by the presence of an inflammatory infiltrate in association with nonischemic damage or necrosis of the adjacent myocytes;[133] these features are termed *the Dallas criteria* (see Chap. 69). The different types of inflammatory cells help define possible etiologies in myocarditis. Lymphocytes are the predominant cell type seen in idiopathic (postviral) myocarditis (Fig. 22-9), sarcoidosis, Lyme disease, Kawasaki's disease, polymyositis, and AIDS myocarditis (see Chap. 70). Eosinophils are commonly found in drug hypersensitivity but also may indicate parasitic infection or a hyper-eosinophilic syndrome. Myocyte necrosis associated with multinucleated giant cells is characteristic of giant-cell myocarditis[134] (Fig. 22-10). Epithelioid histiocytes forming granulomas are seen in cardiac sarcoidosis.[135]

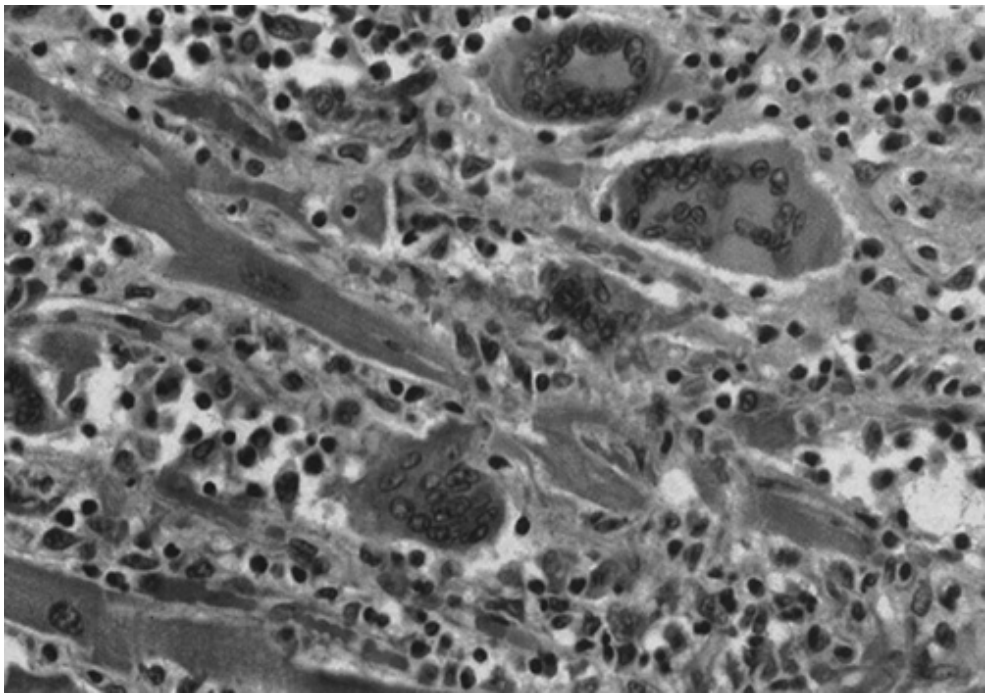

Figure 22-10: Giant-cell myocarditis showing an inflammatory infiltrate composed of lymphocytes, histiocytes, and eosinophils admixed with multinucleated giant cells. Myocyte damage is conspicuous in this case. (H&E ×400)

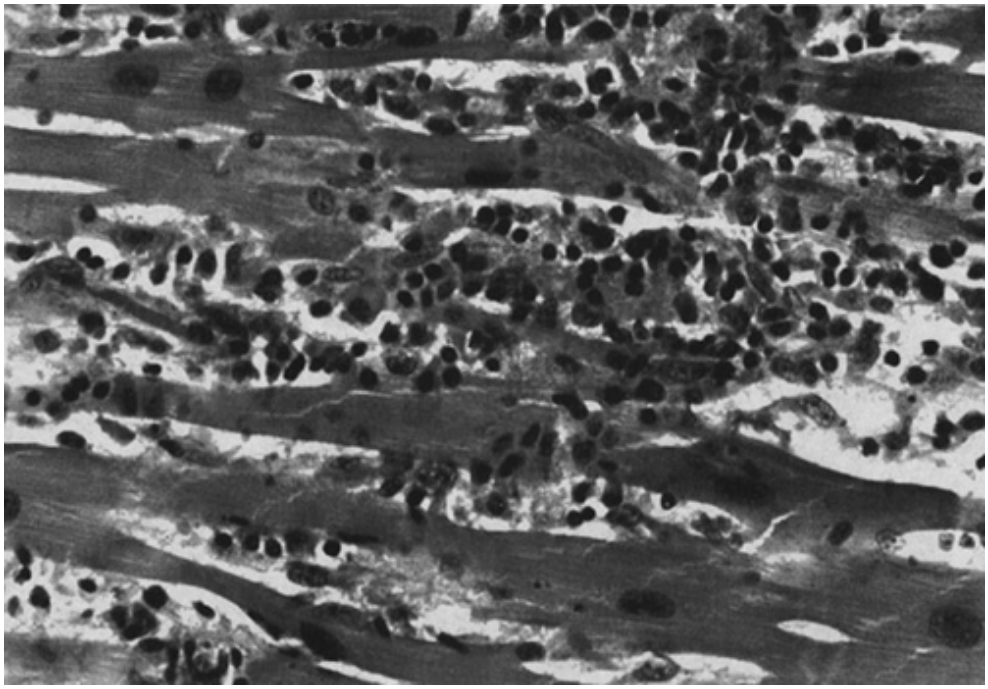

Figure 22-9: Lymphocytic myocarditis in a young man presenting with sudden-onset congestive heart failure. Dense interstitial infiltrates of lymphocytes are seen in association with myocyte damage. (H&E ×400)

Idiopathic Cardiomyopathy

The morphologic diagnosis of idiopathic dilated cardiomyopathy, including familial and postpartum types, is primarily one of exclusion, as a variety of storage and infiltrative heart muscle diseases and myocarditis may mimic dilated cardiomyopathy (see Chaps. 62, 66-69, and 82). Hypertensive, ischemic, and valvular heart disease also must be excluded. Endomyocardial biopsy is used routinely in some institutions in evaluating dilated cardiomyopathy of unknown causes. The morphologic features of idiopathic cardiomyopathy are nonspecific and include myocyte hypertrophy and interstitial fibrosis (Fig. 22-11). Hypertrophic cardiomyopathy is the second most common type of cardiomyopathy. It cannot be diagnosed reliably by endomyocardial biopsy since the characteristic histologic features are found mainly in the midportion of the ventricular septum.[136] Mimics of hypertrophic cardiomyopathy such as amyloidosis can be delineated by biopsy.

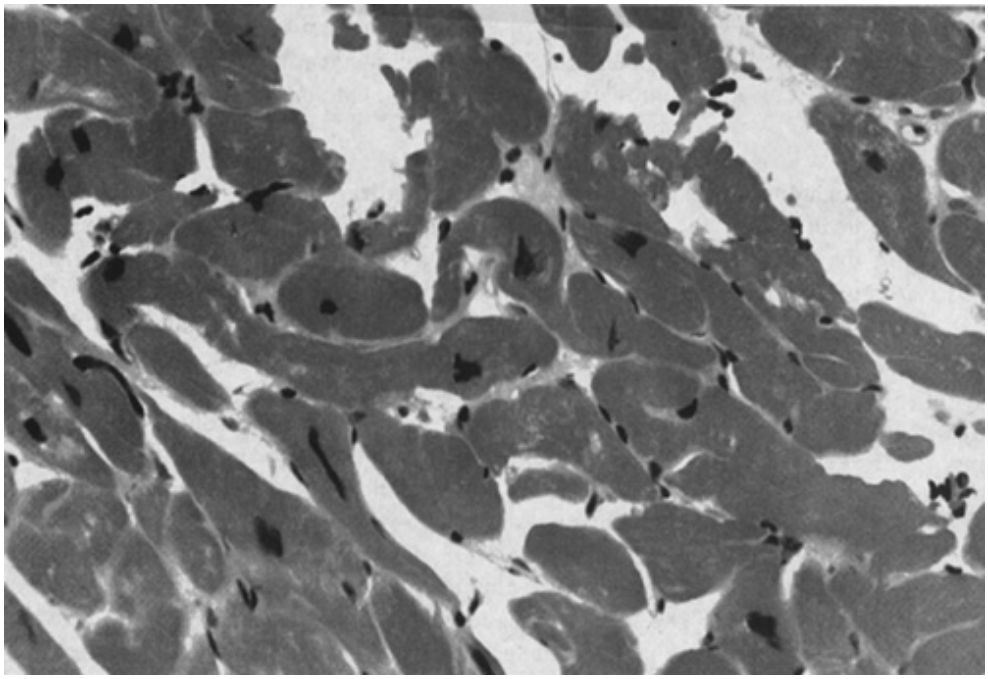

Figure 22-11: A young woman presenting with congestive heart failure. Myocyte hypertrophy characterized by large, irregular nuclei is seen. The findings are compatible with dilated cardiomyopathy. (H&E ×400)

Specific Heart Muscle Diseases

A variety of infiltrative diseases and storage disorders of the myocardium can be readily diagnosed by endomyocardial biopsy (see Chap. 68). Cardiac amyloidosis may be seen with primary amyloidosis, plasma cell dyscrasias, and chronic inflammatory conditions and in elderly patients (senile amyloid). The histologic appearance includes interstitial, subendocardial, or vascular deposits of finely fibrillar, eosinophilic material (Fig. 22-12). Senile amyloid often is characterized by nodular deposits of transthyretin. Histochemical stains such as Congo red and trichrome are useful in distinguishing amyloid from collagen.[137]

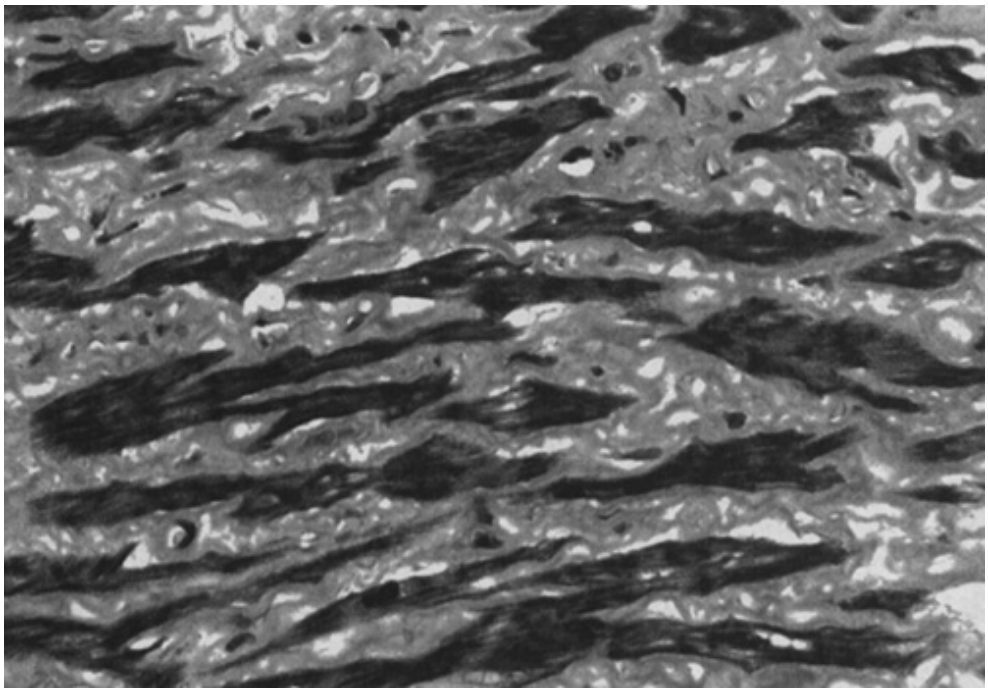

Figure 22-12: Severe interstitial amyloidosis showing fibrillar deposits along the sarcolemma with constriction of the myocytes. (H&E ×400)

Disorders of iron metabolism (hemochromatosis) and iron overload states (hemosiderosis) result in perinuclear accumulations of iron pigment within the myocytes. Special stains such as Prussian blue highlight the pigment (Fig. 22-13). In advanced disease, marked myocyte hypertrophy and interstitial fibrosis are found. The diagnosis of metabolic enzyme deficiencies, including glycogen storage diseases, Gaucher's disease, and Fabry's disease (see Chap. 62), also may be established by endomyocardial biopsy.

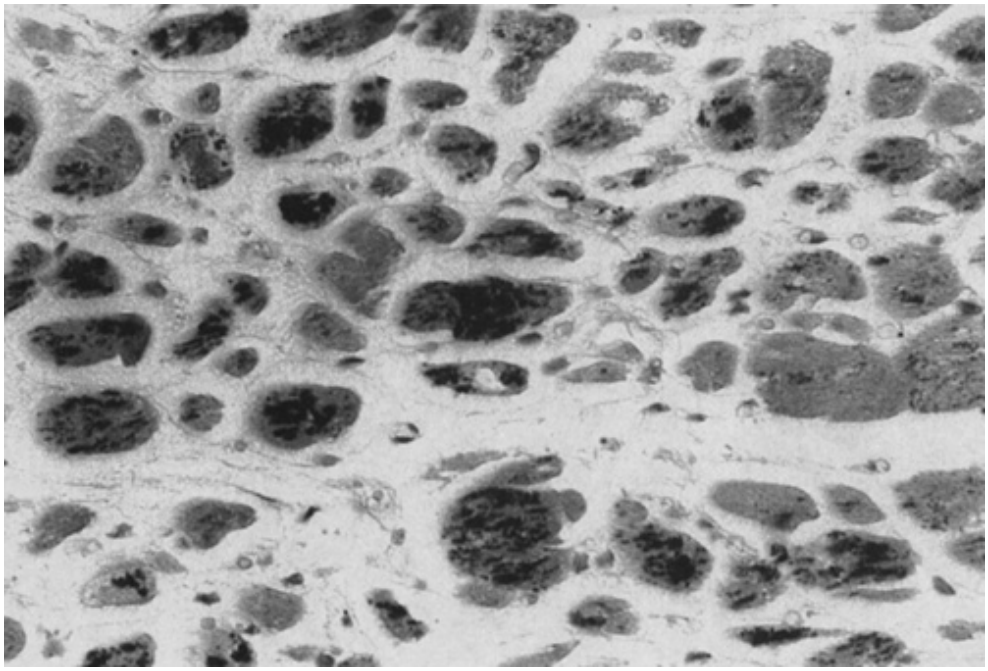

Figure 22-13: Cardiac hemochromatosis in a young man. Dense accumulations of iron pigment are seen in a perinuclear location. (Prussian blue ×400)

Restrictive versus Constrictive Heart Disease

The clinical distinction of restrictive heart disease from constrictive pericardial disease can be difficult, and the therapeutic implications are significant. In some cases, imaging and hemodynamic studies may not provide a definitive diagnosis. Specific heart muscle diseases resulting in restrictive physiologic profiles, including amyloidosis, carcinoid heart disease, endocardial fibrosis, and radiation-induced interstitial fibrosis, can be diagnosed by biopsy[138] (see Chaps. 68 and 72).

Anthracycline Cardiotoxicity

Anthracyclines such as doxorubicin are used commonly in the treatment of solid tumors and hematologic malignancies. Cardiac toxicity in the form of congestive heart failure is the most significant side effect of these agents and may develop months to years after the completion of therapy. The condition is dose-related and generally occurs after a cumulative dose of 550 mg/m^2. Individual patient variation and factors such as prior mediastinal irradiation, hypertension, and increased age may potentiate cardiotoxicity at lower cumulative doses.[139] TEM of heart biopsies remains the "gold standard" for the diagnosis and grading of doxorubicin toxicity.[140]

The Billingham grading scheme for doxorubicin toxicity is based on the percentage of myocytes that demonstrate doxorubicin effect. Grades 0 through 3 are used and are associated with specific therapeutic recommendations.[141] The characteristic changes include myofibrillar loss with Z-band remnants and sarcotubular dilatation within the myocytes (Fig. 22-14). This approach to drug toxicity has provided a

valuable method of monitoring patients and preventing irreversible cardiac failure.[142]

Figure 22-14: Transmission electron micrograph of adriamycin cardiotoxicity. Note the atrophic myocyte with myofibrillar loss surrounded by normal myocytes. (TEM ×3200)

Primary and Metastatic Neoplasms

Endomyocardial biopsy has been used to provide morphologic confirmation and classification of benign and malignant primary cardiac tumors and to document the presence of metastatic malignancies[143] (see Chap. 77). Cardiac myxomas, fibromas, and rhabdomyomas as well as sarcoma, lymphoma, leukemia, and malignant mesothelioma have been diagnosed. Secondary neoplasms such as metastatic carcinoma and melanoma also may be found in right ventricular specimens (Fig. 22-15).

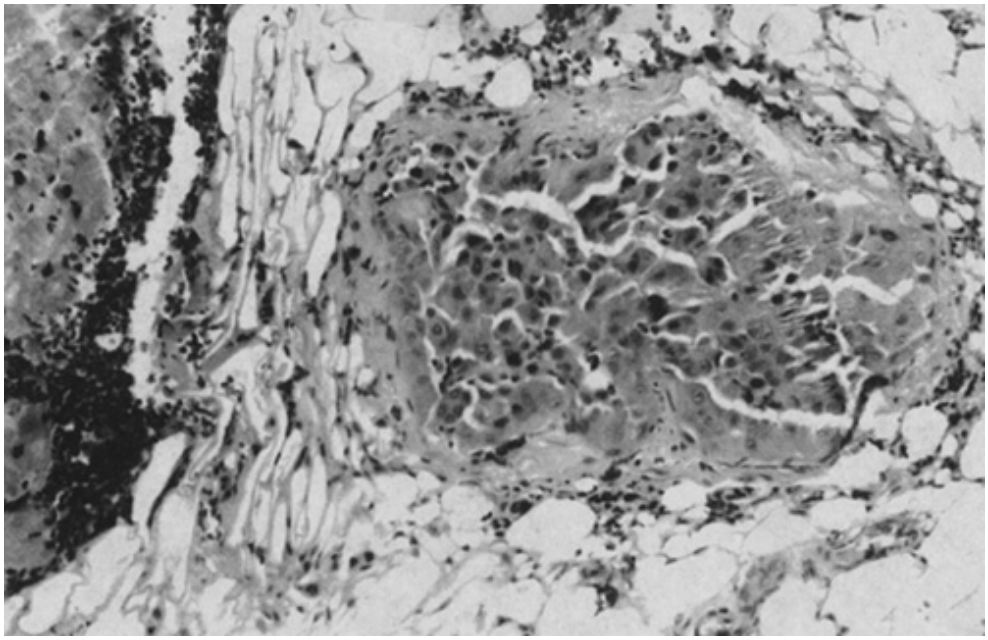

Figure 22-15: Metastatic adenocarcinoma in a 51-year-old woman with sudden-onset congestive heart failure and tamponade. (H&E ×400)

Idiopathic Arrhythmias

In the absence of a documented anatomic abnormality such as ischemic heart disease, cardiomyopathy, or mitral valve prolapse as an explanation for ventricular or supraventricular rhythm disturbances, an endomyocardial biopsy may be helpful. Lesions of the conduction system can result in nonspecific myocyte hypertrophy and interstitial fibrosis. Lymphocytic myocarditis, sarcoidosis, and giant-cell myocarditis all may present with arrhythmias. In a recent study of 80 patients with unexplained arrhythmias 88 percent of the biopsies revealed pathologic changes. Among these patients, 56 percent of the biopsies showed features of cardiomyopathy, 19 percent had clinically unsuspected myocarditis, 10 percent had small vessel disease, 3 percent had amyloidosis, and 1 percent showed an intravascular organizing thrombus.[144] An uncommon cause of arrhythmia is arrhythmogenic right ventricular dysplasia (see Chap. 33). It should be suspected in biopsy specimens showing hypertrophy and fibrosis in association with abundant myocardial deposits of adipose tissue. Clinicopathologic correlation is required for the diagnosis, as myocardial accumulations of fat normally are found in the right ventricle.

Pathology of Acute Rejection

MACROSCOPIC PATHOLOGY

In advanced cardiac rejection, the heart is larger than normal, stiff, and noncompliant. In the early posttransplant period, a fibrinous pericarditis may be seen. The heart appears edematous and hemorrhagic with a dark plum color. Along the atrial sutures a sharp tinctorial delineation between the hemorrhagic myocardium of the donor heart and the pale tan myocardium of the recipient heart is a characteristic of severe rejection. Less commonly, the valves may be swollen and turgid. The trabecular muscles are prominent and often demonstrate subendocardial hemorrhages.

MICROSCOPIC PATHOLOGY

Hyperacute Rejection

This rare pattern of allograft rejection occurs in the setting of preformed circulating antibodies such as ABO blood group incompatibility or, rarely, antibodies against specific endothelial antigens or HLA.[145] The myocardium is globally edematous and hemorrhagic as a result of diffuse interstitial hemorrhages. Neutrophils and fibrin thrombi may be seen within the microvasculature (Fig. 22-16). Hyperacute rejection

manifests as severe graft failure immediately or within the first few hours after transplantation. Without mechanical cardiopulmonary support, plasmapheresis, and emergent retransplantation, the recipient usually does not survive.

Figure 22-16: Hyperacute rejection is characterized by diffuse interstitial hemorrhage. (H&E ×400)

Acute Cellular Rejection

The principal histopathologic features of acute cellular rejection are the distribution and extent of inflammation and the presence or absence of myocyte damage. The severity of the rejection process reflects these features along a morphologic continuum. In 1973, the Stanford grading scheme of mild-moderate-severe rejection was introduced,[146] and modifications were developed by other programs.[147-149] As a result, comparisons of results between institutions and in multicenter clinical trials were not feasible. In 1990, a consensus was reached establishing a uniform and standardized grading system.[150] Currently, a numerical and descriptive grade is assigned to each biopsy sample. This scheme requires at least four pieces of myocardium using a standard bioptome, 50 percent of which must be evaluable myocardium, i.e., not a biopsy site or scar. If a smaller bioptome (7F or smaller) is used, at least six pieces of myocardium are required.

Six patterns of acute cellular rejection have been described (Table 22-10). Mild acute rejection is divided into two patterns on the basis of the cytoarchitectural features. Focal mild rejection (grade IA) represents a circumscribed, usually perivascular arrangement of lymphocytes in one or more sites that is not associated with myocyte damage. In diffuse mild rejection (grade IB), the infiltrates are arranged in a more diffusely interstitial architectural pattern; myocyte damage is not found. Focal moderate rejection (grade II) is characterized by a solitary, sharply circumscribed inflammatory focus that is associated with myocyte damage. The other biopsy pieces may be free of rejection or have a lower grade. In multifocal moderate rejection (grade IIIA), at least two foci of inflammatory infiltrate display myocyte damage. These foci are often in different pieces of myocardium. Diffuse moderate rejection (grade IIIB) is represented by diffuse interstitial infiltrates in most or all of the biopsy pieces. Myocyte damage is significant, and the findings may be classified as borderline severe rejection (Fig. 22-17). In severe rejection (grade IV), a dense polymorphous infiltrate that includes lymphocytes, neutrophils, and eosinophils is present diffusely in the interstitium. Myocyte damage, edema, and hemorrhage are conspicuous as a result of injury of the microvasculature. Resolving or resolved acute rejection is denoted by a lower grade on the biopsy than was denoted on the previous biopsy.

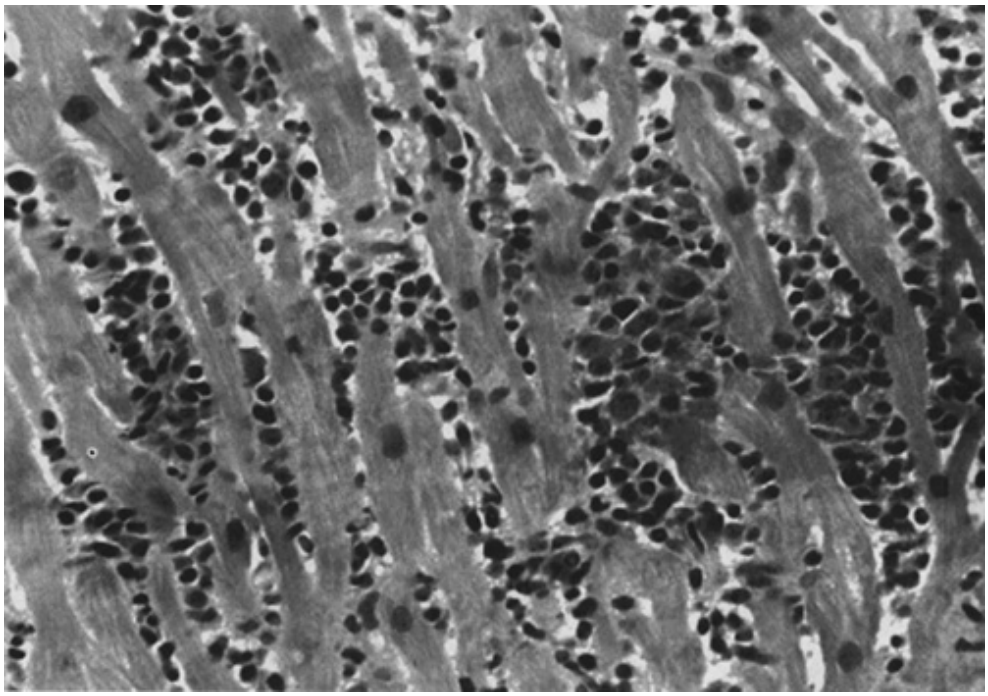

Figure 22-17: Diffuse moderate acute rejection (grade IIIB) showing activated lymphocytes within the interstitium and myocyte damage. (H&E ×400)

Table 22-10: Standardized Cardiac Biopsy Grading (Modified)

'Old' Nomenclature	Grade	'New' Nomenclature
No rejection	0	No rejection
Mild rejection	I	A = Focal (perivascular or focal interstitial infiltrate without myocyte damage)
		B = Sparse focal interstitial infiltrate without myocyte damage
'Focal' moderate rejection	II	One focus only with activated lymphocytes and myocyte damage
'Low' moderate rejection	III	A = Multifocal lymphocytic infiltrates with myocyte damage
'Borderline/severe' rejection		B = Diffuse (sometimes polymorphous) inflammatory process
'Severe/acute' rejection	IV	Diffuse, polymorphous infiltrate with myocyte necrosis ± edema ± hemorrhage ± vasculitis
'Resolving' rejection	Denoted by a lower grade	Healing tissue with fibroblasts and pigmented macrophages
'Resolved' rejection	0	Mature scar tissue

SOURCE: From Billingham ME, Carey NRB, Hammond EH, et al. A working formulation for the standardization of nomenclature in the diagnosis of heart and lung rejection: Heart rejection study group. *J Heart Transplant* 1990; 9:587-592, with permission.

Morphologic Mimics of Acute Rejection

Inflammatory infiltrates and myocyte damage of the allograft may be found in conditions other than cardiac rejection. The diagnosis of acute rejection should be made after the careful exclusion of these histologic mimics (Table 22-11). Within the first 3 weeks after transplantation, biopsies often show evidence of ischemia or preservation injury. Reperfusion of the allograft contributes to myocyte damage. Likewise, the use of pressor agents for hemodynamic support either before or after transplantation may result in small circumscribed foci of myocyte damage. The infiltrates are composed of neutrophils in the initial stages and are replaced by granulation tissue. Sharply delineated endocardial infiltrates composed of lymphocytes and a delicate vascular stroma have been designated the "Quilty effect" and may be confused with rejection when the infiltrate extends into the subadjacent myocardium. Infectious myocarditis, particularly toxoplasmic and CMV myocarditis, can resemble acute rejection. The infiltrates are usually polymorphous (lymphocytes, neutrophils, and eosinophils), and the organisms may be found. Immunohistochemical or molecular techniques are useful in difficult cases.[151] The granulation tissue and inflammation associated with previous biopsy sites may be confused with acute rejection. PTLDs uncommonly involve a cardiac allograft. Both polyclonal and monoclonal lesions have been reported, and histopathologic analysis and clonality studies are essential for classification and prognosis.[152] The presence of atypical lymphocytes, plasmacytoid or immunoblastic cell infiltrates, abundant tissue necrosis, and frequent mitotic figures should suggest the possibility of PTLD.[153]

Table 22-11: Histopathologic Mimics of Acute Rejection

Reperfusion/ischemic injury
Quilty effect
Infectious myocarditis (cytomegalovirus/toxoplasmic)
Previous biopsy site
Posttransplant lymphoproliferative disorder

Acute Vascular (Humoral) Rejection

Most episodes of rejection in the posttransplant period are mediated by lymphocytes and histiocytes and are examples of "cellular" rejection. Hammond and colleagues found cases of allograft dysfunction occurring in the first 6 weeks after transplantation in which the classic features of cellular rejection were absent.[154] Immunofluorescence studies on fresh-frozen myocardial samples demonstrate the presence of immunoglobulin, complement, and fibrinogen, suggesting a humoral immune response mediated by endothelial and B cells. The myocardium displays large prominent endothelial cells in venules and capillaries, perivascular and interstitial edema. Currently, the diagnosis requires both the histologic and immunofluorescence findings. Infection and ischemic changes also must be excluded. A number of studies have suggested that these patients are at higher risk for developing accelerated graft coronary disease.[155] The etiology, incidence, optimum treatment strategies, and natural history of this form of rejection warrant further clinical studies.

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 23:

MECHANISMS OF CARDIAC ARRHYTHMIAS AND CONDUCTION DISTURBANCES

Authors: Albert L. Waldo, Andrew L. Wit

OVERVIEW OF MECHANISMS OF CARDIAC ARRHYTHMIAS AND CONDUCTION DISTURBANCES

Introduction

Because of the increasing availability of sophisticated electrophysiologic techniques for the study of cardiac tissues both in vivo and in vitro and the ability to study arrhythmias and conduction disturbances both in experimental models and in patients, knowledge about the mechanisms of arrhythmias and conduction disturbances has increased greatly. Although much is now known, much remains to be understood. Arrhythmias are due to normal or abnormal impulse generation, abnormal impulse conduction, or a combination of simultaneous abnormalities of impulse generation and conduction.[1] This chapter first provides an overview of these mechanisms and identifies the clinical arrhythmias with which they are thought to be associated. This is followed by a much more detailed discussion of these mechanisms as they are currently understood. The detailed discussion requires that the reader have a rudimentary knowledge of the basic cellular electrophysiology of the heart, including the ionic channels and membrane currents causing the resting potential and the cardiac action potential, as well as the mechanisms for automaticity and conduction. However, much of this material is included in a detailed discussion of the mechanisms of arrhythmias, since the chapter considers how alterations in normal electrophysiology lead to abnormal cardiac rhythms.

Causes of Arrhythmias

NORMAL OR ABNORMAL IMPULSE INITIATION

Automatic Rhythms

NORMAL MECHANISM

Cardiac cells that normally are capable of developing spontaneous diastolic (phase 4) depolarization are called *pacemaker cells*. When pacemaker cells manifest spontaneous diastolic depolarization (Fig. 23-1) and thus are responsible for generating the cardiac rhythm, the rhythm is classified as an *automatic rhythm*. Normally, the dominant pacemaker of the heart is in the sinus node, which in adults fires at a rate of 60 to 100 beats per minute. Cells capable of developing spontaneous diastolic depolarization (i.e., of manifesting automaticity) also are normally found in the specialized fibers in the atria, the atrioventricular (AV) junction, and the His-Purkinje system. The normal rate of impulse formation in adults by these ectopic pacemakers is 40 to 60 beats per minute in the AV junction (the AV node and His bundle). Normal rates of more distally located ectopic pacemakers are probably 20 to 40 beats per minute in the bundle branches. These ectopic (i.e., nonsinus) pacemakers also are called *latent* or *escape* pacemakers for two related reasons: (1) The normal intrinsic rate of these pacemakers is lower than that of the dominant pacemaker, the sinus node, and (2) spontaneous diastolic depolarization of these latent or escape pacemakers normally is suppressed by the more rapid rate of the sinus node pacemaker through the active process of overdrive suppression. Only when the sinus rate slows below the intrinsic rate of these ectopic pacemakers does "the next one in line" warm up and fire (see also "Automaticity," below).

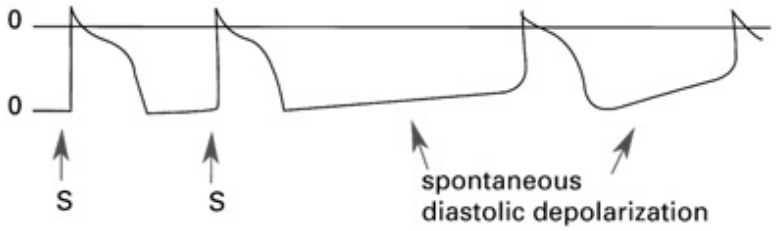

Figure 23-1: Arrhythmias may be caused by normal automaticity. Transmembrane potential recorded from a Purkinje fiber stimulated (S) at a regular rate is shown. When the stimulus is turned off, spontaneous diastolic depolarization develops to cause automatic firing by a normal mechanism.

Arrhythmias of the Sinus Node

An arrhythmia occurs when the sinus node pacemaker fires at a rate above 100 beats per minute (sinus tachycardia) (Table 23-1) or at a rate below 60 beats per minute (sinus bradycardia) and is still the dominant pacemaker of the heart. These are called *arrhythmias resulting from normal automaticity*, since the ionic mechanism causing the pacemaker depolarization is unchanged from the normal sinus rhythm. A sinus tachycardia is usually an appropriate response to a precipitating factor (e.g., exercise, fever, hypotension), although on occasion it may be inappropriate, as in the presence of a sympathetic dysautonomia (inappropriate sinus tachycardia). By contrast, sinus bradycardia often reflects an abnormality not only of the sinus node pacemakers (they are too slow) but also of the latent or escape pacemakers (when the sinus rate slows abnormally, they do not escape). Sinus bradycardia may be due to an intrinsic abnormality of pacemaker cells, a parasympathetic dysautonomia (inappropriate sinus bradycardia), or an extrinsic factor such as suppression of automaticity by drug therapy (e.g., a beta blocker, a Ca^{2+} channel blocker, or an antiarrhythmic agent). For some patients, sinus bradycardia, particularly when it is present only at rest, may simply reflect a normal response to increased vagal tone, as in a well-trained athlete. Marked beat-to-beat variations in cycle length of the sinus rhythm, which are due virtually always to the influence of vagal tone on the pacemaker cells of the sinus node, also is considered an arrhythmia (sinus arrhythmia) even if the overall sinus rate is normal.

Table 23-1: Types of Tachycardias and Their Selected Characteristics and Documented or Presumed Mechanism

Tachycardia	Mechanism	Origin	Rate Range, bpm	AV or VA Conduction
Sinus tachycardia	Automatic (normal)	Sinus node	≥100	1:1
Sinus nod reentry	Reentry	Sinus node and right atrium	?110-180	1:1 or variable
Atrial fibrillation	Reentry	Atria	260-450	Variable
	Fibrillatory conduction	Pulmonary veins, SVC	?	Variable
Atrial flutter	Reentry	Right atrium, left atrium (infrequent)	240-350, usually 300 ± 20	2:1 or variable
Atrial tachycardia	Reentry	Atria	150-240	1:1, 2:1, or variable
	Automatic (normal or abnormal)	Atria	?	?
	Triggered (DADs) 2° to digitalis toxicity	Atria	150-240	1:1, 2:1, or variable

AV nodal reentry tachycardia	Reentry	AV node with an atrial component	120-250, usually 150-220	1:1
AV reentry (WPW or concealed accessory AV connection)	Reentry	Circuit includes accessory AV connection, atria, AV node, His, Purkinje system, ventricles	140-250, usually 150-220	1:1
Accelerated AV junctional tachycardia	Automatic or ? triggered (? digitalis toxicity)	AV junction (AV node and His bundle)	61-200, usually 80-130	1:1 or variable
Accelerated idioventricular rhythm	Abnormal automaticity	Purkinje fibers	>60-?	Variable, 1:1, or AV dissociation
Ventricular tachycardia	Reentry	Ventricles	120-300, usually 140-240	AV dissociation, variable, or dissociation
	Automatic (rare) (normal or abnormal)	Ventricles	?	Variable, 1:1, or AV dissociation
Bundle branch reentrant tachycardia	Reentry	Bundle branches and ventricular septum	160-250, usually 195-240	AV dissociation, variable, or 1:1
Right ventricular outflow tract	? Triggered (DADs)	Right ventricular outflow tract	120-220	AV dissociation, variable, or 1:1
Torsades de pointes tachycardia	? Triggered (EADs) (with reentry)	Ventricles	>200	AV dissociation

ABBREVIATIONS: DAD = delayed afterdepolarization; WPW = Wolff-Parkinson-White syndrome; EAD = early afterdepolarization; bpm = beats per minute; SVC = superior vena cava.

ECTOPIC AUTOMATIC RHYTHMS

Arrhythmias occur when the site of the dominant pacemaker shifts to a site other than the sinus node (Table 23-1). The site of impulse initiation may shift from the sinus node to an ectopic (latent or escape) pacemaker if any of the following occur: (1) The intrinsic rate of the sinus node decreases, e.g., when pacemaker dysfunction is limited to the sinus node. (2) The intrinsic rate of the ectopic (latent or escape) pacemaker increases, e.g., as a result of enhanced automaticity of latent pacemakers. During such rhythms, the sinus node is normally automatic, but overdrive suppression of the sinus node pacemaker usually occurs because the ectopic pacemaker fires at a more rapid rate. Alternatively, if the rate of the ectopic pacemaker is very fast, there may be entrance block into the sinus node, in which case exit block of the sinus impulses rather than overdrive suppression occurs. (3) The normal sinus impulse is prevented from being the dominant pacemaker of the heart because of sinus node exit block or sinoatrial block (i.e., the impulse cannot exit from the sinus node to excite the atria and subsequently the ventricles) or AV block (the impulse cannot excite the ventricles because of conduction block in the specialized AV conduction system, i.e., the AV node, His bundle, or both bundle branches) (see Chaps. 12 and 27). The automaticity at the ectopic pacemaker site is a result of the normal automatic mechanism; hence, these are arrhythmias caused by normal automaticity.

ABNORMAL MECHANISM

Typically, normal working atrial and ventricular myocardial cells do not develop automaticity. Thus, when they manifest normal transmembrane potentials, no evidence of spontaneous diastolic (phase 4) depolarization is present. Under certain conditions, however, these cardiac muscle fibers, as well as specialized atrial and ventricular fibers, can develop an abnormal type of automatic firing. This occurs when the cell is relatively depolarized so that maximum diastolic potential is reduced to levels much lower than normal, usually by intrinsic cardiac disease. When this occurs, spontaneous diastolic (phase 4) depolarization may occur (Fig. 23-2). Such abnormal automaticity is caused by a pacemaker current that is different from the pacemaker current of normally automatic cells. The transmembrane action potentials associated with abnormal automaticity may be of the slow-response type; i.e., the transmembrane action potential upstroke may depend on the slow inward (L-type) Ca^{2+} current because of inactivation of Na^{+} channels at the reduced level of membrane potential. Arrhythmias caused by abnormal automaticity will not be evident unless the rate of the abnormal focus is greater than that of the dominant automatic pacemaker (usually the sinus node) of the heart. They therefore also appear as ectopic automatic rhythms. Accelerated idioventricular rhythms after myocardial infarction sometimes may be caused by abnormal automaticity in Purkinje's cells in the ischemic region (Table 23-1) (see Chap. 47).

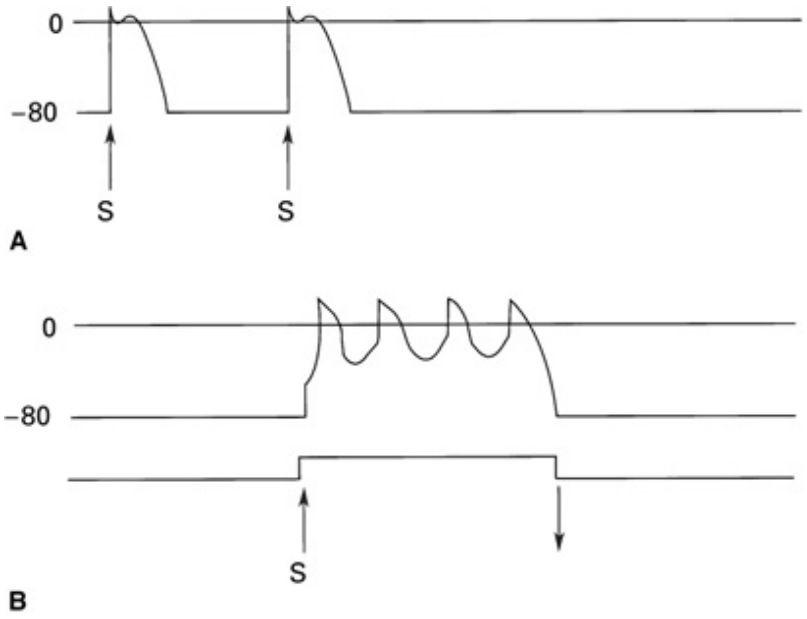

Figure 23-2: Arrhythmias may be caused by abnormal automaticity. The figure shows how abnormal automaticity may develop in a ventricular muscle fiber. *A*. Transmembrane potentials recorded from a muscle fiber with a normal resting potential are shown. When the fiber is not stimulated, phase 4 depolarization and automatic firing do not occur (compare with Fig. 23-1). *B*. At the arrow S, the membrane potential is reduced to -50 mV by a current pulse passed through a microelectrode. Automatic firing occurs at this low level of membrane potential. In the heart, certain abnormal states may cause a similar decrease in membrane potential.

Triggered Rhythms

These arrhythmias are caused by afterdepolarizations (Table 23-1).

Early afterdepolarizations (*EADs*) are associated with a prolongation of the duration of the action potential and occur during repolarization of a transmembrane action potential that has been initiated from a normal level of membrane potential. They appear as a shift in membrane potential in a positive direction relative to the membrane potential expected during normal repolarization (Fig. 23-3*A* and *B*). Repetitive depolarizations may originate from the low level of membrane potential that occurs during the afterdepolarization (Fig. 23-3*B*). A clinical example of a rhythm thought to be initiated by EADs is torsades de pointes. This is a polymorphic ventricular tachycardia that is associated with abnormal QT-interval prolongation (and therefore prolongation of the Purkinje fiber and ventricular muscle action potentials)

caused by any of a variety of factors. This includes a toxic response to class IA or III antiarrhythmic agents or any other agents that prolong the duration of the ventricular action potential, hypokalemia, and hypomagnesemia. It also includes torsades de pointes associated with syndromes characterized by an intrinsic prolongation of the QT interval (and therefore of the Purkinje fiber and ventricular muscle action potentials), such as the congenital long QT syndromes, which also are thought to be initiated by EADs (Table 23-1).

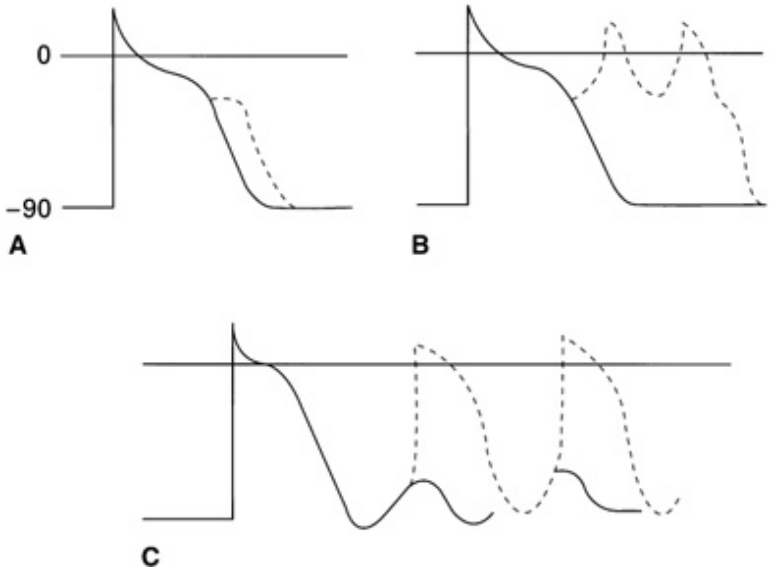

Figure 23-3: Triggered activity is caused by afterdepolarizations. *A.* A solid trace shows the normal transmembrane potential from a Purkinje fiber. The dashed trace shows an EAD that is subthreshold. *B.* Early afterdepolarization reached the threshold for the slow inward current, causing repetitive firing during the plateau of the Purkinje fiber action potential (*dashed trace*). *C.* Solid trace shows a transmembrane action potential followed by a subthreshold DAD. The dashed trace shows the triggered action potentials that occur when the afterdepolarization reaches threshold potential.

Delayed afterdepolarizations (*DADs*) are transient depolarizations that occur after repolarization of the transmembrane action potential (Fig. 23-3*C*). Triggered impulses occur when DADs reach the threshold potential for activation of the inward current responsible for the upstroke of the transmembrane action potential. Delayed afterdepolarizations have been recorded from atrial, ventricular, and Purkinje's cells exposed to catecholamines, digitalis, or abnormally high levels of Ca^{2+} and are caused by abnormally high intracellular Ca^{2+}. The ionic mechanism causing DADs is the transient inward current, a current caused by oscillatory changes in intracellular Ca^{2+} concentrations. Some digitalis toxic rhythms are thought to be due to delayed afterdepolarizations as well as some idiopathic ventricular tachycardias originating in the right ventricular outflow tract (Table 23-1).

ABNORMAL IMPULSE CONDUCTION

Prolongation of Conduction Time

Prolongation of the conduction time of the cardiac impulse may occur anywhere in the heart. It may result from slow conduction and be generalized, as in response to a class IC antiarrhythmic agent, or the slow conduction may be localized to a portion of the heart, e.g., in a portion of the specialized AV conduction system or in ventricular myocardium injured by a myocardial infarction or by other kinds of cardiac disease. Prolongation of conduction time resulting from slow conduction also may occur as a normal response of cardiac tissue, as in prolongation of AV nodal conduction time associated with a propagated premature beat. In addition to slow conduction, prolongation of conduction time may occur when the cardiac impulse takes longer than normal to get from one place to another even though the conduction velocity of the impulse along the route is normal. An example of this is found in patients with an endocardial cushion defect in which the sinus impulse takes an abnormally long time to reach the AV node.

This occurs because the location of the ostium primum defect forces the activation wavefront generated by the sinus impulse to take a longer route to reach the AV node.[2] As is shown below, however, perhaps the most important role of prolongation of conduction time is in the genesis and maintenance of most tachycardias resulting from circus movement or reentrant excitation.

Block of Conduction

Block of the propagating impulse may occur for any number of reasons. It may block because the impulse arrives at tissue that is inexcitable either because the tissue is still in its effective refractory period after a recent depolarization or because it has an abnormally low resting potential caused by disease. Block also may occur because the strength of the propagating wavefront is insufficient to excite the tissue ahead of it despite the fact that that tissue is fully excitable (decremental conduction and block). Block also may occur because the propagating impulse encounters tissue that is intrinsically unable to conduct the cardiac impulse, e.g., scar tissue associated with a prior myocardial infarction or surgical incision. If there is conduction block of the cardiac impulse, disturbances of cardiac rhythm may occur in several different ways. If the sinus impulse fails to propagate to the right atrium (sinus node exit block or sinoatrial block), normally an ectopic (latent or escape) pacemaker will emerge and assume the role of cardiac pacemaker. If propagation of the cardiac impulse is impaired in the specialized AV conduction system so that the ventricles are not activated at a sufficiently rapid rate, an ectopic pacemaker (latent or escape) distal to the site of block often will emerge and assume the role of cardiac pacemaker. When either sinoatrial or AV block occurs, however, an ectopic pacemaker may not emerge quickly enough and/or at a clinically adequate rate under some circumstances. Thus, a period of asystole, marked bradycardia, or both may occur. If either or both happen, the clinical problem may be quite serious and even life-threatening. Block also may occur in one of the bundle branches, causing either left or right bundle branch block. Bundle branch block per se is rarely a clinical problem of consequence except when the block occurs simultaneously in both bundle branches.

Unidirectional Block and Reentry

During normal sinus rhythm, the conducted impulse from the sinus node pacemaker dies out after orderly and sequential activation of the atria, the specialized AV conduction system, and the ventricles because the impulse is prevented from reactivating the myocardium by the refractoriness of the tissue that has just been activated. The heart then must wait for a new impulse from the sinus node pacemaker for each subsequent activation. The phenomenon of reentry occurs when the propagating impulse does not die out but rather continues to propagate and reactivate the heart, because the activation wavefront continuously encounters excitable cardiac tissue. Most clinically important tachyarrhythmias are due to reentry (Table 23-1). For reentry to occur, several conditions must be met. First, there must be a substrate in the cardiac tissue capable of supporting reentry, i.e., a region in the heart with the appropriate electrical properties in which reentry can occur. Second, the excitation wavefront must encounter unidirectional block. Third, the activation wavefront must be able to circulate around a central area of block.

Figure 23-4*A*, *B*, and *C* illustrates a simple model of reentry in a loop of excitable tissue, as was demonstrated first by Mayer in 1906 in the excitable ring of a jellyfish[3] and later by Mines in rings of cardiac tissue cuts from a tortoise heart.[4] The center of the loop is a hole, and this serves as a central area of block around which the reentrant wavefront can circulate. If the loop of excitable tissue is stimulated at a single point, two wavefronts of excitation circulate in the ring in opposite directions from this point (Fig. 23-4*A*). Since the wavefronts collide, they die out. If block of one of the circulating wavefronts occurs (e.g., in the shaded area), however, an excitation wavefront can circulate in only one direction around the loop; i.e., unidirectional block of the stimulated wavefront has occurred (Fig. 23-4*B*). If either conduction of the nonblocked impulse around the loop is slow enough (e.g., because of a region or regions of slow conduction) or, in the presence of normal conduction, the loop is long enough so that by the time the circulating wavefront has returned to its site of origin, this latter region has recovered excitability, the wavefront can then reexcite (i.e., reenter) tissue it has previously excited and continue to circulate (Fig. 23-4*C*). For this to occur, however, the region of block must manifest unidirectional block, i.e., block in the right-to-left direction but conduction in the left-to-right direction (Fig. 23-4*C*). If the region of previous block remains unexcitable, bidirectional block at this site has prevented reentry. Since the block is unidirectional, reentry occurs. In the presence of myocardium manifesting unidirectional block and a

central inexcitable area around which an excitation wavefront can circulate, as long as the wavelength (the product of the conduction velocity of the circulating wavefront and the effective refractory period of the tissue of the potentially reentrant circuit) of the circulating wavefront is shorter than the length of the pathway in which it is traveling, the wavefront will continue to circulate. In other words, as long as myocardium in the reentrant circuit ahead of the propagating reentrant excitation wave has sufficient time to recover excitability after its prior excitation, reentry can continue. The result is classical circus movement or reentrant excitation. Thus, an area of slow conduction is not an absolute requisite for reentrant excitation to occur.

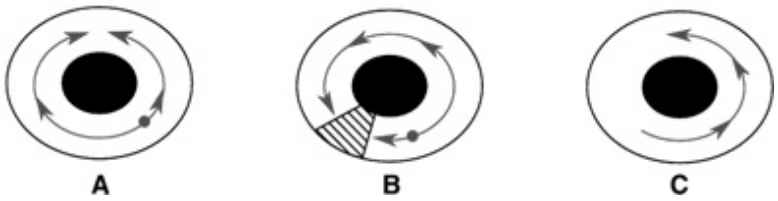

Figure 23-4: Schematic representation of reentry in a ring of excitable tissue. *A*. Ring was stimulated in the area indicated by the black dot. Impulses propagated away from the point of stimulation in both directions (*arrows*) and collided; no reentry occurred. *B*. The striped area was compressed while the ring was stimulated, again at the black dot. The impulse propagated around the ring in only one direction, having been blocked in the other direction by the area of compression. Then, immediately after stimulation, the compression was relieved. *C*. Circulating impulse is shown returning to its point of origin and then continuing around the ring. Identical reentry would occur if the striped area in *B* were a region of permanent unidirectional conduction block with block in the right-to-left direction.

Reentry can occur at normal conduction velocities if the path length is sufficiently long. Most reentrant circuits, however, require the presence of an area of slow conduction. This is the case because in most circumstances, despite the presence of unidirectional block, the length of the potential reentrant circuit is too short, so that without the presence of an area or areas of slow conduction, the nonblocked wavefront would otherwise travel around the circuit so quickly that it would arrive at the point of origin of the wavefront (the stimulus site in Fig. 23-4) before that site had recovered sufficiently to become excitable again. In fact, presumably for this very reason, an area or areas of slow conduction is part of the reentrant circuit for virtually all clinical reentrant rhythms. Reentrant circuits may be located almost anywhere in the heart, and they can assume many sizes and shapes.

Reentry in which the circulating wavefront continuously reenters over the same stable pathway to generate the reentrant rhythm is called *ordered reentry*.[1] The circuit may constitute a well-defined anatomic pathway, an anatomic circuit. One example is the reentrant circuit in AV reentrant tachycardia (atrium, AV node, His-Purkinje system, ventricle, accessory AV connection). Functional circuits, which depend on cellular electrophysiologic properties rather than anatomy, also can be associated with ordered reentry if the electrophysiologic properties crucial for reentry are confined to a specific location and reentry occurs only in that location. Ordered reentry also can involve a combination of anatomic and functional pathways. Examples of arrhythmias caused by ordered reentry include atrial flutter, most monomorphic ventricular tachycardias, AV nodal reentrant tachycardia, AV reentrant tachycardia involving an accessory AV connection, and sinus node reentrant tachycardia (Table 23-1) (see Chap. 27). During random reentry,[1] propagation occurs in reentrant pathways that continuously change their size and location with time. For this to occur, circuits must, at least to a significant degree, be functional. Random reentry need not depend on any special electrophysiologic abnormality in the heart, although electrophysiologic abnormalities also may lead to random reentry. Examples of random reentry include some forms of atrial and ventricular fibrillation (Table 23-1).

Reflection

The term *reflection* has been used to describe a form of reentry in a linear bundle in which two excitable regions are separated by an area of depressed conduction.[5] During reflection, excitation occurs slowly in one direction along the bundle and is followed by continued propagation and excitation occurring in the

opposite direction. One form of reflection may in fact be microreentry based on functional longitudinal dissociation within the depressed segment.[6-8] How this may occur is diagrammed in Fig. 23-5. The diagram at the top of the figure depicts two adjacent fibers in a bundle. The entire shaded area is depressed (reduced membrane potential and slow action potential upstrokes), with the darker area in the upper fiber indicating more severe depression than the lighter area in the lower fiber. Unidirectional conduction block occurs in the more severely depressed region. Arrows labeled I show the impulse entering the two fibers from the left end. Conduction of the impulse (I) blocks in the fiber at the top, in the severely depressed region, but continues in the fiber at the bottom, which is not as depressed. The impulse conducts transversely from the bottom fiber to the top fiber once it is past the region of severe depression. It then conducts retrogradely through this severely depressed region in the top bundle. Arrows labeled II show the reflected impulse returning to reexcite the left end of the bundle. Action potentials that were recorded from sites a, b, and c in the bottom fiber are shown below: action potentials labeled I were recorded as the impulse conducted from left to right; action potentials labeled II were recorded as the impulse conducted from right to left, returning to its origin. It is thought that such reentry may occur in the His bundle, one of the bundle branches or peripheral branches of Purkinje fiber bundles.

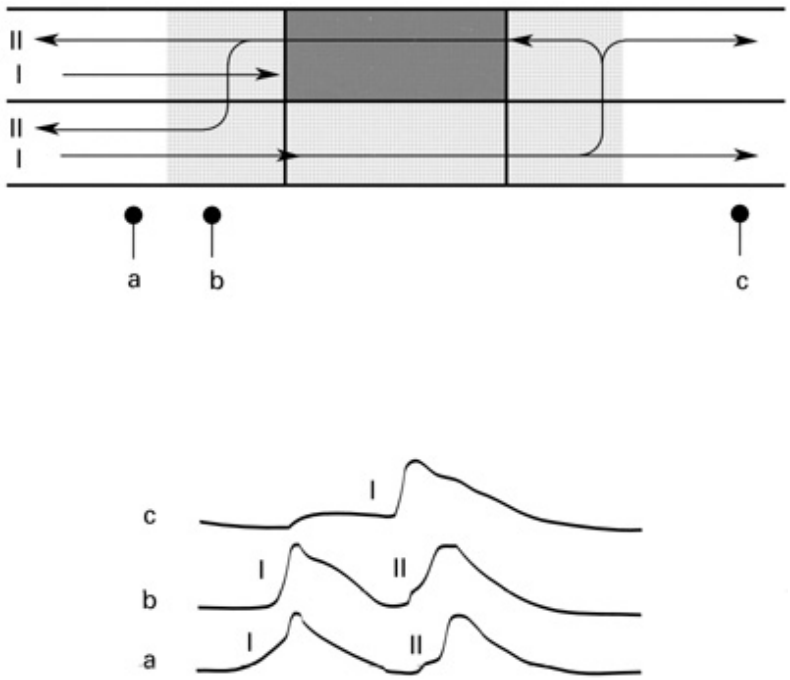

Figure 23-5: Diagram of reflection based on microeentry. *Top*: Schematic representation of two adjacent myocardial fibers. The shaded region indicates an area of depressed conduction. Arrows show the pattern of activation: Arrow I is a wavefront conducting in an antegrade direction, and arrow II is a reflected wavefront conducting in a retrograde direction. The action potentials shown below were recorded at sites a, b, and c on the diagram. SIMULTANEOUS ABNORMALITIES OF IMPULSE GENERATION AND CONDUCTION

Parasystole

At times, an ectopic pacemaker may be connected to the remainder of the heart through tissue or tissues in which there is unidirectional block. The unidirectional block prevents the dominant rhythm, usually a sinus rhythm, from entering the region where the ectopic pacemaker is located. As a result, the ectopic pacemaker is not suppressed by the dominant rhythm of the heart. At the same time, because the block is unidirectional, impulses generated by the ectopic pacemaker can be conducted out to other regions of the heart as long as they are not refractory, causing premature beats or even a tachycardia. This kind of rhythm is called *parasystole*. Thus, parasystole is a rhythm that is due to impulse generation (presumed to be due to

an ectopic pacemaker, but it could be due to any mechanism) in a protected focus. The focus is protected because there is entrance block into the focus (owing to unidirectional block). An impulse may exit the focus and excite the heart if the impulse generated by the parasystolic focus finds tissue that is excitable, i.e., not in the effective refractory period.

Phase 4 Block

Block of an impulse may occur if the impulse arrives at a site-e.g., in the His bundle or one of the bundle branches-that is partially depolarized during spontaneous phase 4 depolarization but has not yet reached threshold. This spontaneous diastolic depolarization can depolarize the tissue sufficiently that the fast Na^+ channels are inactivated enough to cause failure of propagation.[9]

Chapter 23: MECHANISMS OF CARDIAC ARRHYTHMIAS AND CONDUCTION DISTURBANCES

DETAILED DISCUSSION OF MECHANISMS OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

Arrhythmias Caused by Impulse Initiation

INTRODUCTION

The term *impulse initiation* is used to indicate that an electrical impulse can arise in a single cell or a group of closely coupled cells through depolarization of the cell membrane and, once initiated, can spread through the rest of the heart. Impulse initiation occurs because of localized changes in ionic currents that flow across the membranes of single cells. There are two major causes for the impulse initiation that may result in arrhythmias: automaticity and triggered activity. Each has its own unique cellular mechanism that results in membrane depolarization.

AUTOMATICITY

It is convenient to subdivide automaticity into two kinds: normal and abnormal. Normal automaticity is found in the primary pacemaker of the heart, the sinus node, as well as in certain subsidiary or latent pacemakers that can become the pacemaker under the conditions described below. Impulse initiation is a normal property of these latent pacemakers. By contrast, abnormal automaticity, whether the result of experimental interventions or of disease, occurs in cardiac cells only when there are major abnormal changes in their transmembrane potentials, in particular in steady-state depolarization of the membrane potential. This property of abnormal automaticity is not confined to any specific latent pacemaker cell type but may occur almost anywhere in the heart.

Normal Automaticity: Pacemaker Mechanisms

The normal site of impulse initiation is the sinus node. The cause of normal automaticity in the sinus node is a spontaneous decline in the transmembrane potential during diastole, referred to as the *pacemaker potential*, *phase 4*, or *diastolic depolarization* (the terms are interchangeable). Diastolic depolarization is the part of the sinus node membrane potential labeled dd in the top panel (*A*) of Fig. 23-6. When the depolarization reaches the threshold potential (dashed line labeled TP), the upstroke of the spontaneous action potential is initiated. In the case of the sinus node this upstroke is caused mainly by an inward-directed calcium current through L-type calcium channels. This fall in membrane potential during phase 4 reflects a gradual shift in the balance between inward and outward membrane currents in the direction of net inward (depolarizing) current.

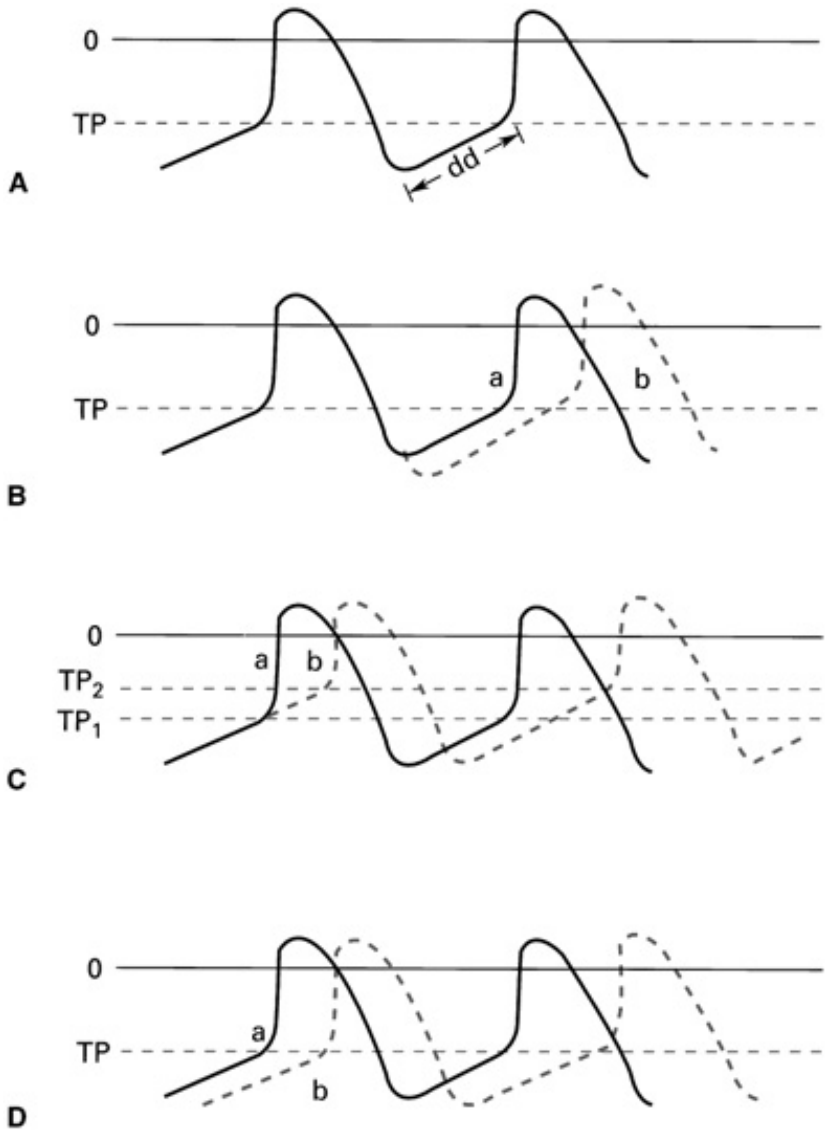

Figure 23-6: Diagrams of sinus node action potentials illustrating normal automaticity caused by spontaneous diastolic depolarization and the factors that change the rate of impulse initiation. *A.* Typial sinus node action potential with spontaneous diastolic depolarization (dd). *B.* Change in the rate when the maximum diastolic potential is shifted to a more negative level (from a to b). *C.* Change in rate caused by change in threshold potential to a less negative level (from TP1 to TP2). *D.* Change in rate that occurs when the slope of phase 4 depolarization is decreased (from a to b). (Modified after Wit AL, Janse MJ. *The Ventricular Arrhythmias of Ischemia and Infarction: The Electrophysiological Mechanisms*. Mount Kisco, NY: Futura; 1992:3. Reproduced with permission from the publisher and authors.)

Studies have been done to elucidate and characterize the membrane currents that cause diastolic (phase 4) depolarization in the sinus node, using voltage clamp techniques in small tissue preparations and in single dissociated sinus node cells. The cause of the pacemaker potential is still controversial. There is some evidence that diastolic depolarization results from the turning on of an inward current, called i_f, which is activated after repolarization of the sinus node action potential. The net inward i_f current is carried largely by Na^+.[10] From the voltage clamp studies, it is known that the i_f channels are inactivated at positive membrane potentials, begin to activate after hyperpolarization to around -40 mV, and are fully activated after hyperpolarization to around -100 mV.[11-13] Since the maximum diastolic potential of the sinus node pacemaker cells is between -60 and -70 mV, the i_f current is turned on during repolarization to this level, although it is not fully activated at the maximum diastolic potential. Activation of the i_f conductance also has

a time dependency; therefore, the inward current continues to increase after complete repolarization, causing the progressive fall in the membrane potential during phase 4. Important roles for other membrane currents, including the potassium current i_K and the T and L Ca^{2+} currents that cause spontaneous diastolic depolarization, also have been proposed.[14-22] Therefore, there may be no single pacemaker current in the sinus node; rather, a number of currents may contribute to the occurrence of automaticity.[18]

The intrinsic rate at which sinus node pacemaker cells initiate impulses is determined by the interplay of three factors:[23] (1) the maximum diastolic potential, (2) the threshold potential, and (3) the rate or slope of phase 4 depolarization. The third factor is related to the properties of the pacemaker current or currents. A change in any one of these factors will alter the time required for phase 4 depolarization to carry the membrane potential from its maximum diastolic level to threshold and thus alter the rate of impulse initiation. For example, if the maximum diastolic potential increases (becomes more negative) going from the solid trace to the dashed trace in Fig. 23-6*B*, spontaneous depolarization to the threshold potential will take longer and the rate of impulse initiation will fall. Conversely, a decrease in the maximum diastolic potential will tend to increase the rate of impulse initiation (going from dashed trace to solid trace). Similarly, changes in threshold potential or changes in the slope of phase 4 depolarization will alter the rate of impulse initiation. In Fig. 23-6*C*, a change in threshold potential from TP1 to the less negative TP2 causes spontaneous diastolic depolarization to proceed for a longer time (dashed action potential trace) before an impulse is initiated, slowing the rate. In Fig. 23-6*D*, a decrease in the slope of spontaneous diastolic depolarization from a to b also results in a longer interval between action potentials (dashed trace) because of the longer time required for membrane potential to reach the threshold potential. In Fig. 23-6*C* and *D*, changes in the threshold potential or slope of diastolic depolarization in the opposite direction would speed up the rate.

The alterations in the rate of impulse initiation in the sinus node resulting from the factors discussed above may lead to arrhythmias. These arrhythmias are often a result of the actions of the autonomic nervous system on the sinus node. Parasympathetic stimulation and the resultant release of acetylcholine hyperpolarize the membrane potential through stimulation of muscarinic receptors and the activation of a K current (Fig. 23-6*B*).[24,25] Acetylcholine also decreases the inward Ca^{2+} current and the i_f pacemaker current.[26] A combination of these effects slows the rate. Sympathetic stimulation and norepinephrine release increase the slope of diastolic depolarization and therefore sinus rate by increasing L-type Ca^{2+} current[27] and increasing activation of the inward i_f current at the completion of action potential repolarization.[12,13,28] These effects are mediated through $beta_1$-receptor stimulation.

In addition to the sinus node, cells with pacemaking capability in the normal heart are located in some parts of the atria and ventricles, although they are not pacemakers while the sinus node is functioning normally. These are latent or subsidiary pacemakers. Since spontaneous diastolic depolarization is a normal property, the automaticity generated by these cells is classified as normal. In the atria, cells with well-polarized membrane potentials (resting potentials of around -80 mV) and action potentials characterized by fast upstrokes, a plateau phase of repolarization, and spontaneous diastolic depolarization are located along the crista terminalis (Fig. 23-7*A*).[29] Subsidiary atrial pacemakers with somewhat lower maximum diastolic potentials (-75 to -70 mV) and prominent phase 4 depolarization are located at the junction of the inferior right atrium and the inferior vena cava, near or on the eustachian ridge (a remnant of the eustachian valve of the inferior vena cava) (Fig. 23-7*B*).[30-32] Other potential atrial pacemakers are at the orifice of the coronary sinus (Fig. 23-7*C*)[33] and in the atrial muscle that extends into the tricuspid and mitral valves (Fig. 23-7*D*).[34-36] Action potentials of cells in the valves have slow upstrokes that probably are caused to a significant extent by L-type Ca^{2+} current. In the AV junction, AV nodal cells possess the intrinsic property of automaticity (Fig. 23-7*E*),[37] although there is still some

uncertainty about the exact location of these pacemakers in the node.[38] The intrinsic rate of the atrial pacemakers is greater than that of AV junctional pacemakers.[39] Both atrial and AV junctional subsidiary pacemakers are under autonomic control, with the sympathetics enhancing pacemaker activity through $beta_1$-adrenergic stimulation and the parasympathetics inhibiting pacemaker activity through muscarinic receptor stimulation.[40-43] In the ventricles, latent or subsidiary pacemakers are found in the His-Purkinje system, where Purkinje fibers have the property of spontaneous diastolic depolarization (Fig. 23-8).[23,44] The intrinsic Purkinje fiber pacemaker rate in general is lower than the rate of atrial and AV junctional pacemakers and decreases from the His bundle to the distal Purkinje branches.[45] The spontaneous diastolic depolarization in this region is also under similar autonomic control. As in the atria, sympathetic activation enhances automaticity,[46] while parasympathetic activation can reduce it, mostly through inhibition of sympathetic influences.[47,48]

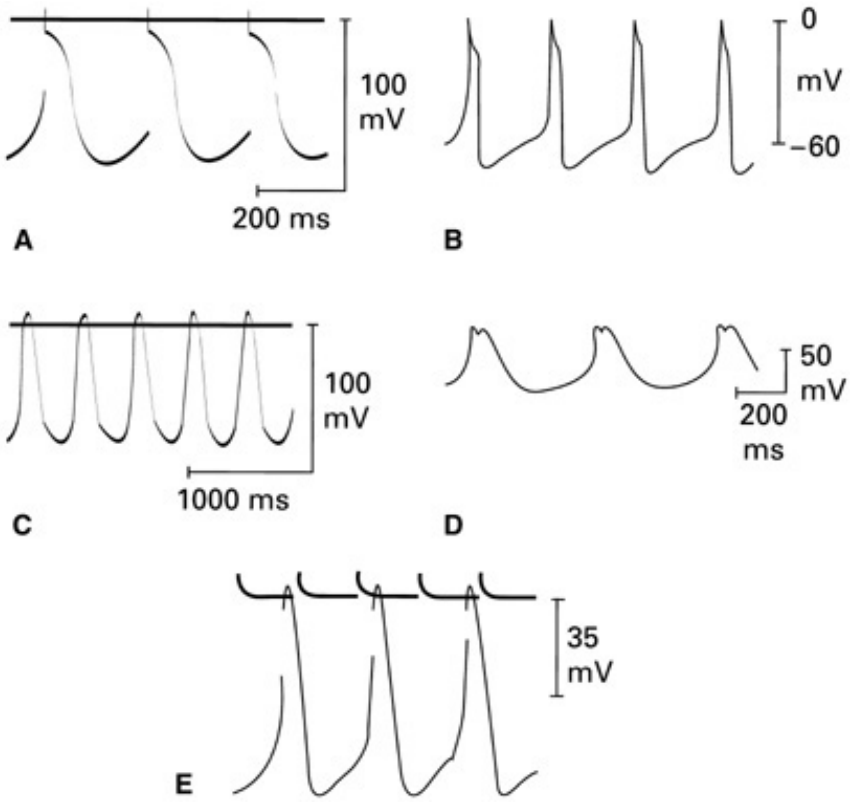

Figure 23-7: Transmembrane potentials recorded in isolated superfused preparations from some subsidiary pacemaker cells with the property of normal automaticity. Spontaneous diastolic depolarization that developed in the absence of overdrive suppression is shown in each panel. *A.* Atrial fiber in the crista terminalis in the presence of isoproterenol. *B.* Atrial fiber in the inferior right atrium. *C.* Atrial fiber in the ostium of the coronary sinus in the presence of norepinephrine. *D.* Atrial fiber in stretched mitral valve leaflet. *E.* Atrioventricular nodal fiber of the rabbit heart after the AV node was separated from the atrium. (From Wit AL, Janse MJ. *The Ventricular Arrhythmias of Ischemia and Infarction: The Electrophysiological Mechanisms*. Mount Kisco, NY: Futura; 1992:7. Reproduced with permission from the publisher and authors.)

The membrane currents that cause the normal spontaneous diastolic depolarization at ectopic sites also have been studied. The most thorough analyses have been done on the pacemaker current in Purkinje's cells, using voltage clamp techniques. These studies have shown the presence of an i_f pacemaker current, as in the sinus node.[28,49,50] The i_f channels are deactivated during the action potential upstroke and the initial plateau phase of repolarization but begin to activate as

repolarization brings the membrane potential to levels more negative than about -60 mV. Since the activation kinetics are slow, the channels continue to activate throughout diastole, leading to an increasing net inward current carried mostly by Na^+ and diastolic depolarization.[49,50] Other currents are also likely to contribute to the pacemaker potential in Purkinje's cells.[28,51-53] It is likely that the net increase in inward current during diastole that causes spontaneous diastolic depolarization in Purkinje fibers is a result of an increase in an inward current i_f and a decrease in outward current (i_{K_1} and i_K).[52]

Abnormal Automaticity: Pacemaker Mechanisms

Working atrial and ventricular myocardial cells do not normally have spontaneous diastolic depolarization and do not initiate spontaneous impulses even when they are not excited for long periods of time by propagating impulses. When the resting potentials of working atrial or ventricular myocardial cells are reduced sufficiently, however, spontaneous diastolic depolarization may occur and cause repetitive impulse initiation, a phenomenon called *depolarization-induced automaticity* or *abnormal automaticity*. The level of membrane potential at which abnormal automaticity occurs is often in a range between -70 and -30 mV (see Fig. 23-2).[54] Likewise, cells in the Purkinje system, which are normally automatic at high levels of membrane potential, also show abnormal automaticity when the membrane potential is reduced.[55] As was discussed before, the i_f channels that participate in normal pacemaker activity in Purkinje fibers have a gating mechanism controlling channel opening and closing that is dependent on the transmembrane voltage. At membrane potentials that are positive to about -60 mV, as occurs after the upstroke and during the early phases of repolarization, the channels are closed. In response to the negative potentials that occur after complete repolarization, the channels reopen, gener ating the inward pacemaker current.[49,50] For this reason, when the steady-state membrane potential of Purkinje fibers is reduced to around -60 mV or less, as sometimes may occur in ischemic regions of the heart, these normal pacemaker channels are not functional and automaticity is not caused by the normal pacemaker mechanism. It can, however, be caused by an "abnormal" mechanism (described below).

In Fig. 23-9, the transmembrane potential recorded from a spontaneously firing Purkinje fiber with normal automaticity is shown in panel *A*, and abnormal automatic activity occurring while the membrane potential is depolarized to progressively lower membrane potentials is shown in panel *B*, 1, 2, and 3. The abnormal automatic rate increased as membrane potential became more positive. This is a general characteristic of abnormal automaticity in atrial and ventricular cells as well. A low level of membrane potential is not the only criterion for defining abnormal automaticity. If this were so, the automaticity of the sinus node would have to be considered abnormal. Therefore, an important distinction between abnormal and normal automaticity is that the membrane potentials of fibers showing the abnormal type of activity are reduced from their own normal level. For this reason, automaticity in the AV node or valves, where membrane potential is normally low, is not classified as abnormal automaticity. A likely cause of automaticity at depolarized membrane potentials in ventricular muscle is activation and deactivation of the delayed rectifier K current.[56,57] The conductance of this K channel is activated during the normal action potential plateau, and the outward current that flows through it normally contributes to repolarization. The channel then deactivates during diastole. No significant outward current flows through this channel at normal diastolic potentials, since the resting potential lies near the reversal potential and the driving force is negligible.[57] When the membrane potential is depolarized, however, an outward current flows through this channel, which is activated at the depolarized membrane potentials. This current hyperpolarizes the membrane potential. As the channel then deactivates at the hyperpolarized potentials, spontaneous diastolic depolarization occurs. If either Na or Ca channels have been reactivated since the preceding action potential, the spontaneous depolarization caused by K-channel deactivation may lead to an upstroke caused by current flowing through one of these channels (depending on the level of the membrane

potential).[57] A similar mechanism may cause abnormal automaticity in partially depolarized Purkinje fibers.

Experiments on depolarized human atrial myocardium from dilated atria indicate that Ca^{2+}-dependent processes also may contribute to abnormal pacemaker activity at low membrane potentials.[58,59] It was proposed that intracellular Ca^{2+} released from the sarcoplasmic reticulum controls membrane permeability to an inward current during diastole, leading to spontaneous diastolic depolarization and abnormal automaticity. The mechanism may be similar to the one that causes the transient inward current responsible for DADs (see "Triggered Rhythms," above). An increase in intracellular Ca^{2+} also is expected to cause an inward Na^+ current through Na^+-Ca^{2+} exchange. In summary, therefore, several different mechanisms probably cause abnormal automaticity, including activation and deactivation of K^+ currents, Ca^{2+}-dependent activation of an inward current, inward Ca^{2+} currents, and even some contribution by the pacemaker current i_f.

It has not been determined which of these mechanisms are operative in the different pathologic conditions in which abnormal automaticity may occur. The upstrokes of the spontaneously occurring action potentials generated by abnormal automaticity may be caused by either Na^+ or Ca^{2+} inward currents or possibly a mixture of the two. In the range of diastolic potentials between approximately -70 and -50 mV, repetitive activity is dependent on extracellular Na^+ concentration and can be decreased or abolished by the Na^+ channel blockers lidocaine and tetrodotoxin, indicating that the Na^+ inward current is involved. In a diastolic potential range of approximately -50 to -30 mV, repetitive activity depends on extracellular Ca^{2+} concentration and is reduced by Ca^{2+} channel blockers, Mn^{2+}, and verapamil, indicating a role for the L-type Ca^{2+} inward current.[5,60] The decrease in the membrane potential of cardiac cells required for abnormal automaticity to occur may be induced by a variety of factors related to cardiac disease. Although an increase in the extracellular potassium concentration can reduce membrane potential, normal or abnormal automaticity in working atrial, ventricular, and Purkinje fibers usually does not occur when $[K]_o$ is elevated because of the increase in K^+ conductance (and hence net outward current) that results from an increase in $[K]_o$.[61,62] This argues against abnormal automaticity being responsible for arrhythmias arising in acutely ischemic myocardium, where cells are partially depolarized by increased extracellular K^+.[63-65] A decrease in $[K]_i$, which also causes a decreased membrane potential, has been shown to occur in the Purkinje fibers that survive on the endocardial surface of infarcts, and this decrease persists for at least 24 h after the coronary occlusion.[66] The reduction in $[K]_i$ contributes to the low membrane potential[67] and the accompanying abnormal automaticity.[68,69] Isolated preparations of diseased atrial and ventricular myocardium from human hearts superfused with Tyrode's solution show phase 4 depolarization and abnormal automaticity at membrane potentials in the range of -50 to -60 mV.[70-72] It has been proposed that a decrease in membrane potassium conductance is an important cause of the low membrane potentials in the atrial fibers.[71]

Suppression of Normal and Abnormal Automatic Subsidiary Pacemakers

During sinus rhythm in a normal heart, the intrinsic rate of impulse initiation resulting from automaticity of cells in the sinus node is higher than that of the other potentially automatic cells, and the latent pacemakers are excited by propagated impulses from the sinus node before they can depolarize spontaneously to threshold potential. Not only are latent pacemakers prevented from initiating an impulse because they are depolarized before they have a chance to fire, but the diastolic (phase 4) depolarization of the latent pacemaker cells with the property of normal automaticity is actually inhibited because they are repeatedly depolarized by the impulses from the sinus node.[73,74] This inhibition can be demonstrated by suddenly stopping the sinus node, e.g., by vagal stimulation (vagal stimulation also inhibits subsidiary pacemakers in the atria and AV junction) or in the tissue bath after termination of overdrive pacing (Fig. 23-8). Impulses

then usually arise from a subsidiary pacemaker in the ventricular Purkinje system, but that impulse initiation generally is preceded by a long period of quiescence.[75,76] Impulse initiation by the Purkinje fiber pacemaker then begins at a low rate and only gradually speeds up to a final steady rate that is, however, still slower than the original sinus rhythm. The quiescent period after abolition of the sinus rhythm reflects the inhibitory influence exerted on the subsidiary pacemaker by the dominant sinus node pacemaker. This inhibition is called *overdrive suppression*. Similarly, the sinus node also overdrive-suppresses subsidiary atrial pacemakers.[77]

The mechanism of overdrive suppression has been characterized in microelectrode studies of isolated Purkinje fiber bundles exhibiting pacemaker activity.[73] It is mediated mostly by enhanced activity of the Na^+-K^+ exchange pump that results from driving a pacemaker cell faster than its intrinsic spontaneous rate. During normal cardiac rhythm, the sinus node drives the latent pacemakers at a faster rate than their normal (intrinsic) automatic rate. As a result, the intracellular Na^+ of the latent pacemakers is increased to a higher level than would be the case if the pacemakers were firing at their own intrinsic rate. This is the result of Na^+ entering the cells during each action potential upstroke. The rate of activity of the Na^+ pump is determined largely by the level of intracellular Na^+ concentration,[78] so that pump activity is enhanced during high rates of stimulation.[73] The increased pump activity prevents intracellular Na^+ from rising to very high levels, although there is some increase in the steady-state Na^+ concentration at high rates of firing. Since the Na^+ pump moves more Na^+ outward than K^+ inward, it generates a net outward (hyperpolarizing) current across the cell membrane.[79] When subsidiary pacemaker cells are driven faster than their intrinsic rate by the sinus node, the enhanced outward pump current hyperpolarizes the membrane potential and suppresses spontaneous impulse initiation in these cells, which, as was described before, is dependent on the net inward current. When the dominant (overdrive) pacemaker is stopped, this suppression continues because the Na^+ pump continues to generate the outward current as it reduces the intracellular Na^+ levels toward normal. The continued Na^+ pump-generated outward current is responsible for the period of quiescence, which lasts until the intracellular Na^+ concentration, and hence the pump current, becomes small enough to allow subsidiary pacemaker cells to depolarize spontaneously to threshold. Intracellular Na^+ concentration decreases during the quiescent period because Na^+ is constantly being pumped out of the cell and little is entering.[60] Intracellular Na^+ and pump current continue to decline even after spontaneous firing begins because of the slow rate, causing a gradual increase in the discharge rate of the subsidiary pacemaker.

The higher the overdrive rate or the longer the duration of overdrive, the greater the enhancement of pump activity, so that the period of quiescence after the cessation of overdrive is directly related to the rate and duration of overdrive.[73] The sinus node itself also can be overdrive-suppressed if it is driven at a rate more rapid than its intrinsic rate. Thus, there may be a quiescent period after termination of either overdrive pacing or a rapid ectopic arrhythmia before the sinus rhythm resumes.[80-83] When overdrive suppression of the normal sinus node occurs, however, it is of lesser magnitude than that of subsidiary pacemakers overdriven at comparable rates.[30,80] The sinus node action potential upstroke is largely dependent on slow inward current carried by Ca^{2+} through the L-type Ca^{2+} channels, and far less Na^+ enters the fiber during the upstroke than occurs in latent pacemaker cells such as Purkinje fibers. As a result, the activity of the Na^+ pump probably is not increased to the same extent in sinus node cells after a period of overdrive; therefore, there is less overdrive suppression caused by enhanced Na^+ pump current. The relative resistance of the normal sinus node to overdrive suppression may be important in enabling it to remain the dominant pacemaker even when its rhythm is perturbed transiently by external influences such as transient shifts of the pacemaker to an ectopic site. The diseased sinus node, however, may be much more easily overdrive-suppressed.[84]

There is an important distinction between the effects of the dominant sinus pacemaker on the two kinds of automaticity, as abnormal automaticity at reduced levels of membrane potential is not

overdrive-suppressed to the same extent as is the normal automaticity that occurs at high levels of membrane potential.[85-87] The amount of suppression of spontaneous diastolic depolarization that causes abnormal automaticity by overdrive is directly related to the level of membrane potential at which the automatic rhythm occurs.[86,87] For example, Purkinje fibers that show automaticity at moderately depolarized membrane potentials of -60 to -70 mV still manifest some overdrive suppression, although less than do fibers with automaticity at -90 mV. Automaticity in Purkinje fibers with membrane potentials less than -60 mV is suppressed only slightly by overdrive, if it is suppressed at all. These differences in the effects of overdrive may be related to the reduction in the amount of Na^+ entering the cell as the membrane potential decreases, as was described for overdrive of the sinus node. At low levels of membrane potential, Na^+ channels are inactivated, decreasing the fast inward Na^+ current; therefore, there is a reduction in the amount of Na^+ entering the cells during overdrive and the degree of stimulation of the sodium-potassium pump.[88]

In addition to overdrive suppression being of paramount importance for maintenance of normal rhythm, the characteristic response of automatic pacemakers to overdrive, as was discussed in the previous paragraphs, is often useful for identifying mechanisms of arrhythmias in the in situ heart, where arrhythmia mechanisms cannot be identified by recording transmembrane potentials because of the technical difficulties. Not all mechanisms of arrhythmogenesis respond in the same way to overdrive that automatic pacemakers do, and the differences in response sometimes can be used to distinguish among mechanisms. These differences are described in detail later in this chapter. In addition to overdrive suppression, a mechanism that may suppress subsidiary pacemakers is the electrotonic interaction between the pacemaker cells and the nonpacemaker cells in the surrounding myocardium.[89] This mechanism may be particularly important in preventing AV nodal automaticity[90,91] or automaticity in the distal Purkinje system, where the pacemaking Purkinje fibers are in contact with nonpacemaking working ventricular muscle.[89,92-93]

Arrhythmias Caused by Automaticity

Arrhythmias caused by normal or abnormal automaticity of cardiac fibers may occur for several different reasons. Such arrhythmias may result simply from an alteration in the rate of impulse initiation by the normal sinus node pacemaker without a shift of impulse origin to a subsidiary pacemaker at an ectopic site. Sinus bradycardia and tachycardia are examples of these arrhythmias. The cellular mechanisms that can change the rate of impulse initiation in the sinus node are described in Fig. 23-6. During alterations in sinus rate, there may be shifts of the pacemaker site within the sinus node.[23,94] A shift in the site of impulse initiation to one of the regions where normal or abnormal subsidiary pacemakers are located also results in arrhythmias. This would be expected to happen when any of the following occurs: (1) The rate at which the sinus node activates subsidiary pacemaker falls considerably below the intrinsic rate of the subsidiary pacemakers, (2) inhibitory electrotonic influences between nonpacemaker cells and pacemaker cells are interrupted, or (3) impulse initiation in subsidiary pacemakers is enhanced.

The rate at which the sinus node activates subsidiary pacemakers may be decreased in a number of situations. Impulse initiation by the sinus node may be slowed or inhibited altogether by heightened activity in the parasympathetic nervous system[95] or as a result of sinus node disease.[96] Alternatively, there may be block of impulse conduction from the sinus node to the atria or block of conduction from the atria to the ventricles. A latent pacemaker also may be protected from being overdriven by the sinus node if it is surrounded by a region in which impulses of sinus origin block (entrance block) before reaching the pacemaker cells. Such block, however, must be unidirectional, so that activity from the pacemaker can propagate into surrounding myocardium whenever the surrounding regions are excitable. Some possible mechanisms for unidirectional block are discussed later in this chapter.

The protected pacemaker is said to be a *parasystolic focus*.[97] In general, under these conditions, a

protected focus of automaticity of this type can fire at its own intrinsic frequency. Electronic current flow from surrounding regions also may influence the cycle length of a protected focus, either prolonging or abbreviating it, depending on whether the surrounding activity occurs during the early or late stage of diastolic depolarization.[98-100] Under any of the above conditions (sinus slowing, sinoatrial or AV block, parasystolic focus), there may be "escape" of a subsidiary pacemaker. There is a natural hierarchy of intrinsic rates of subsidiary pacemakers that have normal automaticity, with atrial pacemakers having faster intrinsic rates than do AV junctional pacemakers and AV junctional pacemakers having faster rates than do ventricular pacemakers.[45,74] Once overdrive suppression is removed by sinus node inhibition, the pacemaker with the fastest rate becomes the site of impulse origin.[74] Sometimes mechanisms responsible for the suppression of impulse initiation in the sinus node also suppress pacemaker activity in the atria. In experimental studies in which the sinus node is damaged or removed, the most prevalent atrial pacemaker site is at the junction of the inferior vena cava and the posterior wall of the right atrium.[30,101-103] These atrial pacemakers may cause atrial arrhythmias if the sinus node or its arterial supply is damaged.[104]

Ectopic impulse initiation may occur in the AV junction. In fact, an AV junctional pacemaker may become the dominant rhythm in the absence of normal sinus node function. Atrioventricular junctional pacemakers may be located either in the AV node or in the His bundle. These different sites have somewhat different properties, including their intrinsic rates (faster in the AV node than in the His bundle) and responses to autonomic nerve activity (parasympathetic activity suppresses AV nodal pacemakers to a greater extent than it does His bundle pacemakers). Atrioventricular junctional rhythms may occur during AV block, since the site of block is often proximal to the AV junctional pacemaker location.[38] If AV junctional pacemakers also are suppressed or if the site of disease causing AV block is in the His bundle or bundle branches, the subsidiary pacemaker location is in the His-Purkinje system. The His bundle at the proximal end of the specialized AV conduction system has a faster intrinsic rate than do the more distally located Purkinje fibers.[45] The electrocardiogram (ECG) during idioventricular rhythm in patients with complete heart block often is characterized by a wide, aberrant QRS complex, suggesting impulse initiation in the distal Purkinje system.[105] In acute myocardial ischemia, particularly when it occurs in the inferior wall, parasympathetic activity may be enhanced, depressing the sinus rate, AV conduction, or both.[106] Ectopic impulse initiation then may arise in the ventricular specialized conduction system.[107]

Any event that decreases intercellular coupling between latent subsidiary pacemaker cells and surrounding nonpacemaker cells may remove the inhibitory influence of electrotonic current flow on the latent pacemakers and allow them to fire at their intrinsic rate.[89] Coupling may be reduced by fibrosis, which can separate myocardial fibers. For example, fibrosis in the atrial aspect of the AV junctional region that results in heart block may release nodal pacemakers from electrotonic suppression by surrounding atrial cells and permit them to become the dominant pacemakers driving the ventricles. Uncoupling also may be caused by factors that increase intracellular Ca^{2+},[108] since elevated intracellular Ca^{2+} levels decrease coupling between myocardial cells by decreasing the conductance of gap junction channels (*connexons*). This may result, for example, from treatment with digitalis,[109] which inhibits Na^{+} extrusion and thus increases Ca^{2+} levels in the cell.[110] In myocardial infarction, Purkinje fiber pacemakers may be uncoupled from damaged ventricular muscle cells, allowing the Purkinje fibers to fire at their intrinsic rates.

Some inhibition of the sinus node is still necessary for the site of impulse initiation to shift to an ectopic site that is no longer inhibited because of uncoupling from surrounding cells, since, as was explained above, the intrinsic firing rate of subsidiary pacemakers is still slower than that of the sinus node. Subsidiary pacemaker activity also may be enhanced, causing impulse initiation to shift to ectopic sites even when sinus node function is normal. One cause may be enhanced sympathetic nerve activity. Norepinephrine released locally from sympathetic nerves steepens the slope of diastolic depolarization of latent pacemaker cells.[23,33,34,111,112] and diminishes the inhibitory effects of overdrive.[113] The increase in slope of spontaneous diastolic depolarization

may result from effects of norepinephrine on the i_f current, as was described above, as well as from an increase in inward Ca^{2+} current in those cells in which this current participates in pacemaker activity. Localized effects on subsidiary pacemakers may occur in the absence of sinus node stimulation.[114] Therefore, sympathetic stimulation may enable the membrane potential of ectopic pacemakers to reach threshold before they are activated by an impulse from the sinus node, resulting in ectopic premature impulses or automatic rhythms. There is evidence that in the subacute phase of myocardial ischemia, increased activity of the sympathetic nervous system may enhance automaticity of Purkinje fibers, enabling them to escape from sinus node domination. Enhanced subsidiary pacemaker activity also may not require sympathetic stimulation. The flow of current between partially depolarized myocardium and normally polarized latent pacemaker cells may enhance automaticity.[115] This mechanism has been proposed to be a cause of some of the ectopic beats that arise at the borders of ischemic areas in the ventricle.[93]

Inhibition of the electrogenic sodium-potassium pump results in a net increase in inward current during diastole because of the decrease in outward current normally generated by the pump and therefore may increase automaticity in subsidiary pacemakers sufficiently to cause arrhythmias. This may occur after adenosine triphosphate (ATP) is depleted during prolonged hypoxia or ischemia or in the presence of toxic amounts of digitalis.[116,117] A decease in the extracellular potassium level also enhances normal automaticity,[75] as does acute stretch.[118] Stretch can induce rapid automatic rates in Purkinje fibers with normal maximum diastolic potentials.[119,120] Stretch of the ventricles also can induce arrhythmias in an intact heart,[121] although the site of origin of the ectopic impulses has not been localized. Stretch of the Purkinje system may occur in akinetic areas after acute ischemia or in ventricular aneurysms in hearts with healed infarcts. At normal sinus rates, there may be little overdrive suppression of pacemakers with abnormal automaticity. As a result of the lack of overdrive suppression, even transient sinus pauses or occasional long sinus cycle lengths may permit an ectopic focus with a slower rate than the sinus node to capture the heart for one or more beats. In contrast, ectopic pacemakers with normal automaticity probably would be quiescent during relatively short, transient sinus pauses because they are overdrive-suppressed.

It is also possible that the depolarized level of membrane potential at which abnormal automaticity occurs may cause entrance block into the focus and prevent it from being overdriven by the sinus node even when impulses initiated in the focus could leave it (unidirectional block).[122] This would lead to parasystole, an example of an arrhythmia caused by a combination of an abnormality of impulse conduction and initiation. All these features of abnormal automaticity are evident in the Purkinje fibers that survive in regions of transmural myocardial infarction and cause ventricular arrhythmias during the subacute phase.[68] The firing rate of an abnormally automatic focus also might be enhanced above that of the sinus node, leading to arrhythmias in the absence of sinus node suppression or conduction block between the focus and the surrounding myocardium. The automatic rate is a direct function of the level of membrane potential: The greater the depolarization, the faster the rate.[5,55,57,123,124] Experimental studies have shown firing rates in muscle and Purkinje fibers of 150 to 200/min at membrane potentials less than -50 mV, and these rates should be sufficiently rapid to enable these pacemakers sometimes to control the rhythm of the heart. Catecholamines also increase the rate of firing caused by abnormal automaticity[125] and therefore may contribute to a shift in the pacemaker site from the sinus node to a region with abnormal automaticity. Among the clinical arrhythmias that are likely to be caused by abnormal automaticity is accelerated idioventricular rhythm after myocardial infarction (see Chap. 47).

TRIGGERED ACTIVITY

Triggered activity is a term used to describe impulse initiation in cardiac fibers that is dependent on afterdepolarizations.[126-128] Afterdepolarizations are oscillations in membrane potential that

follow the upstroke of an action potential. Two kinds of afterdepolarizations may cause triggered activity. One occurs early, i.e., during repolarization of the action potential (EADs), and the other is delayed until repolarization is complete or nearly complete (DADs). When either kind of afterdepolarization is large enough to reach the threshold potential for activation of a regenerative inward current, action potentials result that are referred to as "triggered." Therefore, a key characteristic of triggered activity, discriminating it from automaticity, is that for triggered activity to occur, at least one action potential must precede it (the trigger). Automatic rhythms can arise de novo in the absence of any prior electrical activity, such as after long periods of quiescence, whereas triggered activity cannot.[5,128] Triggered activity will cause arrhythmias when the site of impulse initiation shifts from the sinus node to the triggered focus. For this to occur, the rate of triggered impulses should be faster than the sinus rate either transiently or persistently. This may result when firing of the sinus node is slowed or inhibited, when there is block of sinus impulses, or when the rate of triggered activity is faster than normal sinus node impulse initiation. The factors causing the shift in the site of impulse initiation should be very similar to those described in the discussion of automaticity.

Delayed Afterdepolarizations and Triggered Activity

Figure 23-10 shows an example of a DAD recorded with a microelectrode in a superfused preparation of atrial muscle exposed to catecholamines. The DAD is an oscillation in membrane potential that occurs after repolarization of the action potential (indicated in the figure by the unfilled arrow). The DAD is caused by events occurring during the action potential that will be described below. Figure 23-10*A* also shows that a DAD may be preceded by an afterhyperpolarization (red arrow), in which case the membrane potential transiently becomes more negative after the action potential than it was just before it. Afterhyperpolarizations, however, do not always precede DADs. The transient nature of the DAD clearly distinguishes it from normal spontaneous diastolic (pacemaker) depolarization, during which the membrane potential declines almost monotonically until the next action potential occurs (compare Fig. 23-10*A* with Fig. 23-6). In addition to microelectrode recordings such as the one shown in Fig. 23-10*A*, DADs can be identified by using techniques for recording extracellular potentials.[129,130] A major problem that exists when this technique is used in situ to locate DADs in the heart, however, is discriminating the extracellular voltage deflections caused by afterdepolarizations from deflections that result from the motion of the heart, since movement alone can mimic DADs in extracellular recordings.[131] A second important problem is a possible difficulty in locating focal sites at which afterdepolarizations and triggered activity may be originating. Nevertheless, extracellular electrodes have been used to demonstrate what appear to be DADs occurring in the in situ heart.[132,133]

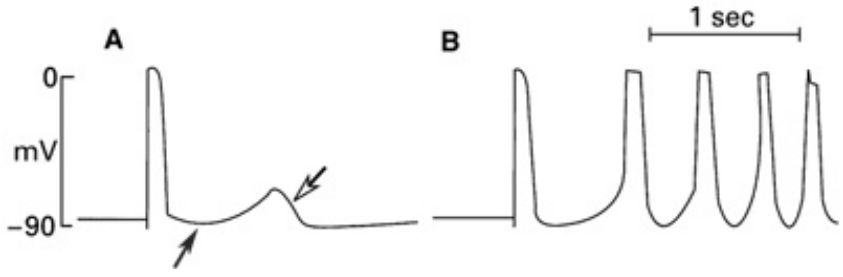

Figure 23-10: An example of a DAD (*white arrow*) recorded with a microelectrode from an atrial fiber in the canine coronary sinus. The red arrow indicates an afterhyperpolarization. *B*. The onset of triggered activity is shown. (From Wit AL, Rosen MR. After depolarizations and triggered activity: Distinction from automaticity as an arrhythmogenic mechanism. In: Fozzard HA, Haber E, Jennings RB, et al., eds. *The Heart and Cardiovascular System*. Scientific Foundations, 2d ed.

New York, Raven Press; 1991:2113. Reproduced with permission from the publisher and author.)

A triggered impulse is initiated when a DAD depolarizes the membrane potential to the threshold potential for activation of the inward current responsible for the upstroke of the action potential. Triggered impulses are shown in Fig. 23-10*B*. Afterdepolarizations do not always reach threshold, so that triggerable fibers sometimes may be stimulated at a regular rate without becoming rhythmically active, e.g., the stimulated action potential in Fig. 23-10*A*. Probably the most important influence that causes subthreshold DADs to reach threshold is a decrease in the cycle length (an increase in the rate) at which action potentials occur. Therefore, arrhythmias triggered by DADs can be expected to be initiated by either a spontaneous or a pacing-induced increase in the heart rate. A triggered action potential also is followed by an afterdepolarization that may or may not reach threshold. When it does not reach threshold, only one triggered action impulse occurs. Quite often, the first triggered action potential is followed by a short or long "train" of additional triggered action potentials, each arising from the afterdepolarization caused by the previous action potential (Fig. 23-10*B*). The merging of the rising phase of the afterdepolarization with the upstroke of the action potential during triggered activity may be smooth, and as a result, the fiber may show phase 4 depolarization that is indistinguishable from the phase 4 depolarization seen during automatic activity.

CAUSES OF DELAYED AFTERDEPOLARIZATIONS AND TRIGGERED ACTIVITY

Delayed afterdepolarizations usually occur under a variety of conditions in which there is an increase in Ca^{2+} in the myoplasm and the sarcoplasmic reticulum above normal levels (sometimes referred to as *Ca overload*). Abnormalities in the sequestration and release of Ca^{2+} by the sarcoplasmic reticulum also may contribute to their occurrence. On depolarization of the membrane during an action potential, the intracellular free Ca^{2+} normally increases, primarily by Ca^{2+} influx through the L-type Ca^{2+} channels. Initially, this rapid rate of change of intracellular Ca^{2+} triggers Ca^{2+} release from the sarcoplasmic reticulum, causing a further rise in intracellular free Ca^{2+} and contraction[134] (see Chap. 3). Repolarization then induces synchronous Ca^{2+} uptake by the sarcoplasmic reticulum in the cell and relaxation. If intracellular Ca^{2+} is very high or if catecholamines or cyclic adenosine monophosphate (AMP) is present, both of which enhance Ca^{2+} uptake by the sarcoplasmic reticulum, the Ca^{2+} in the sarcoplasmic reticulum may rise during repolarization to a critical level, at which time a secondary spontaneous release of Ca^{2+} from the sarcoplasmic reticulum occurs after the action potential and relaxation of contraction.[134] This secondary release of Ca^{2+} generates an aftercontraction as well as the transient inward (TI) current and the afterdepolarization. The TI current is an oscillatory membrane current that is distinct from the pacemaker currents.[135-142] After one or several afterdepolarizations, myoplasmic Ca^{2+} may decrease because Na^+-Ca^{2+} exchange extrudes Ca^{2+} from the cell, and the membrane potential stops oscillating.

The exact mechanism by which the secondary rise in myoplasmic Ca^{2+} after repolarization causes the TI current is unclear. Two possibilities have been considered. The first is that the Ca^{2+} released from the sarcoplasmic reticulum after repolarization acts on the sarcolemma to increase its conductance to ions (mainly Na^+) that flow into the cell down a concentration gradient through membrane channels. The second mechanism proposed for the origin of the TI current is that the rise in Ca^{2+} causes the TI current through an electrogenic (rheogenic) exchange of Ca^{2+} for Na^+. According to this hypothesis, the transient rise in myoplasmic Ca^{2+} released from the sarcoplasmic reticulum after the action potential is expected to result in "transport" of Ca^{2+} out of the cell across the sarcolemma by the Na^+-Ca^{2+} exchanger. Such an efflux is coupled to an Na^+ influx. If more than two Na^+ ions are exchanged for each Ca^{2+} ion, a net inward current occurs.[143-145]

The most widely recognized cause of DAD-dependent triggered activity is digitalis

toxicity.[116,117,145-151] Afterdepolarizations caused by digitalis sometimes may reach threshold to cause triggered action potentials, particularly if the rate of stimulation is sufficiently rapid. Ventricular arrhythmias (repetitive responses) caused by digitalis in the heart in situ also can be initiated by pacing at rapid rates.[152] As toxicity progresses, the duration of the trains of repetitive responses induced by pacing increases.[153-155] It is assumed that these arrhythmias are caused by DADs. In addition, spontaneously occurring accelerated ventricular rhythms and ventricular tachycardia that occur during digitalis toxicity are likely to be caused by DADs.

Cardiac glycosides cause DADs by inhibiting the Na^+-K^+ pump. In toxic amounts, this effect results in a measurable increase in intracellular Na^+.[156,157] An increase in intracellular Na^+ in turn causes an increase in intracellular Ca^{2+}.[158] When intracellular Na^+ is increased, the concentration-dependent driving force for Na^+ across the sarcolemma is decreased, and this in turn diminishes Ca^{2+} extrusion from the cell by Na^+-Ca^{2+} exchange. Hence, there is a net inward Ca^{2+} movement.[44,159-160]

Catecholamines are probably the next most widely recognized cause of DADs. Delayed afterdepolarizations and triggered activity caused by catecholamines have been recorded with microelectrodes in atrial fibers of the mitral valve,[161] atrial fibers lining the coronary sinus,[33] atrial fibers in the inferior right atrium,[31] and atrial fibers from hearts with cardiomyopathy.[162] The DADs in Fig. 23-10 were caused by catecholamines in atrial fibers of the canine coronary sinus. Infusion of catecholamines through a catheter into the coronary sinus in the dog causes atrial tachycardia that has all the characteristics of triggered activity;[163] therefore, some naturally occurring atrial tachycardias caused by triggered activity probably are induced by the sympathetic nervous system. Ventricular muscle and Purkinje fibers also can develop DADs in the presence of catecholamines.[164,165] Sympathetic stimulation therefore may also cause triggered ventricular arrhythmias, possibly some of the ventricular arrhythmias that accompany exercise[166] and some ventricular arrhythmias that occur during ischemia and infarction.[167,168]

Catecholamines may cause DADs by increasing the slow inward L-type Ca^{2+} current through stimulation of beta-adrenergic receptors.[169,170] The net effect is an increase in transsarcolemmal Ca^{2+} entry into cardiac cells. In addition to increasing the inward Ca^{2+} current, catecholamines enhance the uptake of Ca^{2+} by the sarcoplasmic reticulum, leading to increased Ca^{2+} stored in the sarcoplasmic reticulum and the subsequent release of an increased amount of Ca^{2+} from the sarcoplasmic reticulum during contraction.[134,171,172] The increased Ca^{2+} in the sarcoplasmic reticulum induced by catecholamines also may lead to the occurrence of DADs. Delayed afterdepolarizations and triggered activity also may occur in the absence of pharmacologic agents, catecholamines, or an increase in extracellular Ca^{2+}. Triggerable fibers have been found in the upper pectinate muscles bordering the crista terminalis in the rabbit heart, branches of the sinoatrial ring bundle or transitional fibers between the ring bundle and ordinary pectinate muscle,[173] apparently normal fibers in human atrial myocardium,[174] human atrial fibers with very low membrane potentials (below -60 mV) and slow response action potentials,[70,71,174] rat ventricular muscle that is hypertrophic secondary to renovascular hypertension,[175] and ventricular myocardium from diabetic rats.[176]

PROPERTIES OF DELAYED AFTERDEPOLARIZATIONS

The TI current that causes DADs is maximal at around -60 mV and diminishes at more positive and more negative membrane potentials.[138,140,177] As a result of the dependence of the TI current on the level of membrane potential, the amplitude of DADs and therefore the possibility of triggered activity are influenced by the level of membrane potential at which the action potentials occur. In the digitalis-toxic Purkinje system, there is a "window" of membrane voltage for maximum diastolic potential, which is approximately between -75 and -80 mV, at which the

amplitude of DADs tend to be greatest.[178,179] When DADs occur at the membrane potentials that favor a maximum amplitude, any intervention that hyperpolarizes or depolarizes the membrane tends to reduce their magnitude and suppress any rhythms the afterdepolarizations might induce. Similarly, when there are no DADs in the presence of digitalis and the membrane potential is at a voltage less than or greater than the window, interventions that bring membrane potential into this voltage range often induce DADs. A similar dependence on membrane potential has been shown for DADs in atrial fibers of the coronary sinus[180] and in Purkinje fibers from infarcts.[181,182]

Delayed afterdepolarizations are influenced by the action potential duration, with longer action potential durations favoring the occurrence of DADs.[180] When the action potential duration is longer, more Ca^{2+} is able to enter the cell. Drugs such as quinidine, which prolong action potential duration, may increase DAD amplitude,[183] while drugs such as lidocaine, which shorten action potential duration, may decrease DAD amplitude.[184] The amplitude of DADs is dependent on the number of action potentials that precede them; i.e., after a period of quiescence, the initiation of a single action potential may be followed by either no afterdepolarization or only a small one. With continued stimulation, the afterdepolarizations increase in amplitude, and triggered activity eventually may occur.[33,117,147,161,185] The amplitude of DADs and their coupling interval to the previous action potentials also are dependent on the cycle length at which action potentials are occurring, and triggered activity can be induced by a critical decrease in the drive cycle length.[117,147,161,168,173,175,176] This is illustrated by the effects of the stimulus cycle length on the amplitude of DADs recorded from an atrial fiber in the canine coronary sinus (Fig. 23-11). The transmembrane potentials at the left were recorded when the stimulus cycle length was 2000 ms; the afterdepolarization amplitude after the last stimulated impulse is 5 mV. In the center, the stimulus cycle length was 1500 ms, and the afterdepolarization amplitude after the last stimulated impulse is 15 mV. At the right, at a stimulus cycle length of 1200 ms, afterdepolarization amplitude reached 20 mV after the third stimulated action potential before triggered activity was initiated. Digitalis-induced DADs occur either singly or as two or more "damped" oscillations after the action potential.[117,147] When two or more afterdepolarizations are present, their relation to the drive cycle length is complex. As drive cycle length decreases, the amplitude of the first afterdepolarization increases, reaching a peak at a cycle length of about 500 ms, and triggered activity may occur. If it does not, at shorter drive cycle lengths the magnitude of this first afterdepolarization decreases. The second DAD, however, continues to increase in magnitude as drive cycle length shortens further and eventually may reach threshold and induce triggered activity. A decrease in the length of even a single drive cycle (i.e., a premature impulse) also results in an increase in the amplitude of the DAD that follows the premature cycle.

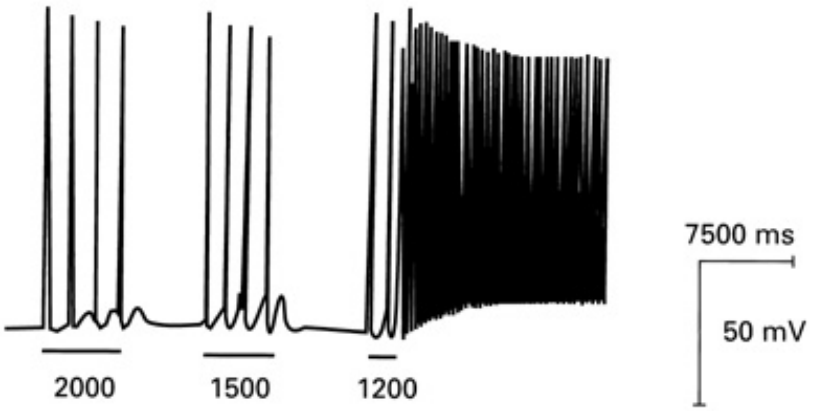

Figure 23-11: Effects of stimulation rate on DADs and triggered activity. Transmembrane action potentials were recorded from an atrial fiber in the canine coronary sinus superfused with Tyrode's solution containing norepinephrine. The stimulus cycle lengths and the periods of stimulation are

indicated by the black bars. Sustained triggered activity occurred after stimulation at a cycle length of 1200 ms. The rate of triggered activity is so rapid that the individual action potentials cannot be seen at the slow oscilloscopic sweep speed. (From Wit AL, Cranefield PF. Triggered and automatic activity in the canine coronary sinus. *Circ Res* 1977; 41:435. Reproduced with permission from the publisher and author.)

The premature coupling interval at which triggered activity occurs is also dependent on the basic drive cycle length. As the basic drive cycle length decreases, the premature coupling interval needed to induce triggered activity increases.[186] Decreasing the drive cycle length, in addition to increasing amplitude, tends to decrease the coupling interval of DADs to the action potential upstroke or terminal phase of repolarization by increasing the rate of depolarization of the afterdepolarization.[33,117,147,173] As a result, there is a direct relation between the drive cycle length at which triggered impulses are initiated and the coupling interval between the first triggered impulse and the last stimulated impulse that induced them; i.e., as the drive cycle length is reduced, the first triggered impulse occurs earlier with respect to the last driven action potential. This characteristic property forms the basis for one of the indirect ways in which triggered activity induced by a decrease in the drive cycle length in the whole heart sometimes is distinguishable from reentrant activity induced by a decrease in the drive cycle length, since the relationship for reentrant impulses initiated by rapid stimulation is often the opposite; i.e., as drive cycle length is reduced, the first reentrant impulse occurs later with respect to the last driven action potential because of rate-dependent conduction slowing in the reentrant pathway (described in more detail later in this chapter). The increased time during which the membrane is in the depolarized state at shorter stimulation cycle lengths or after premature impulses increases Ca^{2+} in the myoplasm and the sarcoplasmic reticulum, thus increasing the TI current responsible for the increased afterdepolarization amplitude and causing the current to reach its maximum amplitude more rapidly, decreasing the coupling interval of triggered impulses. The repetitive depolarizations can increase intracellular Ca^{2+} because of repeated activation of the inward Ca^{2+} current that flows through L-type Ca^{2+} channels.

This chapter has discussed how triggered activity caused by DADs is initiated by stimulation. These characteristics may be of use in identifying triggered activity in the in situ heart (described below). Also of importance in identifying triggered arrhythmias in situ are the effects of electrical stimulation on established triggered activity. In general, triggered activity is influenced markedly by overdrive pacing (i.e., pacing at a rate faster than the rate of the triggered rhythm). The effects of overdrive pacing on triggered activity have been studied only in several experimental situations: in atrial fibers in which triggered activity is caused by catecholamines and in Purkinje fibers in which triggered activity is caused by digitalis or myocardial infarction. These effects are dependent on both the rate and the duration of overdrive pacing.[187,188] When overdrive pacing is done for a critical duration of time and at a critical rate during a catecholamine-dependent triggered rhythm, the maximum diastolic potential after the overdrive pacing increases to levels more negative than before; during the increase in membrane potential, the rate of triggered activity slows until the triggered rhythm stops. When triggered activity stops after a period of overdrive pacing at a moderate rate, some 10 to 50 impulses may occur after termination of the overdrive pacing before termination of the triggered activity occurs. The increase in maximum diastolic potential and the slowing and termination of triggered activity after a period of overdrive pacing are caused by enhanced activity of the electrogenic Na^+ pump.[187] During a period of overdrive pacing, there is a transient increase in intracellular Na^+ because the increased number of action potentials stimulates the pump to generate increased outward current.[73,189]

In digitalis-toxic Purkinje fibers, overdrive pacing also can terminate triggered activity, and this effect is dependent on the overdrive pacing cycle length but not on the overdrive pacing duration.[186,190] Termination occurs more frequently at more rapid overdrive pacing rates and may not be immediate; i.e., several triggered impulses may continue to occur after stimulation is stopped before triggered activity stops.[186] When overdrive pacing is not rapid enough to terminate

the triggered rhythm, it can cause overdrive acceleration. Termination by overdrive pacing is not accompanied by hyperpolarization of the maximum diastolic potential and probably is not caused by increased Na^+-K^+ pump activity, since the pump is partially inhibited by digitalis. The exact mechanism for termination has not been elucidated. Premature stimuli also may terminate triggered rhythms, as shown in digitalis-toxic Purkinje fibers,[186] Purkinje fibers in myocardial infarcts,[191] and atrial fibers exposed to catecholamines,[161,188] although termination is much less common than it is by overdrive pacing.[190] It has not been demonstrated that the premature impulse must occur at a critical point in the cycle length of triggered activity.

Early Afterdepolarizations and Triggered Activity

Early afterdepolarizations are manifest as a sudden change in the time course of repolarization of an action potential such that the membrane potential does not follow the trajectory characteristic of normal repolarization but suddenly shifts in a depolarizing direction. This is illustrated in the example of an EAD recorded with an intracellular microelectrode in a superfused Purkinje fiber shown in Fig. 23-12. The normal time course of repolarization of the action potential is shown in panel *A*. The arrow in panel *B* shows the deviation in membrane potential that constitutes the EAD. Early afterdepolarizations may appear at the plateau level of membrane potential, which is usually more positive than -60 mV, as in Fig. 23-12*B*, or they may appear later, during phase 3 of repolarization. In Fig. 23-13*B*, trace 1 shows the normal time course of repolarization of a Purkinje fiber action potential, while trace 2 shows a deviation from this normal time course late during phase 3, which is the EAD. Early afterdepolarizations occurring late in repolarization occur at membrane potentials more negative than -60 mV in atrial, ventricular, or Purkinje cells that have normal resting potentials. Normally, a net outward membrane current shifts the membrane potential progressively in a negative direction during repolarization of the action potential. An EAD occurs when for some reason the current-voltage relation is altered to cause outward current during repolarization to approach or attain 0, at least transiently. Such a shift can be caused by any factors that either decrease outward current, mostly carried by K^+, or increase inward current, carried by Na^+ or Ca^{2+}. If the change in the current-voltage relation results in a region of net inward current during the plateau range of membrane potentials,[192] it can lead to a secondary depolarization (a triggered action potential) during the plateau or phase 3 by activating a regenerative inward current.

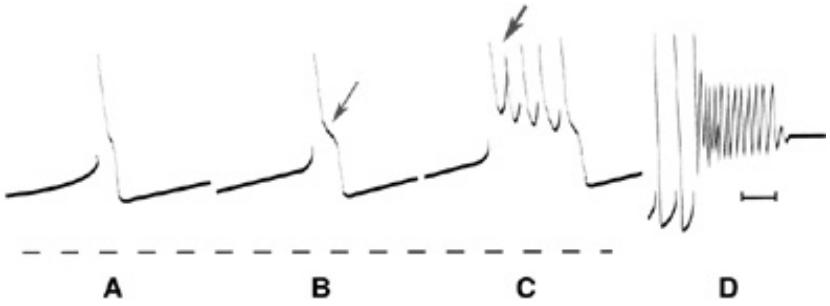

Figure 23-12: Early afterdepolarizations and triggered activity during repolarization in a Purkinje fiber. *A*. Transmembrane potential with normal repolarization of a spontaneously active Purkinje fiber. *B*. Early afterdepolarization (*arrow*) occurring during the plateau phase of the action potential. *C*. Triggered action potentials (*arrow*) during the plateau. *D*. Arrest of repolarization at a low level of membrane potential after a period of triggered activity. (From Cranefield PF. Action potentials, afterpotentials and arrhythmias. *Circ Res* 1977; 41:415-425. Reproduced with permission from the publisher and author.)

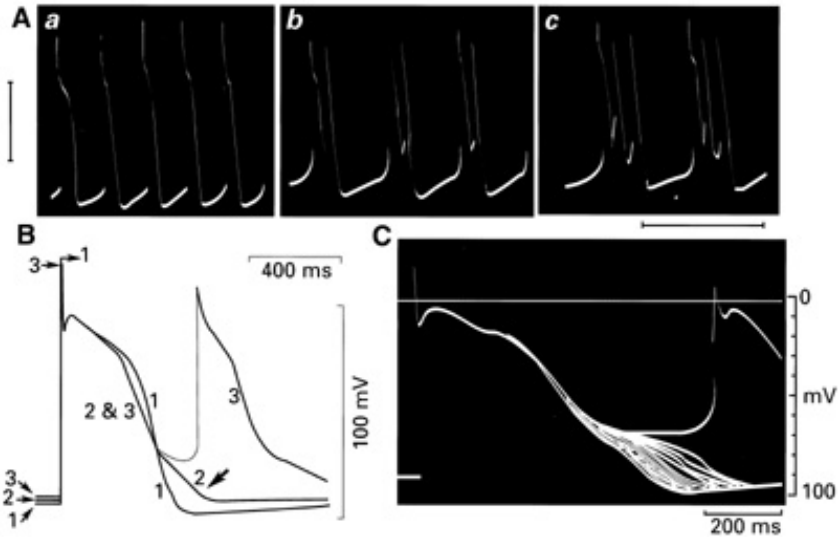

Figure 23-13: Early afterdepolarizations and triggered activity during late repolarization in a Purkinje fiber. *A*. Three panels are shown: (*a*) a spontaneously firing Purkinje fiber with prominent phase 4 depolarization, (*b*) occurrence of a single triggered action potential caused by an EAD, occurring during repolarization of each spontaneous action potential, (*c*) two triggered action potentials caused by an EAD occurring during repolarization of each spontaneous action potential. *B*. Development of an EAD and a triggered action potential in three superimposed traces: (1) normal Purkinje fiber action potential, (2) alteration in the time course of late repolarization leading to the occurrence of an EAD (*arrow*), (3) further alteration in late repolarization, leading to a triggered action potential. *C*. Superimposed traces recorded from a Purkinje fiber in the course of developing EADs and a triggered action potential. (From Coulombe A et al. Role of the "Na window" current and other ionic currents in triggering early after-depolarizations and re-exitation in Purkinje fibers. In: Zipes DP, Jalife J, ed. *Cardiac Electrophysiology and Arrhythmias*. New York: Grune & Stratton; 1985:43. Reproduced with permission from the publisher and author.)

Under certain conditions, EADs can lead to "second upstrokes"[5,127] or action potentials; when an EAD is large enough, the decrease in membrane potential leads to an increase in net inward (depolarizing) current, and a second action potential occurs before complete repolarization of the first, as shown in panel *C* (arrow) of Fig. 23-12 and trace 3 in panel *B* of Fig. 23-13. The second action potential occurring during repolarization is triggered in the sense that it is evoked by an EAD, which in turn is induced by the preceding action potential. The second action potential also may be followed by other action potentials, all occurring at the low level of membrane potential characteristic of the plateau (Fig. 23-12*C*) or at the higher level of membrane potential of later phase 3 (Fig. 23-13, panels *Ab*, *Ac*, and *B*). Without the initiating action potential, there could be no triggered action potentials. The sustained rhythmic activity may continue for a variable number of impulses and terminates when repolarization of the initiating action potential returns membrane potential to a high level (Fig. 23-12*C*). As repolarization occurs, the rate of the triggered rhythm slows because the rate is dependent on the level of membrane potential in the same way that abnormal automaticity is. Sometimes repolarization to the high level of membrane potential may not occur, and membrane potential may remain at the plateau level or at a level intermediate between the plateau level and the resting potential[62] (Fig. 23-12*D*). The sustained rhythmic activity then may continue at the reduced level of membrane potential and assumes the characteristics of abnormal automaticity.[127]

The level of membrane potential at which the triggered action potentials occur determines both the rate of triggered activity and whether the triggered action potentials can propagate and excite adjacent normal regions.[193] At the more positive membrane potentials of the plateau, the rate of

triggered activity is more rapid than it is late during phase 3. Triggered action potentials occurring at the plateau level have slow upstrokes; therefore, conduction of these action potentials sometimes may block,[194,195] while the faster upstrokes of triggered action potentials occurring later during phase 3 enable them to propagate more easily. The ionic current responsible for the upstrokes of the action potentials during triggered activity caused by EADs is determined by the level of membrane potential at which the action potentials occur. Triggered action potentials occurring during the plateau phase and early during phase 3, at a time when most fast Na^+ channels are still inactivated, most likely have upstrokes caused by the inward L-type Ca^{2+} current.[5,196] At higher membrane potentials during late phase 3 of repolarization, where there is partial reactivation of the Na^+ channels, the upstrokes are caused by the fast inward Na^+ current. Current flowing through both L-type Ca^{2+} channels and partially reactivated fast Na^+ channels may be involved over intermediate ranges of membrane potential.

CAUSES OF EARLY AFTERDEPOLARIZATIONS AND TRIGGERED ACTIVITY

Early afterdepolarizations and triggered activity have been produced in experimental studies under a variety of conditions, some of which would never be expected to be associated with naturally occurring arrhythmias in the in situ heart. Most of these conditions somehow delay repolarization of the action potential by increasing inward current or decreasing outward current during the plateau and repolarization phases. Most often, EADs occur more readily in Purkinje fibers than in ventricular or atrial muscle, although EADs can readily occur in the so-called M cells, which are ventricular muscle cells with a prominent plateau phase.[197] Early afterdepolarizations may occur when the rate of stimulation is markedly slowed, reducing the outward current generated by the Na^+-K^+ pump, especially when K^+ in the extracellular environment is lower than normal, also reducing outward current.[128]

At a "physiologic range" of cycle lengths (a range that encompasses the normal sinus rhythm of the adult human heart: 1000 to 700 ms), EADs have rarely occurred in studies of isolated preparations of cardiac fibers. As cycle length is increased and repolarization is prolonged, EADs and triggered activity are more likely to occur.[198] The result is a bradycardia-induced tachycardia during which there may be very slow conduction. Another important characteristic is that the longer the basic drive cycle length, the greater the number of impulses that are triggered by EADs.[198] Once EADs have achieved a steady-state magnitude at a constant drive cycle length, any event that shortens drive cycle length tends to reduce their amplitude.[198] Hence, the initiation of a single premature depolarization, which is associated with an acceleration of repolarization, will reduce the magnitude of the EADs that accompany the premature action potential; as a result, triggered activity is not expected to follow premature stimulation. Polymorphic ventricular tachycardias that sometimes resemble torsades de pointes have been induced in dogs by the infusion of cesium, which blocks i_{K_i} to cause EADs.[199] Occurrence of tachycardia is preceded by QT-interval prolongation, a consequence of delayed repolarization, as is characteristically seen in patients with torsades de pointes.[200] The initial beat of the tachycardia caused by cesium often occurs during repolarization, i.e., during the T wave.

Early depolarizations and triggered activity have been seen in monophasic action potentials recorded from the ventricles in dogs with cesium-induced ventricular tachycardia.[201,202] Because the experimental arrhythmias caused by agents such as cesium, which are known to induce EADs, resemble torsades de pointes, it has been proposed that clinically occurring torsades de pointes sometimes may be caused by EADs. Other agents that can cause EADs and triggered activity are used therapeutically, and therefore, arrhythmias associated with their use may result from triggered activity. Antiarrhythmic drugs that prolong the duration of the action potential of Purkinje fibers or ventricular muscle (e.g., sotalol,[203,204] *N*-acetylprocainamide,[205] and quinidine[206,207]) can cause EADs and triggered activity when administered to isolated preparations, particularly when the rate of stimulation is low and the extracellular K^+

concentration is lower than normal, e.g., <4 m*M*/L.

The mechanisms by which these effects are exerted have been studied in detail for only some of these drugs. Both the d (no beta receptor blockade) and the I (beta-blocking) forms of sotalol prolong the action potential duration by inhibiting the repolarizing K current, i_{K_i}.[204] Similarly, the prolongation of the action potential by quinidine, which may lead to EADs, is related to the blocking effect of quinidine on the outward membrane repolarizing K^+ current, not to that drug's well-known blocking effect on the Na^+ channel.[208] It is known that quinidine may cause ventricular tachyarrhythmias in patients undergoing antiarrhythmic therapy with that drug. Interestingly, the arrhythmias may occur at low plasma quinidine concentrations that do not cause widening of the QRS complex in the ECG,[209] consistent with observations in superfused Purkinje fibers that afterdepolarizations caused by quinidine occur without depression of the action potential upstroke. Hypokalemia and bradycardia both predispose to the occurrence of quinidine-induced torsades de pointes,[200,210] and both have been shown to potentiate the induction of EADs in vitro by quinidine.[206,207] Torsades de pointes also has been associated with the administration to patients of *N*-acetylprocainamide[211] and sotalol.[212] Magnesium has been shown to abolish EAD-dependent triggered activity in experimental studies.[207,213] Magnesium also has been shown to provide effective therapy when used to treat some clinical cases of drug-induced torsades de pointes,[214,215] providing further evidence that this clinical arrhythmia may be a manifestation of triggered activity (see Chap. 27).

Arrhythmias Caused by Reentry

INTRODUCTION

As was discussed previously, the excitation wavefront originating in the sinus node normally activates the cardiac tissues in an orderly sequence and then dies out. Thus, during normal sinus rhythm, each heartbeat is generated by a new pacemaker impulse in the sinus node. There are, however, arrhythmias in which, in the presence of a requisite set of circumstances, an excitation wavefront does not die out but rather can propagate continuously and thus continue to excite the heart because it always encounters excitable tissue. Such an arrhythmia is called reentrant.

REQUISITES FOR REENTRANT EXCITATION

Perhaps the easiest way to illustrate this is to discuss again, but in more detail, the earliest description of reentrant excitation by Mayer[3] in 1906 in the excitable subumbrella ring of tissue of the scyphomedusae (jellyfish), as is shown in Fig. 23-4. This example well illustrates the requisites for reentrant excitation. First, a substrate must be present that will support reentrant excitation, in this case the subumbrella ring of excitable tissue of the jellyfish. Second, the excitation wavefront propagating in this substrate must encounter unidirectional block (Fig. 23-4*B*). Unidirectional block must be present or the excitation wavefronts traveling around the ring will collide and extinguish each other (Fig. 23-4*A*). If the site of unidirectional block instead manifests bidirectional block, reentrant excitation will not occur because the circulating excitation wavefront will be unable to propagate through the area of block to reexcite the tissue that initially was excited. Third, there must be a central area of block around which the reentrant excitation wavefront can circulate. In this example, it is the hole in the center of the ring that clearly is inexcitable. Without a central area of block, the excitation wavefront will not necessarily be conducted around the ring of excitable tissue. Rather, it could take a shortcut, permitting the circulating excitation wavefront to arrive quite early at the site where it originated. If it arrives sufficiently early, the latter tissue will still be refractory, and reentrant excitation will not be possible. But even with the presence of a central area of block and without the presence of a shortcut, the circulating wavefront will manifest reentrant excitation only if the tissue it initially activated has had sufficient time to recover its excitability by the time the reentrant wavefront

returns. Thus, conduction of the circulating excitation wavefront in the rest of the circuit must take long enough for this to happen, and there must always be a gap of excitable tissue (either fully or partially excitable) ahead of the circulating wavefront (the so-called excitable gap). In the case of the experiment by Mayer on the subumbrella ring of excitable tissue of the jellyfish, conduction velocity was constant and the length of the ring was long enough that conduction time around the ring was longer than the effective refractory period of the excitable tissue constituting the ring, permitting reentry. If the length of the ring had been critically shorter or if the conduction velocity had been critically faster, the circulating excitation wavefront would have arrived at the site of initial excitation before sufficient recovery of excitability had occurred, preventing reexcitation.

From these sorts of observations grew the concept of the wavelength of the circulating impulse.[4,216,217] The wavelength is the product of the conduction velocity of the circulating excitation wavefront and the effective refractory period of the tissue in which the excitation wavefront is propagating. It quantifies how far the impulse travels relative to the duration of the refractory period. Thus, the wavelength of the reentrant excitation wavefront must be shorter than the length of the pathway of the potential reentrant circuit for reentrant excitation to occur; i.e., the impulse must travel a distance during the refractory period that is less than the complete reentrant path length to give myocardium ahead of it sufficient time to recover excitability.

For virtually all clinically important reentrant arrhythmias resulting from ordered reentry, however, in the presence of uniform, normal conduction velocity along the reentrant pathway, the wavelength would be too long to permit reentrant excitation. Thus, virtually all these arrhythmias must have, and in fact do have, one or more areas of slow conduction as a part of the reentrant circuit. The associated changes in conduction velocity (as well as associated changes in refractory periods) actually cause the wavelength to change in different parts of the circuit. However, the presence of one or more areas of slow conduction permits the average wavelength of reentrant activation to be shorter than the path length.

The fact that the reentrant circuit of virtually all clinically important reentrant arrhythmias has one or more areas of slow conduction serves to emphasize the fact that the electrophysiologic properties of the cardiac tissue making up the reentrant circuit are not uniform. In fact, there may be, and usually are, variations of conduction velocity and refractoriness along the course of the reentrant circuit. An additional requisite for random reentry is the necessity of a critical mass of tissue to sustain the one or usually more simultaneously circulating reentrant excitation wavefronts.[218] Thus, it is essentially not possible to achieve sustained fibrillation of ventricles of very small normal mammalian hearts and equally difficult to achieve sustained fibrillation of the normal atria of humans or smaller mammals.

Finally, another prerequisite for reentrant excitation to occur is often (but not always) the presence of an initiating trigger. The trigger, usually the occurrence of one or more premature beats, frequently is required because it elicits or brings to a critical state one or more of the conditions necessary to achieve reentrant excitation. Thus, a premature impulse initiating reentry may arrive at one site in the potential reentrant circuit sufficiently early that it encounters unidirectional block because that tissue has had insufficient time to recover excitability after excitation by the prior beat (Fig. 23-4). Furthermore, in the other limb of the potential reentrant circuit, the premature arrival of the excitation wavefront either causes slow conduction or results in further slowing of conduction of the excitation wavefront through an area of already slow conduction. The resulting increase in conduction time around this limb of the potential reentrant circuit serves to allow the region of unidirectional block in the tissue in the other limb activated initially by the premature beat to recover excitability. Thus, when the circulating excitation wavefront of the premature beat arrives at these tissue sites, the excitation wavefront can reexcite the tissue, thus manifesting reentrant excitation (Fig. 23-4).

It should be noted that the mechanism causing the premature beat may be different from the

reentrant mechanism causing the tachycardia. Thus, the premature beat may be caused by automaticity or triggered activity. An example of the latter may be torsade de pointes, in which the initiating beat (or beats) is the result of triggered activity caused by early afterdepolarization, but the remainder of the beats in this rhythm (it is frequently nonsustained) are now thought to be due to reentry.[219] Another example may occur during cardiac catheterization, in which the premature beat may be due to the catheter forcefully hitting the heart wall, i.e., a mechanical cause. However, the trigger to initiate reentrant excitation need not be a premature beat. The trigger to initiate reentrant excitation may be the normal sinus beat. One example is the rhythm known as permanent nonparoxysmal AV junctional reentrant tachycardia.[220,221] In this example, the potential reentrant circuit contains an area of permanent unidirectional block in an antegrade direction. Moreover, the potential reentrant circuit also has a relatively stable area of very slow conduction, causing the wavelength of the propagating excitation wavefront to be shorter than the path length of the potential reentrant circuit. In this circumstance, the normal sinus beat propagates around the reentrant circuit with sufficient delay that when it arrives in a retrograde direction at the area of permanent antegrade unidirectional block, the tissue at that site has recovered excitability. Furthermore, the conduction time around the reentrant circuit is such that the excitation wavefront continually encounters excitable tissue in the direction in which it is propagating, resulting in continuous reentrant excitation and an incessant tachycardia. Another example where a premature beat is not necessary is reentrant premature ventricular beats, as in ventricular bigeminy (see Chap. 24).

COMPONENTS OF THE REENTRANT CIRCUIT

The Substrate

The cardiac tissue that constitutes the substrate for reentrant excitation can be located almost anywhere in the heart. Furthermore, the reentrant circuit may be a variety of sizes and shapes and may include a number of different kinds of myocardial cells, e.g., atrial, ventricular, nodal, and Purkinje. The reentrant circuit may be an anatomic structure such as a loop of fiber bundles in the Purkinje system.[222] The reentrant circuit may be a functionally rather than an anatomically defined pathway, with its existence, size, and shape determined by the electrophysiologic properties of cardiac tissues in which the reentrant wavefront circulates, as has been shown in some patients with atypical atrial flutter.[223,224] Or it may be an anatomic-functional combination, as has been suggested for some intraatrial reentrant rhythms, such as atrial flutter.[224]

The Area(s) of Slow Conduction

As has been discussed, a condition necessary for reentry is that the impulse be delayed sufficiently in the alternative pathway(s) to allow elements proximal to the site of unidirectional block to recover excitability. If reentry is to succeed, the impulse traveling around the reentrant circuit in one direction as a result of the unidirectional block must not return to this site of block before it and regions around it recover excitability. In the presence of normal conduction, sufficient time to allow recovery of excitability may occur if the alternative pathway is sufficiently long. Reentry is facilitated when conduction in all or a part of the alternative pathway is slow, since long pathways that are often not present in the heart are then not necessary. The area(s) of slow conduction may be an anatomic structure normally expected to manifest slow conduction, such as the AV node. Thus, the AV node is the area of slow conduction in AV reentrant tachycardia (a reentrant tachycardia in which the circuit involves the atria, the AV node, the His-Purkinje system, the ventricles, and an accessory AV connection). The area of slow conduction may be in cardiac tissue that normally does not manifest slow conduction. Such an area is not present during sinus rhythm (in contrast to the AV node) but is functionally present during the tachycardia. These areas may develop as a result of premature excitation or may evolve during a rapid transitional rhythm as occurs during atrial flutter.[224,225] An example of a functionally determined area of slow conduction is found in the posterior-inferior right atrium during atrial flutter in patients[226] or in

the free wall of the right atrium of the canine sterile pericarditis mode of atrial flutter.[224] Yet another example may be found in tissue that has been damaged, as after a myocardial infarct. Such tissue normally would not manifest slow conduction but after the injury may become an area of slow conduction even during sinus rhythm.[227] Slow conduction can be a consequence of active membrane properties determining the characteristics of inward currents depolarizing the membrane during the action potential, or it can be a consequence of passive properties governing the flow of current between cardiac cells.

DEPRESSION OF RESTING MEMBRANE POTENTIAL

An important feature of the transmembrane action potential of atrial, ventricular, and Purkinje fibers that governs the speed of propagation is the magnitude of the inward Na^+ current flowing through the fast Na^+ channels in the sarcolemma during the upstroke. The magnitude of this current flow is reflected in the rate at which the cell depolarizes ($V(r)_{max}$ of phase 0)[228] and the overshoot of the upstroke (the positive level of depolarization). The depolarization phase or upstroke of the action potential results from the opening of specific membrane channels (fast Na^+ channels) through which Na^+ ions rapidly pass from the extracellular fluid into the cell.

During conduction of the impulse, the inward transmembrane Na^+ current flowing during the depolarization phase (phase 0) of the action potential results in the flow of axial current along the cardiac fiber through the cytoplasm and the gap junctions of the intercalated disks that connect the cardiac cells. The current flows out of the cells through the membrane ahead as resistive and capacitive current. The conduction velocity depends on both how much capacitive current flows out of the cell at unexcited sites ahead of the propagating wavefront and the distance at which the capacitive current can bring membrane potential to threshold. One important factor that influences the amount of current flowing through the sarcoplasm of a muscle fiber (axial current), and therefore capacitive current, is the amount of fast inward current causing the propagating action potential. A reduction in this inward current, leading to a reduction in the rate or amplitude of depolarization during phase 0, may decrease axial current flow, slow conduction, and lead to conduction block. Such a reduction may result from inactivation of Na^+ channels. The intensity of the inward Na^+ current depends on the fraction of Na^+ channels that open when the cell is excited and the size of the Na^+ electrochemical potential gradient (relative concentration of Na^+ in the extracellular space compared with Na^+ concentration inside the cell[229]). The fraction of Na^+ channels available for opening is determined largely by the level of membrane potential at which an action potential is initiated.[229] The Na^+ channels are inactivated either after the upstroke of an action potential or if the steady-state resting membrane potential is reduced. Immediately after the upstroke, cardiac fibers are inexcitable because of Na^+ channel inactivation at the positive level of membrane potential.

During repolarization, progressive removal of inactivation allows increasingly large Na^+ currents to flow through the still partially inactivated Na^+ channels when the cells are excited. The inward Na^+ current, amplitude, and rate of rise of premature action potentials initiated during this relative refractory period are reduced because the Na^+ channels are only partly reactivated.[229] In Fig. 23-14*B*, premature action potentials *a*, *b*, and *c* have low amplitudes and slow rates of depolarization because they were initiated before full repolarization of the action potential. Hence, the conduction velocity of these premature action potentials is low. Premature activation of the heart therefore may induce reentry because premature impulses conduct slowly in regions of the heart where the cardiac fibers are not completely repolarized (where Na^+ channels are to some extent still inactivated).

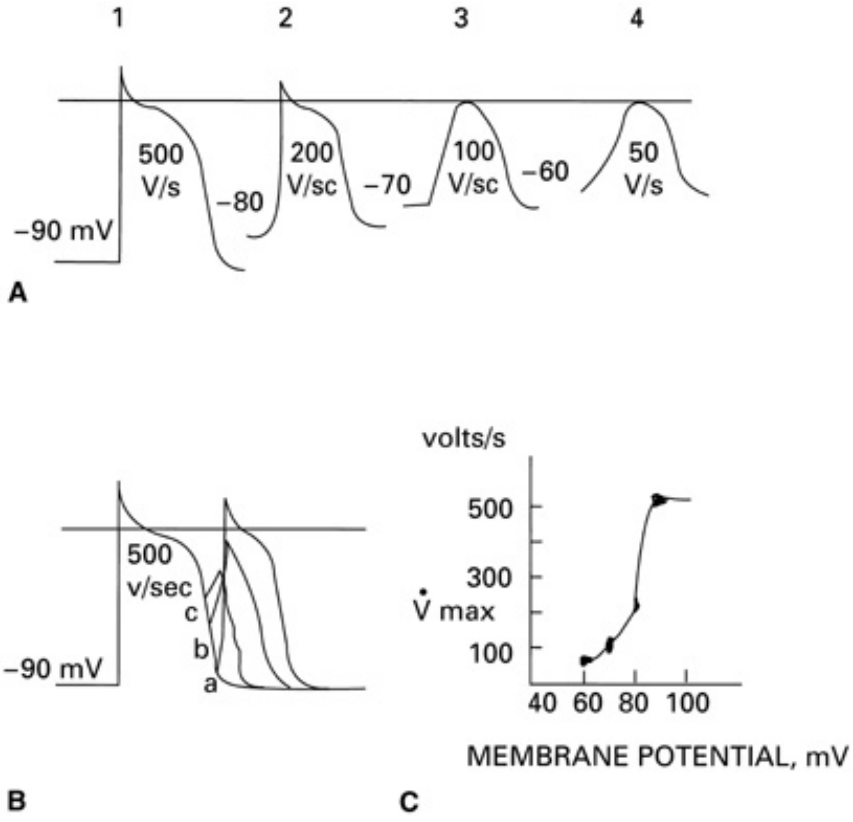

Figure 23-14: Diagrammatic representation of the relation between the level of membrane potential at the onset of phase 0 and the maximum rate of depolarization during phase 0 (dv/dt_{max} or $V(r)_{max}$). *A*. Fiber has been depolarized by progressively increasing the extracellular potassium concentration. As resting membrane potential decreases, the rate of depolarization of the action potential upstroke decreases. *B*. Fiber is activated by premature stimuli that occur at different times during phase 3 (*a*, *b*, and *c*). The premature action potentials have reduced rates of depolarization because they arise at reduced membrane potentials. *C*. For both types of experiments, the general relationship between $V(r)_{max}$ and membrane potential is shown. As the membrane potential becomes smaller (less negative), the rate of phase 0 depolarization ($V(r)_{max}$) decreases and therefore conduction velocity decreases.

Conduction slow enough to facilitate reentry also may occur in cardiac cells with persistently low levels of resting potential (which may be between -60 and -70 mV) caused by disease. At these resting potentials, a significant percentage of the Na^+ channels are inactivated;[229] therefore, they are unavailable for activation by a depolarizing stimulus. Also, at these resting membrane potentials, recovery from inactivation is markedly prolonged and extends beyond complete repolarization.[230] The magnitude of the inward current during phase 0 of the action potential is reduced; consequently, both the speed and the amplitude of the upstroke are diminished (Fig. 23-14*A*, action potentials 2, 3, and 4), decreasing axial current flow and slowing conduction significantly. Such action potentials with upstrokes dependent on inward current flowing via partially inactivated Na^+ channels sometimes are referred to as *depressed fast responses*. Further depolarization of the resting membrane potential and further inactivation of the Na^+ channel may decrease the excitability of cardiac fibers to such an extent that they may become a site of unidirectional conduction block.[231] Thus, in a diseased region with partially depolarized fibers, there may be some areas of slow conduction and some areas of conduction block, depending on the level of resting potential and the amount of Na^+ channels that are inactivated. This combination may cause reentry. The chance for reentry in such fibers is even greater during premature activation or during rhythms at a rapid rate because slow conduction or the possibility of block is increased even further owing to the prolonged time for the Na^+ channels to recover

from inactivation when the resting potential is partially depolarized.

After the upstroke of the normal action potential of atrial, ventricular, or Purkinje cells, membrane potential begins to return to the resting level because the Na^+ channels are inactivated and the fast (depolarizing) Na^+ current ceases to flow. This return, however, is slowed by a second inward current that is smaller and slower than the fast Na^+ current and probably is carried by both Na^+ and Ca^{2+} ions.[232] This secondary inward current flows through L-type Ca^{2+} channels that are distinct from the fast Na^+ channels.[20] The threshold for activation of the L-type Ca^{2+} current is in the range of -30 to -40 mV, compared with about -70 mV for the fast Na^+ current. This current inactivates much more slowly than does the fast Na^+ current and gradually diminishes as the cell repolarizes. It causes much of the plateau phase of the action potential. Under special conditions, this Ca^{2+} current also may underlie the occurrence of the slow conduction that causes reentrant arrhythmias.[5] Although the fast Na^+ channel may be largely inactivated at membrane potentials near -50 mV, the L-type Ca^{2+} channel is not inactivated and is still available for activation.[5,232]

Under certain conditions, when the resting potential is reduced to levels lower than -60 mV (as occurs when membrane conductance is very low or when catecholamines are present), this normally weak inward Ca^{2+} current may give rise to regenerative action potentials that propagate very slowly and are prone to block. The propagated action potential, which is dependent on inward Ca^{2+} current, is referred to as the *slow response*.[5] Slow-response action potentials can occur in diseased cardiac fibers with low resting potentials, but they also occur in some normal tissue of the heart, such as cells of the sinus and AV nodes, where the maximum diastolic potential is normally about -60 mV or less.[5,233] In fact, slow conduction is a normal property of both the sinus and the AV nodes. Thus, it should be of no surprise that either of these nodes may be a critical area of slow conduction in some reentrant circuits, e.g., the AV node in AV reentrant tachycardia involving an accessory AV connection.

ANISOTROPY

The slow conduction that facilitates the occurrence of reentry also can be caused by factors other than a decrease in inward current during the upstroke of the transmembrane action potential. An increased resistance to axial current flow, which can be expressed as *effective axial resistance* (defined as resistance to current flow in the direction of propagation[234,235]) decreases the magnitude and spread of axial current of the propagating impulse among the myocardial fibers and may decrease conduction velocity. During conduction of the impulse, axial current flows from one myocardial cell to the adjacent cell through the gap junctions of the intercalated disks, which form a major source of intercellular resistance to current flow between fiber bundles.[228] Therefore, the structure of the myocardium that governs the extent and distribution of these gap junctions has a profound influence on axial resistance and conduction. This influence can be seen in normal atrial or ventricular myocardium, although the structure is different in different regions.

The atria (crista terminalis) and certain regions of the ventricles (except for the subepicardial muscle) are composed of bundles of myocardial cells that have been called *unit bundles* by Sommer and Dolber.[236] Such bundles are made up of 2 to 30 cells surrounded by a connective tissue sheath. Within a unit bundle, cells are tightly connected or coupled to each other through intercalated disks that contain the gap junctions. All the cells of a unit bundle are connected to each other within the space of 30 to 50 μm down the length of a strand.[236] An individual cardiac myocyte may be connected to as many as nine other myocytes through one or more intercalated disks.[237] These connections are mainly at the ends of the myocytes rather than along their sides, but the overlapping nature of the junctions effectively connects myocytes within a bundle in the transverse direction as well as the longitudinal direction. Therefore, as a consequence of the many intercellular connections, the myocytes in a unit bundle are activated uniformly and synchronously as an impulse propagates along the bundle. The unit bundles also are connected to

each other. Unit bundles lying parallel to each other in normal atrial and ventricular muscle are connected in a lateral (transverse) direction at intervals in the range of 100 to 150 μm.[236] As a consequence of this structure, the myocardium in regions in which unit bundles occur is better coupled in the direction of the long axis of its cells and bundles (because of the high frequency of the gap junctions within a unit bundle) than in the direction transverse to the long axis (because of the low frequency of interconnections between the unit bundles). This is reflected in a lower axial resistivity in the longitudinal direction than in the transverse direction in cardiac tissues that are composed of many unit bundles.[238,239]

The structure of the interconnections between muscle fibers is somewhat different in the subepicardial regions of the ventricles (and possibly other regions as well) but is still a cause of lower longitudinal axial resistance rather than transverse axial resistance. The subepicardial region is not made up of unit bundles.[240] Each ventricular muscle cell is connected to approxi mately 11 to 12 other muscle cells in three dimensions. The junctions that connect the cells occur at both the ends and the sides of cells in roughly equivalent numbers; approximately half of all connections are side to side, and half are end to end. Therefore, activation wavefronts can conduct equally well between individual cells in both the longitudinal and transverse directions because there are equal numbers of gap junctions. In the transverse direction, however, a wavefront encounters more gap junctions than it does over an equivalent distance in the longitudinal direction because cell diameter is much smaller than cell length; therefore, the wavefront must traverse more cells transversely. Thus, there is a greater resistance transversely than longitudinally because of the increased number of gap junctions per unit distance traveled.[238]

As was stated above, the effective axial resistivity is an important determinant of the conduction velocity; therefore, conduction through atrial and ventricular myocardium is much more rapid in the longitudinal direction, owing to the lower resistivity, than it is in the transverse direction. Thus, cardiac muscle is anisotropic; its conduction properties vary depending on the direction in which they are measured.

Spach and associates.[234,235,241,242] classified anisotropy into two major subdivisions: uniform and nonuniform. Uniform anisotropy is characterized by an advancing wavefront that is smooth in all directions (longitudinal and transverse to fiber orientation), indicating relatively tight coupling between groups of fibers in all directions. Uniform anisotropy is exemplified by the conduction properties of normal septal ventricular muscle, as shown in Fig. 23-15*A*. The muscle in the diagram was stimulated in the center (pulse symbol), and activation spread away from this site in all directions. In the direction of the longitudinal axis of the fibers (from top to bottom), the activation isochrones are widely spaced, indicating rapid conduction-in this case, 0.51 m/s. There is a relatively broad area of fast conduction with an elliptic shape of the isochrones that is characteristic of uniform anisotropy.[241] In the direction transverse to the long axis (to the right and to the left), the isochrones are spaced close together, indicating slower conduction: 0.17 m/s in this example. As the direction of propagation changes between these two axes, the apparent conduction velocity changes monotonically from fast to slow, another characteristic of uniform anisotropy.[234]

The slow conduction in the direction transverse to the longitudinal fiber axis occurs despite action potentials with normal resting potentials and upstroke velocities and is caused by the higher transverse axial resistance. Associated with the differences in conduction velocity that are based on the direction of propagation, however, are unexpected changes in the action potentials. Thus, when going from fast longitudinal conduction to slow transverse conduction, the rate of depolarization during the upstroke of the action potential ($V(r)_{max}$) increases and the time constant of the foot of the upstroke decreases without any change in the resting potential, as shown in Fig. 23-15*C*; the upstroke that is dashed was recorded from a cell during longitudinal propagation, while the upstroke indicated by the solid line was recorded from the same cell during transverse propagation.[234] These characteristics are opposite to the changes in the action

potentials associated with slowing of conduction when the membrane currents are altered (e.g., by membrane depolarization).[243,244] Despite the increase in $V(r)_{max}$, when conduction is slowed in the transverse direction, the slowing of conduction is associated with a decrease in the amplitude of the extracellular electrogram, showing that there is a decrease in the extracellular current flow as a result of the increased axial resistivity.

In uniformly anisotropic tissue, the extracellular unipolar waveform has a large-amplitude, smooth biphasic, positivenegative morphology during propagation in the fast longitudinal direction (Fig. 23-15*B*, dashed line) and a low-amplitude, smooth triphasic (negative-positive-negative) morphology in the transverse direction (Fig. 23-15*B*, solid line). The initial negativity of the electrogram in the transverse direction is a reflection of distant activity rapidly propagating along the longitudinal axis.[245]

Nonuniform anisotropy has been defined[235] as tight electrical coupling between cells in the longitudinal direction but recurrent areas in the transverse direction in which side-to-side electrical coupling of adjacent groups of parallel fibers is absent. Therefore, propagation of normal action potentials transverse to the long axis is interrupted so that adjacent bundles are excited in a markedly irregular sequence (*zigzag conduction*).[235,241] In nonuniformly anisotropic muscle, there also may be an abrupt transition in conduction velocity from the fast longitudinal direction to the slow transverse direction, unlike the case with uniform anisotropic muscle, in which intermediate velocities occur between the two directions. This pattern of excitation in nonuniform anisotropic atrial pectinate bundles from older patients is diagrammed in Fig. 23-16*A*. The white arrow on the outline of the preparation indicates the narrow region of fast conduction down the long axis of the fibers when the bundle was excited at the asterisk. The zigzag arrow indicates the irregular course of excitation across the fibers, which occurred all along the length of the zone of fast conduction. Conduction in the transverse direction in these nonuniformly anisotropic bundles was nearly as slow at the slowest conduction associated with membrane depolarization and slow-response action potentials.[5] In pectinate muscles from older patients, mean fast velocity was 0.69 m/s and slow velocity was 0.07 m/s, a ratio of almost 10,[241] despite the normal resting potential and the fast action potential upstroke of the atrial cells. As in uniform anisotropy, the upstroke velocity of the action potential is more rapid in the slow direction transverse to the long axis of the fibers than in the fast direction parallel to the long axis.

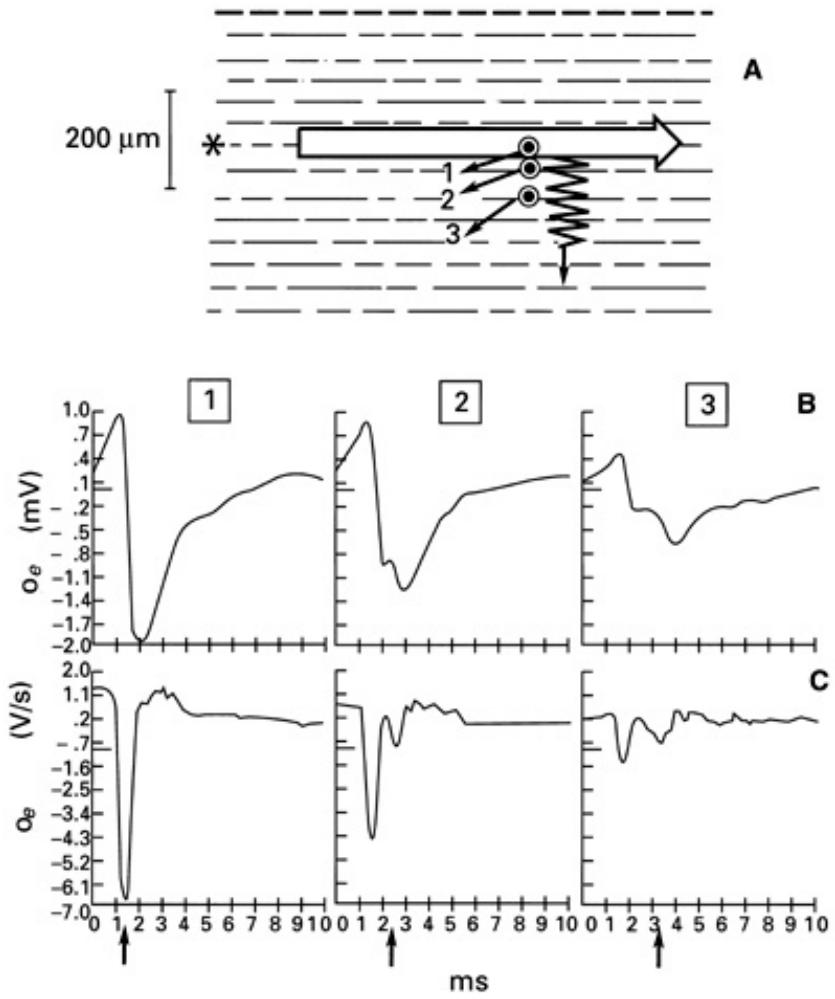

Figure 23-16: *A.* Diagram of a nonuniform anisotropic atrial muscle bundle with the long axis of the myocardial fibers indicated by the dashed lines. The bundle was stimulated at the asterisk. Propagation of the longitudinal wavefront is shown by the large white arrow. Transverse propagation occurred as diagrammed by the zigzag arrow. *B.* Electrograms recorded from sites 1, 2, and 3 on the diagram. *C.* The first derivative of these electrograms is shown. (From Spach MS, Dolber PC. Relating extracellular potentials and their derivatives to anisotropic propagation at a microscopic level in human cardiac muscle: Evidence for uncoupling of side-to-side fiber connections with increasing age. *Circ Res* 1986; 58:356. Reproduced with permission from the publisher and author.)

The morphologic basis for the nonuniform anisotropic properties in human atrial muscle is that the fascicles of muscle bundles are separated in the transverse direction by fibrous tissue that proliferates with aging to form longitudinally oriented insulating boundaries. Intercellular connections cannot occur where the cardiac fibers are separated by connective tissue septa and there is uncoupling between parallel-oriented groups of fibers.[235,241] Part of the reduction of the conduction velocity in this transverse direction may be a result of the tortuous path length necessary for the wavefront to propagate transversely from one bundle to another because of these septa, accounting for the zigzag activation pattern. Similar connective tissue septa cause nonuniform anisotropy in other normal cardiac tissues, such as the crista terminalis and the interatrial band in adult atria or ventricular papillary muscle, as well as pathologic situations such as chronic ischemia or a healing myocardial infarction, in which fibrosis in the myocardium occurs.

The irregular activation transversely is evident in the extracellular electrogram, which is characterized by a sequence of multiple deflections, each representing activation of a separate

bundle of fibers, with the largest, most rapid intrinsic deflection produced by local excitation and less rapid and lower-amplitude deflections produced by excitation of adjacent fascicles.[235] In Fig. 23-16*B*, the multiple deflections can be seen in electrograms recorded from sites 2 and 3 in the atrial pectinate muscle and are even more prominent in the derivatives of these electrograms (Fig. 23-16*C*). A similarly fractionated electrogram also can be recorded from diseased regions of the ventricles. During longitudinal propagation, large biphasic electrograms are still evident (electrogram at site 1).

Anisotropy on a macroscopic scale also can influence conduction at sites where a bundle of cardiac fibers branches or where separate bundles coalesce. Marked slowing can occur when there is a sudden change in the fiber direction, causing an abrupt increase in the effective axial resistivity.[235] Figure 23-17 illustrates this point. The drawings show a small branch of an atrial pectinate muscle from the crista terminalis. The general direction of the fiber orientation is indicated by the thin broken lines, and the pattern of propagation is illustrated by the thick solid lines with arrows. In *A* (1) at the left, wavefronts initiated by stimulation at the top propagate throughout the crista and its branch along the longitudinal axis of the fibers throughout so that there is no conduction delay entering the branch. At the right in *A* (2), wavefronts initiated by stimulation at the bottom propagate up the crista and into the branch, but they encounter a marked change in the direction of the fibers from longitudinal to transverse while entering the branch, resulting in a slowing of conduction because of the sudden increase in axial resistance. Conduction block, which sometimes may be unidirectional, may occur at such junction sites, particularly when the inward current is decreased, as will be described later.

In addition to the structural features of the cellular interconnections influencing axial current flow and conduction as expressed in the anisotropic properties of cardiac muscle, the intercellular resistance may increase because of an increase in gap junctional resistance that results from a decrease in the conductance of the junctions, i.e., a decrease in the ease with which the ions that carry axial current move through the junctions. In a computer model, conduction velocity can be reduced by a factor of 20 by increasing disk resistance, and decremental conduction and block will result.[246,247]

Perhaps the most important influence on gap junctional resistance in pathologic situations is the level of intracellular Ca^{2+}. A significant rise increases resistance to current flow through the junctions and eventually leads to physiologic uncoupling of the cells.[248,249] Intracellular Ca^{2+} increases during ischemia and may be a factor causing slow conduction and reentry. Thus, there are several causes for slow conduction that may lead to reentry: (1) slow responses that are a normal property of some regions of the heart, such as the sinus and AV node, (2) depressed fast responses or slow responses caused by pathology-induced partial depolarization of the membrane potential, (3) anisotropy, and (4) changes in gap junctional resistance.

Unidirectional Block

Unidirectional block occurs when an impulse cannot conduct in one direction along a bundle of cardiac fibers but can conduct in the opposite direction. This condition is necessary for the occurrence of classical reentrant rhythms. Thus, unidirectional block in part of the circuit leaves a return pathway through which the impulse conducts to reenter previously excited areas. A number of mechanisms, involving both active and passive electrical properties of cardiac cells, may cause unidirectional block.

REGIONAL DIFFERENCES IN RECOVERY OF EXCITABILITY

One cause of unidirectional block that allows the initiation of reentry is regional differences in recovery of excitability. When differences in the duration of the effective refractory period occur in adjacent areas, conduction of an appropriately timed premature impulse may be blocked in the

region with the longest refractory period, which then becomes a site of unidirectional block, while conduction continues through regions with a shorter refractory period. Figure 23-18 is a schematic representation of the initiation and continuation of circus movement in an anatomically defined circuit, with differences in effective refractory period duration resulting from differences in the time course of action potential repolarization being the cause of unidirectional block in one of the pathways. The action potentials in various parts of the circuit are shown. In the upper panel (*A*), conduction of a premature impulse (extrasystole), which either can be induced by electrical stimulation or may occur "spontaneously," is blocked in the pathway with the long action potential duration and therefore long effective refractory period (to the left), referred to as the *blocked pathway*. The premature impulse, however, conducts in the other pathway with shorter action potential durations and refractory periods (to the right). This pattern of activation is indicated by the arrows. For block to occur, the premature impulse also must arise in a region with a short effective refractory period so that it occurs before repolarization of the action potentials in the left pathway occurs. In the lower panel (*B*), which shows the continuation of these events, the blocked pathway is invaded retrogradely by the impulse conducting from the right, thus causing the second action potential (arrow at the left). The proximal region where the premature impulse originated is then reexcited (reentry) as the impulse once again enters the right pathway and continues around the reentrant circuit, causing another action potential in the right pathway (large arrow). For successful reexcitation to occur in the region where the premature impulse was initiated, elements in the circuit at the region of block and proximal to it (toward the site of origin) must have regained their excitability by the time the cardiac impulse arrives there. Continuation of reentry induced by a premature impulse also is facilitated because the duration of the effective refractory period associated with conduction of the premature impulse is shortened. Therefore, on the next excursion of the reentrant impulse around the circuit, conduction occurs in a circuit with a shorter effective refractory period. Finally, the conduction velocity of premature impulses may be decreased, shortening the wavelength[250,251] and facilitating successful excitation of the region proximal to the unidirectional block.

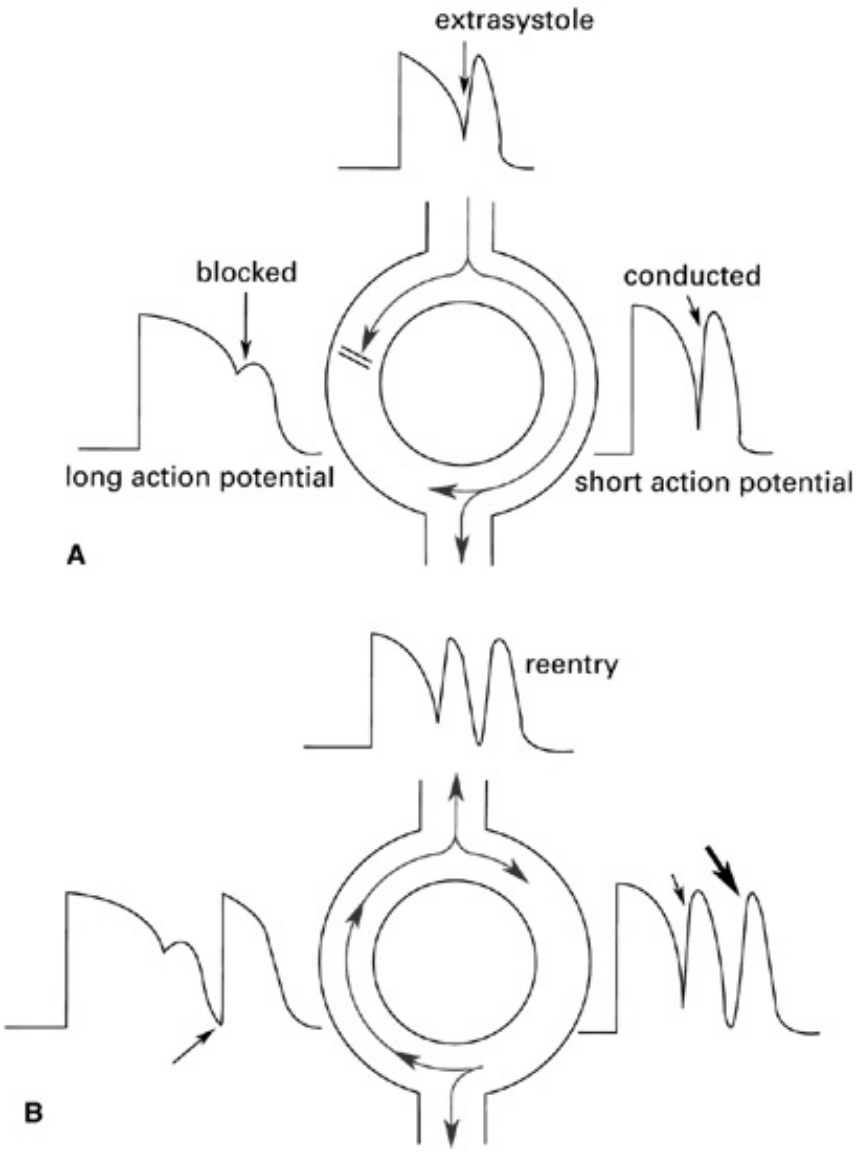

Figure 23-18: Diagram of reentry caused by dispersion in refractory periods. A ring of cardiac tissue is shown, and the pattern of conduction is indicated by the arrows. Action potentials with different durations located in different regions of the ring are diagrammed. (From Wit AL, Janse MJ. *The Ventricular Arrhythmia of Ischemia and Infarction: The Electrophysiological Mechanisms.* Mount Kisco, NY: Futura; 1992:86. Reproduced with permission from the publisher and authors.)

Therefore, unidirectional block caused by regional differences in excitability is actually a result of transient block. Block occurs in the antegrade direction in the left pathway while conduction is successful in the retrograde direction. This kind of unidirectional block can cause the initiation of reentry not only in anatomic circuits, as shown in Fig. 23-18, but also in functional circuits. For reentrant arrhythmias to arise because of regional differences in effective refractory periods, a premature impulse that initiates reentry is as necessary a requirement as are the conditions allowing the perpetuation of reentrant activation. Thus, both a "trigger" (the premature impulse) and a "substrate" (the reentrant circuit) are needed. The mechanism causing the premature impulse may be quite different from the arrhythmia it initiates. It may arise spontaneously by automaticity or result from triggered activity. The premature impulse also may be induced by an electrical stimulus during a programmed stimulation protocol. The degree of nonuniformity in effective refractory period duration necessary for a properly timed premature stimulus to cause unidirectional block may be quite small. This degree of nonuniformity often is referred to as the *dispersion in the refractory periods* or *dispersion in recovery of excitability*, meaning the

difference between the shortest and longest refractory periods.

When stimuli were delivered in the region with the shortest refractory period at the border of two areas with different refractory periods in atrial tissue in the experiments of Allessie and coworkers,[252] the minimal difference in effective refractory period needed to cause block of an appropriately timed stimulated premature impulse was between 11 and 16 ms, well within the normal physiologic range of variation of effective refractory period durations. A properly timed single premature stimulus can initiate reentry in the atria because the differences in refractory period may cause unidirectional block.[252] In the ventricles, where refractory periods are much longer than they are in the atria, the physiologic differences between the longest and shortest refractory period durations is on the order of 40 ms.[253,254] Unlike the case in the atria, dispersion of refractory periods in normal ventricles is not sufficiently large to allow initiation of reentry by premature impulses.

In experiments in which the dispersion of refractory periods was increased by local cooling of the ventricles and a critical difference between the shortest and longest effective refractory periods ranging from 95 to 145 ms was reached, premature stimuli delivered at the site with the shortest effective refractory period induced repetitive activity in the canine left ventricle, presumably because block of the premature impulses in the regions with a long effective refractory period created unidirectional block and permitted reentry.[255,256] Similarly, critical increases in the dispersion of refractory periods that are caused by acute or prolonged ischemia result in reentrant arrhythmias. The difference between the longest and shortest refractory periods is not the only factor that determines whether premature stimuli will induce reentry.[252] If the regions of long and short refractory periods are separated by a large distance, an early premature impulse arising in a region of short refractoriness may not be able to arrive in the region of long refractoriness sufficiently early to cause block because conduction between the regions may be slow. Regions of long refractory periods therefore must be relatively close to a region of shorter refractory periods where the premature impulse arises for block to occur. In addition, if block does occur, the size of the area of unidirectional block is of crucial importance, particularly in a functionally determined reentrant circuit. Even in the presence of large differences in effective refractory period duration, reentry may not occur when the area with long effective refractory periods resulting in unidirectional block is small, because the impulse can travel around the area of unidirectional block along an alternative pathway or pathways and will not be delayed sufficiently to allow reexcitation of the point of origin at the end of the latter's effective refractory period. This cannot occur in an anatomic circuit such as the one shown in Fig. 23-18. Thus, *dispersion in recovery of excitability* is by itself not sufficient to describe the propensity for induction of reentrant arrhythmias. The regional differences in recovery of excitability that lead to unidirectional conduction block also may occur in the absence of regional differences in action potential duration. Computer models have shown that the activation sequence of a propagating impulse can lead to asynchronous repolarization and refractoriness even when membrane properties are homogeneous.[89,247] A stimulated premature impulse can block in a region that has been depolarized most recently by a prior wave of excitation and is therefore still refractory, but it may conduct into another region that was excited much earlier by the prior wave of excitation if it has had time to recover excitability. The conducting premature excitation wave then can later return to excite the area of block after it recovers, resulting in reentry.

ASYMMETRIC DEPRESSION OF EXCITABILITY

Unidirectional conduction block in a reentrant circuit also can be persistent and independent of premature activation. Persistent unidirectional block often is associated with depression of the transmembrane potentials and excitability of cardiac fibers.[257] There are several possible mechanisms for the persistent unidirectional block in a region where action potentials are depressed. One mechanism is asymmetric depression of excitability. This asymmetric depression may occur because of asymmetric distribution of a pathologic event. As a simple example, the

action potential upstrokes in a bundle of fibers may be diminished as a result of a reduction of perfusion after coronary occlusion, but the depression of the upstroke may be more severe toward one end of the bundle than toward the other. This situation is diagrammed in Fig. 23-19. A propagating impulse consisting of an action potential with a normal upstroke velocity (site 1) enters the poorly perfused region (stippled in the diagram) and propagates through this region with decrement (from left to right or from site 1 to 4); i.e., as it conducts from the less depressed end (1) to the more severely depressed end (4), the action potential upstroke velocity and amplitude progressively decrease, as does the axial current flowing toward cells that will be excited by the upstroke (as indicated by the decreasing size of the striped arrows). When the impulse arrives at the opposite end of the depressed segment of the bundle where there is suddenly a normally perfused bundle with normal action potentials (between action potentials 4 and 5), the action potential amplitude is markedly reduced and the weak axial current from site 4 is not sufficient to depolarize the normal membrane to threshold at site 5. Conduction therefore blocks in the left-to-right direction even though the normally perfused region is excitable. Conduction in the opposite direction (from right to left), however, still may succeed. The large axial current generated by the normal action potential at site 5 can flow for a considerable distance through the depressed region and may depolarize to threshold fibers at some distance from the most severely depressed region (perhaps as far as site 3). These cells in turn may be able to excite adjacent fibers in the direction of propagation (from right to left), and as a result, the impulse successfully propagates from site 3 to site 1, as indicated by the black arrows.

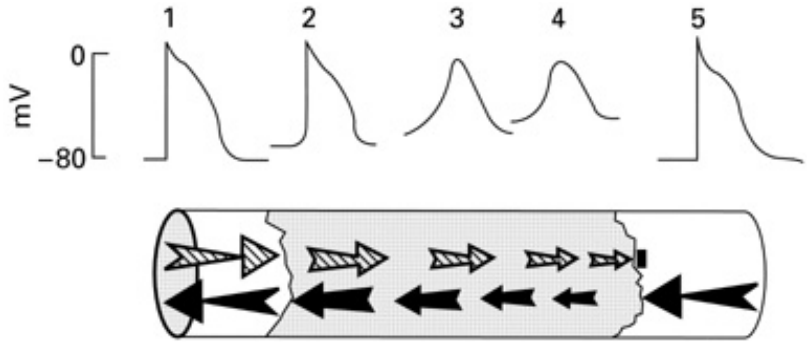

Figure 23-19: Asymmetric depression of excitability as a mechanism for unidirectional conduction block in a bundle of cardiac muscle fibers. The action potentials shown above were recorded from sites on the fiber bundle. The shaded part of the bundle is depressed. Conduction from left to right along the bundle is indicated by the striped arrows, conduction from right to left by the black arrows. (Modified from Wit AL, Rosen MR. Cellular electrophysiological mechanisms of cardiac arrhythmias. In: MacFarlane PW, Veitch Lawrie TD, eds. *Comprehensive Electrocardiology: Theory and Practice in Health and Disease*, vol. 2. New York: Pergamon Press; 1989:801. Reproduced with permission from the publisher and authors.)

GEOMETRIC FACTORS CAUSING UNIDIRECTIONAL BLOCK

Geometric factors related to tissue architecture also may influence impulse conduction and under certain conditions lead to unidirectional block. An impulse can conduct rapidly in either direction along the length of a bundle of atrial, ventricular, or Purkinje fibers with normal electrophysiologic properties. There is usually some asymmetry in the conduction velocity, however, meaning that conduction in one direction may take slightly longer than it does in the other direction.[5,228,231] This is usually of no physiologic significance. The asymmetry of conduction can result from several factors. Bundles of cardiac muscle are composed of interconnecting myocardial fibers with different diameters packed in a connective tissue matrix. These bundles branch frequently (although the individual myocardial fibers do not branch). An impulse conducting in one direction encounters a different sequence of changes in fiber diameter,

branching, and frequency and distribution of gap junctions than it does when traveling in the opposite direction. The configuration of pathways in each direction is not the same.[231] These structural features influence conduction by affecting the axial currents that flow ahead of the propagating wavefront.

The results of theoretical analyses indicate that the conduction velocity of an impulse passing abruptly from a fiber of small diameter to one of large diameter transiently slows at the junction because the larger cable results in a larger sink for the longitudinal axial current (there is more membrane for this current to depolarize to threshold if conduction of the impulse is to continue).[228,231,247,258,259] A similar slowing occurs when an impulse conducts into a region where there is an abrupt increase in branching of the myocardial syncytium; conduction transiently slows because of the larger current sink provided by the increased membrane area that must be depolarized.

In the opposite direction, it can be predicted that conduction will speed transiently as the impulse moves from a larger cable to a smaller cable because the small sink for axial current results in more rapid depolarization of the membrane to threshold.[228,258,259] Theoretically, if there is a large enough difference in the diameter of the two cables, an impulse conducting from the small cable to the large cable should block at the junction, while conduction in the opposite direction (from large cable to small cable) is maintained.

A probable example of unidirectional block based on this geometric factor in the normal heart occurs at the junctions between Purkinje's and muscle cells. At certain sites, propagation from muscle to Purkinje fibers is possible, while propagation from Purkinje fibers to muscle is not.[260] This asymmetry of conduction results from the difference in mass between the Purkinje and muscle layers. The smaller-mass Purkinje fiber bundle is the small-diameter cable, while the larger-mass muscle is the larger-diameter cable. It is unlikely that in normal circumstances these localized sites of unidirectional block predispose to reentry since the myocardium is quickly excited via the many other Purkinje-to-muscle junctions where the geometric differences are not sufficient to cause block. It is possible, however, when conduction in ischemic myocardium is slow and coupling resistance at the junction increases, that such sites of unidirectional block may become important in initiating reentry.[261-263]

It is doubtful that abrupt changes in geometric properties such as fiber diameter of the magnitude required to cause block of the *normal* action potential often exist (except at some Purkinje fiber-muscle junctions, as was described above) because the safety factor for conduction is large; i.e., there is a large excess of activating current over the amount required for propagation.[228] Dodge and Cranefield[231] pointed out that "only if an action potential is a relatively weak stimulus and the unexcited area is not easily excited will plausible changes in membrane resistance, cell diameter, or intercellular coupling produce block." There is a necessity for interaction of abnormal action potentials and decreased excitability with the preexisting anatomic impediments, as occurs in acute ischemia. When the resting potential of fibers in a muscle or Purkinje bundle is decreased, the reduced action potential upstroke results in a decreased axial current, and therefore, the action potential is a weak stimulus. The normal directional differences in conduction are then exaggerated.

At a critical degree of depression of the action potential upstroke, conduction may fail in one direction while being maintained in the other (although it may be slowed markedly). At this critical degree of depression, the reduced axial current may not be sufficient to depolarize the membrane to threshold where the current sink is increased because of the structural changes described above (increased fiber diameter), but the axial current is still more than adequate during conduction in the opposite direction.

The anisotropic properties of cardiac muscle also represent a geometric factor that sometimes may

contribute to the occurrence of unidirectional block. Spach and colleagues[234] indicated that in anisotropic muscle, the safety factor for conduction is lower in the longitudinal direction of rapid conduction than it is in the transverse direction of slow conduction (the opposite of that predicted on the basis of continuous cable theory). The low safety factor longitudinally is a result of a large current load on the membrane associated with the low axial resistivity and large membrane capacitance in the longitudinal direction. This low safety factor may result in a preferential conduction block of premature impulses in the longitudinal direction relative to the transverse direction under certain conditions. In uniformly anisotropic muscle, a decrease in inward current during the depolarization phase of an action potential, as may result from premature activation, results in slowing of conduction in the longitudinal direction more than in the transverse direction, but propagation still continues as a spatially smooth process. Conduction block of early premature impulses occurs in both longitudinal and transverse directions nearly simultaneously in uniformly anisotropic muscle.[242]

In nonuniformly anisotropic muscle, however, premature activation can result in conduction block in the longitudinal direction even when the impulse is conducting from a region with a long refractory period into a region with a shorter refractory period while conduction in the transverse direction continues.[242] The site of block in the longitudinal direction can become a site of unidirectional block that leads to reentry, much like the block of premature impulses caused by a sudden increase in action potential duration and effective refractory period. It can be excited by an impulse propagating in the opposite direction, i.e., by the wavefront initially launched successfully in the transverse direction that later propagates to the distal side of the region of the block. In contrast to the propensity of premature impulses to block in the longitudinal direction in nonuniformly anisotropic myocardium because of the decreased depolarizing current and low safety factor, when coupling resistance between cells is increased, conduction of all impulses will block first in the transverse direction. Preferential block in this direction occurs because an increase in coupling resistance will reduce the safety factor below the critical level needed to maintain transverse conduction before the safety factor for longitudinal conduction is reduced to this critical level.[264,265] Unlike longitudinal block of a premature impulse, which is transient block and may lead to reentry, block in the transverse direction caused by increased coupling resistance may be bidirectional and, if so, should not cause reentry.

Anisotropy also can result in unidirectional block at sites of muscle bundle branching or at the junction of muscle bundles.[235] It was shown in Fig. 23-17*A*(2) that when a wavefront propagating in a bundle of parallel fibers enters a branch formed at an acute angle, the direction of propagation is altered quickly from longitudinal to transverse, causing an abrupt increase in the effective axial resistance in the direction of propagation and a slowing of conduction velocity. If the inward current also is reduced by partial depolarization, as occurs after premature stimulation or elevation of extracellular K^+, conduction block may occur.[235] This is shown in Fig. 23-17*B*(2), where the extracellular K^+ concentration was increased from 4.6 to 9.0 meq/L. Failure of the stimulated impulse to enter the branch is shown by the absence of electrical activity at sites c and d. By contrast, as shown in Fig. 23-17*B*(1), propagation from the other direction into the branch does not involve a change in the direction of the wavefront relative to the fiber orientation since it continues in a parallel direction; therefore, there is no block in this direction.[235] These sites can become areas of unidirectional block that are instrumental in the occurrence of reentry.

Alterations in Refractory Period

Alterations in the effective refractory period may contribute to the occurrence of reentry. A decrease in the effective refractory period decreases the wavelength of the reentrant impulse and therefore the necessary size of the reentrant circuit. If the refractory period is decreased, the degree of slow conduction needed for successful reentry is diminished. The effective refractory period of cardiac fibers in a reentrant circuit may be decreased during rapid tachycardias because

of rate-dependent shortening of the action potential duration.[247,266] The computer model of Quan and Rudy[247] predicts that in circuits with a small or no excitable gap, electrotonic interaction between the head and the tail of the reentrant wavefront also can shorten action potential duration and the refractory period. If the effective refractory period is decreased sufficiently, more than one reentrant circuit can exist at a time in some regions.[267,268] The effective refractory period of atrial muscle, for example, is decreased by the acetylcholine released during vagal stimulation. As a result, reentry in atrial muscle causing atrial fibrillation is more easily induced during vagal stimulation.[269] Several reentrant circuits exist simultaneously during this arrhythmia.[268,270] Action potential duration and effective refractory period are decreased in the ventricle during reperfusion after brief periods of ischemia or in some of the ventricular muscle cells in chronically ischemic areas, probably contributing to the occurrence of reentry.

The Central Area of Block

The central area of block around which the reentrant wavefront circulates may be anatomic, functional, or a combination of the two. Anatomic block is the result of a nonconductive medium in the center of the circuit. An example of an anatomically determined central area of block is in the tricuspid ring reentrant circuit found in a canine model of atrial flutter[266] and perhaps present in a clinical counterpart, the atrial flutter found commonly in patients who have previously had a Mustard procedure to repair transposition of the great vessels.[271] The animal model depends critically on large incisions made in the right atrial free wall, which in fact are similar to those made by the surgeon during the Mustard procedure. Functional block at the center of a circuit occurs when there is block of impulses in otherwise excitable cardiac muscle. An example of a functional center of block was first described by Allessie and associates[272] in a model of reentrant excitation in the rabbit left atrium called the leading circle mechanism of reentry. Functional block subsequently has been described in several other models of atrial flutter.[223,224,273,274] The central area of functional block develops during the initiation of the reentrant circuit by the formation of a line of block that most likely is due to refractoriness. When the reentrant circuit forms, the line of block then is sustained by centripetal activation from the circulating reentrant wavefront, which by repeatedly bombarding the central area of block maintains the state of refractoriness of this region. A combination of an anatomic and a functional central area of block in the reentrant circuit has been described in some models of atrial flutter (e.g., the orifice of one or both of the cavae and an area of functional block continuous with or adjacent to either or both of the caval orifices).[224,275]

The Excitable Gap

The excitable gap in a reentrant circuit is the region of excitable myocardium that immediately precedes the head of the reentrant wavefront and moves around the circuit in advance of the reentrant wavefront. The occurrence of a gap is dependent on the recovery of excitability of the myocardium from its previous excitation by the reentrant wavefront. There are two different measurements of the excitable gap. One is the spatial gap, which is the distance in the circuit ahead of the wavefront that is excitable. The spatial gap may be composed of either partially excitable or fully excitable myocardium, depending on the time interval between successive excitations of the circuit. The size of the spatial gap changes in different parts of the circuit as the wavelength of the reentrant impulse changes because of changes in conduction velocity, refractory periods, or both, as was described previously.

The second measurement of the excitable gap is the temporal excitable gap. This is the time period during the cardiac cycle in which a stimulus can excite the region ahead of the reentrant wavefront. In regard to the spatial gap, the temporal gap in different parts of the reentrant circuit also can have both partially excitable and fully excitable components and varies in different parts of the circuit because of the changes in the wavelength. The characteristics of the excitable gap may be quite different in reentrant circuits caused by different mechanisms. For example, some anatomically determined circuits have been shown to have large excitable gaps with a fully

excitable component, although even in anatomically determined circuits, the gap may be only partially excitable.[276] By comparison, functional reentrant circuits caused by the leading circle mechanism have very small gaps that are only partially excitable,[273] although parts of some functionally determined reentrant circuits may have a small fully excitable gap during part of the reentrant cycle.

TYPES OF REENTRY

It was indicated previously that there are two types of reentry: ordered and random.[1] The reentrant circuits can be anatomically determined, functionally determined, or both. In anatomically determined circuits, the pathway is fixed and the characteristics of the reentrant circuit are determined by the characteristics of the anatomic components of the circuit. Anatomic circuits therefore are associated with ordered reentry. Perhaps the best example is AV reentrant tachycardia, in which the reentrant circuit is composed of atrium, the AV node, the His-Purkinje system, the ventricle, and an accessory AV connection.

In functionally determined circuits, the pathway is formed because of the electrophysiologic properties of the cardiac cells, not by a predetermined anatomic pathway. Functional circuits can be associated with ordered or random reentry. Mechanisms for functionally determined reentrant circuits include the leading circle type of reentry,[272] anisotropic reentry,[277] and spiral wave reentry. Allessie and coworkers[252,272,278] were able to induce stable reentrant tachycardia in small pieces of isolated rabbit left atrium by precisely timed premature impulses in regions that were activated normally at regular rates of stimulation. Initiation of reentry was made possible by the different refractory periods of atrial fibers in close proximity to one another. The premature impulse that initiated reentry blocked in fibers with long refractory periods and conducted in fibers with shorter refractory periods, eventually returning to the initial region of block after excitability recovered there. The impulse then continued to circulate around a central area that was kept refractory because it was bombarded constantly by impulses propagating toward it from all sides of the circuit. This central area provides a functional obstacle that prevents excitation from propagating across the fulcrum of the circuit. No anatomic obstacles or anatomically defined conducting pathways are present in the leading circle, and the reentrant circuit is completely defined by the electrophysiologic properties of the tissue involved. The circumference of the leading circle around a functional obstacle may be as little as 6 to 8 mm and represents a pathway in which the efficacy of stimulation of the circulating wavefront is just sufficient to excite the tissue ahead, which is still in its relative refractory phase. Conduction through the functional reentrant circuit is slowed, therefore, because impulses are propagating in partially refractory tissue (a partially excitable gap). Some of the reentrant excitation that has been mapped in the atria of canine models of atrial flutter may be caused by the leading circle mechanism.[273] The reentrant circuit remains in the same place during the flutter and therefore is ordered reentry. Functional reentrant circuits of the leading circle type also may change their size and location; if they do, they fall under the general category of random reentry. This may occur when leading circle reentry causes fibrillation.

Anisotropy can cause conduction slow enough to result in reentry in small anatomic circuits. Reentrant circuits caused by anisotropy also can occur without well-defined anatomic pathways and may be classified as functional. Unlike the functional characteristic that leads to the leading circle type of reentry (local differences in membrane properties causing a difference in effective refractory periods in adjacent areas), in functional reentry caused by anisotropy, the functional characteristic that is important is the difference in effective axial resistance to impulse propagation dependent on fiber direction. This mechanism has been classified as *anisotropic reentry*.[277] In its pure form, both the unidirectional conduction block and slow conduction in the reentrant circuit result from anisotropic, discontinuous propagation, and there is no need for variations in membrane properties such as regional differences in effective refractory periods or depression of the resting and action potentials.[242]

On the basis of the longitudinal and transverse conduction velocities of premature impulses in nonuniform anisotropic muscle and of measurements of refractory periods in these experiments, Spach and colleagues[242] calculated that circuits in nonuniform anisotropic bundles can be as small as 2 to 4 mm^2 (transverse velocity of 0.5 m/s, dissociated longitudinal velocity of 0.2 m/s) in the absence of nonuniformities in repolarization. Furthermore, anisotropic circuits are elliptical or rectangular because of the directional differences in conduction velocities with the long axis of the ellipse in the fast, longitudinal direction. Circuits with this shape can have a smaller dimension than do circular circuits such as the leading circle.[242] Anisotropic reentrant circuits usually remain in a fixed position to cause ordered reentry.[279] The degree of anisotropy (ratio of longitudinal to transverse conduction velocity) varies in different regions of the heart, and the circuit can reside only in a region where the conduction transverse to the longitudinal axis is sufficiently slow to allow reentry. Stability of anisotropic reentrant circuits also is assisted by the presence of an excitable gap that does not occur in the leading circle functional circuit. The excitable gap is caused by the sudden slowing of conduction velocity and a decrease in the wavelength of excitation as the reentrant impulse turns the corner from the fast longitudinal direction to the slow transverse direction and from the slow transverse direction to the fast longitudinal direction.[280,281]

Another type of functional reentrant excitation, called spiral waves, does not require any inhomogeneities of refractory periods as in leading circle reentry, inhomogeneities in conduction properties as in aniostropic reentry, or a central obstacle, whether functional or anatomic. Spiral waves originally were initiated in computer models of homogeneous elements or in various kinds of homogeneous excitable media (properties do not vary throughout the media), an example of which is molecular diffusion in a chemical system. Under appropriate circumstances, a pulse in two-dimensional, homogeneous, excitable media can be made to circulate as a rotor with a wavelength that is proportional to the square root of the diffusion coefficient of the media.[282-284]

Preexisting functional heterogeneities in conduction (or diffusion) properties or refractoriness (time course of recovery of excitability) are not prerequisites for the initiation of spiral waves in excitable media. The heterogeneity that allows initiation can result from a previous excitation wave and the pattern of recovery from that wave. When heterogeneities in recovery exist, the application of a second stimulus over a large geometric area to initiate a second excitation wave only excites a region where there has been sufficient time for recovery from the previous excitation, not regions that have not yet recovered. An excitation wave is elicited at the excitable site that is in the form of a rotor because the wave cannot move in the direction of the wake of the previous wave but only in the opposite direction, moving into adjacent regions as they in turn recover. The inner tip of the wavefront circulates around a disk of quiescent medium instead of a region of conduction block. The size of this disk expands as the medium is made less excitable.[282-284] The rotor, by definition, has a marked curvature, and this curvature slows down its propagation. A similar pattern of excitation can be induced in cardiac muscle.[285,286]

In the case of a curved depolarization wavefront (rotor) in excitable tissue such as cardiac muscle, slow conduction results from an increased electrical load; e.g., not only must a curved wavefront depolarize cells in front of it in the direction of propagation, but current also flows to cells on its sides. The slow activation by a rotor is not dependent on conduction in relatively refractory myocardium; therefore, there is an excitable gap despite the functional nature of reentry.[282] The location of the rotor can occur anywhere the second stimulated excitation encounters the wake of the first excitation with the appropriate characteristics.[287] Reentrant excitation that occurs during the initiation of ventricular fibrillation by strong electrical shocks[288,289] has characteristics consistent with spiral waves or rotors. These small circulating rotors are not stable and meet the criteria of random reentry. Spiral waves also may cause other kinds of arrhythmias. Even though nonuniform dispersions of refractoriness or anisotropy are not necessary for the initiation of reentrant excitation caused by rotors in excitable media, the myocardium, even when normal, is never homogeneous and the heterogeneities may modify the characteristics of the spiral waves.

Methods to Identify Mechanisms of Arrhythmias

INTRODUCTION

Since the early and classic experiments of Mayer[3,290] on reentry in the Medusa ring and later studies by Mines[4,291] on reentry in ring preparations cut from dogfish auricles or from canine right ventricles, it has been thought that mapping of the sequence of activation of the heart during tachycardia should provide the best evidence for the presence of a reentrant circuit. Even so, the admonition of Mines[291] that "the chief error to be guarded against is that of mistaking a series of automatic beats originating in one point of a ring [substitute "apparent reentrant circuit"] and traveling around it in one direction only owing to a complete block close to the point of origin of the rhythm on one side of this point" for reentrant beats must be kept in mind. The point, of course, is that even sequence of activation mapping may not provide definitive proof of the presence of reentry even though it provides evidence that is consistent with reentry. Mines suggested that severing the ring (again, substitute "the critical portion of the apparent reentrant circuit") and then demonstrating that no further reentrant excitation could occur were required for proof that reentrant excitation had been present. This, of course, has been accomplished in the example of AV reentrant tachycardia, with cure of the arrhythmia following catheter or surgical ablation of the accessory AV connection. Nevertheless, while "severing the ring" is both diagnostic and therapeutic when it can be accomplished to treat a tachyarrhythmia, it is virtually always clinically impractical as a diagnostic tool. Furthermore, until recently, precise sequence of activation cardiac mapping to identify reentry was quite difficult to perform, particularly in patients.

Although it is now possible to obtain remarkably precise maps of the sequence of cardiac activation in vivo by using simultaneous multisite mapping techniques, it is possible only with use of sophisticated recording techniques that require the chest to be open and the heart to be exposed. In fact, for the study of arrhythmias in the in situ heart, it is not routinely possible to obtain the direct electrical recordings (microelectrode studies, simultaneous multisite mapping, etc.) from the arrhythmogenic source that will enable one to determine the electrophysiologic mechanism causing the arrhythmias. A three-dimensional, sequential site-mapping system using a special endocardial catheter system has become available for use in mapping stable reentrant circuits. Indirect approaches have evolved that can provide information that suggests the mechanism of an arrhythmia. These approaches include (1) characterizing the arrhythmia from the ECG, (2) analyzing the response of the arrhythmia to selected forms of cardiac pacing, (3) analyzing the effects of selected pharmacologic agents on the arrhythmia, and (4) analyzing the results of radiofrequency ablation. Since cardiac pacing has long been an important tool in the study of mechanisms of both clinical and experimental arrhythmias and since it is also usually rather easy to apply, the following section presents a discussion of the use of this technique to identify the mechanism of an arrhythmia.

CARDIAC PACING TO DETERMINE ARRHYTHMOGENIC MECHANISMS

The mechanism of an arrhythmia in the in situ heart sometimes can be deduced from the response of the arrhythmia to cardiac pacing. Knowledge about the response of the different arrhythmogenic mechanisms to pacing is based largely on studies in which the effects of electrical stimulation were determined on transmembrane action potentials recorded with microelectrodes in isolated and superfused cardiac tissues. Critical to the ability to use the response to electrical stimulation to determine arrhythmia mechanisms is the requirement that the stimulated impulse(s) reach the site of origin of the arrhythmia. There are many reasons why this may not happen. The stimulated impulse(s) may not reach the site at which the arrhythmia arises because of the electrophysiologic properties of the intervening tissue between the stimulus site and the site of arrhythmia origin. An intervening region of prolonged refractoriness or depressed conduction may cause stimulated impulses to block before they reach the site of origin. If conduction time from

the stimulation site to the site of arrhythmia origin is prolonged for any reason, impulses generated in the arrhythmogenic focus also may be able to leave that focus and depolarize large regions of myocardium around it, preventing the stimulated impulse from reaching the site of arrhythmia origin. Even when the stimulation site is close to the site of arrhythmia origin, areas of depressed conduction may prevent the stimulated impulses from reaching the arrhythmogenic cells.

Two basic patterns of stimulation generally are used to study the mechanisms of arrhythmias: (1) overdrive pacing (pacing at a rate or rates faster than the spontaneous rate of the arrhythmia) and (2) introduction of a premature beat or beats by using programmed stimulation. With either technique, the effects of the stimulated impulses on the spontaneous rhythm are observed. Overdrive pacing generally is used during the arrhythmia to determine whether the overdrive can terminate it or, if it does not, to determine the effect of the overdrive on characteristics of the arrhythmia. Overdrive pacing sometimes is used during sinus rhythm to determine whether the period of stimulation can induce an arrhythmia that previously has occurred spontaneously.

The introduction of a premature beat or beats at selected intervals during electrical diastole by programmed stimulation of the heart can be performed either during the spontaneous arrhythmia to test the effects of the premature beats or during sinus rhythm or fixed-rate pacing to see if the arrhythmia can be induced.

EFFECTS OF ELECTRICAL STIMULATION ON ARRHYTHMIAS CAUSED BY AUTOMATICITY

The prior discussion of automaticity as an arrhythmogenic mechanism included a consideration of how the sinus node pacemaker and electrical stimulation (pacing) influence subsidiary pacemakers with different automatic mechanisms. Overdrive either by the sinus node or by electrical stimuli exerts an inhibitory effect on the normal automatic mechanism of subsidiary or latent pacemakers (overdrive suppression) that is primarily the result of enhanced Na^+-K^+ pump activity but has fewer inhibitory effects on the abnormal automatic mechanism of subsidiary pacemakers. These known effects of overdrive on pacemaker mechanisms are sometimes useful in distinguishing automatic arrhythmias from arrhythmias caused by reentry or triggered activity in the in situ heart. The effects of overdrive pacing also can be of use in distinguishing arrhythmias caused by normal automaticity from those caused by abnormal automaticity.[86] From the results of experimental studies, it can be assumed that arrhythmias caused by normal automaticity in the in situ heart cannot be initiated by overdrive pacing. Arrhythmias caused by normal automaticity can be suppressed transiently but cannot be terminated by overdrive pacing. Microelectrode studies on isolated superfused pacemaker tissues indicate that when overdrive pacing is applied during an ongoing arrhythmia caused by normal automaticity, the arrhythmia is expected to be suppressed transiently immediately after the overdrive pacing is stopped. This is manifest by a transient pause after overdrive and should be followed by a gradual speeding up of the rhythm (so-called warmup) until the original rate of the automatic rhythm is resumed. The duration of the transient pause and the time required for resumption of the original rate are expected to be directly related to the rate and duration of the overdrive. This behavior is mainly the result of the increased activity of the Na^+-K^+ pump, which is dependent both on the rate and on the duration of stimulation. This characteristic behavior of normally automatic pacemakers has been demonstrated in some clinical and experimental electrophysiologic studies of both atrial and ventricular tachycardias.[181,292,293]

Like normal automaticity, arrhythmias caused by abnormal automaticity can be neither initiated nor terminated by overdrive pacing. By contrast, arrhythmias caused by abnormal automaticity should not be suppressed by overdrive pacing unless the overdrive period is long and the rate of overdrive is fast.[86] The difficulty in suppressing such arrhythmias stems from the lesser amount of Na^+ entering the cells during the upstroke of the action potential and therefore less intense Na^+ pump stimulation by overdrive. Short periods of overdrive can even result in a transient speeding

of the rate of impulse generation (overdrive acceleration).[86] Accelerated idioventricular tachycardia in myocardial infarction is not easily overdrivesuppressed and therefore may be caused by abnormal automaticity.

The response of automatic arrhythmias to premature stimulation also is sometimes useful in distinguishing automaticity from other arrhythmogenic mechanisms. Of major importance, automatic rhythms caused by either normal or abnormal automaticity can be neither initiated nor terminated by premature stimuli, in contrast to reentry and triggered activity (discussed below). Other than that, premature impulses induced at different times during diastole may transiently perturb an automatic rhythm for a few cycles. The characteristics of the perturbation sometimes may distinguish automaticity from other arrhythmogenic mechanisms. The response of normal and abnormal automaticity to premature stimulation may be somewhat similar. The characteristic response of an automatic pacemaker to premature stimulation is best exemplified by the response of the sinus node to atrial premature stimulation.[294] Figure 23-20 plots the normalized return cycle (the cycle after the premature impulse) on the *y* axis versus the normalized premature cycle (test cycle) on the *x* axis for a study in which premature stimuli were applied to the atria of the human heart during sinus rhythm. The solid line (*A*) represents the line of identity; points falling on this line are compensatory (the sum of the premature cycle and the return cycle is equal to the sum of two spontaneous cycles). Premature impulses delivered late in the cycle length are followed by a compensatory pause and fall on this line (as the test cycle shortens, the return cycle lengthens in a reciprocal manner) because the premature impulses collide with the impulse emanating from the sinus node pacemaker without reaching and resetting the pacemaker. Therefore, the pacemaker discharge that follows the premature impulse occurs exactly on time. As the premature coupling interval is decreased, a point is reached in the basic cycle where the premature impulse reaches the pacemaker before it has depolarized spontaneously to threshold and depolarizes it early. The pacemaker is reset. When this occurs, the postextrasystolic cycle (which is a result of the stimulated or reset pacemaker cells spontaneously depolarizing to threshold) is less than compensatory and the points fall below the line of identity. For the most part, the postextrasystolic cycle length is expected to be equal to the unperturbed spontaneous cycle length. The dashed line (*B*) on the graph in Fig. 23-20 indicates the cycle length of the basic rhythm, and so the return cycle length relative to the basic cycle length can be seen to be somewhat longer in this study. The prolonged return cycle has been proposed to result from slowed conduction of both the premature impulse into the pacemaker site and the pacemaker impulse out of this site.[294] It also may result, at least partly, from depression of the rate of spontaneous diastolic depolarization. Further shortening of the premature coupling interval to midcycle results in points parallel to the dashed line and possibly slightly above it; this indicates no change in the postextrasystolic cycle length over a wide range of coupling intervals. Finally, conduction of very early premature impulses may block before reaching the pacemaker, and the next pacemaker discharge will again occur on time and be compensatory. Of course, this relationship might be upset by changes in conduction of impulses into and out of the pacemaker site. This relation between premature and return cycle length found in studies of sinus rhythm also has been shown in studies on some ectopic tachycardias and, when found, indicates that the tachycardias are likely to be caused by automaticity.[292,293,295]

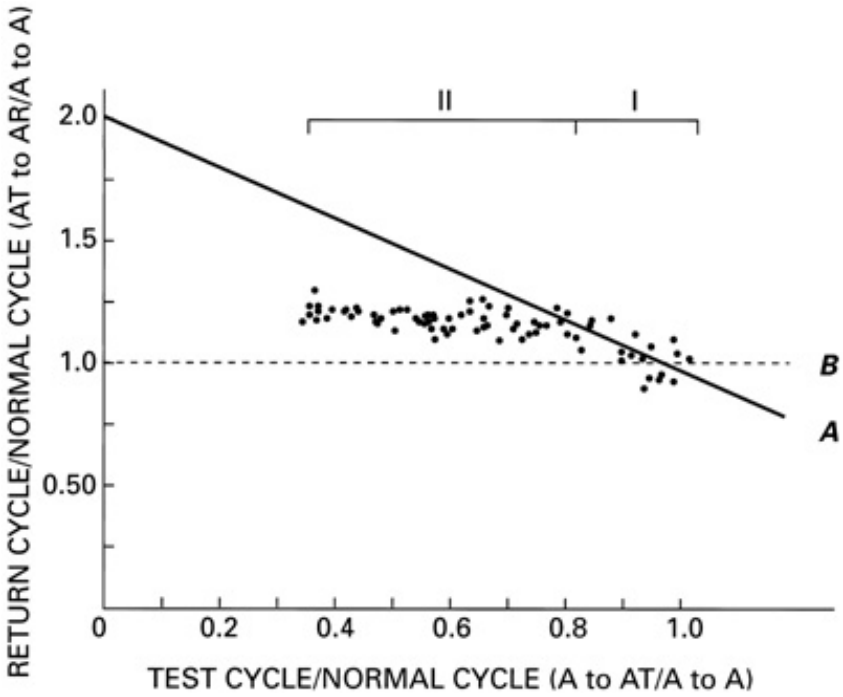

Figure 23-20: Return cycles as a function of premature stimulated cycles during premature atrial stimulation in a patient in sinus rhythm. The graph depicts the relation of the normalized return cycle to the degree of prematurity of the test cycle, which also is normalized. Points falling on line *A* represent nonreset of the sinus pacemaker (fully compensatory pause) and are in zone I. Premature stimulated atrial beats introduced earlier in atrial diastole fall in zone II. Line *B*, projected from the *y* axis, is a reference line indicating the spontaneous sinus cycle length. The distance the zone II points (reset points) are above line *B* is interpreted to indicate conduction time into and out of the sinus node, assuming the sinus node pacemaker cycle length immediately after the stimulated premature atrial beat is identical to the preceding sinus node pacemaker cycle length. (From Strauss HC et al. Premature atrial stimulation as a key to the understanding of sinoatrial conduction in man: A presentation of data and critical review of the literature. *Circulation* 1973; 47:86. Reproduced with permission from the publisher and author.)

Ectopic pacemakers also may exist in an extensive region of slow conduction, much as the pacemaker in the sinus node does, and conduction delays into and out of the pacemaker site may influence to some extent the relationship between the return cycle and the premature cycle. Conduction delays may cause some prolongation of the return cycle. When this relationship is seen, however, it is probably indicative of automaticity (either normal or abnormal), since triggered activity and reentry are expected to show a different behavior. In addition to the atrial arrhythmias discussed here, some ventricular arrhythmias are likely to be caused by automaticity. Idioventricular rhythms in patients with complete heart block respond in the manner shown in microelectrode studies of slowly beating Purkinje fibers; the postextrasystolic cycle that follows late premature impulses is longer than the cycle length of the basic rhythm but less than compensatory, while it is shorter than the basic cycle length that follows early premature impulses (and obviously less than compensatory).[296] Some exercise-provoked ventricular tachycardias also may be caused by normal automaticity.[297,298] By contrast, there is some evidence that accelerated idioventricular rhythms in the clinical setting of myocardial infarction may be caused by abnormal automaticity.

EFFECTS OF ELECTRICAL STIMULATION OF REENTRANT EXCITATION

A hallmark feature of a reentrant rhythm is that it usually can be induced and terminated by electrical stimuli (overdrive pacing, introduction of premature stimuli, or both), unlike automaticity. Initially it was thought sufficient to show that an arrhythmia could be initiated or

terminated by overdrive pacing or programmed stimulation to demonstrate a reentrant mechanism.[299] That was the case because until the 1970s the only other mechanism that was widely considered a cause of arrhythmias was automaticity, and automatic rhythms can be neither initiated nor terminated by pacing. After the 1970s, when the concept of afterdepolarization-induced arrhythmias was revived and expanded, these criteria alone were no longer sufficient, because triggered activity caused by DADs also can be initiated and terminated by pacing.

The induction of arrhythmias by overdrive pacing or the introduction of a premature beat or beats can be used as an indicator of a reentrant mechanism if other characteristics are also present that eliminate the probability of triggered activity that is dependent on DADs. The ability to demonstrate directly that the induction of an arrhythmia is related to a critical amount of slow conduction in the region where the arrhythmia originates adds credence to the interpretation that the arrhythmia is caused by reentry. The sudden large increase in the A-H interval associated with pacing induction of AV nodal reentrant tachycardia is one example. The induction of triggered activity caused by DADs is not dependent on slowed conduction and should not show this relationship. Also, when a tachycardia is initiated by the introduction of a premature beat over a wide range of coupling intervals, there may be an inverse relation between the coupling interval of the premature impulse and the interval from the premature impulse to the first impulse of tachycardia.[300-302] As the premature impulse occurs earlier in the cycle, its conduction through the reentrant pathway is slower, causing the return cycle to prolong. This too is not found with the induction of triggered activity resulting from DADs. Failure to initiate an arrhythmia by stimulated impulses does not per se eliminate reentry as a mechanism for the arrhythmia.

Another feature of reentrant arrhythmias is that they can be terminated by overdrive pacing or premature stimulation. This is not specific for reentry, since triggered activity caused by DADs also can be terminated. As with initiation, termination by overdrive pacing requires a critical rate and duration of the stimulation train, while termination with stimulated premature impulses requires a critical coupling interval between the premature impulse and the previous impulse of the tachyarrhythmia. Failure to terminate an arrhythmia by stimulated impulses does not by itself eliminate reentry as a mechanism for the arrhythmia. Termination of reentry requires that the stimulated impulse enter the reentrant circuit to cause the block of the reentrant wavefront, and this usually requires that the circuit have a fairly large excitable gap. Some reentrant circuits, particularly if they are caused by the leading circle mechanism of reentry, may not have a gap of excitability large enough to allow a premature impulse to penetrate readily into the circuits. If a tachycardia is very rapid, the excitable gap also may be very small, again preventing ready entry into the circuit by stimulated impulses.

Entrainment

In this context, the demonstration of transient entrainment of a tachycardia with or without its subsequent interruption is a relatively easy and reliable way to identify reentry as the mechanism of a tachyarrhythmia. Transient entrainment of a tachycardia was first described in 1977 during rapid pacing to interrupt type I atrial flutter.[303] At that time, although transient entrainment was not well understood, it was recognized as representing an increase in the rate of the tachycardia to the faster pacing rate, with resumption of the intrinsic rate of the tachycardia occuring upon either abrupt cessation of pacing or slowing of the pacing rate below the intrinsic rate of the tachycardia.[303] On the basis of a series of clinical studies during rapid pacing of atrial flutter,[303-306] ventricular tachycardia,[307-309] AV reentrant tachycardia involving an accessory AV connection,[310,311] AV nodal reentrant tachycardia,[312] and intraatrial reentrant tachycardia,[313] it was proposed that transient entrainment represents capture of a reentrant circuit by wavefronts generated by the pacing impulse without causing interruption of the tachycardia. This was confirmed during studies of transient entrainment in animal models of ventricular tachycardia[314-316] and atrial flutter[317,318] that utilized multiplexing techniques to record simultaneously from large numbers of electrodes in direct contact with cardiac tissue. During transient entrainment of a

reentrant tachycardia, the wavefront from each pacing impulse enters into the excitable gap of the reentrant circuit. Once there, it travels in two directions: (1) antidromically, i.e., in the opposite direction of the circulating reentrant wavefront of the spontaneous tachycardia, where it collides with the orthodromic wavefront of the preceding beat, and (2) orthodromically, i.e., in the same direction as the circulating reentrant wavefront of the spontaneous tachycardia, thus both continuing the tachycardia and resetting it to the pacing rate. This explanation is universal for transient entrainment of any tachycardia resulting from reentry with an excitable gap and is diagrammatically illustrated in Fig. 23-21.

The left panel of the figure is a diagrammatic representation of the reentrant circuit during a ventricular tachycardia (VT) at an assumed rate of 145 beats per minute. The *X*s represent the orthodromic wavefronts of the reentrant rhythm. The arrows indicate the direction of spread of the impulse, the box represents an area of slow conduction in the reentrant circuit, the serpentine line indicates slow conduction of the impulse in this latter area, and the dots represent recording sites along the course of the double arc of reentry from which ventricular electrograms (VEGs) are recorded.

The middle panel is a diagrammatic representation of the introduction of the first pacing impulse ($X + 1$) during ventricular pacing at a rate of 150 beats per minute during the VT. The antidromic (anti) wavefronts ($X + 1$) collide with the orthodromic wavefronts from the previous reentrant beat (X), resulting in fusion of ventricular activation. The orthodromic wavefront (ortho) from the pacing impulse ($X + 1$) continues the VT, resetting it to the pacing rate.

The right panel of the figure shows a diagrammatic representation of the introduction of the second pacing impulse ($X + 2$) during ventricular pacing at a rate of 150 beats per minute during the VT. The antidromic wavefronts ($X + 2$) collide with the orthodromic wavefronts from the previous paced beat ($X + 1$), again resulting in ventricular fusion. Once again, the orthodromic wavefront ($X + 2$) from the pacing impulse continues the VT, resetting it to the pacing rate.

CRITERIA TO ESTABLISH TRANSIENT ENTRAINMENT

Four criteria have been established (Table 23-2), any one of which, if demonstrated, establishes the presence of transient entrainment and thus the presence of a reentrant rhythm with an excitable gap. Figures 23-22 to 23-24 demonstrate the four criteria in diagrammatic fashion for the same ventricular tachycardia illustrated in Fig. 23-21. In Fig. 23-22, which illustrates the first criterion (Table 23-2), the left panel is a diagrammatic representation of the termination of ventricular pacing illustrated in Fig. 23-21. In the left panel, the large arrow indicates the wavefront from the last pacing impulse delivered at a rate of 150 beats per minute entering into the reentrant circuit of the ventricular tachycardia, where it is conducted orthodromically and antidromically. The antidromic wavefronts (X_n[a]) collide with the orthodromic wavefronts (X_n[o]) of the previous beat (X_{n-1}), resulting in the fusion of ventricular activation, but the orthodromic wavefront from the last pacing impulse (X_n[o]) continues and resets the tachycardia. The right panel shows that the orthodromic wavefronts from the last pacing impulse are now unopposed by any antidromic wavefronts because there is no subsequent pacing impulse. Thus, no fusion of ventricular activation occurs despite the presence of transient entrainment. This last entrained beat travels around the reentrant circuit, continuing the tachycardia.

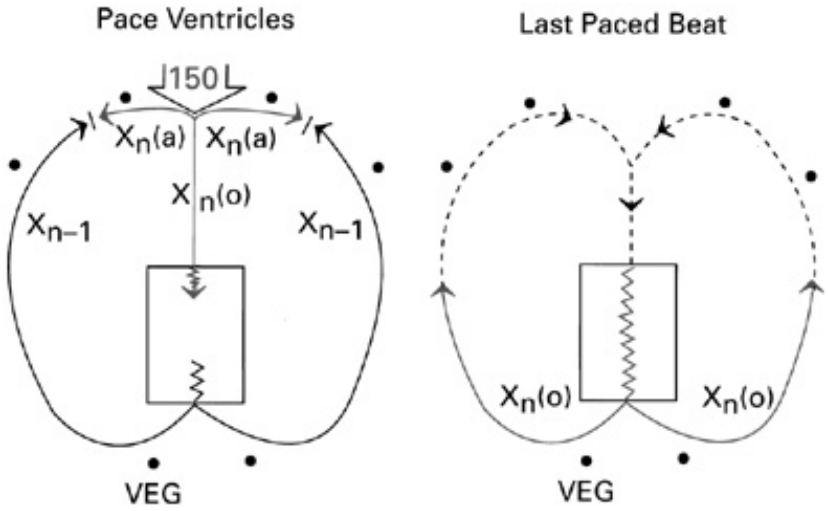

Figure 23-22: Diagrammatic representation of the first entrainment criterion during termination of ventricular pacing illustrated in Fig. 23-21. (From Waldo AL, Henthorn RW. Use of transient entrainment during ventricular tachycardia to localize a critical area in the reentry circuit for ablation. *PACE* 1989; 12:231. Reproduced with permission from the publisher and authors.)

Table 23-2: Criteria to Establish the Presence of Transient Entrainment

1. The demonstration of constant fusion beats in the ECG during the period of rapid pacing at a constant rate except for the last captured beat, which is entrained but not fused (i.e., the last entrained beat demonstrates the ECG morphology of the spontaneous tachycardia)
2. The demonstration of constant fusion beats in the ECG during rapid pacing at any constant rate but different degrees of constant fusion at different rapid rates, i.e., progressive fusion
3. Interruption of the tachycardia associated with localized conduction block to a site(s) for one beat, followed by subsequent activation of that site(s) from a different direction, which manifests itself by a change in morphology of the electrogram at the blocked site(s) and with a shorter conduction time
4. A change in conduction time to and electrogram morphology at one recording site when pacing from another site at two different constant pacing rates, each of which is faster than the spontaneous rate of the tachycardia but fails to interrupt it

---

Figure 23-23 is a diagrammatic representation of entrainment in the same ventricular tachycardia during pacing from the same site proximal to the area of slow conduction of the reentrant circuit at rates of 150 (left panel), 155 (middle panel), and 160 beats per minute (right panel), demonstrating both the second and the fourth entrainment criteria. When pacing is at a rate of 155 beats per minute, the pacing cycle length is shorter than it is at 150 beats per minute, so that the antidromic wavefront from each pacing impulse will penetrate the excitable gap of the reentrant circuit to a further degree in an antidromic direction compared to 150 beats per minute, resulting in a degree of fusion of the QRS complex in the ECG different from that which occurs at a rate of 150 beats per minute. As a result, the QRS complex morphology in the ECG during pacing at 155 beats per minute will be different than it is at 150 beats per minute. This, then, is the demonstration of progressive fusion (Table 23-2). When pacing is at 160 beats per minute, once again the antidromic wavefront from each pacing impulse will collide with the orthodromic wavefront, but at yet a different site. This occurs because the pacing cycle length is shorter than pacing at the previous rates, permitting greater penetration of the excitable gap by the antidromic

wavefront of the pacing impulse, illustrating yet more progressive fusion.

These diagrams also illustrate the fourth criterion (Table 23-2): A site or sites activated by the orthodromic wavefront of each pacing impulse during entrainment at one pacing rate will be activated by the antidromic wavefront of each pacing impulse during entrainment at a faster pacing rate. This will be manifest by both a change in the morphology of the electrogram recorded at the site in question (it will have the same morphology during the tachycardia that it has during pacing at the rate that results in activation of the site by the orthodromic wavefront but a different morphology when activated by the antidromic wavefront of the pacing impulse at a faster pacing rate) and a change in conduction time to the recording site from the pacing site (the stimulus-to-recording site interval will be longer when activated by the orthodromic wavefront of each pacing impulse than when activated by the antidromic wavefront of each pacing impulse). Thus, note that the two middle recording sites denoted by black dots on each side of the reentrant circuit become activated in turn from a different direction and with a shorter conduction time when the pacing rate is increased from 150 to 155 beats per minute and then to 160 beats per minute.

Figure 23-24 is a diagrammatic representation of the third criterion and shows the events during interruption of the ventricular tachycardia by ventricular pacing at a rate of 165 beats per minute. In the left panel, the large arrow indicates the wavefront from the pacing impulse delivered at a rate of 165 beats per minute entering into the reentrant circuit of the ventricular tachycardia, where it is conducted orthodromically ($X + 1$[o]) and antidromically ($X + 1$[a]). The antidromic wavefronts collide with the orthodromic wavefronts from the previous beat (X), resulting in fusion of ventricular activation. Note that this fusion of ventricular activation is at still a site different from the site during pacing at the previous pacing rates (Fig. 23-23). Thus, initially there is still more progressive fusion of the QRS complex morphology in the ECG. This time, however, the orthodromic wavefront does not reset the tachycardia to the pacing rate. Rather, it too is blocked, presumably in the area of slow conduction, during the same beat. Note that each recording site on each of the two arcs of reentry immediately distal to the area of slow conduction is activated by the orthodromic wave front of the previous beat (X) but is not activated by $X + 1$ because the orthodromic wavefront ($X + 1$[o]) never reaches either site (there is localized conduction block for one beat). In the right panel, the large arrows indicate the next pacing impulse ($X + 2$) delivered at the same pacing rate (165 beats per minute) from the same pacing site described in the left diagram. The dashed lines indicate the reentrant circuit present during the previous periods of ventricular tachycardia and transient entrainment of the ventricular tachycardia. Because the ventricular tachycardia has been interrupted by the previous pacing impulse ($X + 1$), the sequence of ventricular activation of the next pacing impulse ($X + 2$) is as one would expect during overdrive pacing of sinus rhythm from that same ventricular pacing site. Therefore, the two electrogram recording sites immediately distal to the previous (but no longer present) area of slow conduction are now activated from a direction different from that during transient entrainment. In addition, because the presumed area of slow conduction is no longer functionally present, the stimulus-to-right-ventricular conduction time is shorter. Thus, the requirements for the third criterion of entrainment are fulfilled (Table 23-2).

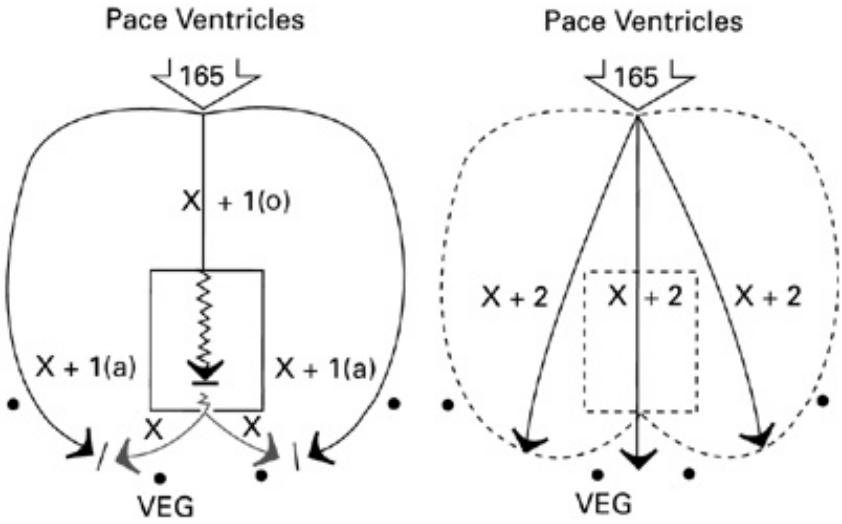

Figure 23-24: Diagrammatic representation of the third entrainment criterion during interruption of the ventricular tachycardia by ventricular pacing at a rate of 165 beats per minute. (From Waldo AL, Henthorn RW. Use of transient entrainment during ventricular tachycardia to localize a critical area in the reentry circuit for ablation. *PACE* 1989; 12:231. Reproduced with permission from the publisher and authors.)

Although these illustrative diagrams show the example of transient entrainment and interruption of ventricular tachycardia, the principles are the same for all the putative reentrant rhythms. For AV nodal reentrant tachycardia, however, only the third criterion has been demonstrated,[312] presumably because there is no ECG manifestation of AV nodal activation, and recording directly from the AV node using surface electrograms has not been reliably demonstrated. Although the phenomena associated with transient entrainment of a tachycardia with or without its subsequent interruption are best explained by reentry, it still must be asked whether any or all of the criteria for the demonstration of transient entrainment can be explained by another mechanism. Present understanding of the response of automatic and triggered rhythms to rapid pacing is not consistent with the phenomena observed during transient entrainment (Table 23-2). Automatic rhythms also should not be interrupted by pacing.

CONCEALED ENTRAINMENT

While the ability to demonstrate transient entrainment of a tachycardia provides an important and powerful tool for the identification and study of reentrant tachyarrhythmias, a limitation is that it is not always possible to demonstrate any of the transient entrainment criteria despite the fact that rapid pacing may indeed have entrained and even interrupted the tachycardia. This phenomenon, called *concealed entrainment*,[309,311] can result when pacing is performed from a site that is orthodromically distal to the area of slow conduction in the reentry circuit, when pacing is done from a site that is rather distant from the reentrant circuit, or when pacing is done from an area of slow conduction in the reentrant circuit.[309,311,319-321]

To label a response of a tachycardia to rapid pacing as concealed entrainment, except in the example of pacing from an area of slow conduction in the reentry circuit, one also must show that transient entrainment can be demonstrated when pacing is from another site. Thus, it is clear that unless one is able to pace from an appropriate site, a reentrant circuit with an excitable gap may be present, but entrainment, though present, will not be demonstrable.

Resetting

The response of an arrhythmia to a prematurely stimulated impulse that does not terminate the

arrhythmia still may provide information useful for determining the mechanism of the arrhythmia. Information on the effects of stimulated premature impulses on reentry comes from studies on experimental preparations of isolated tissues or hearts in which reentrant excitation has been mapped. Other predictions concerning the effects of premature impulses on reentry are based mainly on theoretical considerations using a model of a reentrant circuit with a fixed pathway in which the circuit cannot change its dimensions and in which there is an excitable gap. Such circuits may have a single entrance and exit pathway leading into and out of the circuit, as illustrated in Fig. 23-25, or the entrance and exit pathways may be separate. These characteristics will influence the characteristics of the resetting response as seen on the ECG.

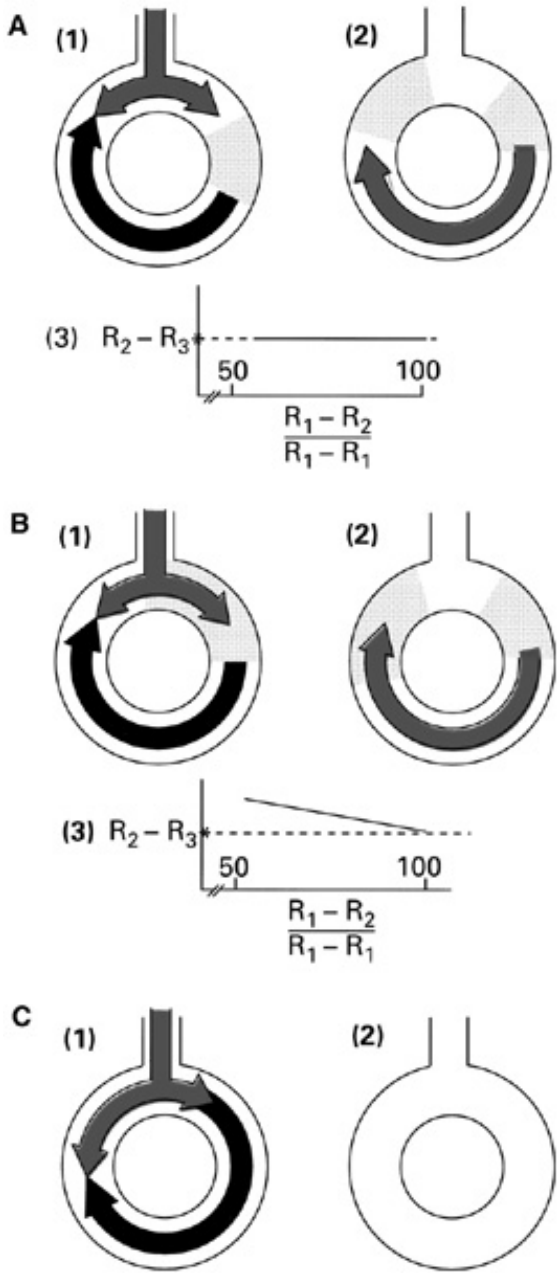

Figure 23-25: Effects of premature impulses on reentrant circuit with an excitable gap. In each panel, diagrams are shown of an anatomic circuit with a single entrance route from above. In *A*(1), *B*(1), and *C*(1), red arrows in the circuit represent the reentrant impulse causing tachycardia. The length of the arrow is the wavelength of the impulse and shows the part of the circuit that is completely refractory, The part of the circuit that is stippled is relatively refractory, and the part of the circuit that is clear is completely excitable (the fully excitable gap). Red arrows entering the

circuit from above represent a prematurely stimulated impulse initiated outside the circuit. *A*(2) and *B*(2) show conduction of the premature impulse in the circuit. Graphs show the expected relation between the return (premature impulse) cycle length (R_2-R_3) and the premature coupling interval (R_1-R_2/R_1-R_1) for premature impulses conducting in the fully excitable gap *A*(3) and in the relatively refractory tissue of a partially excitable gap *B*(3). (Modified after Wit AL, Janse MJ. *The Ventricular Arrhythmias of Ischemia and Infarction: The Electrophysiological Mechanisms*. Mount Kisco, NY: Futura; 1992:135. Reproduced with permission from the publisher and authors.)

The theoretically possible responses of a tachycardia caused by reentrant excitation to premature stimulation are explained in the diagram in Fig. 23-25. An anatomic circuit with fixed dimensions and a single entrance pathway is diagrammed. In this diagram, the entrance pathway also serves as an exit pathway for the reentrant wavefront to enter surrounding myocardium, but other models may have separate entrance and exit pathways. The black arrow in the reentrant circuit represents the reentrant impulse, with the arrow point being the crest of the depolarizing wave and the end of the arrow being the tail. The length of the arrow is the absolutely refractory part of the circuit, the dotted area that trails it is the relatively refractory part, and the clear region is the fully excitable gap (in some instances there may be no fully excitable gap in the reentrant circuit). The transit time of the reentrant impulse around the circuit determines one cycle length of the tachycardia (the R_1-R_1 interval).

In panel *A*(1), a stimulated premature impulse (R_2) (red arrow from above) is shown to reach the circuit and enter it in the region of the fully excitable gap. The stimulated premature wavefront may then propagate both in the orthodromic (to the right) and antidromic (to the left) directions in the reentrant pathway. In the antidromic direction, it collides with the oncoming reentrant wavefront, extinguishing both stimulated and reentrant impulses at the point of collision. In the orthodromic direction, the stimulated impulse becomes the reentrant impulse and propagates through the circuit in completely excitable tissue of the gap (which also moves around the circuit), as shown in panel *A*(2). This stimulated reentrant wavefront would leave the circuit through the normal exit route and become the next tachycardia impulse.

Since the stimulated impulse traveled through the circuit in completely excitable tissue at a normal conduction velocity, the interval between the stimulated impulse (R_2) and the next impulse of tachycardia (R_3) is equal to the normal transit time around the circuit or the normal tachycardia cycle length (R_1-R_1). The rhythm, however, is reset; i.e., the sum of the curtailed (premature) cycle length and the return cycle length (R_1-R_2 + R_2-R_3) (first poststimulus cycle) is less than two cycle lengths of the tachycardia [2(R_1-R_1)]. This holds throughout the range of premature coupling intervals at which the stimulated premature impulse is able to conduct around the circuit at a normal velocity in completely excitable tissue. Thus, a plot showing the relationship between the premature coupling intervals and the return (poststimulus) cycles over this range appears as a flat line. This plot is shown in Fig. 23-25*A*(3). The poststimulus cycle length is the R_2-R_3 interval on the *y* axis. The normalized premature coupling interval is represented by R_1-R_2/R_1-R_1 on the horizontal axis where R_1-R_1 is the basic cycle length of the tachycardia. In this graph, R_2-R_3 remains constant (and equal to R_1-R_1) over the entire range of premature coupling intervals, indicating conduction of the premature impulse in completely excitable tissue. Premature impulses entering the circuit in the relatively refractory part of the excitable gap (stippled region in the circuit) shown by the red arrow from above in Fig. 23-25*B*(1) also collide with the reentrant impulse in the antidromic direction, extinguishing it while conducting in the orthodromic direction. But conduction around the circuit is slower than normal because the impulse is activating relatively refractory tissue, as indicated by the stippled area in Fig. 23-25*B*(2). Therefore, the return (poststimulus) cycle, which is dependent on the conduction time of the stimulated impulse in the circuit, is longer than the tachycardia cycle.

As the coupling interval of the stimulated premature impulse is decreased and this impulse enters the circuit earlier and earlier in the relatively refractory period of the excitable gap, conduction time around the circuit and the return cycle progressively increase. Thus, a plot showing the relation between the premature coupling interval and the return cycle length appears as shown in Fig. 23-25*B*(3). The line representing the R_2-R_3 interval increases as the normalized premature coupling interval (R_1-R_2/R_1-R_1) decreases. It is also apparent on the graph that the conduction time of the premature impulse around the circuit as measured by the R_2-R_3 interval is greater than the conduction time of the normal tachycardia impulse around the circuit, which is indicated by the dashed line. The sum of the premature and return cycle may be less than or greater than compensatory, depending on how slow conduction of the premature is around the circuit. More often, despite slowing of the conduction of the premature impulse in the circuit, the prolonged return cycle does not compensate for the shortened premature cycle.[322-325]

Panel *C* shows what happens when an earlier premature impulse, indicated by the red arrow from above, reaches the circuit when it is even less excitable. It conducts antidromically into the circuit and collides with the wavefront of the reentrant impulse but cannot excite the orthodromic path because it blocks in refractory tissue (black tail of the reentrant impulse). Thus, reentry is terminated, as shown in *C*(2). The range of coupling intervals over which there is evidence that the premature impulse entered the reentrant circuit to reset the tachycardia before the termination of reentry is a rough measurement of the duration of the excitable gap at the entrance route into the circuit if the premature stimuli are applied close to the circuit.[325] Therefore, fixed reentrant circuits with excitable gaps have patterns of responses to premature stimulation that are characteristic of this mechanism.

In sum, the stable tachycardia cycle length (R_1-R_1) is determined by the time it takes the reentrant wavefront to travel one complete revolution around the circuit and reach an exit pathway to the ventricles. When such a circuit is the cause of a tachycardia, premature depolarizations delivered late in the cycle length often are followed by a postextrasystolic pause that is compensatory for the same reason described for automatic tachycardias; i.e., the stimulated impulse may not be able to reach the reentrant circuit, possibly as a result of collision between the stimulated impulse and the impulse coming from the circuit. The next tachycardia impulse then comes precisely on time. In this case, the tachycardia is not reset since the sum of the premature cycle length and the return cycle length is equal to two successive premature cycle lengths. Over the range of premature coupling intervals that do not reset the tachycardia, the relation between the premature coupling interval and the following (return) cycle falls along the line of identity (see Fig. 23-20).

Premature impulses delivered earlier in the tachycardia cycle may have several different effects that are dependent on some of the characteristics of the reentrant circuit. If there is virtually no excitable gap, as might be expected in some functional circuits, no resetting of the tachycardia will occur, since the stimulated impulse cannot enter the circuit and the return cycle will remain compensatory. If the excitable gap is partially excitable, e.g., composed of relatively refractory tissue, premature impulses that succeed in entering the circuit and traveling around it will do so at reduced conduction velocities, as diagrammed in Fig. 23-25*B*.[326] When they emerge from the circuit, they cause the first postextrasystolic (tachycardia) impulse. As a result of the slowing of conduction of the premature impulse around the circuit, the postextrasystolic cycle is longer than the basic cycle [represented by the dashed line in Fig. 23-25*B*(3)].

The conduction time of the premature impulse around the circuit should continue to increase as the premature impulse is delivered earlier and earlier in the cycle, since the premature impulse conducts in more refractory tissue, causing an inverse relation between the premature coupling interval and the postextrasystolic cycle [Fig 23-25*B*(3)]. In the study of Bigger and Goldreyer[301] on AV nodal reentrant tachycardia, the prolongation of the postextrasystolic cycle over the entire range of premature coupling intervals was sufficient to result in a greater than compensatory pause

after the premature impulse. However, the postextrasystolic cycle length can be less than compensatory. An inverse relation between the premature interval and the return cycle interval caused by slowing of the conduction of the premature impulse in the reentrant circuit, as shown in Fig. 23-25*B*(3), is indicative of reentry, since this type of response does not occur with automaticity or triggered activity. Recall that for automatic impulse initiation, the return cycle length is fairly constant over a wide range of premature coupling intervals. If there is a large fully excitable gap, premature impulses reaching the circuit are expected to conduct around the circuit with the same velocity as the reentrant wavefront that is causing the tachycardia, and the postextrasystolic cycle will be equal to the tachycardia cycle and less than compensatory [Fig. 23-25*A*(1) and *A*(2)]. This could occur over a relatively wide range of coupling intervals, resulting in a relationship similar to that expected from a pacemaker over the intermediate range of coupling intervals; the line describing the relationship of the return cycle to the premature cycle would be flat [Fig. 23-25*A*(3)]. Eventually, it is expected that stimulated extrasystoles that are sufficiently premature will invade the circuit when it is relatively refractory, resulting in prolonged return cycles that are inversely related to the premature coupling intervals.

The prolongation of the postextrasystolic cycle after early premature impulses is opposite to that which occurs during automaticity. Thus, a curve might be plotted that consists of a segment that is compensatory at long premature coupling intervals (because the stimulated impulse does not reach the circuit), a segment that is less than compensatory and flat at intermediate premature coupling intervals (when the stimulated impulse is conducting in completely excitable tissue in the circuit), and a segment that is ascending at short premature coupling intervals (when the stimulated impulse is conducting in relatively refractory tissue in the circuit). Still earlier premature impulses might block before reaching a circuit, resulting in interpolation, as described for an automatic focus. A sufficiently early premature impulse also could terminate the tachycardia by blocking in the circuit and causing block of the reentrant wavefront. This is not expected of automatic impulse initiation.

As was mentioned above, the entrance route a stimulated impulse takes into a reentrant circuit and the exit route from the circuit may be separate. When this occurs, the return cycle that follows a premature impulse may be less than the tachycardia cycle because the premature impulse, after entering the circuit, need not conduct around the entire circuit before exiting. The return cycle still may show any of the relationships to the premature cycle described in Fig. 23-25; i.e., it may be flat or show an inverse relationship to the premature coupling interval, depending on whether it is conducting in partially or fully excitable tissue. This expected effect of premature impulses on the cycle length of reentry also may be altered in a functional circuit if the premature impulse somehow can cause a change in the size or shape of the circuit. It is not possible to predict what the effects would be.

In summary, the relation between the postextrasystolic cycle and the curtailed cycle when premature impulses are introduced during a tachycardia caused by reentry may be different from that during automaticity. Therefore, premature stimulation during the study of a tachycardia may provide useful information that helps determine whether reentry is the mechanism. There are, however, a number of confounding influences that, if present, can upset the theoretically predicted relation. They include the absence of a fully excitable gap and properties of intervening tissue between the stimulus site and the site of the circuit that can slow or block conduction of premature impulses into and out of the circuit. Therefore, failure to find the relationships expected for a reentrant mechanism does not necessarily mean that the arrhythmia is caused by a mechanism other than reentry.

EFFECTS OF ELECTRICAL STIMULATION ON ARRHYTHMIAS CAUSED BY TRIGGERED ACTIVITY

Arrhythmias Caused by Delayed Afterdepolarizations

The amplitude of DADs increases with a decrease in the cycle length at which the action potentials occur until the afterdepolarizations reach threshold to cause the triggered activity. Therefore, triggered arrhythmias caused by DADs in the in situ heart should be initiated by either overdrive pacing or programmed premature stimulation. Since automatic arrhythmias are not initiated by pacing, they should be distinguished readily from triggered arrhythmias caused by DADs. Reentrant arrhythmias also can be induced by the same stimulation protocols, however, and so whether there are any other characteristics during arrhythmia induction by pacing that might distinguish between triggered activity and reentry is important. An attempt to distinguish between the two mechanisms is further complicated by the fact that triggered activity caused by DADs may be due to different causes, e.g., digitalis and catecholamines, each with somewhat different characteristics.

The following guidelines have been proposed to assist in distinguishing DAD-induced triggered activity from other causes of arrhythmias.[327,328] The guidelines are based on the characteristics of triggered activity determined from in vitro studies with microelectrodes. Triggered activity caused by DADs has been more easily induced by rapid pacing or by several successive premature stimuli than by a single premature stimulus in studies of isolated tissue preparations. This characteristic, which should be expected to occur in the in situ human heart, probably is explained by the fact that rapid pacing or the introduction of a number of premature stimuli is more effective than a single premature stimulus in increasing intracellular Ca^{+} levels. The Ca^{+} levels control the afterdepolarization amplitude. Also, arrhythmias caused by triggered activity should be more easily induced by premature stimuli superimposed on a rapid drive rate than on a slow one because during rapid pacing, the afterdepolarization amplitude is larger and the membrane potential at the peak of the afterpolarization is closer to threshold. In contrast, ordered reentrant rhythms in humans (with the exception of atrial flutter) seem to be more easily and reproducibly induced by premature impulses than by rapid pacing, although several premature impulses in succession sometimes are necessary. One reason for this may be that premature impulses block more effectively in areas with long refractory periods than do impulses during rapid pacing because rapid pacing can shorten refractory period duration. This, of course, is important because block is a prerequisite for the initiation of reentry.

Both extrasystoles and the first beat of a tachycardia, when caused by DAD-dependent triggered activity initiated by pacing, are predicted to occur late in the cardiac cycle.[327] This proposal is based on experimental data from studies of isolated tissue that show that DADs rarely reach their peak amplitude at less than 50 percent of the cardiac cycle when the drive cycle length is shorter than 1000 ms. In contrast, reentrant beats often occur early in the cycle. One would expect a direct relationship between the pacing cycle length that induces triggered activity resulting from DADs and the coupling interval from the last stimulated impulse to the first beat of the induced tachycardia. As the pacing cycle length decreases, the coupling interval from the last stimulated impulse to the first impulse of tachycardia should decrease because at short cycle lengths, the coupling interval of the afterdepolarizations to the proceeding action potential decreases.

A direct relationship between pacing cycle length and the coupling interval of the first impulse of the tachycardia has been shown to occur in arrhythmias caused by digitalis toxicity.[329] This relationship sometimes may be complicated by the presence of two afterdepolarizations and the possibility of a triggered impulse arising from either one.[330] No comparable data are available from pacing studies on digitalis-toxic human hearts. The direct relation also has been shown in some cases of idiopathic ventricular tachycardia believed to be caused by triggered activity.[166] A direct relation like this is not expected during the initiation of reentrant arrhythmias. Failure to show the direct relation, however, cannot be taken as proof that the arrhythmia is not caused by triggered activity, since slow conduction into or out of the triggerable focus can distort it. In microelectrode studies, during the initiation of triggered activity with premature stimuli, no significant effects of the premature stimulus coupling interval were observed on the relation (coupling interval) of the first triggered impulse to the premature stimulus.[188] On the basis of

these data, it is expected that during the initiation of arrhythmias caused by triggered activity in situ with programmed premature stimulation, the coupling interval of the first beat of tachycardia should remain relatively constant over a range of coupling intervals of introduced premature impulses. The response to premature stimulation is also contrary to that expected during the initiation of reentrant arrhythmias, where an inverse relation is expected between the premature stimulus coupling interval and the coupling interval between the premature impulse and the first impulse of tachycardia.

Triggered arrhythmias, unlike automatic arrhythmias but like reentrant arrhythmias, are predicted to be terminated by cardiac pacing. Single premature impulses may terminate triggered arrhythmias, but on the basis of the results of microelectrode studies, termination should be infrequent and not usually reproducible at the same critical premature cycle length. In contrast, single premature impulses often terminate reentrant arrhythmias in a reproducible manner and over a consistent range of premature cycle length in any single individual as long as the reentrant circuit has an excitable gap.[331,332] Therefore, an arrhythmia that is terminated readily by a single prematurely stimulated impulse is more likely to be caused by reentry than by triggered activity.

The effects of premature impulses that do not terminate sustained triggered activity also have been determined.[191] The response is almost identical to that of automaticity. The return cycle length remains fairly constant over a wide range of premature coupling intervals and is nearly the same as the cycle length of the basic triggered rhythm (less than compensatory). By contrast, overdrive pacing should terminate triggered arrhythmias caused by afterdepolarizations. This termination requires a critical rate and duration of overdrive,[186-188] just as it does with reentry.[302,303,307] Overdrive stimulation may cause acceleration of triggered arrhythmias followed by gradual slowing and termination, or rapid overdrive may cause abrupt termination. Although reentrant rhythms may be accelerated by overdrive pacing, a gradual slowing of the rate before termination is not expected. Overdrive pacing that does not terminate triggered activity, as occurs when the cycle length of the overdrive is too long or when the duration of trains of stimuli are too short, does not entrain the arrhythmia either.[333] In fact, none of the characteristics of entrainment are expected during overdrive pacing of triggered activity caused by DADs.

It therefore is apparent that although the response of triggered arrhythmias caused by DADs to stimulation can be predicted from experimental studies, there is no single feature that would positively allow a triggered rhythm to be distinguished from reentry except entrainment. Since the characteristics of initiation and termination of triggered rhythms by stimulation are very different from the characteristics of automatic rhythms, it should be easier to distinguish between these mechanisms by using pacing techniques. This differentiation may be made more difficult when an arrhythmia is persistent and the initiation cannot be studied. Also, entrance block of stimulated impulses into arrhythmogenic foci, whether automatic, triggered, or reentrant, may negate the use of pacing techniques to distinguish between these mechanisms.

The characteristics of some clinical arrhythmias occasionally conform to those expected of DAD-dependent triggered activity.[128,334] In addition to digitalis toxicity, an example is some cases of exercise-induced ventricular tachycardia in patients with no structural heart disease.[166,298] This tachycardia, which occurs spontaneously during exertion, sometimes can be initiated by overdrive pacing or programmed premature stimulation. An isoproterenol infusion during stimulation may be required for successful initiation. Lerman and coworkers[166] proposed that these tachycardias are caused by a catecholamine-induced increase in cyclic AMP, which is known to cause DADs. Evidence supporting this hypothesis is provided by the termination of tachycardias by intravenous injection of adenosine, which antagonizes the electrophysiologic effects of catecholamines mediated through the adenylate cyclase-cyclic AMP system. Jackman and associates[335] proposed that some forms of ventricular tachycardia associated with the congenital long QT syndrome and dependent on adrenergic stimulation result from triggered activity caused by DADs. Cranefield and Aronson[128] provided a detailed review of the clinical arrhythmias that may be caused by

triggered activity (see Chap. 27).

Arrhythmias Caused by Early Afterdepolarizations

Arrhythmias caused by EADs should not be inducible by overdrive pacing, similar to automatic arrhythmias and unlike arrhythmias caused by DADs or reentry. Similarly, triggered activity dependent on EADs is not expected immediately to follow the short cycle length of one or several prematurely stimulated impulses. As has been shown in experimental studies, the appearance of EAD-induced triggered activity is facilitated by long cycle lengths. Therefore, this kind of triggered activity should be initiated by slowing the basic heart rate. Of course, if an increase in heart rate caused by pacing resulted in entrance block into a focus where EADs occur, the block could cause a prolongation of the cycle length in that focus that might result in triggered activity.[128] Prematurely stimulated impulses also may initiate triggered activity if there is a long compensatory pause after the stimulated impulse. The long cycle might trigger an arrhythmia that would follow it.[128] In the absence of such entrance block, bursts of tachycardia caused by EADs should occur more frequently when the heart rate is slowed, and pacing the heart at rates faster than the basic underlying rhythm is predicted to cause disappearance of the period of tachycardia. Increasing the basic heart rate shortens action potential duration and thereby suppresses EADs. When the pacing is stopped, arrhythmias should reappear, as the action potential returns to its original duration. The reappearance of the arrhythmias may not be immediate, however, since it requires some time for the action potential duration to lengthen owing to the enhanced pump current that follows a period of rapid stimulation.

Many of these characteristics have been shown to apply to the experimental triggered arrhythmias caused by cesium in the in situ canine heart[199] and have been demonstrated in some cases of torsades de pointes in human patients. Acquired forms of the syndrome (e.g., prolonged QT and torsades de pointes by quinidine) exhibit all the features expected of triggered activity caused by EADs, whereas other forms (e.g., congenital) may not be due to this mechanism.[336] Torsades de pointes invariably occurs after a preceding long R-R interval,[200] is unlikely to be initiated by programmed stimulation,[337] and can be prevented from occurring by pacing the heart at a rapid rate.[200,337] Parenthetically, it has been suggested that such rhythms are initiated by EADs but maintained by reentrant excitation.[219] In contrast, triggered arrhythmias caused by DADs may become more frequent as heart rate increases,[327] and the effect of increasing the heart rate on extrasystoles caused by reentry is variable; i.e., reentry may be exacerbated or may stop.[222]

There may be some difficulty in distinguishing EAD-dependent triggered arrhythmias from automatic arrhythmias only on the basis of their response to electrical stimulation, however, since the occurrence of automatic arrhythmias is facilitated by slow heart rates and increasing the basic heart rate by overdrive pacing may cause disappearance of automatic arrhythmias during the periods of pacing. The ECG characteristics of arrhythmias caused by triggered activity resulting from EADs and by automaticity may be of additional help. The triggered rhythms are more likely to occur in bursts or salvos of different lengths, with the first few cycle lengths of a burst decreasing progressively and the last few cycle lengths increasing progressively.

Triggered arrhythmias caused by EADs not only may occur in bursts but also may be sustained. When sustained, their response to single premature stimuli or overdrive pacing can be predicted on the basis of the results of in vitro studies. Some arrhythmias may be terminated by premature stimuli, but this should be a relatively rare occurrence. The effects of premature stimulated impulses that do not terminate the arrhythmia are expected to be the same as their effects on automatic impulse initiation. Some arrhythmias also may be terminated by overdrive pacing, but termination should not be the usual effect. When termination occurs, it is expected to follow the overdrive immediately, whereas termination of triggered activity caused by DADs sometimes may be preceded by up to 10 triggered "afterbeats."[186,187] When termination does not occur, overdrive is not expected to cause any significant effect on the rhythm; the response should be more like that

of an arrhythmia caused by abnormal automaticity[191] than one caused by normal automaticity, which is readily overdrive-suppressed.[73] Because of this variability of response, stimulation during a sustained tachycardia caused by EADs is not much help in determining the mechanism.

Therefore, as in the triggered arrhythmias caused by DADs, there is no single feature in the response to cardiac pacing that would positively enable EAD-induced triggered rhythms to be distinguished from other arrhythmogenic mechanisms. Early afterdepolarization-induced nonsustained arrhythmias usually can be differentiated from rhythms induced by DADs or automaticity at high membrane potentials and sometimes from reentry by pacing, but the response of sustained triggered activity to pacing is often indistinguishable from abnormal automaticity at low membrane potentials.

SUMMARY OF EFFECTS OF ELECTRICAL STIMULATION

Despite the fact that there are exceptions and inconsistencies to virtually all the rules that can be proposed to distinguish among the different arrhythmogenic mechanisms using pacing techniques, determining the effects of electrical stimulation is quite useful. The following is a summary of the most important points: (1) Initiation of a tachycardia by stimulation indicates that the arrhythmia is caused by reentry or delayed afterdepolarization-induced triggered activity. Other characteristics of initiation are then useful in distinguishing between the two. Other mechanisms of arrhythmias-such as automaticity and triggered activity caused by early afterdepolarizations-are eliminated when a tachycardia is induced by cardiac pacing. (2) Termination of a tachycardia by overdrive pacing or premature stimulation is expected of reentry or triggered activity caused by delayed afterdepolarizations but not of automaticity and early afterdepolarization-dependent triggered activity. Overdrive suppression is expected of arrhythmias caused by normal automaticity, and overdrive acceleration may occur with arrhythmias caused by abnormal automaticity. (3) Demonstration of entrainment of a tachycardia during overdrive pacing is indicative of a reentrant mechanism and is not expected of other mechanisms. (4) The response to premature stimulation is different during arrhythmias caused by automaticity and those caused by reentry. During automatic arrhythmias, the return cycle length should not increase as the premature coupling interval decreases. The return cycle should be less than compensatory. During reentrant arrhythmias, the return cycle length should increase as the premature impulse occurs earlier in the dominant cycle. The increase sometimes may begin to occur with late coupled premature impulses or may not occur until premature impulses are early coupled. The return cycle length is often less than compensatory.

List of Figures

Figure 23-6: Diagrams of sinus node action potentials illustrating normal automaticity caused by spontaneous diastolic depolarization and the factors that change the rate of impulse initiation. *A.* Typial sinus node action potential with spontaneous diastolic depolarization (dd). *B.* Change in the rate when the maximum diastolic potential is shifted to a more negative level (from a to b). *C.* Change in rate caused by change in threshold potential to a less negative level (from TP1 to TP2). *D.* Change in rate that occurs when the slope of phase 4 depolarization is decreased (from a to b). (Modified after Wit AL, Janse MJ. *The Ventricular Arrhythmias of Ischemia and Infarction: The Electrophysiological Mechanisms*. Mount Kisco, NY: Futura; 1992:3. Reproduced with permission from the publisher and authors.)

Figure 23-7: Transmembrane potentials recorded in isolated superfused preparations from some subsidiary pacemaker cells with the property of normal automaticity. Spontaneous diastolic depolarization that developed in the absence of overdrive suppression is shown in each panel. *A.* Atrial fiber in the crista terminalis in the presence of isoproterenol. *B.* Atrial fiber in the inferior right atrium. *C.* Atrial fiber in the ostium of the coronary sinus in the presence of norepinephrine. *D.* Atrial fiber in stretched mitral valve leaflet. *E.* Atrioventricular nodal fiber of the rabbit heart after the AV node was separated from the atrium. (From Wit AL, Janse MJ. *The Ventricular Arrhythmias of Ischemia and Infarction: The Electrophysiological Mechanisms*. Mount Kisco, NY: Futura; 1992:7. Reproduced with permission from the publisher and authors.)

Figure 23-8: Overdrive suppression of normal automaticity in a canine Purkinje fiber. The action potentials are displayed at a slow oscilloscopic sweep speed, and so the time course of repolarization cannot be seen. Note the warmup of the spontaneous pacemaker after the termination of pacing. (From Cranefield PF. *The Conduction of the Cardiac Impulse: The Slow Response and Cardiac Arrhythmia*. Mount Kisco, NY: Futura; 1975. Reproduced with permisson from the publisher and author.)

Figure 23-9: Normal and abnormal automaticity in a canine Purkinje fiber. *A.* Transmembrane potential recording from a Purkinje fiber with a normal maximum diastolic potential of -85 mV and spontaneous diastolic depolarization. *B.* Abnormal automaticity that occurred when membrane potential was decreased: (1) Fiber was depolarized (*at arrow*) to a membrane potential of -45 mV by the injection of a long-lasting current pulse through a microelectrode, (2) membrane potential was reduced to -40 mV (*at arrow*), (3) membrane potential was reduced to -30 mV (*at arrow*). (Reproduced from Wit AL, Friedman PF. Basis for ventricular arrhythmias accompanying myocardial infarction: Alterations in electrical activity of ventricular muscle and Purkinje fibers after coronary artery occlusion. *Arch Intern Med* 1975; 135:459. Reproduced with permission from the publisher and author.)

Figure 23-10: An example of a DAD (*white arrow*) recorded with a microelectrode from an atrial fiber in the canine coronary sinus. The red arrow indicates an afterhyperpolarization. *B.* The onset of triggered activity is shown. (From Wit AL, Rosen MR. After depolarizations and triggered activity: Distinction from automaticity as an arrhythmogenic mechanism. In: Fozzard HA, Haber E, Jennings RB, et al., eds. *The Heart and Cardiovascular System*. Scientific Foundations, 2d ed. New York, Raven Press; 1991:2113. Reproduced with permission from the publisher and author.)

Figure 23-11: Effects of stimulation rate on DADs and triggered activity. Transmembrane action potentials were recorded from an atrial fiber in the canine coronary sinus superfused with Tyrode's solution containing norepinephrine. The stimulus cycle lengths and the periods of stimulation are indicated by the black bars. Sustained triggered activity occurred after stimulation at a cycle length of 1200 ms. The rate of triggered activity is so rapid that the individual action potentials cannot be seen at the slow oscilloscopic sweep speed. (From Wit AL, Cranefield PF. Triggered and automatic activity in the canine coronary sinus. *Circ Res* 1977; 41:435. Reproduced with permission from the publisher and author.)

Figure 23-12: Early afterdepolarizations and triggered activity during repolarization in a Purkinje fiber. *A*. Transmembrane potential with normal repolarization of a spontaneously active Purkinje fiber. *B*. Early afterdepolarization (*arrow*) occurring during the plateau phase of the action potential. *C*. Triggered action potentials (*arrow*) during the plateau. *D*. Arrest of repolarization at a low level of membrane potential after a period of triggered activity. (From Cranefield PF. Action potentials, afterpotentials and arrhythmias. *Circ Res* 1977; 41:415-425. Reproduced with permission from the publisher and author.)

Figure 23-13: Early afterdepolarizations and triggered activity during late repolarization in a Purkinje fiber. *A*. Three panels are shown: (*a*) a spontaneously firing Purkinje fiber with prominent phase 4 depolarization, (*b*) occurrence of a single triggered action potential caused by an EAD, occurring during repolarization of each spontaneous action potential, (*c*) two triggered action potentials caused by an EAD occurring during repolarization of each spontaneous action potential. *B*. Development of an EAD and a triggered action potential in three superimposed traces: (1) normal Purkinje fiber action potential, (2) alteration in the time course of late repolarization leading to the occurrence of an EAD (*arrow*), (3) further alteration in late repolarization, leading to a triggered action potential. *C*. Superimposed traces recorded from a Purkinje fiber in the course of developing EADs and a triggered action potential. (From Coulombe A et al. Role of the "Na window" current and other ionic currents in triggering early after-depolarizations and re-exitation in Purkinje fibers. In: Zipes DP, Jalife J, ed. *Cardiac Electrophysiology and Arrhythmias*. New York: Grune & Stratton; 1985:43. Reproduced with permission from the publisher and author.)

Figure 23-14: Diagrammatic representation of the relation between the level of membrane potential at the onset of phase 0 and the maximum rate of depolarization during phase 0 (dv/dt_{max} or $V(r)_{max}$). *A*. Fiber has been depolarized by progressively increasing the extracellular potassium concentration. As resting membrane potential decreases, the rate of depolarization of the action potential upstroke decreases. *B*. Fiber is activated by premature stimuli that occur at different times during phase 3 (*a*, *b*, and *c*). The premature action potentials have reduced rates of depolarization because they arise at reduced membrane potentials. *C*. For both types of experiments, the general relationship between $V(r)_{max}$ and membrane potential is shown. As the membrane potential becomes smaller (less negative), the rate of phase 0 depolarization ($V(r)_{max}$) decreases and therefore conduction velocity decreases.

Figure 23-15: Relation between the spread of excitation in uniform anisotropic ventricular muscle (*A*) and extracellular (*B*) and transmembrane potential waveforms (*C*). The excitation sequence in *A* was constructed from the extracellular waveforms measured at 100 positions on the endocardial surface of the right ventricular septum. The extracellular waveforms in *B* were measured at the sites indicated by the solid dots superimposed on the isochrones of *A*. The direction of propagation at the single transmembrane recording site was altered by initiating propagation at different locations, one to produce propagation along the longitudinal axis of the impaled fiber and the other to produce propagation along the transverse axis. Panel *C* shows the effects of the different directions of propagation on the upstroke of the action potential. (From Spach MS, Dolber PC. The relation between discontinuous propagation in anisotropic cardiac muscle and the "vulnerable period" of reentry. In: Zipes DP, Jalife J, eds. *Cardiac Electrophysiology and Arrhythmias*. New York: Grune & Stratton, 1985:241. Reproduced with permission from the publisher and author.)

Figure 23-16: *A*. Diagram of a nonuniform anisotropic atrial muscle bundle with the long axis of the myocardial fibers indicated by the dashed lines. The bundle was stimulated at the asterisk. Propagation of the longitudinal wavefront is shown by the large white arrow. Transverse propagation occurred as diagrammed by the zigzag arrow. *B*. Electrograms recorded from sites 1, 2, and 3 on the diagram. *C*. The first derivative of these electrograms is shown. (From Spach MS, Dolber PC. Relating extracellular potentials and their derivatives to anisotropic propagation at a microscopic level in human cardiac muscle: Evidence for uncoupling of side-to-side fiber connections with increasing age. *Circ Res* 1986; 58:356. Reproduced with permission from the publisher and author.)

Figure 23-17: Conduction characteristics and unidirectional block at branch sites. The drawings represent a small branch formed by the origin of a pectinate muscle from the larger crista terminalis. The general direction of the fiber orientation is indicated by the broken lines. The patterns of propagation are shown by the solid arrows. Extracellular waveforms recorded at sites indicated by the dashed lines also are shown. (From Spach MS et al. The functional role of structural complexities in the propagation of depolarization in the atrium of the dog: Cardiac conduction disturbances due to discontinuities of effective axial resistivity. *Circ Res* 1982; 50:175. Reproduced with permission from the publisher and authors.)

Figure 23-18: Diagram of reentry caused by dispersion in refractory periods. A ring of cardiac tissue is shown, and the pattern of conduction is indicated by the arrows. Action potentials with different durations located in different regions of the ring are diagrammed. (From Wit AL, Janse MJ. *The Ventricular Arrhythmia of Ischemia and Infarction: The Electrophysiological Mechanisms.* Mount Kisco, NY: Futura; 1992:86. Reproduced with permission from the publisher and authors.)

Figure 23-19: Asymmetric depression of excitability as a mechanism for unidirectional conduction block in a bundle of cardiac muscle fibers. The action potentials shown above were recorded from sites on the fiber bundle. The shaded part of the bundle is depressed. Conduction from left to right along the bundle is indicated by the striped arrows, conduction from right to left by the black arrows. (Modified from Wit AL, Rosen MR. Cellular electrophysiological mechanisms of cardiac arrhythmias. In: MacFarlane PW, Veitch Lawrie TD, eds. *Comprehensive Electrocardiology: Theory and Practice in Health and Disease*, vol. 2. New York: Pergamon Press; 1989:801. Reproduced with permission from the publisher and authors.)

Figure 23-20: Return cycles as a function of premature stimulated cycles during premature atrial stimulation in a patient in sinus rhythm. The graph depicts the relation of the normalized return cycle to the degree of prematurity of the test cycle, which also is normalized. Points falling on line *A* represent nonreset of the sinus pacemaker (fully compensatory pause) and are in zone I. Premature stimulated atrial beats introduced earlier in atrial diastole fall in zone II. Line *B*, projected from the *y* axis, is a reference line indicating the spontaneous sinus cycle length. The distance the zone II points (reset points) are above line *B* is interpreted to indicate conduction time into and out of the sinus node, assuming the sinus node pacemaker cycle length immediately after the stimulated premature atrial beat is identical to the preceding sinus node pacemaker cycle length. (From Strauss HC et al. Premature atrial stimulation as a key to the understanding of sinoatrial conduction in man: A presentation of data and critical review of the literature. *Circulation* 1973; 47:86. Reproduced with permission from the publisher and author.)

Figure 23-21: Diagrammatic representation of the reentrant circuit during spontaneous ventricular tachycardia (VT) and the first two beats of entrainment of the ventricular tachycardia at a rate of 150 beats per minute (*middle and right panels, respectively*). Each *X* represents the orthodromic wavefronts of the reentrant rhythm. In this and subsequent diagrams, the arrows indicate the direction of spread of the impulse, the box represents an area of slow conduction, the serpentine line indicates slow conduction of the impulse in the area of slow conduction, the dots represent recording sites along the course of the double arc of reentry from which ventricular electrograms (VEGs) are recorded, and the large arrow indicates the wavefront from the pacing impulse entering into the ventricular tachycardia reentry circuit, where it is conducted orthodromically (ortho) and antidromically (anti). (From Waldo AL, Henthorn RW. Use of transient entrainment during ventricular tachycardia to localize a critical area in the reentry circuit for ablation. *PACE* 1981; 12:231. Reproduced with permission from the publisher and authors.)

Figure 23-22: Diagrammatic representation of the first entrainment criterion during termination of ventricular pacing illustrated in Fig. 23-21. (From Waldo AL, Henthorn RW. Use of transient entrainment during ventricular tachycardia to localize a critical area in the reentry circuit for ablation. *PACE* 1989; 12:231. Reproduced with permission from the publisher and authors.)

Figure 23-23: Diagrammatic representation of the second and fourth entrainment criteria during entrainment of the same spontaneous ventricular tachycardia shown in Fig. 23-21 by ventricular pacing at rates of 150 (*left panel*), 155 (*middle panel*), and 160 (*right panel*) beats per minute. (From Waldo AL, Henthorn RW. Use of transient entrainment during ventricular tachycardia to localize a critical area in the reentry circuit for ablation. *PACE* 1989; 12:231. Reproduced with permission from the publisher and authors.)

Figure 23-24: Diagrammatic representation of the third entrainment criterion during interruption of the ventricular tachycardia by ventricular pacing at a rate of 165 beats per minute. (From Waldo AL, Henthorn RW. Use of transient entrainment during ventricular tachycardia to localize a critical area in the reentry circuit for ablation. *PACE* 1989; 12:231. Reproduced with permission from the publisher and authors.)

Figure 23-25: Effects of premature impulses on reentrant circuit with an excitable gap. In each panel, diagrams are shown of an anatomic circuit with a single entrance route from above. In *A*(1), *B*(1), and *C*(1), red arrows in the circuit represent the reentrant impulse causing tachycardia. The length of the arrow is the wavelength of the impulse and shows the part of the circuit that is completely refractory, The part of the circuit that is stippled is relatively refractory, and the part of the circuit that is clear is completely excitable (the fully excitable gap). Red arrows entering the circuit from above represent a prematurely stimulated impulse initiated outside the circuit. *A*(2) and *B*(2) show conduction of the premature impulse in the circuit. Graphs show the expected relation between the return (premature impulse) cycle length (R_2-R_3) and the premature coupling interval (R_1-R_2/R_1-R_1) for premature impulses conducting in the fully excitable gap *A*(3) and in the relatively refractory tissue of a partially excitable gap *B*(3). (Modified after Wit AL, Janse MJ. *The Ventricular Arrhythmias of Ischemia and Infarction: The Electrophysiological Mechanisms*. Mount Kisco, NY: Futura; 1992:135. Reproduced with permission from the publisher and authors.)

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 24:

RECOGNITION, CLINICAL ASSESSMENT, AND MANAGEMENT OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

Authors: Robert J. Myerburg, E. Martín Kloosterman, Agustin Castellanos

The diagnosis and management of cardiac arrhythmias and conduction disturbances require the coordination of (1) electrocardiographic (ECG) analysis of the rhythm disturbance, (2) assessment of the clinical setting, and (3) identification of an end point and method of therapy.[1]

ECG recognition of arrhythmias requires an organized system of analysis of atrial and ventricular myocardial activation and deduction of atrioventricular (AV) conduction patterns. Forms of arrhythmias are separated into those that cause limited symptoms but may trigger symptomatic sustained arrhythmias under appropriate conditions (e.g., premature atrial or ventricular impulses) and those that are sustained symptomatic and/or potentially fatal arrhythmias [e.g., supraventricular tachycardias (SVTs), ventricular tachycardias (VTs), ventricular fibrillation (VF), or bradycardias] (Table 24-1).

Table 24-1: Assessment of Cardiac Arrhythmias

Forms of cardiac arrhythmias
Ambient or triggering arrhythmias (e.g., premature atrial or ventricular impulses)
Sustained or potentially lethal arrhythmias (e.g., supraventricular or ventricular tachycardias, ventricular fibrillation, sustained bradyarrhythmias)
Clinical settings in which arrhythmias occur
Acute, transient (e.g., acute ischemic events, metabolic disturbances)
Chronic, persistent, recurrent (e.g., chronic ischemic heart disease, cardiomyopathy, anatomic or physiologic substrate for paroxysmal supraventricular tachycardia, chronic conducting system disease)
End points of management
Antiarrhythmia (suppress ambient or triggering arrhythmias)
Antitachycardia or antifibrillatory (prevent or revert tachycardias or fibrillation)
Heart rate support (prevent symptomatic bradycardias)

SOURCE: Modified from Myerburg et al.,[1] with permission of the *American Heart Journal.*

Clinical settings are broadly divided into those that are acute or transient, such as acute ischemia, the acute phase of myocardial infarction, electrolyte disturbances, or proarrhythmic effects of antiarrhythmic drugs, and those that provide a persistent substrate for arrhythmias, such as chronic ischemic heart disease, cardiomyopathies, and anatomic and physiologic substrates for the various paroxysmal supraventricular tachyarrhythmias.[2,3] Analogous to the concept of "triggering" and "sustained" arrhythmias, transient ischemia and hemodynamic disturbances may be viewed as triggering events and chronic ischemic heart disease and the hypertrophied or myopathic heart as sustaining substrates.

The goals, or end points, of therapy of cardiac arrhythmias are dependent on the forms, clinical settings, and mechanisms of arrhythmia. Broadly, goals of treatment may be antiarrhythmic (targeted to the suppression of ambient or triggering arrhythmias or events) or antitachycardiac, antifibrillatory, or heart-rate supporting (in which the goal is prevention or reversion of sustained arrhythmias), whether the arrhythmias are well tolerated, symptomatic, or life-threatening.

PRINCIPLES OF CARDIAC RHYTHM ANALYSIS

The Standard Electrocardiogram

The standard 12-lead ECG and rhythm strips provide a direct and easily accessible method for diagnosing disturbances of cardiac rhythm. The simultaneous-lead rhythm strip accompanying the 12-lead ECG on many current ECG machines, plus the option of recording longer multilead rhythm strips, will yield sufficient information for a prompt and accurate diagnosis of most cardiac rhythm disturbances.

For many arrhythmias, analysis requires only the recognition of P-wave and QRS morphology, their relative timing, and their vectors. Simple inspection of the tracing, with caliper-assisted measurements, may be sufficient; but the analysis of more complex arrhythmias is facilitated by the use of ladder diagrams. First used extensively by Sir Thomas Lewis, they are also referred to as Lewis lines. The ladders are usually constructed with three tiers-A, AV, and V (Fig. 24-1*A*)-but additional tiers may be helpful in depicting events related to sinoatrial (SA) conduction (Fig. 24-1*B*) or ventricular ectopic rhythms (Fig. 24-1*C*). The A and V tiers are used to depict activation of atrial and ventricular muscle, respectively. The middle tier (AV) is used to infer conduction characteristics in the AV junction. Since atrial and ventricular activation are the only direct registrations of cardiac electrical activity on the standard ECG, they are diagrammed first. The A line is drawn from the beginning of the P wave and the V line from the beginning of the QRS. Time is indicated by the slope of the line, and the site within a tier in which impulse propagation begins (upper, middle, or lower) shows the direction the impulse is traveling. The site of origin may be represented by a black dot. A blocked impulse is indicated by a short bar at a right angle to the line indicating direction of conduction, and aberrant intraventricular conduction is shown as a pair of slightly divergent lines. A variety of such examples are shown in Fig. 24-1. In using the diagram, particularly for complex arrhythmias, the first caution is to draw only what can be seen or inferred with certainty. Subsequently, the AV tier can be used to diagram proposed mechanisms of conduction (Fig. 24-2).

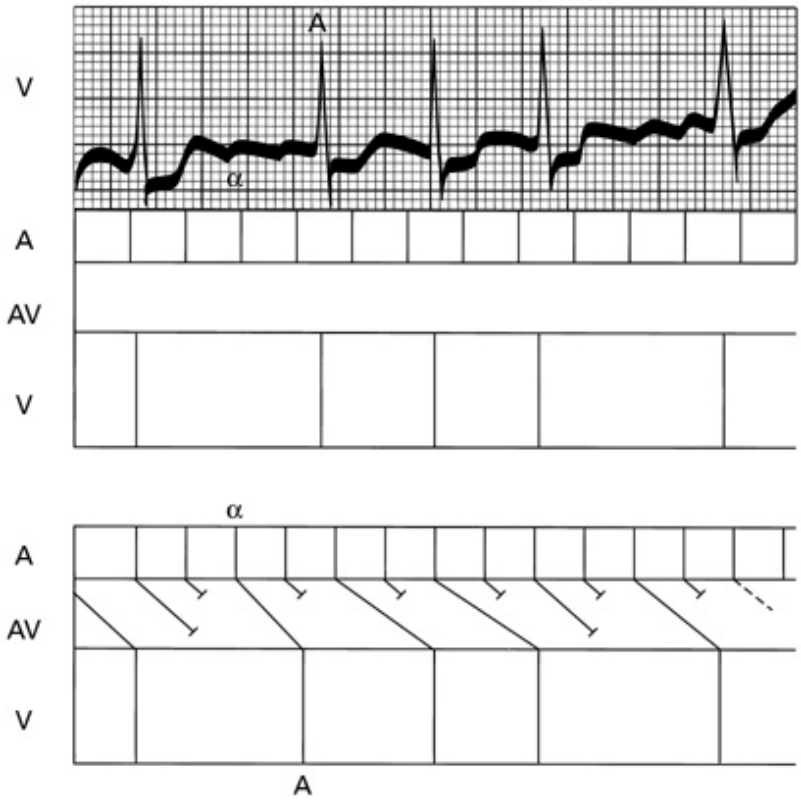

Figure 24-2: Construction of ladder diagrams for analyzing specific arrhythmias. *Stage 1:* Draw lines to represent atrial activity (seen and inferred by measurement) and ventricular complexes. *Stage 2:* Since the FR interval in flutter usually ranges between 0.26 and 0.45 s, start by connecting the F wave (α) to the QRS (A) in this example. As successive impulses are diagrammed, it becomes apparent that there is a basic 2:1 AV conduction with a Wenckebach period during the alternate cycles. (From Marriott HJL. *Armchair Arrhythmias.* Tampa, FL: Tampa Tracings; 1966. Reproduced with permission from the publisher and authors.)

Special Leads

When the standard ECG does not provide sufficient information to establish a diagnosis, usually due to inability to identify P waves, special lead systems may be used. The simplest is the Lewis lead configuration, in which the right and left arm electrodes are deployed as a bipolar lead to the right of the sternum in a superior-inferior orientation.

A bipolar esophageal lead can record left atrial activity, and an intraatrial electrode catheter can record atrial activity from within the right atrium. For both techniques, it is necessary to have at least one standard surface ECG lead recorded simultaneously with the special lead.

Continuous Monitor Recordings

Continuous monitoring of cardiac rhythm may be performed in hospital in special care units or in the ambulatory patient using various types of portable recording devices. Some systems provide the capability for simultaneous multilead recordings that improve diagnostic yield considerably. Long-term storage capabilities for inpatient monitoring permit off-line analysis of complex rhythm disturbances if the physician is not available at the time the arrhythmia occurs. The two most popular leads for use in bedside monitoring are lead II and MCL-I, the latter providing a pattern similar to V_1.

For infrequently occurring arrhythmias, a number of event recorders are now available. They allow the patient to activate the device when an event occurs, providing internal storage that can be transmitted by telephone to a central station for later review. Transtelephonic transmitters also can be used in real time for more persistent or frequent events. Finally, a small subcutaneous implantable recorder is available for patients with infrequent arrhythmias that warrant an aggressive documentation attempt.[4] The device may be

explanted after a diagnosis is established.

Exercise Testing for Cardiac Arrhythmias

Treadmill stress testing may be used to initiate an evanescent arrhythmia, document an exercise relationship to its onset, and evaluate both efficacy and adverse responses to therapy. The standard treadmill is used, and thallium or echocardiographic imaging is not necessary unless an ischemic basis correlating with the onset of arrhythmia is suspected. The procedure is especially useful for eliciting and evaluating therapy of exercise-induced ventricular arrhythmias, for distinguishing autonomic from structural disease mechanisms of sinus or AV node dysfunction, and for evaluating adverse effects of drug therapy, such as rate-dependent proarrhythmic effects, as may occur with strong Na^+-channel blockers, such as flecainide[5] (see below).

Exercise testing may also provide some general insights into the refractory period of an accessory pathway in Wolff-Parkinson-White (WPW) syndrome. Abrupt disappearance of the delta wave during exercise-induced increase in heart rate suggests encroachment on the refractory period, while gradual disappearance may simply be due to enhanced AV nodal conduction.[6]

Signal-Averaged Electrocardiography, Heart Rate Variability, and Baroreceptor Sensitivity

Signal-averaged electrocardiography, heart rate variability, and baroreceptor sensitivity provide information on mortality risk and the probability of life-threatening arrhythmias, whether used separately or combined with other estimates of risk [e.g., premature ventricular contractions (PVCs) and nonsustained VT on 24-h ambulatory monitoring and ejection fraction (EF) measurements]. They have been applied most intensively after myocardial infarction.

Signal-averaged electrocardiography employs amplification of low-amplitude signals occurring after the termination of the standard electrocardiographic QRS complex, as recorded by high-amplification techniques. The low-amplitude signals are repetitive electrical events caused by a delayed activation sequence of part or parts of the ventricular muscle mass. Their repetitive timing allows them to be amplified during signal averaging, while random noise is being canceled out. The resultant signal is a high-gain, high-frequency QRS complex, followed by low-amplitude signals representing the late potentials. The terminal delayed activation pattern represents a pathophysiologic marker for susceptibility to ventricular arrhythmias. It results from fragmented activation in an area of delayed conduction, which is a well-established substrate for reentrant arrhythmias. The characteristics of an abnormal signal-averaged ECG include (1) a prolonged filtered QRS complex (115 ms) with a normal duration of the standard QRS complex, (2) the terminal portion of the filtered QRS complex less than 40 μV for 39 ms, and (3) less than 20 μV of amplitude during the last 40 ms of the filtered QRS complex.[7] At least two of the three criteria must be abnormal to consider the tracing abnormal, and many would require all three to be abnormal (Fig. 24-3). Residual high-frequency noise content must be less than 1 μV with a 25-Hz high-pass cutoff (less than 0.7 μV with a 40-Hz high-pass cutoff).

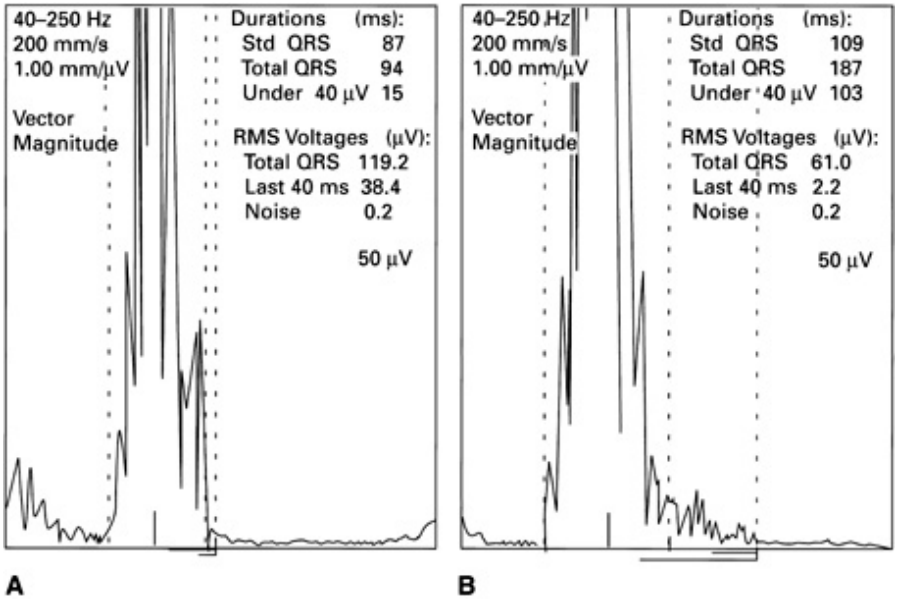

Figure 24-3: *A.* Normal signal-averaged vector complex. *B.* Abnormal signal-averaged vector complex. All three signal-averaged measurements are abnormal. The signal-averaged QRS duration is 187 ms, low-amplitude signals are 103 ms in duration, and the root-mean-square voltage is 2.2 μV. (Courtesy of Paul F. Walter, M.D.)

Signal-averaged electrocardiography is most useful for demonstrating presence and absence of risk for ventricular arrhythmias and sudden death after myocardial infarction.[8] It is most powerful as a negative predictor of risk, in that a normal signal-averaged ECG after healing of myocardial infarction identifies a greater than 97 percent probability of remaining free of ventricular arrhythmias. The positive predictive accuracy is less powerful and is heavily influenced by other variables, such as EF and ambient ventricular arrhythmias. Signal-averaged electrocardiography alone has a positive predictive value in the range of 20 percent, and combined with a low EF and ambient arrhythmias, the risk may be as high as 50 percent in some subgroups (see "Ventricular Arrhythmias," below).

Heart rate variability studies provide estimates of sympathetic and parasympathetic balance.[9] Blunting of the normal patterns of variability of sinus rate over time in subgroups of myocardial infarction and cardiac arrest survivors appears to increase the risk of life-threatening events.[9,10] As is the case for signal-averaged electrocardiography, the test is used primarily for prognostic information rather than as a therapeutic guide.

Baroreceptor sensitivity estimates the relationship between phenylephrine-induced blood pressure increase and concomitant fall in heart rate as an indication of parasympathetic responsiveness to the pure α-adrenergic stimulus.[11] Following a myocardial infarction, a blunted baroreceptor sensitivity predicts an increased risk of VT and death. A recent large study also demonstrated its power for predicting adverse outcome following a myocardial infarction, which was further enhanced when combined with other risk variables, such as low EF and ambient arrhythmias.[12]

Intracardiac Electrocardiography and Programmed Electrophysiologic Studies

Intracardiac electrocardiography and programmed electrophysiologic studies, which are described in detail in Chap. 26, can be used to diagnose many disturbances in rhythm and conduction for which surface electrocardiography is insufficient. Intracardiac electrophysiologic studies are also used to define appropriate therapy and to test the results of therapy for various forms of supraventricular and ventricular arrhythmias. The use of multicatheter electrode systems, providing simultaneous recordings from many intracardiac sites (Fig. 24-4), allows mapping of the sequence of excitation in the atria, AV junction, and ventricle. Intracardiac mapping procedures permit the identification of sites of accessory pathways, mechanisms of ventricular tachyarrhythmias, and the reentrant circuits or sites of origin of supraventricular tachyarrhythmias. Such techniques provide the basis for electrocardiographically guided therapy, such as radiofrequency (RF) ablation. In addition, the distinction between AV block above and below the level of the bundle of His and between true AV block and pseudo-AV block caused by concealed extrasystoles is

also possible. Specific clinical applications are provided in the appropriate sections below and in Chap. 26.

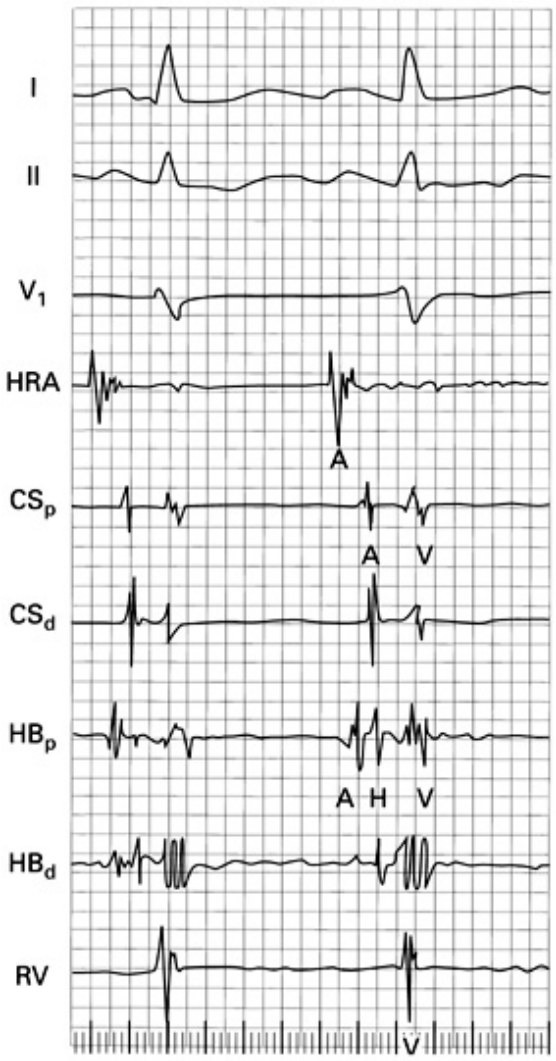

Figure 24-4: Intracardiac recordings during electrophysiologic testing. Recordings during sinus rhythm in a multicatheter study are illustrated. The intracardiac study includes the recording of atrial activity (A), the His bundle deflection (H), and ventricular activity (V) used to determine the timing and sequences of activation at various intracardiac sites. A activity is recorded from the high right atrium (HRA); and both A and V activity are recorded from a proximal (HBp) and distal (HBd) site in the His bundle region and from proximal (CSp) and distal (CSd) sites within the coronary sinus. The CS sites record atrial and ventricular activity from the posterior-posteroseptal and posterolateral-lateral areas, respectively. V activity is also recorded from the right ventricle (RV), either the apex or outflow tract, depending upon the positioning of the catheter in the right ventricle. For more detailed mapping procedures, more sites in the coronary sinus or sites around the tricuspid ring can be recorded, or the left ventricle can be mapped by a retrograde recording catheter from the femoral artery. Less extensive studies using fewer catheters and recording sites can be used for different clinical purposes. The configuration shown is standard for studies of supraventricular tachycardias. For ventricular tachycardia studies, three catheters can be used (HRA, HB, and RV) for the diagnostic study.

Endocardial Catheter Mapping and Intraoperative Multiarray Epicardial Mapping

Techniques for mapping pathways and sites of origin for both ventricular and supraventricular tachyarrhythmias, originally developed for intraoperative mapping during antiarrhythmic surgery, have found broad application in catheter-based procedures. Greatly improved catheter-ablation techniques for many arrhythmias, in conjunction with the development of sophisticated computer-based recording,

storage, and retrieval systems,[13,14] have limited the role of intraoperative mapping and interventions with the expansion of catheter techniques. The new mapping systems allow simultaneous recordings from many points, generating on-line maps of activation during a procedure. This technology allows the clinical electrophysiologist to identify target areas for delivery of RF energy during an ablation procedure. Figure 24-5 (Plate 74), provides an example of a computer-generated atrial endocardial activation map from such a system, demonstrating a focal atrial tachycardia. The technique of left ventricular (LV) endocardial catheter mapping for identification of sites appropriate for catheter ablation of VT is demonstrated in Fig. 24-6. Computer-generated maps are now also available for ventricular arrhythmias.

Chapter 24: RECOGNITION, CLINICAL ASSESSMENT, AND MANAGEMENT OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

OVERVIEW OF MANAGEMENT STRATEGIES

Strategies for the prevention and management of cardiac arrhythmias are based on an understanding of the mechanisms of specific arrhythmias (Table 24-2), in conjunction with systemic and cardiac factors that can be modified to influence predisposition to arrhythmias, and the range of indications for pharmacologic therapy and nonpharmacologic interventions (Table 24-3). Many patients are managed with multiple interventions, one therapeutic mode being complementary to another.

Table 24-3: Summary of Approaches to Arrhythmia Management

General systemic interventions
Respiratory support
Hemodynamic support
Metabolic and electrolyte control
Neurophysiologic control
Electropharmacologic therapy
Control triggering events
Suppress triggering arrhythmias
Prevent or reverse arrhythmogenic factors (e.g., anti-ischemic therapy, or electrolyte replacement)
Control sustained arrhythmias
Acute interventions
Chronic prevention
Control ventricular rate
Catheter ablation procedures
Supraventricular tachycardias
AV nodal reentry
WPW syndrome
AV node ablation in atrial fibrillation
Atrial flutter
Atrial fibrillation, focal mechanisms[a]
Atrial, sinus node, and AV junctional tachycardias
Ventricular tachycardias

Surgical intervention
Antiarrhythmic surgery
Anomalous pathways[a]
Aneurysmectomy, endocardial resection[a]
Cryoablation[a]
Maze procedure for atrial fibrillation[a]
Anti-ischemic surgery
Structural heart disease surgery
Electronic device
Acute applications
Cardioversion
Defibrillation
Temporary pacemakers
Long-term applications
Permanent pacemakers
Implantable cardioverter defibrillators

[a]Limited clinical application at the time of this writing.

A complete management plan for any arrhythmia must coordinate three spheres of information: (1) the underlying structural etiology (coronary heart disease, cardiomyopathy, WPW syndrome, etc.); (2) transient triggering factors that interact with the underlying structural abnormality (e.g., transient ischemia and hemodynamic, electrolyte, metabolic, and respiratory abnormalities; see Table 24-4),[2,3] and (3) individual patients' preferences and decisions regarding pharmacologic versus interventional approaches. The identification of contributing factors, which interact with underlying etiology as the proximate causes of an arrhythmia, is inherent to any treatment plan. Contributing factors may be systemic or cardiac. The major systemic abnormalities include hemodynamic dysfunction, hypoxia, acidosis, electrolyte disturbances, toxic or proarrhythmic drug effects, and endocrine abnormalities. Central nervous system factors, including fluctuations in autonomic tone, may cause or aggravate specific arrhythmias. Prompt reversal of serious arrhythmias may follow control of these disturbances.

Table 24-4: Causes of Cardiac Arrhythmias: Structure and Function

Structural Abnormalities	Functional Factors
Coronary heart disease	Transient alterations of coronary blood flow
Acute myocardial infarction	Vasomotor dynamics
Chronic ischemic heart disease	Acute ischemia
	Reperfusion after ischemia
Ventricular hypertrophy	
Secondary left ventricular hyper-trophy	Systemic factors
Hypertrophic cardiomyopathy	Hemodynamic fluctuations
Obstructive	Hypoxia, acidosis
Nonobstructive	Electrolyte imbalance
Myopathic ventricles	Neurophysiologic alterations
Dilated cardiomyopathy	Central nervous system influences
Pericarditis, myocarditis	Receptor function
Noninfectious inflammatory diseases	Neurotransmitters
Infiltrative diseases	
	Toxic substances
Structural electrophysiology abnor-malities	Proarrhythmic drugs
Sinus node, AV node, and His-Purkinje disease	Idiosyncratic
Accessory pathways	Dose dependent
Abnormalities of molecular structure (ion channels)	Cardiotoxic substances

SOURCE: Modified from Myerburg et al.,[3] with permission of the *American Journal of Cardiology*.

Primary and secondary arrhythmias must be distinguished for both management and prognosis. Medical writings contain conflicting definitions of the term *primary arrhythmia*, which must be clarified for interpretation of investigative data. Historically, a primary arrhythmia was first described as one that resulted from an electrophysiologic disturbance caused by a disease process, in the absence of a significant change in hemodynamic function. An arrhythmia that resulted from an electrical disturbance caused or perpetuated by hemodynamic deterioration or metabolic abnormalities was defined as a secondary arrhythmia (Fig. 24-7). In the former, antiarrhythmic drugs alone may be useful, while a secondary arrhythmia requires the concomitant use of hemodynamically active drugs to support the failing circulation. In secondary arrhythmias, antiarrhythmic and hemodynamically active drugs have complementary roles. Subsequent uses of the term *primary arrhythmia* were an arrhythmia that was the first clinical manifestation of disease, such as cardiac arrest due to ventricular fibrillation in coronary heart disease, or an arrhythmia in the absence of structural disease. To avoid confusion, the term primary must be carefully defined with each use.

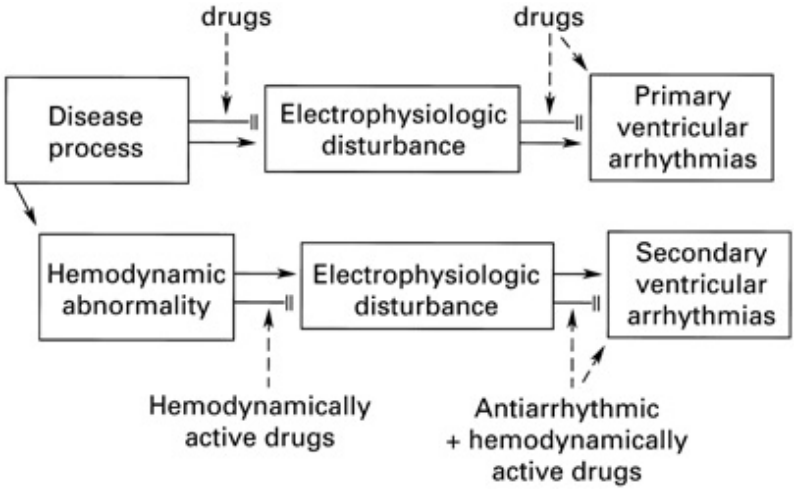

Figure 24-7: Primary and secondary arrhythmias. When a disease process directly initiates an electrophysiologic disturbance, the resulting arrhythmia is referred to as primary. In contrast, when the disease process produces a hemodynamic abnormality that in turn initiates the electrophysiologic disturbance, a resulting arrhythmia is referred to as secondary. Antiarrhythmic drugs may be used to prevent the electrophysiologic disturbance, prevent the electrophysiologically unstable heart from developing a manifest arrhythmia, or reverse a primary arrhythmia. In secondary arrhythmias, hemodynamically active drugs are used to prevent or reverse secondary electrophysiologic disturbances, usually in conjunction with antiarrhythmic drugs. Antiarrhythmic drugs alone are less likely to be effective for secondary arrhythmias. (Modified from Myerburg et al.[1] Reproduced with permission from the publisher and authors.)

Direct cardiac interventions for control of arrhythmias include pharmacologic approaches, ablation of specific foci involved in arrhythmogenesis, antiarrhythmic surgical approaches, and implantable devices designed to control tachyarrhythmic events or to prevent symptomatic bradyarrhythmias (Table 24-3). Antiarrhythmic drugs may be classified into groups using the modified Vaughn Williams system, which categorizes them on the basis of electropharmacologic and electrophysiologic properties (see Table 24-5). This classification is useful and practical for the clinician but has shortcomings. These include difficulty categorizing new drugs, exclusion of some drugs with obvious antiarrhythmic properties (e.g., adenosine), and inability to correlate drug class with specific effects as antiarrhythmic agents. Another classification system, the Sicilian gambit,[15] was developed for the purpose of providing deeper insight into drug effects, therapeutic targets, mechanisms of action, and responses (Fig. 24-8). While it is too complex for use as a practical clinical tool, it provides an excellent teaching method for understanding applied pharmacology. The usual dosages and routes of administration for the antiarrhythmic agents approved by the U.S. Food and Drug Administration at the time of writing are listed in Table 24-6. A number of other drugs are currently at various stages of study for ventricular and supraventricular arrhythmia indications.

Table 24-5: Modified Vaughn Williams Classification of Drugs Approved for Antiarrhythmic Uses

Examples	Depolarization	Repolarization
Class I: Membrane-active drugs		
IA Quinidine (Quinaglute, Quinidex, Cardioquin)Procainamide (Pronestyl, Procan-SR)Disopyramide (Norpace)Moricizine (Ethmozine)	Moderate depression of Na^+ current; intermediate kinetics	Prolonged
IB Lidocaine (Xylocaine)	Limited depression of	No effect or shortened
Tocainide (Tonocard)	Na^+ current; rapid kinetics	
Mexiletine (Mexitil)		

Phenytoin (Dilantin)			
IC	Flecainide (Tambocor)	Marked depression of Na^+ current; slow kinetics	Minimal effect
Propafenone (Rhythmol)			
Class II: Beta-adrenoceptor blocking drugs			
	Propranolol (Inderal)		
	Esmolol (Brevibloc)		
	Acebutolol (Sectral)		
Class III: Drugs that prolong repolarization			
	Amiodarone (Cordarone)		
	Bretylium tosylate (Bretylol)		
	Sotalol (Betapace; Betapace AF)		
	Ibutilide (Corvert)		
	Dofetilide (Tikosyn)		
Class IV: Ca^{2+}-entry blocking drugs			
	Verapamil (Isoptin, Calan)		
	Diltiazem (Cardizem)		
Unclassified in this system			
	Digoxin (Lanoxin)		
	Adenosine (Adenocard)		

NOTE: Drugs identified by name are limited to those approved for antiarrhythmic use by the U.S. Food and Drug Administration at the time of this writing (not necessarily inclusive of all brand names).

Table 24-6: Antiarrhythmic Drugs: Dosage and Kinetics

Drug	Usual Dosing Range[a]	Half-Life, h	Therapeutic Range, μg/mL	Plasma Protein Binding, %	Major Route of Excretion
Class IA					
Quinidine	Oral sulfate: 200-600 mg q 6 h	5-7	2.3-5	80	H
	Oral long acting: 330-660 mg, q 8 h or q 6 h				
Procainamide	Oral: 250-750 mg, q 4 h or q 6 h	3-5	4-10	15	R[b]

	Oral long-acting: 500-1500 mg, q 8 h or q 6 h				
	IV: 10-15 mg/kg at 25 mg/min, then 1-6 mg/min				
Disopyramide	Oral: 100-200 mg, q 8 h or q 6 h	8-9	2-5	35-95	H/R
Moricizine[c]	Oral: 150-300 mg, q 12 h or q 8 h	6-13	-	95	H
Class IB					
Lidocaine	IV: 1-3 mg/kg at 20-50 mg/min, then 1-4 mg/min	1-2	1-5	60	H
Tocainide	Oral: 400-600 mg q 8-12 h	15	4-10	10	H
Mexiletine	Oral: 200-400 mg q 8 h	10-12	0.5-2.0	55	H
Class IC					
Flecainide	Oral: 100-200 mg q 12 h	20	0.4-1.0	40	H
Propafenone[d]	Oral: 150-300 mg q 8 h	2-10	0.5-1.5[e]	95	H
Class II					
Propanolol	Oral: 10-100 mg q 6 h	4-6	0.04-0.10	95	H
	IV: 0.1 mg/kg in divided 1-mg doses				
Esmolol	IV: 500 mg/kg per min x 1 min followed by 50 mg/kg per min x 4 min, repeat with 50-mg increments to maintenance dose to 200 mg/kg per min	9 min	-	55	H
Acebutolol	Oral: 200-600 mg q 12 h	3-4	-	26	H/R
Class III					
Amiodarone	Oral: 600-1600 mg/day × 1-3 weeks, then 200-400 mg/day	50 days	1-2.5	96	H
	IV: 15 mg/min × 10 min, then 1 mg/min × 6 h, then maintenance at 0.5 mg/min	?	?		
Bretylium	IV: 5-10 mg/kg at 1-2 mg/kg, then 0.5-2.0 mg/min	8-14	0.5-1.5	-	R

Sotalol[d]	Oral: 80-240-mg q 12 h	10-15	-	0	R
Ibutilide	IV: (for >60 kg) 1 mg over 10 min; may repeat × 1 10 min after completion of initial dose[f]	2-12	-	40	H
Dofetilide	Oral: 500 μg q 12 h; creatinine clearance must be calculated and dose adjusted accordingly	10	1.0-3.5 (in ng/mL)	60-70%	R
Class IV					
Verapamil	Oral: 80-32 mg q 6-8 h	3-8	0.1-0.15	90	H
	IV: 5-10 mg in 1-2 min				
Diltiazem	IV: 0.25 mg/kg body wt over 2 min; if response inadequate, wait 15 min, then 0.35 mg/kg over 2 min; maintenance 10-15 mg/h	3.5-5.0	0.1-3.0	70-80	H
Other					
Digoxin	Oral 1.25-1.5 mg in divided doses over 24 h followed by 0.125-0.375 mg/day	36	0.8-1.4 (in ng/mL)	30	R
	IV: Approximately 70% of oral dose				
Adenosine	IV: 6 mg rapidly; if unsuccessful within 1-2 min, 12 mg rapidly	10 s	-	-	-

[a]All dosing should follow FDA-approved guidelines as outlined in package insert or *Physicians' Desk Reference* (see also Chap. 27; does not include pediatric use in infants and young children).
[b]Parent compound metabolized to active metabolite (NAPA) in liver; both active metabolite and unmetabolized parent compound excreted by kidneys.
[c]Shares class IB and IC activities.
[d]Shares class II activity.
[e]Active metabolite limits significance of these measurements.
[f]D/C upon arrhythmia conversion or for ventricular tachycardia or non-pharmacologic prolongation of QT or QT_c.

ABBREVIATIONS: H-hepatic; R-renal.

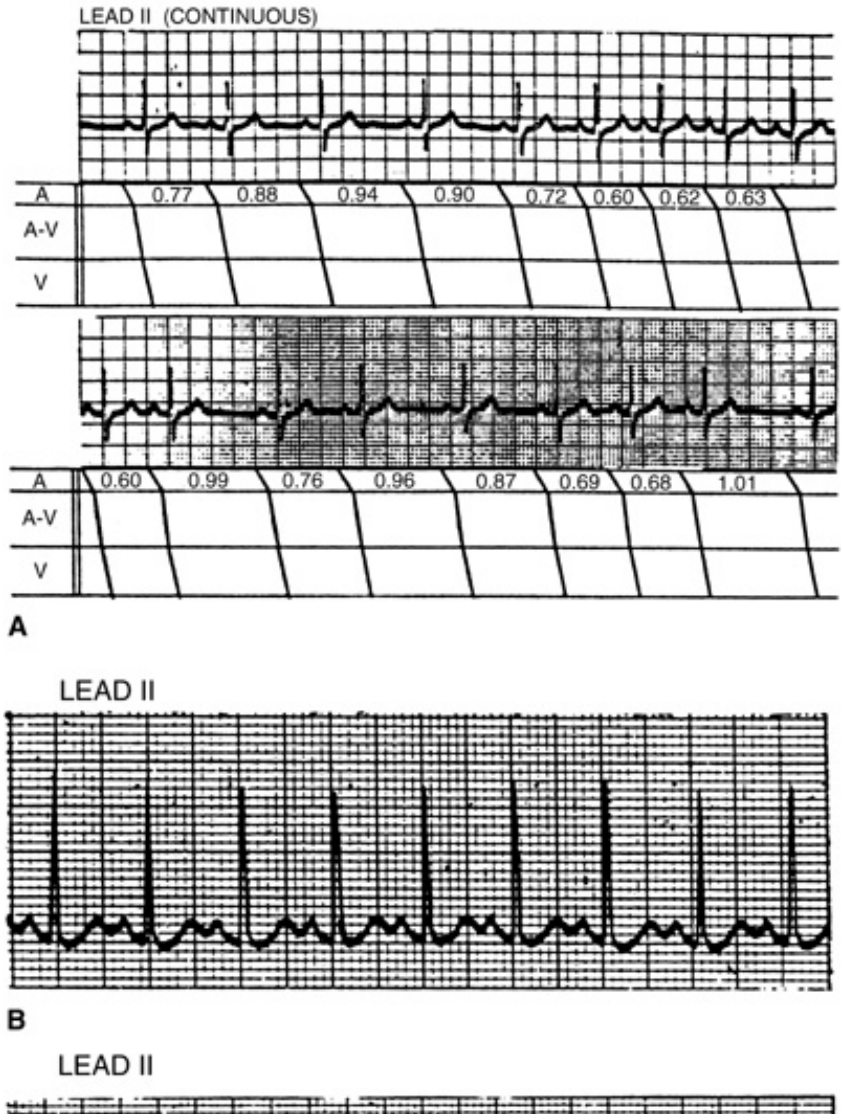
Chapter 24: RECOGNITION, CLINICAL ASSESSMENT, AND MANAGEMENT OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

SUPRAVENTRICULAR ARRHYTHMIAS

Figure 24-9 compares mechanisms, clinical features, diagnosis, and electrocardiography of the supraventricular arrhythmias described in this section.

Spectrum of Sinus Rhythms and Sinus Tachycardia

The range of rates defining normal sinus rhythm is between 60 and 100 impulses per minute. The rhythm is usually regular, but a rhythmic variation exceeding 0.12 s between the longest and shortest cycles in a sequence on a resting tracing defines sinus arrhythmia (Fig. 24-10*A*). This normal variant is most common in children and decreases with advancing age. It usually has a phasic pattern, in which the cycle lengths shorten with inspiration and lengthen with expiration. If the cycle is unrelated to the respiratory cycle, it is referred to as nonphasic.



C

Figure 24-10: *A.* Sinus arrhythmia. The sinus cycles are indicated in seconds in the atrial (A) tier; they range from 0.60 to 1.01 s. Note that the P-wave amplitude increases as the sinus pacemaker accelerates. *B.* Sinus tachycardia. Note normally shaped and directed P waves, normal PR interval, and a rate of almost 150 per minute. *C.* Sinus bradycardia. Note normally directed (but abnormally wide) P waves, normal PR interval, and a rate of slightly more than 50 per minute.

A sinus rhythm at a rate below 60 impulses per minute is defined as sinus bradycardia (Fig. 24-10*C*); its significance is largely dependent upon clinical circumstances (see "Sinus Bradycardia," below). It may be normal, even at rates in the mid- to low 30s, in highly trained young athletes at rest, while it is generally considered abnormal, even at rates in the high 40s, in the elderly.

A sinus rate above 100 impulses per minute is defined as sinus tachycardia. Sinus rates in excess of 100 per minute are normal in infants and children under 2 years of age. Occasionally, otherwise normal older children and adults have sinus rates persistently or intermmitently (the latter often positional) in excess of 100 per minute in the absence of normal physiologic or pathologic stimuli for heart rate increases. Such forms of inappropriate sinus tachycardia, apparently mediated by autonomic factors in most cases[16,17] and by electrophysiologic factors in some,[17] may cause disturbing or disabling symptoms.[16,17] If fast enough and persisting for months, it may precipitate a reversible form of tachycardia-induced heart failure.[17,18]

The category of physiologic sinus tachycardias includes the normal sinus rate responses to exercise, excitement, anxiety, and other emotional stresses. Pharmacologic sinus tachycardias result from medications such as epinephrine, ephedrine, amyl nitrate, isoproterenol, and atropine, and may occur upon exposure to alcohol, nicotine, or caffeine. The heart rate responses are a result of the pharmacologic properties of these drugs. Pathologic sinus tachycardia may be secondary to noncardiac systemic factors or due to specific cardiac abnormalities. Among the secondary causes are fever, hypoxemia, hemorrhage, hypotension, thyrotoxicosis, and anemia. Cardiovascular causes include congestive heart failure, myocardial infarction, and pulmonary embolism.

ELECTROCARDIOGRAPHIC FEATURES

The ECG in sinus tachycardia reveals a rate in excess of 100 per minute accompanied by a normal PR relationship and a normal P-wave vector (Fig. 24-10*B*). The upper rate range of sinus tachycardia varies according to the patient's clinical status and factors responsible for the tachycardia. For instance, in the physiologic tachycardia group, the upper limit in the normal adult during exercise testing may range from 160 to 190 per minute, whereas the highly trained athlete may attain a rate of at least 200 per minute under maximal effort. In contrast, the pharmacologic tachycardias do not commonly induce a rate exceeding 140 per minute, whereas rates secondary to pathologic states usually range from just over 100 per minute to 150 per minute (e.g., hypotension, hypovolemia, hemorrhage, or fever) to 160 per minute (hyperthyroidism or severe heart failure). In a persistent sinus tachycardia, the rate characteristically varies during the course of the day, in contrast to the fixed rate that occurs in ectopic tachycardias or AV nodal reentrant tachycardia. Carotid sinus massage usually slows sinus tachycardia transiently.

MANAGEMENT OF SINUS TACHYCARDIA

Sinus tachycardia, except when it is an appropriate response to acute physical or emotional stress, is usually categorized as persistent and is easily recognized. Its management almost always depends on control of exogenous or endogenous systemic factors or of an underlying cardiac disease. Its differentiation from other SVTs at rates of 150 or more a minute may be achieved with carotid sinus massage. Specific therapy is rarely required. When it is required, beta-adrenergic blockade will often achieve at least partial control. In uncomplicated acute myocardial infarction, the sinus rate may be controlled with small doses of propranolol (10 to 20 mg every 6 h). Persistent sinus tachycardia occurs in thyrotoxicosis, and higher doses of propranolol may be required for its control. Sinus tachycardia during heart failure or hypovolemic states will respond promptly to improving hemodynamic status. The chronic or intermittent form of nonparoxysmal inappropriate sinus tachycardia, when symptomatic or associated with tachycardia-induced heart failure, may require RF energy modification or ablation of the sinus node area[19] if it is not controllable by drug therapy.

Premature Atrial Impulses

Atrial extrasystoles or premature atrial contractions (PACs) are extremely common and may occur in normal individuals or in the presence of systemic or cardiac abnormalities. They occur at any age, including infancy. Both endogenous (febrile illnesses, thyrotoxicosis, emotional stress, etc.) and exogenous (alcohol, tobacco, or caffeine consumption) systemic factors may initiate or worsen atrial extrasystolic activity. Among cardiac causes, myopericarditis, ischemia, heart failure, and digitalis intoxication are all precipitating or contributing factors.

ELECTROCARDIOGRAPHIC FEATURES

The PAC is characterized by (1) a P wave that occurs before the next expected sinus impulse and (2) a change in the vector of the premature P wave. For example, a negative P-wave deflection in leads II, III, and aVF suggests an origin from the lower portion of the atrium. The features of the PAC in leads I and V_1 can help distinguish right and left atrial origins. If the premature P wave is positive in lead I and negative in V_1, the impulse is probably of right atrial origin. A negative P wave in leads I and V_6, and a positive P wave in V_1 is consistent with a left atrial origin. If a premature P wave is narrower than in sinus and positive in aVR and aVL, a septal origin is probable. When a premature P wave is negative in aVL and positive in the inferior leads, a right superior pulmonary vein origin should be suspected.

The PR interval of the conducted PAC may be normal or prolonged (see Fig. 24-11). Marked prolongation of the PR interval may occur when the PAC is very premature and may also indicate the presence of dual AV nodal pathways. Subtle electrocardiographic patterns include (1) superimposition of the premature P wave on the T wave of the preceding sinus impulse and (2) an unexpected pause due to failure of conduction of a PAC to the ventricles. In both instances, careful inspection of the T wave of the sinus impulse before the PAC will reveal a distortion of the T wave, sometimes minimal, indicating the presence of the PAC. When the coupling interval of the PAC to the previous sinus P wave is short, aberrant intraventricular conduction makes the diagnosis dependent upon recognition of the P wave distorting the previous T wave (Fig. 24-11*B*). The hallmark of timing of PACs is the less than fully compensatory pause. Since the premature impulse commonly resets the sinus cycle, the PAC is bracketed by a cycle terminated by the early P wave and a return cycle close to the underlying sinus cycle length (Fig. 24-11*A*). The sum of the two cycles will be less than fully compensatory. Occasionally, fully compensatory pauses or longer than compensatory pauses occur because of failure to invade and reset the sinus node cycle or delay of its return because of overdrive suppression.

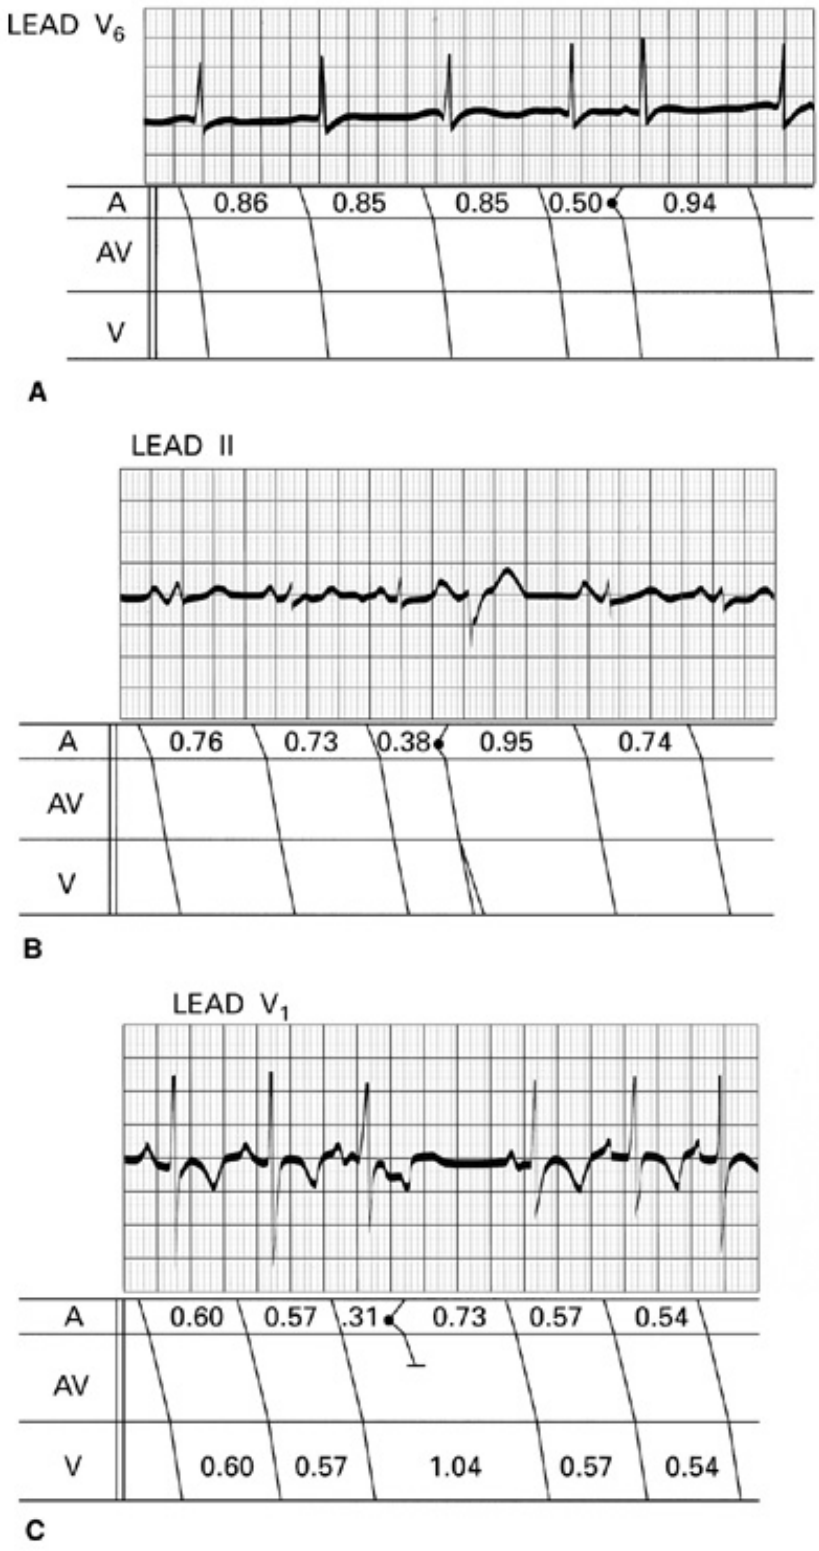


Figure 24-11: *A*. The fifth impulse is an atrial premature beat; there is a premature P wave (usually labeled P) followed by a normal QRS-T complex, and the postextrasystolic pause is longer than the sinus cycle but less than compensatory. *B*. The fourth impulse is an atrial premature beat with aberrant intraventricular conduction; there is a premature P wave followed by an anomalous QRS-T complex; the postextrasystolic pause is less than compensatory. *C*. Nonconducted atrial premature beat. Following the third ventricular complex, a P wave negatively deforms the ST segment and is not followed by a ventricular response.

MANAGEMENT OF PREMATURE ATRIAL CONTRACTIONS

PACs usually do not require treatment, especially when they occur in normal individuals or when due to systemic influences or minor cardiac abnormalities such as mitral valve prolapse and acute viral pericarditis. When PACs may be the triggering events for sustained arrhythmias, their management may become important. Generally, SVT due to AV nodal reentry or the WPW syndrome, paroxysmal atrial fibrillation, or the rare instances of induction of sustained ventricular arrhythmia by supraventricular impulses are best managed by therapy targeted to the prevention of the sustained arrhythmias, but occasionally suppression of triggering PACs is helpful. In recent years, repetitive focal PACs and atrial tachycardia on ambulatory monitor recordings from patients prone to atrial fibrillation have been identified as RF ablation targets during studies in the electrophysiology laboratory. In some patients, these forms of PACs appear to act not only as triggers, but also as drivers, of atrial fibrillation episodes.[20]

Annoying palpitations are a common symptom of PACs in patients who have either no underlying heart disease or mitral valve prolapse. Reassuring the patient of the benign nature of the arrhythmia may suffice, and no therapy is necessary other than removal of inciting factors, such as cigarettes, coffee, alcohol, and excessive fatigue. When the palpitations are sufficiently bothersome to affect on the quality of life, an intervention must be considered. A low dose of a beta-adrenergic blocking agent is preferred to more aggressive (and more dangerous) membrane-active antiarrhythmic agents. Digitalis has been tried, but no systematic studies of its efficacy have been reported.

When it is necessary to treat PACs because of intolerable palpitations, conventional antiarrhythmic agents may be effective. Depending upon tolerance and side effects, any of the membrane-active drugs or adrenoceptor-blocking agents may be considered. Few data are available on the efficacy of antiarrhythmic drug therapy for PACs, but clinical experience suggests that it may be effective, particularly in the absence of structural cardiac or pulmonary disease. Antiarrhythmic drugs have not been approved for this indication in the United States, and the threshold for their use for a troublesome but benign arrhythmia is high. Class IC (see Table 24-5) drugs should be avoided for this indication in patients with even the remote possibility of coronary artery disease because of the adverse outcome in the Cardiac Arrhythmia Suppression Trial (CAST).[21,22] Atrial distention in heart failure may induce PACs; they usually disappear as hemodynamics improve and antiarrhythmic drugs are avoided.

Supraventricular Tachyarrhythmias

Supraventricular tachyarrhythmias include all tachyarrhythmias that originate above the bifurcation of the bundle of His or incorporate tissues proximal to the bifurcation of the bundle of His in a reentrant circuit (Fig. 24-9). The diagnosis requires an atrial chamber rate of 100 impulses per minute or more; the ventricular rate may be less when AV conduction is incomplete. SVTs usually have narrow QRS complexes, but they may be wide because of aberrant conduction through the intraventricular conducting tissue, because of participation of a bypass tract in the ventricular depolarization pattern, or when bundle branch block coexists independently.

SVTs may be separated into three groups based on duration: brief paroxysms, persistent, and chronic. Arrhythmias that are paroxysmal in onset and offset [e.g., paroxysmal SVT (PSVT) due to AV nodal reentry or WPW syndrome, paroxysmal atrial fibrillation, and paroxysmal atrial flutter] tend to be recurrent and of short duration, lasting from seconds to hours. Persistent tachycardias [e.g., sinus tachycardia, ectopic atrial tachycardia (nonparoxysmal), multifocal atrial tachycardia, longer episodes of PSVT, or atrial flutter or fibrillation] may last for days or weeks and may be associated with a specific contributing pathophysiologic factor, such as decompensated chronic obstructive pulmonary disease, pulmonary emboli, electrolyte disturbances, or drug toxicity. They tend to be recurrent when an underlying structural cause, such as atrial disease or mitral valve disease, is the dominant pathophysiologic factor. When a transient

functional abnormality dominates, such as hypoxemia, heart failure, or an electrolyte abnormality, it may be an isolated clinical event, reappearing only if or when the inciting event occurs. Longstanding or chronic SVTs (e.g., chronic atrial fibrillation or chronic atrial flutter), particularly in the presence of advanced structural heart disease, generally do not revert if untreated, may fail to revert even with attempted treatment, and if reverted will frequently recur despite therapy.

THE REENTRANT PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIAS

PSVT may be due to AV nodal reentry, the WPW syndrome, or intraatrial or sinoatrial reentry. Most of the interventions for SVT listed in Table 24-7 are applicable to these arrhythmias.

Table 24-7: Management of Paroxysmal Supraventricular Tachycardias

Interventions	Acute	Long-Term
Physiologic interventions	Rest, sedationValsalva maneuverCarotid sinus massage	Self-administered Valsalva maneuver, carotid sinus massageAvoidance of inciting factors
Pharmacologic therapy	Drugs with direct effect on AV nodal or accessory pathway	Drugs that alter properties of AV node or accessory pathways
	Drugs that control ventricular rate	Drugs that control ventricular rate
Catheter ablation and surgical techniques	-	Ablation of reentrant pathwayModification of AV node
Electronic devices	Temporary pacingCardioversion	Permanent pacemaker

PSVT due to AV Nodal Reentry

The commonest form of PSVT is due to AV nodal reentry. The underlying disturbance in AV nodal reentry is the presence of dual AV nodal pathway physiology. Previously thought to be restricted to the compact anatomic AV node itself, the dual-pathway physiology is now known to exist in the *region* of the AV node. One pathway is capable of faster conduction and usually has a longer refractory period; the other conducts more slowly and has a shorter refractory period. Both the slow and the fast pathways have components in the low atrial approaches to the AV node as well as in the AV node itself (Fig. 24-12).

In the presence of dual AV nodal physiology, a premature atrial impulse with a coupling interval sho enough to encroach on the refractory period of the fast pathway may block in the fast pathway while allowing conduction to proceed through the slow pathway (Fig. 24-12*B*). This results in slower-than-normal conduction through the AV node, prolonging the PR interval abruptly. The slowly propagating impulse may then reenter the fast pathway in the retrograde direction and arrive at the proximal end after it has recovered excitability. When this occurs, a circuit is completed and the impulse may then reenter the slow pathway if it too has regained excitability (Fig. 24-12*C*). Once established, this reentrant pattern will continue until the relationship between conduction times and refractory periods in the two pathways is disturbed so as to interrupt the cycle. The circulating impulse progresses through the His-Purkinje system to ventricular muscle each time it passes the distal end of the reentrant loop and provides retrograde atrial activation each time it passes the proximal end. Because antegrade conduction is slow and retrograde conduction rapid, atrial activity begins soon after the onset of ventricular activation,

usually creating an inability to identify P waves on the standard ECG during AV nodal reentrant tachycardia (Fig. 24-13) because they are within the QRS complex. The characteristic alignment of electrograms recorded during AV nodal reentrant tachycardia is shown in Fig. 24-14*A*. In a much less common form of AV nodal reentry, the circulating wavefront proceeds antegradely down the fast pathway and retrogradely up the slow pathway, creating a sequence of excitation of atria that is delayed relative to ventricular activation because of slow retrograde conduction. This form of AV nodal reentrant tachycardia is characterized by a long RP interval and a short PR interval, with a clearly visible inverted P wave in II, III, and aVF (Fig. 24-9). The electrophysiologic findings in the common and uncommon forms of AV nodal reentry are compared in Figs. 24-14*A* and -14*B* (see also Chap. 23).

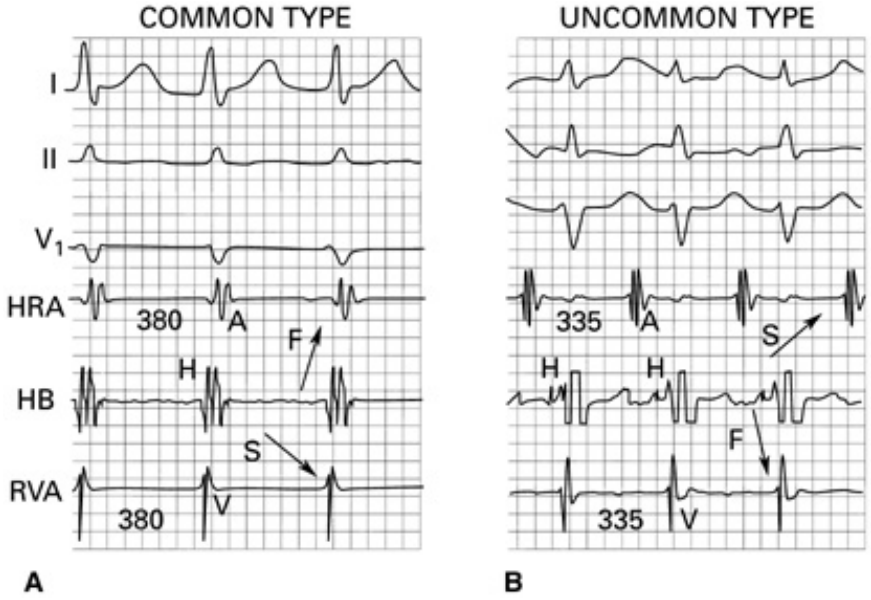

Figure 24-14: Common and uncommon forms of AV nodal reentrant tachycardia recorded during electrophysiologic studies. *A*. The common type of AV nodal reentrant tachycardia, antegrade conduction in the slow pathway and retrograde in the fast pathway, results in atrial (A) and ventricular (V) activation that are close to one another in time. Characteristically, intracardiac recordings demonstrate a 'lining up' of atrial and ventricular electrograms, indicating that the atria are activated before completion of ventricular activation. *B*. In the uncommon type of AV nodal reentrant tachycardia, antegrade fast pathway and retrograde slow pathway conduction change the relative timing pattern so that atrial activation is delayed relative to ventricular activation, and the electrograms are not in line. In this form of PSVT, the RP interval is longer than the PR interval on the ECG, which results in inscription of the retrograde P wave *after* the ST-T wave of the related ventricular impulse. The uncommon type of AV nodal reentrant tachycardia may be difficult to distinguish from other arrhythmias, such as ectopic atrial tachyarrhythmias or concealed WPW syndrome (see the text).

ELECTROCARDIOGRAPHIC FEATURES

PSVT due to AV nodal reentry is characterized by an abrupt onset and offset, and usually has a narrow QRS complex without clearly discernible P waves. Occasionally, however, P waves can be seen as "pseudo-R" waves, particularly in V_1 and the inferior leads, and more rarely as "pseudo-Q" waves, when the retrograde atrial depolarization precedes ventricular depolarization. Comparison with QRS morphology during sinus rhythm is essential to establish the presence of these waves.

The heart rate during PSVT due to AV nodal reentry is commonly in the range of 160 to 190 per minute but may be as slow as 120 to 130 per minute and occasionally faster than 200 per minute. When preexisting bundle-branch block is present, the tachycardia will reflect the preexisting wide QRS complex, and functional bundle-branch block due to tachycardia may also occur, making a distinction from ventricular tachyarrhythmias difficult (Fig. 24-15). Functional bundle-branch block may have either a left or a right bundle-branch block pattern.

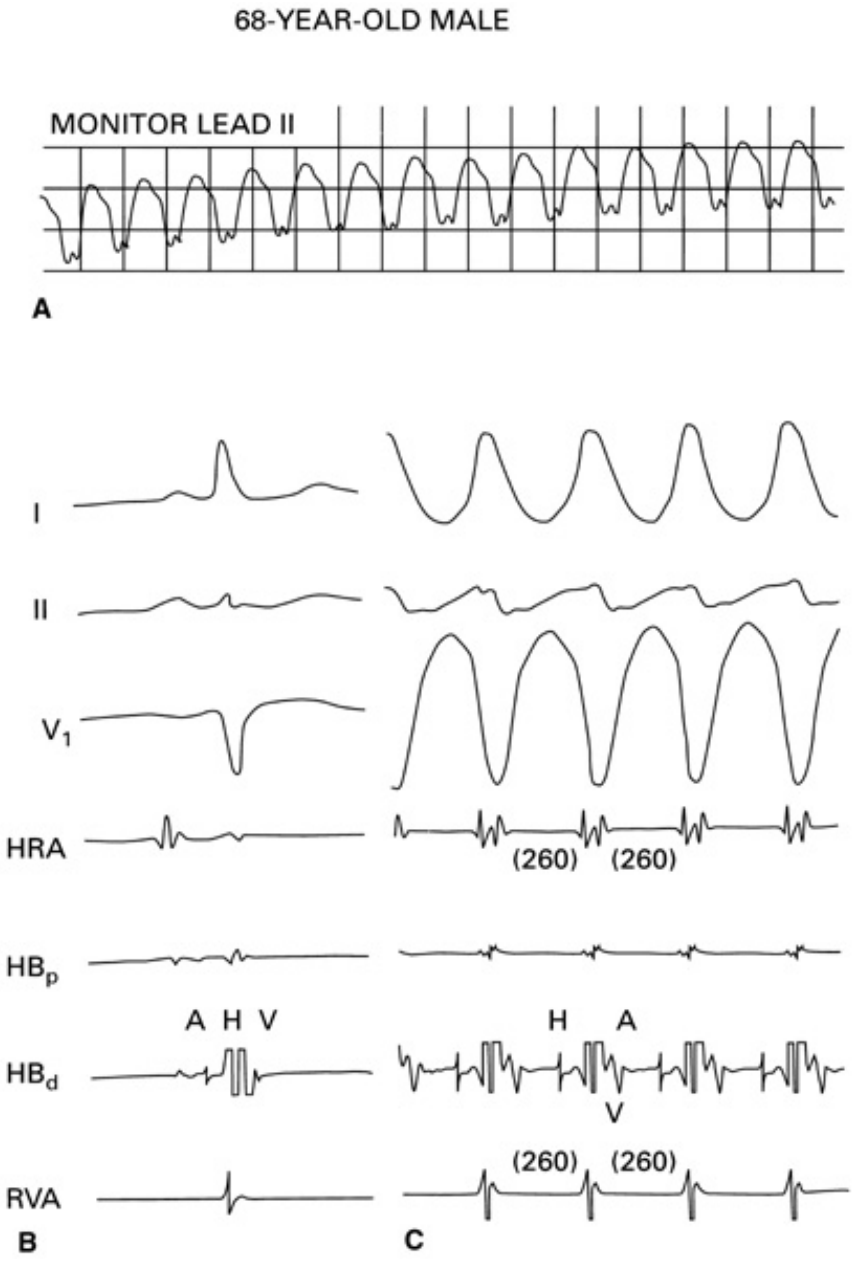

Figure 24-15: PSVT due to AV nodal reentry. *A.* The initial presenting rhythm was a wide-QRS tachycardia with a vertical axis and a left bundle-branch block pattern. *B.* A sinus impulse with intracardiac recordings demonstrating normal sequences of AV conduction. *C.* Recording during a wide-QRS tachycardia with a left bundle-branch block pattern. The nearly simultaneous A and V activation patterns in the retrograde and antegrade directions (i.e., atrial activation before the end of ventricular activation) suggest the common form of AV nodal reentry rather than ventricular tachycardia.

MANAGEMENT OF PSVT DUE TO AV NODAL REENTRY

PSVT due to AV nodal reentry is a benign disturbance requiring intervention primarily for the patient's comfort and sense of well-being. When it coexists with other disease processes in which the tachyarrhythmia is poorly tolerated, such as ischemic heart disease or mitral stenosis, it may have more serious implications. Occasionally, the rate is rapid enough to cause near-syncope or syncope in otherwise normal individuals, although such rates are more common in PSVT due to WPW (see below).

Rest, sedation, and vagotonic maneuvers are simple means of reverting acute episodes, and patients can be taught self-administered vagotonic maneuvers for recurrences. Patients should be advised to avoid inciting factors, such as smoking, alcohol, extreme fatigue, and stress. Many of the effective pharmacologic interventions for acute episodes used in the past have given way to new drug therapy. Infusions of sympathomimetic drugs (e.g., phenylephrine or methoxamine), parasympathomimetic drugs (e.g., edrophonium or neostigmine), and digoxin have been supplanted by intravenous adenosine, Ca^{2+}-entry blockers, or beta-adrenergic blockers for managing the acute episodes. Adenosine, 6 mg given intravenously (see Fig. 24-13), followed by one or two 12-mg boluses if necessary, is effective and safe[23] for acute treatment. Because of its very short duration of action and lack of the negative inotropic effects of Ca^{2+}-entry blockers, it is now preferred to other acute pharmacologic therapies, especially when managing a patient with concomitant structural heart disease. A 5-mg bolus of verapamil, followed by one or two additional 5-mg boluses 10 min apart if the initial dose does not convert the arrhythmia, has been an effective regimen in up to 90 percent of patients with PSVT due to AV node reentry.[24,25] However, it must not be used for an unknown wide QRS tachycardia because of risk of adverse effects when used in patients who have VT.[26] Intravenous diltiazem is also effective.[27,28] Initial treatment consists of a bolus of 0.25 mg/kg body weight administered over 2 min. If the response is inadequate, a repeat bolus of 0.35 mg/kg over 2 min is administered 15 min later. Intravenous digoxin, 0.5 mg infused over 10 min and repeated if necessary, may convert the arrhythmia. An additional 0.25 mg every 4 h to a maximum dose of 1.5 mg in 24 h may be used. A slow infusion of propranolol may be used;[29] 1 mg/min is given to a total dose of 5 to 10 mg or a significant fall in blood pressure. The class IA antiarrhythmic agents, which appear to depress conduction in the fast pathway, may be tried if other drugs fail,[30] a strategy that is rarely needed.

Several special points must be remembered. When the QRS complex is wide and VT is mistakenly diagnosed as SVT with aberrant conduction, intravenous verapamil frequently causes a clinically significant fall in blood pressure and potentially lethal events.[26] Unless it is known with certainty that a wide QRS tachycardia is due to aberrant intraventricular conduction or preexisting bundle-branch block, verapamil should not be used. Similarly, in patients with coexisting hemodynamically significant underlying heart disease, intravenous propranolol must be used with caution, if at all. For those few patients in whom the clinical setting demands an immediate return to a normal sinus mechanism, DC cardioversion can be employed. A low-energy shock (10 to 50 W·s) may be sufficient; larger energies are used if necessary. If DC cardioversion should be avoided, pacing the right atrium or ventricle via a temporary pacing catheter is usually successful (see Chap. 31).

Long-term prevention of recurrent PSVT due to AV nodal reentry may be achieved with pharmacologic therapy or catheter ablation. Surgical techniques and electronic devices have been used in the past but are now obsolete. Patients who have infrequent, well-tolerated episodes that are short-lived and/or respond to self-administered physiologic maneuvers (Table 24-7) may require no long-term interventions. In many others, pharmacologic therapy is sufficient. Most patients have reduced numbers and severity of attacks with simple medications such as propranolol, verapamil, or digoxin. These drugs act by altering conduction velocities and refractory periods in the AV nodal pathways, disrupting the delicate balance required for initiation or maintenance of sustained arrhythmias. Membrane-active antiarrhythmic drugs may prevent

recurrences, both by suppressing triggering premature impulses and by depressing conduction in the anterograde (fast) pathway of the AV nodal reentrant circuit.[30] However, the risk of potentially serious proarrhythmic responses, combined with other troublesome side effects, limits their use for these arrhythmias.

RF catheter ablation is safe and very effective for PSVT due to AV nodal reentrant tachycardia.[31,32] It has therefore emerged as the treatment of choice for patients with frequent arrhythmic episodes and/or poor tolerance of drugs. It is also the preferred option for pharmacologically controllable AV nodal reentrant tachycardia among patients who want to avoid pharmacologic side effects. Among women who have a history of clustering of episodes of AV nodal reentrant tachycardia when perimenstrual, RF ablation procedures should be scheduled when they are premenstrual, in order to maximize the chance of inducing the target arrhythmia during the procedure.[33]

PSVT due to Accessory Pathways: Wolff-Parkinson-White Syndrome

As in AV nodal reentry, the pathophysiology of reentrant tachyarrhythmias in WPW syndrome is a consequence of the presence of two pathways between the atria and the ventricles that have different conduction properties and refractory periods. WPW syndrome appears to be the second commonest cause of PSVT. Since it also occurs in a concealed form, in which the standard ECG is normal during sinus rhythm because of inability of the accessory pathway (AP) to conduct in the antegrade direction, the total number of PSVTs that are due to APs may be considerably higher than previous estimates. In the majority of patients, the effective refractory period of the AP exceeds that of the normal AV nodal-His-Purkinje pathway. Therefore, a premature atrial impulse may block at the AP and conduct antegradely in the normal pathway, ultimately entering the AP in the retrograde direction and reentering the atrium to establish a circus movement tachycardia referred to as orthodromic (Fig. 24-16*A*). Since the AP joins ordinary atrial and ventricular muscle and is not composed of specialized conduction tissue, AP conduction is rarely decremental (as it is in the AV node).

Because the normal pathway is responsible for ventricular activation and the AP for return to the atria, the delta wave is absent during orthodromic tachycardia, causing the QRS complex to normalize. In addition, since the AP provides retrograde conduction to the atria, P waves, if seen, are usually inverted in the inferior and lateral leads. The stability of the reentrant circuit depends upon the balance between conduction properties and refractory periods of the two pathways. In a much less common form of PSVT, a shorter refractory period in the anomalous pathway results in block of an initiating premature atrial impulse in the normal pathway, with antegrade conduction down the AP and then retrograde invasion of the normal AV nodal pathway to establish an antidromic tachycardia. The QRS complex is wide, having the characteristics of a ventricular complex originating near the insertion site of the AP (Fig. 24-16*B*). These wide QRS tachycardias may be difficult to distinguish from ventricular tachyarrhythmias if the existence of WPW syndrome is not established prior to presentation with a tachyarrhythmia. In the concealed form of WPW syndrome,[34,35] only orthodromic tachycardias can occur, because of inability of the AP to conduct in the antegrade direction. Distinction between concealed WPW syndrome and AV nodal reentrant tachycardia may be difficult, although a faster rate (greater than 200 per minute) and a visible retrograde P wave after, rather than lost within, the QRS complex favor concealed WPW syndrome. When atrial flutter or fibrillation occurs in patients with WPW syndrome, the risk of potentially lethal arrhythmias due to very rapid conduction across APs must be considered. The risk is particularly treacherous in patients with short-refractory-period APs, since atrial fibrillation may induce ventricular fibrillation in that circumstance.

PSVT in WPW syndrome may begin in childhood or may not appear until middle age. Among women, there appears to be an increased propensity for the first tachyarrhythmic event to occur during pregnancy.[36] In asymptomatic patients, the probability of losing the capacity for antegrade

conduction across the AP increases with advancing age.[37] Symptomatic arrhythmias may be due to PSVT, atrial fibrillation or flutter, or both in individual patients. In a series of 212 patients with tachyarrhythmias and WPW, PSVT alone occurred in 64 percent, atrial fibrillation alone in 20 percent, and both in 16 percent.[38] Since the reentrant tachyarrhythmias tend to be more rapid than those in patients with AV nodal reentry, they may be more symptomatic. Light-headedness, near-syncope, and syncope appear to occur more commonly in WPW with PSVT or atrial fibrillation than in AV nodal reentry. A risk of sudden death in patients with WPW has been emphasized, but the magnitude of the risk is unknown, even among those with APs that have short refractory periods. Other factors that appear to influence risk are the presence of multiple bypass tracts and a family history of premature sudden death.[39]

ELECTROCARDIOGRAPHIC FEATURES

During normal sinus rhythm, the presence of an AP capable of antegrade conduction (manifest WPW) is recognized by the presence of a short PR interval, followed by slurred initial forces of the QRS complex-the delta wave-resulting from early activation (preexcitation) of the portion of ventricular muscle because specialized conduction has been bypassed. Several algorithms have been developed to identify the location of the AP electrocardiographically.[40,41] Some useful general rules include the following:

1. If the delta wave is positive in lead I and negative in lead V_1, the AP is probably right-sided; the vectors are generally opposite for left-sided tracts.
2. If the delta wave is positive in the inferior leads, the tract is likely to be anterior, and if it is negative in these leads, posterior. If it is negative in aVL, a left lateral AP is likely (Fig. 24-17).

The most common patterns recorded during PSVT due to WPW syndrome are narrow QRS tachycardias at rates ranging from 160 to 240 per minute. Rates may occasionally be faster or somewhat slower. When the tachycardia is antidromic, the QRS complexes are wide and have characteristics similar to fully preexcited impulses during sinus rhythm or PACs (see Fig. 24-16*B*). In atrial fibrillation with WPW syndrome, if the AP has a refractory period longer than the normal pathway, the delta wave will disappear and patterns typical of atrial fibrillation with narrow QRS complexes will be recorded. In contrast, when the refractory period of the AP is shorter, wide QRS complexes dominate the tracing (Fig. 24-18). Multiple bypass tracts are suggested by multiple wide-QRS-complex morphologies during atrial fibrillation with preexcited conduction (Fig. 24-18*B*). A grossly irregular rhythm with wide QRS complexes and a mean ventricular rate in excess of 200 per minute is a clue supporting WPW with atrial fibrillation in the differential diagnosis of a wide-QRS-complex tachycardia. Another form of wide-QRS tachycardia in WPW is orthodromic tachycardia with functional bundle-branch block. When a patient with left lateral bypass tract abruptly develops a wide QRS complex with a left bundle-branch block pattern during orthodromic tachycardia, the diagnosis of SVT with aberrancy is strongly suspected when the cycle length of the tachycardia *lengthens*. Functional left bundle-branch block delays arrival of the circulating impulse at the distal end of a left-sided AP, thereby lengthening the tachycardia cycle. Under most other conditions, appearance of functional left bundle-branch block correlates with *shortening* of the tachycardia cycle length, because the accelerating tachycardia rate encroaches on the refractory period of the left bundle branch (see also Chap. 23).

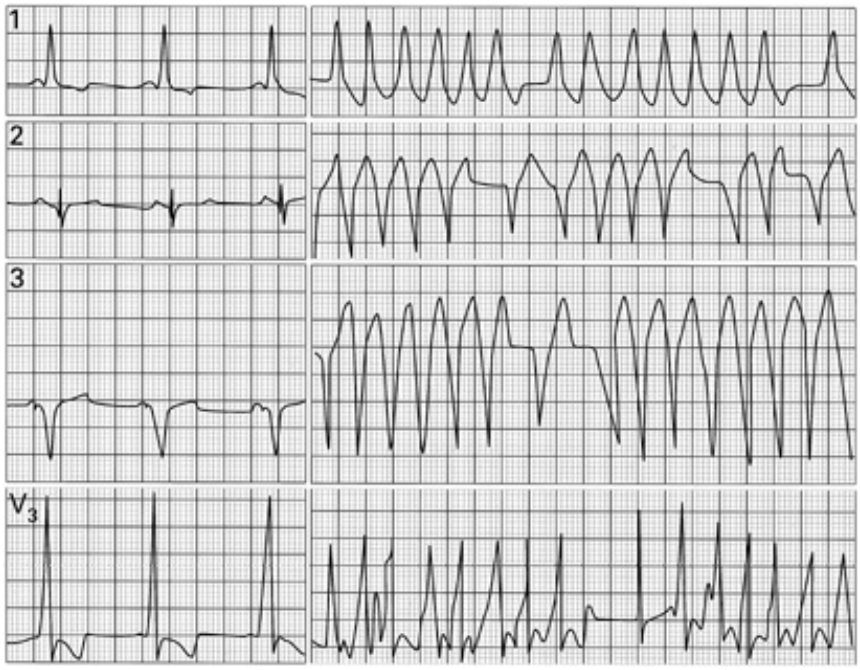

Figure 24-18: Atrial fibrillation in WPW syndrome with accessory pathway conduction. *Left.* Sinus rhythm with a typical preexcitation (delta-wave) pattern. *Right.* Accessory pathway conduction during atrial fibrillation. The QRS axis has shifted to the left, and the ventricular rhythm is now irregular, at a rate in excess of 200 per minute. (From Marriott HJL, Rogers HM. Mimics of ventricular tachycardia associated with the WPW syndrome. *J Electrocardiol* 1969; 2:77. Reproduced with permission from the publisher and authors.)

MANAGEMENT OF PSVT DUE TO WPW SYNDROME

This form of reentrant SVT is amenable to a broad range of interventions. Careful attention to the details of therapy is required because a subgroup of patients is at risk for potentially lethal arrhythmias due to very rapid conduction across the AP during atrial flutter or fibrillation. This concern influences the pharmacologic approaches to PSVT in the WPW syndrome, since drugs have different effects on APs and the AV node and because reciprocating PSVT may convert to atrial flutter or fibrillation.[42]

Physiologic interventions and vagomimetic drugs can be used safely during acute episodes of reciprocating tachycardia. In addition, adenosine, verapamil diltiazem, propranolol, and membrane-active antiarrhythmic agents, such as procainamide, quinidine, or disopyramide, may be used to convert acute reentrant tachycardias. Verapamil[43,44] and lidocaine[45] may accelerate the ventricular rate during atrial flutter or fibrillation in the WPW syndrome, however, and should be avoided if atrial fibrillation is present or if the patient has previously demonstrated alternation between atrial fibrillation and reciprocating tachycardia. Digoxin must be avoided in patients with WPW because it may shorten the refractory period of the AP[46] as well as atrial muscle. Should this occur in the presence of unrecognized atrial flutter or fibrillation or with the conversion of a reciprocating tachycardia to atrial fibrillation, the patient could develop a life-threatening tachyarrhythmia due to rapid AP conduction.[47] Whenever there is doubt, therapy should be limited to those drugs that will depress conduction in the AP or prolong its refractory period, such as the membrane-active antiarrhythmic agents (e.g., intravenous procainamide), or to agents, such as adenosine, that usually have no effect on an AP. Electrical cardioversion should be used if other means have failed or as initial therapy if the patient has extremely rapid rates causing hemodynamic intolerance of the tachycardia.

The approach to long-term management of patients with WPW syndrome is determined by the

physiologic characteristics of the bypass tract and the frequency, duration, and symptoms of arrhythmias. Two primary approaches to therapy are available: drugs and catheter ablation. The latter, using an RF energy source (Fig. 24-19), is the preferred method for treatment of patients with tachycardias symptomatic enough to limit their quality of life (e.g., near-syncope or syncope) or with symptomatic life-threatening arrhythmias in WPW (e.g, atrial fibrillation with short refractory period bypass tract)[34,48] (see Chap. 28). Surgery is a rarely used secondary approach, reserved for the occasional patients requiring treatment and not amenable to catheter ablation or pharmacologic therapy and for some who require surgery for other causes as well.[49] Although intracardiac electrophysiologic studies provide information on drug efficacy and pharmacologic effects on the bypass tract,[50] this invasive procedure is seldom performed for this purpose any longer.[51] Patients who demonstrate a good clinical response to therapy, measured in terms of reduced frequency or rate of tachyarrhythmic episodes, can be managed noninvasively; patients with an intermittent delta wave and no clinical arrhythmia need no therapy. On the other hand, patients who have frequent or poorly tolerated tachyarrhythmias, those who are prone to episodes of atrial flutter or fibrillation[52] (particularly if they develop wide QRS complexes during their tachyarrhythmias, suggesting bypass tract conduction), or those who have a family history of WPW and sudden death[39,53] should be evaluated by electrophysiologic testing. In such patients, catheter ablation using RF energy is the intervention of choice when available in an experienced laboratory and accepted by the patient.[32,48,54] In the event of failure of the technique to interrupt the tract or tracts, surgical interventions may be considered,[55,56] but the threshold for surgical intervention is higher. Among those with symptomatic or life-threatening arrhythmias for whom RF ablation is not available, accepted, or feasible, a clear-cut response to antiarrhythmic therapy is mandated. Among the antiarrhythmic agents, the class IA, IC, and III drugs (see Table 24-5) may be useful. Not all drugs in these categories are approved for this indication in the United States, but efficacy studies are impressive.[57-61] Because of its side-effect profile, the threshold for use of amiodarone has been higher, despite good efficacy[59] (see also Chap. 27). PSVT also occurs in patients with *concealed* WPW syndrome,[35,62] a condition in which the bypass tract is incapable of conducting in the antegrade direction. Thus, there is no delta wave during sinus rhythm, but intact retrograde conduction permits completion of reciprocating tachycardia circuits. The diagnosis is suggested by longer RP intervals on the ECG during tachycardia than occur in AV nodal reentry[35] and can be established by electrophysiologic testing. Management is similar to that for other WPW syndrome patients. However, even though atrial fibrillation may occur, there is no concern about risk of degenerating to ventricular fibrillation. In such patients, the ventricular rate is controlled by normal AV nodal properties, since the AP cannot provide antegrade conduction.

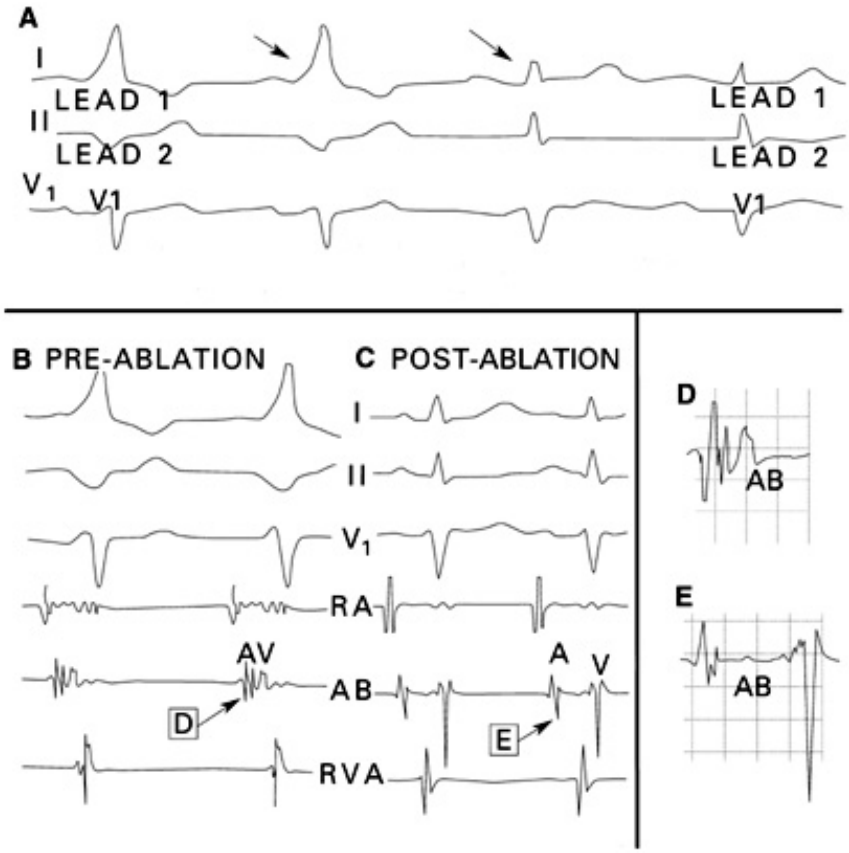

Figure 24-19: RF ablation in WPW syndrome in a 52-year-old female. The patient had frequent recurrent supraventricular tachycardias due to WPW syndrome. *A.* Standard leads I, II, and V_1 demonstrate disappearance of the delta wave from one impulse to the next 5 s after beginning the application of RF energy (compare successive QRS complexes indicated by arrows). *B.* Prior to ventricular ablation, the interval between atrial (A) and (V) activation at the site of the ablation catheter is less than 50 ms, and the sharp spike between A and V likely represents activity in the bypass tract. *C.* Immediately after ablation, the AV interval at the site of the ablation catheter is lengthened to 150 ms, and the accessory pathway spike has disappeared. *D, E.* Enlargements from panels B and C, respectively. AB, ablation catheter; RA, right atrium; RVA, right ventricular apex.

Other Paroxysmal Reentrant SVTs

The other reentrant SVTs are far less common than PSVT due to AV node reentry or WPW syndrome. The PSVT due to sinus node reentry[63,64] is difficult to distinguish clinically and by ECG from sinus tachycardia, except for its paroxysmal onset and offset. P-wave morphology is similar to that in sinus tachycardia. Intraatrial reentry[64,65] may be difficult to distinguish from certain forms of automatic ectopic atrial tachycardia. Intraatrial and sinus node reentry are distinguished from PSVT due to AV node reentry or WPW on a standard ECG because P waves precede narrow QRS complexes during these tachycardias.

Atriofascicular and nodoventricular pathways (Mahaim tracts)[66] may cause PSVT with wide QRS complexes having a left bundle-branch block pattern. Intracardiac electrophysiologic studies are usually necessary for specific diagnosis and treatment of these various PSVTs. There is no generally accepted and predictably effective approach to therapy. Intraatrial reentrant tachycardia may be treated with conventional membrane-active antiarrhythmic agents (beta-adrenergic blocking agents, or perhaps Ca^{2+}-entry blockers). Sinus node reentry may respond to digoxin, propranolol, diltiazem, or verapamil. Surgical interventions[67] are only rarely considered for these

arrhythmias because of their usually benign nature, but catheter ablation with RF energy has proved to be useful for many (see also Chap. 28).

ECTOPIC ATRIAL TACHYCARDIAS

These arrhythmias are usually persistent, are commonly referred to as "nonparoxysmal," and may be associated with specific inciting factors. There are experimental and clinical reasons to support the notion that ectopic atrial tachycardias can be due to mechanisms of reentry,[68] automaticity (enhanced spontaneous phase 4 depolarization),[69] or triggered activity.[70] An underlying toxic or metabolic cause is commonly identified as the factor responsible for ectopic atrial tachycardia, but some are persistent or recurrent, likely due to focal atrial disease. When an ectopic atrial rate is in the range of 160 to greater than 200 per minute and associated with 2:1 conduction or variable block in a patient receiving digitalis, a digitalis-toxic rhythm must be suspected strongly. Decompensated chronic lung disease, metabolic abnormalities (including acute alcohol abuse), electrolyte disturbances, and hypoxemia should be considered when digitalis toxicity has been excluded. Various forms of cardiac disease, including acute myocardial infarction, also may cause ectopic atrial tachycardia. Ectopic tachycardias also may originate from atrial suture lines in patients who have previously had complex congenital heart disease surgery.[71] The atrial arrhythmias may appear many years after the surgery.

Electrocardiographic Features

P waves are usually normal to small in amplitude and may be difficult to identify when the ventricular rate is rapid (Fig. 24-20). Atrial activity does not slow during carotid sinus massage, but AV conduction is usually impeded, making P waves more evident. When ectopic atrial tachycardia is due to digitalis intoxication or occurs in the presence of hyperkalemia, P waves may be "diminutive" (Fig. 24-21*A*).

Management of Ectopic Atrial Tachycardias

Treatment is dictated by identification and reversal of inciting factors, by ablation of a defined focal source when identifiable, and by control of the heart rate when necessary. Temporary pacing is required infrequently. More commonly, the problem is one of a rapid ventricular rate. Attempts to control the ectopic atrial arrhythmias with membrane-active antiarrhythmic drugs have not been generally successful. (Beta-adrenergic blocking agents or Ca^{2+}-entry blocking agents may be successful in controlling the arrhythmia in some patients, but a uniformly beneficial response should not be expected. Electrical cardioversion is not indicated because it is usually unsuccessful.

The mainstay of therapy remains the removal or reversal of inciting factors. If a controllable inciting factor cannot be identified or reversed, antiarrhythmic drugs may be tried. In addition, catheter ablation techniques may have a short-term success rate of as much as 80 percent among those whose arrhythmia has a structural basis.[72] It is not useful for metabolic or toxic causes and is very limited for those having multiple foci of origin.

MULTIFOCAL ATRIAL TACHYCARDIA: CHAOTIC ATRIAL RHYTHM

The diagnosis of multifocal atrial tachycardia, or chaotic atrial rhythm, requires the electrocardiographic identification of P waves having three or more different morphologies, occurring at different cycle lengths (Fig. 24-21*B*). The rhythm, as the name indicates, is usually very irregular, but the rate is not usually excessive (less than 140 per minute).[73] It is most commonly associated with underlying lung disease, metabolic abnormalities, electrolyte disturbances, and, in rare instances, toxic causes, such as digitalis intoxication. Calcium-entry blockers have been tried with some success[74] when given acutely, but there is little success with

conventional membrane-active antiarrhythmic ages. Beta-adrenergic blockers have also been suggested,[75] but feasibility of their use may be limited by the nature of the underlying disease (e.g., chronic obstructive pulmonary disease). Removal of inciting factors (e.g., improvement of P_{O_2}, P_{CO_2}, pH, and/or electrolyte status) has been the most successful approach when the rhythm is associated with pulmonary or metabolic dysfunction, but many patients are forced to tolerate a chronic low-grade tachyarrhythmia because of inefficacy of any approach. There is no role for cardioversion, implantable devices, surgery, or catheter ablation.

ATRIAL FLUTTER

Atrial flutter is a rapid, regular atrial tachyarrhythmia that is less common than the PSVTs or atrial fibrillation. It is observed infrequently in normal individuals[76] but may occur at any age in the presence of underlying atrial abnormalities, such as those secondary to mitral valve disease, congenital heart disease, cardiomyopathies, and, less frequently, coronary artery disease. Subgroups at particularly high risk for developing atrial flutter are children, adolescents, and young adults who have undergone corrective surgery for complex congenital heart diseases, most notably transposition of the great vessels, tetralogy of Fallot, or atrial septal defects.[77]

Atrial flutter has been separated into two types: classic, or type I, and type II.[78] Classic type I flutter is characterized by a single right atrial macroreentrant circuit with defined anatomic and functional boundaries and an obligate pathway through an area of slow conduction, the subeustachian isthmus. This isthmus-dependent conduction pattern in classic type I atrial flutter travels in a counterclockwise rotation up the interatrial septum, down the atrial free wall, and along the crista terminalis, which serves as an anatomic barrier.[79] The other boundaries of this reentrant circuit include the tricuspid valve ring on one side and an area of probable anatomic block in the region extending from the venae cavae to the eustachian valve and ridge on the other side. A clockwise rotation around the same circuit can generate a variant of type I atrial flutter that may occur spontaneously and may also be induced repeatedly during electrophysiologic studies.

The distinction between type I and type II atrial flutter is based upon (1) the ability to entrain and interrupt type I flutter with atrial pacing techniques and (2) a faster atrial rate in type II flutter. Untreated type I flutter usually has atrial rates between 280 and 320 per minute, commonly very close to 300 per minute. Type I, however, may occur infrequently at rates as low as 240 to 250 and as high as 340 per minute. In type II flutter, the atrial rate is commonly at least 340 to 350 per minute and occasionally may be as fast as 450 per minute. The ventricular rate in atrial flutter is usually a defined fraction of the atrial rate, for example, 2:1 conduction in type I flutter generating a characteristic ventricular rate of 150 per minute and 4:1 conduction at 75 per minute. Group beating may occur, often reflecting two levels of block in the AV junction with a Wenckebach phenomenon influencing the impulses conducting below the site of 2:1 block.[80] Clinically, atrial flutter may occur in brief, persistent, or chronic forms, and therapeutic approaches are influenced by the clinical pattern.

Electrocardiographic Features

Atrial flutter generates a defined pattern of atrial activity in the ECG. In typical type I atrial flutter with counterclockwise rotation, the classically described sawtooth pattern is identifiable in leads II, III, and aVF (Fig. 24-22). The electrical activity appears continuous in these leads, without a defined isoelectric baseline between flutter waves. In contrast, a discernible isoelectric line may appear in these leads when type I atrial flutter is slower than usual, as may occur in the presence of antiarrhythmic drugs. An isoelectric baseline may also be discernable in type I atrial flutter with clockwise rotation.

In contrast to the pattern observed in leads II, III, and aVF, other leads (most notably lead V_1)

generally have discrete flutter waves inscribed with an isoelectric line between them (Fig. 24-22). The pattern in leads II, III, and aVF likely reflects continuous electrical activity in the reentrant pathway in the low right atrium, while the pattern in lead V_1 reflects discrete wavefronts of activation approaching an area remote from the reentrant loop.

The most common AV conduction ratios in atrial flutter are 2:1 and 4:1, generating a ventricular rate of approximately 150 and 75 per minute, respectively. In young children and, rarely, in adults, 1:1 AV conduction may occur, resulting in a ventricular rate of 300 per minute. Continuous 3:1 and 5:1 ratios are very rare, but alternating 2:1 and 4:1 ratios are common, generating a bigeminal pattern. Such patterns commonly contain Wenckebach periods at the lower level of block (Fig. 24-23). Occasionally, the second impulse of the bigeminal pattern is aberrantly conducted in the ventricles, requiring a distinction between Ashman's phenomenon (aberrant intraventricular conduction due to long-short cycle sequences) and a ventricular ectopic beat. Atrial flutter associated with high-grade or complete AV block will produce a ventricular rate below 60 per minute, with dissociation between flutter waves and QRS complexes in the case of complete AV block (Fig. 24-24).

A narrow QRS complex tachycardia at a rate of 150 per minute should always lead to the consideration of atrial flutter. Carotid sinus massage will not interrupt atrial flutter but nonetheless may be very helpful in distinguishing flutter from other mechanisms because of a characteristic two-component response to this parasympathetic stimulus (Fig. 24-25). One component is impairment of AV nodal conduction, which causes an abrupt change from a rate of 150 per minute to 75 per minute or less. The unmasking of hidden flutter waves at the slower ventricular rate will make the diagnosis evident. The other component is the unique *acceleration* of the atrial rate in atrial flutter during carotid sinus massage (Fig. 24-25). The combination of abrupt *slowing* of the ventricular rate and an *increased rate* of atrial electrical activity strongly supports the diagnosis of atrial flutter. Occasionally, carotid sinus massage will cause atrial flutter to convert to atrial fibrillation.

Management of Paroxysmal Atrial Flutter

Treatment of acute paroxysmal atrial flutter differs from the treatment of PSVT due to AV nodal reentry or AV reciprocating mechanisms. Carotid sinus massage will not interrupt atrial flutter but transiently slows the ventricular rate by impairing AV nodal conduction (Fig. 24-25). The pharmacologic treatment of atrial flutter may be directed to reversion to a sinus mechanism or to control of the ventricular rate. The usual ventricular rate of 150 impulses per minute (±10 impulses per minute) may be well tolerated in the absence of myocardial dysfunction, symptomatic coronary artery disease, or mitral stenosis. The ventricular rate should be slowed with digitalis before antiarrhythmics are instituted to convert the atrial arrhythmia to avoid very rapid rates associated with drug-induced 1:1 AV conduction.[82] Control of the heart rate during the paroxysm may also be achieved with Ca^{2+}-entry blocking agents.[25] Verapamil has been studied in detail, and intravenous diltiazem is also successful.

When the ventricular rate is poorly tolerated due to effects on hemodynamics or coronary blood flow, electrical cardioversion is used as initial treatment. An attempt using 10 to 50 J may be successful; higher energies are often necessary. Membrane-active antiarrhythmic agents are used to convert flutter to sinus rhythm, but efficacy is unpredictable. Historically, quinidine has been the initial drug of choice, but the other class IA antiarrhythmic agents may be equally effective. Conventional dosing schedules are now used, in contrast to the highly toxic aggressive quinidine protocols of the past. The class IC drugs (e.g., flecainide or propafenone) may also be effective for pharmacologic reversion of atrial flutter,[57] although they slow intraatrial conduction without lengthening refractory periods. This drug effect may result in slowing atrial flutter from 300 per minute to less than 240 per minute, allowing 1:1 conduction to the ventricles at rates as high as 220 to 240 per minute. Because of the concomitant rate-dependent effect on ventricular

conduction velocity, the slowed atrial rate with 1:1 conduction may generate wide QRS complexes mimicking ventricular tachycardia.[81] Ibutelide, an intravenous drug with class III effects, is also effective for acute treatment of atrial flutter.[86] Its major concern is the short-term risk of torsades de pointes, which necessitates monitoring for several hours after administration. Failing conversion or achieving an acceptable rate with drugs, elective DC cardioversion is usually successful. If cardioversion is contraindicated or fails, an attempt to entrain the atrium with rapid atrial pacing may result in conversion to sinus rhythm[83,84] (see Chap. 31). Occasionally, rapid pacing may convert atrial flutter to atrial fibrillation, which will have a slower ventricular response. Pharmacologic management for recurrences of the paroxysmal form of atrial flutter includes long-term use of antiarrhythmic therapy to prevent the arrhythmia and the use of AV nodal blocking agents to control heart rate during recurrences. For the former, the class IA antiarrhythmic agents, especially quinidine, have been used with variable success. Class IC and class III drugs are potentially useful, but the concern with the mechanism of action of class IC drugs in atrial flutter cited above limits their use. Control of ventricular rate is best achieved with digitalis because of safety and efficacy considerations. Long-term oral use of verapamil for control of rate in recurrent atrial flutter is less predictably effective than intravenous use to slow the rate during a paroxysm.[24] Beta-adrenergic blocking agents have been used, and if the drugs are well tolerated, the dose can be titrated to clinical beta-blocking efficacy by heart rate and blood pressure criteria. Subsequent observations of ventricular rates during recurrences will establish efficacy. There is no known excess incidence of embolic events during paroxysmal atrial flutter or during its reversion. Anticoagulants are not used before, during, or after reversion. In recent years, RF catheter ablation procedures have been used with increasing frequency for patients with atrial flutter, especially for patients with frequent symptomatic episodes of atrial flutter or those resistant to drug therapy. A linear RF ablation lesion across the subeustachian isthmus, between the tricuspid valve annulus and the inferior vena cava, interrupts the reentrant pathway responsible for type I flutter. The procedure has a high probability of permanent clinical success,[85,87] avoiding the need for long-term pharmacologic therapy among these patients.

Management of Persistent Atrial Flutter

Atrial flutter may occur in a persistent form secondary to noncardiac factors, such as thyrotoxicosis or pulmonary embolism, although it is most common in the presence of chronic heart disease. Persistent or chronic atrial flutter occurs, but not commonly, in otherwise normal persons. Patients subject to recurrent episodes of persistent atrial flutter can be maintained on long-term antiarrhythmic therapy. However, RF ablation has emerged as the therapy of choice for symptomatic patients in this category.[85] Recurrence of atrial flutter after an RF ablation procedure occurs in approximately 15 percent and is usually due to gaps in the linear lesion across the isthmus, maintaining continuity of conduction in the reentrant pathway.[85,88] These gaps can often be identified and sealed during a repeat RF ablation procedure. If RF ablation fails or is not desired by the patient, therapeutic approaches during recurrences include additional antiarrhythmic agents for reverting atrial flutter and agents that will control the ventricular rate. Acute antiarrhythmic therapy may include intravenous procainamide or ibutilide[86] or orally administered drugs that prolong refractoriness (e.g., sotolol). Electrical reversion, however, may still be required.

Management of Chronic Atrial Flutter

Some patients will remain in chronic atrial flutter despite aggressive antiarrhythmic or interventional therapy, and flutter may recur predictably shortly after DC cardioversion. This usually occurs in the setting of advanced heart disease, may occur as the forerunner of chronic atrial fibrillation, and appears to be especially frequent with the variants of flutter, such as type II atrial flutter. It may occur rarely in otherwise normal persons[76] and more commonly in association with other SVTs, such as WPW and AV nodal reentry.[89] If the ventricular rate is adequately controlled and the patient is asymptomatic, chronic atrial flutter need not be treated aggressively.

In these cases, there is little justification for the use of complex antiarrhythmic drug regimens with adverse side-effect profiles. Rather, catheter ablation procedures can be used, especially for type I flutter, where the success rate is high. Surgical ablation of atrial flutter is feasible but is used only in rare circumstances, usually in conjunction with surgery being performed for another primary indication.

Control of ventricular rate is the major issue for management. AV nodal blocking agents, such as digoxin, beta-adrenergic blockers, and Ca^{2+}-entry blockers, may be tried. The major problem is the tendency for AV conduction to respond to pharmacologic control in step patterns. The patient who is well controlled with 4:1 conduction at a ventricular rate of 75 per minute may abruptly increase to 150 per minute under conditions of stress, which enhance AV nodal conduction.

In patients with enhanced AV nodal conduction and atrial flutter, it may be difficult to slow the rate below 150 per minute pharmacologically. Verapamil appears to be more effective than digoxin for the AV node with enhanced conduction but is not uniformly effective. Rarely, catheter ablation for AV node modification or interruption, with pacemaker implantation, is used for heart rate control in patients who are resistant to or intolerant of AV nodal blocking drugs and who have failed ablation attempts to interrupt the flutter pathway.

In the past, long-term anticoagulation was not generally recommended for patients with chronic atrial flutter. However, the potential risk of thromboembolism in atrial flutter has been reevaluated,[90,91] and it is now recommended to follow the guidelines of anticoagulation for atrial fibrillation in patients with atrial flutter.[92,93] Although the precise risk of stroke associated with atrial flutter has not been yet established by a large prospective clinical trial, the retrospective observations cited suggest an incidence of stroke similar to that expected in chronic atrial fibrillation. There is transesophageal echocardiographic evidence of atrial clot formation and spontaneous contrast in these patients. Finally, it is clinically difficult to ensure that a patient with atrial flutter will not have occasional periods of atrial fibrillation.

ATRIAL FIBRILLATION

Atrial fibrillation is the commonest among the cardiac rhythm disturbances that require treatment. In cross-sectional population studies, there is a large gradient of prevalence across age categories, ranging from less than 0.5 percent in young adults to 1 to 5 percent through the decades from 40 to 70 years and reaching rates in excess of 10 percent in some beyond age 70.[94] The arrhythmia should not be viewed as a single entity for practical clinical purposes. Risk, relevance, and management strategies are heavily influenced by the temporal pattern of the arrhythmia (paroxysmal, persistent, or permanent; Fig. 24-26) and by the clinical setting in which it occurs (Fig. 24-27).

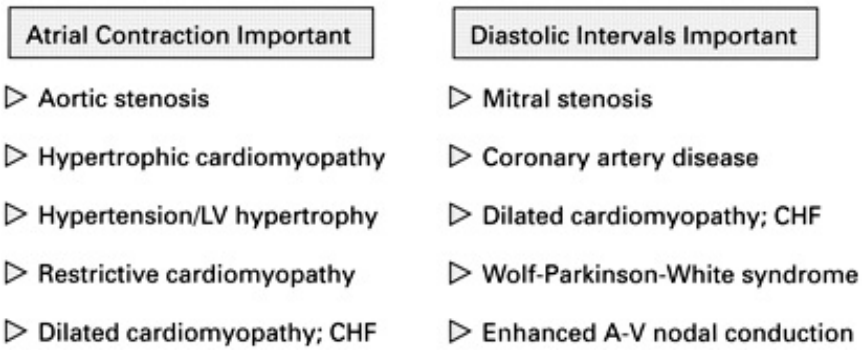

Figure 24-27: Hemodynamic factors in atrial fibrillation. Atrial fibrillation creates the potential

for two hemodynamic defects: (1) loss of atrial contraction, which provides the presystolic atrial "kick"; and (2) rate-related reduction of the diastolic filling period. Atrial contraction is important to ventricles with reduced compliance and low-output states due to myocardial factors. Diastolic filling time is important in conditions in which a longer diastolic is beneficial to impaired flow states, such as mitral stenosis, coronary atherosclerosis, and some myopathic ventricles.

The electrophysiologic mechanism of atrial fibrillation also influences treatment options. The commonest mechanism by far is multiple reentrant atrial wavelet circuits, producing loss of mechanical and electrical synchronization of the atria and variable AV nodal penetration and conduction, which in turn results in an irregular ventricular response. A less common but strategically important mechanism is focal atrial tachycardia originating in muscle fibers in the distal pulmonary veins in the left atrium or the crista terminalis or elsewhere in the right atrium.[20,95] Premature atrial impulses may be an expression of the presence of such sites of focal activity and serve as a guide to ablation therapy. They may also serve as triggers for initiation of the reentrant forms.

The clinical presentations and associations of atrial fibrillation are very broad. At one end of the spectrum is lone atrial fibrillation (absence of any form of structural cardiac abnormality) with arrhythmia symptoms that range from unrecognized to very symptomatic. The other extreme includes patients with advanced structural diseases, such as mitral or aortic stenosis, restrictive cardiomyopathies, or advanced LV dysfunction, in which the onset of atrial fibrillation may cause severe hemodynamic deterioration. Valvular heart disease has received much attention historically. The high prevalence of the arrhythmia in rheumatic mitral valve disease has been emphasized in the past, but it is likely that risk with any cause of mitral valve disease of equivalent severity is just as high. Between these extremes, atrial fibrillation may herald the presence of noncardiac disorders (e.g., thyrotoxicosis), alert to the significance of another cardiac disorder (e.g., WPW syndrome), constitute a transient complicating factor of another cardiac disorder (e.g., acute myocardial infarction or systemic arterial hypertension), or occur during the postoperative period after cardiac surgery.

The hemodynamic consequences of atrial fibrillation are due to two factors: (1) the loss of atrial systole may impair ventricular function in the noncompliant ventricle [e.g., aortic stenosis or left ventricular hypertrophy (LVH)] or the dilated ventricle with systolic dysfunction, and (2) a rapid ventricular rate will encroach upon the diastolic filling period of the left ventricle and the diastolic flow time of the coronary arteries (see Fig. 24-27). The risk of embolism and stroke is a long-term concern of special importance (see below).

Electrocardiographic Features

Atrial fibrillation is characterized electrocardiographically by grossly disorganized atrial electrical activity that is irregular in respect to both rate and rhythm. There is no visually discernible timing pattern to the atrial electrical activity on the surface ECG or to electrogram sequences recorded by catheter electrodes. Specific patterns of AV conduction sequences (ventricular responses) have been proposed as a result of sophisticated analytic techniques;[96] this analysis provides some physiologic insight but does not yet have practical clinical value. Atrial fibrillatory waves are best seen in standard lead V_1 and are usually clearly evident in II, III, and aVF as well. They may be quite large and coarse or almost imperceptible (compare Fig. 24-28*A* and *B*). In the absence of discernible atrial electrical activity, a grossly irregular ventricular rhythm still suggests the presence of atrial fibrillation. Coarse atrial fibrillation is occasionally difficult to distinguish from atrial flutter waves, but the irregular ventricular response, in the absence of a repetitive pattern, is again helpful in making the distinction. In contrast, obvious coarse fibrillatory waves with a regular ventricular response, especially when slow, suggests the coexistence of high-grade AV block with atrial fibrillation.

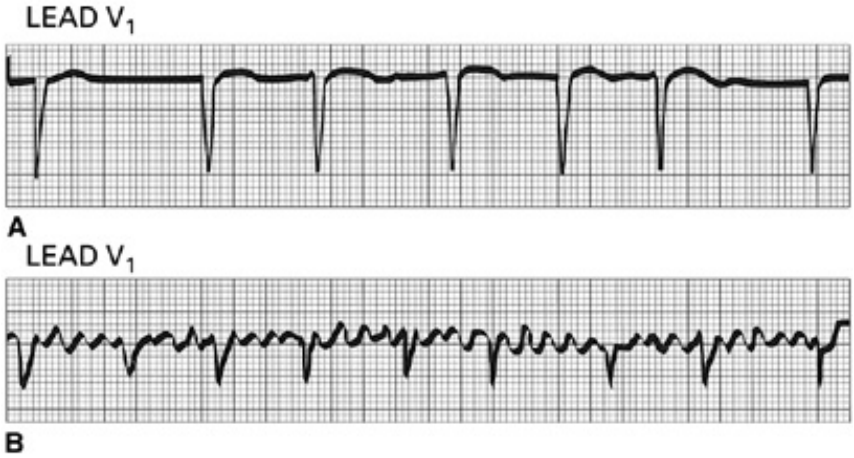

Figure 24-28: *A.* Fine atrial fibrillation, leaving virtually no imprint on the baseline ("straight-line" fibrillation). *B.* Coarse atrial fibrillation; the fibrillatory waves are the size of respectable flutter waves but are irregular.

One of the more challenging exercises in clinical electrocardiography is the distinction between aberrant intraventricular conduction and ventricular ectopy in the presence of atrial fibrillation. Aberrant conduction tends to occur when a long ventricular cycle is followed by a short cycle. This long-short cycle sequence, with the short cycle terminated by an aberrantly conducted beat, is referred to as Ashman's phenomenon.[97] It is important to recognize that *long* and *short* are relative terms in this context and carry no implications of absolute value (compare Figs. 24-29 and 24-30). A series of short cycles, if short enough, may generate runs of consecutively aberrant beats imitating VT (Fig. 24-30). Thus, additional criteria for distinction between aberrancy and ectopy are required. In general, an initial QRS vector similar or identical to that of narrow QRS complexes and a typical right bundle-branch block pattern, in association with a long-short cycle sequence, strongly favor aberrancy over ectopy.[98] Left bundle-branch block aberrancy also occurs but is far less common. It is more likely when aberrant conduction is persistent (i.e., functional bundle-branch block during a sustained SVT; see Fig. 24-15), while it is unusual in single-cycle aberrancy (Fig. 24-29). Atrial fibrillation alters intraventricular conduction only through the following mechanisms: (1) functional bundle-branch block or aberrancy (Fig. 24-31), (2) loss of delta waves in WPW syndrome with normal pathway conduction during atrial fibrillation, or (3) totally preexcited QRS complexes during atrial fibrillation in WPW syndrome (see Fig. 24-18). The QRS complex during atrial fibrillation will be similar to that recorded during sinus rhythm under all other circumstances. In patients with preexisting bundle-branch block who develop atrial fibrillation with rapid ventricular responses, the distinction from VT may be difficult.

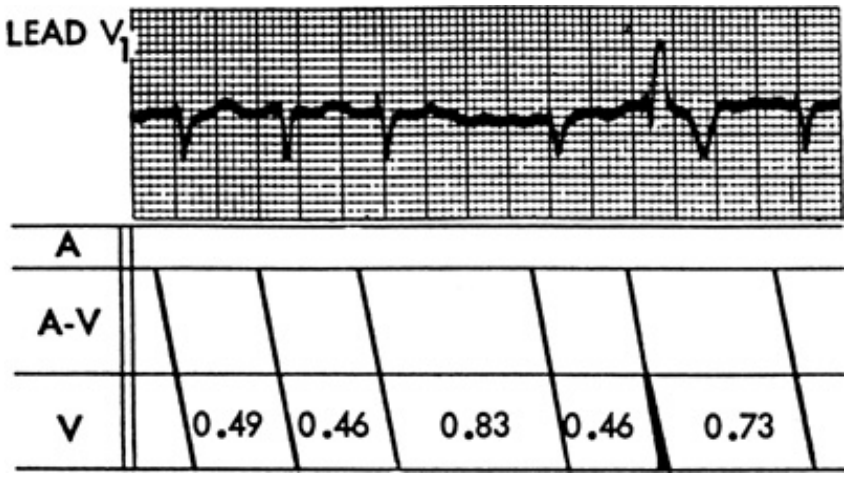

Figure 24-29: Ashman's phenomenon. During atrial fibrillation, the impulse ending a short cycle preceded by a relatively long cycle manifests aberrant intraventricular conduction. In this example, the aberrant impulse shows typical right bundle-branch block type aberration in lead V_1, with an rSR pattern and the initial deflection identical to that of the preceding and following normally conducted impulses.

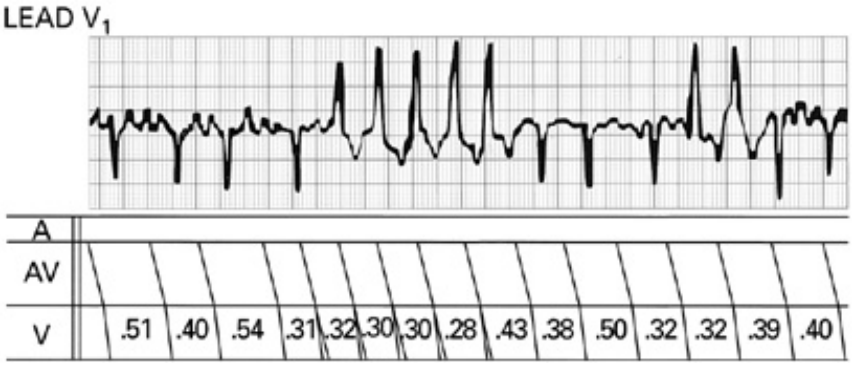

Figure 24-30: Atrial fibrillation with repetitive aberrant ventricular conduction. The impulses that end the shortest ventricular cycles (0.28 to 0.32 s) are anomalous, widened complexes. Note that the cycle preceding the onset of the salvos of anomalous beats is *relatively* long in comparison with the anomalous complexes (0.54 and 0.50 s), in accordance with Ashman's phenomenon. Thus, these almost certainly represent a right bundle-branch block type of ventricular aberration rather than ventrcular ectopy.

Evaluation and Management of the First Episode of Atrial Fibrillation

The first episode of atrial fibrillation requires special considerations. A thorough investigation of the clinical status is needed to determine whether the event is caused by a primary electrical mechanism, underlying structural heart disease, hemodynamic abnormalities, or a systemic disorder that predisposes to atrial fibrillation. Previously unrecognized mitral or aortic stenosis or regurgitation, hypertension, coronary heart disease, cardiomyopathy, atrial septal defect, pericarditis, or atrial abnormalities secondary to left or right ventricular overload are among cardiac causes that must be excluded. Heart failure may be either a cause or a consequence of atrial fibrillation. Pulmonary emboli and metabolic abnormalities such as thyrotoxicosis also must be considered. The identification of associated factors at the time of the first episode of atrial fibrillation dictate future management. In the absence of an identifiable cause, so-called lone atrial fibrillation, the prognosis is good,[99] especially if it is a single event or intermittently recurrent. Chronic lone atrial fibrillation may indicate a higher risk,[100] although conflicting data[99] question

the validity of this conclusion. In a young, healthy individual in whom there is no evidence of structural heart disease, paroxysmal episodes of lone atrial fibrillation may occur under conditions of exogenous precipitating factors, such as excessive cigarette, alcohol, and/or coffee consumption; exposure to so-called "recreational drugs," such as cocaine and amphetamines; stress or fatigue; or upon cessation of extreme exercise.

In the absence of organic heart disease or coexistent WPW syndrome, long-term management after the first episode need include no more than avoidance or removal of precipitating factors and following the patient over time to estimate the frequency of recurrences. Long-term antiarrhythmic therapy is generally not indicated following the first episode of lone atrial fibrillation. In the presence of treatable cardiac or noncardiac causes, management must include attention to precipitating and predisposing factors. For instance, in atrial fibrillation occurring during the acute phase of myocardial infarction, which has been observed in up to 18 percent of monitored patients, spontaneous reversion is very common, and rate control is the only therapy needed. In the setting of thyrotoxicosis, there is no rationale for trying to convert atrial fibrillation until the thyrotoxic state is controlled; in the interim, the ventricular rate may be slowed with propranolol and anticoagulation maintained (see below) until sinus rhythm is restored after the patient is euthyroid. When atrial fibrillation calls attention to previously undiagnosed mitral stenosis, atrial enlargement may limit success of attempts to obtain and maintain sinus rhythm.

Ventricular rate should be controlled, and conversion of atrial fibrillation can await correction of the mitral valve obstruction. In atrial septal defect, atrial fibrillation is generally a sign of advanced hemodynamic deterioration, such as pulmonary hypertension and balanced or reversing shunts; these patients must be evaluated for surgery promptly. In patients with *advanced* heart disease of any etiology and dilated atria, the first episode may herald a chronic fibrillatory state. An attempt to revert the rhythm, either pharmacologically or electrically, the latter usually with a concomitant pharmacologic agent, may be an appropriate option; but the recurrence rate is very high.[101-103] If the patient will benefit from the hemodynamic advantage provided by an atrial contraction, the attempt at reversion is warranted despite the high probability of recurrence. The recent onset of chronic atrial fibrillation has special implications for anticoagulation therapy (see below).

In hemodynamically significant mitral stenosis or aortic stenosis, acute pulmonary edema may complicate the first episode of rapid atrial fibrillation, making immediate control of heart rate or electrical cardioversion mandatory. In mitral stenosis, recurrences can be expected; but even a short time in sinus rhythm can provide hemodynamic benefit and allow institution of therapy that will control the ventricular rate for the next episode. A slower heart rate, with a resultant longer diastolic filling period, may help prevent the recurrence of pulmonary edema. In aortic stenosis, dependence upon the atrial kick for optimal hemodynamic function of the noncompliant hypertrophied left ventricle, rather than encroachment on the diastolic filling period, is the major concern.

Management of Recurrent Episodes of Paroxysmal Atrial Fibrillation

Paroxysms of atrial fibrillation lasting less than 48 h in the absence of underlying heart disease are usually managed conservatively. Rest, mild sedation with 5 to 10 mg of diazepam, and Ca^{2+}-entry blockers, beta-adrenergic blockers, or digitalis for control of the ventricular rate constitute an accepted approach. After the first episode, patients who have lone atrial fibrillation can be reassured in respect to the absence of underlying organic heart disease and guided to avoid precipitating factors. In the presence of heart disease, particularly when the hemodynamic circumstances require either the mechanical benefit of atrial systole or a properly controlled ventricular rate for adequate diastolic filling (see Fig. 24-27), immediate reversion to sinus rhythm or slowing of the ventricular rate may be mandatory. The presence of clinical signs of heart failure requires immediate cardioversion to achieve either or both of these goals.

If the patient is tachycardic but clinically stable, pharmacologic approaches to control the rate (digitalis or intravenous verapamil or diltiazem) may be attempted. The overall probability of spontaneous conversion of paroxysmal atrial fibrillation within 24 h is approximately 50 percent.[104] However, a number of antiarrhythmic drug strategies have been used to achieve earlier reversion or increase the reversion rate without electrical cardioversion. Intravenous procainamide[105,106] and ibutilide[86] have been used for pharmacologic reversion of acute paroxysms. The latter must be used with caution because it may prolong the QT interval acutely, with the short-term risk of torsades de pointes. Although not available in the United States, intravenous formulations of the class IC drugs flecainide and propafenone have also been used successfully for treatment of acute atrial fibrillation.[107] Oral bolus therapy using flecainide (300-mg dose) or propafenone (600 mg) in a single dose has been used,[108,109] although it is not clear whether it provides more or simply earlier conversions than in control subjects.[110]

Long-term pharmacologic therapy in the absence of underlying heart disease or in the presence of trivial abnormalities is intended to reduce or eliminate recurrent episodes and to control ventricular rate during recurrences, should they occur. Digitalis, beta-adrenergic blockers, or Ca^{2+}-entry blockers are used for rate control as described for atrial flutter. Digitalis controls ventricular rate at rest, although it appears less effective for limiting effort-induced increases in ventricular rate during atrial fibrillation.[111]

Prevention of episodes of atrial fibrillation may be achieved with class IA, IC, or III antiarrhythmic drugs. If episodes are clinically benign and infrequent, the threshold for such treatment is higher than if they are more frequent and symptomatic. Efficacy is uneven and proarrhythmic or toxic side effects are of concern. During short paroxysms of atrial fibrillation (up to 48 h), anticoagulation is not required prior to reversion; long-term anticoagulation is not necessary for patients subject to brief paroxysmal attacks[112] (see Fig. 24-26; Tables 24-8 and 24-9).

Table 24-9: Anticoagulation of Patients with Atrial Fibrillation

Indications
Rheumatic mitral valve disease with recurrent or chronic atrial fibrillation
Dilated cardiomyopathy with recurrent persistent or chronic atrial fibrillation
Prosthetic valves
Prior to (≥3 weeks) elective cardioversion of persistent or chronic atrial fibrillation
Coronary heart disease or hypertensive heart disease with recurrent persistent or chronic atrial fibrillation
Atrial fibrillation in thyrotoxicosis (while awaiting long-term control; elective cardioversion)
Chronic or persistent lone atrial fibrillation, age ≥60 years
Controversial, or limited data
Coronary or hypertensive heart disease with normal left atrial size, after first episode of paroxysmal atrial fibrillation
Elective cardioversion of atrial fibrillation of short duration (2-3 days) with normal left atrial size

Chronic or persistent lone atrial fibrillation, age <60 years
Not indicated
Lone atrial fibrillation, paroxysmal (<48 h, age <65)
Most clinical settings associated with short paroxysms (minutes to hours)
Relative contraindications
Difficulty controlling prothrombin times
Dementia
Malignancies, especially associated with bleeding risk
Prior major bleeding events
Uncontrolled hypertension

Management of Persistent Atrial Fibrillation

The decision to intervene in longer episodes of atrial fibrillation is based on the balance between hemodynamic tolerance and the likelihood of being able to control future episodes. Because of the demonstrated effects of "electrical remodeling" of atrial myocytes during persistent atrial fibrillation,[113] which favors persistence of the arrhythmia and resistance to reversion, there is a tendency toward a more aggressive approach to early reversion.[114]

Many patients with organic heart disease have intermittent episodes of persistent atrial fibrillation prior to establishing chronic atrial fibrillation.[115] Among these patients, antiarrhythmic efficacy for control of recurrences is unpredictable. Prediction of the ability to control ventricular rate by AV nodal blocking agents is better but still imperfect. When a patient has had multiple recurrences of persistent atrial fibrillation despite trials of several antiarrhythmic agents and the arrhythmia is well tolerated hemodynamically, many clinicians avoid repeated electrical cardioversions, especially in the presence of advanced heart disease. If elective cardioversion is to be attempted, 3 weeks of anticoagulation should precede the procedure to reduce embolic risk. A more expeditious alternative strategy is to perform a transesophageal echocardiogram to rule out the presence of atrial thrombi.[116] If results are negative, heparin can be started and chemical or electrical cardioversion performed. However, there remains some debate about the efficacy of this strategy.[117]

If cardioversion is not attempted and the patient has recurrent episodes of atrial fibrillation lasting 48 to 72 h, long-term anticoagulant with warfarin is indicated. If the patient is without structural disease, is less than 60 years of age, and has a normal echocardiogram and no prior history of embolism, long-term warfarin therapy is unnecessary.

In the presence of advanced or progressive cardiac disease, atrial fibrillation is likely to revert and recur intermittently until the condition evolves into chronic atrial fibrillation. When this occurs, the best therapeutic approach may be control of ventricular rate during recurrences. Membrane-active antiarrhythmic agents are often used in an attempt to limit the number of recurrences, but efficacy is unpredictable, and risk of side effects is high. The flecainide data suggest efficacy,[61,119] especially for patients with good LV function and those free of underlying coronary artery disease.[19] Class III antiarrhythmic drugs, including sotalol,[120] amiodarone,[121] dofetilide,[122]

and azemilide,[123] are also effective. The latter two drugs have not yet been approved for use by the U.S. Food and Drug Administration. The long-term benefit of prevention of atrial fibrillation by antiarrhythmic drug therapy versus control of heart rate remains uncertain. A large multicenter study is currently in progress to answer this question.[124]

Management of Chronic (Permanent) Atrial Fibrillation

The ventricular rate in chronic atrial fibrillation is usually more predictably controlled than in recurrent episodes of paroxysmal or persistent atrial fibrillation. Pharmacologic or electrical cardioversion in patients with advanced heart disease and atrial enlargement is attempted in the hope of achieving a hemodynamic benefit, but the probability of maintaining sinus rhythm is low.[101-103] Until more data are available, the choice between attempting to restore sinus rhythm and simply controlling heart rate (with anticoagulation) is a matter for individual clinical judgment. Among patients with advanced heart disease who have been electrically cardioverted while taking antiarrhythmic drug therapy, approximately one-third will revert to atrial fibrillation within 1 week and two-thirds within 12 months.[101-103] If the rhythm reverts to chronic atrial fibrillation shortly after cardioversion, the probability of long-term maintenance of sinus rhythm by additional pharmacologic approaches is very low. The ventricular rate is then controlled as outlined above.

Pharmacologic control of ventricular rate may be problematic in recurrent episodes of both persistent and chronic atrial fibrillation. Under both circumstances, catheter modification of the AV junction or complete interruption (catheter ablation) of the AV junction with permanent pacing may provide heart rate control.[125] Other nonpharmacologic strategies for control of atrial fibrillation include surgical procedures designed to establish sinus node control of the ventricular rate and rhythm, implantable device therapy, and catheter ablation procedures. Among the surgical approaches, the "corridor" procedure[126] establishes a pathway from sinus node to AV node, while the MAZE procedure[127] interrupts pathways necessary for maintaining fibrillation and reestablishes both rate control and mechanical function. The MAZE technique has been used both as primary surgery and as an added procedure for patients undergoing cardiac surgery for other reasons.

An implantable atrial defibrillator[128] has been developed for use in patients with chronic recurrent atrial fibrillation. It appears to have only limited applicability as a stand-alone device, but integration of the technology within the platform of conventional implantable cardioverter defibrillators (ICDs)[129] may be useful for patients with paroxysmal atrial fibrillation at risk for life-threatening ventricular arrythmias. Another device strategy being evaluated is the use of dual-site atrial pacing in an attempt to resynchronize atrial depolarization and avoid dispersion of atrial refractoriness.[130]

Catheter ablation techniques for preventing atrial fibrillation (i.e., catheter-based MAZE procedure or ablation of focal triggering sites for atrial fibrillation)[131,132] are currently being evaluated. The ultimate role for these approaches in the management of patients with recurrent or chronic atrial fibrillation remains to be determined.

Anticoagulation of Patients with Atrial Fibrillation

Patients with atrial fibrillation have a greater than fivefold increase in risk of stroke compared to control populations without atrial fibrillation.[133-136] In addition, there are specific high-risk subgroups. Among patients with rheumatic heart disease, the risk exceeds by up to 17 times that of a control group.[134,135] Other subgroups at high risk include patients with dilated cardiomyopathy, dilated left atrium of any cause, atrial fibrillation of recent onset, and a history of prior embolism. Patients with atrial fibrillation and LVH are also at increased risk, as are

thyrotoxic patients.[137] In one study, the chronic form of lone atrial fibrillation has been reported to be associated with a relative increase in risk of embolic stroke,[138] although other studies have not identified an increased risk. It is generally agreed, however, that patients older than 60 years with lone atrial fibrillation are at risk and should be anticoagulated with warfarin.[139] As a group, the nonrheumatic disease states associated with atrial fibrillation tend to have excess risks in the range of five- to sixfold, according to various studies.[94] Absolute risks differ little among the various rheumatic and nonrheumatic etiologies, however, with event rates in the range of 4 to 6 percent for each, except for lone atrial fibrillation, which has a considerably lower rate.[92,99,138] The risk of embolic events tends to cluster around changes in rhythm, the highest incidence occurring within the first year after onset of chronic atrial fibrillation[134] and a concentrated 1 to 2 percent risk occurring in the first days after restoration of sinus rhythm,[140-142] whether by pharmacologic strategies or DC cardioversion.

The issue of anticoagulation in atrial fibrillation hinges on a balance between efficacy of preventing embolic events and risk of bleeding (see Tables 24-8 and 24-9). Indicators of increased risk of embolic events, in addition to the general presence of structural heart disease, include previous stroke or transient ischemic attack, hypertension, heart failure, prosthetic heart valves, and hyperthyroidism.[137,143] Age and female gender (particularly elderly women) also identify increased risk.[139] Efficacy and risk both relate well to the level of anticoagulation with warfarin. Measured as the now-standard international normalized ratio (INR), benefit is optimal at or above an INR of 2.0, while bleeding risk increases above an INR of 3.5 to 4.0.[143] Until recently, most of the data on efficacy of anticoagulation for reducing incidence of embolic events in atrial fibrillation were from poorly controlled or uncontrolled studies, and there was no consensus based on the available data.[133] The available combination of risk data and retrospective or uncontrolled efficacy data[101,111,133] tended to result in the practice of using long-term anticoagulation for patients with a rheumatic etiology and for those with advanced structural diseases associated with atrial fibrillation (see Table 24-8). Such patients included those with coronary artery disease and a prior embolism, idiopathic dilated cardiomyopathy, and prosthetic cardiac valves. Several recent placebo-controlled studies have now provided clarification of the role and methods for anticoagulation in patients with nonrheumatic atrial fibrillation. In one multicenter randomized trial, the Stroke Prevention in Atrial Fibrillation (SPAF) Study, aspirin, 325 mg/day, and warfarin, with prolongation of prothrombin times to 1.3 to 1.8 times those of the control subjects were each compared to placebo among a population of 1330 patients.[144] During a mean follow-up of 1.3 years, ischemic stroke or systemic embolization occurred at a rate of 6.3 percent per year in the placebo group, compared to 3.6 percent per year in the aspirin-treated group, a 42 percent reduction in the treated group ($p < .02$). Among the patients eligible for warfarin, the event rate in the untreated group was 7.4 percent, compared to 2.3 percent in the treated group, a 67 percent reduction ($p < .01$). Primary embolic events and deaths combined were reduced by 58 percent in the warfarin group and 32 percent in the aspirin group.

Thus, both warfarin and aspirin were effective, but the design of the study prevented comparison of the two treatments. Although both chronic atrial fibrillation and intermittent atrial fibrillation were included in the study, the data reported do not permit a determination of any difference in risk or benefit for the two patterns. In another study, the Canadian Atrial Fibrillation Anticoagulation (CAFA) Study, the placebo group experienced a 5.2 percent embolism/stroke rate compared to 3.5 percent in a warfarin-treated group, a relative reduction of 37 percent with treatment.[145] The differences did not reach statistical significance, since the study was prematurely terminated because of outcome data from other large studies suggesting benefit. Among two other studies, the Copenhagen AFASK Study[146] and the Boston Area Anticoagulation Trial in Atrial Fibrillation,[148] warfarin again demonstrated significant reductions in risk (82 and 87 percent, respectively), while aspirin demonstrated only a 14 percent reduction in the Copenhagen study (nonsignificant),[146] even though it was associated with a 42 percent reduction in the SPAF study.[144] Collectively, these studies demonstrate a significant benefit for

reduction of embolism and stroke in nonrheumatic atrial fibrillation patients with the use of warfarin and likely with aspirin as a less effective alternative (see Chap. 89). More recent data have reaffirmed that warfarin is superior to aspirin and provided additional insight into effective warfarin dose ranges.[148] In patients at high risk for embolic events, fixed low-dose warfarin (0.5 to 3.0 mg/day; INR = 1.2 to 1.5) plus aspirin (325 mg/day) was inferior to conventional dose-adjusted warfarin (INR target = 2.0 to 3.0). Indications for anticoagulation prior to elective cardioversion have not undergone the same scrutiny for efficacy as has now been provided for intermittent and chronic atrial fibrillation. Nonetheless, there is enough information available to warrant the routine use of anticoagulation prior to elective cardioversion of recent onset (more than 48 to 72 h), persistent atrial fibrillation or chronic atrial fibrillation, particularly when associated with an enlarged left atrium or other structural diseases regardless of etiology. Anticoagulation with warfarin is started 3 to 4 weeks before elective cardioversion and is maintained for 3 to 4 weeks subsequently. If there is concern about the ability of a patient to recognize a recurrence of atrial fibrillation, it may be warranted to maintain anticoagulation indefinitely, particularly if the patient has advanced structural heart disease.

The risk-benefit data are less clear for anticoagulation prior to elective cardioversion of atrial fibrillation of short duration (less than or equal to 48 h), particularly lone atrial fibrillation or when associated with minimal structural disease and normal atrial dimensions. The potential efficacy of anticoagulation must be weighed against its risk. Patients receiving anticoagulants retain a risk of embolization ranging from 1 to greater than 3 percent per year,[94,102,142-147] depending upon disease states. Furthermore, there is a significant incidence of life-threatening bleeding or major events requiring transfusion among patients on long-term anticoagulation. In one report,[149] the incidence was 4.3 percent per treatment-year. In the SPAF study,[144] however, bleeding risk hovered around 1.5 percent and did not differ among aspirin-treated, warfarin-treated, and placebo groups. Lower warfarin dosing than used previously, titrated to an INR of 2.0 to 3.0,[150] may be one reason for the reduction of bleeding risk with warfarin use. Since the risk of bleeding is increased significantly with an INR of 5.0, the inability to control the prothrombin time, including the inability of the patient to comply with the prescribed dosages, must be considered relative contraindications. The major complication of intracranial bleeding may have an incidence of 1 to 2 percent per treatment-year.[151] Table 24-9 lists indications and relative contraindications for anticoagulation in patients with atrial fibrillation. The physician must balance accepted indications and risks in judging whether to use anticoagulation in individual patients. In most circumstances now, however, one should err on the side of use rather than avoidance if the risk-benefit relationship is not clear, assuming the INR is assiduously maintained between 2.0 and 3.0 in candidates at higher risk for bleeding complications.

Chapter 24: RECOGNITION, CLINICAL ASSESSMENT, AND MANAGEMENT OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

ATRIOVENTRICULAR JUNCTIONAL AND ACCELERATED VENTRICULAR RHYTHMS

Rhythm disturbances that originate in the AV junction include premature AV junctional impulses, accelerated junctional rhythms, and AV junctional tachycardias that may be automatic or reentrant. Echo beats and tachycardias that incorporate the atria and AV junction as part of the reentrant pathway in PSVT due to AV nodal reentry or WPW syndrome are discussed elsewhere. Junctional escape rhythms at rates of 40 to 60 per minute during sinus bradycardia or AV block are normal physiologic backup phenomena that are usually hemodynamically stable; failure of normal junctional escape mechanisms may result in significant bradycardias.

The normal inherent rate of AV junctional automatic activity is 40 to 60 per minute, and those of subordinate pacemakers at the fascicular or ventricular level are 20 to 40 per minute. Faster rates from either of these levels are considered "accelerated" for rates up to 100 impulses per minute, at which point they take on the general definition of a tachycardia. Accelerated junctional and ventricular rhythms and most nonparoxysmal AV junctional tachycardias are thought to be due to enhanced automatic activity (phase 4 depolarization).[152,153] Other forms of abnormal automaticity, including triggered activity initiated by afterdepolarizations, may also originate in the AV junction[154,155] (see also Chap. 23).

AV Junctional Premature Beats

AV junctional premature beats occur much less frequently than do premature atrial or ventricular complexes. The timing of P waves and QRS complexes is variable, however. The P waves may precede QRS complexes by 0.12 s or less, may be concealed within the QRS complexes, or may appear in the ST segment following the QRS complex (Fig. 24-32). The P waves are usually inverted in leads II, III, and aVF; isoelectric to slightly negative in leads I and V_6; and upright in the right precordial leads. The QRS complexes are narrow except when aberrant intraventricular conduction is present. When the P waves precede the QRS complex, distinction from premature atrial complexes may be difficult, and when aberrant intraventricular conduction is present and the P wave is within or after the QRS complex, the distinction from premature ventricular complexes may be impossible without intracardiac recordings. AV junctional premature beats generally require no treatment; when treated, however, they are approached using the same principles applied to the treatment of premature ventricular complexes (see below).

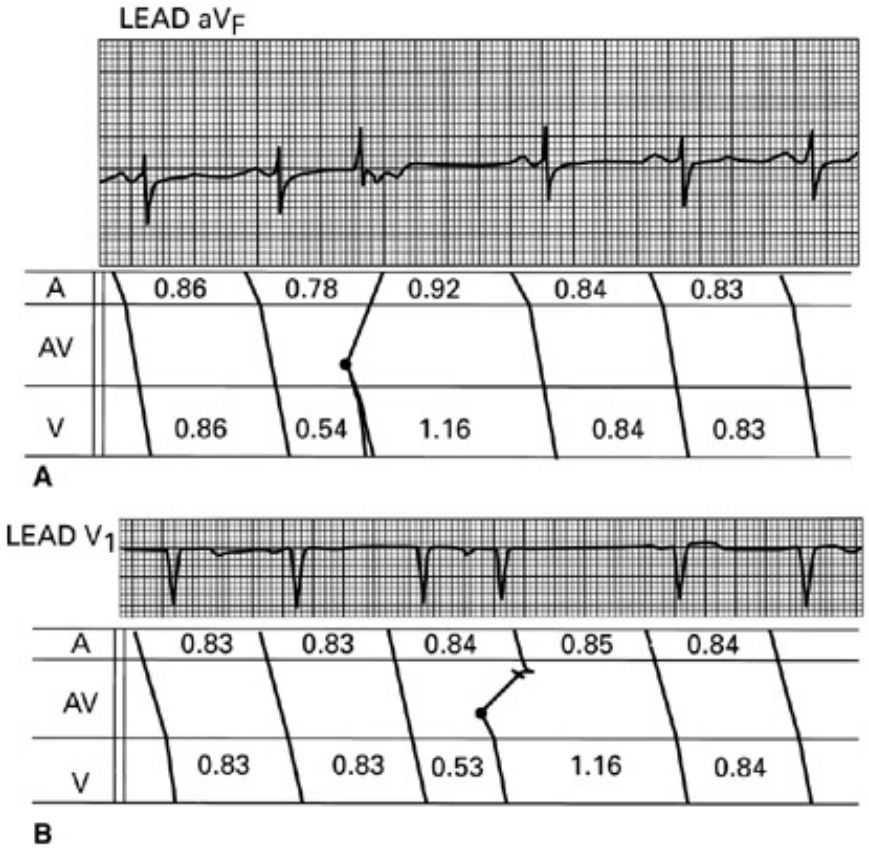

Figure 24-32: *A.* AV junctional extrasystole. The retrograde P wave follows the premature QRS complex, which shows some degree of ventricular aberration. *B.* The fourth complex is an AV premature impulse without retroconduction to the atria, leaving the sinus rhythm undisturbed.

Accelerated Junctional and AcceleratedVentricular Rhythms

Accelerated rhythms derive from subordinate pacemakers and emerge when the sinus rate is less than the normally suppressed focus. Sinus bradycardia combined with enhanced automaticity of the subordinate site is the common pathophysiology. Ischemia (especially inferior wall myocardial ischemia or infarction), digitalis intoxication, electrolyte disturbances (especially hypokalemia), and hypoxemia may enhance phase 4 depolarization in the AV junction or intraventricular specialized conducting system, accelerating the rate of impulse formation of the subordinate pacemakers located at these sites. Digitalis intoxication, various degrees of AV block, and sinus node depression may accompany AV junctional acceleration, producing complex ECG patterns. In inferior wall ischemia, subordinate pacemaker acceleration is commonly associated with sinus node depression, the latter permitting escape and usurpation of pacemaker function, even with only modest AV junctional acceleration (e.g., 60 to 70 impulses per minute). These rhythms are almost always hemodynamically stable.

The typical electrocardiographic pattern is apparent shortening of the PR interval as the PP intervals prolong, leading to emergence of the subordinate QRS complexes as they assume the pacemaker function (Fig. 24-33). After a variable duration, the PP interval begins to shorten, P waves reappear in front of the QRS complex, and ventricular capture by atrial activity is reestablished. The QRS complexes of accelerated AV junctional rhythm commonly have slightly altered vectors, durations, and morphology, often accompanied by minor changes in the T-wave vectors. Such alterations are due to slight changes in conduction patterns resulting from the altered origin of the propagating wavefront in the ventricles. These changes may be diagnostically useful.

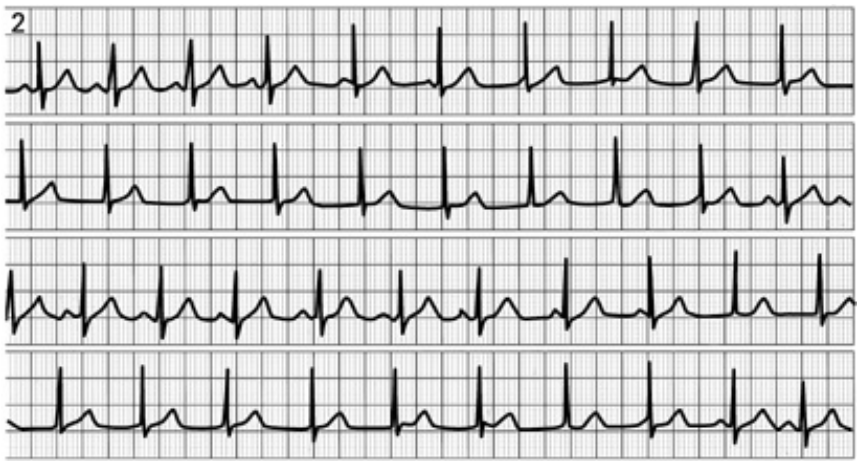

Figure 24-33: Accelerated idiojunctional rhythm with isorhythmic AV dissociation. After four sinus beats, the sinus rate slows slightly, enabling an accelerated junctional pacemaker to escape at a rate of 94 per minute. After several seconds, the sinus pacemaker accelerates and recaptures the ventricles. The same sequence is then repeated (the strips are continuous). (From Marriott HJL. *Workshop in Electrocardiography.* Tampa, FL: Tampa Tracings; 1972. Reproduced with permission from the publisher and author.)

Accelerated AV junctional and ventricular rhythms generally require no specific antiarrhythmic therapy. In ischemia, they are usually self-limiting in duration and of no major consequence hemodynamically; when associated with digitalis intoxication or electrolyte disturbances, they promptly reverse with control of these toxic or metabolic influences. In fact, specific antiarrhythmic drugs might suppress a subordinate pacemaker that is needed to maintain cardiac output in the presence of dysfunction of normal sinus node pacemakers. If a faster ventricular rate or AV sequencing is desirable for hemodynamic benefits, attempts to enhance cardiac rates may be achieved pharmacologically or by pacing. Atropine, 0.6 to 1.2 mg intravenously, may increase sinus rate and allow the sinus to resume its normal pacemaking function if AV conduction is intact. Atropine will have little or no influence on the rate of the accelerated AV junction focus. Temporary atrial or ventricular pacing may be used to support the heart rate if it is slow enough to impair hemodynamics, but pacing is rarely necessary.

AV Junctional Tachycardia

Enhanced AV junctional rhythm may occasionally double its rate abruptly to a true tachycardic range.[156] This phenomenon likely represents an automatic focus firing at the faster rate with 2:1 exit block, which abruptly changes to 1:1 exit. In acute ischemic events, it may be desirable to reduce the rate with antiarrhythmic agents. These incidents are commonly self-limited, however, and will usually cease spontaneously or revert to 2:1 exit block.

Ectopic or persistent nonparoxysmal AV junctional tachycardia may occur intermittently in patients with chronic heart disease and appears to be more frequent and more important in children, particularly after surgical correction of congenital defects.[157,158] The response to treatment is unpredictable, and the rhythm may be resistant to conventional antiarrhythmic drugs. Catheter ablation has been suggested for some patients, however.[158]

An arrhythmia referred to as permanent junctional reciprocating tachycardia (PJRT) is characterized by a long RP-short PR reentry pattern and is due to a very slowly conducting retrograde accessory pathway.[159-161] It is persistent but not truly incessant, occasionally causes tachycardia-induced cardiomyopathy, tends to occur in children, and is difficult to treat pharmacologically. Some success with class IC antiarrhythmic agents has been reported in children,[162] but catheter ablation has become the treatment of choice.

Chapter 24: RECOGNITION, CLINICAL ASSESSMENT, AND MANAGEMENT OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

VENTRICULAR ARRHYTHMIAS

Approaches to the evaluation and management of ventricular arrhythmias have changed dramatically in recent years. New insight into risks of ventricular arrhythmias in various clinical settings, clarification of the risk-benefit ratio of antiarrhythmic drug treatment, and the refinement of nonpharmacologic methods of therapy all have developed in parallel in recent years. The equilibrium between the risk implied by an arrhythmia and the proarrhythmic risk of a drug[163-165] was dramatically emphasized by the results of the Cardiac Arrhythmia Suppression Trial (CAST)[21,227] and Survival with Oral D-Sotalol (SWORD)[166] study, which resulted in major changes in indications and methods for treatment of some ventricular arrhythmias.

The *urge* to treat, based upon limited scientific support in the past, has yielded to indications based upon the *need* to treat, modulated by a better definition of the *risk* of treatment. Clinical approaches to the patient with ventricular arrhythmias require a clear analysis of the interrelationships between electrocardiographic forms of arrhythmias, the specific clinical setting in which it occurs, and realistic goals of therapy (see Tables 24-1 and 24-3).

Definitions, Classification of Risk, and End Points of Therapy

Forms of ventricular arrhythmias may be separated into the various patterns of ambient PVCs and of sustained arrhythmias, such as sustained VT or Ventricular fibrillation (VF). The former are present intermittently and identify risk in the presence of structural heart disease. They may also serve a triggering function for hemodynamically significant or life-threatening arrhythmias (VT or VF) under appropriate conditions.

The conventional definition of VT, three or more consecutive ventricular ectopic impulses at a rate of 120 or greater, is too broad to apply to current evaluation and management strategies. A distinction between bursts of nonsustained VT lasting for up to 30 s and sustained VT lasting 30 s or more (Table 24-10) is more useful for evaluation at the bedside, ambulatory monitoring data, the results of invasive electrophysiologic testing, and responses to therapy. In addition to defining VT by its duration, useful information is contained in the definition of VT from its ECG pattern. Slow, monomorphic patterns of nonsustained VT are less symptomatic and may denote lower risk than faster, polymorphic VT patterns.

Table 24-10: Specific Forms of Ventricular Tachycardia

Duration	ECG Pattern
Salvo (3-5 impulses)	Uniform morphology VT
Nonsustained VT (6 impulses, 29 s)	Polymorphic VT, torsades de pointes
Sustained VT (≥30 s)	Right ventricular outflow pattern
	Bidirectional tachycardia

Data on the risk predicted by PVCs after convalescence from myocardial infarction have been analyzed relative to both frequency and forms.[167-172] Based upon the frequency in Fig. 24-34, most studies demonstrate increased risk with frequencies of 10 or more ectopic impulses per hour, and one major study demonstrated a sharp increase in risk moving across the range of 1 to 9 impulses per hour.[172] Similarly, in

the hierarchy of forms, couplets indicate only a small increase in risk compared to uniform or multiform single PVCs,[172] and salvos indicate a significantly higher risk.[171,172] There are insufficient data to determine whether longer runs (i.e., nonsustained VTs of six consecutive impulses) constitute an even higher risk. Patterns such as bigeminy and trigeminy are simply an expression of frequency and contain no inherent information concerning risk beyond frequency.

HIERARCHY OF FREQUENCIES	HIERARCHY OF FORMS
CLASS 0 – NIL	CLASS A – UNIFORM MORPHOLOGY, UNIFOCAL
CLASS I – RARE < 1 ectopic impulse/hour	CLASS B – MULTIFORM, MULTIFOCAL
CLASS II – INFREQUENT 1 to 9 ectopic impulses/hour	CLASS C – REPETITIVE FORMS • COUPLETS • SALVOS, REPETITIVE RESPONSES (3–5 consecutive inpulses)
CLASS III – INTERMEDIATE 10 to 29 ectopic impulses/hour	CLASS D – NON-SUSTAINED VENTRICULAR TACHYCARDIA (from 6 consecutive ectopic impulses to runs lasting up to 30 seconds)
CLASS IV – FREQUENT ≥ 30 ectopic impulses/hour	CLASS E – SUSTAINED VENTRICULAR TACHYCARDIA (runs of ectopic activity ≥ 30 seconds)

Figure 24-34: Classification of ventricular arrhythmias based on hierarchies of frequency and forms. Hierarchical schemes for estimating risk of ventricular arrhythmias have been developed based on frequency and forms of ventricular arrhythmias. In some clinical settings, frequencies in the range of 1 to 9 ectopic impulses per hour become significant, and in most settings of clinically significant heart disease, risk based on frequency plateaus in the range of 10 to 30 ectopic impulses per hour. Among forms of ventricular arrhythmias, the repetitive forms, particularly salvos or nonsustained ventricular tachycardia, indicate higher risk in most clinical settings. (Modified from Myerburg et al.[138] Reproduced with permission from the publisher and authors.)

For evaluating risk and prescribing therapy, clinical information beyond the pattern of the arrhythmia itself must be considered. Very high frequencies and/or advanced forms usually connote little or no increased risk in the absence of structural heart disease, except for certain polymorphic nonsustained VTs. Risk begins to increase with the presence of structural heart disease and becomes prominent with falling EF.[171,172] A simplified but useful clinically based classification incorporates both form and frequency along with clinical disease information. Bigger[173] suggested classifying ventricular arrhythmias as benign, potentially malignant, and malignant based on these considerations. As an extension of this concept, frequency, forms, severity of cardiac disease, and LV function (EF) can be integrated into a clinical classification of benign (no independent increase in risk), significant (independent increase in risk), and potentially lethal (untreated, can lead to proximate fatality). While these clinically based approaches have not been quantitated, they do provide a conceptual framework for classifying arrhythmias.

Management of PVCs must be further analyzed in regard to specific etiology (e.g., low-risk mitral valve prolapse versus high-risk idiopathic dilated cardiomyopathy), and PVCs in acute or subacute clinical settings must be distinguished from those occurring in chronic settings. Finally, end points of therapy that are based upon suppression of underlying ectopy (i.e., background PVCs) are separated from end points based upon prevention of potentially lethal arrhythmias (i.e., sustained VT or VF; see Table 24-1). *There are no data supporting the notion that PVC suppression itself improves mortality rates, despite the connotation of risk in specific clinical settings. Indications for therapy are based on symptoms, evaluated in the light of the known or suspected risks of therapy.*

Premature Ventricular Contractions

ELECTROCARDIOGRAPHIC RECOGNITION OF PVCS

Ventricular arrhythmias originate in the specialized conducting tissue distal to the bifurcation of the bundle of His or in true ventricular myocardium. Accordingly, they are characterized by a prolonged ventricular depolarization (i.e., wide QRS complex), an alteration in the sequence of ventricular activation (i.e., a change in the QRS vector), and alterations in the timing sequence of consecutive QRS complexes (i.e., prematurity or escape rhythms). None of these criteria is totally sensitive and specific for ectopic impulses of ventricular origin. On occasion, PVCs demonstrate narrow QRS complexes, have a vector very similar to the normal QRS vector, or have timing little changed from the normal sinus sequence. Nonetheless, the majority of impulses originating in the ventricles have QRS complexes of at least 0.12 s and a shift in the QRS vector, and most single PVCs or initiating beats for runs of ventricular ectopic activity are premature. PVCs may fail to conduct to the atria or may demonstrate retrograde atrial activation. In either case, the sinus cycle is usually not interrupted, resulting in a *fully compensatory pause* (Fig. 24-35). The pause is characterized by an interval between the P wave of the sinus impulse immediately before the PVC and the first sinus P wave after the PVC equal to twice the sinus cycle length (Fig. 24-35*A*). If the sinus rate is relatively slow, PVCs may be interpolated between two sinus beats with no alteration of the sinus cycle length (Fig. 24-35*B*). Exceptions to the compensatory pause rule do occur (Fig. 24-36) and occasionally complicate diagnostic criteria. PVCs that presumably originate in the fascicles of the specialized conducting system may have more narrow QRS complexes with only slight alterations in the QRS vector.

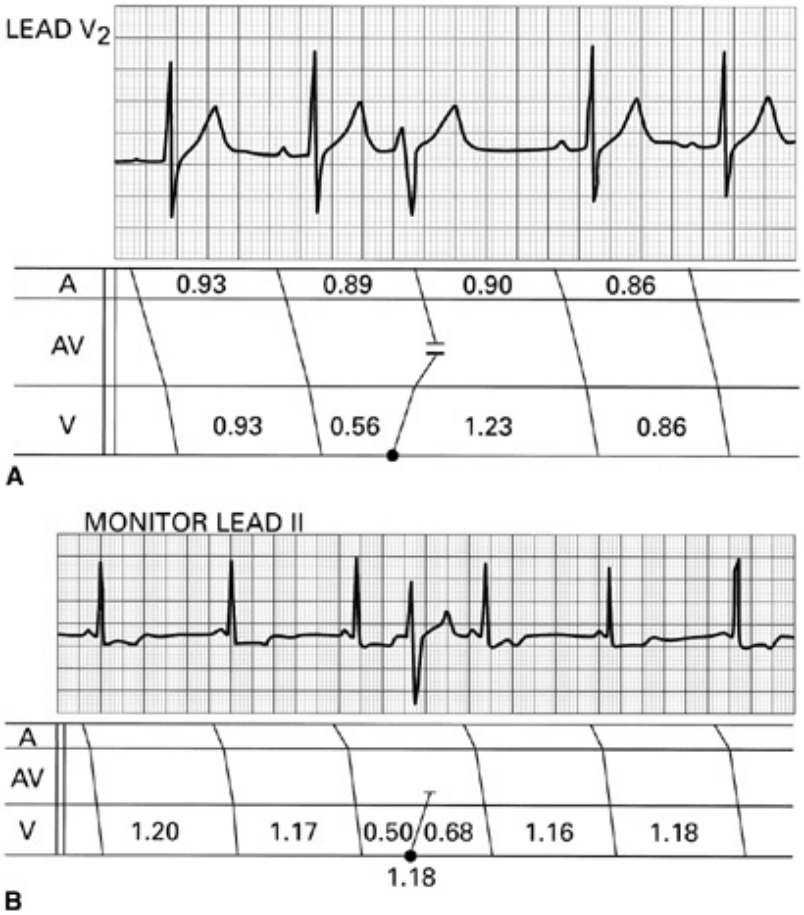

Figure 24-35: Ventricular premature contractions. *A.* The third impulse is wide and bizarre, and since the sinus rhythm is undisturbed (next sinus P wave indicated by arrow), the postextrasystolic pause is compensatory. *B.* The fourth impulse is an interpolated ventricular premature contraction; it is sandwiched between two consecutive conducted sinus beats.

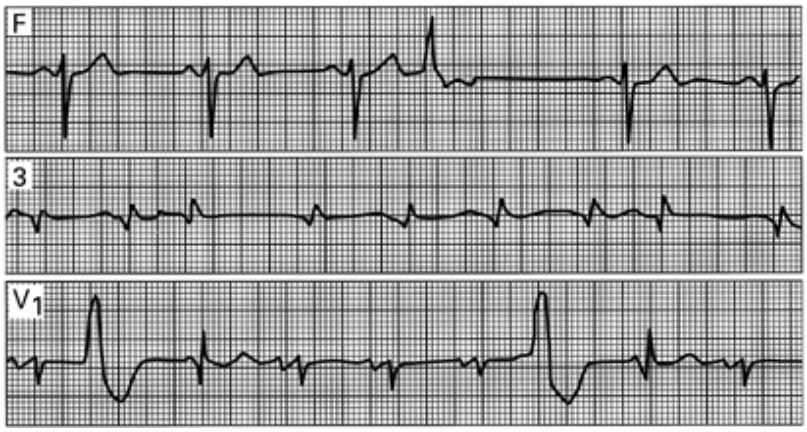

Figure 24-36: Exceptions to the rules for compensatory pauses. *Top*. Ventricular extrasystole with less than compensatory pause. Retrograde conduction to the atria (retrograde P wave deforms first part of ST segment) discharges the sinus pacemaker early and thus shortens the postextrasystolic cycle. *Middle*. Atrial premature contraction followed by fully compensatory pause. The third and eighth beats are atrial extrasystoles, but presumably because they suppress the sinus pacemaker, they are followed by compensatory pauses. *Bottom*. Ventricular extrasystoles with less than compensatory pauses. Each postextrasystolic cycle ends in an escape beat and so is slightly less than compensatory.

PVCs are usually coupled to the preceding sinus beat by a fixed coupling interval. This generalization has exceptions, in that PVCs having different QRS morphologies may have different coupling intervals,[174] and PVCs having the same morphology in a given patient may have different coupling intervals as pathophysiologic conditions change. The pattern of fixed coupling has led to a concept of a physiologic relationship between the sinus beat and the PVC, an argument in favor of reentrant or triggered-activity mechanisms for common PVCs. In contrast, parasystolic rhythms refer to an independent ectopic rhythm, with the focus of origin being protected in the sense that descending impulses cannot enter and reset the parasystolic focus but can create a field of refractoriness around it, limiting the rate and timing of impulses that exit the focus. Thus, the parasystolic focus, automatic in nature, can deliver impulses to the myocardium but cannot be reset by impulses originating elsewhere. Accordingly, the ECG reflects the presence of competing pacemakers, the sinus node, and a protected automatic ectopic ventricular focus, creating the classic triad of (1) variable coupling between sinus beats and ectopic QRS complexes, (2) fusion beats, and (3) a fixed common denominator of interectopic intervals between manifest parasystolic extrasystoles (Fig. 24-37). However, classic concepts of parasystole have been altered by the discovery that parasystole may be modulated by relationships between the parasystolic focus and impulses originating in the sinus node. Sinus impulses occurring early in the parasystolic cycle tend to shorten the cycle length of the parasystolic focus, whereas those arriving in the latter half of the cycle tend to lengthen the cycle length of the parasystolic focus.[175] Parasystolic patterns may also occur with atrial extrasystolic activity.

MANAGEMENT OF PREMATURE VENTRICULAR CONTRACTIONS

Management of PVCs in the Absence of Significant Structural Heart Disease

PVCs occur in many healthy individuals. In the absence of heart disease, there is little or no increased risk,[176] and the risk-benefit ratio of antiarrhythmic therapy does not support a need for routine treatment. For the patient who complains of disturbing or disabling palpitations due to PVCs, however, the clinician may have to treat for symptom relief (Fig. 24-38). Reassurance and avoidance of potentially aggravating factors (e.g., tobacco, coffee, caffeine-containing soft drinks, environmental stress, or stimulants) should be tried before pharmacologic therapy. For the latter, mild anxiolytic drugs or beta-adrenergic blockers (which may sedate, reduce PVC frequency, and decrease the strength of postextrasystolic impulses causing the perception of palpitations) are preferred. When used for this purpose, low doses of beta-adrenergic blockers are often sufficient. The end point, relief of symptoms, may not necessarily be accompanied by significantly reduced PVC frequency. The frequency of PVCs may be modulated by underlying heart

rate,[177] and thus manipulations of sympathetic and parasympathetic balance may be useful. Because of their side-effect profiles, class I antiarrhythmic agents are rarely indicated in this clinical setting, and the class III agent amiodarone is unnecessarily potent. PVCs are often more prominent with pregnancy and premenstrually and increase in frequency with age.[178]

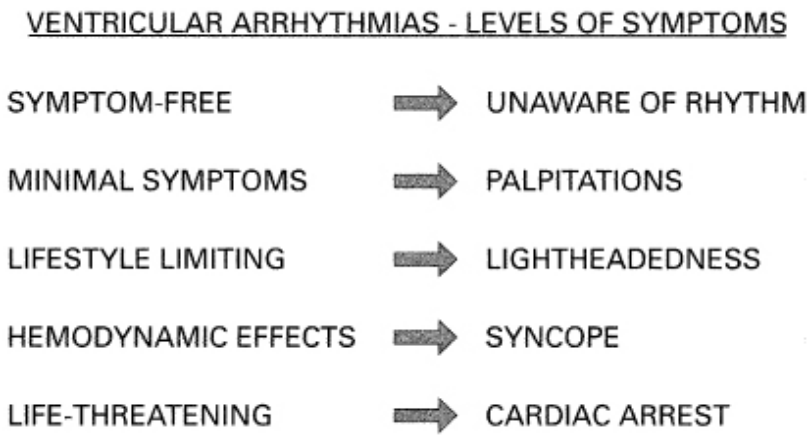

Figure 24-38: Approaches to management of ventricular arrhythmias. Treatment of ventricular arrhythmias is dictated by symptoms and clinical risk. Asymptomatic PVCs in the absence of disease usually need not be treated. Ventricular arrhythmias in the presence of advanced and/or acute disease states commonly indicate high risk, although therapy is not necessarily targeted to the PVCs themselves. A range of considerations of risk versus quality of life exists between these two extremes (see the text for details).

There may be an urge to be more aggressive in the management of patients who have advanced forms of PVCs (e.g., salvos or nonsustained VT) or a high frequency of PVCs (30 or more PVCs per hour) in the absence of structural disease. Kennedy et al.,[176] however, reported no increased risk of death in a cohort of such persons followed for a mean of over 6 years. Some specific forms of nonsustained VT, for example, polymorphic runs, may predict some increase in risk (see below).

The occurrence of PVCs in patients with mitral valve prolapse has gained special attention for three reasons: (1) the high prevalence of mitral valve prolapse, (2) the prevalence of PVCs in patients with mitral valve prolapse, and (3) the very small risk of sustained VT or VF. Annoying palpitations are a common complaint, but the arrhythmia does not require treatment in the vast majority. There are limited data suggesting that the patients at highest risk for serious ventricular arrhythmias can be subgrouped by the presence of nonspecific ST-T wave changes in leads II, III, and aVF[179,180] in conjunction with advanced grades of ventricular arrhythmias and redundancy of the mitral valve echocardiographically.[181] The approach to treatment of patients with benign forms of PVCs in mitral valve prolapse should be no different than that outlined for individuals with no structural abnormalities. Beta-adrenergic blocking agents are often sufficient to control the symptoms, and membrane-active antiarrhythmic drugs should be avoided.

Patients at risk for more serious arrhythmias, as outlined above, may require more aggressive treatment; membrane-active drugs are considered for use in this special situation for patients with salvos or nonsustained VT. The rare mitral valve prolapse patient who has had sustained VT or survived after VF is managed by the approaches generally used for these potentially lethal arrhythmias in other clinical settings (see below).

Management of PVCs in Acute Syndromes

PVCs are nearly ubiquitous in acute myocardial infarction, but the threshold for treatment remains unsettled. The original concept of "warning arrhythmias" published by Lown et al.[182] remains an indication for aggressive treatment, even though the predictive value of such warning arrhythmias remains unsubstantiated.[183,184]

The concept of routine treatment of all patients with acute infarctions with lidocaine to prevent PVCs as

well as VT or VF[185,186] is no longer applied, having yielded to a threshold for treatment at various frequencies of manifest PVCs. Suppression of PVCs in acute myocardial infarction is usually accomplished with intravenous lidocaine (a bolus of 50 to 100 mg followed by a continuous infusion of 2 to 4 mg/min), with intravenous procainamide as a second choice (100 mg every 5 min to a total dose of 500 to 750 mg, followed by an infusion of 1 to 4 mg/min). Both drugs have significant side effects, especially with improper dosing. Furthermore, these drugs have not been shown to change hospital mortality rates for patients for whom prompt medical attention and electrical defibrillation are available. Lidocaine levels and binding both increase during the course of acute myocardial infarction,[187] theoretically rendering free drug levels stable. The practice of tapering the lidocaine infusion to avoid toxicity[188] is not appropriate if free drug concentration represents active drug and does not rise (see also Chap. 42).

A number of other acute cardiac states are associated with the emergence of PVCs. For example, PVCs may emerge during and immediately after transient myocardial ischemia and are accompanied by a risk for sustained VT or VF.[189-191] The primary intervention for controlling PVCs in these settings is the reversal of ischemia.[189] On first contact, however, intravenous lidocaine or procainamide should be administered to suppress the arrhythmias. Clinical circumstances characterized by myocardial reperfusion-such as Prinzmetal's angina, thrombolysis in AMI, or balloon deflation during percutaneous transluminal coronary angioplasty (PTCA)-may cause reperfusion-induced arrhythmias. The arrhythmias generated include PVCs and accelerated ventricular rhythms (e.g., postthrombolysis or PTCA) or nonsustained VT (often polymorphic) after reversal of coronary spasm.[191] These arrhythmias are usually transient and self-limiting but may evolve into sustained VT or VF.[190,191] Although there are theoretical and experimental reasons to suspect that Ca^{2+}-mediated electrophysiologic disturbances occur during reperfusion,[192,194] intravenous lidocaine is currently used to treat reperfusion-induced arrhythmias. It is used in the same dose and with the same infusion techniques as in acute myocardial infarction. Severe heart failure and acute pulmonary edema are commonly accompanied by frequent and advanced forms of PVCs;[194,195] as in acute myocardial infarction with low-output states, the PVCs are considered secondary to the hemodynamic abnormality (see Fig. 24-1). The use of antiarrhythmic agents while the hemodynamic status is being stabilized is appropriate but may have only limited success until adequate hemodynamic control is achieved.

Acute and subacute myocarditis and pericarditis are commonly accompanied by PVCs, and sustained VT or VF may occur infrequently,[196] even in the absence of significant myocardial dysfunction. Frequent PVCs and salvos or nonsustained VT are usually treated until the carditis has resolved. In those patients who have not had sustained VT or VF conventional antiarrhythmic agents are given orally and titrated to suppression of the PVCs if possible, or at least to achieve suppression of repetitive forms. Antiarrhythmic therapy is continued for a minimum of 2 months, and then the patient is taken off antiarrhythmic drugs while still being monitored. If advanced forms do not reappear, the drug is not restarted; if they do reappear, treatment is continued for another 2 to 3 months, after which the same procedure is carried out. Myocarditis that has not evolved into a cardiomyopathic state is only rarely followed by frequent or complex forms of PVCs beyond 6 months. Virtually all other acute cardiac syndromes and many acute systemic disorders may be associated with PVCs that will abate with resolution of the initiating abnormality.

Management of Chronic PVCs in the Presence of Cardiac Disease

Chronic PVCs carry a different connotation in patients with established heart disease than in those free of disease. Sudden and total death rates are increased in patients who have frequent or repetitive PVCs in the major categories of chronic cardiac disease in the United States, including chronic ischemic heart disease,[168-172] hypertensive heart disease, and the cardiomyopathies.[1,194,195,197,198]

When frequent PVCs and/or salvos or runs of nonsustained VT are accompanied by a reduced EF, both the arrhythmia and the EF contribute to risk, and the rate of sudden death is increased.[200,201] Bigger et al.[201] observed a 2-year mortality rate of 42 percent for postinfarction patients with salvos or nonsustained VT and an EF of less than 30 percent, compared to a 2-year mortality rate of 12 percent for patients with salvos or nonsustained VT and an EF of 50 percent or more. The 2-year rate fell to 7 percent for patients with only single PVCs and an EF of 50 percent or more.

Management of frequent and repetitive forms of chronic PVCs after myocardial infarction has changed dramatically since the results of the CAST study were published.[21,199] Previous studies[200,201] as well as

CAST itself[21] had demonstrated that PVC suppression was feasible in these patients, but CAST clearly demonstrated a significant excess risk of sudden cardiovascular death among the treatment groups receiving the two class IC agents (flecainide and encainide) evaluated in the study. CAST II, the continuation of the study with moricizine, the one drug that had not crossed a boundary of significance during CAST I, demonstrated neither benefit nor adverse effect, showing only an early classic proarrhythmic mortality risk, which did not influence long-term outcome.[199] By design, the enrollment in the moricizine arm of CAST I and in CAST II was a population with more advanced disease. Meta-analyses of data derived from previous smaller randomized studies, as well as the subsequent (SWORD) study,[166] testing the effect of antiarrhythmic drugs on mortality rates after myocardial infarction, also suggested an adverse effect of most antiarrhythmic drugs when used in postmyocardial infarction patients.[202] Accordingly, the drugs used in CAST are now contraindicated following myocardial infarction in patients with asymptomatic or mildly symptomatic PVCs, and there is a trend away from the use of any membrane-active antiarrhythmic agent in such patients. Recent large randomized, placebo-controlled trials testing the possible benefit of amiodarone in postmyocardial infarction patients (EMIAT and CAMIAT) demonstrated no benefit on total mortality rates.[203,204] Beta-adrenoceptor blocking agents, however, have a substantial beneficial effect on long-term outcome in the postmyocardial infarction patient[205,206] as well as improving total mortality rates in the subgroups of the amiodarone postmyocardial infarction trials in whom beta-adrenoceptor-blocking agents were used with amiodarone.[207] In addition, beta-adrenoceptor-blocking agents are effective in suppressing repetitive forms of PVCs in many patients.[209]

Beta blockers, therefore, have evolved as the drugs of choice following myocardial infarction in patients with mildly symptomatic PVCs. While no properly randomized study directed to a sudden and total death outcome as a result of PVC suppression using beta-adrenoceptor-blocking agents has been reported, the existing randomized data on mortality rates in patients following myocardial infarction in general demonstrates beneficial effects.[205,206]

In patients with *symptomatic* PVCs (e.g., palpitations or repetitive beats) following myocardial infarction, especially when accompanied by a low EF, management becomes more difficult. Such patients have a higher mortality rate, and it is not known whether the CAST data should be extrapolated to this population. Because of CAST, class IC agents are avoided in these patients, but clinicians may use other antiarrhythmic drugs if they are well tolerated and no adverse effects are observed. However, the threshold for initiation of therapy is generally higher than it was prior to CAST. Even if the EF is depressed, beta-adrenergic blocking agents should be tried initially. If they are effective and well tolerated, they are the preferred treatment. Class III (e.g., sotalol and amiodarone) and perhaps class IA drugs also appear to be safe and may be used if treatment is necessary.

Chronic PVCs are very common in patients with advanced idiopathic dilated cardiomyopathy and in patients with hypertrophic cardiomyopathy, and both groups have a major risk of arrhythmic sudden death. In some reports, more than 90 percent of patients with dilated cardiomyopathy have frequent PVCs, and over 50 percent have salvos or nonsustained VT.[194,195] Efficacy of antiarrhythmic therapy for both suppression of chronic PVCs and prevention of VT and VF is unclear and perhaps is quite limited in these patients. Treatment is controversial. It is not known whether the CAST data can be extrapolated to this group or whether there is any mortality benefit from the use of antiarrhythmic drugs among these patients. When treatment is prescribed, the patient should be hospitalized for initiation of antiarrhythmic therapy because of proarrhythmic risk in cardiomyopathy.[214] Secondary ventricular arrhythmias in patients who have chronic heart failure (see Fig. 24-1) may respond to control of heart failure. In one carefully designed study, treatment with an angiotensin-converting enzyme inhibitor had a very favorable effect on both parameters of heart failure and ventricular ectopy.[215]

When antiarrhythmic drugs are to be used, the selection of a drug or a combination of drugs for high-risk patients with chronic PVCs is complex. The class IA drugs are moderately effective but have a high incidence of allergic reactions (e.g., procainamide) and poorly tolerated side effects (e.g., quinidine causing thrombocytopenia). They may also produce significant further myocardial depression in patients with an already reduced EF (e.g., disopyramide). Moricizine appears to be better tolerated, but all have significant risks of proarrhythmic effects, although many of these events are not life-threatening.[216] Among the class IB agents (e.g., tocainide and mexiletine), efficacy might be good in some patients and the proarrhythmic incidence is lower, but there is a high incidence of uncomfortable side effects. The currently available IC agents (flecainide and propafenone) are very effective for reducing ventricular ectopy and are well tolerated

in patients with normal or only minimally depressed LV function. Their use is not indicated for patients with ischemic heart disease because of the adverse outcome observed in CAST[21] and is limited more generally by the fact that the incidence of proarrhythmic effects and myocardial depression is highest in the subgroup at greatest need for the intervention: those with repetitive forms and impaired LV function. It is not yet known, however, whether the higher absolute risk of adverse effects in patients with abnormal LV function is balanced by a benefit in this higher-risk group.[217] Specifically, the long-term effects of the class I agents on death rates in groups of patients other than the lower-risk category enrolled in CAST are unknown at present.

There are differences in adverse proarrhythmic effects among the various drug groups. Class IA drugs are predominantly associated with classical proarrhythmia. Class III drugs have the same pattern of proarrhythmia, perhaps with a lower incidence of torsades de pointes for amiodarone. Sotalol demonstrates a dose-dependent incidence of torsades de pointes, in contrast to the idiosyncratic pattern for the class IA drugs. The common denominator between class IA and class III drugs, which likely contributes to this concordant proarrhythmic pattern, is moderate to marked prolongation of repolarization, as reflected in QT interval prolongation. In contrast, the class IC drugs, which have minimal effect on repolarization, have a low rate of classic proarrhythmia: torsades de pointes. They may, however, worsen clinical arrhythmias or generate a new rapid sinusoidal sustained VT.[219] In addition, the excess death rate in CAST, attributed to proarrhythmia, extended over the entire period of drug exposure rather than being close in time to the start of treatment. A possible explanation for this pattern is a tendency for the class IC drugs to interact with sporadic intercurrent events, such as transient ischemia or LV dysfunction.[22] Such an explanation is consistent with disturbed conduction patterns (depolarization) contributing to proarrhythmia rather than repolarization abnormalities[15] (see also Chap. 27). It is also consistent with the observation in CAST that increased risk of mortality in the flecainide and encainide arms was accompanied by a decreased incidence of nonfatal ischemic events compared to their placebo groups. Combining drug classes has been found to be effective by some, although carefully controlled studies are limited;[220] combinations such as a class IA and a class IB drug may be tried. The class II drugs, beta-adrenergic blocking agents, have been mentioned earlier, and many consider them the first choice of therapy even if the EF is reduced. They may be used in combination with class I drugs in some patients. Class III drugs have been approved only for use in life-threatening arrhythmias, although amiodarone and sotalol are both appropriate for selected patients with symptomatic runs of nonsustained VT and advanced LV dysfunction. The available data on amiodarone is promising for patients with life-threatening arrhythmias,[221,222] but the specific benefit for patients with PVCs and nonsustained VT in the presence of advanced heart disease is unclear. In the Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure (CHF-STAT) study, which randomized ischemic and nonischemic myopathies and PVCs to amiodarone and placebo, no mortality benefit was observed.[223] Another study, GESICA, which randomized cardiomyopathic patients to the same drug versus placebo, however, showed a survival benefit for the amiodarone-treated group.[224] PVC stratification was not carried out in the latter. In both studies, amiodarone-treated patients with nonischemic cardiomyopathies tended to respond more favorably to the drug than those with ischemic cardiomyopathies. The class IV drugs, Ca^{2+}-entry blockers, have no role in the treatment of chronic PVCs.

With any of these drugs or drug combinations, attention to underlying heart disease and systemic factors is necessary. Treatment for limiting the frequency of episodes of transient ischemia, maximizing LV function, maintaining electrolyte balance, and controlling blood pressure all may act in concert with antiarrhythmic agents to limit the risk of cardiac morbidity and mortality in patients with chronic PVCs. The end point of treatment (see Table 24-1) of patients who have structural heart disease and high-risk forms and frequency of chronic PVCs is not at all clear. The pharmacodynamics of PVC suppression differ from those of VT prevention,[225] and quantitative PVC suppression is difficult to achieve.

Suppression of advanced forms of PVCs (e.g., couplets, salvos, and nonsustained VT) is sometimes achieved,[226] even if quantitative PVC suppression fails. General guidelines have included suppression of 70 to 80 percent of total PVCs on a 24-h ambulatory monitor[227] and complete (or nearly complete) suppression of repetitive forms.[228] An ongoing trial, MADIT II, is designed to determine whether mortality rates can be improved by ICDs in postmyocardial infarction patients with PVCs and ejection fractions of 30 percent or less.[229]

Nonsustained Ventricular Tachycardia

Nonsustained runs of VT (salvos of three to five consecutive impulses or nonsustained VT of six impulses to 30 s; Fig. 24-39) are considered indicators of high risk for potentially fatal arrhythmias (sustained VT or VF) in most clinical settings. There are important exceptions, however. Patients who have no organic disease or limited cardiac abnormalities do not appear to have increased risk, although some patients who have very rapid polymorphic VT may be at increased risk. Even in the absence of an increased mortality risk, symptoms such as transient light-headedness, near-syncope, or syncope require therapy (see Fig. 24-38). At the other extreme, cardiomyopathy patients and those who have advanced coronary artery disease with a very low EF are among the highest risk groups. Conceptually, nonsustained VT may be viewed as self-terminating VTor as an intense triggering event in a susceptible myocardium.[1]

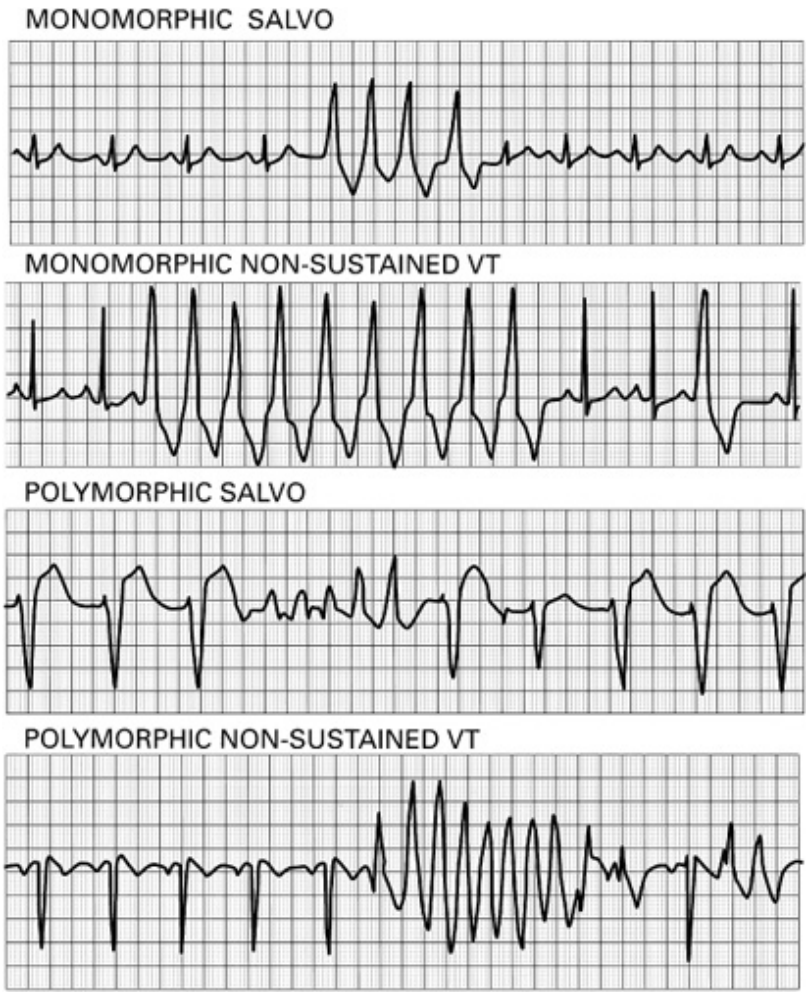

Figure 24-39: Nonsustained forms of VT. Runs of repetitive ventricular impulses (rate 100 per minute) lasting less than 30 s are subgrouped into salvos of three to five consecutive impulses and nonsustained VT of six or more impulses in duration. Both forms may be further defined according to morphology as monomorphic or polymorphic.

Treatment is generally similar to that outlined for other patterns of PVCs, although patients with prior myocardial infarction who have nonsustained VT and low EFs and are inducible into VT in the clinical electrophysiology laboratory are thought to be at higher risk than those with nonsustained VT who have better EFs and are noninducible.[210] In MADIT, ICD therapy demonstrated lower mortality rates than with the best conventional therapy in a randomized study design of such patients (nonsustained VT, EF 35 percent or less, inducible sustained VT, and failed supression of inducibility of VT during programmed stimulation-guided therapy with intravenous procainamide).[211] In the Multicenter Unsustained Tachycardia Trial (MUSTT), a similar group of patients appeared to benefit from ICDs, as opposed to electrophysiologically guided drug therapy.[230]

Repetitive Monomorphic Ventricular Tachycardia

Repetitive monomorphic VT is an uncommon form of repetitive salvos or runs of nonsustained VT, often separated from one another by only a few sinus impulses (Fig. 24-40).[233] Occasionally, this arrhythmia is continuous and fulfills the definition of sustained VT. The tachycardia rate is usually 150 or less per minute but may be greater than 200 per minute in rare cases. The syndrome is more common in women and is usually benign.[233,234] The QRS patterns of the tachycardia on 12-lead ECGs suggest a right ventricular outflow tract origin (left bundle-branch block pattern with an axis between 0° and +90°, or slightly rightward), and the mechanism is likely a form of enhanced automaticity.[235] Treatment is considered only when structural heart disease is also present, when the palpitations are poorly tolerated by the patient, or when the patient has light-headedness, near-syncope, or syncope caused by the arrhythmia. Membrane-active antiarrhythmic drugs should be avoided if possible, and beta-adrenoceptor and Ca^{2+}-entry blocking agents are effective in some. Catheter ablation is an option for the more sustained or symptomatic forms and has a high probability of success[236] (Fig. 24-41).

Sustained Ventricular Tachycardia

Sustained VT may originate in the specialized conducting system distal to the bundle of His, in ventricular myocardium, or by an interaction between the two. By definition, it occurs at a heart rate of 100 per minute or more and lasts for 30 s or more. A ventricular rhythm faster than 40 to 50 impulses per minute but slower than 100 per minute is referred to as an accelerated ventricular rhythm. Runs of VT lasting less than 30 s that impair hemodynamics enough to cause symptoms of reduced peripheral or central nervous system blood flow are considered the functional equivalent of a sustained VT. Although generally considered to be included among the life-threatening cardiac arrhythmias, benign forms of sustained VT do exist. They occur in persons without structural heart disease, and a functional basis can be identified in some instances (see below).

The etiology of VT will determine its mechanism and clinical presentation (Table 24-11). For example, in the patient with prior myocardial infarction and a defined ventricular aneurysm, sustained monomorphic VT occurs at rates ranging from 140 to 200 per minute, most commonly in the range of 150 to 180 per minute (Fig. 24-42*A*). This arrhythmia usually employs stable reentrant pathways and may be hemodynamically well tolerated. In contrast, patients with transient myocardial ischemia often have more rapid ventricular tachyarrhythmias (in excess of 200 per minute) that may be polymorphic or sinusoidal (Fig. 24-42*B*). The mechanism is not clearly defined but likely may be either reentrant or automatic, including the possibility of triggered activity. These forms of VT tend to be hemodynamically and electrically unstable, with a higher risk of degenerating to VF than chronic recurrent monomorphic VT. They tend to persist for only short periods of time, in contrast to the sustained mono-morphic VTs, which may persist for hours in some pa tients. These forms of VT either degenerate to VF, convert to a stable monomorphic VT, or spontaneously revert to sinus rhythm (see also Chap. 23).

Some patients will tolerate sustained monomorphic VT remarkably well, although the risk that sustained VT will degenerate into VF must always be kept in mind. When the hemodynamic status is stable and there is no evidence of myocardial ischemia, acute infarction, or poor central nervous system perfusion, electrical cardioversion can await a therapeutic trial of intravenous drug. With acute myocardial infarction, falling blood pressure, or evidence of ischemia, immediate cardioversion is indicated. In patients who are already receiving antiarrhythmic agents because of prior sustained VT or for treatment of other ventricular arrhythmias, recurrent sustained VT presents a challenging therapeutic problem. If it is known that the patient has not complied with antiarrhythmic regimens, standard intravenous regimens may be tried, but more commonly this is not the case. Plasma concentrations of the prescribed antiarrhythmics should be ordered at the time of presentation, even though the information may not be available for initial management. The distinction between recurrence of the previous VT and proarrhythmic effects caused by antiarrhythmic agents is a major dilemma. Proarrhythmia should be suspected if the VT morphology is different from the previously identified clinical VT morphology, if antiarrhythmic agents have been recently prescribed or changed, if there is marked prolongation of the QT interval, or if the VT has a polymorphic or torsades de pointes configuration. If there are repeated recurrences after cardioversion, the possibility of proarrhythmia should be seriously entertained, and temporary pacing may be useful. Other causes of repeated recurrence include ischemia, heart failure, autonomic surges, or electrolyte disturbances.

ELECTROCARDIOGRAPHIC RECOGNITION OF SUSTAINED VENTRICULAR TACHYCARDIA

Having met the rate and duration criteria for a sustained tachyarrhythmia, the distinction between sustained VT and supraventricular tachyarrhythmias with abnormal intraventricular conduction patterns is based upon a complex set of electrocardiographic criteria. The evaluation of the patient's general clinical status, short of cardiac arrest, is only of limited value for distinguishing very rapid SVT from VT as the cause of hypotension or syncope. Nonetheless, the distinction between SVT and VT at the bedside is important because of its clinical and therapeutic implications.

Electrocardiographic criteria derive from atrioventricular timing relationships and from QRS durations, configurations, and axes. The presence of ventriculoatrial dissociation with clearly discernible P waves independent of a regular QRS rhythm is strongly suggestive of VT (Fig. 24-43*A*), as is the presence of P waves associated with alternate QRS complexes (Fig. 24-44). The latter, best identified in lead V_1, is due to 2:1 retrograde block because of the rate of the tachycardia. The presence of a 1:1 relationship between P waves and QRS complexes, with a short RP interval (as in Fig. 24-43*B*), is also considered supportive evidence for VT. A variety of SVTs with aberrant intraventricular conduction may mimic this pattern, however, and therefore it is not conclusive. Finally, in the presence of ventriculoatrial dissociation, a fortuitously timed sinus impulse may fuse with the wide QRS complex due to VT and produce a single cycle of an altered (usually narrowed) QRS complex (Fig. 24-43*C*). Such fusion beats are helpful when present but are not common.

A QRS duration greater than 0.14 s favors VT as the cause of a wide QRS complex tachyarrhythmia. It is nonspecific, however, and is commonly observed in patients with SVT in the presence of a preexisting bundle-branch block. SVT with QRS complexes greater than 0.14 s occurs only rarely as a consequence of aberrant intraventricular conduction when QRS complexes are normal during sinus rhythm. In addition, antidromic tachycardias in WPW syndrome usually have QRS complexes longer than 0.14 s in duration and therefore may mimic VT. The mean QRS axis is also of limited help in distinguishing between SVT with aberration and VT. Abnormal left-axis deviation (-30° or beyond) favors VT but does not exclude SVT with preexisting bundle-branch block or various supraventricular arrhythmias associated with accessory pathways. Some unusual VTs are associated with a left bundle-branch block pattern and right-axis deviation.

QRS configurations have been carefully studied in both VT and SVT with aberrant intraventricular conduction and are of considerable help in distinguishing between the two. Generally, concordantly positive or negative QRS complexes across the precordium from V_1 to V_6 strongly favor VT over aberrant intraventricular conduction (Fig. 24-45). In addition, patterns in specific leads may be helpful. In V_1, a right bundle-branch block configuration that is monophasic (R) or biphasic (qR) suggests VT, while a triphasic pattern (rSR) strongly favors aberrant intraventricular conduction.[237] R-wave amplitude in V_1 during the tachycardia that exceeds that during sinus rhythm favors VT, and an initial R wave during the tachycardia of 30 ms duration or longer also favors VT. In V_1 and V_2, a notched downslope on an S wave suggests VT, as does an interval of 70 ms or more from onset of the QRS to the negative peak of the S wave. In lead V_6, a deep S wave with an R:S ratio below 1 and a qR or QS pattern both favor VT.[238,239] Each of these criteria may be altered or modified in individual cases by the presence of preexisting intraventricular conduction abnormalities.

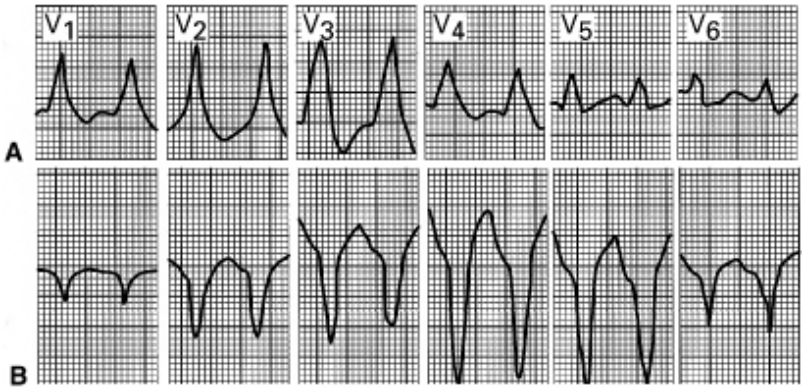

Figure 24-45: VT with concordant QRS complexes across precordium. *A.* All upright. *B.* All inverted.

Several additional features of tachyarrhythmias may be helpful. Polymorphic tachyarrhythmias are almost exclusively ventricular in origin but must be carefully distinguished from atrial fibrillation in patients with WPW syndrome who have multiple bypass tracts.[240] A tachycardia characterized by a wide QRS pattern with a left bundle-branch configuration in the precordial leads and right-axis deviation in the frontal plane leads is also usually ventricular in origin. A regular rhythm with alternating QRS axes (a bidirectional pattern) alteration is likely to be ventricular in origin, while paired group beating with bidirectional alteration is likely to be due to aberrant conduction terminating the shorter cycles. Finally, VTs, presumably originating in proximal bundle branches or fascicles, may inscribe relatively or absolutely narrow QRS complexes Fig. 24-46.

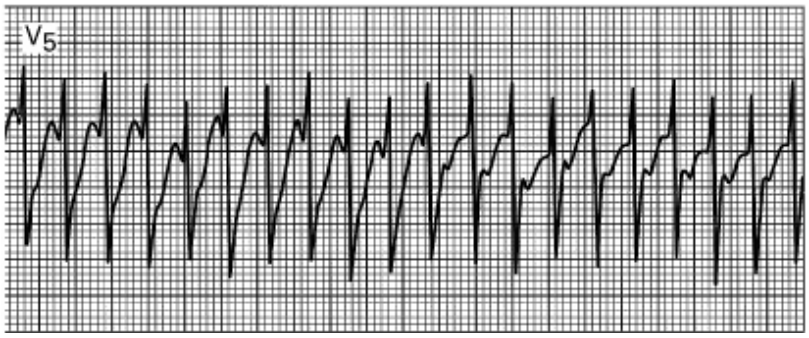

Figure 24-46: VT with narrow QRS complexes. The tracings were recorded from a 39-year-old male with ischemic cardiomyopathy and recurrent VT. Multiple VT morphologies were recorded, one of which was this narrow QRS morphology. These may be recognized by their onset if the latter is available but often may be very difficult to distinguish from supraventricular tachycardia with altered repolarization patterns. The diagnosis of the narrow QRS VT shown was confirmed by invasive electrophysiologic studies.

The cycle length of tachyarrhythmias is of little additional value in distinguishing between VTs and SVTs. Although monomorphic VTs associated with coronary heart disease and LV aneurysms tend to have rates below 220 per minute, ventricular arrhythmias due to ischemia and/or reperfusion may be considerably faster, in some instances approaching 250 to 280 per minute (Fig. 24-42*B*). SVTs, particularly those associated with WPW syndrome, may approach similar rates and may be difficult to distinguish from VTs. Antiarrhythmic drugs may also alter electrocardiographic patterns. An example is the slowing of atrial flutter by class IA or class IC antiarrhythmic agents to atrial rates of 240 per minute or less, allowing 1:1 conduction. Particularly for the class IC agents, slowed intraventricular conduction at these rates widens the QRS complexes, resulting in patterns that may be difficult to distinguish from rapid sustained *ventricular* tachyarrhythmias.

ACUTE MANAGEMENT OF SUSTAINED MONOMORPHIC VENTRICULAR TACHYCARDIA

Sustained monomorphic VT may occur in acute or chronic ischemic heart disease syndromes, in idiopathic

dilated or hypertrophic cardiomyopathy, and, less frequently, in inflammatory or infiltrative disease states. It occurs occasionally as a primary electrical disturbance. Management depends upon the clinical setting and the clinical characteristics of the tachycardia.

In acute myocardial infarction, sustained VT occurs most commonly within 24 h of the onset. Although degeneration into VF is uncommon, sustained VT carries that risk and must be treated aggressively. If the patient is clinically stable and the arrhythmia electrically stable, a 75- to 100-mg bolus of intravenous lidocaine, followed by a continuous infusion of 1 to 4 mg/min, may be tried. The infusion dose depends upon the patient's age, size, and general clinical status.[241] In heart failure and low-output states, the dose should be reduced. If the VT does not revert immediately or if the patient is hypotensive, immediate DC cardioversion is required. Following cardioversion, intravenous lidocaine is continued to prevent recurrences. If VT recurs with lidocaine, 100-mg boluses of procainamide are infused at 5-min intervals to a total loading dose of 500 to 1000 mg, followed by a constant infusion of 2 to 4 mg/min.[242] If breakthroughs occur on both drugs, the next drug of choice is intravenous amiodarone[243] or bretylium tosylate.[244] Amiodarone, currently the preferred therapy for this indication, is administered intravenously with a loading dose of 150 mg infused over 10 min, followed by a continuous infusion of 1 mg/min for 6 h and then a maintenance infusion at a rate of 0.5 mg/min. Bretylium, less commonly used than in the past, is administered as a loading dose of 5 mg/kg intravenously infused over 15 min, repeated if necessary, and followed by a 0.5- to 2.0-mg/min infusion. Total dose should not exceed 25 mg/kg per 24 h. Antiarrhythmic therapy may be stopped after 48 to 72 h, since the risk of recurrence is small at that point. Sustained VT during the acute phase of transmural myocardial infarction is due to transient factors and does not predict later recurrent arrhythmias (see also Chap. 42).

A second category of sustained VT related to acute myocardial infarction is that which occurs during the convalescent period.[245] It is unrelated pathophysiologically to the VT that occurs early and has much more serious long-term implications. It is most common in patients with large anterior wall myocardial infarction. Management of the acute event requires intravenous antiarrhythmic drugs and/or cardioversion, using an algorithm similar to that described for acute-phase VT. There is, however, a very high death rate during follow-up of these patients, in part related to the size of the infarct. One report cited an 83 percent death rate during a mean follow-up of 7 months using empiric antiarrhythmic therapy.[246] Others have reported a somewhat better outcome when such patients undergo electrophysiologic testing for evaluation of drug therapy and/or surgical interventions,[247] although mortality is still high: approximately 25 percent total mortality during a mean follow-up of 16 months. Sustained VT in patients beyond the convalescent phase of myocardial infarction (6 to 8 weeks) has a somewhat less ominous prognosis than does convalescent-phase VT but is still considered life-threatening and requires special interventions (see below).[246]

Sustained VT may complicate other acute or transient cardiac syndromes, including ischemia-reperfusion sequences associated with coronary spasm or thrombolysis early after the onset of myocardial infarction, heart failure,[248] acute myocarditis,[196] and almost any toxic or metabolic disturbance of sufficient severity. Therapeutic approaches include both conventional arrhythmia treatment, as described above for sustained VT in acute myocardial infarction, and careful attention to underlying predisposing factors.

LONG-TERM MANAGEMENT OF VENTRICULAR TACHYCARDIA IN CHRONIC ISCHEMICHEART DISEASE

The long-term management of recurrent VT in patients with chronic ischemic heart disease has evolved into a complex clinical exercise. Prevention of recurrences is related to successful management of the underlying precipitating factors, such as ischemia and hemodynamic status, as well as to specific antiarrhythmic approaches.

Four general approaches to antiarrhythmic therapy are available: (1) antiarrhythmic therapy guided by invasive electrophysiologic testing or by ambulatory monitoring or exercise testing, (2) surgical procedures designed to excise or cryoablate reentrant pathways or automatic foci, (3) catheter ablation procedures, and (4) ICDs (Fig. 24-47). The relative proportion of patients managed by each of these four techniques has changed in recent years, with fewer and more selective surgical approaches, fewer antiarrhythmic drug trials, and broader use of ICD therapy. The use of catheter ablation techniques for VT in chronic ischemic

heart disease is largely palliative,[249] often employed as adjunctive therapy with other primary approaches. As technology improves, however, it may develop broader applications (see below).

Pharmacologic Management

Invasive electrophysiologic testing to guide pharmacologic therapy in patients with recurrent monomorphic sustained VT due to ischemic heart disease has yielded, in large part, to empiric antiarrhythmic therapy (primarily amiodarone), ICD implantation, and catheter ablation. At one time the index for the initial treatment strategy for such patients, the initial study free of antiarrhythmic drugs required to demonstrate inducibility of the clinical VT and its characteristics at baseline, is now largely used for risk stratification. Several clinical trials[211,230-232] have demonstrated that inducibility predicts risk along with better outcomes with ICD therapy than with drug therapy in high-risk patients.[230] It is also useful in conjuction with ablation or surgical procedures.

Although there have been controversies about the validity of different protocols for programmed electrical stimulation in patients who have clinical sustained ventricular arrhythmias,[251] up to 95 percent of inducible sustained monomorphic VTs can be induced by right ventricular stimulation, using up to two drive cycle lengths between 600 and 400 ms from two right ventricular locations (apex and outflow tract) with up to three extrastimuli (see also Chap. 26). In at least 80 percent of patients with chronic ischemic heart disease and recurrent monomorphic sustained VT, the clinical tachyarrhythmias can be induced during a baseline study free of antiarrhythmic agents. The subsequent identification of a drug regimen that will prevent reinduction into the same sustained monomorphic VT is associated with a reduction of risk of recurrent VT at 1 year of follow-up. The risk appears to decrease from 30 to 40 percent if VT remains inducible on therapy to 10 to 15 percent if therapy results in noninducibility.[252] The results of acute intravenous testing of a drug should not be extrapolated to long-term oral therapy without retesting on the oral regimen, because intravenous regimens do not predict responses on oral drugs.[253] In addition, a drug capable of preventing induction of a VT previously induced during baseline testing can be identified in only a minority of patients (approximately 20 to 35 percent in various studies). Moreover, the success rate for membrane-active drugs is considerably lower if multiple monomorphic VTs are induced at baseline.[254] Left ventricular EF strongly influences probability of recurrence. Among cardiac arrest survivors, an EF of 30 percent or less predicts a mortality rate approximately twice as high as for patients in the same category with EFs above 30 percent.[255] A similar relationship likely exists for patients who present clinically with sustained VT. Unfortunately, all statements about the potential benefit of therapy guided by programmed electrical stimulation are based upon comparisons of groups who did (responders) or did not (nonresponders) convert from an inducible status to a noninducible status as a result of the therapy. Randomized, placebo-controlled studies of patients who convert to a noninducible status on therapy, with a similar strategy for patients with VT that remains inducible, are still lacking. Such studies would determine whether it is the therapy or simply the ability to change inducibility status that is determining outcome. In one study of patients who had had VT or VF and met criteria for both the invasive electrophysiologic approach (i.e., inducibility at baseline) and the ambulatory monitoring approach (30 or more PVCs per hour), a randomized comparison revealed a significantly lower arrhythmia recurrence rate with therapy guided by the invasive testing technique:[256] 20 percent recurrence rate of symptomatic VT at 24 months with invasive procedures versus 50 percent with noninvasive procedures. The study, however, did not identify a difference in death rate, possibly because of the small number of patients randomized. In another study, a drug or drug combination that did not prevent inducibility during invasive electrophysiologic study but did prolong the cycle length of induced VT by more than 100 ms with stable hemodynamics predicted a favorable mortality outcome, even though the incidence of recurrent VT was not different from that in those who failed to show any measure of a successful response.[257] Patients who have a partial response to a drug regimen (i.e., induced runs of 6 or more but fewer than 15 impulses) also appear to have a lower risk of recurrent VT.[258] Many electrophysiologists currently will accept induced runs of less than 10 impulses on therapy as a satisfactory end point, and almost all will accept less than 6. Any change in therapy established by invasive electrophysiologic testing because of drug intolerance or clinical failure should be evaluated by repeat testing.[252,259]

Finally, a recently reported trial in postmyocardial infarction patients, the MUSTT study, demonstrated that patients who had nonsustained VT on ambulatory monitoring with inducible VT at baseline study and failed antiarrhythmic drug therapy during repeat study had better long-term survival rates if they received ICDs than if they received drug therapy.[250] It is important to note that patients who received ICDs based on

failed electrophysiologic testing-considered a high-risk group-did even better than those who had a successful electrophysiologic study on drug therapy.

Noninvasive management strategies for VT require identification of frequent (i.e., 10 to 30 PVCs per hour in various studies) and/or repetitive PVC forms (i.e., salvos or nonsustained VT) at baseline monitoring or VT induced during exercise testing. Reduction of PVC frequency (80 percent or more suppression) and abolition of complex forms has been used as the index of a successful end point. This approach has been reported to be successful in some studies,[226,260] even among patients who have failed to achieve a successful end point by invasive electrophysiologic testing.[260] Unfortunately, the *residual risk* among many patient groups with successful noninvasive or invasive end points is still very high.[261] Thus, because of the *relative* benefit of ICDs in several patient groups compared to empiric amiodarone, many clinicians now prefer implantable devices for both primary and secondary prevention of life-threatening arrhythmias in these high-risk patients.

A large multicenter randomized trial, entitled Electrophysiological Study Versus Electrocardiographic Monitoring (ESVEM), was designed to compare programmed electrical stimulation with ambulatory monitoring techniques for guiding therapy in patients who had sustained VT, had survived cardiac arrest, or had syncope presumed due to a ventricular arrhythmia.[262,263] The data showed no difference between the two methods for prediction of efficacy or mortality benefit, although there was a small trend favoring programmed stimulation during early follow-up in the coronary disease subgroup (see Chap. 30). Failure by both invasive and noninvasive criteria connotes a poor prognosis and requires other considerations for therapy, namely, surgery or implantable devices.

Pharmacologic therapy has an increasingly important role as adjunct therapy in patients who have implanted defibrillators. It is used to reduce VT events requiring ICD therapy, slow tachycardia rates to favor antitachycardia pacing therapy over shocks, and reduce the incidence of atrial tachycardia that can initiate shock therapy unnecessarily (e.g., atrial fibrillation or flutter). A randomized trial has demonstrated that these goals can be achieved.[264]

Surgical Therapy

Patients who have recurrent sustained monomorphic VT associated with prior myocardial infarction and inducibility into a hemodynamically stable tachycardia were uniformly considered for antiarrhythmic surgery until recent years. The indication was reinforced by the presence of discrete ventricular aneurysms and bypassable coronary artery lesions. With the development of ICDs capable of flexible antitachycardia pacing programs, many patients who were formerly surgical candidates are now receiving ICDs. However, surgery is still recommended, in the absence of contraindications, for a small number of such patients,[252,265,266] particularly if they require revascularization surgery as well or their tachycardias are not easily pace-terminated during induction studies. Patients without discrete aneurysms who have large dyskinetic areas may have sites of origin of VT mapped in the cardiac electrophysiology laboratory and operating room if they are inducible into stable monomorphic tachycardias. Mapping allows the identification of areas that may be attacked by endocardial resection or surgical cryoablation.[267] Map-guided surgical procedures employing resection, cryoablation, and revascularization have markedly improved the clinical outcome of surgically treated patients.[268] Overall surgical results have also benefited from the preferred use of ICDs in patients previously referred for surgery out of desperation (see Chap. 30). Coronary bypass surgery may be used as primary therapy for patients who have recurrent VT initiated by transient ischemic episodes.[269] It is also a valuable adjunct to antiarrhythmic surgery (see Fig. 24-47).

Catheter Ablation Procedures for Ventricular Tachyarrhythmias

The combination of LV endocardial mapping by catheter techniques and RF energy delivery systems provides the capability for catheter ablation therapy of sustained, hemodynamically stable VTs.[249,270,271] While these techniques are currently limited to only a small fraction of patients as primary therapy,[271] they are useful as an adjunct to ICD therapy (Fig. 24-48). Improvements of mapping techniques capable of storage and recall of spatial activation maps[272,273] and improved energy delivery systems will enhance the use of catheter ablation as primary therapy and as more effective ancillary therapy in the future.

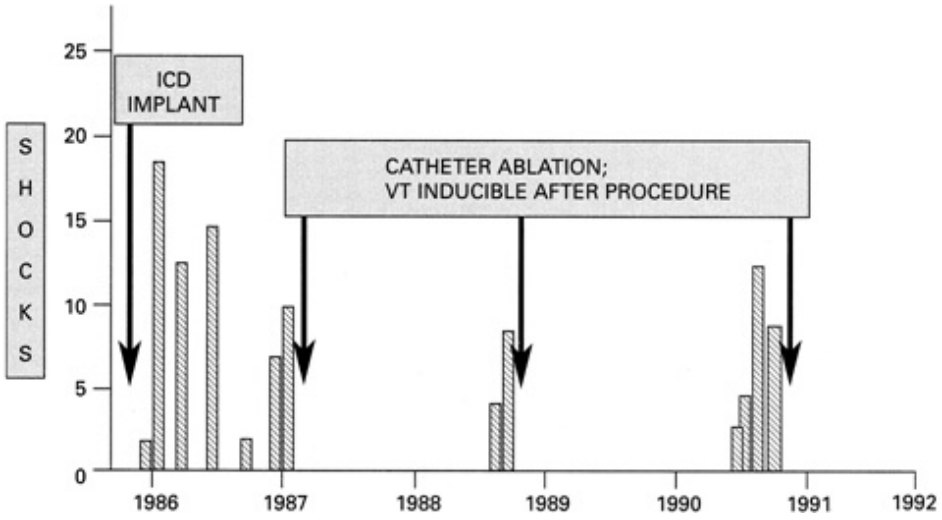

Figure 24-48: Catheter ablation for VT as an adjunct to an ICD. A 57-year-old male with recurrent life-threatening episodes of sustained VT who received an ICD had multiple shocks for arrhythmias that were resistant to all antiarrhythmic agents attempted. LV mapping and catheter ablation in a VT reentrant pathway in 1987 provided freedom from recurrent ICD discharges for approximately 19 months, after which the multiple ICD discharges recurred. Additional ablation procedures 18 or more months apart provided relief from the recurrent discharges despite the fact that VT remained inducible. While of limited value as primary therapy for life-threatening ventricular arrhythmias in patients with coronary heart disease or cardiomyopathy because of risk of recurrence (see the text), this procedure can provide benefit as an adjunct to other primary forms of therapy by avoiding frequent discharges and improving the quality of life.

Implantable Defibrillators

As a result of the outcomes of several large clinical trials[211,230-232] and advances in technology that resulted in a significant decrease in device size and range of functions, the role of ICD therapy for patients with ventricular tachyarrhythmias has expanded dramatically in recent years (see Fig. 24-47). It is no longer necessary or desirable to test a long sequence of antiarrhythmic drugs in patients with sustained monomorphic VT. For those subgroups among whom ICDs have not been demonstrated to be superior to drug therapy (e.g., those with EFs greater than 40 percent), failure of no more than one or two drugs during electrophysiologic study is generally considered an indication for ICD therapy. Their use is amplified by such enrichments as antitachycardia pacing, allowing effective programmable tiered-therapy algorithms, back-up bradyarrhythmia pacing (including dual-chamber pacing in some devices), and electrogram storage for retrieving and analyzing events.

Patients who present with clinical VT and have inducible, hemodynamically *unstable* VT associated with ischemia before surgery should receive an ICD after revascularization surgery if they remain inducible into VT. The routine use of an ICD after antiarrhythmic surgery, even if successful by postsurgical programmed stimulation study, has been advocated[275] but has gained only limited acceptance. The CABG-Patch trial tested the value of ICDs after revascularization surgery among patients with positive signal-averaged ECGs but no history of clinical VT. The results demonstrated no cumulative survival benefit of this strategy[276] even though there was a suggestion that the devices reduced arrhythmic deaths.[277]

ICDs are indicated for patients with recurrent or unstable VT whose arrhythmias cannot be controlled medically or surgically or who belong to subgroups that have been demonstrated to benefit specifically from device therapy. Antitachycardia pacing capabilities and programmable tiered therapy have expanded the scope of ICD therapy for recurrent sustained VT. The availability of antitachycardia pacing obviates the need for antiarrhythmic surgery in many patients who had been considered surgical candidates on the basis of anatomy and physiology in the past (Fig. 24-49; see also Chap. 30).

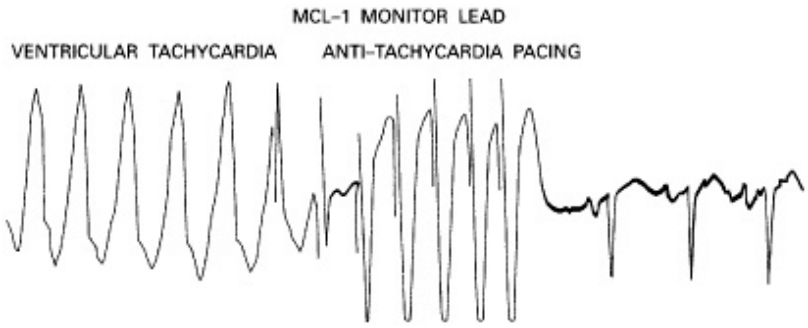

Figure 24-49: ICD with antitachycardia pacing. The figure demonstrates the end of a run of induced sustained VT (*left*) followed by antitachycardia pacing that converts the rhythm back to normal sinus (*right*). The device will revert to a defibrillator mode if programmed pacing sequences fail to convert the rhythm.

LONG-TERM MANAGEMENT OF VENTRICULAR TACHYCARDIA IN NONISCHEMIC HEART DISEASE

Sustained VT in patients with idiopathic dilated cardiomyopathy, dilated cardiomyopathies due to specific etiologies, or hypertrophic cardiomyopathies carries a poor prognosis. Management approaches differ from those used for patients with ischemic heart disease (Fig. 24-50). Invasive electrophysiologic testing, to identify risk or guide therapy is less predictably useful in the small fraction of patients with dilated cardiomyopathy who have clinical sustained monomorphic VT[278,279] than it is in coronary heart disease patients. In a subgroup of these patients, however, sustained VT is due to bundle-branch reentry,[280] which can be cured by catheter ablation of the right bundle branch. Electrophysiologically guided management does not appear useful in idiopathic dilated cardiomyopathy patients who have survived out-of-hospital VF or have clinical nonsustained VT.[281] There is almost no role for surgical therapy in these patients at present, but the ICD is an appropriate means of management. The device appears effective for reverting potentially fatal arrhythmias in patients who have cardiomyopathy,[282] but the long-term outcome may be dominated by LV function. The evaluation of ICD therapy in these patients has been confounded by the observation that, in some (perhaps a substantial fraction) of these patients, sudden death is caused by the bradyarrhythmic asystole-pulseless electrical activity complex, which would not benefit from any form of antiarrhythmic therapy.[283] The availability of ICD with electrogram storage capability should begin to clarify the magnitude of this problem. Ultimately, identification of groups at risk for specific mechanisms will help define the best therapy, but such data are currently lacking.

Sustained VT is also a late consequence and poor prognostic sign in patients with hypertrophic cardiomyopathy.[284-286] In this setting, the use of electrophysiologic testing has been limited because of unvalidated concerns about the ability to cardiovert the severely hypertrophied and obstructed ventricle,[286,287] and there is no uniform opinion regarding the best approach to management of these patients, other than the accepted need for therapy. The recent trend toward ICD therapy, rather than pharmacologic therapy, particularly among higher-risk subgroups, has now received support from multicenter observational data suggesting ICD benefit.[288] Preoperative electrophysiologic testing is generally avoided in patients with severe aortic stenosis who have survived sustained VT or VF.

Less Common Clinical Causes of Sustained Monomorphic Ventricular Tachycardia

CATECHOLAMINE- AND METABOLICALLY MEDIATED VENTRICULAR TACHYCARDIA

In a small number of patients, sustained VT appears to be mediated by catecholamines or other neurophysiologic influences.[289,290] Sustained VT in these patients is commonly induced by physical or emotional stress. Isoproterenol infusions may be used to initiate the VT, which may then be suppressed and subsequently prevented by beta-adrenergic blocking agents (Fig. 24-51). Another small group of patients have sustained VT that may respond to Ca^{2+}-entry blockers.[291-293] This is a heterogeneous group of VTs

that includes adenosine-sensitive VT,[291] and an unusual VT with a right bundle-branch block, left-axis deviation QRS pattern originating in the low interventricular septum.[293] Catecholamine-mediated VT may occur in the presence or absence of structural heart disease; when it is responsive to Ca^{2+}-entry blockers, it generally occurs in the absence of structural heart disease.

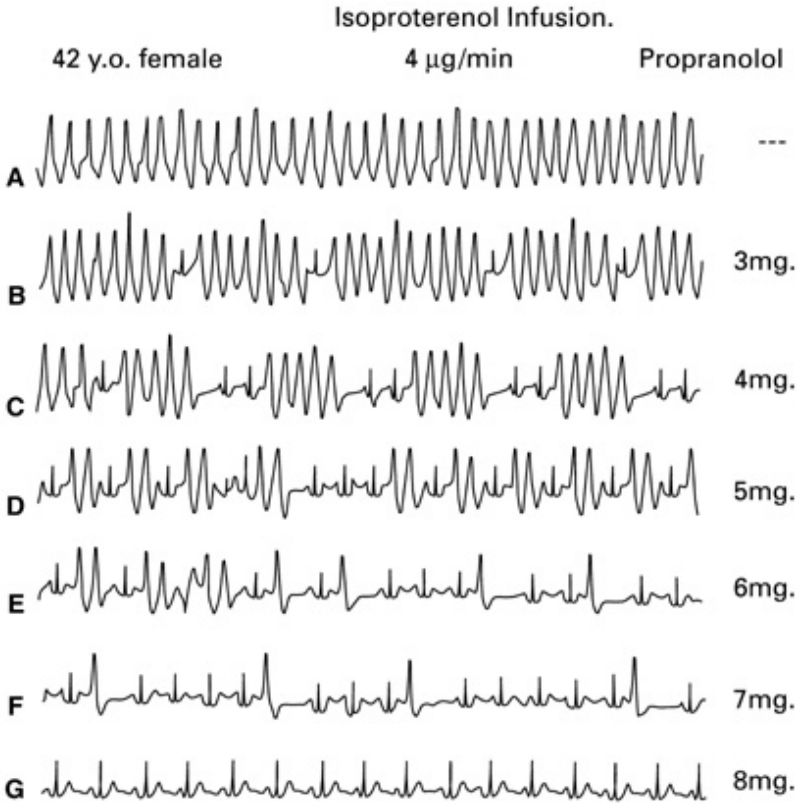

Figure 24-51: Catecholamine-mediated VT in an otherwise healthy female. Psychologic stress or isoproterenol infusion could initiate the arrhythmia in this patient. During this sequence, a 4-µg/min isoproterenol infusion initiated the VT (*A*), and the patient was treated with intravenous propranolol. After the first 3 mg of propranolol (*B*), occasional sinus beats interrupted the tachycardia. On a milligram-by-milligram basis up to a total dose of 8 mg of propranolol, there was further suppression of VT to the point of salvos (*C, D, E*), frequent PVCs (*F*), and complete suppression of ectopic activity (*G*).

RIGHT VENTRICULAR DYSPLASIA AND VENTRICULAR ARRHYTHMIAS

Arrhythmogenic right ventricular dysplasia (ARVD) or right ventricular cardiomyopathy (RVCM) may be associated with nonsustained or sustained VT and/or sudden cardiac death. Patients with a stable monomorphic VT without near-syncope may have a better prognosis,[294] but it is clear that sudden death, presumably due to VF, may be the first and only manifestation of the disease.[295]

The term isolated right ventricular cardiomyopathy[295,297] has been used as an alternative for ARVD, and, more recently, the ARVD-RVCM complex[298] is being labeled simply right ventricular dysplasia (RVD). The entity may occur sporadically or in familial clusters, with up to 40 to 50 percnt currently appearing to be familial. A number of loci are identified from linkage analyses studies in affected families,[299,300] but no specific gene abnormalities have been identified to date.

The 12-lead electrocardiographic pattern of the patient with ARVD is helpful. In sinus rhythm, anterior precordial T-wave inversions are commonly present (Fig. 24-52), sometimes with notching in the early part of the ST segment of V_1 and V_2 as well (epsilon waves). The monomorphic tachycardia has a left bundle-branch block morphology, reflecting its origin from the right ventricle.

At initial presentation, the future course cannot be predicted, and preventive measures should be aggressive. Pharmacologic and surgical approaches have been used for the management of ARVD.[294,296] Amiodarone and class IC drugs have been suggested to be effective for ARVD patients with symptomatic arrhythmias. However, because of its high risk of sudden death and unpredictable response to treatment, there is an increasing trend toward the use of ICD therapy, especially in patients with symptomatic arrhythmias, syncope, and a family history of sudden death in affected family members.

VENTRICULAR TACHYCARDIA AFTER CONGENITAL HEART DISEASE SURGERY

Sustained VT or VF may appear years after repair of complex congenital heart defects,[301] especially tetralogy of Fallot and transposition of the great vessels. The arrhythmias are potentially lethal and must be treated pharmacologically,[302] surgically,[303] or with ICDs in selected cases.

BIDIRECTIONAL VENTRICULAR TACHYCARDIA

Bidirectional ventricular tachycardia (Fig. 24-53) is usually a manifestation of digitalis intoxication and responds to standard measures.

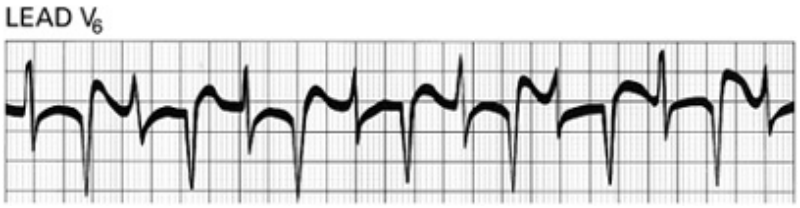

Figure 24-53: Bidirectional tachycardia. The tachycardia is regular at a rate of 160, but the vector of the QRS-T complexes alternates.

Polymorphic Ventricular Tachycardia, Including Torsades de Pointes

The polymorphic VTs, including the specific variant referred to as torsades de pointes, is a tachycardia pattern with important clinical implications. As a group, the polymorphic tachycardias tend to be more unstable electrically than the monomorphic tachycardias, occur at faster rates, have a higher likelihood of producing transient central nervous system symptoms (syncope or near-syncope) due to reduced cardiac output, and establish a higher risk for spontaneous degeneration to VF. The polymorphic tachycardias generally do not persist as long as the monomorphic tachycardias, either spontaneously reverting to a normal rhythm, degenerating to VF, or triggering a monomorphic tachycardia in susceptible patients.

The specific variant of polymorphic tachycardia characterized by QRS peaks that seem to twist around the baseline (Fig. 24-54) is referred to as torsades de pointes. The orthodox definition of torsades de pointes includes the predisposing electrocardiographic pattern, namely, a prolonged QT interval.[304] The same electrocardiographic pattern, however, may occur in the absence of QT prolongation.[305] Torsades de pointes may occur as a consequence of congenital prolongation of the QT interval or may be associated with acquired QT prolongations due to any of a group of diverse factors (see below). Less specific patterns of polymorphic VT may also occur in a number of other acquired disease settings, often not associated with prolonged QT intervals or with transient prolongations.

CONGENITAL LONG QT INTERVAL SYNDROME

The congenital long QT interval syndrome, which is present persistently from childhood, is characterized by the presence of long QT intervals and/or prominent U waves on the standard 12-lead ECG (Fig. 24-55). The affected patients are prone to episodes of torsades de pointes, which may cause transient lightheadedness, syncope, or sudden cardiac death. Arrhythmias may occur at rest, under emotional stress or with exercise (Fig 24-56). The two general patterns of the syndrome are the Romano-Ward syndrome,[306,307] which has an autosomal dominant inheritance pattern, and the much less common Jervell

and Lange-Nielsen syndrome,[308] which has an autosomal recessive inheritance pattern and is associated with congenital deafness.

For many years, congenital long QT interval syndrome has been viewed as a consequence of abnormal patterns of cardiac autonomic neural innervation, based in part upon the fact that the entity could be treated with beta-adrenergic blocking agents or surgical ablation of the left stellate ganglion.[309] Progress in the molecular genetics of the syndrome, however, has clearly demonstrated that inherited defects in membrane ion-channel molecular structure and function underlie the disease. The ion-channel abnormalities constitute the structural basis of the disorder at a molecular level; neurophysiologic, environmental, or transient risk factors (e.g., stress or hypokalemia) may then trigger the arrhythmias.

Multiple specific mutations have been identified at loci on five chromosomes and the specific gene products and their physiologic dysfunctions studied (Fig. 24-57).[311,312,325,326] The first abnormality suggested from linkage analysis was on chromosome 11. An association with the Harvey-*ras* gene was suggested, but subsequent observations demonstrated that the affected locus encodes a component of a potassium channel, I_{KS}, the slowly activating delayed rectifier channel. This channel also appears to be affected in at least one variety of the Jervell and Lange-Nielsen syndrome. Subsequently, two other gene loci have been identified among multiple families. An abnormality has been mapped to a locus on chromosome 7, which encodes HERG,[311] the rapidly activating delayed rectifier channel, I_{KR}, which carries a major repolarizing current. Another locus, SCN5A, on chromosome 3, encodes the human cardiac sodium channel gene.[312] One defective pattern on the latter gene encodes a three-amino acid deletion, which results in failure of the channel to close properly after activation. The depolarizing leak of sodium current competes with and delays repolarization by the normal potassium channels. Drugs that block the sodium channel, such as mexiletine, have been suggested as a possible pharmacologic therapy for this specific variant of the syndrome.[313] A fourth locus for an as yet unidentified genetic abnormality on chromosome 4 has been identified in a single family and may be a unique mutant in that family.[314] Finally, the fifth locus affected is chromosome 21. It encodes another subunit of I_{KS} and has a role in both the Romano-Ward and the Jervell and Lange-Nielsen forms of the syndrome. A syndrome of torsades de pointes with normal QT intervals has been described. It may also have a congenital basis, although cases are infrequent and adequate studies have not yet occurred. In addition, some subjects genotypically affected with known long QT interval variants are intermittently or persistently normal phenotypes, at least based on ECGs.

ACQUIRED LONG QT INTERVAL SYNDROME

The commonest causes for acquired long QT interval syndromes are the antiarrhythmic drugs, classically quinidine, but also other class IA agents and class III agents. Prolongation of the QT interval usually precedes the arrhythmia.[275] Bradycardia, hypokalemia, and hypomagnesemia potentiate the risk.[316-318] QT prolongation induced by class IA agents appears to be idiosyncratic, often appearing in a dose-independent manner at the onset of therapy. It occurs among a small subsegment of the population exposed to the drugs, suggesting specific individual susceptibility, but no inheritance pattern has as yet been identified. It is commoner among women because women have longer QT intervals. However, other factors that interact with repolarization may act to generate risk of arrhythmias sporadically, unrelated to initiation of therapy. These factors include hypokalemia, bradycardia, LV dysfunction, and possibly LV hypertrophy. The class III drugs, particularly sotalol, prolong the QT interval in a dose-dependent pattern, consistent with its major pharmacologic effect of blocking the delayed rectifier channel and thus prolonging the QT interval. This fact has implications for monitoring adverse drug effects at the initiation of therapy.

There is a growing list of other drugs that may also block repolarizing currents, prolong the QT interval, and establish susceptibility to torsades de pointes (Table 24-12), including the phenothiazines, certain antibiotics, pentamidine (Nebupent), cocaine, and terfenadine (Seldane) and other antihistamines, among others. The mechanisms of terfenadine-induced torsades de pointes is particularly instructive.[319] In addition to having antihistamine effects, the parent compound blocks the delayed rectifier current, which can result in prolongation of the QT interval. Under normal conditions after oral ingestion, however, the parent compound is converted by a P450 enzyme in the liver to a metabolite that is an effective antihistamine but does not block the delayed rectifier current. Concomitant use of drugs that block specific enzymes in the hepatic P450 enzyme system, [e.g., ketoconazole (Nizoral)], however, allows the parent compound to be

absorbed and to circulate, creating the propensity to torsades de pointes in a small group of patients. Sudden deaths have been reported with this combination therapy.[320] Other causes of acquired long QT interval syndrome with torsades de pointes include acute ischemia and reperfusion, acute central nervous system injury, liquid protein diets, and various other drugs.[317,321,322]

Table 24-12: Drugs Associated with Acquired Long QT Syndrome and to Be Avoided in Congenital Long QT Syndrome

Antiarrhythmics
Class IA: quinidine, procainamide, disopyramide
Class III: sotalol, dofetilide, ibutilide, bretylium, N-acetyl procainamide, amiodarone (rare)
Antibiotics
Macrolides: erythromycin, clindamycin, clarithromycin, trimethoprim-sulfamethoxazole, chloroquine, pentamidine, amantadine, ha-lofantrine
Antifungals
Itraconazole, ketoconazole
Psychotropics
Antidepressants: tricyclics (i.e., amitriptyline and desipramine), tetracyclics, fluvoxamine
Haloperidol, droperidol, thiothixene, doxepin, risperidone, phenothiazines
Antihistamines
Astemizole, terfenadine
Others
Cisapride
Glibenclamide
Organophosphate insecticides
Diuretics, with hypokalemia, hypomagnesemia, or hypocalcemia

NOTE: Some drugs cause risk only in combination (e.g., terfenadine and ketoconazole). Some observations are based on limited clinical data from case reports (e.g., clindamycin and newer nonsedating H_1 receptor antagonists); this list is current at the time of writing in an evolving field requiring continuous physician updating.

ELECTROCARDIOGRAPHIC FEATURES

Torsades de pointes is characterized by sequential beat-to-beat variations in mean QRS axis, causing the QRS complexes to appear to twist about the baseline (see Figs. 24-54 and 24-56). Characteristically, the tachycardia rate varies between 150 and 300 per minute, and the QT interval is prolonged during sinus rhythm. Episodes of tachycardia may be nonsustained or sustained, preceded by a long-short cycle sequence initiated by late PVCs, and may degenerate into VF.

Torsades de pointes is a classic proarrhythmic manifestation of class IA antiarrhythmic agents. Class IC antiarrhythmic agents may express proarrhythmia in the form of an incessant monomorphic VT that is

sinusoidal in pattern and often at rates less than 160 per minute (see also Chap. 23).

MANAGEMENT OF CONGENITAL LONG QT INTERVAL SYNDROME

The clinical expression of arrhythmias in congenital long QT interval syndrome is episodic and transient, ranging from palpitations to syncope to sudden death. Ambient arrhythmias are not usually sustained enough to make acute management a common clinical need. When required, however, intravenous beta-adrenergic blockade, intravenous Mg^{2+}, pacing, and/or lidocaine are appropriate, depending on the genetic variant and pattern of the arrhythmia. A new category of drugs, the K^+-channel openers, may ultimately prove useful as well.

Because of the continuing risk of transition of torsades de pointes to VF in patients with congenital long QT interval syndrome throughout life, careful long-term management is important from the time of diagnosis. A 12-lead ECG should be recorded in anyone with *unexplained* near-syncope, syncope, and/or symptomatic palpitations, especially with repetitive beats. In selected patients, stress testing and ambulatory monitoring may help clarify uncertain findings. Genetic testing should be carried out in selected members of affected families. An important subgroup consists of symptomatic relatives with phenotypically normal ECGs, since ECG expression appears to be intermittent, or even silent, in some.[321,322]

Long-term therapy includes beta-adrenergic blockade and/or left cardiac sympathetic denervation.[309,324] ICD implantation is indicated for patients with arrhythmias resistant to betaadrenergic blockers or survivors of cardiac arrest due to long QT syndrome. Recurrent syncope without arrhythmia documentation despite beta-adrenergic blocker therapy is also an indication, especially if there is a family history of sudden death. Finally, ICD implantation may be considered for genotypically positive relatives in a family with a strong history of fatal long QT syndrome.

The present information on a variety of genetically controlled ion-channel dysfunctions may lead to new therapeutic approaches in the future. For instance, mexiletine may be a specific therapy for the variant associated with the SCN5A gene on chromosome 3, which encodes the cardiac sodium channel.[313] It is possible that other channel-specific therapies will be identified in the future.

MANAGEMENT OF ACQUIRED LONG QT INTERVAL SYNDROME

Treatment is directed at the underlying cause, or causes, with careful attention to electrolyte and metabolic disturbances and to identifying and reversing or removing iatrogenic factors. Although electrical cardioversion may interrupt torsades de pointes, the arrhythmia frequently recurs as long as the offending influence is present. In addition, many runs are nonsustained. Intravenous magnesium sulfate is often effective, especially when torsades de pointes is due to quinidine. It may be given in a dose of 2 g over 2 min followed by an infusion of 2 to 20 mg/min. Although Mg^{2+} will effectively control the arrhythmia, it will not reduce the duration of the QT interval. That must await clearance of the offending agent.

Overdrive atrial or ventricular pacing to induce rate-related QT shortening may also be required. Acceleration of the underlying heart rate with isoproterenol infusion to shorten the acquired QT interval prolongation may be effective but should be avoided in patients with symptomatic ischemic heart disease, if possible. Lidocaine also may be beneficial, as may other class IB drugs. These drugs tend to shorten the QT interval in normal myocardium. Class IA and class III antiarrhythmic agents should be avoided, since they prolong the QT interval.

THE SYNDROME OF RIGHT BUNDLE-BRANCH BLOCK, ST-SEGMENT ELEVATION, AND LIFE-THREATENING VENTRICULAR ARRHYTHMIAS (BRUGADA'S SYNDROME)

A complex of right bundle-branch block, ST-segment elevation in the anterior precordial leads, and risk of sudden death has been described. The reported patients often have spontaneous and inducible polymorphic VT, sustained or nonsustained, with normal QT intervals. There is no associated structural heart disease described to date, and some patients are aymptomatic. It is commonest in adolescent and young adult males, among whom it appears to confer a high risk of sudden death.[325,329,330] It has been suggested as the basis for so-called "sleep death" in young Asian males.[331] The syndrome is familial, and a mutation on

chromosome 3 (SCN5A, the cardiac Na^+-channel) has been identified,[330] and others suggested.[330]

The diagnosis may be difficult because the right bundle-branch block and ST elevations may be subtle and intermittent.[325] They may be unmasked or enhanced by antiarrhythmic drug challenges with procainamide or flecainide[328,329] (Fig. 24-58), although the sensitivity and specificity of such challenges remains unknown. The entity is considered high risk, and ICD therapy has been suggested, even for asymptomatic affected individuals, particularly if there is a history of sudden death in young family members. Unfortunately, there are no prospective studies comparing ICDs to antiarrhythmic drug therapy for this disorder.

Ventricular Fibrillation and Flutter

Ventricular fibrillation is a terminal arrhythmia, uniformly requiring rapid initiation of emergency measures. Ventricular flutter with loss of consciousness and rapid unstable VT are clinical and hemodynamic equivalents of VF and treated identically when accompanied by the clinical picture of cardiac arrest. VF occurs most commonly in the setting of acute ischemic events (unstable angina pectoris or acute myocardial infarction) or unpredictably in advanced chronic ischemic heart disease. In the latter, it may be triggered by transient ischemia and perhaps transient or uncontrolled hemodynamic dysfunction. Moreover, it is the apparent mode of death in 25 to 50 percent of all cardiac fatalities. Among patients with nonischemic cardiomyopathies,[322,333] cardiac arrest is the mode of death in up to 50 percent of all fatalities. In the past, it has been assumed that VF is the mechanism of most of these events, but it is clear now that a substantial proportion of these events are due to bradyarrhythmias and asystole[333] and, it is important to note, to acute hemodynamic dysfunction.

VF may also develop during ischemia caused by coronary artery spasm, some hypoxic states, atrial fibrillation with rapid ventricular responses in WPW syndrome, pacing on the T-wave or asynchronized cardioversion, electrical accidents due to improper grounding of electrical devices, or proarrhythmic effects of antiarrhythmic drugs. A particularly high-risk setting for VF is acute myocardial infarction with right or left bundle-branch block. VF may occur de novo, but among patients with out-of-hospital cardiac arrest, VT commonly precedes the onset of VF (see also Chap. 23).

ELECTROCARDIOGRAPHIC FEATURES

The electrocardiographic pattern of VF is described by gross disorganization without identifiable repetitive waveforms or intervals (see Fig. 24-42*D* and *E*). At the onset VF may be "coarse" in pattern, but over time it loses its amplitude and becomes "fine" (less than 0.2 mV). Successful defibrillation and survival rates are decreased in patients with the fine pattern of VF. In ventricular flutter (see Fig. 24-42*C*), a sine wave configuration is present, having a cycle length in the range of 200 to 240 ms. Rapid polymorphic VTs may be difficult to distinguish from VF electrocardiographically, but maintained consciousness suggests VT rather than VF, the latter defined by loss of effective mechanical function. Hemodynamic findings may be initially stable in ventricular flutter or very rapid polymorphic VT, but hypotension, loss of consciousness, and degeneration to VF are common.

MANAGEMENT OF VENTRICULAR FLUTTER AND VENTRICULAR FIBRILLATION

There are two major goals of therapy: (1) immediate life support and resuscitation and (2) long-term prevention of recurrences. Basic life support with standard cardiopulmonary resuscitation (Chap. 34) is used until emergency defibrillation at 200 J or more can be carried out (see Chaps. 29A and 29B). After three unsuccessful shocks at energies up to 360 J, 1 mg of epinephrine should be administered by intravenous push and defibrillation attempted again.

Early defibrillation is essential to survival.[334] Resistance of defibrillation may occur due to the patient's size, improper paddle placement, improper use of conducting media, acidosis, hypoxemia, or electrolyte disturbances.[335] Some antiarrhythmic drugs may raise the defibrillation threshold. Energy thresholds for defibrillation may be decreased by administration of bretylium, lidocaine, or epinephrine, the latter especially when the fibrillatory waveform is fine. Immediate steps to improve metabolic and electrolyte disturbances are required, paramount of which is to establish an airway, followed by techniques to support

ventilation.[336] In rare instances, "spontaneous" reversion of VF[336] or "medical" defibrillation with bretylium[243] has been reported. A physiologic or pharmacologic increase in catecholamines has been postulated as the underlying mechanism.

After successful defibrillation, careful attention to the total clinical status of the patient and prophylactic antiarrhythmic drugs are required. Intravenous therapy with lidocaine is commonly used initially. For recurrent and resistant cases, intravenous procainamide or amiodarone[337] can be administered intravenously, the latter having replaced bretylium tosylate in order of priority and urgency. In addition to oxygenation and improving the metabolic milieu, aggressive steps to identify and treat or prevent recurrent ischemia or heart failure are necessary, since they may act as pathophysiologic triggers for recurrences.[4,248]

In the in-hospital setting, early recognition and aggressive treatment of VT may prevent VF. In the patient with acute myocardial infarction, early VF (48 h), as with early VT, is not associated with an independent influence on posthospital mortality risk and does not justify long-term antiarrhythmic therapy.[339-341] When VF occurs as a convalescent-phase complication of acute myocardial infarction, however, aggressive long-term antiarrhythmic management is indicated (see above).[342,343] The vast majority of patients who have VT or VF in the convalescent phase after acute myocardial infarction (3 days to 8 weeks) will have inducible ventricular arrhythmias at baseline electrophysiologic study.[247]

Among survivors of out-of-hospital VF not caused by acute myocardial infarction, control of ischemia and heart failure is essential. The clinical context[344,345] is evaluated in terms of the interaction between structural abnormalities (e.g., coronary heart disease, myopathy, hypertrophy, or anatomic electrical abnormalities) and functional states (e.g., ischemia-reperfusion, or systemic factors, including congestive heart failur, metabolic and electrolyte disturbances, neurophysiologic interactions, and toxic effects). For long-term estimate of the risk of arrhythmic death, invasive electrophysiologic testing of pharmacologic efficacy is one accepted approach.[346] Only about 33 to 40 percent of survivors, however, will be inducible into a reproducibly inducible ventricular tachyarrhythmia at baseline.[345,346] A similar fraction will be inducible into nonsustained VT or VF (Fig. 24-59), and 20 to 30 percent are noninducible. The subgroup whose unexpected VF is related to transient ischemia, in contrast to an underlying structural basis, is less likely to be inducible at baseline.[347] With high-risk forms of arrhythmias on ambulatory monitoring or exercise testing but without inducible arrhythmia at baseline by invasive testing, drug therapy can be guided by suppression of these spontaneous arrhythmias by noninvasive techniques[226,260,261] as long as the EF is greater than 40 percent. For such patients with lower EFs, the use of ICDs is emerging as the preferred treatment.

Usefulness of long-term drug therapy is limited by the fact that no more than 20 to 30 percent of the patients with inducible arrhythmias will have a drug identified that will prevent inducibility. In one randomized study without placebo control (ESVEM), a class III antiarrhythmic agent with beta-blocking effect, sotalol, appeared more effective than other drugs for survivors of VT and VF.[263] Whether amiodarone will have equivalent (or greater) benefit remains to be determined.

Patients who have recurrences despite drug therapy predicted to be effective during testing, those in whom an end point of therapy cannot be established, or those in whom the risk of recurrence remains high because underlying precipitating factors cannot be adequately controlled should receive ICDs.[345] The development of programmable devices with diagnostic electrogram storage capability and transvenous lead systems is expanding the set of circumstances in which ICDs are preferred therapy (see Chap. 30). Moreover, for secondary prevention of recurrent cardiac arrest, the relative benefit of ICDs now has been shown to be greater than that of empiric amiodarone (and likely other drugs), measured as total mortality during long-term follow-up.

Chapter 24: RECOGNITION, CLINICAL ASSESSMENT, AND MANAGEMENT OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

BRADYARRHYTHMIAS

Bradyarrhythmias may be due to depression or failure of impulse formation or to failure of AV conduction (Table 24-13). They are often asymptomatic, requiring no treatment. However, treatment is required when symptoms of hypoperfusion occur, resulting from inadequate cerebral or coronary blood flow, or worsening of congestive heart failure at rest or during exercise. Symptoms are almost always due to inadequate heart rate, although under some circumstances, such as with aortic stenosis or hypertrophic cardiomyopathy, loss of synchronized atrial contraction may contribute to symptoms. Bradyarrhythmias may be due solely to cardiac factors but are often caused or aggravated by noncardiac factors, such as drugs, autonomic imbalance, hypothyroidism, hypothermia, or hyperkalemia.[348] Furthermore, the hypoperfusion associated with bradycardia may be multifactorial, such as may occur in acute inferior wall infarction, in which bradycardia and LV dysfunction may be additive. In all cases, careful evaluation of both cardiac and noncardiac factors is necessary. If the patient is symptomatic, the first step in management is to increase the heart rate, which is readily accomplished by parasympatholytic drugs (e.g., atropine) or sympathomimetic drugs (e.g., isoproterenol). Underdosing with atropine (e.g., 0.3 mg) may cause a centrally mediated bradycardia and should be avoided. In addition, sympathomimetics must be used cautiously in all patients and avoided in the patient with ischemic symptoms. Temporary external pacing offers a logical alternative.[349,350] Stable, reliable increases in heart rate are afforded by temporary ventricular demand pacing from a pacing catheter positioned in the right ventricular apex. Temporary dual-chamber pacing is required in cases in which synchronized atrial contraction is deemed beneficial, such as bradycardia associated with inferior wall and right ventricular infarction.[351] General circulatory support and elimination of drugs that aggravate bradycardia is the second step in management.

Table 24-13: Classification of Bradyarrhythmias

FAILURE OF IMPULSE FORMATION

AV CONDUCTION ABNORMALITIES
First-degree heart block
Second-degree heart block
Type I (Wenckebach)
Type II
Third-degree heart block
Paroxysmal
Intermittent, transient

Chronic: congenital, acquired
AV dissociation

Failure of Impulse Formation

SINUS BRADYCARDIA

Sinus bradycardia ranges from a benign asymptomatic physiologic adjustment in heart rate to a symptomatic expression of sinus node dysfunction. The asymptomatic forms are most often benign and related to physiologic (e.g., training effect) or pathologic (e.g., inferior wall infarction) excesses in vagal tone.[352-356] Drugs that can cause sinus node depression include beta blockers, calcium channel blockers, amiodarone, lithium, cimetidine, and adenosine. Radiographic contrast materials can also cause it in sensitive patients. Although most commonly due to impaired impulse formation, it may also be caused by impaired conduction from the sinus node to atrial muscle (SA block).

Electrocardiographic Features of Sinus Bradycardia and Sinoatrial Block

Sinus bradycardia is defined as a rate less than 60 impulses per minute, with the pacemaker impulse originating in the sinus node, resulting in P waves of normal amplitude and vector. It is rarely considered outside of the physiologic range until rates are under 50 per minute. In well-trained athletes and during sleep, rates of 40 per minute or less may occur as a normal variant. Sinus bradycardia may be accompanied by some degree of sinus arrhythmia.

SA block is categorized as first-degree (delayed conduction), second-degree (intermittent), or third-degree (complete) block. Vagal stimulation, digitalis, and ischemia are the most common predisposing factors in this rare conduction disorder. SA block is recognized by the absence of expected P waves and the subsequent QRS complex. First- and third-degree SA blocks cannot be recognized on the standard clinical ECG, but second-degree SA block may be identified because of its intermittent pattern. Characteristically, in SA Wenckebach, the PP and RR intervals will progressively shorten together before a dropped P-QRS complex results in a pause; a recurrent pattern may be identified (Fig. 24-60*B*). SA Wenckebach periods are frequently overlooked or mislabeled as sinus arrhythmia. Intermittent 2:1 block may also be deduced from standard rhythm strips (Fig. 24-61), but persistent 2:1 SA block is indistinguishable from sinus bradycardia.

Management of Sinus Bradyarrhythmias

Treatment of patients who have asymptomatic bradycardia is often unnecessary. In the symptomatic patient, elimination of reversible aggravating factors is an essential step in management. When this is ineffective or negative chronotropic agents are essential to overall patient management, permanent pacing may be needed (see Chap. 31). A similar approach is taken for patients with sinus pauses, sinus arrest, or SA exit block, which may be associated with myocardial infarction, myocarditis, sinus node fibrosis, digitalis excess, or excess vagal tone.[357,358] In the patient with symptomatic hypersensitive carotid sinus syndrome,[359,360] medical treatment is usually inadequate. Permanent ventricular or dual-chamber pacing[361] is usually effective but occasionally may not relieve symptoms because of a coexisting vasodepressor reflex.[362]

The complex of neurocardiogenic syncope, or neurally mediated vasodepressor syncope, has combined manifestations of sinus bradycardia and vasodepressor responses. It is revealed by the response to head-up tilt testing and is due to an abnormal reflex, the afferent limb of which originates in the LV wall.[363] The efferent limb is parasympathetic, causing both decreases in peripheral vascular tone, leading to hypotension, and sinus node depression, leading to sinus bradycardia or a junctional escape rhythm. In the majority of patients, the vasodepressor component dominates, limiting the effectiveness of pacing therapy.[364] However, among the subgroup of patients in whom the cardioinhibitory component predominates, cardiac pacing featuring "rate-drop response" or a similar algorithm appears to be effective.[365] Among pharmacologic agents,[366,367] beta-adrenergic blockers have been most useful,

presumably by the mechanism of blocking the sympathetically mediated afferent limb of the reflex[367] (see Chap. 32).

SICK-SINUS SYNDROME

Sick-sinus syndrome[368-370] is a general term used to indicate abnormalities of cardiac impulse formation and intraatrial and AV conduction[352,371,372] that may be manifested by various combinations of brady- and tachyarrhythmias.[373] Treatment, therefore, must be individualized to each patient's manifestations of the syndrome.[374] Often the patient is asymptomatic, or the symptoms are mild and nonspecific. Negative chronotropic agents are avoided or discontinued,[370,375] and permanent pacing may be delayed until the patient is more clearly symptomatic.[376,377] Although decisions regarding therapy often can be made from the combination of clinical, ECG, and monitoring data, invasive electrophysiologic studies may assist in decision making in some patients. Quantitative measures of sinus node function, such as sinus node recovery time and perhaps SA conduction time, and of conduction system status, such as HV interval and its response to membrane suppressants, are occasionally helpful. In the clearly symptomatic patient, treatment may include a combination of antiarrhythmic agents and permanent pacing for intrinsic and drug-induced bradycardias. Ironically, the eventual development of atrial fibrillation in patients with sick-sinus syndrome may alleviate symptoms, since heart rate control in atrial fibrillation can be more consistently achieved. Dual-chamber pacing is preferred, to avoid pacemaker syndrome, since 50 to 80 percent of patients with sick-sinus syndrome have preserved ventriculoatrial conduction (see Chap. 31), and DDD pacing with rate-responsive functions is preferred for patients with intermittent or persistent sinus bradyarrhythmias. Among patients without evidence of AV nodal dysfunction or requiring AV nodal blocking drugs, pacing in the AAI mode, using a single atrial lead, is feasible. This system is less expensive and avoids the risks and complications of a second lead implant (ventricular), which may be important in patients with difficult vascular access. Later development of AV nodal disease is uncommon among these patients, and it usually presents in a slowly progressive pattern.[378-380] DDD pacing with automatic mode-switching function is useful for patients with intermittent tachyarrhythmias, and rate-responsive VVI pacing is preferred for patients with chronic atrial fibrillation.[381]

Digitalis is used with caution[375] and, when needed, is easier to titrate once the patient has a permanent pacemaker. When such patients require therapy with antiarrhythmic drugs that slow sinus rates and/or impair AV conduction (e.g., beta blockers or amiodarone), management of drug therapy may be facilitated by pacemaker backup.

It is important to recognize that the risk of development of new-onset atrial fibrillation is high in patients with sick-sinus syndrome, approximately 5.2 percent per year in a retrospective analysis of several studies. The incidence of the arrhythmia and its thromboembolic complications may be reduced by atrial or DDD pacing, compared to VVI or no pacing.[382,383] Anticoagulation should be considered part of the management of patients with sick-sinus syndrome, especially when they have documented atrial fibrillation episodes. Although there is clearly a symptomatic improvement in patients with sick-sinus syndrome by cardiac pacing and a trend toward reduction of incidence of heart failure, it is not yet known whether cardiac pacing improves survival.[382,383]

CAROTID SINUS HYPERSENSITIVITY

The pathophysiology of carotid sinus hypersensitivity is poorly understood. Among the explanations are abnormalities of the neuromuscular structures surrounding the carotid sinus mechanoreceptors, a central defect of the autonomic nervous system, and association with artherosclerotic disease.[384,385] A hypersensitive response to carotid sinus stimulation is defined as asystole due to sinus arrest of more than 3 s, a substantial symptomatic decrease in blood pressure, or both. It is important to evaluate and correlate the patient's symptoms because an abnormal response to carotid sinus pressure may be found in elderly patients or in patients sensitized by digitalis or other drugs, without clinical significance. In patients with associated syncope or near syncope, pacing is indicated.[385-388]

Atrioventricular Conduction Abnormalities

Abnormal prolongation or block of AV node conduction can be due to physiologic, reversible or permanent

acquired or congenital causes (Tables 24-14 and 24-15). Although the term *block* is applied generally to most patterns of conduction abnormalities, it is a misnomer when referring to impaired impulse conduction through the AV node or the bundle branches, in which there is an abnormal delay, rather than complete block, of conduction. Delayed conduction may result from normal physiologic variations (e.g., vagal tone) or pathologic influences.[389] Management is determined by assessing the degree of block, symptoms, and clinical setting. Recurrent episodes of the Wenckebach phenomen (type I, second-degree AV block) may be asymptomatic and require no therapy in the well-conditioned individual or athlete. These individuals may have resting heart rates of 40 impulses per minute or less and as low as 30 per minute during sleep, due to sinus bradycardia and/or second-degree AV block. Sinus pauses as long as 2.8 s may occur. All of these phenomena are due to high vagal tone in this setting.[390,391] In contrast, transient second-degree or complete AV block accompanying an acute anterior wall myocardial infarction is usually infranodal, a marker of massive muscle loss and predictive of a high mortality rate, even without symptoms of AV block and despite permanent pacing,[392,393] whether or not symptoms of AV block have occurred.

Table 24-14: Effect of Maneuvers on Sinus Node and Conducting System Function

Maneuver	Effect on SN	Functional (AV Nodal Block)	Structural (AV Nodal, Hisian, or Infrahisian Disease)
Atropine	↑ Heart rate	Improve AV conduction, decrease block	Worsen AV conduction, increase block
Exercise	↑ Heart rate	Improve AV conduction, decrease block	Worsen AV conduction, increase block
CSM	↓ Heart rate	Worsen AV conduction, increase block	Improve AV conduction, decrease block

ABBREVIATIONS: CSM = carotid sinus massage; SN = sinus node.

AV block associated with inferior wall myocardial infarction is much commoner (10 to 15 percent versus 5 percent) than with anterior wall infarction and has a more benign prognosis. It is usually due to AV nodal, rather than infranodal, conduction abnormalities and is commonly vagally mediated rather than structural. Onset is within the first 24 h, and it is almost always transient and commonly reversible with atropine, if treatment is needed at all. This form of AV block is not associated with an adverse long-term prognosis, although in-hospital mortality rates are slightly increased. Temporary pacing is occasionally required, but permanent pacing is very rarely indicated.

ELECTROCARDIOGRAPHIC PATTERNS

First-degree AV block is defined as a PR interval in excess of 0.2 s at normal heart rates. When the QRS complexes are of normal duration and configuration, it is usually due to prolonged conduction at the level of the AV node. If bundle-branch or fascicular block is present, the conduction delay may be at the level of either the AV node or the His-Purkinje system.

Second-degree AV block is characterized by intermittent failure of conduction from atria to ventricles and is further subdivided into type I (Wenckebach phenomenon) and Möbitz type II second-degree block. Type I second-degree AV block is characterized electrocardiographically by progressive lengthening of the PR interval, eventually leading to a nonconducted P wave (Fig. 24-60*A*). This often recurs with regularity, and patterns of "group beating" are recognized. The degree of block can be quantified by the conduction ratio, the ratio of the number of P waves to the number of QRS complexes in each episode or period terminated by the pause. Because the magnitude of PR lengthening typically is less with subsequent RR intervals, the RR intervals themselves progressively shorten before the pause caused by the blocked P wave. Atypical patterns may demonstrate lengthening of RR intervals in later cycles of a Wenckebach

period. The greatest decrement between successive RR intervals occurs from the first to the second cycle of a Wenckebach period, and, even with atypical patterns, shortening of the second RR cycle is always present. Wenckebach block may be physiologic in athletes (especially during sleep) or induced by digitalis. It is almost always due to impaired conduction across the AV node and is usually accompanied by a QRS complex of normal duration (see also Chap. 31). A Wenckebach conduction pattern may occur rarely across an area of disease in the His-Purkinje system.

In type II second-degree AV block, appropriately timed P waves fail to conduct, but there is not a pattern of progressive PR lengthening. Isolated P waves may fail to conduct, or fixed patterns (e.g., 2:1 at rates that are expected to conduct 1:1 under normal physiologic conditions) may occur. Infranodal block is the rule, and QRS complexes tend to be widened due to disease in the His bundle or intraventricular conducting system. Type II block is most often associated with organic cardiac disease and is frequently progressive. When the QRS complex is narrow with Möbitz type II block, block in the His bundle is likely (Fig. 24-62); when it is widened, block below the His bundle is the rule. At times, the conduction ratio of P waves to QRS complexes is fixed at 2:1. Only a single PR interval is recorded, and PR lengthening cannot be discerned; therefore, the absolute distinction between type I (2:1 Wenckebach) and type II block cannot be made. A narrow QRS complex and type I block at other times on the tracing suggest that 2:1 block is a manifestation of type I block (Wenckebach-AV nodal) physiology. Wide QRS complexes favor type II block. If the PR interval of conducted beats is 300 ms or longer, conduction block is likely at the level of the AV node; if it is 160 ms or less, Hisian or infra-Hisian block is likely. Evidence of VA conduction, such as retrograde P waves following a PVC favors the His-Purkinje system as the site of block. The response to certain maneuvers can be of help establishing the site of block (see Table 24-14).[415] In the electrophysiology laboratory, recording an HV interval of greater than 80 ms (normal = 45 to 55 ms) identifies high risk for AV block, and a pacemaker is indicated if the patient is symptomatic. If the HV is 100 ms or more, a pacemaker implantation is indicated, even in asymptomatic patients.[410]

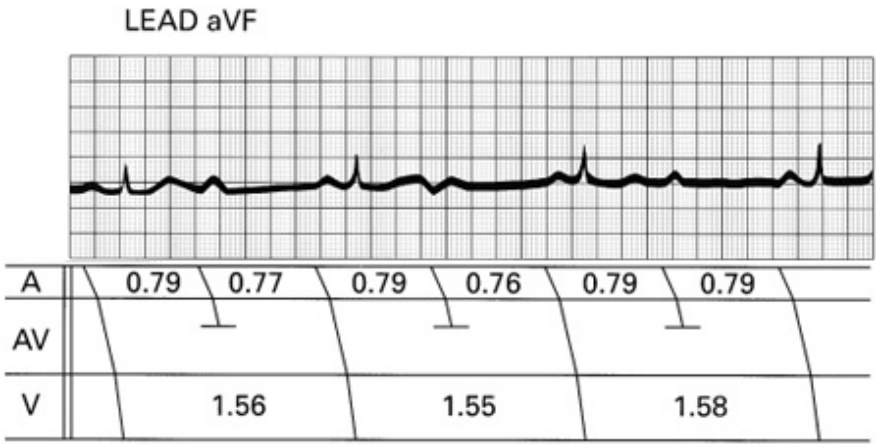

Figure 24-62: A form of second-degree AV block. There are two P waves to each QRS 2:1 AV block (alternate sinus impulses are blocked). This pattern can be caused by block in the AV node (Wenckebach), intra-Hisian block, or distal block (see the text).

Occasionally, the intervals between P waves may vary, with a pattern of shorter PP intervals when a QRS is between the two P waves, and the PP interval is longer when the two P waves are consecutive. This phenomenon is called ventriculophasic sinus arrhythmia and is related to baroreceptor reflexes. High conduction ratios, such as 3:1 and greater, may be diagnosed simply as paroxysmal or high-grade AV block.

In third-degree (complete) AV block, the atrial and ventricular rates are regular but dissociated (Fig. 24-63). At times, the P waves and QRS rates are so similar (isorhythmic dissociation) as to make this judgment difficult. Maneuvers by the patient, such as arm movement, standing up, or marching in place, may increase the sinus rate (P waves) without corresponding changes in the ventricular escape rate, confirming loss of AV conduction. In contrast, the development of 1:1 conduction suggests that the impaired conduction was at the AV nodal level. Morphology of the QRS complexes suggests the escape of junctional (narrow QRS)

or ventricular (wide QRS) subordinate pacemakers. Complete AV block may be preceded by years of varying and/or progressive lower grades of block, as well as by bundle-branch and fascicular blocks. It is common to observe long rhythm strips that demonstrate not quite complete AV block. Occasional capture beats interrupt a regular escape rhythm. The conducted P waves are critically timed within a narrow range, usually at a long interval after the preceding escape QRS complex. The clinical implication of this pattern is the same as complete heart block. Transient AV block or sinus pauses on telemetry or ambulatory monitoring are common and occasionally of concern. Occurring at night or without symptoms, sinus pauses of less than 3 s are not uncommon (2.4 percent of patients) and usually represent variations in response to autonomic fluctuations rather than disease. Pauses greater than 3 s are rarer (0.8 percent of patients) and may require further evaluation. Patients with sleep apnea may develop sinus pauses or transient AV block, usually preceded by a decrease in sinus rate, a clue of increased vagal tone. These patients require therapy for the respiratory problem rather than pacemaker implantation.[410]

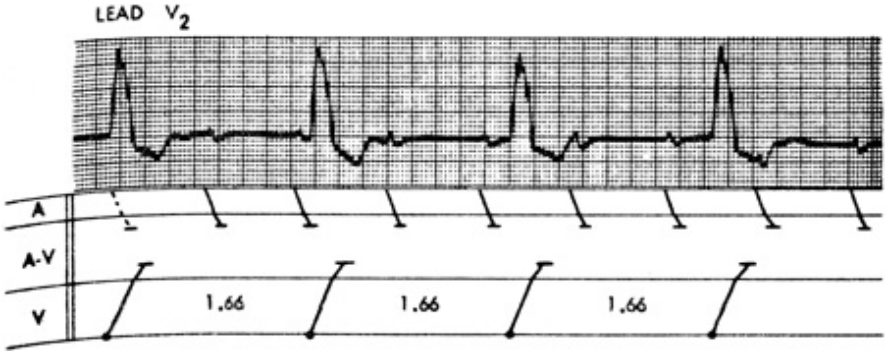

Figure 24-63: Complete (third-degree) AV block. There is a regular idioventricular rhythm at rate 36 impulses per minute, and the P waves indicate their independence by changing their relationship to the QRS complexes.

MANAGEMENT OF ATRIOVENTRICULAR BLOCK

First-Degree Heart Block

Isolated first-degree AV block is asymptomatic and is not an indication for temporary or permanent pacing.[410,416,417] However, one possible exception is a subgroup of patients with marked first-degree AV block (greater than 300 ms) associated with LV dysfunction and symptoms of congestive heart failure in whom a shorter AV interval caused by sequential AV pacing results in hemodynamic improvement.[410,414]

Second-Degree Heart Block

Möbitz type I AV block, or the Wenckebach phenomenon, is usually associated with an adequate ventricular rate and is rarely symptomatic.[415] It occurs in highly trained athletes[419] and is a normal response to rapid atrial pacing. In most patients who have the Wenckebach phenomenon secondary to AV nodal disease, routine prophylactic pacing is not advised, since it is minimally symptomatic (if at all) and tends not to progress.[369] Rarely, the effective ventricular rate is slow and patients are symptomatic, requiring pacing if vagolytic maneuvers are ineffective. The prognosis in patients who have underlying organic heart disease is determined by the extent of the underlying disease, not the Möbitz type I block.[420] Second-degree heart block is common in the acute phase of inferior wall myocardial infarction and rarely requires temporary pacing in this setting. Reversion is usually prompt-measured in hours to days.

Möbitz type II block is less common but implies more significant disease in the conduction system. The site of block is almost always below the AV node and usually below the bundle of His. Therefore, slower escape rhythms and risk of progression to complete heart block are of concern. It is almost always associated with a defined disease process. Permanent pacing is indicated,[410] except where Möbitz type II block is induced by rapid artificial pacing.[421,422] The purpose of pacing is primarily to protect against symptomatic events, such as syncope, and thus to protect the patient from injuring him- or herself or others.

Available data do not suggest that pacemakers will prolong the life of patients with Möbitz type II block. The selection among specific designs of pacing devices is discussed in Chap. 31.

A special circumstance involves 2:1 AV block in which the underlying mechanism and site of block remain obscure. The decision to treat is inferred from the clinical setting. Wide QRS complexes, sudden onset of periods of block, and inadequate escape rates favor type II block, whereas narrow complexes and coincident episodes of typical type I block favor Wenckebach block.

Another variant pattern is multilevel block in the AV junction. This commonly occurs during atrial tachycardias and may be functional, pharmacologic, or pathologic. The pattern of multilevel block during atrial tachycardia may be deceiving. This pattern is a basic 2:1 pattern with Wenckebach conduction patterns of the impulses that conduct through the area of 2:1, and it produces group beating of the ventricles. This may result in relatively slow ventricular rates, but the primary problem is the atrial arrhythmias with physiologic or insignificant pathologic responses at the level of the AV node. His-bundle electrograms may be diagnostic, but such invasive studies are indicated only when needed for a therapeutic decision.[422-425]

Paroxysmal AV Block

Runs of consecutive atrial impulses that fail to conduct to the ventricles may last for up to 10 to 20 s and may be associated with syncope. Unless a clearly defined, reversible cause is identified, permanent pacing is required. Bradycardia-dependent AV block, or phase 4 block, usually affects patients with underlying conduction system disease. It is characterized by spontaneous phase 4 depolarization of tissue in the His-Purkinje system. The partially depolarized tissue impairs ventricular conduction of propagating impulses of sinus origin, most commonly affecting the conduction in the left bundle-branch system (bradycardia-dependent left bundle-branch block). Block by this mechanism at a more proximal site in the conducting system may result in complete heart block, not responsive to atropine or isoproterenol, but only to cardiac pacing. A precordial thump may produce a PVC able to depolarize and reset the ventricle including the site of automatic activity, thereby allowing resumption AV conduction down the distal conducting system.[426-429]

Complete AV Block

Complete heart block may be acute in onset or slowly progressive and chronic; it may produce abrupt, clinically significant symptoms or may remain asymptomatic and be discovered incidentally. When acute and symptomatic, evaluation and rate support are urgently needed. Pharmacologic intervention with atropine or isoproterenol is usually most readily available.

The latter should be avoided in the presence of ischemic heart disease, and external pacing instituted if needed.[437,438] Reliable rate control is achieved by ventricular or dual-chamber temporary cardiac pacing. Permanent pacing is indicated unless those factors responsible for the heart block are reversible or when transient complete block complicates an acute inferior wall myocardial infarction.[410] Since the advent of thrombolytic therapy and primary angioplasty in acute myocardial infarction, the incidence of complete heart block in myocardial infarction has decreased. However, in acute anterior wall infarction, the prognosis remains grave, even after permanent pacemaker implantation.[395,401,404]

Isolated congenital AV block usually occurs at the level of the AV node and is accompanied by an adequate junctional escape rate. Although it is often well tolerated in the young, adult patients ultimately may develop symptoms of exercise intolerance, and thus permanent pacemaker implantation is a commonly used management strategy. When AV block coexists with other congenital structural abnormalities, the risk of symptoms with congenital AV block is higher, and pacemakers are more clearly indicated. There are specific guidelines for pacemaker implantation in the pediatric population.[410]

The choice between ventricular and dual-chamber pacing and considerations for rate-responsive pacing in various clinical conditions are discussed in Chap. 31.

Atrioventricular Dissociation

AV dissociation is not synonymous with AV block but occurs in conjunction with block as well as in its absence. It implies an abnormality of intrinsic pacemaker activity that may be slowing of normal pacemaker activity (*default*), acceleration of a normally subordinate or latent pacemaker (*usurpation*), AV block, or a combination of these phenomena.

ELECTROCARDIOGRAPHIC FINDINGS

AV dissociation implies that the atria and ventricles each have manifest independent pacemakers. In the setting of AV block, a junctional or ventricular pacemaker emerges as an escape rhythm; if it fails or if the escape is too slow, AV block will become a symptomatic or terminal rhythm. The atria and ventricles may beat independently if a normally subordinate junctional or ventricular pacemaker discharges faster than the sinus or atrial pacemaker and 1:1 retrograde conduction is absent. Since AV block is not necessarily present, ventricular capture by impulses of sinus origin commonly occur as a result of fortuitous timing relationships between sinus node activity and ventricular refractoriness. At times, capture beats and junctional or ventricular beats coincide and generate fusion beats (Fig. 24-64).

MANAGEMENT

Treatment, when needed, is directed toward the underlying cause. It is important to evaluate whether symptoms are present and whether they are due to a rapid or slow rate. Suppression of tachyarrhythmias, such as AV dissociation in VT, is the primary goal when symptoms are related primarily to the tachyarrhythmia and an intact intrinsic or artificial pacemaker is present. Intermittent ventricular ectopy may be an escape phenomenon in an otherwise asymptomatic patient who has an underlying persistent bradycardia. In such cases, rate support with pacing is indicated to relieve bradycardia symptoms, and the escape ventricular ectopy will resolve secondarily. If initial therapy is targeted to a tachycardia in the presence of an underlying bradycardia, symptoms may worsen due to drug suppression of lower intrinsic pacemaker sites.[430]

Indications For Pacing

Pacing is indicated for symptomatic bradyarrhythmias that have no identifiable reversible cardiac or noncardiac cause.[410] Prophylactic pacing to prevent death or the onset of life-threatening symptoms is controversial, since increased risk of death is more likely related to the severity of underlying organic heart disease. The mortality benefits of pacing, though theoretically sound, often lack rigorous proof of effectiveness. Less controversial is the use of permanent pacing for morbidity benefit, namely, to reduce symptomatic bradyarrhythmic events and their consequences (see also Chap. 31).

Temporary pacing is indicated for AV block associated with acute anterior wall infarction if the heart rate is excessively slow and/or associated with rate-dependent hypotension, and if there is a newly acquired left or right bundle-branch block accompanied by hemiblock.[431] The availability of external pacing techniques[349,350] has tended to relax the sense of urgency for prophylactic pacing catheters in these settings. New left bundle-branch block or preexisting right or left bundle-branch block is managed with less immediate urgency and often does not require pacing. Permanent pacing is often recommended for those with acute anterior wall infarction who have had transient complete heart block.[432] The change in long-term survival, however, is not well documented.[433] Temporary pacing can often be avoided in AV block associated with inferior infarction, since block is often related to ischemia or parasympathetic reflexes, is usually asymptomatic, and reverses with time.[434] If hypotension occurs in inferior infarction that is not due to hypovolemia or right ventricular infarct, temporary pacing for severe sinus bradycardia or higher grades of AV block is often used. Permanent pacing after AV block in inferior infarction is required only very rarely.

Permanent prophylactic pacing in bifascicular block without symptoms of transient AV block is not routinely recommended.[435,436] In patients at high risk for complete heart block (e.g., Kearns-Sayre syndrome) or recurrent neurologic symptoms associated with advanced HV prolongation (e.g., HV longer than 70 to 80 ms), however, prophylactic pacing may be of benefit.[437] Guidelines for permanent cardiac pacemaker implantation have been published[410] and are further discussed in Chap. 31.

Pacemaker-Associated Arrhythmias

As pacemakers have become more sophisticated, there has been an increasing need to identify normal and abnormal pacemaker function and related arrhythmias electrocardiographically. The baseline pacing pattern is dependent on the pacemaker design and the interaction with the patient's intrinsic rhythm. These aspects, as well as pacemaker testing, are reviewed in detail in Chap. 31. Apparent pacemaker malfunctions are frequently due to observer inexperience and lack of knowledge of pacemaker electronics. Unusually rapid or slow rates may connote pacemaker malfunction, but programming changes, magnet activation, and over- and undersensing must be excluded. Fusion beats, pseudofusion, and ventricular-triggered pacing may cause confusion. Fusion beats occur when there is overlap in the timing of paced and normal beats and the morphology of the fused complex is midway between the normal and paced QRS complexes. Ventricular-triggered pacing becomes confusing when a PVC occurs and is thought to be triggered by the pacemaker because of the width of the complex and the presence of a pacemaker artifact. The pacing artifact occurs slightly after the initiation of the PVC, providing a clue to ventricular ectopy. Inappropriate bradycardias may be induced by oversensing by the pacemaker or by normal sensing of extracardiac stimuli, such as myopotentials (skeletal muscle activity) or extracorporeal inhibition by electromagnetic or RF waves. "Cross-talk" can result in arrhythmias, for instance, when the ventricular lead senses atrial activity.

Dual-chamber pacing may lead to a variety of arrhythmias that are actually an undesirable byproduct of normal pacemaker function. Arrhythmias may be initiated by asynchronous ventricular or atrial stimulation (DVI pacemakers), interruption of ventricular sensing during ventricular blanking (all dual-chamber pacemakers), or asynchronous atrial or ventricular stimulation in the magnet mode (all dual-chamber pacemakers). Furthermore, dual-chamber units create an artificial bypass tract that may become operative in the presence of ventriculoatrial conduction. When a ventricular event, either paced or spontaneous, results in retrograde atrial activation, the latter may be sensed by the atrial electrode returning to the ventricle after an appropriate AV delay. A paced ventricular response follows, and the process repeats itself. This artificial arrhythmia has been called an endless-loop tachycardia[438] (Fig. 24-65). Spontaneous termination of the reentry tachycardia may occur by fatigue or block in the retrograde limb. Treatment includes reprogramming of pacemaker parameters, including extension of the atrial refractory period of the pacemaker or avoidance of the DDD or VDD mode (at the extreme, the VVI mode is used). In order to guard against rapid ventricular pacing and response to sudden increases in atrial rate, physiologic pacemakers tend to have an upper rate limit control. Earlier models suddenly drop to 2:1 pacing rates. Recent models often induce a gradual Wenckebach-type response. The pacemaker electronically creates a Wenckebach phenomenon with a gradually increasing number of dropped QRS complexes (see Chap. 31).

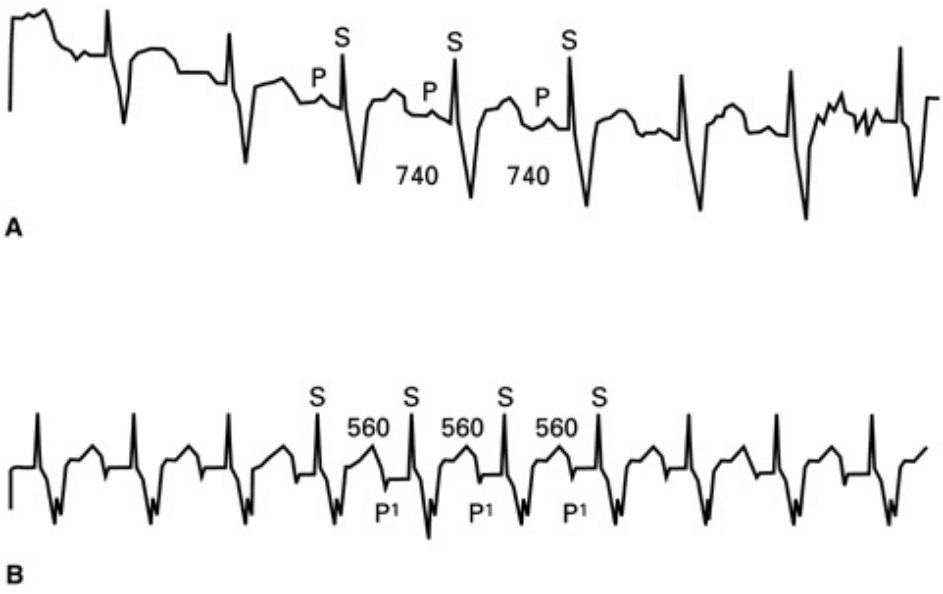

Figure 24-65: Pacemaker-mediated (endless-loop) tachycardia. The patient had a DDD pacemaker and presented with episodes of sustained rapid heart action. The tracing (lead II) demonstrates (*A*) atrial

tracking with ventricular pacing at a cycle length of 740 ms and (*B*) ventricular pacing with retrograde atrial activation. The retrograde P waves (P) following each paced QRS are sensed by the atrial sensing lead and trigger a ventricular pacing spike (S), followed by the paced QRS with repeated retrograde atrial activation.

Chapter 24: RECOGNITION, CLINICAL ASSESSMENT, AND MANAGEMENT OF ARRHYTHMIAS AND CONDUCTION DISTURBANCES

List of Figures

Figure 24-5: (Plate 74) Catheter-based mapping of the right atrium using a nonfluoroscopic electroanatomic mapping system that allows computer storage and recall of multisite activation patterns. Panels A and B demonstrate the activation sequence during normal sinus rhythm, with the earliest activation in the region of the sinus node (*arrows*) shown from (*A*) anterior and (*B*) posterior perspectives. The sequence of activation is indicated by the gradation of the color scale, based upon the reference times shown in the spectral bar. *C* and *D* were recorded from another patient who had episodic ectopic atrial tachycardia. In this oblique view, the sequence of activation during sinus rhythm is shown in *C*, with the earliest site of activation in red (*arrow*) representing the region of the sinus node. *D* was recorded during a low right atrial ectopic tachycardia. The earliest site of activation is indicated by the arrow.

Figure 24-6: Left ventricular endocardial catheter mapping and radiofrequency ablation of ventricular tachycardia (VT) *A*. Bipolar (Bi) and Unipolar (Uni) recordings from an LV mapping site. The sustained ventricular tachycardia has a cycle length ranging from 420 to 450 ms. Onset of the VT QRS is indicated by the vertical line. Fractionated electrical activity is recorded from the distal bipolar electrode pair (Bi 1-2). A small potential immediately precedes the QRS onset, and fractionated signals extend 210 ms after the onset. *B*. The tachycardia is entrained during pacing and a cycle length of 400 ms [note the identical morphology of the complexes following pacing stimuli (concealed entrainment, entrainment with concealed fusion)], and a return to the spontaneous (unpaced) VT cycle length after cessation of pacing. The interval between the pacing stimulus and the onset of the responding QRS complex is the same as the interval between the end of the fractionated electrogram in *A* and the onset of the following QRS complex. *C*. RF energy applied through a catheter positioned at the same location results in prompt termination of the tachycardia, loss of fractionated electrograms, and return to sinus rhythm. (From Stevenson WG, et al. Identification of reentry circuits sites during catheter mapping and radiofrequency ablation of ventricular tachycardia late after myocardial infarction. *Circulation* 1993; 88[part 1]:1647-1670. Reproduced with permission from the American Heart Association.)

Figure 24-7: Primary and secondary arrhythmias. When a disease process directly initiates an electrophysiologic disturbance, the resulting arrhythmia is referred to as primary. In contrast, when the disease process produces a hemodynamic abnormality that in turn initiates the electrophysiologic disturbance, a resulting arrhythmia is referred to as secondary. Antiarrhythmic drugs may be used to prevent the electrophysiologic disturbance, prevent the electrophysiologically unstable heart from developing a manifest arrhythmia, or reverse a primary arrhythmia. In secondary arrhythmias, hemodynamically active drugs are used to prevent or reverse secondary electrophysiologic disturbances, usually in conjunction with antiarrhythmic drugs. Antiarrhythmic drugs alone are less likely to be effective for secondary arrhythmias. (Modified from Myerburg et al.[1] Reproduced with permission from the publisher and authors.)

Figure 24-8: The Sicilian gambit approach to antiarrhythmic drugs. This figure summarizes the important actions of drugs on membrane channels, receptors, and ion pumps in the heart as well as on the ECG, sinus rate, and LV function. Because clinical and ECG effects are diverse, the table unavoidably includes some degree of subjectivity. Accordingly, the shading of the symbols and the direction of the arrows should not be taken as absolute. Moreover, the clinical information presented refers to the patient who does not have significantly compromised LV function prior to the drug administration. For the section on channels, receptors, and pumps, the actions of drugs on the sodium (Na+), calcium (Ca2+), potassium channels (I_K and I_f) are indicated. Sodium channel blockade is subdivided into three groups of actions characterized by fast (tau less than 300 ms), medium (tau 200 to 1500 ms), and slow (tau greater than 1500 ms) time constants for recovery from block. This parameter is a measure of use dependence and predicts the likelihood that a drug will decrease conduction velocity of normal Na+-dependent tissues in the heart and perhaps the propensity of a drug for causing bundle-branch block or proarrhythmia. The rate constant for onset of block may be even more clinically relevant.

Blockade in the inactivated (I) or activated (A) state is indicated. Drug interaction with receptors [beta-adrenergic, alpha-adrenergic, muscarinic subtype 2 (M_2), and A_1 purinergic (P)] and drug effects on the sodium-potassium pump (Na+, K+-ATPase) are indicated. The absence of a symbol indicates lack of effect. The use of a question mark indicates uncertainty concerning effect. The arrows in the clinical effect and ECG section indicate direction; no quantitative differentiation has been made between weak and strong effects. The effects listed for ECG, LV function, sinus rate, and extracardiac are those that may be seen at therapeutic plasma levels. Deleterious effects that may appear with concentrations above the therapeutic range are not listed. [From Schwartz PJ, Zaga A. The Sicilian gambit revisited. *Eur Heart J* 1992; 13(suppl F):23-29. Reproduced with permission from the publisher and authors.]

Figure 24-9: Comparison of mechanisms, electrocardiographic and clinical features, responses to adenosine, activation patterns, and electrocardiographic appearance of the various supraventricular rhythms. See the text for description of the individual arrhythmias.

Figure 24-10: *A.* Sinus arrhythmia. The sinus cycles are indicated in seconds in the atrial (A) tier; they range from 0.60 to 1.01 s. Note that the P-wave amplitude increases as the sinus pacemaker accelerates. *B.* Sinus tachycardia. Note normally shaped and directed P waves, normal PR interval, and a rate of almost 150 per minute. *C.* Sinus bradycardia. Note normally directed (but abnormally wide) P waves, normal PR interval, and a rate of slightly more than 50 per minute.

Figure 24-11: *A.* The fifth impulse is an atrial premature beat; there is a premature P wave (usually labeled P) followed by a normal QRS-T complex, and the postextrasystolic pause is longer than the sinus cycle but less than compensatory. *B.* The fourth impulse is an atrial premature beat with aberrant intraventricular conduction; there is a premature P wave followed by an anomalous QRS-T complex; the postextrasystolic pause is less than compensatory. *C.* Nonconducted atrial premature beat. Following the third ventricular complex, a P wave negatively deforms the ST segment and is not followed by a ventricular response.

Figure 24-12: Mechanism of PSVT due to AV nodal reentry. This arrhythmia is due to the presence of dual AV nodal pathways with different conduction properties and refractory periods. Although the fast and slow pathways were previously thought to be within the anatomic AV node, the pathways are now viewed as having critical components in the atrial approaches to the AV node. Nonetheless, the dual-pathway physiology concept is valid. *A.* During sinus rhythm in the presence of a dual AV nodal pathway, the fast pathway (which generally has a longer refractory period) is primarily responsible for AV transmission because of slower propagation in the other pathway. *B.* A premature atrial impulse blocks in the fast pathway because of its longer refractory period and propagates down the slow pathway, prolonging the PR interval and allowing retrograde invasion of the fast pathway because its tissue remains polarized due to block of the descending impulse. *C.* Echo beats or AV nodal reentrant tachycardia will occur when the time relationships between slow pathway conduction and recovery of excitability at the site of block in the fast pathway allow the impulse to reenter the slow pathway after retrograde fast pathway transmission. The atria are also activated retrogradely. In a much less common form of AV nodal reentry, a shorter refractory period in the fast pathway reverses the loop, with antegrade conduction down the fast pathway and retrograde conduction up the slow pathway (see Fig. 24-13 for examples). RF energy for slow pathway ablation therapy is applied at the site indicated by the asterisk.

Figure 24-13: PSVT due to AV nodal reentry. Narrow QRS complexes with ST-segment depression are seen (*upper panel*). Adenosine, 6 mg intravenously, abruptly alters AV nodal properties and terminates the tachycardia (*lower panel*). The ST-T wave pattern immediately returns to normal.

Figure 24-14: Common and uncommon forms of AV nodal reentrant tachycardia recorded during electrophysiologic studies. *A.* The common type of AV nodal reentrant tachycardia, antegrade conduction in the slow pathway and retrograde in the fast pathway, results in atrial (A) and ventricular (V) activation that are close to one another in time. Characteristically, intracardiac recordings demonstrate a "lining up" of atrial and ventricular electrograms, indicating that the atria are activated before completion of ventricular activation. *B.* In the uncommon type of AV nodal reentrant tachycardia, antegrade fast pathway and retrograde slow pathway conduction change the relative timing pattern so that atrial activation is delayed relative to ventricular activation, and the electrograms are not in line. In this form of PSVT, the RP interval is longer than the PR interval on the ECG, which results in inscription of the retrograde P wave *after* the ST-T wave of the related ventricular impulse. The uncommon type of AV nodal reentrant tachycardia may be difficult to distinguish from other arrhythmias, such as ectopic atrial tachyarrhythmias or concealed WPW syndrome (see the text).

Figure 24-15: PSVT due to AV nodal reentry. *A.* The initial presenting rhythm was a wide-QRS tachycardia with a vertical axis and a left bundle-branch block pattern. *B.* A sinus impulse with intracardiac recordings demonstrating normal sequences of AV conduction. *C.* Recording during a wide-QRS tachycardia with a left bundle-branch block pattern. The nearly simultaneous A and V activation patterns in the retrograde and antegrade directions (i.e., atrial activation before the end of ventricular activation) suggest the common form of AV nodal reentry rather than ventricular tachycardia.

Figure 24-16: WPW syndrome with reciprocating tachycardia. *A.* Before and during an "orthodromic" tachycardia. *B.* From another patient before and during an "antidromic" tachycardia.

Figure 24-17: Localization of accessory pathways in patients with WPW syndrome. The line drawings illustrate the anatomic relationships between the tricuspid (TV) and mitral valves (MV), the coronary sinus (CS), AV conducting system, and accessory pathways. For each accessory pathway location indicated, the combination of QRS vectors most likely to result are shown, based on upright (+) or inverted (-) QRS waveforms. These vectorial guidelines are generally useful but not necessarily precise, since activation patterns from specific sites may vary in individual patients. Nomenclature for accessory pathway location: RA, anterior; RAL, right anterolateral; RL, right lateral; RPL, right posterolateral; RP, right posterior; PSTA, posteroseptal tricuspid annulus; CSOs, coronary sinus ostium; MSTA, mid-septal tricuspid annulus; AS, anteroseptal; RAPS, right anterior paraseptal; MCV, middle cardiac vein (coronary vein); CS, coronary sinus; venous anomaly (coronary sinus diverticulum); PSMA, posteroseptal mitral annulus; LP, left posterior; LPL, left posterolateral; LL, left lateral; LAL, left anterolateral. (From Arruda MS et al.[40] Reprinted with permission from the publisher and authors.)

Figure 24-18: Atrial fibrillation in WPW syndrome with accessory pathway conduction. *Left.* Sinus rhythm with a typical preexcitation (delta-wave) pattern. *Right.* Accessory pathway conduction during atrial fibrillation. The QRS axis has shifted to the left, and the ventricular rhythm is now irregular, at a rate in excess of 200 per minute. (From Marriott HJL, Rogers HM. Mimics of ventricular tachycardia associated with the WPW syndrome. *J Electrocardiol* 1969; 2:77. Reproduced with permission from the publisher and authors.)

Figure 24-19: RF ablation in WPW syndrome in a 52-year-old female. The patient had frequent recurrent supraventricular tachycardias due to WPW syndrome. *A.* Standard leads I, II, and V_1 demonstrate disappearance of the delta wave from one impulse to the next 5 s after beginning the application of RF energy (compare successive QRS complexes indicated by arrows). *B.* Prior to ventricular ablation, the interval between atrial (A) and (V) activation at the site of the ablation catheter is less than 50 ms, and the sharp spike between A and V likely represents activity in the bypass tract. *C.* Immediately after ablation, the AV interval at the site of the ablation catheter is lengthened to 150 ms, and the accessory pathway spike has disappeared. *D, E.* Enlargements from panels B and C, respectively. AB, ablation catheter; RA, right atrium; RVA, right ventricular apex.

Figure 24-20: Ectopic atrial tachycardia. *A.* A 20-s continuous recording demonstrates a regular tachycardia at a ventricular rate of approximately 140 per minute. *B.* During carotid sinus massage, ventricular conduction becomes irregular, and diminutive P waves at twice the basic ventricular rate are evident. Impaired AV conduction with little or no effect on atrial activity is characteristic of the response of an ectopic atrial tachycardia to carotid sinus massage.

Figure 24-21: *A.* Atrial tachycardia with 2:1 AV block due to digitalis intoxication. Note the diminitive P waves, barely visible even in V_1. *B.* Multifocal (chaotic) atrial tachycardia. Note the constantly changing form of the ectopic P waves and the irregular rhythm at a mean rate of 122 per minute. Three or more distinct P-wave morphologies are required to make the diagnosis.

Figure 24-22: Atrial flutter. Note the "sawtooth" pattern in leads II and III, discrete atrial waves in V_1, and poorly registered atrial activity in leads I and V_6.

Figure 24-23: Atrial flutter with alternating 4:1 and 2:1 conduction. This common cause of bigeminal rhythm is almost always due to 2:1 AV conduction high in the AV junction and 3:2 Wenckebach periods at a lower level, as diagrammed.

Figure 24-24: Atrial flutter (type II) with complete AV block. The atrial rate is 366 per minute, and the ventricular rate is 40 per minute. The ventricular rhythm remains regular, while the relationship between atrial and ventricular complexes varies.

Figure 24-25: Atrial flutter and carotid sinus massage. At the beginning of the strip, AV conduction is occurring at the common 2:1 ratio, and flutter waves can be suspected but not proved. However, during carotid sinus massage, the conduction ratio increases to 4:1, and the flutter waves are easily recognized. Note the tendency of the atrial (flutter) rate to increase slightly during the parasympathetic stimulus.

Figure 24-26: Clinical expression of atrial fibrillation. Atrial fibrillation may occur in brief paroxysms, a more persistent form lasting from days to weeks, or chronically. Approaches to therapy are dictated by these patterns in conjunction with the hemodynamic considerations shown in Fig. 24-27. Methods of management include sedation while awaiting spontaneous conversion, DC cardioversion, bolus antiarrhythmic therapy (oral or intravenous), and standard oral antiarrhythmic therapy. There is a relationship between the efficacy of each therapy and the clinical expression of the arrhythmia. Short-lasting paroxysmal atrial fibrillation (less than 1 h) undergo spontaneous return to sinus rhythm by definition, but DC cardioversion may be necessary based on the hemodynamic response in patients with cardiac diseases such as aortic stenosis or mitral stenosis. Longer-lasting paroxysms of atrial fibrillation or persistent patterns of atrial fibrillation (see the text) may be treated with bolus therapy, standard therapy, or cardioversion, the latter having better efficacy in patients with more advanced disease if they are pretreated with antiarrhythmic agents. Chronic atrial fibrillation will not convert spontaneously but may respond to the various therapies listed. However, long-term maintenance of sinus rhythm is limited among patients in this category, particularly if the heart disease is advanced.

Figure 24-27: Hemodynamic factors in atrial fibrillation. Atrial fibrillation creates the potential for two hemodynamic defects: (1) loss of atrial contraction, which provides the presystolic atrial "kick"; and (2) rate-related reduction of the diastolic filling period. Atrial contraction is important to ventricles with reduced compliance and low-output states due to myocardial factors. Diastolic filling time is important in conditions in which a longer diastolic is beneficial to impaired flow states, such as mitral stenosis, coronary atherosclerosis, and some myopathic ventricles.

Figure 24-28: *A.* Fine atrial fibrillation, leaving virtually no imprint on the baseline ("straight-line" fibrillation). *B.* Coarse atrial fibrillation; the fibrillatory waves are the size of respectable flutter waves but are irregular.

Figure 24-29: Ashman's phenomenon. During atrial fibrillation, the impulse ending a short cycle preceded by a relatively long cycle manifests aberrant intraventricular conduction. In this example, the aberrant impulse shows typical right bundle-branch block type aberration in lead V_1, with an rSR pattern and the initial deflection identical to that of the preceding and following normally conducted impulses.

Figure 24-30: Atrial fibrillation with repetitive aberrant ventricular conduction. The impulses that end the shortest ventricular cycles (0.28 to 0.32 s) are anomalous, widened complexes. Note that the cycle preceding the onset of the salvos of anomalous beats is *relatively* long in comparison with the anomalous complexes (0.54 and 0.50 s), in accordance with Ashman's phenomenon. Thus, these almost certainly represent a right bundle-branch block type of ventricular aberration rather than ventrcular ectopy.

Figure 24-31: Irregular wide QRS tachycardia. A rapid irregular rhythm with wide QRS complexes having a left bundle-branch block pattern is recorded. The rhythm is atrial fibrillation with abnormal intraventricular conduction. Irregular, wide QRS tachycardias also occur in WPW syndrome, with atrial fibrillation and conduction down the accessory pathway or in rare cases of irregular ventricular tachycardia.

Figure 24-32: *A*. AV junctional extrasystole. The retrograde P wave follows the premature QRS complex, which shows some degree of ventricular aberration. *B*. The fourth complex is an AV premature impulse without retroconduction to the atria, leaving the sinus rhythm undisturbed.

Figure 24-33: Accelerated idiojunctional rhythm with isorhythmic AV dissociation. After four sinus beats, the sinus rate slows slightly, enabling an accelerated junctional pacemaker to escape at a rate of 94 per minute. After several seconds, the sinus pacemaker accelerates and recaptures the ventricles. The same sequence is then repeated (the strips are continuous). (From Marriott HJL. *Workshop in Electrocardiography*. Tampa, FL: Tampa Tracings; 1972. Reproduced with permission from the publisher and author.)

Figure 24-34: Classification of ventricular arrhythmias based on hierarchies of frequency and forms. Hierarchical schemes for estimating risk of ventricular arrhythmias have been developed based on frequency and forms of ventricular arrhythmias. In some clinical settings, frequencies in the range of 1 to 9 ectopic impulses per hour become significant, and in most settings of clinically significant heart disease, risk based on frequency plateaus in the range of 10 to 30 ectopic impulses per hour. Among forms of ventricular arrhythmias, the repetitive forms, particularly salvos or nonsustained ventricular tachycardia, indicate higher risk in most clinical settings. (Modified from Myerburg et al.[138] Reproduced with permission from the publisher and authors.)

Figure 24-35: Ventricular premature contractions. *A*. The third impulse is wide and bizarre, and since the sinus rhythm is undisturbed (next sinus P wave indicated by arrow), the postextrasystolic pause is compensatory. *B*. The fourth impulse is an interpolated ventricular premature contraction; it is sandwiched between two consecutive conducted sinus beats.

Figure 24-36: Exceptions to the rules for compensatory pauses. *Top*. Ventricular extrasystole with less than compensatory pause. Retrograde conduction to the atria (retrograde P wave deforms first part of ST segment) discharges the sinus pacemaker early and thus shortens the postextrasystolic cycle. *Middle*. Atrial premature contraction followed by fully compensatory pause. The third and eighth beats are atrial extrasystoles, but presumably because they suppress the sinus pacemaker, they are followed by compensatory pauses. *Bottom*. Ventricular extrasystoles with less than compensatory pauses. Each postextrasystolic cycle ends in an escape beat and so is slightly less than compensatory.

Figure 24-47: figuremeasure Therapeutic options for patients with ventricular tachyarrhythmias or cardiac arrest in association with coronary artery disease. Six categories of arrhythmias or clinical events are presented, and for each the associated observations during programmed electrical stimulation are provided. Four categories of therapeutic option are shown. Under "Drug Therapy," membrane-active antiarrhythmic drugs include amiodarone unless amiodarone is cited specifically, in which case the other membrane-active antiarrhythmic drugs are not considered therapeutic options. Also included in drug therapy are the beta-adrenergic-blocking agents. The second category is surgical and interventional approaches, which include antiarrhythmic surgery and catheterbased and surgical revascularization procedures. The third category is implantable devices, under which indications and preferred programming modes are presented. Catheter ablation is the final category. For each of the categories of therapy, indications shown on the bottom of the illustration discriminate patients with EFs greater than 35 percent (*blue*) and those with EFs of 35 percent or less (*red*). Therapeutic categories are not mutually exclusive and may be competing primary therapy options, primary versus secondary choices, or in some cases primary and adjunctive therapies. Specific details are provided in the text.

Figure 24-48: Catheter ablation for VT as an adjunct to an ICD. A 57-year-old male with recurrent life-threatening episodes of sustained VT who received an ICD had multiple shocks for arrhythmias that were resistant to all antiarrhythmic agents attempted. LV mapping and catheter ablation in a VT reentrant pathway in 1987 provided freedom from recurrent ICD discharges for approximately 19 months, after which the multiple ICD discharges recurred. Additional ablation procedures 18 or more months apart provided relief from the recurrent discharges despite the fact that VT remained inducible. While of limited value as primary therapy for life-threatening ventricular arrhythmias in patients with coronary heart disease or cardiomyopathy because of risk of recurrence (see the text), this procedure can provide benefit as an adjunct to other primary forms of therapy by avoiding frequent discharges and improving the quality of life.

Figure 24-49: ICD with antitachycardia pacing. The figure demonstrates the end of a run of induced sustained VT (*left*) followed by antitachycardia pacing that converts the rhythm back to normal sinus (*right*). The device will revert to a defibrillator mode if programmed pacing sequences fail to convert the rhythm.

Figure 24-50: Therapeutic options for patients with VTs or cardiac arrest due to nonischemic cardiomyopathies. See the legend for Fig. 24-47 for a description of the figure design. The surgical/angioplasty category is excluded for the nonischemic cardiomyopathies. The indications, based upon priorities of therapy, are the same as described for coronary heart disease-related arrhythmias. See the text for further details.

Figure 24-51: Catecholamine-mediated VT in an otherwise healthy female. Psychologic stress or isoproterenol infusion could initiate the arrhythmia in this patient. During this sequence, a 4-μg/min isoproterenol infusion initiated the VT (*A*), and the patient was treated with intravenous propranolol. After the first 3 mg of propranolol (*B*), occasional sinus beats interrupted the tachycardia. On a milligram-by-milligram basis up to a total dose of 8 mg of propranolol, there was further suppression of VT to the point of salvos (*C, D, E*), frequent PVCs (*F*), and complete suppression of ectopic activity (*G*).

Figure 24-52: Right ventricular dysplasia with VT. Episodic wide QRS tachycardia with near-syncope in a 33-year-old man. The left bundle-branch block pattern of the tachycardia suggests a right ventricular origin, and the inverted T waves in V_1 to V_3 are characteristic of right ventricular dysplasia.

Figure 24-53: Bidirectional tachycardia. The tachycardia is regular at a rate of 160, but the vector of the QRS-T complexes alternates.

Figure 24-54: Torsades de pointes. The patient, a 49-year-old female, has complete heart block and was receiving quinidine sulfate for a ventricular arrhythmia. The rhythm shown in the bottom two strips occurred shortly after institution of therapy. Note the prolonged QT(U) interval (0.67 s) and the onset of classical torsades de pointes.

Figure 24-55: Congenital long QT interval syndrome. A 12-lead ECG was recorded in a 25-year-old female with congenital deafness and a history of recurrent syncope throughout her life (Jervell and Lange-Nielsen syndrome). Many episodes of syncope occurred during or immediately after exercise and were commonly preceded by palpitations. She had never been treated. The tracing reveals a corrected QT interval of 610 ms with marked notching of the TU waves in the anterior precordial leads.

Figure 24-56: Congenital long QT interval syndrome. Treadmill stress testing was carried out in the patient shown in Fig. 24-55. *A*. At 4 min and 2 s into a Bruce protocol, ST-T alternans was observed, followed shortly by torsades de pointes (*B*).

Figure 24-57: Genetic basis for congenital long QT interval syndromes. Abnormalities have been linked to five chromosomes among families with the Romano-Ward form of congenital long QT interval syndromes. At present, specific genetic abnormalities and gene products are identified, in part, for four of the five. Multiple mutations or deletions are possible at each locus. The genetic basis for the Jervell and Lange-Nielsen syndrome (autosomal recessive inheritance and associated deafness) includes LQT-1 abnormalities in some families, but other loci are likely as well. The last two columns provide the gene products and defective currents for each of the known loci. See the text for further details.

Figure 24-58: Syndrome of right bundle-branch block and ST-segment elevation in the anterior precordial leads and risk of sudden cardiac death (Brugada). In this syndrome, the electrocardiographic hallmarks of right bundle-branch block and ST elevation in the anterior leads are not consistently present, but they may be evoked by drug provocation using procainamide or flecainide. The left panel shows strips from leads V_1, V_3, and I, recorded from a 17-yearold male with Brugada's syndrome and a strong Family history of sudden cardiac death in males. The baseline ECG was normal. After a 300-mg oral bolus of flecainide, an ECG recorded 2 h later revealed a ST-segment elevation and a right bundle-branch block pattern in leads V_1 and V_2. After 4 h, this had reverted to baseline. See the text for details.

Figure 24-59: Programmed electrical stimulation study in a survivor of out-of-hospital cardiac arrest. The patient had ischemic heart disease, and polymorphic VT degenerating to VF was reproducibly induced prior to bypass surgery. After surgery, the tachycardia was no longer inducible.

Figure 24-60: Wenckebach phenomenon. *A*. A 5:4 and 6:5 AV Wenckebach period. Note that the PR interval progressively lengthens, but by a decreasing increment; therefore, the ventricular cycle tends to shorten (at least for the first two cycles following the dropped beat). *B*. A 3:2 and 4:3 SA Wenckebach period with 2:1 SA block at beginning and end of strip. (From Hurst JW, Myerburg R. *Introduction to Electrocardiography*. New York: McGraw-Hill; 1973. Reproduced with permission from the publisher and authors).

Figure 24-61: SA block. In each pause the entire P-QRS-T sequence is missing, and the long cycle is approximately equal to two of the sinus cycles. The pattern is the equivalent of a Möbitz-type II block at the level of the AV junction.

Figure 24-62: A form of second-degree AV block. There are two P waves to each QRS 2:1 AV block (alternate sinus impulses are blocked). This pattern can be caused by block in the AV node (Wenckebach), intra-Hisian block, or distal block (see the text).

Figure 24-63: Complete (third-degree) AV block. There is a regular idioventricular rhythm at rate 36 impulses per minute, and the P waves indicate their independence by changing their relationship to the QRS complexes.

Figure 24-64: AV dissociation *A*. Sinus arrhythmia. The bradycardic phase enables the AV node to escape, with resulting dissociation. *B*. AV tachycardia. The tachycardia enables the AV pacemaker to usurp control of the ventricles, with resulting dissociation; the seventh and eighth beats are ventricular captures, the seventh, ending the shorter cycle, showing ventricular aberration. *C*. High-grade AV block permits the AV node to escape (second, fourth, and fifth beats), with resulting dissociation.

Figure 24-65: Pacemaker-mediated (endless-loop) tachycardia. The patient had a DDD pacemaker and presented with episodes of sustained rapid heart action. The tracing (lead II) demonstrates (*A*) atrial tracking with ventricular pacing at a cycle length of 740 ms and (*B*) ventricular pacing with retrograde atrial activation. The retrograde P waves (P) following each paced QRS are sensed by the atrial sensing lead and trigger a ventricular pacing spike (S), followed by the paced QRS with repeated retrograde atrial activation.

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 25:

LONG-TERM CONTINUOUS ELECTROCARDIOGRAPHIC RECORDING

Authors: R. Joe Noble, Eric N. Prystowsky

Long-term electrocardiographic recording is a method of recording the electrocardiogram (ECG) over extended time periods; the recording is subsequently analyzed for rhythm and ST-segment and T-wave alterations.[1-3] Technological advances in the past few years have provided a diversity of recording, transmitting, and analysis systems.

INDICATIONS

Ambulatory ECG (AECG) recording may be helpful in recognizing, characterizing, and less frequently, quantitating arrhythmias in patients with symptoms potentially related to an arrhythmia; the recording of a rhythm disturbance simultaneous with a patient's symptoms may be the only means of diagnosis, particularly when the symptoms and arrhythmia are relatively infrequent (Fig. 25-1). Importantly, the recording of a normal rhythm when the patient is symptomatic may prove equally valuable in excluding a rhythm disturbance as the cause for the patient's symptoms. Not only is it important to correlate an abnormal rate and rhythm with the symptom complex but, from the ambulatory record, also to determine the precise mechanism of arrhythmia. Some concept of the frequency of the arrhythmia, as demonstrated by the ambulatory record, is clinically helpful, but precise quantitation of the frequency of premature ventricular complexes, for instance, is rarely required.

AECG recordings may be indicated in certain patients to assess risk for future cardiac events-specifically in those patients with idiopathic hypertrophic cardiomyopathy, patients who have survived myocardial infarction with substantial left ventricular (LV) dysfunction, patients with long QT intervals, patients with dilated cardiomyopathy and symptoms consistent with arrhythmia, and in some patients with the Wolff-Parkinson-White syndrome.[4] The value of AECG in predicting risk is compromised by low sensitivity and specificity. Furthermore, since the effect of treatment of any arrhythmia recorded in these conditions is unclear, there is little support for routine AECG recording in risk stratification.[4]

Patients who undergo treatment for complex arrhythmias, such as sustained supraventricular tachyarrhythmias or ventricular tachycardia, may benefit from AECG recordings in order to assess the efficacy of therapy-both suppression of arrhythmia and rate control (Fig. 25-2). Similarly, patients in whom pacemakers have been implanted who have symptoms consistent with pacemaker malfunction or who require evaluation of their rate-responsive physiologic pacing function may require long-term AECG recording.

Heart rate variability and QT dispersion may be measured accurately by long-term AECG recording, which also may be helpful in patients with sleep apnea or those having suffered a previous myocardial infarction in whom further prognostic information is sought. However, the predictive value of the measurement limits it application.[4]

The recording of the pattern on AECG (as opposed to the rhythm) may be helpful in the detection

of myocardial ischemia. Long-term AECG recording is indicated for patients suspected of Prinzmetal's variant angina, in whom the simultaneous recording of ST-segment elevation with symptoms should confirm the diagnosis (Fig. 25-3). Long-term recording may be of diagnostic help in patients with symptomatic angina who are unable to undergo exercise testing; preoperative risk stratification would be one indication.

Another potential use of prolonged ECG pattern recording is to correlate symptoms that occur during normal daily activity with ECG evidence of ischemia. In this setting, the demonstration of significant ST segment-T-wave alterations that cannot be reproduced by hyperventilation or by change in position, particularly when reinforced by documentation in the patient's diary of simultaneous symptoms of angina, proves highly suggestive of ischemic heart disease. Particularly in patients in whom exercise testing produces negative results yet symptoms highly suggestive of myocardial ischemia continue with other specific activities, AECG recording provides useful information.

The reader is referred to *Guidelines for Ambulatory Electrocardiography*, published jointly by the American College of Cardiology and the American Heart Association, for a more complete consideration of clinical indications for ambulatory AECG recordings.[4]

Chapter 25: LONG-TERM CONTINUOUS ELECTROCARDIOGRAPHIC RECORDING

RECORDING TECHNIQUES

Three general types of instruments for acquiring data are currently available: continuous recorders, intermittent or event recorders, and instruments for real-time recording and transmission of ECGs (Table 25-1).

Table 25-1: Types of Electrocardiographic Recording Instruments

Type	Recording	Scanning	Transmitting
HOLTER			
Analog	All ECG complexes 'Full Disclosure'	Technician with computer assistance, templating, area determination and superimposition	None
Digital-continuous recording	All ECG complexes 'Full Disclosure'	Technician with computer assistance, templating, area determination and superimposition	Transtelephonic
Digital-real-time analysis	Computer analysis of ECG and selected ECG printouts	Real time by microprocessor with retrospective technician editing	None
EVENT RECORDER			
'Postevent,' nonlooping, without memory			
Hand-held (including credit card size) wristwatch-type	ECG, selected by patient activation	Direct visualization	Transtelephonic
Automatic electronic sensor, in DDD pacemaker	ECG, when activated automatically by sensor	Direct visualization of analysis or ECG	Direct telemetry
'Preevent,' looping, with memory monitor worn with attached electrodes	ECG, selected by patient activation, with memory of pre-event	Direct visualization	Transtelephonic
Subcutaneous, implanted digital recorder	ECG, selected by patient activation with memory of pre-event	Direct visualization	Direct telemetry

Automatic electronic sensor, in ICD or pacemaker	ECG, when activated by firing of ICD or recognized by sensor in pacemaker, with memory	Direct visualization of analysis or ECG	Direct telemetry
REAL TIME			
Real-time transtelephonic monitoring	ECG at central monitoring station-no recording at device	Direct visualization	Transtelephonic

Continuous Recorders

The ECG can be recorded continuously on cassette tape or digitally in solid-state memory. The tape recorder is a battery-powered, miniature device with a very slow tape speed that is small enough to be suspended by a strap over the shoulder or around the waist.

All digital recording systems amplify, digitize, and store the ECG in solid-state memory. Two types of digital recorders are available. In the first, each QRS complex is recorded, similar in this sense to the continuous tape recording. "Full disclosure" of the ECG is provided by enhanced storage capacity on a memory card the size of a credit card. With the second, microcomputers and microelectronic circuits sample the cardiac rhythm in real time as it is being recorded, convert the analog signal into a digital signal, and analyze the data in terms of maximal and minimal rates, RR intervals, and changes in RR intervals. Within minutes of the instrument's disconnection from the patient, the information can be retrieved in the form of a histogram covering the entire recording period, and a printout of selected segments in real time can be obtained. This instrument is different from those used to make continuous tape or digital recordings in that the actual ECG has not been recorded on tape; only the histogram has been stored. Selected brief segments of the patient's ECG, e.g., 6- to 10-s intervals, also can be stored, however. Microcomputers that can analyze electronic data over prolonged periods, even several days, have been developed.

The lead systems on recorders vary from one manufacturer to another. Meticulous attention must be paid to placing the electrodes on the patient's chest, since poor electrode contact will produce technically inadequate recordings.

Event Recorders

An alternative method records not continuously but only when the patient senses symptoms or an event. Of the numerous event recorders available, there are two basic types, which are differentiated on the basis of memory.

In the *postevent recorder*, without memory, the unit may continuously monitor the ECG via attached leads. The patient wears the recorder continuously, activating it when symptoms appear; this device does not record the ECG until it is activated. Alternatively, the patient may carry a miniature solid-state recorder (sufficiently small to fit into a pocket or purse) with which the rhythm can be recorded whenever the symptoms appear simply by placing the unit on the precordium. Some newer devices are the size of a credit card, to be carried in a wallet or worn as a necklace or wristwatch. The recorded data are stored in memory until the patient submits the information either directly or transtelephonically to an ECG receiver, where it is recorded. When a tape is employed, the tape is then erased, and subsequent data can be recorded and transmitted to facilitate the recording of rhythm or pattern during several symptomatic episodes. When digital

acquisition devices are used, a prolonged, continuous event can be recorded and stored or the device can be programmed to acquire multiple events.

With a *preevent recorder*, employing a memory loop, the rhythm is monitored continuously via leads either at the extremities or over the precordium, connected to a recorder typically worn on a belt. Patients activate the unit when they experience symptoms so that an abnormal rhythm or an ECG synchronous with the symptoms can be recorded. The loop recorder is capable of recording information several seconds or minutes before or after a recognized event; the number of events that can be recorded and the allotment of recording time prior to and after activation of the unit are programmable.

A miniaturized *event recorder* has been developed that can be implanted subcutaneously to be mechanically activated by the patient to record an ECG when the patient suffers serious symptoms (such as syncope) at widely spaced intervals.[5,6] Incorporating a memory loop, the preevent ECG is recorded, and the resulting recording is transmitted by telemetry to a receiver for analysis.

Event recording is also provided by some newer-generation DDD pacemakers and implantable cardioverter defibrillators (Fig. 25-4). These instruments automatically recognize abnormal rhythms, such as tachycardia, and provide, via telemetric transmission, either actual ECG records or an analysis of the number, rate, and duration of recognized arrhythmias.

Real-Time Monitoring

As another variation, the device that acquires data can transmit the ECG information directly and transtelephonically, in real time, without recording the data in the unit. With such a device, for instance, the patient can transmit his or her ECG daily or even multiple times each day, with or without symptoms, at some distance from the medical institution to the recording station.

Recordings of ST Segments and T Waves

For several reasons, both technical and physiologic, long-term ECG recording devices do not provide the same degree of reliability in interpretation of the pattern of the ST segment and T wave as in the detection of rhythm disturbances.[7,8] Technical limitations include certain characteristics of the patient's ECG; normal sinus rhythm, an isoelectric ST segment, and absence of broad Q waves, intraventricular conduction delays, and LV hypertrophy are prerequisites. The patient cannot be treated with digitalis and some other drugs that alter ST-segment-T-wave morphology. Electrode preparation and placement must be meticulous. AECG recordings of ST-segment-T-wave morphology should be performed only by physicians and institutions trained and experienced in these techniques. With these considerations, however, newer-generation digital recording systems and those with improved low-frequency characteristics more accurately reproduce ST-T segments; some new systems either directly record or derive full 12-lead ECGs.

Even more important than these technical considerations, however, are certain physiologic limitations. For instance, standing, hyperventilation, eating, anxiety, use of drugs, and change in heart rate or autonomic tone are all daily events that may result in depression of the ST segment or inversion of the T wave to simulate ischemic changes. Striking ST-segment elevation has been recorded during prolonged recording in patients without organic heart disease.[9]

Chapter 25: LONG-TERM CONTINUOUS ELECTROCARDIOGRAPHIC RECORDING

SCANNING AND ANALYSIS TECHNIQUES

The recording can be analyzed by scanning the tape or digital record at high speed, by printing it out directly, or-as in the case of microcomputers-by processing during the recording and printing out the analysis at the end of sampling.

Scanning techniques include technician-dependent analysis, in which a technician interprets the cardiac rhythm as it is played back at high speed on an oscilloscope at 30 to 240 times the speed of the actual event. One commonly used method of scanning superimposes each QRS complex on the immediately preceding complex so that identical QRS contours present as a stationary image. Variations in QRS contour then become readily apparent. Simultaneously displayed on the oscilloscope for each cardiac cycle is a vertical bar graph, the height of which is directly proportional to each RR interval and QRS morphology. Thus the occurrence of a premature ventricular extrasystole would alter the stationary image by producing a variation in the QRS contour, alter the pitch and sound of the audio signal, and shorten the vertical bar reflecting cycle lengths. When such an abnormal event is noted, the tape can be played at a normal rate of speed for analysis on a standard ECG machine.

To minimize the human factor and provide accurate quantitative data, the tape can be analyzed by a semiautomated electronic analyzer, which quantitates the number of abnormalities it recognizes. The accuracy of the system depends on the system's ability to distinguish abnormal from normal.

A computer can be interfaced with the scanner to quantitate the data even more accurately. The playback analysis can occur at up to 240 times the normal rate. Electronic analyzers and computers, as well as the scanner, can be programmed to recognize the patient's own QRS complex template and then to recognize any deviation from normal. The computer program can provide summaries of heart rates, heart rate variability, frequency of premature atrial or ventricular extrasystoles, coupling intervals, runs of tachycardia or other arrhythmias, and variations in QRS, ST, QT, or T-wave pattern during any time period. Hard copies can be printed out for verification. When arrhythmias or pattern changes are detected, an automatic ECG printout can be triggered by the event marker or by the computer.

Scanning services are available and generally can provide reasonably accurate analysis at less cost than can small institutions or offices with smaller volumes of long-term ECG recordings. Recorders can be purchased, leased, or rented.

An alternative to scanning is the direct printout of the entire record. Prolonged ECG records are compressed to reduce the amount of paper that the physician must examine; when brief events are recorded, compression is not necessary. By writing out the entire ECG directly, the need for a trained technician and scanners may be obviated.

Since microcomputers assess the ECG in real time, as it is recorded, there is no need for a scanner or expert technician when the results are printed out. The physician evaluates the trend chart or any recorded rhythm strip.

As noted in Table 25-1, all the event recordings, the real-time recording, as well as some of the continuous recordings can be transmitted transtelephonically to receivers for analysis and

interpretation. These recordings of implanted pacemakers or defibrillators are available by telemetry.

Chapter 25: LONG-TERM CONTINUOUS ELECTROCARDIOGRAPHIC RECORDING

COMPARISON OF TECHNIQUES FOR PROLONGED ELECTROCARDIOGRAPHIC RECORDING

Operator-dependent high-speed audiovisual analysis of the tape, without direct printout or electronic analysis, recognizes serious rhythm disturbances. On the other hand, the operator can fail to recognize as many as one-third to two-thirds of ventricular and supraventricular arrhythmias. Operator-dependent systems are affected by the capabilities of the operator. If quantitation is unimportant, this system of analysis is quite adequate.

Electronic analysis systems improve on the sensitivity and specificity of interpretation of long-term ECG recordings. Computer analysis systems are said to be 90 to 95 percent accurate in quantitating ectopic complexes.[10-12] Current computer-based systems that permit operator editing are even more sensitive and accurate, but both electronic and computer analysis systems increase cost. One reason for the stated accuracy of computer interpretations is that ventricular ectopy is responsible for most broad, complex beats. Supraventricular ectopy with aberrancy or intermittent preexcitation is not accurately diagnosed by computer, but the relatively low frequency of these complexes does not statistically alter sensitivity calculations. In fact, the accuracy of arrhythmia diagnosis is also questionable when the data are not fully disclosed.

"Full disclosure"-i.e., hard-copy printout of the entire record-provides a visual analysis of the record to identify complex disturbances such as ventricular tachycardia or prolonged asystolic intervals. In addition, it is often useful to have hard-copy ECG data available (as opposed to those derived from analysis of the ECG data) with which to compare subsequent records. The direct printout does not quantitate the actual number of events. Assuming care in interpretation, the direct printout may be more sensitive than high-speed operator-dependent and semiautomated systems with operator editing in identifying pairs or triplets of consecutive ectopic complexes.

An event recorder does not require a scanner or an experienced technician; however, the continuously recording event recorder itself is more expensive than a continuously recording tape recorder. The postevent recorder, without memory, which the patient applies only when symptoms appear, is less expensive. Both types of event recorders provide an ECG record more quickly than a system that requires scanning,[13] but neither creates a long-term record of the ECG during asymptomatic intervals. The automatic event recorders incorporated in pacemakers and implantable defibrillators are limited by the accuracy and sensitivity of the algorithm used to detect abnormalities yet enhanced by analysis of intracardiac signals. Any event recorder clearly allows correlation between the patient's symptoms and the rhythm. The only technique currently available to record rhythm events leading up to and following infrequently occurring symptoms is the memory-loop event recorder.

When more rapid identification of a rhythm abnormality in an outpatient is essential, as in the patient with a potentially dangerous rhythm disturbance, real-time transmitters permit frequent and even automatic transtelephonic transmission of the ambulatory record to a hospital or clinic telemetry receiver. The monitor technician can then quickly identify a serious rhythm abnormality and arrange for the patient's proper management.

Those microcomputers which analyze the rhythm in real time, simultaneous with the recording, should prove at least as accurate as other high-speed playback analysis systems. More important,

longer periods can be monitored than are practical for other systems. The cost of the analysis is independent of the duration of recording, so patient cost should be less for prolonged periods of monitoring. Finally, the analysis of the entire recording and the actual printout of the specific ECG segment are available within minutes of the recording. On the other hand, only limited segments of actual ECG records are generally available, and the accuracy of abnormal rhythm or pattern recognition remains dependent on the computer algorithm; this recognition is far from perfect, since many problems in the computer analysis of complex rhythm disturbances remain unsolved.

When the ECG pattern is monitored for ischemia, newer-generation methodologies-either digital or with enhanced low-frequency recording-are required. Whichever system is employed, the ultimate accuracy of ECG interpretation depends on the technician and overreading physician; scanners and computers cannot differentiate complex patterns (supraventricular arrhythmias with aberrancy as opposed to ventricular arrhythmias or preexcitation) or even artifacts. The clinical application of the data is solely the function of the responsible physician. No data-acquisition system or scanner, no computer, and no technician can substitute for the well-trained physician in determining the significance of any recorded data and their clinical utility.

Selection of Device

The ultimate selection of a long-term ECG recording system depends on individual patient needs. If a precise count of ectopy is required, a continuous recorder with computer-based analysis is essential. These devices are also very useful to evaluate ventricular rate control in atrial fibrillation (see Fig. 25-2). On the other hand, if the purpose of the recording is to detect ventricular tachycardia or asystole, an event recorder, a microcomputer, or direct printout of the entire record would be an excellent choice. Either a microcomputer or an event recorder provides an opportunity to monitor over prolonged periods of time, and either is of benefit to the patient whose rhythm disturbance occurs infrequently. When the goal is to correlate the patient's rhythm or ECG pattern with symptoms that are very infrequent (at weekly intervals or less), the patient-applied and patient-activated event recorder is the optimal choice. However, if the patient's symptoms are of such brief duration (seconds) or severe (frank syncope) to preclude capture by such a unit, then a loop event recorder is required. This and the direct printout are less expensive for an individual physician's or small clinic's use, and both are more cost-effective than prolonged ambulatory (Holter) recordings, whether indicated for assessment of palpitations[14,15] or such serious symptoms as syncope[15] (see Fig. 25-1). The implantable event recorder with memory may prove optimal for those patients with syncopal events so widely spaced (months) as to render other devices impractical.[6]

Except with large scanning services, it is impractical for an individual physician to have available all the monitoring techniques for each individual patient's needs. Hence the physician's selection of a system is based on his or her own patient population, the frequency of using this test, the availability of dependable scanning services, and the associated cost analysis. The physician would do well to realize that any or all of the systems described herein are available alone or in combination. The more detailed and precisely quantitated the final report, generally the more expensive are the equipment and personnel required. All systems recognize marked tachycardia or bradycardia and, qualitatively at least, detect ectopy. For clinical purposes, this amount of information is usually sufficient. The practicing physician does not really require precise quantitation, since the therapeutic and prognostic significance of such quantitation is not yet known. In short, technology exceeds clinical assimilation of the results at the present time.

Chapter 25: LONG-TERM CONTINUOUS ELECTROCARDIOGRAPHIC RECORDING

DURATION OF RECORDING

Arrhythmias are often evanescent, occurring only rarely. In such patients, 24-h ECG recordings are unlikely to detect the abnormal rhythm. Even when arrhythmias are frequent, marked variation in the frequency and complexity of the rhythm disturbance is expected, with variations occurring during and between days. Spontaneous reduction in the frequency of ventricular ectopy of 50 to 90 percent is common.[16,17] For screening purposes, 24-h ECG tape recording seems an optimal compromise between the practical limits of recording and the point of diminishing return.[18-20]

If a reduction in total number of premature ventricular complexes is the goal of antiarrhythmic therapy, then more than one control 24-h ECG recording and several recordings while the patient is receiving therapy are required to prove efficacy.[18,19] The total number of premature ventricular complexes must be reduced by about 80 percent.[16,17,21,22] On the other hand, since it has not yet been demonstrated that reducing the total number of premature ventricular complexes necessarily implies the elimination of more dire ventricular rhythm disturbances or sudden death, this is often not the physician's goal. Instead, simply preventing sustained, symptomatic ventricular tachycardia may be the therapeutic goal,[23] in which case multiple 24-h recordings are less essential.

The frequency and degree of ST-segment depression also vary chronologically.[24-26] Forty-eight hours is probably the optimal duration for monitoring ST-segment changes.[27] When comparing a 48-h recording prior to and following therapy, the frequency of ST-segment deviation must be reduced by 75 percent to infer a therapeutic efficacy.[28]

The ideal duration of recording varies from patient to patient, depending on the physician's goals. If the objective is to correlate the cardiac rhythm or pattern with a symptom such as syncope, palpitations, or chest pain, then the monitoring period must be extended sufficiently to incorporate a symptomatic period, whether these intervals occur with a frequency of hours or months. The actual recording period, however, may be only seconds.

Chapter 25: LONG-TERM CONTINUOUS ELECTROCARDIOGRAPHIC RECORDING

ARTIFACTS AND ERRORS

Artifacts registered during prolonged ECG recording have mimicked virtually every variety of supraventricular and ventricular bradycardia and tachycardia and have led to misdiagnosis[29,30] and inappropriate and unnecessary treatment.[31]

Most of these artifacts are identical to those plaguing the standard 12-lead ECG but are simply detected more frequently due to the length of the recording; however, many are unique to extended recording by virtue of the magnetic tape recorder.

Probably the most common artifact is that resulting from a loose electrode (Fig. 25-5) or mechanical "stimulation" of the electrode. Failure of either the battery or the motor of the recorder generally results in a slowing of the tape speed as the ECG is recorded. When played back, the heart rate will appear fast; i.e., it will mimic a tachycardia (Fig. 25-6). The interpreter may be alerted to the artifact by the concomitant shortening of all ECG intervals (PR, QRS, QT, and RR) and decrease in QRS voltage. Conversely, transient slowing or sticking of the tape during playback will suggest bradycardia or atrioventricular (AV) or intraventricular conduction disturbances (Fig. 25-7). Recording an ECG on a previously used tape that is incompletely erased results in the simultaneous registration of two ECGs and potentially the misinterpretation of a "parasystolic" ectopic rhythm (Fig. 25-8). Digital recording in solid-state memory eliminates these various mechanical failures of tape recordings.

The technician and/or physician who interprets prolonged ECG recordings must have a working knowledge of these and other potential artifacts in order to interpret the records properly.

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 26:

TECHNIQUES OF ELECTROPHYSIOLOGIC EVALUATION

Author: Masood Akhtar

The recording of intracavitary electrocardiographic signals and various forms of pacing programs have experienced enormous growth during the past 3 decades. Recordings of intracardiac signals from the region of the His bundle, initially made by Scherlag et al.,[1] were rapidly applied to clinical problems including atrioventricular (AV) blocks and supraventricular and ventricular tachyarrhythmias.[1-10] Such recordings were then complemented by pacing to unmask sinus node dysfunction and AV conduction abnormalities as well as to initiate supraventricular tachycardias (SVTs).[3-8] Intracardiac electrophysiologic studies (EPSs) have since found utility in a variety of cardiac arrhythmias, including sinus node dysfunction, intraventricular and AV conduction disturbances, SVTs, ventricular tachycardias (VTs), preexcitation syndromes, and ventricular fibrillation (VF). Such studies are now also employed as a prelude to correction of various arrhythmias and conduction defects. This chapter addresses recording and pacing techniques and their clinical utility.[9,10]

TECHNIQUES OF INTRACARDIAC ELECTROPHYSIOLOGIC STUDIES

The exact type of electric signal recordings, specific equipment used, and pacing protocol depend upon the nature of the clinical problem, the type of electrophysiologic assessment, and the anticipated course of action. Routine cardiac EPSs are performed while patients are in a nonsedated postabsorptive state.[11] Although some degree of sedation is advisable in apprehensive patients, the use of drugs that may alter the properties of the cardiac conduction system should be avoided. Antiarrhythmic drugs are usually stopped prior to these studies. In selected cases, antiarrhythmic drugs may be continued if a clinical event occurred while the patient was on a specific agent. Customarily, other cardioactive drugs that are necessary for nonarrhythmic cardiovascular problems such as hypertension, angina, and heart failure are continued.

The typical electrode catheters used for both recording and cardiac stimulation are multipolar (sizes varying from 4 to 8 F). Catheters can be inserted via peripheral veins such as the antecubital or femoral veins and, at times, the subclavian or internal jugular veins. When a catheter is intended to be left in place for several days, subclavian and internal jugular veins are preferable. After using local anesthesia, a guide wire is inserted percutaneously through a needle, and a sheath is advanced over the guide wire. A catheter is then guided fluoroscopically through the sheath to position in the appropriate cardiac chamber. For most electrophysiologic testing, the catheter is placed in the high right atrium, at the His bundle, or at the right bundle branch region across the tricuspid valve and right ventricular apex or outflow. For accessory pathways or AV junctional tachycardias, a catheter is placed in the region of the coronary sinus. Heparinization is recommended at approximately 1000 units per hour. For EPSs, good contact between the electrodes and the walls of the various chambers is critical. For His bundle and right bundle branch recording, the catheter is introduced via the femoral vein, advanced across the tricuspid valve, and gradually withdrawn until an appropriate recording from the right bundle and/or the His bundle is obtained (Fig. 26-1). A coronary sinus catheter can be placed via an arm, internal jugular, or subclavian vein. If necessary, coronary sinus catheterization can also be accomplished via a femoral approach. Right atrial catheter placement can be done via any of the

larger peripheral veins. For a routine study, left-sided heart catheterization is seldom necessary. In patients with VT and/or left-sided accessory pathways, however, this is performed for diagnostic or therapeutic purposes. Continuous heparinization is desirable for left heart catheterization to avoid thromboembolic complications.

Electrophysiologic Recordings

Once the electrode catheters are placed appropriately, the connections are made via a junction box and isolation units to prevent excess current in the event of random electrical surges. All of the electrograms are displayed simultaneously on a multichannel oscilloscopic recorder. In addition to the intracardiac signals, several unfiltered surface electrocardiographic leads (i.e., X, Y, and Z or leads I, II, or aV_F and V_1) are recorded. To reduce the noise generated with the low-frequency signals, the usual filtering frequency for intracardiac signals is between 30 and 40 Hz for the high-pass and 500 Hz for the low-pass filters. Although appropriately placed electrode catheters will record desired signals at any filtering frequency, filter settings between 30 to 40 and 500 Hz are best suited for sharp intracardiac signals such as those from the His bundle and accessory pathways (Fig. 26-2). Undesirable low-frequency signals can be reduced by a high-pass filter setting of more than 50 to 100 Hz. On the other hand, 60-cycle interference can be eliminated with a low-pass filter setting at 50 Hz. Alteration in the high-bandpass filter for surface electrocardiography can markedly alter the scalar electrocardiographic morphology. Amplification is frequently necessary to identify desirable signals from the specialized conduction system. This can lead to superimposition of the larger myocardial signals on various electrocardiographic tracings. In most recording equipment, however, limiting filters allow the adjustment of amplitude limits.

The main value of intracardiac/electrocardiographic tracings is timing of electric events and to determine the direction of impulse propagation. To acquire true local electrical activity, a bipolar electrogram with an interelectrode distance of less than 1 cm is desirable. When unipolar electrograms are obtained, a rapid intrinsic deflection will identify a point of local activation. For routine intracardiac electrocardiographic studies, unipolar electrograms provide relatively limited advantage over bipolar signals, and therefore the latter are more often utilized. The foregoing description relates to the routine diagnostic invasive EPSs. In other clinical situations, different types of diagnostic methods are employed. For example, during intraoperative mapping, direct placement of electrodes over the epicardium or endocardium is necessary to get appropriate signals for identifying the precise origin and route of impulse propagation.[12] These electrodes can be in the form of either hand-held probes or plaques that can be placed or sutured over the myocardium. Socks and balloons incorporating several electrodes can also be used for epicardial and endocardial mapping techniques, respectively.[13,14] All electrical signals can be recorded on either a disk or frequency-modulated tape for permanent storage.

More recently, several other types of mapping and recording equipment have emerged to locate the origin of cardiac arrhythmias more accurately. Two of the systems likely to find clinical utility in the mapping of arrhythmic origins are (1) nonfluoroscopic electromagnetic endocardial mapping ([CARTO, Biosense (Cordis Webster) Marlton, NJ] and (2) noncontact mapping (EnSite, Endocardial Solutions, Saint Paul, MN).

1. The CARTO system consists of a magnetic field generator locator pad placed under the patient table, a sensor-mounted catheter and a reference catheter placed intracardially, a mapping system and a graphic computer.[15] The catheter tip allows orientation in relation to the reference signal. The accuracy of catheter tip position is within a millimeter of arrhythmia location in this low magnetic field. By moving the sensor sequentially, one can generate a three-dimensional (3D) activation map. By color coding, both the earliest and the latest directions of electrical activation can be recorded. Once the initial fluoroscopy-guided placement of reference catheter and other catheters is satisfactory, several points are acquired. A 3D map is generated, and sensor-mounted

catheters are manipulated further without the help of fluoroscopy.

Aside from creation of an accurate map guiding the origin and activation sequence, the CARTO system is also helpful in separating micro from macro reentry circuits. For example, in atrial flutter, by virtue of its large circuit, the impulse propagation along the entire route can be outlined. The atrial tachycardia, on the other hand, can be distinguished by its radial spread from an atrial focus. A typical map generated during this technique is shown in Fig. 26-3, Plate 75.

2. Noncontact mapping using the Endocardial Solutions EnSite 3000 system.[16] The Endocardial Solutions EnSite 3000 is a new endocardial mapping system that takes a different approach to such mapping (Fig. 26-4, Plate 76). Like the CARTO system, the EnSite 3000 system also makes use of an amplifier and computer system with custom software. The EnSite catheter uses a balloon design with a 64-electrode array arranged over the outside of the balloon. This balloon is positioned in the center of the chamber and does not come in contact with the walls of the chamber being mapped. Using data from the 64-electrode array catheter, the computer uses sophisticated algorithms to compute an *inverse solution* to determine the activation sequence on the endocardial surface. Data from all points in the chamber are acquired simultaneously.

To create a map, the balloon catheter is positioned in the chamber and deployed. A conventional (roving) deflectable catheter is also positioned in the chamber and used to collect geometry information. A 5-kHz signal is emitted from the tip electrode of the conventional catheter, and the computer analyzes this signal to determine the position of the roving catheter relative to the position of the balloon. The roving catheter is moved throughout the chamber, and the location information is collected by the system. Using this information, the computer creates a model, called a *convex hull*, of the chamber during diastole. After the chamber geometry is determined, mapping can begin. The arrhythmia is induced, and data are acquired. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. The inverse-solution computations are performed by the system in real time and projected on to the surface of the convex-hull model, creating a 3D model showing the activation sequence within the chamber. Following this, the segment must be analyzed by the operator to find the early activation or vulnerable region of the reentry circuit. The locator technology that was used to collect the geometry information for the convex hull can then be used to guide an ablation catheter to the proper location in the heart.

Because data from the entire chamber are collected simultaneously with the EnSite 3000 system, it can be used to map nonsustained rhythms such as premature atrial complexes, irregular rhythms such as atrial fibrillation or polymorphic VT, and rhythms that are not hemodynamically stable. The system is highly useful for identifying focal arrhythmias (Fig 26-4) and atrial flutter. Currently approved indications, however, are for the right atrium only. The other significant limitation of the system results from its reliance on the large-diameter balloon catheter with its current 9.5-F lumen.

These mapping systems, both of which are relatively new, provide electrophysiologists with new tools for diagnosing and treating what are often complex arrhythmias. They make use of state-of-the-art technology to accomplish their objectives and improve the state of the art in arrhythmia management. Because these technologies are so new, further enhancements can be expected that will further the usefulness of advanced mapping techniques in the practice of electrophysiology.

Programmed Electrical Stimulation

After satisfactory placement of the electrode catheters, patches, or other forms of recording equipment, baseline recordings are made and programmed stimulation is initiated. The usual site of pacing is the right atrium or left atrium via the coronary sinus. For ventricular stimulation, the pacing sites are the right ventricular apex, outflow tract, and rarely some other right ventricular

site. A variety of pacing programs can be utilized, depending upon the nature of the underlying arrhythmic problem under investigation. At least two formats of pacing protocol are common. The first is incremental pacing, which is pacing at a constant cycle length with gradual shortening until the occurrence of a desirable event, such as induction of a tachycardia or production of AV block. Otherwise the incremental atrial pacing is continued until the onset of AV nodal Wenckebach's phenomenon: a physiologic response at faster pacing rates. Fixed-cycle-length ventricular pacing is also used for the induction of supraventricular tachyarrhythmias and study of ventriculoatrial conduction. Bursts of pacing at a constant cycle length are occasionally used to induce SVT, VT, or VF or for study of sinus node function and integrity of subsidiary pacemakers.

The second pacing format is premature (or extra) stimulation from atrial or ventricular sites. For the study of a physiologic phenomenon, refractory periods, and conduction characteristics, a single extra stimulus is usually applied after a series of beats with a constant cycle length (Fig. 26-5). The scanning is initiated late during electrical diastole, and the coupling interval is progressively decreased until the atrial and/or ventricular muscle is refractory. For induction of SVTs, single, two, or more extra stimuli are delivered (Fig. 26-6). For the induction of VT, up to three ventricular extra stimuli are employed. The sensitivity of pacing protocols seems to be directly related to the number of extra stimuli utilized.[17] This occurs, however, at the expense of specificity when polymorphic VT/VF can be induced at very short coupling intervals by using multiple extra stimuli. Regardless of the pacing protocol, the induction of sustained monomorphic VT constitutes a specific response and is seldom induced in patients not prone to such arrhythmias clinically. In contrast, the induction of polymorphic VT/VF with three extra stimuli at short coupling intervals can be nonspecific and does not provide a reliable guide for serial testing. Both polymorphic VT and VF can be avoided to a great extent at short coupling intervals (<200 ms) and the induction of latency between the stimulus artifact and the local ventricular electrograms is avoided.[18]

During routine EPSs, a variety of electrophysiologic parameters are measured, including sinus node function and intraatrial, AV nodal, and His-Purkinje system conduction. Initiation of SVT and VT is attempted to determine the mechanisms, the site of origin (by pacing and mapping techniques), and the potential of overdrive termination as a therapy option. After baseline studies, intravenous drugs are frequently administered to facilitate either induction of tachycardias, aggravation of sinus node function, or production of AV block (Fig. 26-7), or to determine drug efficacy.[17] At the completion of testing, the catheters are withdrawn, and gentle pressure is applied at the area of catheter insertion. Unless arterial catheterization is performed, patients are usually allowed to ambulate after 4 to 6 h. The role of EPSs in patient management has evolved over the past decades from a purely diagnostic method to a frequently applied therapeutic tool. A brief outline of the value of clinical EPSs in various arrhythmia settings is outlined separately under diagnostic and therapeutic categories.

Chapter 26: TECHNIQUES OF ELECTROPHYSIOLOGIC EVALUATION

INVASIVE ELECTROPHYSIOLOGIC STUDIES FOR DIAGNOSIS

Sinus Node Dysfunction

EPSs are generally performed to detect suspected sinus node dysfunction in patients with dizziness, presyncope, syncope, etc., in whom the diagnosis cannot be made noninvasively. The most frequently performed test is that of sinus node suppression by using overdrive atrial pacing. After pacing at several basic cycle lengths for a period of approximately 30 s or longer, the pacing is interrupted. The resultant escape interval, which is called *sinus node recovery time*, is measured. By deducting the predominant sinus cycle length from this interval, one can obtain the so-called corrected sinus node recovery time. In one study, sinus node recovery time in patients with sinus node disease averaged 3087 ms,[3] and averaged 1073 ms in normal individuals. In another series,[6] the value for corrected sinus node recovery time was less than 525 ms in normal individuals and exceeded those values in patients with overt sinus node dysfunction. Direct sinus node recordings have been obtained by amplification of recording from catheters placed in close proximity to the sinus node,[20,21] where both the sinus node automaticity and sinoatrial conduction can be determined more accurately.

In the vast majority of patients with true sinus node disease, sinoatrial conduction abnormalities are the predominant reason for sinus node dysfunction. The sinoatrial conduction time in the absence of obvious sinus node disease is less than 100 ms. The sensitivity of sinus node recovery time for the detection of sinus node dysfunction is 54 percent, whereas that of sinoatrial conduction time is 51 percent, with a combined sensitivity of the two tests of around 64 percent. Poor sensitivity of such testing relates in part to the fact that, in previous studies, documented episodes of sinus bradycardia or sinus arrest due to neurocardiogenic mechanisms may have been included as examples of sinus node dysfunction.[22] The specificity of the two tests combined is approximately 88 percent. It is important to test the AV conduction in patients with sinus node dysfunction, since the former is also frequently abnormal. In patients with bradycardia/tachycardia syndrome, tachycardias are frequent, particularly those arising in the atrium, and testing may also be necessary for the proper diagnosis and therapy of the concomitant tachyarrhythmia.

Atrioventricular Block

In asymptomatic patients with first-degree AV block (prolonged PR interval), electrophysiologic assessment is unnecessary, regardless of the QRS morphology of the conducted beats. In asymptomatic individuals with second-degree AV block, electrophysiologic assessment is used to find the site of the block (Fig. 26-8). Patients with intra-Hisian or infra-Hisian block tend to have a more unpredictable course, and permanent pacing is desirable.[23] On the other hand, asymptomatic patients with AV nodal block generally do not require permanent pacing. Even though the intranodal block usually presents as Wenckebach's phenomenon or Mobitz type I, it is not uncommon to see Wenckebach phenomena within the His-Purkinje system or within the His bundle. There is no difference in prognosis regardless of how the infra- or intra-Hisian second-degree block manifests itself, i.e., type I versus type II (Fig. 26-8). On occasion, intranodal blocks are preceded by no discernible change in PR interval and from a surface electrocardiogram may appear as forms of Mobitz type II. The absolute length of the PR interval is usually quite diagnostic in that it is markedly prolonged (i.e., >300 ms), and there is a PR shortening exceeding 100 ms following the block beat (Fig. 26-8). In symptomatic patients with second-degree

AV block, the role of EPS is limited because permanent pacing is the appropriate intervention. On the other hand, if the patient's symptoms cannot be explained on the basis of AV block and may be related to another arrhythmia, such as VT, EPSs should be considered. In patients with third-degree or complete AV block, EPSs are seldom required, and permanent pacing is the obvious option in symptomatic patients.

For EPSs to determine the site of AV block, it is critical to have the catheter across the AV junction that records the His bundle. A discernible His bundle recording enables one to determine the exact site of AV conduction abnormality, i.e., proximal to, within, or distal to the His bundle region. This, in combination with surface electrocardiographic morphology of conducted beats, enables one to identify precisely the location of conduction abnormality. The normal atrial to His bundle activation time (A-H) is approximately 50 to 140 ms, whereas the His to ventricular myocardial depolarization interval (H-V) measures 35 to 55 ms.

If 1:1 AV conduction is noted during EPSs in patients suspected of intermittent AV block, incremental atrial pacing should be done to see whether AV block can be reproduced. AV block in the His-Purkinje system is abnormal during incremental atrial pacing but is a physiologic response during atrial extrastimulation (see Fig. 26-5*A*) or with abrupt acceleration of atrial pacing rate. First- and second-degree blocks in the AV node are considered physiologic responses during incremental atrial pacing or atrial extrastimulation (see Fig. 26-5*B*).

Wide QRS Tachycardia

Wide QRS tachycardia occurs due to a variety of electrophysiologic mechanisms, both from supraventricular and ventricular mechanisms in the presence and absence of accessory pathways (Fig. 26-9).[24] The underlying nature of the wide QRS tachycardia is critical for both prognosis and therapy. EPSs have proven invaluable in distinguishing the various etiologies (Fig. 26-10). With few exceptions, when the nature of the arrhythmic problem is not known and the direction of therapy is not clear, patients with wide QRS tachycardia should undergo EPS. This is particularly true in situations where nonpharmacologic therapy is the desired goal.

Unexplained Syncope

Unexplained syncope is predominantly due to cardiovascular mechanisms. The two most common reasons for cardiovascular syncope are cardiac arrhythmias and neurocardiogenic dysfunction, often referred to as *vasodepressor syncope*.[23-28] Electrophysiologic evaluation constitutes an integral part of the evaluation of patients with unexplained syncope. During such studies, all arrhythmic possibilities such as sinus node dysfunction, AV conduction abnormalities, SVT, and VT should be excluded. Neurocardiogenic mechanisms constitute the most common causes of syncope in patients without structural heart disease, and incomplete assessment of these patients may lead to inappropriate therapy (Fig. 26-11).[22,25] The possibility of neurocardiogenic dysfunction should always be considered in younger patients (<50 years of age) with syncope and documented bradycardia (sinus arrest or AV block) and can be unmasked on a tilt table. The triage of patients toward one or the other, i.e., electrophysiologic testing versus head-up tilt, is fairly simple and predicted by clinical history and the presence or absence of structural heart disease.[25-30] Patients with underlying structural heart disease, such as old myocardial infarction, primary myocardial disease, or poor left ventricular function, generally have underlying VT to explain the symptoms of syncope (Fig. 26-12). When arrhythmias occur in patients without overt structural heart disease, sinus node dysfunction, AV block (particularly intra-Hisian block), or SVTs are likely. Less frequently, VT can occur in the absence of an overt structural heart disease.

Survivors of Sudden Cardiac Death

In most patients with documented episodes of cardiac arrest from the onset, VF can be documented. Patients dying suddenly generally have underlying structural heart disease (usually coronary artery disease or primary myocardial disease) and are prone to VT/VF due to electrical instability. It seems prudent to investigate both the nature and extent of organic heart disease and also to assess vulnerability to recurrent VT/VF. At present, EPS is considered a routine part of the overall patient assessment in this group of individuals.[31,32]

EPSs in survivors of VT/VF are desirable for a variety of reasons. Some are listed here:

1. Not infrequently, the underlying VT leading to cardiac arrest is bundle branch reentry or BBR (Fig. 26-13). Almost 40 percent of patients with monomorphic VT in association with idiopathic dilated cardiomyopathy and valvular heart disease have BBR as the underlying mechanism. This arrhythmia is preferably managed with bundle branch ablation, which is curative, rather than with an implantable cardioverter defibrillator (ICD) alone.

2. Several VT morphologies or other types of tachycardia may be induced in addition to VT. Lack of awareness of such arrhythmias may complicate patient management. For example, the presence of rapid SVT may require separate attention to prevent unnecessary ICD shocks.

3. In some cases, supraventricular arrhythmia may trigger VT/VF. This may happen in patients with severe coronary artery disease, congestive heart failure, Wolff-Parkinson-White syndrome, etc. Elimination of the underlying causes is a more rational therapeutic approach in such cases.

4. Patients with VT/VF often have underlying sick sinus syndrome or AV block, which can be further aggravated with antiarrhythmic drugs and may require permanent pacing. Assessment for this eventuality can be done during the conduct of an EPS and may help selection of a particular device. Because of the increasing flexibility of these devices this need for EPS may be less relevant in the future.

Chapter 26: TECHNIQUES OF ELECTROPHYSIOLOGIC EVALUATION

INVASIVE CARDIAC ELECTROPHYSIOLOGIC STUDIES FOR THERAPEUTIC INTERVENTION

Because of the episodic nature of most cardiac arrhythmias, the efficacy of any therapeutic intervention is difficult to assess unless the arrhythmia in question can be replicated. Diagnostic EPS provides that opportunity, and it seems logical to use the same tool to assess therapeutic interventions.[34-36] This method to assess efficacy can be applied for both pharmacologic and nonpharmacologic therapy.

Pharmacologic Therapy

It is arguable whether the assessment of pharmacologic intervention is essential in patients with relatively benign cardiac arrhythmias. The clinical course can be observed to determine whether control has been achieved. With life-threatening tachycardias, such as VT/VF, or with severe manifestations of cardiac arrhythmias, such as syncope or presyncope, it is desirable to assess efficacy of pharmacologic intervention (Fig. 26-14).[35,36] The technique of drug testing has been developed whereby the elimination of inducibility of a given tachycardia is assessed following a drug administration. Both the drug efficacy or inefficacy can be evaluated by this method. When drug therapy does eliminate induction of a previously inducible tachycardia, the addition of isoproterenol will frequently demonstrate reversal of therapeutic drug effect.[37,38] This is helpful in considering additional beta-blocker therapy. The latter can be accomplished with ease in patients with good left ventricular function, whereas the addition of beta blockers may pose a problem in patients with VT and poor left ventricular function. Failure of serial drug testing is associated with a significant recurrence rate and a strong indication for nonpharmacologic intervention.

Some controversy has arisen regarding the value of EPS for prediction of drug efficacy in comparison to ambulatory monitoring.[39] However, because of the infrequency of spontaneous VT/VF in most patients with life-threatening ventricular arrhythmias, ambulatory monitoring is an impractical approach. At present, serial drug studies with multiple oral antiarrhythmic agents are seldom carried out for SVT or VT.

Nonpharmacologic Therapy

Nonpharmacologic intervention has become an integral part of patient management in cardiac arrhythmias. With documented cardiac arrest from VF, implantation of an automatic ICD is fairly common, and electrophysiologic assessment before such therapy is routine.[40] Both preoperative and postimplant electrophysiologic evaluation can be done through permanent leads of an ICD through a wand and programmer. Pacing, antitachycardia function, low-energy cardioversion, and cardiac defibrillation can all be programmed with newer devices. When problems are encountered following discharge of a patient with an ICD, electrophysiologic reassessment via ICD is frequently necessary, both for reprogramming and for the detection of any unexplained events. For assessment of certain other electrophysiologic parameters (e.g., AV conduction and mechanism of SVTs), however, transvenous catheterization may be necessary.

Patients with coronary artery disease and mappable VT are also candidates for VT surgery when it

cannot be managed with ICD, antiarrhythmic drugs and for catheter ablation.[41-43] Preoperative EPS assessment for this possibility is important. Surgery for VT in the form of endocardial resection or cryoablation can be performed very effectively and relatively safely in patients with a left ventricular ejection fraction greater than 20 percent. This curative procedure provides effective control in approximately 75 percent of the patients who have monomorphic VT that can be appropriately mapped, and it may be considered when other forms of therapies are ineffective.

Surgery for SVT has gone through a significant evolution. The introduction of catheter ablative techniques has made it rare for patients to undergo surgery for Wolff-Parkinson-White syndrome and/or AV nodal reentrant tachycardia. Some individuals with resistant atrial fibrillation and flutter and those who fail catheter ablative therapy may still be considered candidates for such a procedure, but this is now becoming exceedingly less frequent.

Chapter 26: TECHNIQUES OF ELECTROPHYSIOLOGIC EVALUATION

CATHETER ABLATION TECHNIQUES

The realization that the origin of VT and SVT can be effectively mapped has made the catheter ablative technique a rational approach. The radiofrequency form of energy delivered through a catheter has permitted controlled trauma to cardiac tissue to abolish or modify reentrant circuits. This is true for both SVT and VT. Unifocal atrial tachycardia, AV nodal reentry of all varieties, and accessory pathways including atriofascicular fibers can be cured in over 90 percent of patients with radiofrequency catheter ablation. Among the VTs, BBR tachycardia seen in association with dilated cardiomyopathy (both ischemic and nonischemic) and valvular disease is an ideal substrate for catheter ablation. Patients with monomorphic VT associated with myocardial scarring or other substrates can also be considered candidates, particularly when they are not suitable for VT surgery and have failed drug therapy. Additionally, in patients with incessant VT or frequency VT with inadequate control despite ICD therapy, VT ablation should be considered. By using the electromagnetic mapping, the scarred area can be mapped during sinus rhythm and ablation of this substrate can effectively eliminate VT. Noncontact mapping techniques outlined earlier are likely to further help improve ablation success rate with unifocal or possibly multifocal tachycardias.

Chapter 26: TECHNIQUES OF ELECTROPHYSIOLOGIC EVALUATION

IATROGENIC PROBLEMS ENCOUNTERED DURING ELECTROPHYSIOLOGIC STUDIES

Mechanical irritation from catheters during placement and even when not being manipulated can cause a variety of arrhythmias and conduction disturbances.[49] These include induction of atrial, junctional, and ventricular ectopic beats and right bundle branch block and thus AV block in the His-Purkinje system in patients with preexisting left bundle branch block during right ventricular catheterization.[47] Obviously, AV block in the His-Purkinje system can occur in patients with preexisting right bundle branch block during left ventricular catheterization. Ventricular stimulation can also occur from physical movement of the ventricular catheter coincident with atrial contraction, producing electrocardiographic patterns of ventricular preexcitation. Recognition of all these iatrogenic patterns is important for avoiding misinterpretation of electrophysiologic phenomena and the significance of findings in the laboratory.

Certain types of arrhythmias must be avoided at all costs, such as atrial and VF. Atrial fibrillation will obviously not permit study of any other form of SVT, and VF will require prompt cardioversion, making it difficult to continue the EPS. If atrial fibrillation must be initiated for diagnostic purposes (i.e., to assess ventricular response over the accessory pathway in Wolff-Parkinson-White syndrome), it should be done at the end of the study. Patients with a prior history of atrial fibrillation are more prone to the occurrence of sustained atrial fibrillation in the laboratory. Frequently, this will occur during initial placement of catheters, and excessive manipulation of catheters in the atria should therefore be avoided. Catheter trauma resulting in abolition of accessory pathway conduction or reentrant pathway may make the curative ablation difficult or impossible.

Risks and Complications

The complication rate is relatively low when only right heart catheterization is done, with almost negligible mortality.[50,51] Other complications include deep venous thrombosis, pulmonary embolism, infection at catheter sites, systemic infection, pneumothorax, and perforation of a cardiac chamber or coronary sinus. Potentially lethal arrhythmias such as rapid VT or VF are common in the laboratory. These are not necessarily counted as complications, however, but are often expected and anticipated. Nonetheless, their common occurrence makes the electrophysiology laboratory a place for only highly trained personnel equipped to handle such problems.

Chapter 26: TECHNIQUES OF ELECTROPHYSIOLOGIC EVALUATION

List of Figures

Figure 26-6: Induction of supraventricular tachycardia (SVT) in Wolff-Parkinson-White syndrome. The tracings are labeled. Atrial pacing from coronary sinus (CS) is done at a 700-ms basic cycle. During the basic drive pacing, left free wall accessory pathway conduction to the ventricle produces ventricular preexcitation. A single premature beat (S_2) blocks in the accessory pathway (AP) and conducts over the normal pathway with a left bundle branch block morphology, and the SVT is initiated. Note the intermittent normalization of the QRS complex during this SVT. (From Jazayeri et al.[53] Reproduced with permission from the publisher and authors.)

Figure 26-7: Atrioventricular (AV) block in the His-Purkinje system (HPS). *A*. Control. A 1:1 AV conduction is depicted in a patient with unexplained syncope. Following 150 mg of intravenous procainamide (*B*), a second-degree AV block in the HPS is noted (i.e., His bundle potential is not followed by a QRS complex), an abnormal response to a small dose of procainamide suggesting AV block in the HPS as a potential cause of syncope.

Figure 26-8: His bundle (HB) electrograms in atrioventricular (AV) block. The tracings are from three different patients with second-degree AV block. In *A* and *B*, the conducted QRS complexes are wide and associated with bundle branch block. In *A*, the block is within the AV node (i.e., the A wave on the HB is not followed by an HB deflection). In *B*, it can be appreciated that the block is distal to the HB even though the surface electrocardiogram (ECG) demonstrates a Wenckebach phenomenon. The latter can obviously occur in the His-Purkinje system as well, as depicted in this figure. *C*. The site of the block is within the HB. This is suggested by split HB potentials (labeled H and H′), and the block is distal to the H but proximal to the H′. Intra-His block is difficult to diagnose from the surface ECG but can be suspected when a Mobitz type II occurs in association with a normal PR interval and a narrow QRS complex. (From Akhtar.[11] Reproduced with permission from the publisher and author.)

Figure 26-9: Wide QRS tachycardia. Routes of impulse propagation during a wide QRS tachycardia in various settings are depicted. It should be noted that only in *A* and *B* is His bundle activation expected to precede ventricular activation. This helps the delineation from other causes of wide QRS tachycardia shown in *C* and *D*.

Figure 26-10: Wide QRS tachycardia. *A*. Wide QRS complexes of at least two varieties are seen. Those showing a left bundle branch block pattern are due to conduction over an accessory pathway, while those with a right bundle branch pattern are aberrant in nature. Note the His bundle activation prior to both narrow and aberrant complexes but not before preexcited complexes. A right posteroseptal preexcitation can be appreciated in *B*, with a short PR, a delta wave (*d*), an His to ventricle (HV) of zero, and negative delta wave in lead V_1.

Figure 26-11: Asystole in neurocardiogenic syncope. Note the normal heart rate (HR) and blood pressure (BP) in supine position. At the beginning of head-up tilt at 70° (*B*), some degree of tachycardia is noted. Seven minutes after the onset of tilt (*C*), an episode of atrioventricular block occurs and is followed by sinus arrest and a total asystole of 20 s. Syncopal episodes follow. Presyncope is still present when asystole is prevented by atropine (*F*). Findings in *C* might tempt one to prescribe permanent pacing, an inappropriate choice of therapy. In this patient with neurocardiogenic syncope, disopyramide (*G*) prevented hypotension and syncope without the need for a permanent pacemaker. This patient has remained asymptomatic on this therapy for more than 6 years now. (From Sra et al.[22] Reproduced with permission from the publisher and authors.)

Figure 26-12: Arrhythmic causes of syncope. *A*. Sinus rhythm in a patient with unexplained syncope. Sinus bradycardia, bifascicular block, and a long PR interval from surface electrocardiogram suggest possible bradycardia etiology. In this patient, however, ventricular tachycardia (*B*) was inducible with ventricular extrastimulation and was the actual cause of syncope. Control of ventricular tachycardia (VT) without a pacemaker was sufficient to prevent syncope in this patient. Termination of tachycardia and restoration of sinus rhythm are shown in *B*.

Figure 26-13: Induction of sustained ventricular tachycardia due to bundle branch reentry (BBR). The surface electrocardiogram and intracardiac tracings are labeled. Basic cycle length (S_1S_1) is 400 ms during ventricular pacing. Sustained BBR is induced with two extra stimuli (S_2S_3). Note that the His bundle and right bundle (RB) deflections precede the QRS, suggesting supraventricular tachycardia with aberrant conduction. However, there is 2:1 ventricular atrial (VA) block, indicating the ventricular nature of this tachycardia. Without His bundle/right bundle (HB/RB) recordings, the diagnosis can be difficult and, consequently, the likelihood of inappropriate therapy will be high. RB-RB and V-V (ventricular) intervals are labeled. (From Jazayeri et al.[54] Reproduced with permission from the publisher and authors.)

Figure 26-14: *A.* Control. *B.* Post procainamide (PA) + mexiletine. Initiation of sustained monomorphic ventricular tachycardia (VT) of myocardial origin is shown in *A.* After oral procainamide and mexiletine, the sustained VT could not be induced despite using a more aggressive pacing protocol.

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 27:

ANTIARRHYTHMIC DRUGS

Author: Raymond L. Woosley

Antiarrhythmic drugs have been developed with the expectation that they would extend and improve life for many patients with cardiovascular disease and those with a history of life-threatening arrhythmias. Their usefulness, however, has been, limited by ineffectiveness and/or toxicity. In mortality trials, benefit has not been clearly demonstrated, and worsened mortality rates have been observed with several drugs. Care must be taken, therefore, in deciding on the mode of treatment or in fact whether to treat at all. Many antiarrhythmic agents are available today, and more are under development. So many are needed because no agent is completely effective for all patients, and every agent has the potential for inducing serious adverse effects. Drug selection is often empiric. In fact, the side-effect profiles of the available drugs are very different and are often the determining factor in drug selection. Known side effects may completely eliminate the use of certain classes of drugs for a specific patient. Because of the narrow margin between effective and potentially toxic dosages, it is essential that physicians be thoroughly familiar with the clinical pharmacology, dosage, and adverse effects of any of these agents.

The use of antiarrhythmic drugs has been dramatically altered by the findings of the Cardiac Arrhythmia Suppression Trial (CAST).[1] This landmark study was designed to test the hypothesis that suppression of asymptomatic ventricular arrhythmias in patients with recent myocardial infarction would reduce mortality rates due to cardiac arrest and/or arrhythmic sudden death. Prior to the CAST, antiarrhythmic drugs were prescribed for these patients to suppress asymptomatic arrhythmias and thus improve mortality rates. Based on the results of a feasibility and planning trial, the Cardiac Arrhythmia Pilot Study (CAPS), the CAST evaluated encainide, flecainide, and moricizine. These drugs were chosen because they were all tolerated and had reasonable ability to suppress symptomatic ventricular arrhythmias. In April 1989, the CAST was interrupted by the Data Safety and Monitoring Committee, and encainide and flecainide were removed because they had been found to increase mortality rates two- to threefold. The CAST II continued to evaluate the remaining drug, moricizine. However, the CAST II was also terminated prematurely in August 1991 when it became apparent that moricizine was producing a similar trend toward harm, and there was no reasonable chance that a beneficial effect on the mortality rate could be detected.[2] These results shocked the medical community but have influenced thinking in this and many other areas of medicine. Hine et al.[3] reported a meta-analysis of the CAST and similar studies with sodium channel-blocking antiarrhythmic drugs and found overall support for the conclusion of the CAST. The CAST has also led to recommendations by the U.S. Food and Drug Administration (FDA) for more restrictive labeling for all sodium channel-blocking antiarrhythmic drugs. In 1991, these drugs were given class labeling with indications for the treatment of documented ventricular arrhythmias that, in the judgment of the physician, are life threatening. Exceptions among the sodium channel-blocking drugs are quinidine, propafenone, and flecainide, which have an additional indication for supraventricular arrhythmias.

Because of discouraging results with sodium channel-blocking drugs, drugs that prolong the action potential (often termed class III) have been studied. Developers had been encouraged, since one drug with this action, amiodarone, may improve, or at least not worsen, mortality rates in

patients with cardiac disease.[4,5] Dofetilide, ibutilide, and the *d*-isomer of sotalol all prolong the action potential duration and were developed in the hope that they would have the efficacy of amiodarone but lack its propensity to cause serious side effects. However, the first of these drugs to be evaluated in a mortality trial, *d*-sotalol, was found to increase mortality rates after myocardial infarction.[6] Development of *d*-sotalol was halted, but the other two have been marketed with restrictions placed on their indications and/or clinical use. Clearly, antiarrhythmic drugs are the most complex drugs in clinical use today and require care in their use.

CLASSIFICATION OF ANTIARRHYTHMIC DRUGS

Antiarrhythmic drugs are often classified according to their electrophysiologic effects.[7] The scheme most often employed was originally proposed by Vaughan Williams as a classification of drug actions that should be antiarrhythmic, not a classification of drugs.[7] This is a subtle but important distinction that is made for the following reasons:

- Most antiarrhythmic drugs have multiple actions; hence, their pharmacology is more complex than indicated by a simple drug classification scheme.
- The actions of a given drug differ in different cardiac tissues.
- Many antiarrhythmic agents have pharmacologically active metabolites whose activity may be quite different from and in a class other than that of the parent compound.
- The relative amounts of these metabolites produced are genetically determined for several of these drugs and often vary extensively within the population.

Drugs having class I action possess "local anesthetic," or "membrane-stabilizing," activity. Their predominant action is to block the fast inward sodium channel. This produces a decrease in the maximum depolarization rate, $_{max}$, of the action potential (phase 0) and slows intracardiac conduction. These agents have been further subclassified as belonging to class IA, IB, or IC on the basis of their effects on specific aspects of intracardiac conduction and refractoriness.[8] Drugs having class IA action include quinidine, procainamide, and disopyramide. These agents also produce measurable increases in ventricular refractoriness and prolongation of the QT interval. Lidocaine, mexiletine, and tocainide have actions belonging to class IB. Their potency for blocking sodium channels is only moderate, and in isolated tissues they shorten the action potential duration (APD) and refractoriness. They generally exert little effect on PR, QRS, or QT intervals. Drugs with class IC actions are the more potent agents: flecainide and propafenone. Because these are potent sodium channel inhibitors, slowing conduction velocity while having little effect on repolarization, they increase the PR and QRS intervals but cause little change in QT.

Class II action refers to beta-adrenergic antagonism, possessed by agents such as propranolol, timolol, and metoprolol. While these drugs are effective for treatment of supraventricular arrhythmias and tachyarrhythmias secondary to excessive sympathetic activity, they are not very effective in the treatment of severe arrhythmias, such as recurrent ventricular tachycardia. Although the mechanism is unknown, they are the only antiarrhythmic drugs found clearly effective in preventing sudden cardiac death in patients with prior myocardial infarction.

Drugs whose predominant effect is to prolong the duration of the cardiac action potential and refractoriness have class III action. These drugs include amiodarone, sotalol, bretylium, ibutilide, dofetilide, and *N*-acetylprocainamide (NAPA), the major metabolite of procainamide.

Class IV action is calcium channel antagonism. Antiarrhythmic drugs with this action include verapamil, bepridil, diltiazem, and nifedipine.

Because of the many limitations of the Vaughan Williams classification of antiarrhythmic drugs, a new approach has been proposed,[9] termed the Sicilian gambit. This classification system is based

on the differential effects of antiarrhythmic drugs on (1) channels, (2) receptors, and (3) transmembrane pumps. The grouping is based primarily on the predominant action of drugs but also considers the other ancillary actions that may be clinically relevant. As shown in Fig. 27-1, because of the sequence of drugs listed, the symbols for these primary actions are generally aligned diagonally. For example, in this system quinidine is a sodium channel antagonist with potassium channel- and alpha-blocking activity. This provides a more complete and accurate description of the pharmacologic actions of the drugs than simply designating it class IA. When combined with an understanding of the electrophysiologic role of these actions, one can predict the effects likely to occur in vivo. In this case one would expect conduction slowing, increased APD (and refractoriness), and vasodilation to result from these three actions of quinidine.

The Sicilian gambit also creates a framework in which newly discovered actions of drugs can be readily added. It emphasizes the multiple actions of drugs and the subtle differences and similarities that exist, and is more complete. At present, our understanding of the pharmacology of these drugs has progressed to the point that oversimplification can be misleading. The increased detail of the new system reflects the current state of our knowledge at a level necessary for optimal use of these drugs.

Due to the low efficacy of any one agent, the treatment of acute or chronic ventricular arrhythmias frequently necessitates the use of multiple drugs, sequentially or in combination. One may produce increased sodium channel blockade and, it is hoped, increase drug efficacy by using combinations of drugs with different kinetics of interaction with the sodium channel. Basic to these considerations is an understanding of the regulation of sodium channel function. Hodgkin and Huxley[10] proposed that sodium channels exist in three distinct states: open, closed, and inactivated. According to the modulated receptor theory of cardiac sodium channel regulation proposed by Hille and by Hondeghem and Katzung,[11] sodium channels in each of these states have differing affinities for a given local anesthetic drug (Fig. 27-2).

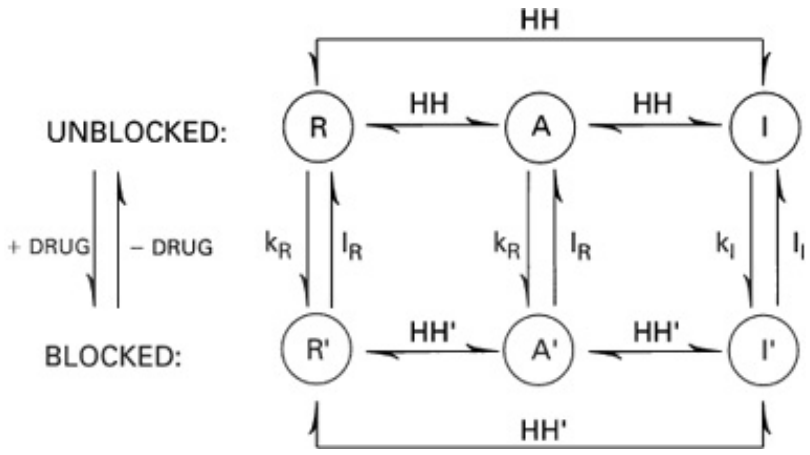

Figure 27-2: Diagram of the modulated receptor mechanism for antiarrhythmic drug action. The three fractions of the sodium channel population proposed by Hodgkin and Huxley are represented in the upper part of the figure in the drug-free condition and in the lower part of the figure blocked by an antiarrhythmic agent (R′, A′, and I′, respectively). HH, standard Hodgkin-Huxley rate constants; HH′, HH with voltage dependence altered by drug binding; k_R, k_A, and k_I, association rate constants; I_R, I_A, and I_I, dissociation rate constants for the respective channel fractions. (From Hondeghem and Katzung,[11] reproduced with permission from the authors and the American Heart Association.)

The theory also provides a potential explanation for the phenomenon of "frequency," or "use,"

dependence. Use dependence is the increase in conduction block observed at an increasing rate of stimulation in response to sodium channel-blocking antiarrhythmic agents. Since an increase in the rate of stimulation increases the number of sodium channels in the open and inactivated states, antiarrhythmic agents having greater affinity for activated (open) or inactivated channels (as opposed to rested channels) would have a greater opportunity to bind to the receptor and slow conduction. Therefore, greater block will occur during tachycardia, leaving less drug action at normal heart rates. Also, antiarrhythmic drugs have different affinities for the different states of the sodium channel, and this is manifested as different rates for onset or recovery from block. Drugs that slowly associate with the receptor will cause block to accumulate over the first few cardiac cycles, such as shown for procainamide in Fig. 27-3. Drugs that associate more rapidly, such as lidocaine, produce little additional block after the first beat in a train of stimuli. This effect is compared to that of procainamide in Fig. 27-3. Likewise, drugs dissociate from the sodium channel at different rates, leading to differences in rates of recovery from block. The rate of onset of block of sodium channels has been proposed as a means of subclassifying antiarrhythmic drugs.[12] This is the electrophysiologic correlate of the subclassification of sodium channel blockers proposed by Harrison that was based on differences in clinical effects of the drugs.[8]

This chapter reviews the clinical pharmacology and applications of the currently available antiarrhythmic drugs, excluding digoxin, beta-receptor antagonists, and calcium channel blockers, which are addressed in other chapters. The drugs reappear in the same order as listed in Fig. 27-1, an updated revision of the Sicilian gambit classification. The pharmacokinetics, usual dosages, and ranges of plasma concentration for the major drugs are listed in Tables 27-1 and 27-2.

Chapter 27: ANTIARRHYTHMIC DRUGS

DRUGS

Lidocaine (Xylocaine)

CLINICAL APPLICATIONS

Lidocaine, introduced as a local anesthetic, was first used as an antiarrhythmic agent in the 1950s for the treatment of arrhythmias arising during cardiac catheterization.[13] It is still the most widely used intravenous antiarrhythmic drug. Since extensive first-pass metabolism makes it unsatisfactory for oral use, congeners such as mexiletine were developed that would possess similar sodium channel-blocking actions and be active when taken orally.

Lidocaine is very often the drug of first choice for the acute suppression of ventricular arrhythmias. Although such therapy does not reduce total mortality rates, it is effective in decreasing the incidence of primary ventricular fibrillation in patients with documented acute myocardial infarction.[14,15] Because of the complex pharmacokinetics of lidocaine, a monitored environment is desirable to permit evaluation of the patient's response and detection of toxicity.

Lidocaine has little effect on atrial tissue in vitro,[16] consistent with the clinical observation that it has no value in treating supraventricular tachyarrhythmias. Although lidocaine has been used to decrease the ventricular response during atrial fibrillation in patients whose atrioventricular (AV) conduction follows an accessory pathway,[17] some workers have reported accelerated conduction,[18] and other drugs, such as procainamide, are preferred in this situation.

MECHANISM OF ACTION

In concentrations similar to those attained during clinical use, lidocaine reduces $_{max}$ and produces shortening or no change in APD and the effective refractory period of normal Purkinje fibers. This contrasts with quinidine and procainamide, which additionally block potassium channels and produce lengthening of APD.[19,20] Lidocaine has little effect on the electrophysiology of the normal conduction system, but in patients with conduction system abnormalities, it has produced variable effects. Some studies have failed to detect significant changes in conduction,[21,22] while others have found slowing of ventricular rate or potentiation of infranodal block in patients with conduction system defects.[23,24] Variability in dosage and pharmacokinetics may explain some of these discrepancies.

CLINICAL PHARMACOLOGY

Orally administered lidocaine is well absorbed, but it has poor oral bioavailability because it undergoes extensive first-pass hepatic metabolism. Lidocaine clearance is well approximated by measurement of liver blood flow.[25,26] The two desethyl metabolites, which are excreted by the kidneys, have less antiarrhythmic potency than the parent drug and may contribute to the production of central nervous system side effects occurring with lidocaine.[27,28] Following intravenous administration, lidocaine's biphasic disposition is well represented by a two-compartment pharmacokinetic model.[29] Since antiarrhythmic activity is correlated with lidocaine's concentration in the central compartment and the half-life of distribution out of this

compartment is rapid (8 min), regimens employing a series of multiple loading doses and a maintenance infusion should be used to achieve and then maintain a therapeutic concentration in plasma and myocardial tissue.

Regardless of the initial regimen employed, during prolonged constant infusion the lidocaine concentration eventually reaches steady state, dependent only on the drug infusion rate and clearance of lidocaine. The time required to reach steady-state conditions is approximately 8 to 10 h in normal individuals and up to 20 to 24 h in some patients with heart failure and/or liver disease. This is longer than often anticipated because of the failure to recognize the relatively long elimination half-life (1.5 to 2 h in normal subjects and longer in patients with heart failure or hepatic disease).

DOSAGE AND ADMINISTRATION

The primary use of lidocaine is for acute rapid suppression of highly symptomatic ventricular arrhythmias. Single intravenous boluses will achieve only transient therapeutic effects because the drug is rapidly distributed out of the plasma and myocardium; therefore, multiple loading doses should be used in order to achieve more sustained therapeutic plasma levels of lidocaine rapidly. Based on pharmacokinetic models validated in clinical studies, several regimens have been designed to maintain a relatively constant therapeutic level. For a stable patient, a total loading dose of lidocaine should be approximately 3 to 4 mg/kg body weight administered over 20 to 30 min. After injection of an initial dose of 1 mg/kg over 2 min, a series of three loading boluses can be administered slowly (approximately 50 mg each over 2 min) 8 to 10 min apart, while the patient is continuously observed for the development of side effects. Loading should be stopped should the transient, usually mild, central nervous system side effects persist or serious unwanted effects occur.

Another effective and well-tolerated loading regimen was suggested by Wyman et al.[30] For a 75-kg person, an initial bolus of 75 mg is recommended, followed by 50 mg every 5 min repeated three times to a total dose of 225 mg. This regimen usually achieves and maintains plasma concentrations within usual therapeutic guidelines (1.5 to 5 μg/mL). A priming dose of 75 mg followed by a loading infusion of 150 mg over 18 min has also been used successfully.[31] At the time of initiation of the loading regimen, a maintenance infusion, designed to replace ongoing losses due to drug elimination, should be started. This may be calculated as the product of the desired plasma concentration (about 3 μg/mL) and the expected clearance. This calculation usually yields a dosage in the range of 20 to 60 μg/kg of body weight per minute.

Even in normal individuals, there is great variability in the peak plasma concentration and, consequently, in the calculated size of the central compartment for lidocaine. Therefore, during loading, the patient's electrocardiogram (ECG), blood pressure, and mental status should be monitored; the process should be stopped at the first sign of lidocaine excess. When symptomatic arrhythmias persist in the presence of documented adequate dosage, defined by side effects or plasma concentration in excess of 5 to 7 μg/mL, another agent should be used.

If the maintenance infusion has reached steady state but the concentration is below the level needed to prevent recurrence and the arrhythmia reappears while side effects are absent, the appropriate actions are as follows: (1) obtain a plasma sample for measurement of lidocaine concentration for future reference, (2) administer a small bolus of lidocaine (25 to 50 mg over 2 min), and (3) increase the maintenance infusion rate proportionally. The plasma concentration can be used to estimate clearance for calculation of the final maintenance infusion (i.e., maintenance dosage = clearance × desired plasma concentration, and clearance = infusion rate ÷ plasma concentration measured at steady state). Little therapeutic effect is evident at lidocaine plasma concentrations below 1.5 μg/mL, while the risk of toxicity increases above 5 μg/mL. In some patients, however, concentrations in the range of 5 to 9 μg/mL may be required for arrhythmia

suppression and can safely be achieved with cautious drug administration.[32]

Once steady-state conditions have been achieved, simply terminating a lidocaine infusion will result in a gradual decline in plasma levels over the next 8 to 10 h as elimination occurs. Not only is there no reason to taper lidocaine infusions, but it may be dangerous if oral antiarrhythmic therapy is initiated too early, since unpredictable additive effects may occur between lidocaine and newly started oral therapy. If a patient has reached steady-state equilibrium, it is possible to estimate when the plasma lidocaine concentration will fall below usually therapeutic levels. The plasma lidocaine concentration should be determined at the time the infusion is terminated, and the number of half-lives needed for that level to reach approximately 1.5 μg/mL can be estimated. The half-life of lidocaine for an individual patient can be estimated from the following equation: $t_{1/2}$ = plasma concentration × V_D × 0.693/infusion rate, where V_D is the final volume of distribution.

The measured plasma concentration and the infusion rate are known components of the equation. V_D is usually 1.1 L/kg but may be reduced by 50 percent or more in patients with heart failure.

MODIFICATION OF DOSAGE IN DISEASE STATES

Initial loading regimens require no adjustment in patients with renal or liver disease[29]; however, maintenance infusions must be decreased in liver disease and heart failure to compensate for decreased clearance. Since clearance alone is altered in liver disease, with little change in the volume of distribution, the half-life of elimination is prolonged greatly (as much as 5 h), and steady-state conditions may not be achieved until 20 to 25 h following the institution of an intravenous infusion. Despite the fact that lidocaine metabolites are excreted by the kidneys, renal disease has not been reported to exert any significant effect on lidocaine dosing regimens. With mechanical ventilation, there is often a decrease in cardiac output and hepatic blood flow, and a decrease in lidocaine dosage may be required.[33] Patients with congestive heart failure achieve lidocaine levels that are almost double those in normal individuals given the same dose.[29] Since the central volume of distribution is generally halved in heart failure, loading doses should be reduced by 50 percent; since clearance is also approximately halved, maintenance doses should be reduced proportionately from an infusion rate of 30 μg/kg body weight per minute used for usual patients to about half that figure. The time required to achieve steady-state conditions following the institution of a maintenance infusion is still 8 to 10 h in many patients with heart failure because of concomitant changes in V_D and clearance, resulting in a half-life similar to that seen in patients without heart failure.

In summary, general recommendations for initial lidocaine dosage selection should be adjusted for each patient based on clinical presentation, clinical response, and the results of plasma level monitoring. Some patients with congestive heart failure may experience toxicity when given an infusion as low as 0.5 mg/mL; thus, blood level monitoring is essential for proper dosage adjustment. In postmyocardial infarction patients receiving lidocaine infusions for more than 24 h, plasma lidocaine levels can increase, and the elimination phase half-life can increase up to 50 percent.[34] This increase is due, in part, to changes occurring in protein binding of lidocaine during the first few days of therapy. Assays for plasma lidocaine measure the sum of both protein-bound and free lidocaine as total lidocaine and thus do not give a true picture of the amount of free drug available. An increase in plasma lidocaine occurring at this time often reflects an elevation in plasma levels of alpha-1-acid glycoprotein (AAG), to which it binds,[35] and does not always indicate an increase in free, active drug. In this case, the lidocaine dosage should not be reduced to compensate for the higher total plasma concentration as long as the patient displays no adverse effects. Subsequent decreases in AAG concentrations will result in an apparent decrease in plasma lidocaine, which may reflect a drop in only that fraction bound to AAG.

ADVERSE REACTIONS

Central nervous system symptoms are the most frequent side effects of lidocaine administration. A rapid bolus can induce tinnitus or seizures. With more gradual attainment of excessive levels, drowsiness, dysarthria, confusion, hallucinations, and dysesthesia may occur. Excessive lidocaine can also cause coma, which should be a consideration in patients after cardiac arrest. Lidocaine can depress cardiac function, which decreases its clearance, and produces an even greater increase in lidocaine concentrations. Advanced degrees of sinus node dysfunction have been reported in isolated instances.[36,37] In patients with known conduction abnormalities below the AV node, lidocaine should be administered cautiously, if at all, unless a temporary pacemaker is readily available.

DRUG INTERACTIONS

An additive or synergistic depression of myocardial function or conduction may occur when using lidocaine combined with other antiarrhythmic agents,[38] especially during conversion from lidocaine to another antiarrhythmic agent. A pharmacokinetic drug interaction between propranolol and lidocaine has been described experimentally and in humans in which beta-adrenergic blockade caused decreases in cardiac output and liver blood flow, with a resultant decreased lidocaine clearance.[39] Cimetidine has been reported to decrease lidocaine's volume of distribution, decrease splanchnic (and hence liver) blood flow, and inhibit the enzymes responsible for lidocaine metabolism. This may raise lidocaine plasma concentrations, and both loading and maintenance dosages may require downward adjustment in patients receiving cimetidine.[40]

Mexiletine (Mexitil)

CLINICAL APPLICATIONS

Mexiletine is used in the treatment of ventricular arrhythmias and has, on occasion, been effective in treating arrhythmias that were refractory to other agents. Success rates vary between 6 and 60 percent, and more than half of the studies suggest limited efficacy (less than 20 percent).[41] Mexiletine does not prolong the QT interval and therefore can be useful for patients with a history of drug-induced torsades de pointes or long-QT syndrome when quinidine, sotalol, procainamide, or disopyramide are contraindicated. While the rate of response to mexiletine when used alone is low, it has been combined successfully with quinidine,[42] propranolol,[43] or procainamide.[44] This mode of therapy takes advantage of the additive, and perhaps synergistic, antiarrhythmic response produced by the combination of these agents. Since lower than usual dosages of both agents can be used, dosage-related adverse effects are reduced concomitantly. Mexiletine exerts minimal effects on both hemodynamics and myocardial contractility, even in patients with severe congestive heart failure.[45]

MECHANISM OF ACTION

Mexiletine is an orally active lidocaine congener with class IB sodium channel-blocking activity and structural similarity to tocainide. It was originally developed as an anorexiant and anticonvulsant agent, and its antiarrhythmic properties were only later recognized. Mexiletine blocks fast sodium channels, decreasing $_{max}$ and shortening the repolarization phase of ventricular myocardium.[46]

CLINICAL PHARMACOLOGY

The systemic bioavailability of mexiletine approximates 90 percent,[47] with a large volume of

distribution (5.5 to 9.5 L/kg), reflecting extensive tissue uptake. About 1 percent of total body content of mexiletine is in the plasma compartment, with approximately 70 percent of this bound to serum proteins. Mexiletine has little first-pass metabolism but is eliminated primarily by hepatic metabolism, with only 10 to 15 percent being excreted unchanged in the urine. Its half-life of elimination is between 8 and 20 h (9 and 12 h for healthy subjects), with the time needed to reach steady state ranging between 1 and 3 days.[48] Mexiletine undergoes extensive hepatic metabolism by cytochrome P450 2D6 (CYP2D6),[49,50] and, consequently, clearance is extremely variable (see below).[51]

DOSAGE AND ADMINISTRATION

Mexiletine therapy should be initiated with a low dosage, which is increased at 2- to 3-day intervals until efficacy or intolerable side effects, such as tremor or other central nervous system symptoms, develop. With normal renal function, the recommended initial oral mexiletine dosage is 200 mg every 8 h. As with most drugs having extensive liver metabolism, clearance will be widely variable within the population. This is especially true for mexiletine because CYP2D6, responsible for its metabolism, is absent in 7 percent of the Caucasian population. Also, consideration of dosage adjustment to compensate for the action of agents (discussed below) that induce or inhibit hepatic mexiletine metabolism is required.

MODIFICATION OF DOSAGE IN DISEASE STATES

Patients with renal failure who also inherit a deficiency of hepatic CYP2D6 are likely to have extremely slow elimination for mexiletine,[52] and for this reason, all renal failure patients should be given low initial doses. Elimination half-life and clearance may be prolonged by overt congestive heart failure[53] and hepatic failure,[54] and dosage reduction is required.

ADVERSE REACTIONS

Adverse reactions to mexiletine are dose-related and neurologic and include tremor, visual blurring, dizziness, dysphoria, and nausea. Thrombocytopenia has been reported to occur infrequently with mexiletine therapy,[55,56] and a positive antinuclear antibody test result occurs rarely. Severe bradycardia and abnormal prolongation of sinus node recovery time have been reported in patients with the sick-sinus syndrome,[57] and, at high concentrations, worsening of heart block has been reported.[58] Oral mexiletine does not depress ventricular function or induce increased heart failure,[59] although intravenous mexiletine, which is not available in the United States, has been noted to increase congestive heart failure.[60]

DRUG INTERACTIONS

The hepatic metabolism of mexiletine can be increased by phenobarbital, phenytoin (Dilantin), or rifampicin, which reduce the half-life of mexiletine, possibly changing an effective dose to an ineffective one.[41,48,61] Conversely, if treatment with an inducing agent is stopped, an effective dose may become toxic.

In one study, mexiletine decreased the clearance and increased the plasma concentrations of theophylline.[62] Quinidine inhibits the CYP2D6 enzyme primarily responsible for the metabolic clearance of mexiletine, and plasma concentration of mexiletine may increase in those individuals who express the enzyme (93 percent of Caucasians).

Procainamide (Pronestyl-SR, Procan-SR)

CLINICAL APPLICATIONS

Procainamide, like quinidine, is effective against both supraventricular and ventricular arrhythmias.[63] Although the two drugs have similar electrophysiologic effects, they are clinically different, and one agent may be effective for a patient when the other is not. Procainamide is useful in acute management of patients with reentrant supraventricular tachycardia and atrial fibrillation and flutter associated with Wolff-Parkinson-White syndrome.[64]

Although lidocaine is more often used, procainamide is also used intravenously to suppress ventricular arrhythmias occurring immediatiely following myocardial infarction or to convert sustained ventricular tachycardia. Since it takes approximately 20 min to administer a loading dose of procainamide safely, its use is limited to those situations where adequate time is available. Its advantage over lidocaine is the potential for conversion to oral therapy using the same agent. Lidocaine is usually used, however, because the initial loading dose can be given within a 2- to 5-min period.

The active metabolite of procainamide, *N*-acetylprocainamide (acecainide or NAPA), produces class III antiarrhythmic activity in some patients, although not always those who respond to procainamide.[65] This is most likely due to the very different electrophysiologic actions of procainamide and NAPA.[66] NAPA was investigated as an antiarrhythmic drug and was shown to be effective in the treatment of ventricular arrhythmias, but since its use was limited by a narrow therapeutic index, development was halted.[65]

The development of procainamide as an antiarrhythmic agent resulted from a systematic search for a useful congener of procaine, whose use was precluded by adverse reactions.[67] Since procainamide is an effective agent but is not without adverse effects, it has served as a prototype for development of several of the newer antiarrhythmic agents.

MECHANISM OF ACTION

Like other agents demonstrating class I activity, procainamide slows conduction and decreases automaticity and excitability of atrial and ventricular myocardium and Purkinje fibers.[68] Because of its effect on potassium channels, it also prolongs APD and refractoriness. Compared to quinidine, procainamide has very little vagolytic activity and does not prolong the QT interval to as great an extent.[63] NAPA has predominantly class III antiarrhythmic activity; it prolongs APD and refractoriness in both atrial and ventricular myocardium and prolongs the QT interval.[69,70] It has little or no effect on $_{max}$ in either Purkinje fibers or ventricular cells and does not alter His-Purkinje conduction velocity because of its very low potency as a sodium channel antagonist.

CLINICAL PHARMACOLOGY

Procainamide is rapidly absorbed and 100 percent orally bioavailable. About 15 percent of procainamide is bound to serum proteins. Its short half-life of elimination, 2 to 4 h in patients with normal renal function, necessitates dosing every 3 to 6 h. Dosing every 6, 8, or 12 h is possible with sustained-release preparations, and the frequency depends upon the formulation. The varied formulations and their very different dosing requirements often create confusion and can lead to dangerous mistakes in dosing.

Slightly more than half of the general population are phenotypically rapid acetylators of procainamide and quickly convert it to NAPA, a metabolite with very pure class III antiarrhythmic action.[65] As would be expected, however, the response to one agent does not predict response to the other. When each is given as the sole agent, the usually effective plasma concentration is 4 to 8 μg/mL for procainamide and 7 to 15 μg/mL for NAPA.[65] During oral

procainamide therapy, both agents are present in variable amounts, and there is no way to determine readily the contribution of NAPA to arrhythmia suppression under these conditions. Consequently, the utility of measuring plasma levels of procainamide during chronic therapy is limited because of this variable hepatic conversion to NAPA. Monitoring plasma concentrations for determination of compliance or prevention of toxicity is feasible and recommended (see below).

DOSAGE AND ADMINISTRATION

Procainamide is available for either intravenous or oral use. With normal renal and cardiac function, the initial recommended oral maintenance dose is 50 mg/kg per day. Frequent administration is required for oral procainamide, which is inconvenient and makes compliance difficult. Sustained-release forms of procainamide are available, which permits dosing every 6, 8, or 12 h, depending upon the formulation. During chronic therapy, levels of NAPA may accumulate to effective or toxic levels in some individuals, resulting in achievement of maximum pharmacologic effect long after the time procainamide has reached steady state.[65,71] Therefore, the elimination half-life of 2 to 4 h for procainamide may be misleading as a predictor of time to the occurrence of stable pharmacologic action. Thus, dosage should be initiated at conservative levels, and the patient should be monitored carefully until both procainamide and its metabolite have reached steady state. Patients with ventricular tachycardia may need higher dosages[65] for prevention of arrhythmia induction by programmed stimulation,[72] although such dosages often lead to adverse effects. Since the electrophysiologic effects of procainamide and NAPA are quite different, monitoring of patients receiving procainamide should at some point include measurement of plasma concentrations of both agents to determine their relative concentrations. Patients who are rapid acetylators or who have impaired renal function usually have plasma concentrations of NAPA higher than those of procainamide at steady state. These individuals should be monitored for excessive accumulation of NAPA during dose titration to maintain plasma levels of NAPA below 20 μg/mL. The practice of using the sum of the plasma concentration of procainamide and NAPA is not recommended.

When administered intravenously, procainamide can be given as a constant 25-min loading infusion of 275 μg/min per kilogram of body weight or by a series of doses (100 mg delivered over 3 min) given every 5 min, up to a total dose of 1 g.[73,74] If the loading infusion is well tolerated with no hypotension and less than 25 percent QRS or QT widening, a maintenance intravenous infusion of 20 to 60 μg/kg per minute can then be given. Larger and more rapid loading infusions of 1 g over 15 to 20 min have been given in the electrophysiology laboratory to prevent induction of ventricular tachycardia by programmed ventricular stimulation. A second loading infusion of 0.5 to 1 g has been given in some instances where an initial loading infusion was well tolerated but ineffective. These large dosages are accompanied by a higher incidence of hypotension and conduction disturbance and often result in attainment of unacceptably high plasma concentration.

MODIFICATION OF DOSAGE IN DISEASE STATES

With renal dysfunction or a low cardiac output, both procainamide and NAPA in usual doses may accumulate to potentially toxic levels, and the dose should be reduced.[75] Increased plasma levels of procainamide and/or NAPA may occur with congestive heart failure because of decreased urinary excretion and hydrolysis of procainamide.[76] On the other hand, one study of procainamide pharmacokinetics following a single intravenous bolus revealed no difference in volume of distribution, clearance, elimination half-life, unbound drug fraction, and peak procainamide concentrations between patients with congestive heart failure and normal individuals.[77] Although intravenous procainamide does depress myocardial contractility and lower blood pressure, worsening of heart failure is uncommon during oral therapy when the usual dosages and plasma

concentrations are maintained.

ADVERSE REACTIONS

Side effects associated with long-term procainamide therapy limit its usefulness. Up to 40 percent of patients discontinue therapy in the first 6 months due to adverse reactions. The potential exists for arrhythmia aggravation, including the development of torsades de pointes due to procainamide or, more often, NAPA.[78] Therefore, just as with all agents possessing class IA activity, procainamide should not be used in patients with a long-QT syndrome, a history of torsades de pointes, or hypokalemia.[79] In order to reduce the occurrence of proarrhythmia, potassium levels should be maintained above 4 meq/L when taking procainamide. Heart block and sinus node dysfunction can occur in patients with preexisting conduction system abnormalities.[80]

Between 15 and 20 percent of patients receiving chronic oral procainamide therapy develop a lupus-like syndrome, which is often difficult to recognize but regresses with discontinuation of treatment. The syndrome usually begins insidiously as mild arthralgia but progresses to frank arthritis, fever, malar erythematous rash, and pleural and/or pericardial effusions, with serum antibodies against nucleoprotein (histone) appearing as antinuclear antibodies with a "smooth" or "diffuse" pattern. These symptoms abate if procainamide is discontinued and generally resolve at a rate proportional to their duration.

Almost all patients treated chronically develop detectable antinuclear antibodies, but only 15 to 20 percent develop symptoms of the lupus syndrome. Therefore, it is unnecessary to discontinue therapy solely because of the positive antinuclear antibody titer. The patient should be fully informed of the symptoms, which should be reported, so that therapy can be discontinued at the earliest symptoms or signs of the lupus syndrome. Continuing procainamide after the development of the early symptoms of the lupus syndrome is dangerous because of the above-noted possibility of pleural effusion and potentially lethal pericardial tamponade.[81]

More recently, procainamide therapy has been associated with the development of agranulocytosis. It has been suggested, but not proven, that the sustained-release form of the drug may be especially capable of inducing this toxicity.[82] The manufacturer recommends that a white blood count be obtained every 2 weeks for the first 3 months.

DRUG INTERACTIONS

Unlike quinidine, procainamide does not cause an increase in digoxin levels. There are few reports of interactions between procainamide and other drugs. Its clearance is reduced between 30 and 50 percent by cimetidine, which blocks the renal tubular secretion of procainamide.[83,84] A similar competition has been found between procainamide and its predominant metabolite, NAPA.[85] Ranitidine affects procainamide pharmacokinetics by reducing both its renal clearance and its absorption, the former by 14 to 23 percent and the latter by 10 to 24 percent, depending on the dose.[86]

Disopyramide (Norpace)

CLINICAL APPLICATIONS

Disopyramide is effective against a broad range of supraventricular and ventricular arrhythmias, its antiarrhythmic profile being similar to that of quinidine and procainamide. Disopyramide, in contrast to quinidine and procainamide, is better suited for long-term therapy, having relatively little associated chronic toxicity. While newer than quinidine or procainamide, disopyramide is still one of the older antiarrhythmic agents, having been in use in the United States since 1977. Its

negative inotropic and anticholinergic actions occur frequently and limit its usefulness.

MECHANISMS OF ACTION

The class IA antiarrhythmic effects of disopyramide are predominantly those associated with sodium and potassium channel blockade. Its effects are similar to those of quinidine and procainamide on automaticity, conduction, and refractoriness in atrial and ventricular tissue.[87]

CLINICAL PHARMACOLOGY

The oral bioavailability of disopyramide is 80 to 90 percent.[88] Its half-life of elimination, usually 6 to 8 h, is lengthened to as much as 15 h in cardiac patients.[89] About half of the compound is eliminated by the kidneys unchanged, and the remainder as an active metabolite resulting from hepatic *N*-dealkylation.[90] Protein binding of disopyramide is complex, with between 20 and 50 percent of disopyramide being bound to plasma proteins. For most drugs, the percentage bound to plasma protein is a constant over the usual range of therapeutic concentrations. The saturation of disopyramide-binding sites on plasma proteins at usual doses means that there are disproportionate increases in levels of free drug in plasma compared to the magnitude of dosage increment.[91]

DOSAGE AND ADMINISTRATION

Loading doses are not recommended with disopyramide. The usually effective dosage for disopyramide is 100 to 400 mg three to four times daily, to a maximal dose of 800 mg/day. Therapy should be very carefully titrated, beginning with low doses and allowing ample time for achievement of steady-state equilibrium.

While rapid fluctuations in plasma concentration are undesirable, they are difficult to avoid because of disopyramide's saturable protein binding. The controlled-release form of disopyramide may be useful in reducing adverse effects by decreasing fluctuations in the concentration of free disopyramide in plasma.[92] Because of saturable protein binding,[16] the generally accepted therapeutic range for total disopyramide in plasma, 2 to 5 μg/mL, should not be strictly relied on. While monitoring the plasma concentrations of free disopyramide has been recommended,[93] the range of concentrations associated with arrhythmia suppression has not been clearly delineated and overlaps with that causing adverse effects.

MODIFICATION OF DOSAGE IN DISEASE STATES

The patient's response to disopyramide should be monitored especially closely following acute myocardial infarction because both the absorption and elimination of disopyramide are decreased at this time.[94] In fact, in view of the negative inotropic actions of disopyramide and changes in levels of binding proteins in plasma following a myocardial infarction, other antiarrhythmic agents should be considered first.

Disopyramide is contraindicated in patients with uncompensated heart failure because it can worsen failure.[95] The initial dosage of disopyramide should be reduced to 50 to 100 mg every 12 h in patients with renal insufficiency[96] or decreased hepatic function.[97]

ADVERSE REACTIONS

The predominant side effects of disopyramide include new or worsened congestive heart failure and symptoms resulting from dose-related anticholinergic actions, including urinary retention, constipation, dry mouth, and esophageal reflux. Because of this anticholinergic action, patients

with obstructive uropathy or glaucoma should not receive this agent.[98] For some patients, the anticholinergic side effects can be prevented or alleviated by concomitant use of cholinesterase inhibitors, such as physostigmine and neostigmine, without reduction in antiarrhythmic efficacy.[99] As with all agents that prolong repolarization, disopyramide should not be used in patients with long-QT syndrome, hypokalemia, or a history of torsades de pointes[100] because of the potential for arrhythmia aggravation. Direct actions of disopyramide on the sinus node can lead to excessive bradycardia in patients with sinus nodal dysfunction,[101] and this may contribute to development of torsades de pointes in patients with hypokalemia.[102]

DRUG INTERACTIONS

Disopyramide does not increase digoxin levels,[103] and the effects of warfarin are not potentiated by disopyramide.[104] Phenytoin, rifampicin, and phenobarbital induce hepatic metabolism of disopyramide, thus increasing its elimination and potentially leading to loss of antiarrhythmic effect.[105] Significant depression of myocardial contractility may result from the combined administration of disopyramide with beta-adrenergic or calcium channel antagonists and should be avoided in patients with impairment of ventricular function.[106]

Quinidine (Quinaglute, Quinadex, Others)

CLINICAL APPLICATIONS

Quinidine has been used successfully for a variety of supraventricular and ventricular arrhythmias, including conversion of atrial fibrillation or flutter,[107,108] supraventricular tachycardia,[107,108] ventricular extrasystoles,[109] and ventricular tachycardia and fibrillation.[110,111] Digitalis is used in the treatment of atrial fibrillation, atrial flutter, and other arrhythmias. This important drug is discussed in Chap. 23.

A grouped analysis of six small placebo-controlled trials in patients with atrial fibrillation showed a statistically significant increase in mortality rate for the patients treated with quinidine.[112] Because of the similar negative effects on mortality rate seen in the CAST and CAST II, one must assume that the results of this meta-analysis are valid until a definitive prospective study is available.

MECHANISM OF ACTION

Quinidine has multiple actions, but the action thought by many to be primarily responsible for its efficacy is block of the rapid inward sodium channel. This results in a decrease in $_{max}$ of the action potential upstroke and slowed conduction, more marked in the His-Purkinje system than in the atria. The effects of quinidine on sodium channels are greatest at increased heart rate and less negative membrane potential; that is, they are pH-, rate-, and voltage-dependent. Dose-related changes in the ECG are increases in PR, QRS, and QT_c intervals, which reflect the multiple actions of quinidine.[113]

CLINICAL PHARMACOLOGY

The effective dosage of quinidine varies among individuals because of several factors. Although quinidine sulfate is usually administered every 6 h, there are wide interindividual differences in its elimination half-life, which varies from 3 to 19 h.[114] Plasma protein binding also varies widely, ranging from 50 to 95 percent.[114] Oral bioavailability is approximately 70 percent, and clearance after oral administration ranges from 200 to 400 mL/min. Quinidine is inactivated or eliminated by both hepatic metabolism (50 to 90 percent) and renal elimination (10 to 30 percent). Several

potentially active metabolites are formed in amounts that vary among individuals,[115] but for most, their clinical role has not been determined. One of the metabolites of quinidine, 3-hydroxyquinidine, has been shown to possess antiarrhythmic activity when given to humans.[115] Experimental data indicate some contribution by metabolites of quinidine to its antiarrhythmic action.[116,117,118]

DOSAGE AND ADMINISTRATION

Quinidine therapy (as the sulfate) is usually initiated with an oral dosage of 200 mg every 6 h, and the dosage is carefully titrated every 3 or more days. Elderly patients often require lower dosages of quinidine because of both reduced clearance and volume of distribution. Quinidine is available commercially in at least three different forms: quinidine sulfate, gluconate, and polygalacturonate. Since the quinidine content varies among these at 83, 62, and 60 percent, respectively, the need for dosage adjustment should be considered if one form is substituted for another. The usually effective dosage of quinidine sulfate ranges from 800 to 2400 mg/day, with the maximum recommended single dose being 600 mg. Because the half-life varies from 3 to 19 h, one should wait 4 days between dosage increases to prevent unexpected drug accumulation. The range of therapeutic plasma concentrations measured using assays that differentiate quinidine from its metabolites is 0.7 to 5.5 μg/mL.[119,120] Rapid escalation in quinidine dosage has been used to convert atrial fibrillation, but this therapy is no longer recommended because of unnecessary toxicity.

Intravenous therapy with quinidine is usually avoided if alternatives are feasible. Vasodilation and hypotension result from quinidine-induced alpha-adrenergic blockade. If quinidine is given intravenously (as quinidine gluconate), the patient should be carefully monitored and the infusion rate should be no greater than 16 mg/min. This should be discontinued if hypotension is observed or the QRS is prolonged by more than 30 percent.

MODIFICATION OF DOSAGE IN DISEASE STATES

No adjustment in initial dosage is usually needed for patients with renal or hepatic disease,[121,122] although, due to decreased protein binding in patients with hepatic failure, lower than usual total plasma concentration can produce toxicity.[123] Slower dose titration is advisable to permit attainment of steady state and complete accumulation of active metabolites; however, because the usual range of effective dosages is wide, dosage for these patients is not markedly different. Patients with rapid quinidine elimination may require higher dosages (up to 600 mg every 6 h). This is often due to induction of hepatic metabolism caused by other drugs.

Patients with congenital long-QT syndrome, hypokalemia, or a history of torsades de pointes[124] should not be given quinidine because of their increased risk for this form of proarrhythmic event. For patients with congestive heart failure, problems associated with use of quinidine are proarrhythmia and digitalis (either digitoxin or digoxin) toxicity. Prudent use of quinidine in individuals taking digitalis requires the following: (1) that titration begin at a reduced dosage, (2) that dosage of any cardiac glycoside being administered concomitantly be reduced, and (3) that plasma electrolyte levels, especially potassium levels, be maintained above 4 meq/L.

Although quinidine does possess some direct negative inotropic effects, they are usually counteracted by its vasodilatory effect; therefore, oral quinidine is well tolerated hemodynamically when given at dosages producing usual plasma concentrations, even in patients with reduced ventricular function.[125] In a study of over 650 patients, 35 percent of whom had congestive heart failure, quinidine therapy resulted in no induction or worsening of congestive heart failure.[126] On the other hand, a significant problem for patients with congestive heart failure receiving quinidine therapy is proarrhythmia, with quinidine-induced torsades de pointes being potentiated in the setting of bradycardia and low serum levels of magnesium or potassium.[102,127]

ADVERSE REACTIONS

Marked prolongation of the QT interval has been seen in some patients receiving low or usual dosages of quinidine, and the risk of torsades de pointes is markedly increased. This arrhythmia may be responsible for quinidine syncope, which occurs in as many as 5 to 10 percent of patients within the first days of quinidine treatment, and for quinidine-induced sudden death.[128] Torsades de pointes usually occurs in patients (more often females than males) with low serum concentrations of quinidine, hypokalemia, poor ventricular function, and bradycardia.[128,129] In a study by Drici et al., dihydrotestosterone reduced the sensitivity to the effects of quinidine on the QT interval in animals.[130] This study[130] and a subsequent study by Benton et al.[131] in which women were shown to be more sensitive to the effects of quinidine on the QT interval, provide evidence that sex hormones have direct effects on cardiac tissue that may be responsible for the difference in the incidence of torsades de pointes in men and women.[129]

For patients who develop torsades de pointes, treatment with pacing or isoproterenol is very effective. Magnesium sulfate injection is often recommended as initial therapy for torsades de pointes, although controlled trials are not available. These measures should also include correction of hypokalemia. Clinically, it is essential to distinguish torsades de pointes from polymorphic ventricular tachycardia occurring in the setting of a normal QT interval, because the latter should be treated with local anesthetic antiarrhythmic drugs and may be worsened by the above-mentioned treatment for torsades de pointes.

Since quinidine acts via alpha-adrenergic blockade to produce vasodilatation,[132] hypotension may occur, especially in patients concomitantly receiving nitrates or other vasodilators. Other adverse effects include a high incidence of diarrhea and vomiting, tinnitus at high plasma levels, rare thrombocytopenia,[133] and, in unusual cases, conduction block in patients with existing conduction system disease.[126] In patients treated with quinidine for atrial flutter without prior AV nodal blockade by digitalis, there have been reports of sudden increases in AV conduction and rapid ventricular rates.[132] This results from a slight reduction of the flutter rate and enhanced AV nodal conduction due to the anticholinergic effects of quinidine. This permits 1:1 conduction through the AV node, often at 200 to 250 beats per minute. This may be of particular concern for patients receiving other drugs that increase conduction time through the AV node, such as beta-adrenergic agonists.

DRUG INTERACTIONS

Quinidine metabolism is inhibited by cimetidine[134] and induced by phenytoin, phenobarbital,[135] and rifampicin,[133] with the latter agents leading to reduced, often subtherapeutic, quinidine concentrations. Clinical digoxin toxicity has been described in 20 to 40 percent of patients receiving quinidine and digoxin concurrently.[134] The magnitude of this interaction is dependent on quinidine dosage, and in some patients it may not appear until the dosage is increased to higher levels.[136,137] The rise in digoxin levels appears with the first dose of quinidine; therefore, it is suggested that digoxin dosage be halved when quinidine therapy is initiated. A similar interaction has been reported for quinidine and digitoxin.

Quinidine is a potent inhibitor of the hepatic cytochrome P450 (CYP) specific for debrisoquine metabolism (CYP2D6),[138,139] although it is not metabolized by this specific P450 isozyme.[140,141] Thus, it may interfere with the biotransformation and actions of pharmacologic agents dependent on this cytochrome for their metabolism, which include propafenone, mexiletine, flecainide, metoprolol, timolol, sparteine, and bufuralol.[142] Quinidine worsens neuromuscular blockade in patients with myasthenia gravis[143] and may prolong the effects of succinylcholine.[144]

Propafenone (Rythmol)

CLINICAL APPLICATIONS

Propafenone was developed in Germany, where it has been marketed since 1977. It is similar to other antiarrhythmic agents in overall efficacy and tolerance by patients. It has a role in the treatment of many types of arrhythmias, including supraventricular arrhythmias.[145]

CLINICAL PHARMACOLOGY

Propafenone has been described as having class IC antiarrhythmic activity because of its potent ability to slow conduction velocity with little change in APD.[146,147] It has a marked structural similarity to propranolol, and studies have shown that propafenone can accumulate during continued administration to levels capable of producing clinically significant beta-adrenergic inhibition.[148]

Propafenone, like mexiletine and flecainide, is eliminated by a metabolic pathway that has a polymorphic pattern of inheritance. Patients deficient in CYP2D6 activity have very slow elimination of propafenone and fail to form measurable quantities of the potentially active metabolite, 5-hydroxypropafenone.[149] The accumulation of high concentrations of propafenone leads to significant beta-receptor antagonism at both low and high dosages in poor metabolizers but only at high dosages in extensive metabolizers of propafenone.[150] Although metabolic phenotype does not seem to dramatically influence the antiarrhythmic response to propafenone in many patients,[149] it clearly influences the degree of beta blockade occurring during therapy.

DOSAGE AND ADMINISTRATION

Effective dosages range from 300 to 900 mg/day in two to four divided dosages. In order to prevent unexpected accumulation of pharmacologic action, propafenone dosage should not be changed more frequently than every 3 days; there is slow elimination of the parent drug in poor metabolizers, and there is slow accumulation of the metabolite or metabolites in extensive metabolizers.

Patients with reduced ventricular function, especially those receiving propafenone, should be carefully monitored for deterioration in ventricular function, which may result from beta-adrenergic receptor antagonism and/or the direct negative inotropic effect.[151]

MODIFICATION OF DOSAGE IN DISEASE STATES

Dosage recommendations for patients with cardiac, renal, or hepatic dysfunction are not yet available.

DRUG INTERACTIONS

It is very likely that there will be drug interactions between propafenone and other agents that utilize or inhibit cytochrome CYP2D6 for their metabolism. Such an interaction has been documented already between propafenone and metoprolol[152] and should be expected with timolol, many antidepressants, many neuroleptics, and perhaps other agents. Quinidine, which inhibits this cytochrome, inhibits the formation of 5-hydroxypropafenone in extensive metabolizers[153]; however, the clinical consequence of such inhibition is unknown and difficult to predict. One would expect greater beta blockade to occur after combining quinidine with propafenone therapy because of the resulting higher propafenone concentrations.

Flecainide (Tambocor)

CLINICAL APPLICATIONS

Flecainide is very effective in suppressing a variety of ventricular and supraventricular tachycardias.[154,155] The finding of increased mortality rates when flecainide is given to patients with ischemic heart disease has led to restricted usage (see above); however, there has been no evidence to indicate that this increase in mortality rate is seen when flecainide is given to treat supraventricular arrhythmias in patients without known coronary artery disease.[156] Overall, the antiarrhythmic response to flecainide in patients with symptomatic life-threatening ventricular arrhythmias is not markedly better than with older agents, such as quinidine or procainamide.[154,157] Although it is far better tolerated than older agents, the negative inotropic actions of flecainide restrict its use to patients having moderately well-preserved ventricular function. Likewise, its potential to increase mortality rates in patients with ischemic heart disease limits its usefulness.

MECHANISM OF ACTION

Flecainide has sodium channel-blocking activity and is considered to have class IC actions. It has also been found to block the delayed rectifier potassium channel in feline ventricular myocytes, and this action may be clinically relevant.[158]

Flecainide slows intraventricular conduction velocity more than it prolongs effective refractory periods.[159] It prolongs AH and HV intervals and measurably increases PR and QRS intervals on the surface ECG at therapeutic doses. The QT_c interval is slightly increased, primarily due to prolongation of the QRS, but its ability to block the delayed rectifier potassium channel may contribute to QT changes.

CLINICAL PHARMACOLOGY

The systemic bioavailability of oral flecainide is 90 to 95 percent,[160] and flecainide is predominantly metabolized in the liver to compounds that are not pharmacologically active at the concentrations usually found in plasma.[154] Flecainide, like many other antiarrhythmic agents, is metabolized by CYP2D6.[161] Because flecainide is also eliminated by the kidneys to a considerable extent, the enzyme deficiency has little effect on the pharmacokinetics of flecainide. If, however, those patients without the enzyme develop renal insufficiency or if renal patients are given a drug that blocks the metabolism of flecainide, extremely high plasma concentrations are likely to occur.[162] A potential advantage of flecainide is its very slow elimination, with half-life ranging from 7 to 23 h in normal individuals and tending to be even longer (14 to 26 h) in patients with cardiac disease, even in the absence of heart failure.[160,163]

DOSAGE AND ADMINISTRATION

The usual dosage of flecainide for ventricular arrhythmias is 100 to 150 mg every 12 h in patients without cardiac or renal failure. A total daily dosage of more than 400 mg may sometimes be used under close medical monitoring (see below). Patients with supraventricular tachycardia are recommended to receive 50 mg every 12 h as a starting dose. The range of therapeutic plasma concentrations of flecainide is reported to be between 200 and 1000 ng/mL, although adverse effects may occur in some patients at concentrations within this range,[164,165] and many patients tolerate concentrations well above this range. To reduce the incidence of adverse effects, flecainide therapy should start with a low dosage that is maintained until steady state has been reached (at least 4 days) and altered relative to clinical response.

MODIFICATION OF DOSAGE IN DISEASE STATES

With cardiac failure, the usual initial dose is 50 to 100 mg every 12 h. Since 7 percent of Caucasian patients with renal failure will not have the CYP2D6 enzyme and because flecainide is usually eliminated by both metabolism and renal excretion, all patients with renal failure should be given very low dosages and titrated very carefully. Plasma concentration monitoring will be essential in patients with renal disease or cardiac or hepatic dysfunction. Any significant reduction in ejection fraction should be expected to lengthen elimination half-life and hence the time needed to attain steady-state equilibrium, while reductions in clearance may occur in renal or hepatic dysfunction and lead to higher plasma concentrations at steady state.

ADVERSE REACTIONS

Although aggravation of arrhythmias seen in the early days of the evaluation of flecainide was often due to excessive initial doses and frequent dose increments, flecainide has a potential to induce proarrhythmic events, even when prescribed as recommended. This is especially true in patients with severe heart disease and if flecainide is given in higher dosages.[166] Because of its negative inotropic effects at dosages necessary to suppress arrhythmias, flecainide produces a measurable decrease in left ventricular function in most patients.[167,168] The increased mortality rate seen in the CAST seemed to be confined to patients with structural heart disease.[156] A retrospective study of five multiple-dose efficacy trials showed that, of patients with a history of congestive heart failure, oral flecainide precipitated heart failure in 15 percent. A dose-related depression of myocardial performance was found after rapid (1 to 2 mg/kg) intravenous injections.[169]

Other side effects of flecainide include depression of sinus node activity in patients with preexisting sinus node dysfunction[170] and prolongation of QRS and PR intervals on the surface ECG. If below 25 percent, these effects do not necessarily indicate excessive dosage.

Flecainide increases pacing thresholds by as much as 200 percent and should therefore be used with caution in patients dependent upon pacemakers.[171,172] Since it also increases the threshold for electrical defibrillation, patients with implanted devices should be evaluated carefully.[173]

DRUG INTERACTIONS

Cimetidine reduces flecainide clearance and prolongs flecainide elimination half-life.[174] Studies in normal volunteers have demonstrated an increase in the plasma concentrations of digoxin and propranolol when flecainide is coadministered.[175,176] Not unexpectedly, propranolol and flecainide have been found to have additive negative inotropic effects. An interaction with amiodarone, resulting in elevation of plasma flecainide concentration and necessitating reduction of flecainide dosage, has been described.[177]

Calcium Channel Blockers

Some calcium channel blockers are also used as antiarrhythmic agents.[178,179] Verapamil and diltiazem are useful in the management of supraventricular tachycardia, where they are administered to slow the ventricular rate in patients with atrial fibrillation or flutter and to treat and prevent AV nodal reentrant tachycardia. Intravenous diltiazem is useful for the temporary control of rapid ventricular rate during atrial fibrillation and flutter. In controlled clinical trials, conversion to sinus rhythm occurred with diltiazem and placebo with equal frequency.

Bretylium (Bretylol)

CLINICAL APPLICATIONS

Bretylium is effective for acute therapy of ventricular tachycardia and/or ventricular fibrillation. Because of its sympatholytic activity, bretylium tosylate was first evaluated in the 1950s for the treatment of hypertension; however, a very high incidence of orthostatic hypotension and unreliable oral absorption led to its disfavor for chronic therapy. After its antiarrhythmic activity was discovered in animals,[180] it was eventually marketed in the United States as intravenous therapy for life-threatening ventricular arrhythmias. Bretylium is usually employed only after patients have not responded to lidocaine.

MECHANISM OF ACTION

In addition to the indirect electrophysiologic changes caused by a biphasic action on postganglionic autonomic neurons, bretylium has a direct class III action that causes an increase in APD and refractoriness in ventricular muscle and Purkinje fibers.[181] When clinically relevant concentrations of bretylium are studied in normal tissues, no changes are seen in $_{max}$, maximum diastolic potential, or conduction velocity. Studies have found that bretylium reduces the degree of dispersion of repolarization across the boundary between normal and ischemic tissue by acting predominantly on normal tissue.[182] Transient increases in membrane potential and conduction velocity are seen early after bretylium administration and are presumed to be due to the local release of catecholamines.

When initially administered, bretylium causes the release of norepinephrine from postganglionic adrenergic neurons.[183] Bretylium is transported into the neuron by the norepinephrine pump, and extensive accumulation in the neuron is then associated with a blockade of further release or uptake of norepinephrine by the neuron. The blockade of uptake of circulating or infused catecholamines leads to supersenitivity that is functionally similar to a denervated state.

CLINICAL PHARMACOLOGY

Bretylium is poorly absorbed after oral administration, with average bioavailability of approximately 25 percent, and is available only for parenteral administration. It is eliminated almost entirely unchanged in the urine, and clearance correlates well with creatinine clearance.[184]

DOSAGE AND ADMINISTRATION

The usual intravenous dosage for bretylium is 5 mg/kg given at a rate dependent upon the clinical setting.[185] During cardiac emergencies, it should be given by rapid injection into a central intravenous line. In less acute situations, giving a loading infusion of the same dose, but over 10 to 20 min, will reduce the incidence of nausea and vomiting. The loading dose should be repeated after 20 min if the arrhythmia is still present. A total loading dose of 20 mg/kg may be required, and dosages up to 9 g in 24 h have been given without serious adverse effects. Maintenance infusions of 1 to 4 mg/min should be given, depending upon body size and renal function. Heart rhythm and blood pressure should be monitored carefully, especially during the first few hours of bretylium therapy.

MODIFICATION OF DOSAGE IN DISEASE STATES

In patients with renal insufficiency, bretylium clearance is reduced and half-life prolonged; therefore, the maintenance infusion for bretylium should be reduced to the lowest effective dosage. There are few data to guide dosage adjustment in cardiac or hepatic impairment, but it is unlikely that the dosage should be altered in these patients.

ADVERSE REACTIONS

When bretylium is given by rapid intravenous injection, many patients experience nausea and vomiting. The release of norepinephrine by bretylium has the potential to cause increased blood pressure, but severe hypertension has not been described. Increased frequency of ventricular arrhythmias is often seen at this time and can lead to the need for more frequent cardioversion. The reduction in peripheral vascular resistance can cause symptomatic hypotension in volume-depleted patients, but this can be readily corrected if recognized, although hypotension could prove dangerous in patients with fixed valvular obstruction. Bradycardia has been reported in some patients with abnormalities of the conduction system when given large intravenous dosages of bretylium.

In stable patients, either initial or subsequent doses of bretylium can cause a transient increase in heart rate, blood pressure, contractility, peripheral vascular resistance, and arrhythmia frequency, followed by a fall in standing blood pressure and peripheral vascular resistance.[186] Orthostatic hypotension is almost uniformly seen in patients receiving bretylium and sometimes lasts for days after discontinuation of therapy. Dosages that are well below those required for antiarrhythmic efficacy are capable of causing orthostatic hypotension. When hypotension develops during bretylium therapy, it should be corrected with intravenous volume expansion to enable adequate doses of bretylium for suppression of arrhythmias.

DRUG INTERACTIONS

Other than those with tricyclic antidepressants, no drug interactions have been reported. One would expect, however, that there might be competition for renal tubular secretion with procainamide, NAPA, cimetidine, and other organic bases.

Sotalol (Betapace)

CLINICAL APPLICATIONS

Sotalol has been used for up to 20 years in many countries for angina and hypertension, and it was in this setting that its value as an antiarrhythmic agent was first observed. Sotalol is unlike other beta-adrenergic antagonists in that it prolongs the action potential, producing a dose-related increase in refractoriness of cardiac tissues.[187] This unique combination of properties makes sotalol effective in a variety of supraventricular and ventricular arrhythmias. It has been found to be effective in patients with sustained ventricular tachycardia evaluated by programmed ventricular stimulation. In a controlled comparison to procainamide, sotalol was effective in 30 percent of patients with inducible sustained ventricular tachycardia, whereas only 20 percent responded to procainamide ($p < .2$).[188] This is consistent with the response rate for sotalol (31 percent) in the Electrophysiology Study Versus ECG Monitoring (ESVEM) trial sponsored by the National Institutes of Health, which compared therapy guided by programmed electrical stimulation to therapy guided by ambulatory monitoring.[189] In this study, a mean of only 12 percent of patients responded to the other antiarrhythmic drugs evaluated.

MECHANISM OF ACTION

Sotalol has two main actions, each of which can contribute to its antiarrhythmic efficacy.[190] The drug was originally synthesized for its actions as a beta-adrenergic receptor antagonist. Unlike other beta-receptor antagonists, it markedly prolongs refractoriness in atrial and ventricular tissues, a class III antiarrhythmic action. These actions slow heart rate, decrease AV nodal conduction, and increase refractoriness of atrial, ventricular, AV nodal, and AV accessory pathways in both the anterograde and retrograde directions.[191] When given in dosages between

160 and 640 mg/day, there are increases of 40 to 100 ms in the QT interval and 10 to 40 ms in QT_c.[192]

CLINICAL PHARMACOLOGY

Oral bioavailability of sotalol is greater than 90 percent, and peak concentrations are seen 2.5 to 4 h after a dose. It is not bound to plasma proteins and is eliminated by the kidneys unchanged, with an elimination half-life of approximately 12 h. Because of the relatively long half-life and twice daily dosing regimen, it is recommended that testing for efficacy be conducted near the end of the dosing interval at steady state. The age of the patient per se does not influence the pharmacokinetics of sotalol other than that due to the natural decline in renal function that occurs with age.

DOSAGE AND ADMINISTRATION

Sotalol is available only in the oral form in the United States. The recommended initial dose of sotalol is 80 mg every 12 h. In patients with relatively normal renal function, steady state is reached in 2 to 3 days. If evaluation at this dosage indicates a lack of response without evidence of excessive effects on repolarization (QT below 500 ms), the dosage may be increased to 160 mg twice daily and, if necessary, to 240 mg twice daily. Some patients with life-threatening arrhythmias have required dosages of 640 mg/day. Accelerated titration regimens have been used with close monitoring without apparent increase in the frequency of adverse events.[193]

MODIFICATION OF DOSAGE IN DISEASE STATES

Because sotalol is mainly eliminated unchanged in the urine, the dosage must be adjusted for altered renal function. For patients with a creatinine clearance greater than 60 mL/min, the usual dosing interval is every 12 h. If the creatinine clearance (CL_{CR}) is between 30 and 60 mL/min, the recommended interval between doses is 24 h. For patients with CL_{CR} between 10 and 30 mL/min, the interval should be every 36 to 48 h or the usual dose halved and given every 24 h. The dosage for patients with CL_{CR} below 10 mL/min should be individualized. Because of the increased risk of proarrhythmia and congestive heart failure, patients with reduced cardiac output should be given lower doses and monitored carefully.

ADVERSE REACTIONS

A major concern with sotalol treatment has been the occurrence of torsades de pointes. Reports of this syndrome have predominantly been cases of suicidal overdoses or in patients who were receiving concomitant diuretics and inadequate potassium replacement. Clearly, hypokalemia and bradycardia are predisposing factors for the development of this arrhythmia during sotalol therapy, as they are with quinidine, disopyramide, and procainamide. The manufacturer observed an overall incidence of torsades de pointes of 2 percent, broken down to 4 percent of patients with sustained ventricular tachycardia and 1.5 percent of patients with supraventricular arrhythmias. It is more common in females and patients with congestive heart failure and those with a history of sustained ventricular tachycardia (7 percent). The incidence of torsades de pointes should be minimized by careful screening and consideration of predisposing factors, such as gender, bradycardia, baseline prolongation of the QT interval, and electrolyte disturbances, (especially hypokalemia); careful dose escalation beginning at 160 mg/day; and limiting the maximum QT-interval prolongation to less than 550 ms.

The incidence of new or worsened congestive heart failure is only about 3 percent. This may be attenuated because of the increased inotropy produced by its action to prolong repolarization. Other side effects typical of beta blockers are to be expected, including bronchospasm in

asthmatic patients, masking the signs and symptoms of hypoglycemia in diabetic patients, and catecholamine hypersensitivity withdrawal syndrome.

DRUG INTERACTIONS

Concomitant use of sotalol with agents that prolong repolarization has the potential to increase the likelihood of torsades de pointes. No pharmacokinetic interactions have been seen with sotalol and/or warfarin, digoxin, cholestyramine, or hydrochlorothiazide. Because of the beta-blocking actions of sotalol, it is likely that there would be increased pharmacologic effect if the drug is combined with amiodarone, calcium channel blockers, antihypertensive agents, or antiarrhythmic agents.

Amiodarone (Cordarone)

CLINICAL APPLICATIONS

Although amiodarone has been reported to have efficacy in a wide range of arrhythmias, the FDA has recommended it only for life-threatening ventricular arrhythmias refractory to other available forms of therapy. Nevertheless, there are now numerous trials in the literature describing the efficacy of amiodarone in the conversion and slowing of atrial fibrillation, AV nodal reentrant tachycardia, and tachycardias associated with the Wolff-Parkinson-White syndrome.[194,195] The reasons for the limited labeling of amiodarone are (1) the documented potentially lethal complications of chronic amiodarone therapy, (2) the complications associated with its variable onset of action, and (3) multiple dangerous drug interactions.

After the results of CAST, antiarrhythmic drugs have been examined for their effects on mortality rate. After several small or uncontrolled trials seemed to indicate that amiodarone could have a beneficial effect on mortality rate,[4,196] adequate trials were undertaken. The Veteran's Administration trial, Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy (CHF STAT),[5] examined the effects of amiodarone on total mortality rate in patients with a history of congestive heart failure, more than 10 premature ventricular contractions per hour on ambulatory monitoring, and an ejection fraction below 40 percent. The study found no difference in the placebo- and amiodarone-treated arms. Two other major trials have evaluated amiodarone in patients with recent myocardial infarction. The Canadian Myocardial Infarction Amiodarone Trial (CAMIAT)[197] and the European Myocardial Infarction Amiodarone Trial (EMIAT)[198] were recently completed. The results of these trials are mixed, in that neither found amiodarone to reduce overall mortality rate, but the Canadian trial reported a reduced incidence of ventricular fibrillation or arrhythmic death among survivors of myocardial infarction with ventricular ectopy. It is important to note that there was no increase in mortality rate, as has been seen with other antiarrhythmic drugs. In recent years, there have been attempts to perform meta-analyses of the many trials with amiodarone.[199,200] They have generally confirmed a modest reduction in mortality rate in cardiac patients. One study concluded that the benefit could be extended to patients with congestive heart failure,[200] but another did not.[199] The NIH-sponsored Antiarrhythmics versus Implanted Devices (AVID) trial found that the devices were superior to amiodarone in reducing mortality rates in patients who had been resuscitated from sudden death or who had sustained ventricular tachycardia.

In 1993, an intravenous formulation of amiodarone became available in the United States. Although it had been used extensively in most countries for many years, controlled trials only became available in recent years. Three completed controlled trials demonstrated the value of amiodarone in patients with recurrent life-threatening ventricular tachycardia or fibrillation. A comparison of three dosages found that the recurrence of arrhythmia decreased with increasing dosages of 125, 500, and 1000 mg per 24 h.[201] Hypotension was the major side effect seen, but it occurred equally in all groups, about 26 percent. The second study in a similar group of patients

was a comparison of bretylium to two doses of amiodarone.[202] The arrhythmia event rate for the first 48 h of therapy was equivalent for the high dose of amiodarone and bretylium, and both were more effective than the low dose of amiodarone. Hypotension was common in all groups but significantly higher in the bretylium group. Amiodarone was approved for intravenous therapy of ventricular arrhythmia by the FDA in 1998. Although not yet approved in labeling, a recent study found intravenous amiodarone effective for prevention of postoperative atrial fibrillation.[203]

MECHANISM OF ACTION

Amiodarone is an iodinated benzofuran that has structural similarity to thyroxine and procainamide and was originally developed as an antianginal agent. It was incidentally noted to suppress a wide variety of ventricular and supraventricular arrhythmias. This efficacy has been assumed to be due to its prolongation of refractoriness and APD in myocardial tissue (Vaughan Williams class III antiarrhythmic activity), although amiodarone has been found to have many diverse pharmacologic actions (see Table 27-1); the action or actions responsible for its high degree of antiarrhythmic efficacy remain unidentified.

In intracellular recordings of rabbit cardiac myocytes, amiodarone prolongs APD and increases refractoriness of both atrial and ventricular myocardium, Purkinje fibers, and sinus and AV nodal tissues. Amiodarone decreases phase 3 depolarization of myocardial cells, blocks sodium channels that are in the inactivated state, and slows phase 4 depolarization of the sinus node as well as conduction through the AV node.[204,205] The electrophysiologic actions of the major metabolite of amiodarone, desethylamiodarone (DEA), differ from those of amiodarone, with the metabolite having greater effects on sodium channels and, hence, upon conduction.[206] Intracoronary injection of amiodarone has shown little cardiac effect compared to the ability of DEA to prolong cardiac refractoriness.[207]

Electrophysiologic changes in humans depend on the route of administration and the duration of therapy. Following acute intravenous amiodarone administration, prolongation of the AH interval and an increase in the refractory periods of the AV node and bypass tracts are seen, but this may be due to the presence of the solubilizing agent polysorbate 80 (Tween 80) in the intravenous formulation. No acute changes occur in either sinus rate or atrial or ventricular refractoriness, which are prolonged during chronic oral therapy. Chronic amiodarone therapy also prolongs the AH and HV intervals and the PR and QT intervals of the surface ECG. Data conflict on the time course of these changes and how they may relate to antiarrhythmic efficacy.

Changes in APD and refractoriness are seen in hypothyroidism that are similar to changes resulting from oral amiodarone therapy.[208] Since these changes can be prevented in animals by coadministration of thyroid hormone with amiodarone,[209] some have concluded that the antiarrhythmic efficacy of amiodarone is due to production of "cardiac hypothyroidism." This is supported by the observation that the major metabolite of amiodarone causes noncompetitive inhibition of thyroid hormone binding to nuclear receptors.[210] On the other hand, amiodarone also causes noncompetitive blockade of alpha and beta receptors[211] and muscarinic receptors,[212] and both calcium and sodium channel blockade, any combination of which may contribute to its antiarrhythmic efficacy.

CLINICAL PHARMACOLOGY

Amiodarone is a highly lipid-soluble compound with extremely variable and complex pharmacokinetics. It is slowly absorbed from the gastrointestinal tract, and bioavailability varies over a fourfold range.[213] Amiodarone is extensively metabolized to DEA, and little, if any, is excreted unchanged in the urine. Concentrations of DEA in plasma vary from 0.4 to 2.0 times that

of amiodarone during chronic therapy.[214] This metabolite has antiarrhythmic potency equal to or greater than amiodarone in in vitro and animal models.[215] Amiodarone is rapidly concentrated in some tissues, including myocardium, but accumulates more slowly in others, such as adipose tissue. It redistributes out of myocardial tissue while still accumulating in adipose and other tissues.[214,216] Until all tissues are saturated, rapid redistribution out of the myocardium may be responsible for early recurrence of arrhythmias after discontinuation of therapy or rapid reduction of dosage. Because of drug accumulation in tissues, the volume of distribution for amiodarone is very large, 20 to 200 L/kg.[216] After intravenous administration, the measured half-life in plasma is from 4.8 to 68.2 h,[217] with tissue uptake being the primary factor responsible for the decline in plasma concentration. As tissues become saturated, however, the decline in plasma levels is slow, reflecting mainly elimination and slow redistribution of the drug out of adipose and muscle tissues. This leads to slow and extremely variable elimination from plasma, with half-lives ranging from 13 to 103 days at steady state.[216] It is also possible that amiodarone inhibits its own elimination after chronic therapy, contributing to the differences between half-life early in therapy to that after prolonged therapy.

DOSAGE AND ADMINISTRATION

Without a loading-dose regimen, amiodarone requires several weeks to months before producing its antiarrhythmic action. Large intravenous dosages or oral loading dosages can hasten the onset of therapeutic effects. From small prospective studies, loading dosages have varied from 600 to 1400 mg/day for 2 to 21 days.[218] Recent large clinical trials have utilized a lower loading dose, of 600 to 800 mg daily for 14 days.[5,219] Because of relatively rapid redistribution out of myocardial tissue, the dosage should be tapered over a period of several weeks. The usual maintenance dose varies from 200 to 600 mg/day, and because of the severe nature of adverse reactions, the lowest effective dosage should be prescribed. Patients with supraventricular arrhythmias may respond to lower dosages than those with ventricular arrhythmias, but there are many exceptions. Because of the variable pharmacokinetics and oral bioavailability, such generalizations may be unreliable. Some patients with extensive absorption (approximately 80 to 90 percent bioavailability) of even low doses may have the same drug exposure as a person with limited bioavailability given a high dose.

For intravenous administration, the manufacturer recommends a three-phase infusion over the first 24 h: 150 mg over 10 min, followed by 360 mg over the next 6 h, followed by 0.5 mg/min. The drug can be continued at this rate, but monitoring of plasma concentrations is recommended. An additional 150 mg can be infused over 10 min for those patients who continue to have recurrent ventricular tachycardia or fibrillation or whose arrhythmia recurs during downward titration of the infusion. Concentrations of drug greater than 3 mg/mL should be infused through a central catheter to prevent phlebitis. Also, the surfactant properties of the drug alter the size of a drop of infusate, and pumps that count drops will give approximately 30 percent less drug than intended.

Amiodarone concentrations are usually between 1 and 2 μg/mL during effective oral therapy.[220,221] Similar concentrations of DEA accumulate during therapy and, although this is unproven, are likely to contribute to antiarrhythmic efficacy. Because of extensive overlap between the range of concentrations required for arrhythmia suppression and those associated with toxicity, monitoring of plasma concentrations is of limited value. Clearly, levels of amiodarone above 3 to 4 μg/mL for prolonged periods of time are associated with a higher incidence of adverse effects.[222]

MODIFICATION OF DOSAGE IN DISEASE STATES

Long-term oral therapy with amiodarone appears to be well tolerated hemodynamically in patients with congestive heart failure. In the CHF STAT study, discussed above, amiodarone failed to

prolong life for congestive heart failure patients with arrhythmias but was associated with improved ventricular function as measured by radionuclide ejection fraction.[5]

ADVERSE REACTIONS

Intravenous amiodarone at dosages greater than 5 mg/kg decreases cardiac contractility and peripheral vascular resistance, producing severe hypotension in some instances. Some of this effect, like the electrophysiologic effects described earlier, may be due to the effects of polysorbate 80 or benzyl alcohol, since oral administration at usual dosages improves myocardial contractility.

The safety of amiodarone is controversial. The early reports found it to be very well tolerated and described it as the "ideal antiarrhythmic drug." Some studies continue to find that it is relatively safe and effective, even in the treatment of arrhythmias in children.[223] The early experience with amiodarone in the United States, with a very high incidence of intolerable and sometimes lethal reactions, may have been the result of high dosages required for control of life-threatening arrhythmias. In less urgent conditions, lower dosages are given and are much better tolerated. Determination of the incidence of adverse reactions is difficult because of highly variable dosages and durations of treatment.[204,224]

The most serious adverse reaction is lethal interstitial pneumonitis,[204,225] which may be more common in patients with preexisting lung disease. Monitoring is essential, since the pneumonitis is reversible if detected early. A chest x-ray every 3 months may be useful, but serial pulmonary function tests are of little value for follow-up. Hyper- or hypothyroidism is seen in about 4 percent of patients treated chronically.[208] Accumulation of corneal microdeposits is almost uniform during long-term therapy and in many cases can progress to the point of interfering with vision.[226] Some Caucasian patients develop a slate-gray or bluish discoloration of sun-exposed areas of the skin.[227] Many also complain of photosensitivity, which can sometimes be prevented or alleviated with sunscreens and garments. Thirty percent or more of patients have abnormally elevated serum hepatic enzyme levels, and progression to jaundice and cirrhosis has been reported.[228,229] Serial laboratory tests to screen for amiodarone toxicity can be costly and generally are of limited value; however, it is wise to obtain a reliable assessment of baseline test results, including complete blood count, blood chemistry, tests of thyroid and pulmonary function, a slit-lamp examination, and measurement of blood levels of other drugs whenever possible.

DRUG INTERACTIONS

Amiodarone interferes with the clearance of many drugs. This may involve the formation of a metabolically inactive cytochrome P450 Fe(II)-metabolite complex, which has been described in animals treated with amiodarone,[230] and may explain the reduced metabolism and unexpected accumulation of warfarin,[231] quinidine, procainamide, disopyramide, mexiletine, and propafenone[232] and the resulting bleeding, heart block, or torsades de pointes. It does not, however, explain interaction with drugs eliminated predominantly by the kidneys, such as digoxin.[233] The elimination of other drugs may be impaired by amiodarone, and the lowest effective dosage should be sought.

Ibutilide (Corvert)

CLINICAL APPLICATIONS

Ibutilide was given FDA approval for the rapid conversion of recent-onset atrial fibrillation or flutter in 1995.[234,235] It has completed testing in other arrhythmias or in patients with atrial fibrillation or flutter of long duration (greater than 90 days). It should not be given to patients who

have hypokalemia, hypomagnesemia, or QT_c prolongation at baseline greater than 440 ms. In placebo-controlled studies summarized in the manufacturer's labeling, the placebo conversion rate for atrial fibrillation or flutter was approximately 2 percent. Ibutilide terminated the arrhythmia in approximately 44 percent of patients treated with 1 mg followed by either 0.5 or 1 mg. Approximately 20 percent of patients responded to the first infusion, and approximately 25 percent of those not responding to the first infusion responded to the second infusion. Response usually occurred at 20 to 30 min, ranging from 5 to 88 min after infusion. The response in patients with atrial fibrillation and atrial flutter was not significantly different in the early trials performed. However, in patients with postoperative arrhythmias, there was a greater response in patients with atrial flutter, with an overall conversion rate of 57 percent compared to 15 percent with placebo.[236] Ibutilide may have value in conversion of atrial fibrillation in patients with Wolff-Parkinson-White syndrome.[236]

MECHANISM OF ACTION

Ibutilide is a remarkably potent methanesulfonamide analog of sotalol that has class III action to prolong cardiac refractoriness and action potential duration.

The mechanism of action of ibutilide is unclear. The manufacturer's data indicate that the class III action of the drug is due to an increase in inward sodium current, as observed in guinea pig ventricular myocytes at 10^{-7}-*M* concentrations. They observed that higher concentrations (10^{-5} *M*) increase an outward potassium current to shorten action potential duration.[237] Other investigators reported that, as has been seen with dofetilide, sotalol, and other methanesulfonamides, 10^{-8} *M* concentrations of ibutilide block the rapid component of the delayed rectifier potassium current, I_{KR}, in mouse and human cardiac cells.[238]

CLINICAL PHARMACOLOGY

Ibutilide is available only for intravenous administration. When given over 10 min, it distributes rapidly in a multiexponential fashion, with the relevant component having a half-life from 2 to 12 h (mean 6 h). The plasma concentration and pharmacokinetics are highly variable, and dosing is recommended on the basis of weight. The drug is mainly eliminated by oxidative hepatic metabolism, and systemic clearance is rapid (about 29 mL/min per kilogram). Since formal drug interaction studies have not been performed, it is not possible to anticipate which enzymes are likely responsible for its elimination.

DOSAGE AND ADMINISTRATION

Ibutilide is given undiluted or diluted in saline as an infusion over 10 min. The recommended dose for a patient over 60 kg is 1 mg and for a patient under 60 kg, 0.01 mg/kg. For patients whose arrhythmias have not converted by 10 min after completion of the first dose, a second dose of equal size may be administered. Since conversion of the arrhythmias is usually associated with peak levels, slower infusion rates are not likely to be as effective.

It is essential that patients receiving ibutilide be treated in a carefully monitored environment during and at least 4 h subsequent to treatment. The FDA-approved labeling recommends that skilled personnel, facilities, and medication for defibrillation or resuscitation be readily available.

MODIFICATION OF DOSAGE IN DISEASE STATES

Although specific studies with heart failure and renal or hepatic disease have not been conducted, current information does not indicate that any dosage adjustments should be necessary in these conditions. Patients with severe left ventricular dysfunction, however, have a higher risk of

developing ventricular arrhythmias, including torsades de pointes. Since the duration of drug effect is determined by distribution, it is very possible that patients with severe congestive heart failure will have decreased volumes of distribution and hence an exaggerated and prolonged duration of effect.

ADVERSE REACTIONS

The most serious adverse reaction to ibutilide is torsades de pointes. There were, however, only 586 patients participating in trials before marketing, and patients with a QT_c greater than 440 ms or potassium concentrations less than 4 meq/L were excluded. In spite of these precautions, the incidence of sustained polymorphic ventricular tachycardia requiring cardioversion was 1.7 percent. Another 2.7 percent developed nonsustained polymorphic ventricular tachycardia, 4.9 percent had nonsustained monomorphic ventricular tachycardia, 1.5 percent had AV block, and 1.9 percent had bundle-branch block. The risk of polymorphic ventricular tachycardia was highest in patients who were female and/or who had evidence of reduced ventricular performance. The incidence of these adverse effects may well be higher in general clinical use, where electrolyte disorders and concomitant therapies may be more common. Bradycardia and multiple episodes of sinus arrest have been reported.[236,239] A single case of acute renal failure has been reported with ibutilide.[240]

DRUG INTERACTIONS

No specific drug interaction studies have been performed. Concomitant beta-receptor or calcium channel antagonists do not apparently interact, although data are limited. The manufacturer's labeling warns against combining ibutilide with other drugs that prolong the QT interval. During the development of ibutilide, such drugs were discontinued for at least five half-lives prior to administration of ibutilide and were not allowed until at least 4 h after administration.

Dofetilide (Tikosyn)

CLINICAL APPLICATIONS

Dofetilide was approved and marketed in 2000 for oral therapy of atrial fibrillation and flutter. In controlled trials of approximately 1000 patients, about 30 percent of patients with atrial fibrillation given a dosage of 500 μg bid converted to normal sinus rhythm, compared to 6 percent in the control group treated with sotalol and 1 percent of patients given placebo. Prevention of recurrence was demonstrated, with 62 to 71 percent remaining in sinus rhythm after 6 months, compared to 59 percent for sotalol and 26 to 37 percent for placebo (personal communication, S. Singh, Washington, DC). A large mortality trial (the Danish Investigators of Arrhythmia and Mortality on Dofetilide trial, or DIAMOND) in 1518 patients with reduced ejection fraction and symptoms of heart failure examined the effects of dofetilide on mortality rate and atrial fibrillation. A decrease in the incidence of hospitalization for heart failure was observed. Although the antiarrhythmic efficacy of dofetilide was confirmed in the lower incidence of atrial fibrillation, a positive effect on mortality rate was not observed. However, because of the previously observed increases in mortality rate with sodium channel blockers (CAST[1,241] and CAST II[2]) and with *d*-sotalol (SWORD[6]), the lack of harm in the DIAMOND trial with dofetilide[242] was interpreted as a positive indication of the safety of the drug. A caveat to this safety was the potentially important role of extensive screening and monitoring for potential harm. Even with these efforts, 3.3 percent of patients in this trial developed torsades de pointes. Because of the risk of torsades de pointes, the manufacturer will require physicians to receive special training prior to prescribing dofetilide, and the FDA has required that labeling include a warning that therapy should be initiated in the hospital, with continuous ECG monitoring for at least 3 days.

MECHANISM OF ACTION

Dofetilide is one of the most potent I_{KR} blockers of the rapid component of the delayed rectifier potassium current (I_{KR}) ever synthesized. Perhaps an additional advantage is the twofold greater ability to prolong action potential duration in atrial compared to ventricular tissue.[243] It does not depress cardiac function at usual dosages, even in patients with reduced ejection fraction.

CLINICAL PHARMACOLOGY

Dofetilide is well absorbed after oral administration and is partially metabolized by cytochrome P450 3A4[244] to inactive metabolites and excreted predominantly in urine. In most patients, the elimination half-life ranges from 8 to 10 h but is prolonged, and clearance is reduced in patients with renal failure. Dofetilide is susceptible to several drug interactions because it is metabolized by CYP3A4 (see below). It is very likely that these interactions increase the risk of torsades de pointes.

DOSAGE AND ADMINISTRATION

The recommended dosage of dofetilide is 500 μg bid. Lower dosages are recommended for patients who develop excessive QT_c prolongation on 500 μg bid. In the largest clinical trial, excessive was defined as greater than 550 ms or greater than 20 percent longer than baseline.

MODIFICATION OF DOSAGE IN DISEASE STATES

Dosage should be reduced in patients with renal disease (250 mg bid for creatinine clearance 60 to 40 mL/min and 250 mg daily for creatinine clearance 40 to 20 mL/min). Data are not available for adjustment of dosage in patients with liver disease. It is not clear whether the greater risk of torsades de pointes in women is influenced by a pharmacokinetic difference between sexes.

ADVERSE DRUG REACTIONS

The major adverse effect of dofetilide is torsades de pointes. The overall incidence during clinical development was 0.9 percent. In the DIAMOND trial, 3.3 percent of patients with a history of heart failure developed torsades de pointes.

DRUG INTERACTIONS

Concomitant administration of dofetilide with verapamil, ketoconazole, or cimetidine (but not ranitidine) results in increased plasma concentrations of dofetilide, especially in patients with reduced renal function.[245] Because it is known to be a substrate for CYP3A4, there may be other important interactions with erythromycin, other macrolides, or antifungals. No interactions have been seen between dofetilide and digoxin or warfarin.

Beta-Receptor Antagonists

See Chap. 40 for a discussion of beta-receptor antagonists.

Adenosine (Adenocard)

CLINICAL APPLICATIONS

Adenosine is very effective for the acute conversion of paroxysmal supraventricular tachycardia

(PSVT) due to reentry involving the AV node. Sixty percent of patients respond at a dose of 6 mg, and an additional 32 percent respond when given a higher dose, of 12 mg. Because of the fleeting and relatively selective action of adenosine on the AV node, some have suggested that it be used as a diagnostic tool in patients with narrow- and wide-complex tachycardia.[246] However, it is preferable, when possible, to make the correct diagnosis before giving any drugs, because of their risk of adverse effects.

MECHANISM OF ACTION

Adenosine is a nucleoside formed in the body by serial dephosphorylation of adenosine triphosphate (ATP), from cyclic adenosine monophosphate, or from hydrolysis of *S*-adenosylhomocysteine. It is formed both intra- and extracellularly, and its actions are rapidly terminated by active transport into cells followed by metabolism. The actions of adenosine are highly dependent on the rate and route of administration. A rapid intravenous injection into a central venous line is thought to activate carotid body chemoreceptors and usually produces an initial increase in blood pressure of 10 to 15 mmHg, followed by a small and transient decrease. These reflexes are attenuated during surgery, and in this setting adenosine decreases peripheral vascular resistance, increases cardiac output, and increases heart rate moderately. Bolus injections also produce biphasic effects on heart rate. Approximately 20 s after injection, sinus bradycardia occurs for 10 to 15 s, followed by sinus tachycardia thought to be due to chemoreceptor activation. Activation of the carotid chemoreceptors stimulates respiration and causes secondary activation of pulmonary stretch receptors. Adenosine has a direct effect of slowing AV nodal conduction, which can result in transient AV block. Although adenosine has no direct effect on the His-Purkinje system, it does attenuate the effects of catecholamine stimulation and, in patients with heart block, can block acceleration of the ventricular escape rate by isoproterenol. Adenosine usually has no effect on anterograde or retrograde accessory pathway conduction. Pathways that demonstrate decremental conduction often respond to adenosine, probably because they are partially depolarized and can be hyperpolarized by adenosine. Slow injections into a peripheral line often produce no clinical benefit or changes in blood pressure or heart rate.

The development of synthetic agonists and antagonists of adenosine receptors has made possible the subclassification of A_1 and A_2 receptor subtypes. The A_1 receptors are present in myocardial cells and mediate the negative inotropic, dromotropic, and chronotropic actions of adenosine. The A_2 receptors are present in the endothelium and vascular smooth muscle cells and cause coronary vasodilatation when activated.

The efficacy of adenosine in PVST is most likely due to the following actions in atrial myocardium and the AV node: (1) hyperpolarization of sinoatrial nodal cells and slowing of rate of firing, (2) shortening of the action potential of atrial cells, and (3) depression of conduction velocity in the AV node. These actions are due to activation of A_1 adenosine-receptor subtypes, which leads to activation of cyclic AMP-independent, acetylcholine/adenosine-regulated potassium current, $I_{K_{ACh,Ado}}$.

CLINICAL PHARMACOLOGY

After intravenous injection, adenosine is rapidly transported into red blood cells and endothelial cells. A half-life of elimination has ranged from 1.5 to 10 s. The drug is rapidly metabolized in the plasma and in cells to form inosine and adenosine monophosphate. Maximal pharmacologic effects are seen within 30 s after injection into a peripheral intravenous line but occur within 10 to 20 s when given into a central line.

DOSAGE AND ADMINISTRATION

Adenosine should be injected intravenously into a proximal tubing site and flushed quickly with saline solution. For adults, the initial dose is 6 mg injected over 1 to 2 s. If the arrhythmia persists, a 12-mg dose can be injected 1 to 2 min later. This can be repeated, but doses larger than 12 mg are not recommended by the manufacturer. A dosage regimen based on body weight has been proposed, with an initial dose of 50 μg/kg incremented by 50 μg/kg until the PSVT is terminated or side effects become intolerable.[246] Higher doses may be required for patients who have received caffeine or theophylline because of their antagonistic effects at A_1 receptors. Lower doses are recommended if the patients are receiving dipyridamole or carbamazepine.

MODIFICATION OF DOSAGE IN DISEASE STATES

Although the pharmacokinetics of adenosine are unlikely to be altered in patients with renal or hepatic disease, these patients often have electrolyte imbalances that could alter the clinical response. Although patients with congestive heart failure have not been reported to respond abnormally, cardiac transplant patients appear to require one-third to one-fifth of the usual dose because of denervation hypersensitivity.[247]

ADVERSE REACTIONS

Adenosine is contraindicated in patients with sick-sinus syndrome or second- or third-degree heart block unless the patient has a functioning artificial pacemaker. Because of the rapid clearance of adenosine, side effects such as facial flushing, dyspnea, or chest pressure last less than 60 s. Although intrapulmonary administration of adenosine has precipitated bronchospasm in asthmatic patients, this has not been reported with intravenous administration. Other less frequent side effects include nausea, lightheadedness, headache, sweating, palpitations, hypotension, and blurred vision. Intravenous theophylline, which has been recommended to reverse the effects of adenosine, should be prepared and ready for injection in high-risk patients.

DRUG INTERACTIONS

Several proven interactions can increase or decrease the activity of adenosine. Dipyridamole pretreatment increases the potency of adenosine, probably because it blocks cellular uptake of adenosine.[248] On the other hand, caffeine and theophylline antagonize the actions of adenosine.[249] The manufacturer cautions that carbamazepine may potentiate the actions of adenosine.

Chapter 27: ANTIARRHYTHMIC DRUGS

INVESTIGATIONAL DRUGS

Only a few new antiarrhythmic agents are currently under development in the United States. Several of these are analogs of amiodarone, such as ATI-2001,[250] dronedarone,[251] and SR-33589.[252] Some impetus for the development of these agents lies in the hope that they will have the efficacy of amiodarone without complex pharmacokinetics and/or its toxicity.[250,251,252]

Azimilide is another drug with class III action that was initially believed to be a highly selective blocker of the slow component of the delayed rectifier (I_{KS}), but recent studies suggest that azimilide also blocks I_{KR}. It is unclear whether the effects on I_{KS} contribute any novel aspects to its actions or safety. I_{KS} blockade is thought to be desirable because the effect is resistant to antagonism by isoproterenol. Other drugs, such as ambasilide, are also in clinical development, and chromanol 293B is in preclinical testing.

A new class of serotonergic antagonist drugs is being developed. Stimulation of 5-HT_4 receptors increases atrial chronotropic and inotropic responses. Whether other electrophysiologic effects are produced is unknown. In humans and swine, 5-HT_4 receptors are present only in atrium. In porcine atrial tissue, RS-100302 prolonged the effective refractory period and minimally slowed conduction velocity. The drug produced no electrophysiologic effects on ventricular tissue. It terminated pacing-induced atrial flutter in six of eight animals and atrial fibrillation in eight of nine animals, and prevented reinduction of sustained tachycardia in all animals. The electrophysiologic profile of RS-100302 suggests that it may have atrial antiarrhythmic potential without producing ventricular proarrhythmic effects.

Chapter 27: ANTIARRHYTHMIC DRUGS

List of Figures

Figure 27-1: Summary of the potentially most important actions of drugs on membrane channels, receptors, and ionic pumps in the heart. Listed are drugs used to modify cardiac rhythm. Most are marketed as antiarrhythmic agents. The drugs (rows) are ordered in a fashion similar to the columns so that generally the darker symbols for their predominant action or actions form a diagonal. Drugs with multiple actions (e.g., amiodarone) depart strikingly from the diagonal trend. The actions of drugs on the sodium, calcium, and potassium channels are indicated. Sodium channel blockade is subdivided into three groups of actions characterized by fast (300 ms), medium (med; 300-1500 ms), and slow (greater than or equal to 1500 ms) time constants for recovery from block. This parameter is a measure of "use dependence" and predicts the likelihood that a drug will decrease conduction velocity of normal sodium-dependent tissues in the heart and perhaps the propensity of a drug for causing bundle-branch block or proarrhythmia. Drug interactions with receptors alpha, beta, M_2, and P (alpha- and beta-adrenergic, muscarinic subtype, and A_1 purinergic) and drug effects on the sodium-potassium pump (Na/K ATPase) are indicated. Symbols indicate the type of actions at receptors or channels (Antagonist relative potency: ○ low; ▪, moderate; ▪, high; ▲, agonist; ▲, agonist/antagonist). Filled triangles for bretylium indicate its biphasic action to initially stimulate alpha and beta receptors by release of norepinephrine, followed by blocking of norepinephrine release and indirect antagonism of these receptors. (Adapted from the Task Force of the Working Group on Arrhythmias of the European Society of Cardiology,[9] with permission.)

Figure 27-2: Diagram of the modulated receptor mechanism for antiarrhythmic drug action. The three fractions of the sodium channel population proposed by Hodgkin and Huxley are represented in the upper part of the figure in the drug-free condition and in the lower part of the figure blocked by an antiarrhythmic agent (R′, A′, and I′, respectively). HH, standard Hodgkin-Huxley rate constants; HH′, HH with voltage dependence altered by drug binding; k_R, k_A, and k_I, association rate constants; I_R, I_A, and I_I, dissociation rate constants for the respective channel fractions. (From Hondeghem and Katzung,[11] reproduced with permission from the authors and the American Heart Association.)

Figure 27-3: Rate- (interval-)dependent depression of .$_{max}$ by lidocaine and procainamide. Following a 20-s rest period, a train of 16 action potentials was elicited using interstimulus intervals (ISIs) of 1 s or 200 ms in the presence (triangles) or absence (circles) of lidocaine or procainamide. For the duration of the train, $_{max}$ was relatively constant when measured at either ISI in the absence of drug. *A*. In the presence of lidocaine (22 μ*M*), stimulation at an ISI of 1 s produced no use-dependent block. *B*. However, stimulation at 200 ms produced a 50 percent reduction in $_{max}$ from baseline, which was first observed for the second action potential and was constant thereafter. *C*. A different pattern is seen in the presence of 276 μ*M* procainamide, which produced a significant depression of $_{max}$ at an ISI of 1 s. *D*. This depression was more pronounced when the ISI was shortened to 200 ms. Unlike the case for lidocaine, the use-dependent depression of $_{max}$ due to procainamide required multiple action potentials to approach steady-state values. (From Ehring BR, Moyer JW, Hondeghem LM. Quantitative structure activity studies of antiarrhythmic properties in a series of lidocaine and procainamide derivatives. *J Pharmacol Exp Ther* 1989; 244:479-492. Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 28:

TREATMENT OF CARDIAC ARRHYTHMIAS WITH CATHETER-ABLATIVE TECHNIQUES

Authors: Eugen C. Palma, Melvin M. Scheinman

Over the past several years, various techniques have been introduced using catheter ablative procedures for patients with cardiac arrhythmias. Particularly impressive are some of the newer techniques using radiofrequency energy sources for patients with supraventricular arrhythmias. This chapter reviews the techniques, results, and clinical indications for these procedures.

TECHNIQUES

Ablation of the Atrioventricular Junction

The technique of catheter ablation of the atrioventricular (AV) junction was first developed in canines[1] and subsequently applied for control of drug-refractory atrial arrhythmias in patients.[2,3] Multipolar electrode catheters are inserted by vein and positioned just across the tricuspid valve and against the apex of the right ventricle (Fig. 28-1). The catheter across the tricuspid valve is manipulated to allow recording of the largest unipolar His bundle potential[2] (Fig. 28-2). Radiofrequency energy of 350 to 500 kHz is applied between the distal electrode and a large back patch. After persistent AV block is observed, a permanent cardiac pacemaker is inserted (Fig. 28-3).

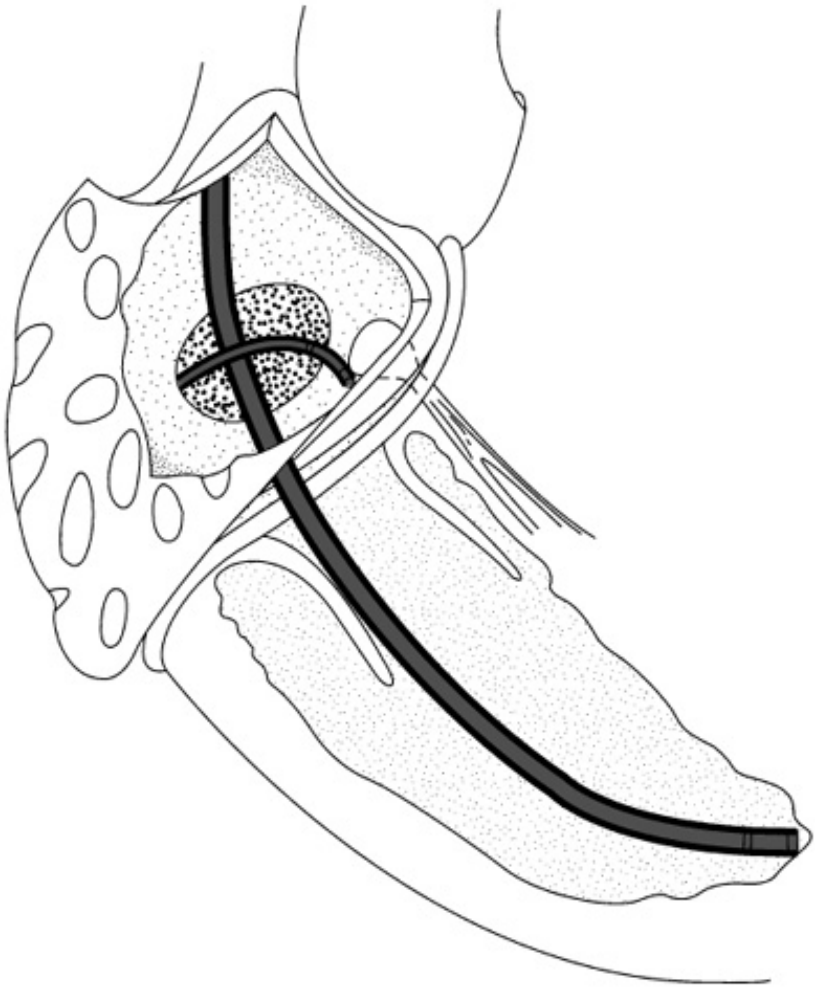

Figure 28-1: Catheter positions for patients undergoing AV junctional ablation. One catheter is placed over the region of the AV node, while a second catheter is placed against the apex of the right ventricle.

AV Nodal Modification for Patients with Atrial Fibrillation

A more recent innovation has been the use of AV nodal modification for achieving rate control in patients with atrial fibrillation.[4-6] This technique involves placement of radiofrequency lesions over the posterior or midseptum in order to achieve the desired reduction in rate during atrial fibrillation. The procedure entails a 16 percent risk of inducing complete AV block, which usually occurs within the first 72 h after the ablation.[6] In addition, a late recurrence of rapid rate has been reported in approximately 10 percent of patients.[6] The available data over a 19-month follow-up period suggest that the bulk of suitably selected patients with atrial fibrillation and rapid rate resistant to drug therapy will respond to AV nodal modification. However, this technique is of no value for the relief of symptoms related to the irregular rhythm per se.

Ablation of Accessory Pathways

Patients with accessory extranodal pathways often experience reentrant arrhythmias, with the circuit of the tachycardia involving antegrade conduction over the normal AV nodal conduction system and retrograde conduction over the accessory pathway.[7] Surgical techniques have in the past proved very effective and safe in the interruption of these pathways.[8] More recently, a number of catheter techniques have been introduced for catheter ablation of these pathways. Fisher et al.[9] were the first to use this technique for ablation of left free wall accessory pathways

via the coronary sinus. Accessory AV pathways occur anywhere along the cardiac annulus or in the septum. The majority of pathways are found traversing the left AV groove. These pathways are currently approached by inserting a steerable multipolar electrode catheter into the femoral artery with retrograde catheterization of the left ventricle.[10] The catheter is then placed under the mitral annulus in the putative site of the accessory pathway (Fig. 28-4). An alternative technique involves use of transseptal catheterization with placement of the catheter along the atrial margin of the mitral annulus.[11] One or more applications of radiofrequency energy are used to ablate the pathways. In contrast, most septal and all right free wall pathways are approached by right-sided catheterization.

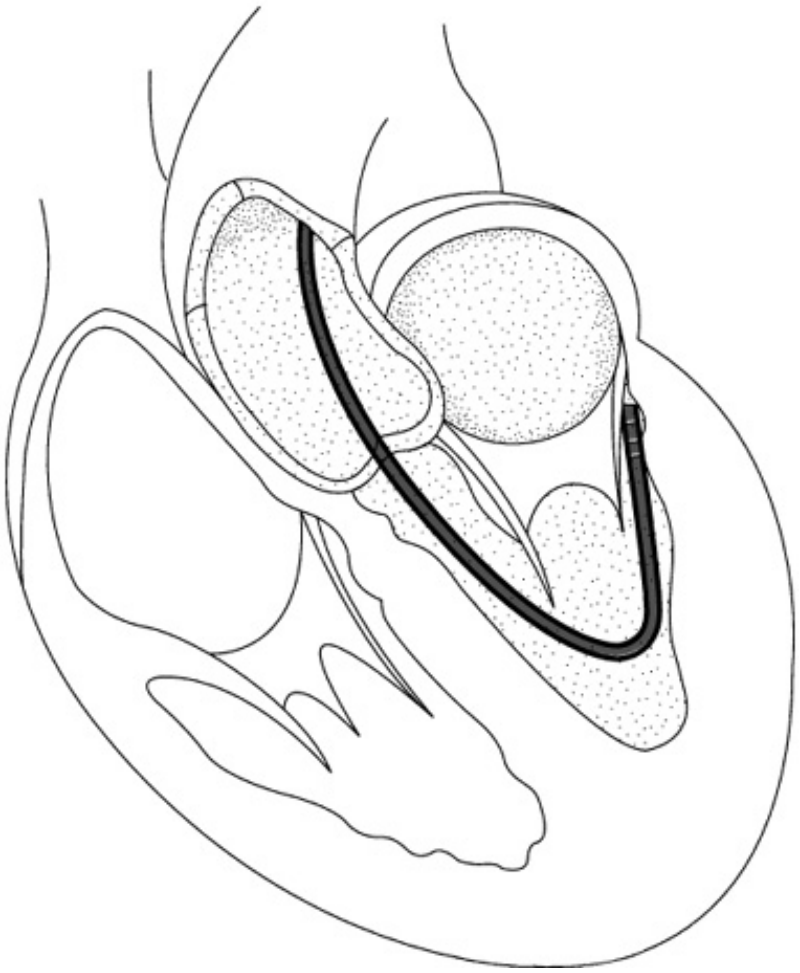

Figure 28-4: Schema depicting retrograde aortic technique for ablation of a left free wall accessory pathway. The catheter is passed across the aortic valve and placed under the mitral annulus.

Modification of the AV Node in AV Nodal Reentrant Tachycardia

Patients with AV nodal reentrant tachycardia are thought to have two pathways within or in close proximity to the AV node. These pathways show fast and slow conducting properties and have different refractory periods. Techniques have been introduced that allow for selective ablation of either pathway. The fast pathway is approached by withdrawing the catheter to a more proximal location while recording the His bundle potential, which is associated with a large-amplitude atrial electrogram and a very small or absent His deflection.[12] Application of radiofrequency energy to this area results in abrupt prolongation of the PR interval, since ablation of the fast pathway forces

conduction to occur over the slow pathway. An alternative technique for ablation of the slow pathway was introduced by Roman et al.,[13] where the radiofrequency energy is applied posteriorly between the os of the coronary sinus and the septal leaflet of the tricuspid valve. Successful application of the latter technique does not result in a change in the PR interval. The approach described for slow-pathway ablation may be accomplished successfully either by using anatomic landmarks or searching for specific so-called slow-pathway potentials. This technique has proved to be more effective and safer than attempts at fast-pathway ablation.

Ablation of Atrial Flutter/Atrial Tachycardia

Very effective techniques have been introduced recently for ablation of atrial flutter. Patients with a "typical" flutter pattern have a reentrant circuit localized to the right atrium. The critical slow zone appears to reside in the isthmus between the inferior vena cava and the tricuspid annulus.[14] A catheter is used to apply serial lesions, creating a line of block across the isthmus, with initial results suggesting success in 85 to 90 percent of patients.[15]

Patients with atrial tachycardia may be treated with catheter-ablative techniques.[16] The catheter is manipulated to find the earliest endocardial atrial potential relative to the surface P wave (Fig. 28-5). Foci of atrial tachycardia are localized along the crista terminalis or atrial appendage in the right atrium. Left atrial foci occur around the superior pulmonary veins or left atrial appendage.[17] Once the earliest site is located, radiofrequency energy is applied to ablate the atrial focus (Fig. 28-6).

Figure 28-5: Simultaneous surface V_1, I, II, and intracardiac recordings from the high right atrium (HRA), distal (ABL_d), and proximal (ABL_p) electrodes from the ablating catheter, coronary sinus (CS), and low right atrial septum (Septum) in a patient with atrial tachycardia. The earliest atrial electrogram was 35 ms prior to inscription of the surface P waves.

Ablation of Focal Atrial Fibrillation

Recently, a subset of patients with atrial fibrillation has been discovered to have the initiation of atrial fibrillation arise from foci located in the pulmonary veins.[18,19] The successful ablation of these initiating foci has been encouraging as a possible cure for this subset of atrial fibrillation. However, while the initial results have been encouraging, further study on the efficacy and short- and long-term complications of this procedure is still needed. In order to map the site of these initiating foci, one or more multipolar catheters are positioned in the different pulmonary veins via a transseptal puncture. These catheters are then used to map the earliest signal arising from the pulmonary veins that initiate either atrial fibrillation or atrial premature beats as a surrogate of atrial fibrillation. Criteria to predict successful sites of ablation while limiting complications including that of pulmonary vein stenosis are still being developed.

Modification of Sinus Node Function in Patients with Inappropriate Sinus Tachycardia

Patients with inappropriate sinus tachycardia have a resting tachycardia with abrupt increases in rate with mild exertion.[20] Typically, the arrhythmia shows diurnal variation, with slowing to normal rates at night. These patients have an increased intrinsic heart rate and excessive response to exercise or catecholamines.[20] Catheter-ablative techniques have been introduced that allow for identification of the most rapid pacemaker region of the sinus node complex.[21] This is usually found over the superior crest of the crista terminalis. One or more radiofrequency lesions are placed in this area, producing dramatic decreases in the sinus rate.[22] In addition, when this procedure is successful, there is marked attenuation of the heart rate response to exercise or catecholamines. However, narrowing of the superior vena cava-right atrium junction has been reported,[23] and the long-term follow-up of these patients may not be as encouraging as previously thought.

Ablation of Ventricular Tachycardia Foci

One of the most demanding of the catheter-ablative techniques is attempted ablation of foci initiating ventricular tachycardia. For this procedure, multipolar electrode catheters are inserted into the right ventricle, coronary sinus, and left ventricle. Ventricular tachycardia is induced by using standard stimulation protocols, and the catheters are manipulated within the ventricles to determine the earliest ventricular endocardial electrogram (during ventricular tachycardia) in relation to at least three reference orthogonal surface leads.[24] Ventricular overdrive pacing is used in an attempt to entrain the tachycardia and to prove that the earliest endocardial potentials precede (rather than follow) the tachycardia complex. In addition, the putative focus of ventricular tachycardia is paced in an effort to determine whether the paced complexes are identical or similar to the induced tachycardia.[25] The latter procedure is known as *pace mapping*. For patients with ventricular tachycardia due to coronary artery disease, concealed entrainment is manifest by a prolonged paced spike to QRS, a paced QRS identical to spontaneous tachycardia, and a postpacing interval identical to the spontaneous ventricular tachycardia cycle length, which appears to best identify the critical slow zone for the ventricular tachycardia reentrant circuit.[26] Once the putative isthmus is found, one or more radiofrequency applications are delivered from the distal electrode near this endocardial site to a chest-wall patch.

A subset of patients with ventricular tachycardia and structural heart disease particularly amenable to catheter ablation are those with bundle-branch reentrant arrhythmias. These patients are recognized by having a left intraventricular conduction delay or a frank pattern of left bundle-branch block. The majority have an associated cardiomyopathy, and all have prolonged infranodal conduction. In these patients, the tachycardic mechanism involves bundle-to-bundle conduction.[27] Catheter cure may be achieved by ablation of the right bundle branch. The right bundle usually is draped superficially over the right septal surface, and the right bundle potential usually is located easily. The right bundle may be ablated either by direct current or preferably by radiofrequency

discharges.[27] Even after successful ablation of the right bundle branch, further electrophysiologic testing is in order to exclude ventricular tachycardia emanating from myocardial sources.

Other forms of ventricular tachycardia that may be particularly amenable to catheter ablation are those occurring in patients without structural cardiac disease. These patients present with tachycardia emanating from either the right ventricular outflow tract[28] or from the inferior left septum.[29] Patients with tachycardia emanating from the right ventricular outflow show a pattern of left bundle-branch block with an inferior axis. The arrhythmia is often exercise-induced and may respond to carotid massage or treatment with adenosine or beta blockers. This arrhythmia is thought to be a cyclic AMP-dependent triggered arrhythmia. The hallmark of proper ablation includes detection of early areas in the outflow tract and a precise correspondence between the paced map and spontaneous ventricular tachycardia. Another important site of ventricular tachycardia in normal hearts may emanate from the left apical septum. This arrhythmia is characterized by a pattern of right bundle-branch block associated with a left superior axis. This arrhythmia most often responds to intravenous verapamil. Ablative approaches include recording a Purkinje potential just in front of the QRS complex and/or a paced map that corresponds to the spontaneous tachycardia.

Chapter 28: TREATMENT OF CARDIAC ARRHYTHMIAS WITH CATHETER-ABLATIVE TECHNIQUES

RESULTS OF CATHETER-ABLATIVE PROCEDURES

AV Junctional Ablation

In 1998, the largest prospective study in the United States relating to the various ablative procedures was gathered from the voluntary ablation registry of NASPE[30] (Tables 28-1 and 28-2). At present, AV junctional ablation is performed using radiofrequency energy application, with a success rate of 98.2 percent and very infrequent complications. The most serious complication is postprocedure death, which occurred in 1 of 629 patients undergoing ablation. The death was due to loss of pacemaker capture after the procedure.

Table 28-2: Results of Catheter Ablation for Ventricular Tachycardia from NASPE Voluntary Registry, 1998

	VT with CAD	VT with Cardiomyopathy	VT with Structurally Normal Heart
Total performed	53	42	119
Success (%)	58.5	61.9	84.9

ABBREVIATIONS: VT, ventricular tachycardia.
SOURCE: Unpublished data from NASPE Voluntary Registry, 1998.

Ablation of Accessory Pathways

In the NASPE voluntary registry,[30] ablation of accessory pathways was attempted in 654 patients. The overall rate of successful ablation for left-sided pathways was 94 percent, as compared with a success rate of 96 percent for right free wall and 84 percent for septal accessory pathways. Significant complications, including 4 procedure-related deaths, occurred in 1.8 percent of patients. The major complications reported were hematoma/bleeding (12 patients), cardiac tamponade (7 patients), inadvertent heart block (5 patients), and damage to the coronary arteries, including a patient who required angioplasty.

Ablation for Patients with AV Node Reentry

The largest reported series of patients undergoing catheter treatment of AV node reentry again comes from the NASPE voluntary registry,[30] which included 1197 patients who underwent ablation of a slow pathway. The success rate was 96 percent in these patients, with the development of inadvertent AV block in only 4 patients (0.33 percent).

Ablation of Atrial Flutter/Atrial Tachycardia

A total of 477 patients underwent attempted flutter ablation in the NASPE registry. The reported success rate for flutter was 85 percent and for atrial tachycardia (227 patients) 72 percent. Reported complications included development of complete AV block (3 patients) and cardiac tamponade (3 patients).

Ablation of Focal Atrial Fibrillation

To date, in the published series of patients who have undergone ablation of focal atrial fibrillation, no recurrence of atrial fibrillation has been reported in 62 and 86 percent of patients in 8- and 6-month follow-up periods.[18,19] Reported complications[19,32] have included cerebral transient ischemic attacks (2 patients), hemothorax (1 patient), hemopericardium (1 patient), and pulmonary vein stenosis (5 patients).

Ablation of Ventricular Tachycardia

Successful ablation was more frequent in those with ventricular tachycardia associated with no structural heart disease (85 percent), including those with right ventricular outflow tract tachycardia or left septal tachycardia, compared with ablation for ventricular tachycardia associated with coronary artery disease (58 percent) or idiopathic cardiomyopathy (62 percent).[30] Major complications included a post-procedural death from presumed respiratory failure and cardiac tamponade, pulmonary edema, systemic emboli, AV block, and femoral artery thrombosis.

Chapter 28: TREATMENT OF CARDIAC ARRHYTHMIAS WITH CATHETER-ABLATIVE TECHNIQUES

ADVANTAGES AND DISADVANTAGES OF CATHETER-ABLATIVE TECHNIQUES

Advantages

The use of catheter-ablative techniques has greatly affected our approach to the management of patients with supraventricular tachycardia. Catheter ablation of the AV junction has replaced the need for surgical ablation of the His bundle for patients with atrial arrhythmias refractory to drug therapy. Furthermore, use of catheter procedures allows cure of patients with reentrant supraventricular arrhythmias. The initial reports suggest a cure rate of 90 to 100 percent with minimal serious adverse effects.[31] For selected patients with ventricular tachycardia, catheter-ablative procedures may obviate the need for surgical intervention. This is particularly true for patients with bundle-branch reentry or for those with right ventricular outflow tract or left septal tachycardias.

Disadvantages

The chief disadvantage of AV junctional ablation is the need for chronic cardiac pacing after successful ablation. Another serious adverse effect is the reported 2 to 4 percent incidence of polymorphous ventricular tachycardia occurring in the postablative period.[33] This arrhythmia is more common in patients with severe myocardial disease, bradycardia, and electrolyte abnormalities, and may be prevented by temporarily pacing the heart at relatively fast rates immediately after ablation. The chief complication reported for patients undergoing AV modification procedures for AV nodal reentry is the risk of complete AV block. Attempted ablation of the slow AV nodal pathway promises to diminish or obviate this risk.

The risks of catheter ablation of accessory pathways appears to be related to the pathway site. Reported complications for left free wall pathways include the risk of systemic embolization, tamponade, or damage to the left circumflex coronary artery. Ablation of septal pathways carries the risk of causing inadvertent complete AV block. Fortunately, the risk of significant complications appears to be on the order of approximately 2 percent.

Major complications have been reported in the use of catheter-ablation treatment of ventricular tachycardia. Such complications include the risk of cerebrovascular accidents, damage to the aortic valve, or tamponade.

Chapter 28: TREATMENT OF CARDIAC ARRHYTHMIAS WITH CATHETER-ABLATIVE TECHNIQUES

CONCLUSION

The introduction of catheter-ablative techniques has completely revolutionized our approach to the management of patients with supraventricular tachycardia. These techniques have evolved to the point where curative ablative procedures are recommended as the treatment of choice for all symptomatic patients with tachycardias mediated by accessory pathways or with atrial flutter and for most patients with symptomatic AV nodal reentrant tachycardia. Complete AV junctional ablation is the procedure of choice for those with drug-refractory atrial arrhythmias, whereas selected patients with ventricular arrhythmias may benefit from catheter-ablative techniques; however, the vast majority of these patients are best managed by drugs, devices, or surgical therapy.

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 29A:

PRINCIPLES OF EXTERNAL AND INTERNAL CARDIOVERSION AND DEFIBRILLATION

Authors: Bernard Lown, Regis A. DeSilva

The application of electrical current is standard treatment for termination of atrial and ventricular tachyarrhythmias in emergency situations and when these conditions are refractory to pharmacologic treatment.[1] *Cardioversion* is the discharge of electrical energy synchronized on the R wave, while *defibrillation* refers to unsynchronized discharge. Cardioversion is, by definition, a synchronized direct-current discharge; thus this term does not apply to ventricular defibrillation or to the pharmacologic reversal of arrhythmias. The standard unit of measurement is the joule (J), and 1 J equals 1 watt-second. As there may be a wide discrepancy between the stored energy level indicated on the defibrillator and the actual delivered energy, the device should be periodically checked across a standardized resistance for reliability. The electrophysiologic basis for cardioversion is probably the closure of the "excitable gap" in a reentrant electrical circuit. Abolition of the circuit for the arrhythmia may be accomplished with energy levels as low as 1 to 5 J, and this might account for the success in terminating reentrant arrhythmias such as atrial flutter and ventricular tachycardia. Defibrillation requires much higher energy levels, which may be due to the necessity for depolarizing a large number of multiple asynchronous reentrant circuits. Energy requirements for cardioversion and defibrillation may be affected by such factors as the duration of the arrhythmia, electrolyte imbalance, underlying metabolic states, and the use of antiarrhythmic drugs such as amiodarone.

PROCEDURE

Elective cardioversion should preferably be done early in the morning in the fasting state. In urgent cases, meals should be withheld for as long as possible. Serum levels for electrolytes, digoxin, blood urea nitrogen, and creatinine should be obtained and hypokalemia corrected before cardioversion is attempted. Digitalis glycosides should be withheld only on the day of cardioversion, but if digitalis toxicity is suspected, the procedure is postponed until the problem is resolved. An intravenous line is inserted, vital signs and the electrocardiogram (ECG) are monitored, and equipment for cardiopulmonary resuscitation (CPR) is made available. General anesthesia is administered via a face mask or intravenous diazepam or midazolam is used for sedation.

Synchronization with the tallest R wave on the ECG prevents accidental triggering of ventricular fibrillation (VF); (see Fig. 29B-1) resynchronization should be checked after each discharge, as the device may revert to the default setting for defibrillation. Improper synchronization may occur when there is bundle-branch block with a tall R wave, when the T wave is highly peaked, and with artifactual spikes from a malfunctioning pacemaker. Electrodes are placed in either an anterolateral or an anteroposterior position. The anterior electrode is placed parasternally over the right second and third intercostal spaces. The lateral electrode is positioned over the cardiac apex. If a flat posterior electrode is available, it is placed at the tip of the angle of the left scapula. Current flow in either configuration is along the long axis of the heart, encompasses the bulk of cardiac tissue and minimizes travel through high-impedance bony tissue. Electrode paste, with firm pressure on the paddles, should be used to provide adequate electrical contact and reduce transthoracic impedance. Bridging of the electrodes by conductive paste

should be avoided, as this will reduce the amount of energy delivered to the heart. Pregelled adhesive electrodes may also be used in the positions described above. Prior to discharge, cardiopulmonary resuscitation (CPR) should be stopped and an "All clear" signal should be given to avoid the accidental shocking of attendants. Defibrillator waveforms are discussed in Chap. 29B.

Energy titration reduces both energy use and complications. The initial setting may be as low as 10 J, as this may be successful for atrial flutter and stable ventricular tachycardia. Energy output is increased progressively to 25, 50, 100, 200, and 360 J. Lead II of the ECG is monitored to determine whether normal sinus rhythm (NSR) has been reestablished. If serious ventricular arrhythmias emerge after a discharge, especially if digitalis toxicity is suspected, the procedure is discontinued. Alternatively, xylocaine may be administered prophylactically before the next discharge and cardioversion cautiously continued. Following cardioversion, a proper airway is maintained and adequate ventilation delivered until recovery from anesthesia occurs. Vital signs and cardiac rhythm are monitored for at least 24 h to detect the late emergence of malignant ventricular arrhythmias or recurrence of the underlying arrhythmia.

Chapter 29A: PRINCIPLES OF EXTERNAL AND INTERNAL CARDIOVERSION AND DEFIBRILLATION

TREATMENT OF SPECIFIC ARRHYTHMIAS

Atrial Fibrillation

Approximately 50 percent of patients admitted to hospital for atrial fibrillation (AF) will revert spontaneously to normal sinus rhythm (NSR) within 48 h.[2] Cardioversion is the treatment of choice if spontaneous or pharmacologic reversion to NSR does not occur, if the patient is symptomatic with chest pain during myocardial infarction, or during rapid ventricular rates in preexcitation syndrome when VF may supervene. Normal rhythm following cardioversion obviates the need for long-term anticoagulation. There is also a decrease in fatigue, increase in exercise capacity, and improvement in cerebral blood flow. Both physical and electrical remodeling occurring with AF may be reversed following cardioversion, with changes in right and left atrial volumes.[3,4] Treatment with sotalol, quinidine, disopyramide, or verapamil for at least 48 h before cardioversion may prevent early recurrence. Success of cardioversion in maintaining NSR is dependent on factors such as the duration of arrhythmia, the size of the left atrium, underlying conduction system disease, presence of valvular heart disease, and the patient's age. Overall, the success rate is over 90 percent using 200 J or less and the mean energy level required is 87 J (see also Chap. 29B). The use of atropine to abolish high vagal tone facilitates reversion to NSR.[5] Infusion of ibutelide promotes reversion to NSR experimentally. The use of high-energy cardioversion with 720 J has also been described for refractory AF.[6] Recurrence of arrhythmia is predicted by a left atrial size of 45 mm or greater and a less than 10 percent increase in the *a* wave on Doppler echocardiography following cardioversion.[7]

Higher energy levels may be required to terminate AF in congestive heart failure. Treatment of heart failure before cardioversion will increase the success rate. Acute myocardial infarction is not a contraindication to cardioversion and, in fact, prompt reversion will help prevent infarct extension by decreasing heart rate and reducing oxygen consumption. In patients with conduction system disease, emergence of atrial ectopic activity, severe sinus bradycardia, sinus arrest, junctional rhythm, or multifocal atrial tachycardia may follow cardioversion, with gradual restoration of NSR. In such cases, atropine or isoproterenol treatment may be required. If conduction system disease is suspected (e.g., a slow ventricular response in the absence of drug treatment), a temporary pacemaker is inserted prior to cardioversion, as asystole may result following the shock. Energy titration, as described earlier, anticipates this complication, and if pacing is not available, cardioversion should be abandoned if the first few discharges evoke severe bradyarrhythmia.

Cardioversion may not benefit patients with severe mitral valve disease who have "giant" scarred atria, those with mitral valve replacement, and patients with chronic recurrent paroxysmal atrial tachyarrhythmias. Although successful low-energy internal cardioversion can be performed and implantable devices are available for long-term treatment of AF, these methods are rarely indicated and seldom justified.

Thromboembolism is a major risk of atrial fibrillation resulting from stasis and inadequate emptying of the left atrial appendage and low transmitral flow velocity. Anticoagulation reduces the incidence of emboli and is recommended in the absence of contraindications.[8,9] Warfarin is

started a minimum of 3 weeks before cardioversion to maintain a prothrombin time of 1.3 to 1.5 times the control value, or an International Normalized Ratio (INR) of 2.0-3.0. Treatment is maintained for 4 weeks after cardioversion because delayed embolism may occur. Such embolism may result if there is delayed resumption of atrial activity due to "stunning" after successful cardioversion of AF. Doppler echocardiography is useful in documenting the presence of atrial contraction, as the absence of an atrial *a* wave suggests electromechanical dissociation.[7] Anticoagulation beyond 4 weeks may be indicated in the presence of recurrent bouts of AF, prosthetic valves, or cardiomyopathy or if there is a history of previous embolization or stroke.

In cases where AF is known to be of acute onset (i.e., <24 h) or in emergency situations, cardioversion may be performed without long-term anticoagulation. Heparin is started and simultaneous treatment with warfarin may be necessary, as AF may recur or embolization may occur later due to delayed resumption of atrial contraction. In elective cases, the absence of thrombus documented by transesophageal echocardiography (TEE) is not an adequate reason to withhold anticoagulation as it does not protect the patient from the risk of thromboembolism.[10-13] Because of differences in sophistication of the equipment used for TEE, patient selection, and conflicting data, absence of intraatrial clot by TEE cannot be recommended as the standard for decision making prior to cardioversion.[12] Late embolic complications result from one of three possible mechanisms: delayed resumption of atrial mechanical activity due to stunning of the atria, formation of clots after cardioversion during sinus rhythm, or relapse of AF. In 98 percent of cases, embolization occurs within 10 days of cardioversion.[14] If warfarin is contraindicated, aspirin may be utilized, but there is no persuasive evidence that such treatment protects against embolism during or following cardioversion.

Atrial Flutter

If drug treatment with an agent such propafenone or sotalol is unsuccessful, cardioversion is the treatment of choice for this arrhythmia. In many cases, the arrhythmia does not recur and maintenance of drug treatment may be unnecessary. The arrhythmia is often benign unless there is 1:1 atrioventricular conduction, when syncope may occur. Low-energy shocks easily revert atrial flutter to sinus rhythm. The mean energy level generally required is 25 J, and in 95 percent of cases 50 J or less suffices. Anticoagulation should be administered before and after cardioversion, as for AF, because of the risk of embolism.

Supraventricular Tachycardia

Because this arrhythmia is often responsive to vagal maneuvers and/or to several antiarrhythmic drugs, cardioversion is only rarely necessary for reversion. If such treatment fails, cardioversion with energy levels between 100 and 360 J is required. In paroxysmal atrial tachycardia with block due to digitalis intoxication, cardioversion is extremely hazardous, as VF and death may result. When digitalis toxicity is suspected, energy titration is cautiously attempted, with xylocaine pretreatment for ventricular arrhythmia if necessary. If low-energy discharges provoke high grades of arrhythmia or atrioventricular block, cardioversion is discontinued.

Ventricular Tachycardia

When a chest thump and intravenous xylocaine or procainamide fail to terminate ventricular tachycardia (VT), cardioversion should be performed promptly. Unless the arrhythmia is clinically unstable, sedation is administered. Energy titration is performed in stable VT and as little of 1 to 5 J may succeed; in 90 percent of cases, 10 J or less is successful in terminating the arrhythmia. Only rarely is more than 100 J necessary. When VT is rapid and the QRS complex and T wave indistinguishable, or if the patient becomes syncopal due to hemodynamic deterioration, an unsynchronized discharge of 100 J is delivered immediately. If this attempt fails, discharges of

200, 300, and 360 J should be administered consecutively until sinus rhythm is restored. Polymorphic VT and torsades de pointes, which are not self-terminating or responsive to drugs, may be similarly treated.

Ventricular Fibrillation

Unsynchronized discharge is the treatment of choice for VF and is performed using a standard defibrillator or an automatic external defibrillator (AED). This setting is also used for "blind defibrillation" in an unmonitored patient in cardiac arrest; the electrode positions are similar to those used for cardioversion. The procedure for defibrillation is delivery of an initial shock of 200 J following institution of CPR, followed by a second 200- or 300-J shock and a third 360-J shock if VF persists. If these attempts fail, 0.5 to 1.0 mg of intravenous epinephrine is given and defibrillation at 360 J is attempted again. There is no clear evidence that there is a relationship between body weight and energy requirements for defibrillation. For children, 1 to 2 J/kg is recommended; in small children and infants, a little as 10 J might suffice.

A variety of lightweight AEDs using either damped sinusoidal or monophasic truncated exponential waveforms, with varying types of hardware and software, are now available.[15-17] These devices include features such as strip-chart recorders, screen displays, and voice-synthesizer messages for the operator and devices to record the ECG and the voices of the operators. These defibrillators are equipped with computerized algorithms that recognize VF or rapid VT, permitting automatic or semiautomatic firing of the device within 8 to 10 s. These devices are intended for use in the field, where highly trained personnel are not available and therapeutic options are limited. Adhesive defibrillator pads are attached to the patient's chest in the position suggested for standard defibrillation. Resuscitative maneuvers are stopped and radio transmitters and receivers not operated during initial signal recording so as to prevent interference. Signal recognition may take up to 15 s before the defibrillator discharges; prior to this the device will automatically announce the imminent delivery of a shock by providing a printed message, a visual alarm, or a voice statement so that the attendants are not accidentally shocked. Following delivery of the first shock, CPR is not reinstituted so that the device can accomplish signal analysis and deliver additional shocks if necessary. Following successful termination of ventricular fibrillation, the airway is kept clear of secretions and vomitus, adequate ventilation with supplemental oxygen is continued, and the patient is monitored in an appropriate setting for further management. If defibrillation occurs outside of a medical facility, the patient is intubated if necessary, hemodynamically stabilized, and transported to a hospital as soon as possible.

The major determinant of success or failure of defibrillation relates to the time elapsed between the onset of cardiac arrest and defibrillation. Failure to terminate VF may be due to operator error or due to irreversibility of the underlying condition. In refractory VF, correction of hypoxia, acid-base imbalance, and electrolyte derangements as well as administration of isoproterenol (to convert fine-grain fibrillation to coarse-grain fibrillation) all render successful defibrillation more likely. If this approach is unsuccessful, rapid serial delivery of two or three 360-J shocks may succeed owing to reduction in transthoracic impedance following consecutive shocks. Rarely, fine-grain fibrillation may appear as asystole on a monitor and defibrillation should be attempted. In this setting, automatic defibrillators may fail to trigger a discharge. Current-based defibrillation (rather than an energy-based system) delivering approximately 30 to 40 A per shock has been advocated to increase success rates.[17-19] Automatic measurement of transthoracic impedance (ranging from 70 to 80 ohms in adults) before delivery of the shock avoids delivery of high currents in patients with low chest impedance and low currents in those with high impedance. Thus, success rates for defibrillation may be increased and cardiac damage minimized. If all defibrillation attempts fail to revive the patient, a rapid and thorough assessment of the resuscitative and defibrillation procedures is necessary to check for errors, such as improper electrode placement and the use of inappropriate energy levels. With AEDs, it is essential to check

for proper contact of the defibrillator pads and for proper signal analysis. If, however, no errors are detected and if the patient is unresponsive, a decision about terminating resuscitation is warranted, as severe brain damage occurs with prolonged resuscitation.

Chapter 29A: PRINCIPLES OF EXTERNAL AND INTERNAL CARDIOVERSION AND DEFIBRILLATION

COMPLICATIONS

Morphologic and functional cardiac damage may follow the use of high-energy shocks. Creatine kinase elevation following electrical discharge is transient, derives from skeletal muscle, and usually does not mask the diagnosis of acute myocardial infarction. Intracellular potassium is released from electrical trauma and may contribute to the intractability of ventricular fibrillation. Hyperkalemia may result from repeated high-energy shocks. The occurrence of postcardioversion ventricular arrhythmias is related to the presence of hypokalemia, digitalis toxicity, severe heart disease, improper synchronization, and the repeated use of high-energy discharges. Asystole and cardiac arrest are rare and occur when there is severe conduction system disease. When VF occurs several hours after cardioversion, it may be due to toxicity from digoxin, quinidine, or other antiarrhythmic agents.

Pulmonary edema following cardioversion occurs most often in the presence of mitral or aortic valvular disease or left ventricular dysfunction. It may also relate to electrically induced alterations in myocardial function, fluid overload, delayed return of atrial function, and pulmonary embolism. The risk of systemic embolization has already been discussed. Unexplained hypotension, possibly due to vasodilation, sometimes occurs after cardioversion; fluid replacement will usually correct this problem.

In the presence of implanted cardioverter-defibrillators (ICD) and pacemakers, defibrillator electrodes should be placed at least 12 cm from the generator before discharge to prevent temporary or permanent malfunction. Additionally, the metal generator may absorb electrical energy and reduce the effectiveness of the discharge. Following cardioversion or defibrillation, pacing thresholds may increase due to myocardial burns caused by transmission of electrical energy to the paced site. Because the pacing threshold may increase gradually over weeks with subsequent loss of capture by the pacemaker, serial threshold measurements should be checked not only immediately following discharge but also for 2 months afterward.

Cardioversion has been safely performed during pregnancy and fetal death has not been reported as a direct consequence of treatment. Nonetheless, fetal monitoring with an obstetrician in consultation is appropriate in this situation. Despite the possible complications described with the use of electrical energy, cardioversion and defibrillation have been performed for several decades now with a high degree of safety.

The implantable atrial defibrillator is discussed in Chap. 29B.

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 29B:

CLINICAL APPLICATION OF EXTERNAL AND INTERNAL CARDIOVERSION AND DEFIBRILLATION

Authors: Hein J. J. Wellens, Carl Timmermans, Luz-Maria Rodriguez

Electricity was first applied to the heart in 1775 when Abildgaard used electric current both to stun and to revive animals.[1] The first successful human ventricular defibrillation was reported by Beck in 1947.[2] Cardioversion of atrial fibrillation to sinus rhythm by a synchronized direct current shock was introduced by Lown in 1962[3] (see Chap. 29A). Nowadays, the application of electric current is a standard treatment for termination of atrial and ventricular tachyarrhythmias. *Cardioversion* refers to the discharge of electrical energy synchronized on the R wave, whereas *defibrillation* refers to an unsynchronized discharge. Further progress in the electrical treatment of tachyarrhythmias was made when external defibrillation paddles or skin patches were replaced by internal defibrillation electrodes (or patches) and when biphasic, instead of monophasic sinusoidal, defibrillator waveforms were used (see also Chap. 29A).

EXTERNAL CARDIOVERSION AND DEFIBRILLATION

Technique

After the procedure has been explained to the patient, a physical examination should be performed prior to elective external cardioversion. Patients should be cardioverted in a fasting state. The serum potassium level should be normal. Knowledge of renal function is helpful in guiding the dosage of adjunctive medication. If there is clinical or electrocardiographic suspicion of digitalis toxicity, the procedure needs to be postponed. The use of anticoagulation is discussed in the section "Treatment of Specific Arrhythmias," below. The patient should have a reliable intravenous access, and dentures should be removed. A short-acting anesthetic or sedative agent (preferably with amnesic effects, e.g., midazolam) is administrated by a qualified physician. The cardioversion should be carried out in an area with facilities for an eventual cardiopulmonary resuscitation. A 12-lead electrocardiogram is recorded before and after the procedure, and during the cardioversion, a rhythm strip is obtained, or at least the patient's rhythm should be shown on a monitor screen. Synchronization of shock delivery with the R wave of the QRS complex is essential during cardioversion. Although properly synchronized shocks rarely, if ever, induce ventricular fibrillation, unsynchronized shocks may be delivered in the ventricular vulnerable period of the preceding beat (near the apex of the T wave) and result in ventricular fibrillation (Fig. 29B-1). The appropriateness of synchronization of each shock delivery always should be verified because a large or tall T wave or P wave, artifacts, or noise can be misidentified as the R wave. Improper synchronization also may occur when the QRS complex has a right bundle-branch block configuration with a tall secondary R wave.

The two standard electrode positions are the anterolateral and anteroposterior positions. In the anterolateral position, the anterior electrode is placed parasternally over the right second and third intercostal spaces, and the lateral electrode is placed just below the fourth intercostal space in the midaxillary line. In the anteroposterior position, the anterior electrode is placed as previously mentioned, and the posterior electrode is positioned just below the left scapula. In case of failure to terminate the arrhythmia, shock delivery can be repeated using the other electrode location.

Some authors do not recommend the anterolateral position for cardioversion of atrial fibrillation because this position probably does not provide optimal current flow through the atria.[4]

Successful defibrillation and cardioversion requires sufficient flow of electric current through the appropriate chambers of the heart. Current flow is determined by the shock strength and the transthoracic impedance. Most available defibrillators have a maximum energy setting of 360 J, representing the maximal amount of energy delivered through a 50-Ω resistance. It was determined that the transthoracic impedance in adults of a first shock of 100 J or more varies between 25 and 150 Ω, with an average of 75 Ω.[5] If the impedance is high, low-energy shocks will fail to terminate the arrhythmia. Several authors reported on the different factors that influence transthoracic impedance, including the electrode size, the distance between the electrodes, the couplant medium and pressure between the electrode and the chest wall, the phase of respiration, a recent sternotomy, and previous shocks.[4,6] Optimal electrode size seems to be 8 to 12 cm in diameter for adults. This electrode size also should be used for children weighing more than 10 kg. Wide separation of the electrodes must be maintained especially if the coupling medium is a paste or gel. In women, the lateral electrode should be placed lateral to or under the breast. Although self-adhesive disposable electrode pads have advantages in certain circumstances with high-risk cardiac patients, their slightly higher impedance makes their use not optimal in patients predisposed to a high transthoracic impedance. Firm electrode pressure with the patient in full expiration reduces transthoracic impedance and enhances the likelihood of shock success. A sternotomy reduces transthoracic impedance for at least 1 month after the procedure. Finally, impedance also lowers after repeated shock delivery.

Prior to each shock delivery, attendants should be warned in order to avoid their accidental shocking. Following cardioversion, a proper airway is maintained, and adequate ventilation is delivered until recovery from anesthesia occurs.

Defibrillator Waveforms

Alternating current was first used for ventricular defibrillation. It is a sine wave that oscillates between positive and negative polarity with a well-defined frequency (Fig. 29B-2*A*). Because of significant side effects and technical constraints, alternating current was replaced by a single-capacitor discharge or direct-current defibrillation.[7] A single-capacitor discharge generates a high-voltage peaked wave with an exponential decay (undamped exponential waveform,[3,7] see Fig. 29B-2*B*). Rounding of this initial peak using an inductor (damped capacitor discharge) gave rise to the until now most frequently used monophasic damped sinusoidal waveform for external defibrillation and cardioversion (Fig. 29B-3). Depending on the defibrillator characteristics and the impedance of the patient, the monophasic sinusoidal waveform does not oscillate between the baseline (critically damped capacitor discharge; Edmark waveform, see Fig. 29-3*A*) or has one or more terminal negative components (underdamped capacitor discharge; Lown or Gurvich waveform).[7] Less frequently, a defibrillator uses an undamped capacitor discharge with a long time constant that is then truncated so that it resembles a square or trapezoidal wave (monophasic truncated exponential waveform,[7] see Fig. 29-3*B*). Only limited clinical information is available on the effectiveness of this waveform.[8]

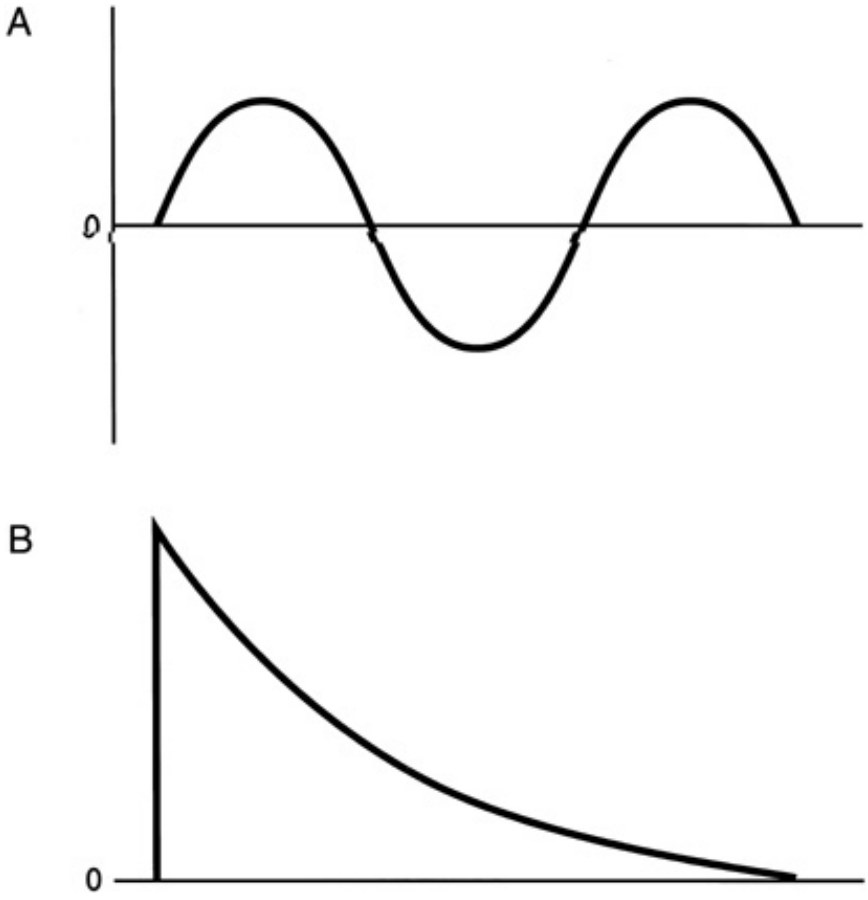

Figure 29b-2: *A.* Alternating current. *B.* Direct current.

Due to the development of an implantable cardioverter defibrillator, biphasic waveforms have been examined in several experimental and clinical studies over the last two decades. A biphasic truncated waveform, which consists of both a positive and a negative phase (see Fig. 29-3*C*), may offer several technical advantages over a monophasic sinusoidal waveform and seems to allow external defibrillation at lower energy levels. These lower amounts of energy, together with removal of the inductor, makes an external defibrillator using a biphasic waveform small, light, cheap, and easy to maintain. In a multicenter study it was demonstrated that 115- to 130-J biphasic truncated transthoracic shocks defibrillate ventricular fibrillation as well as 200-J monophasic damped sine-wave transthoracic shocks.[9] However, in this study, the 115- or 130-J biphasic shocks appeared to be not as successful as the 360-J monophasic shocks.

Recently, low-energy impedance-compensating biphasic waveforms have been evaluated for the treatment of ventricular as well as atrial arrhythmias. These defibrillators automatically adjust the duration of the waveform for the transthoracic impedance of the patient during shock delivery.[10]

Chapter 29B: CLINICAL APPLICATION OF EXTERNAL AND INTERNAL CARDIOVERSION AND DEFIBRILLATION

TREATMENT OF SPECIFIC ARRHYTHMIAS

Atrial Fibrillation

Because cardioversion of atrial fibrillation is a safe and effective method to restore sinus rhythm, the procedure should be attempted at least once in every patient with chronic atrial fibrillation. Furthermore, due to the proarrhythmogenic effect of antiarrhythmic drugs, cardioversion also may be preferred to the intravenous administration of these drugs in patients with symptomatic, long-standing paroxysmal atrial fibrillation. Overt congestive heart failure and hyperthyroidism should be controlled as much as possible before cardioversion. Acute myocardial infarction is not a contraindication to cardioversion; prompt restoration of sinus rhythm would help prevent infarct extension by decreasing the heart rate and reducing oxygen consumption. If atrioventricular conduction disturbances are suspected (e.g., a slow ventricular response in the absence of antiarrhythmic drug treatment), cardioversion should be avoided because asystole may result or should be performed after the insertion of a temporary transvenous pacing catheter.

The immediate success rate of external cardioversion varies between 70 and 94 percent.[3,11] This variation in outcome may be due to the use of different definitions for a successful cardioversion, other patient characteristics, and pretreatment with antiarrhythmic drugs. The probability of a successful cardioversion depends mainly on the duration of the atrial fibrillation episode.[3,11] Other factors such as the transthoracic impedance,[5] left atrial size, and the patient's age[12] are also important for acute success. The maintenance of sinus rhythm after cardioversion is less favorable. In a metaanalysis performed by Coplen et al.,[13] only 45, 33, and 25 percent of the patients who were not taking antiarrhythmic drugs remained in sinus rhythm at 3, 6, and 12 months after cardioversion, respectively. Although the administration of antiarrhythmic drugs prolongs to a certain extent the arrhythmia-free period after external cardioversion, use of these drugs is not without risk. Several clinical variables including etiology and duration of atrial fibrillation, age, and echocardiographic variables such as size and function of the left atrium and left atrial appendix are considered to have a certain predictive value for the recurrence of the arrhythmia.

The initial shock strength should be 100 J, followed by a second 200-J shock and a third 360-J shock if atrial fibrillation persists. In patients in whom 360 J fails to restore sinus rhythm, a second 360-J shock may be delivered again. Shocks lower than 200 J are particularly likely to be effective when the duration of atrial fibrillation is shorter than 24 h or when the patient does not have structural heart disease or is not receiving antiarrhythmic drugs.[14]

Patients undergoing electrical cardioversion are at risk for thromboembolic complications. Two mechanisms may be responsible: (1) dislodgment of a preexisting atrial thrombus after resumption of mechanical atrial activity and (2) left atrial appendage stunning or impaired function immediate after cardioversion. It is recommended for patients with atrial fibrillation of unknown or long duration that anticoagulation should be given for 3 weeks before elective cardioversion to maintain an international normalized ratio (INR) of 2.0 to 3.0. Anticoagulation should be continued for 4 weeks after successful cardioversion. It is usual clinical practice not to give anticoagulation to patients certain to have had the onset of atrial fibrillation within the preceding 24 to 48 h.[15] The absence of a thrombus documented by transesophageal echocardiography is not

an adequate reason to withhold anticoagulation because it does not protect the patient from the risk for thromboembolism.[16] Even if short-term anticoagulation is combined with transesophageal echocardiography, this approach has not yet proved to be safer than the prophylactic anticoagulation 3 weeks before cardioversion.[17] In any case, the short-term anticoagulation needs to be extended to 4 weeks after cardioversion.

Other Supraventricular Tachycardias

Presently, recurrent episodes of atrial flutter are usually permanently cured with radiofrequency catheter ablation.[18] In patients with atrial flutter and 1:1 atrioventricular conduction, external cardioversion can restore sinus rhythm effectively and safely. In contrast to atrial fibrillation, most episodes of atrial flutter are terminated with lower amounts of energy ranging from 50 to 100 J. An initial shock strength of 100 J is more efficient for restoration of sinus rhythm and induces less frequent atrial fibrillation compared with 50 J.[19] Patients with atrial flutter are considered at low risk for thromboembolism due to the synchronous atrial contraction. Nevertheless, several studies suggest that the thromboembolic risk at the time of cardioversion is higher than expected.[20,21] Intermittent transition to atrial fibrillation may explain the development of thrombi, and patients with atrial flutter are also at risk of developing atrial stunning after cardioversion. Therefore, consideration should be given to anticoagulate patients with atrial flutter the same as patients with atrial fibrillation.[15]

Other supraventricular tachycardias rarely require external cardioversion unless they produce hypotension, heart failure, or myocardial ischemia (see also Chap. 29A). These arrhythmias also may be terminated by external cardioversion if they are refractory to antiarrhythmic drugs.

Ventricular Tachycardia

When a hemodynamically well-tolerated sustained monomorphic ventricular tachycardia outside an acute ischemic episode cannot be terminated by intravenous procainamide,[22] a low-energy synchronized shock ranging from 25 to 50 J should be delivered. However, these low amounts of energy incidentally may induce ventricular fibrillation. In hemodynamically not tolerated sustained monomorphic ventricular or polymorphic ventricular tachycardia, a 200-J shock should be given, followed by 300 and 360 J if earlier shocks are not successful. In hemodynamically unstable patients with fast ventricular tachycardia, the QRS complex is often indistinguishable from the T wave, and unsynchronized shocks are recommended.

In pediatric patients with hemodynamically not tolerated (supra-) ventricular tachycardia, it is recommended to deliver an initial synchronized shock of 0.5 J/kg. The dose is increased with subsequent attempts if necessary.[23]

Ventricular Fibrillation

Ventricular fibrillation is best explained as a re-entrant mechanism where the waves initially follow certain routes and thereafter degenerate into smaller reentry circuits. This pattern of ventricular activation causes loss of coordinated myocyte contraction and results in loss of mechanical function of the ventricles, leading to death. The arrhythmia is eminently treatable with an unsynchronized discharge of electrical energy. The recommended first shock strength for defibrillation is 200 J. If the first shock fails to defibrillate, a second 200- or 300-J shock should be delivered. The following arguments favor the administration of a second shock of 200 J. First, every defibrillation attempt with a selected amount of energy has a certain probability to terminate ventricular fibrillation. For repeated shocks, the probability should be additive. Second, since transthoracic impedance lowers after repeated shocks, higher current will be delivered to the myocardium using a second shock of the same energy as the first one. The argument favoring the use of a second shock of 300 J is that a greater and more predictable increase in current will occur.

If ventricular fibrillation persists after two shocks, a third 360-J shock should be given.[23] In case of recurrent ventricular fibrillation after a successful defibrillation, shocks with the same energy level as those which were effective previously should be delivered. Higher shock energies should be used only if a shock fails to terminate ventricular fibrillation.

With the advent of biphasic defibrillators, the American Heart Association stated that low-energy (150-J), nonprogressive (150 J-150 J-150 J) biphasic waveform defibrillators may be used for both out-of-hospital and in-hospital ventricular fibrillation arrest, including persistent or recurrent ventricular fibrillation that does not respond to the initial low-energy shock.[24] Ventricular fibrillation is uncommon in children; if it occurs, usually an initial shock strength of 2 J/kg is used. If successful defibrillation has not been obtained, the shock strength should be doubled and repeated. If defibrillation fails, a second shock of 4 J/kg needs to be delivered.[23]

Ventricular fibrillation is the most common cardiac mechanism for sudden death. In the chain-of-survival concept, early defibrillation is a key link to improve survival.[25] Technological improvements in automated external defibrillators, developed almost 20 years ago, made possible the use of defibrillation by non(para)medics. Self-adhesive pads attached to the patient on the standard electrode positions recommended for conventional external defibrillation are used for recording the electrogram and for eventual defibrillation. The automated external defibrillators are fitted with accurate arrhythmia analysis algorithms that recognize ventricular fibrillation or rapid ventricular tachycardia when presented with approximately 8 s of cardiac rhythm, permitting defibrillation within 8 to 10 s either automatically or by advising a rescuer to press a button that delivers a shock. A potential clinical advantage of automated external defibrillators using the conventional monophasic waveform over newer devices equipped with biphasic waveforms for treatment of patients in out-of-hospital arrest awaits proper clinical trials.[24]

Complications

The overall incidence of complications with external cardioversion and defibrillation is low. No myocardial injury occurs following the delivery of even high-energy shocks, as detected by the release of the cardiac isotype of troponin I, a highly specific marker of myocardial lesions.[26] After cardioversion, ST-segment elevation and negative T-waves occasionally may occur. The ST-segment changes usually persist several minutes after shock delivery, whereas the T-wave changes usually last longer. These electrocardiographic changes are related to the amount of energy delivered, but their exact mechanism is unknown. It has been postulated that postshock transient enhanced permeability of the cellular membrane occurs, allowing ionic exchange that leads to membrane depolarization (electroporation).[27] The electroporation is macroscopically manifested as ST-segment changes.

The occurrence of serious ventricular arrhythmias is related to the presence of hypokalemia, digitalis toxicity, severity of heart disease, improper synchronization, and the repeated use of high levels of energy. Asystole and cardiac arrest are rare and occur when there are severe conduction disturbances. Postshock bradycardia may be due to an underlying sick sinus syndrome, the use of antiarrhythmic drugs, or the presence of myocardial ischemia. The risk of embolization after cardioversion of atrial arrhythmias is prevented by adequate anticoagulation.

Damage to the electric circuitry of pacemakers or to the electrode-myocardial interface may occur following cardioversion or defibrillation.[28] Defibrillation electrodes should be placed as far from the pacemaker as possible, preferably in the anteroposterior position. Because pacing thresholds may increase gradually over weeks with subsequent loss of capture by the device, serial pacing threshold measurements for 2 months are recommended. Pulmonary edema, occurring minutes to hours after cardioversion, is a rare complication. It may be due to delayed return of left atrial function, left ventricular dysfunction, and possibly neurohumoral mechanisms.[29] Unexplained hypotension sometimes occurs after cardioversion, and fluid treatment will correct this problem.

External cardioversion and defibrillation cause first-degree skin burns, which are related to the amount of energy used.[30] Rarely, fractures of vertebrae or long bones following cardioversion or defibrillation may occur.

Chapter 29B: CLINICAL APPLICATION OF EXTERNAL AND INTERNAL CARDIOVERSION AND DEFIBRILLATION

INTERNAL CARDIOVERSION AND DEFIBRILLATION

Initially, the intracardiac delivery of energy was used for the development of implantable cardioverter defibrillators. Chapter 30 is dedicated to the use of these devices for the treatment of ventricular tachyarrhythmia. Only recently, internal cardioversion was introduced as a new treatment modality for patients with atrial fibrillation. The gradual replacement of external defibrillation paddles or skin patches by defibrillation electrodes resulted in effective intracardiac cardioversion of atrial fibrillation using only a small fraction of the energy required for external cardioversion. An esophageal electrode-cutaneous patch configuration allowed the cardioversion of patients with atrial fibrillation with an amount of energy three to four times lower than the energy required for conventional external cardioversion.[31] An early attempt to obtain lower atrial defibrillation thresholds using a single right atrial electrode in combination with a cutaneous patch was disappointing.[32] However, a randomized comparison of this technique with conventional external cardioversion demonstrated a higher immediate success rate of internal cardioversion compared with external cardioversion.[33] In the first study where both defibrillation electrodes were located in the right side of the heart, none of the patients with atrial fibrillation were cardioverted successfully.[34] Only after experimental studies in sheep was it recognized that the optimal lead configuration for internal defibrillation of atrial fibrillation required electrodes encircling as much of the fibrillating atrium as possible.[35] In that study, four right atrial electrode positions (superior vena cava, right atrial appendage, and middle and low right atrium) and three left atrial positions (coronary sinus, left pulmonary artery, and left axillary subcutaneous patch) were evaluated. Additionally, the efficacy of monophasic and biphasic waveforms was compared. It was shown that a 3/3-ms biphasic shock delivered between the right atrium and the coronary sinus had the lowest defibrillation threshold (1.3 ± 0.4 J). The remarkably low amount of energy to convert atrial fibrillation in animals prompted several centers to investigate the use of intracardiac shocks in patients with atrial fibrillation.

Technique

Similar to external cardioversion, evaluation of patients undergoing elective internal cardioversion of atrial fibrillation includes a clinical history, a physical examination, routine laboratory and thyroid function tests, and a 12-lead electrocardiogram. The same oral anticoagulation recommendations should be used as discussed previously for external cardioversion, except that the anticoagulant needs to be interrupted before the procedure to perform a safe venous puncture. Patients are cardioverted in a fasting state, and whenever needed, conscious sedation is provided. Although several techniques are used for internal cardioversion, the following is the most frequently used. Three temporary catheters are inserted in the venous system and positioned under fluoroscopic guidance. Two large-surface-area catheters are used for shock delivery, and a third quadripolar catheter is used for R-wave synchronization and temporary ventricular postshock pacing. In case no ventricular catheter is inserted, the surface electrocardiogram is used for R-wave synchronization. Improperly synchronized shocks, also of low energy, induce ventricular fibrillation (see Fig. 29B-1). The first defibrillation catheter is advanced in the distal coronary sinus, and the second preferably is positioned in the right atrium appendix or, otherwise, in the lateral wall of the right atrium (Fig. 29B-4*A*). The defibrillation catheters are connected to an external defibrillator delivering biphasic shocks. The quadripolar catheter is placed in the apex of the right ventricle and is also connected to an external pacemaker. The right

atrial and right ventricular catheters usually are introduced via a femoral approach. The coronary sinus catheter can be inserted through a femoral, subclavian, jugular, or brachial vein. Alternative positions for the defibrillation catheters are the left pulmonary artery (see Fig. 29B-4*B*) or the left atrium through a patent foramen ovale (see Fig. 29B-4*C*).

Internal cardioversion of atrial fibrillation has several clinical applications such as the treatment of patients resistant to external cardioversion or in whom general anesthesia is contraindicated or hazardous, the conversion to sinus rhythm of inadvertently induced atrial fibrillation during an electrophysiologic study, and the evaluation of patients with recurrent symptomatic atrial fibrillation, resistant to antiarrhythmic drugs, for treatment with an implantable atrial defibrillator. A comparison of the reported success rates and energy requirements for catheter-based restoration of sinus rhythm is not only difficult because of the variable use of a preestablished energy limit for termination of the procedure but also because of the heterogeneous populations treated, the evaluation of several technological improvements of the defibrillation system, and the differences in lead configurations.

Between December of 1995 and February of 1999, 120 patients (89 men, mean age 59 ± 12 years) with a mixture of heart disease seen in the general population with atrial fibrillation underwent 141 internal cardioversions in our hospital. Most of the patients were taking antiarrhythmic drugs at the time of the procedure. The left atrial size ranged from 42 to 70 (53 ± 6) mm and the left ventricular ejection fraction from 21 to 72 (55 ± 12) percent. Atrial fibrillation was induced in 16 patients, and in the other 125 patients the average duration of the treated spontaneous episode was 306 ± 564 (0.1-3650) days. In all procedures, a right atrium to coronary sinus defibrillation vector was used. Shocks were delivered using a 0.5-J start, a 0.5-J step-up protocol until 3 J, followed by 1.0-J steps until cardioversion of atrial fibrillation occurred. All 141 atrial fibrillation episodes were cardioverted successfully with a mean energy of 5.6 ± 4.7 (0.4-35) J. In patients with long-standing atrial fibrillation, the atrial defibrillation threshold is higher than in patients with induced or paroxysmal atrial fibrillation. Although internal cardioversion has a higher acute efficacy in restoring sinus rhythm as compared with external cardioversion, the long-term outcome seems to be independent of the method of cardioversion.

An intriguing phenomenon after internal and external cardioversion of atrial fibrillation is the immediate reinitiation of the arrhythmia occurring within minutes of successful shock delivery (Fig. 29B-5). Because the intracardiac electrograms following an internal cardioversion are frequently monitored, immediate resumption of atrial fibrillation is detected more often as compared with external cardioversion.[36] Complications of internal cardioversion are rare and, if they occur, are related to the invasive nature of the procedure, improper synchronization, and inadequate anticoagulation.

Chapter 29B: CLINICAL APPLICATION OF EXTERNAL AND INTERNAL CARDIOVERSION AND DEFIBRILLATION

IMPLANTABLE ATRIAL DEFIBRILLATOR

Antiarrhythmic drugs and external defibrillation are presently the primary modes of treatment of patients with atrial fibrillation. Due to the limited efficacy and safety of antiarrhythmic drugs and the repeated hospitalizations for external cardioversion requiring anesthesia, several non-pharmacologic options have been developed, especially for patients with recurrent atrial fibrillation. One of them, the implantable atrial defibrillator, only recently has been evaluated clinically. At present, a stand-alone atrial defibrillator and an atrioventricular cardioverter-defibrillator with dual-chamber pacemaker facilities are available. Because these devices are intended for use outside the hospital, ventricular tachyarrhythmia induced by atrial shocks, especially from a stand-alone atrial defibrillator, could have disastrous consequences. Prior experimental animal studies[37] resulted in programming the atrial shock synchronized to a QRS complex that occurs at least 500 ms after the preceding QRS complex, in the absence of a long-short sequence, to avoid the potential ventricular proarrhythmia risk in a stand-alone atrial defibrillator.

In selected patients with recurrent atrial fibrillation, a stand-alone atrial defibrillator was able to restore sinus rhythm promptly and safely with low amounts of energy.[38] Ambulatory therapy with the stand-alone atrial defibrillator is feasible because the device can terminate most of the episodes of atrial fibrillation in the patient's ambient setting without induction of ventricular proarrhythmia. Interestingly, in the majority of patients, atrial fibrillation can be treated with the device without sedation. The need for sedation is related to the number of shocks delivered to treat an atrial fibrillation episode.[39] A clinical study for the evaluation of a dual-chamber cardioverter-defibrillator for termination of spontaneous atrial fibrillation episodes in patients without indication for implantation of a ventricular defibrillator is presently ongoing. Whether an implantable atrial defibrillator modifies the natural history of atrial fibrillation, improves quality of life, and is cost-effective needs to be defined.

Part 4: RHYTHM AND CONDUCTION DISCORDERS
Chapter 30:

THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

Authors: Peter A. O'Callaghan, Jeremy N. Ruskin

HISTORICAL PERSPECTIVE

Sudden and unexpected cardiac death (SCD) is estimated to claim 300,000 lives annually in the United States.[1] Despite a significant reduction in total cardiac mortality rates in recent years, the proportion of deaths that are sudden has remained unchanged. In-field electrocardiogram monitoring has demonstrated that the principal cause of SCD in victims of out-of-hospital cardiac arrest is ventricular fibrillation (VF).[2] In more than 80 percent of cases, sudden death is caused by the abrupt onset of ventricular tachycardia (VT) that progresses to VF.[3] Since self-termination of VF is exceedingly rare, the single most important factor determining survival is the time between event onset and first defibrillation attempt.[4] Overall mortality rates associated with out-of-hospital cardiac arrest are unacceptably high, mainly because of the delay in providing effective therapy.[5] In Seattle, Washington, only 10 percent of all out-of-hospital SCD victims are discharged from the hospital neurologically intact, despite good emergency medical response times, prompt cardiopulmonary resuscitation, and the use of automatic external defibrillators.[6]

As originally conceived by Mirowski, the implantable cardioverter defibrillator (ICD) was designed to circumvent the delay in providing definitive therapy to ambulatory individuals with life-threatening ventricular tachyarrhythmias.[7] The internal defibrillator responds by delivering an internal electrical shock within 10 to 20 s of arrhythmia onset, a time frame in which the potential for arrhythmia reversal approaches 100 percent. The first experimental model was successfully tested in 1969 in a dog.[8] After 10 years of research and development, Mirowski and coworkers implanted the first ICD in a human at the Johns Hopkins University Medical Center in 1980.[9] In the original article, the authors state, "It is intended to protect patients at particularly high risk of sudden death whenever and wherever they are stricken by these lethal arrhythmias (...) the only purpose of this device is to achieve defibrillation automatically, before the victim of a lethal arrhythmia can be reached by a cardiac resuscitation team." In 1985, the ICD received approval from the U.S. Food and Drug Administration for market release. Since then, the indications for ICD implantation have greatly expanded, and the number of devices implanted annually has steadily increased, reaching 50,000 new implants worldwide in 1999.

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

FUNCTIONAL CHARACTERISTICS

The ICD system consists of two basic components: a pulse generator and a lead electrode or electrodes for arrhythmia detection and for therapy delivery. In addition to internal defibrillation, ICDs also provide pacing (antitachycardia and antibradycardia), synchronized cardioversion, telemetry, and diagnostics (event electrograms and history logs). The pulse generator is essentially a self-powered computer within a hermetically sealed titanium can.[10] Lithium vanadium oxide batteries and defibrillator capacitors occupy the bulk of the space. The operational circuitry-including resistors, capacitors, transformers, and microprocessors-occupies the remaining space and is separated into low-power circuit components (sensing and pacing) and high-power circuit components (defibrillation). A header made of epoxy provides an electrical interface between the internal circuitry and the lead electrode as well as electrical insulation from the surrounding tissues. Since the 1990s, designs have focused on a progressive increase in device functions combined with a gradual reduction in pulse generator size.

Sensing Ventricular Depolarizations

Reliable sensing of ventricular depolarizations is essential for proper functioning of the ICD. Sensing electrodes transmit raw (unfiltered) electrograms to the sense amplifier of the ICD. The sense amplifer amplifies, filters, and rectifies the incoming signals. It then compares them to a sensing threshold and produces a set of RR intervals for the detection algorithm to use (Fig. 30-1*A*). Intracardiac electrogram amplitude can vary markedly among rhythms, such as sinus rhythm, VT, and VF, or even during the same rhythm (e.g., VF). Fixed gain and sensitivity, as used in pacemaker technology, would result in either undersensing or oversensing, depending on the settings chosen. Therefore, all ICDs utilize some form of automatically adjusting signal amplifier (Fig. 30-1*B*). Automatic gain control automatically and continuously varies the gain so that the amplitude of the processed signal is constant. Autoadjusting sensitivity threshold sets the sensitivity to a proportion of the amplitude of the last sensed event, and the sensitivity then gradually increases until the next event is sensed. Sensed events are then analyzed using a detection algorithm. The range of all possible ventricular cycle lengths is divided into rate zones that do not overlap, including a VF zone, VT zones (between 0 and 3 programmable), a normal rate zone, and a bradycardia zone.

Ventricular Fibrillation Detection

Devices employ rate criteria as the sole method of detecting VF. An *X/Y* detector triggers when *X* out of the previous *Y* sensed intervals (typical setting 8/12 intervals) are shorter than the VF detection interval. This approach is very good at ignoring the effect of a small number of undersensed events due to small-amplitude signals during VF. The utilization of rate detection in an *X/Y* detection algorithm results in maximal sensitivity at the expense of specificity. Any tachycardia with a cycle length less than the tachycardia detection interval will be detected as VF by the device, and VF therapy will be initiated. At the end of capacitor charging and prior to the delivery of therapy, a reconfirmation algorithm must be fulfilled (noncommitted device). This prevents inappropriate shock therapy for self-terminating events, such as nonsustained VT.

Ventricular Tachycardia Detection

ICDs have multiple programmable tachyarrhythmia detection zones. Although rate is the principal detection criterion, the VT detection algorithm is different from that in the VF zone. In contrast to VF detection, most VT detection algorithms require a programmable number of consecutive intervals shorter than the VT detection interval. An interval longer than the detection interval (e.g., due to RR variability in atrial fibrillation) would reset the counters.

In certain patients, both ventricular and supraventricular tachycardias (e.g., sinus tachycardia, atrial fibrillation, or atrial flutter) may result in ventricular rates within the VT zone or zones. Up to 25 percent of ICD discharges are inappropriate when rate is employed as the sole criterion for VT therapy.[12] These inappropriate discharges are poorly tolerated by patients and constitute a major clinical problem.

To increase specificity, optional VT detection enhancements are programmable. This approach should be limited to tachycardia rates that are hemodynamically tolerated by the patient. Detection enhancements include sudden onset, rate stability, and electrogram morphologic (QRS width) criteria. These programmable options are not available in the VF zone, where maximal sensitivity is required. The onset criterion is intended to distinguish sinus tachycardia with a gradual rate increase from VT characterized by a sudden rate increase (e.g., greater than 9 percent shortening in cycle length at onset of episode). The rate stability criterion is used to differentiate sustained monomorphic VT with a small variation in cycle length (e.g., less than 40 ms) from atrial fibrillation with large cycle length variability. The electrogram morphologic criterion measures the width of the intracardiac electrogram to differentiate ventricular from supraventricular tachycardias with normal conduction. Although programming these options improves specificity, it does so at the risk of prolonging detection times and of failure to detect an episode of VT. "Sustained-rate duration" is a programmable maximum period of time (e.g., 30 to 120 s) during which therapy is inhibited if the programmed enhancement criteria are not met. At the end of this period, if the tachycardia rate persists above the VT cutoff rate, therapy will be delivered. As a safety feature, sustained-rate duration is nearly always programmed "on" whenever enhancement criteria are employed. In one study, programming stability and onset criteria plus sustained-rate duration significantly reduced inappropriate therapies to 13 percent, compared to 28 percent in patients using a rate criterion only.[13] Addition of an electrogram morphologic criterion can reduce inappropriate detection even further.[14] However, optimal programming of ICD width criterion requires testing during exercise as well as at rest.[15]

The lack of specificity of VT detection despite optional VT detection enhancements is a significant limitation of single-chamber ICDs. Dual-chamber pacemaker-defibrillators, requiring an additional atrial lead, provide not only the hemodynamic benefits of dual-chamber pacing but also dual-chamber detection algorithms.[16] Detection algorithms in these devices employ a stepwise analysis of rate, stability, atrioventricular (AV) association, and onset (ventricular acceleration, atrial acceleration, or nonaccelerated).[17] Again, these programmable options are not available in the VF zone, where maximal sensitivity is required. Preliminary clinical experience is mixed. In one study, all episodes (122) of VT and VF were correctly diagnosed, and 51 of 53 episodes of supraventricular tachyarrhythmias were correctly diagnosed. Only 2 episodes of atrial fibrillation with rapid regular ventricular rates were incorrectly diagnosed as VT.[18] However, a nonrandomized study comparing a dual-chamber ICD with an optimally programmed single-chamber device found that the number of inappropriate therapies for atrial fibrillation was not decreased.[19]

Ventricular Fibrillation Therapy

ICDs employ electrical defibrillation as the sole therapy option for the treatment of VF. In contrast

to cardiac pacing, which requires depolarization during diastole of a small number of cells located very close to the electrode, defibrillation requires depolarization of the majority of ventricular myocardial cells, many of which are relatively refractory and can be up to 10 cm away. Successful defibrillation may require voltages up to 100 times greater than the voltage of the ICD battery (approximately 6.4 V). A capacitor is used to store charge immediately prior to therapy delivery. This energy is then delivered between the high-voltage electrodes and depolarizes the intervening myocardium, thereby restoring baseline rhythm (Fig. 30-2). Reversing electrode polarity during capacitor discharge (biphasic waveform) lowers defibrillation energy requirements and was one of the main factors that facilitated the introduction of smaller, lower-energy pectoral devices.[20,21]

The time interval between VF onset and delivery of defibrillation energy is usually 10 to 15 s, with capacitor charge time accounting for most of the delay. During this time, the subject may experience presyncope or syncope with restoration of consciousness after successful defibrillation and restoration of cardiac output. One study of ICD recipients found that 16 percent of patients who received device therapy experienced syncope. In comparison, 65 percent of these patients had experienced syncope during tachyarrhythmia prior to device implantation.[22]

Ventricular Tachycardia Therapy

In contrast to VF therapy, treatment options in the VT zone or zones include antitachycardia pacing (ATP), cardioversion, and defibrillation. Therapy progresses through a programmable sequence of responses (tiered therapy) until the episode is terminated. Most sustained monomorphic VTs, particularly in patients with coronary artery disease, are due to reentry and can be terminated by a critical pacing sequence.[23] Pacing at faster rates increases the probability of VT termination but also increases the risk of tachycardia acceleration. ATP, with backup defibrillation if acceleration occurs, is an attractive, well-tolerated treatment that avoids high-energy shock therapy, which is painful and diminishes battery life (Fig. 30-3). The most common form of ATP is adaptive-burst pacing, which delivers a train of stimuli at a fixed percentage of the tachycardia cycle length. Repeated and more aggressive pacing trains can be administered, resulting in either termination of the tachycardia or progression to the next treatment modality (cardioversion or defibrillation). ATP is extremely effective, with over 90 percent successful termination of spontaneous VTs.[24,25] Gross et al. reported that the addition of ATP to ICD therapy significantly reduced the cumulative occurrence of first ICD shock from 36 to 28 percent at a mean follow-up of 2 years.[26]

Cardioversion, in contrast to defibrillation, is a synchronized shock, usually of low energy. Compared to high-energy defibrillation, low-energy cardioversion reduces the time to therapy and conserves battery life. Efficacy rates and acceleration rates are similar for these two treatment modalities.[27]

Bradycardia Pacing

Bradycardia ventricular demand pacing is a standard feature of all single-chamber ICDs. Dual-chamber pacemaker-defibrillators provide not only improved diagnostic specificity but also the benefits of dual-chamber pacing, rate-responsiveness, and mode switching. In contrast to single-chamber devices, dual-chamber ICDs have reasonable longevity despite continuous pacing. Approximately 20 percent of ICD recipients need antibradycardia pacing, and most of them would benefit from a dual-chamber device.[28] If one includes patients with poor ejection fraction and patients who would benefit from dual-chamber sensing, it is possible that up to 50 percent of ICD recipients may benefit from implantation of a dual-chamber ICD.[29,30]

Pacing thresholds during VT and after defibrillation are frequently higher than those needed for bradycardia pacing, and the pacing output for these various conditions is separately programmable. Welsh et al. reported that the postshock pacing threshold was on average 2.8 times greater than the diastolic pacing threshold and advised programming postshock pacing outputs to at least 4 times the diastolic pacing threshold to maintain adequate safety margins.[31]

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

DEVICE IMPLANTATION

Methods of Implantation

ICDs are implanted in the pectoral region using techniques similar to those for permanent pacemaker implantation (Fig. 30-4). An integrated lead consisting of pace-sense electrodes and either one (right ventricular) or two (right ventricular and superior vena cava) high-energy defibrillation coils is inserted, preferably via the cephalic vein to avoid the risks of subclavian puncture and possibly future subclavian crush syndrome.[32]

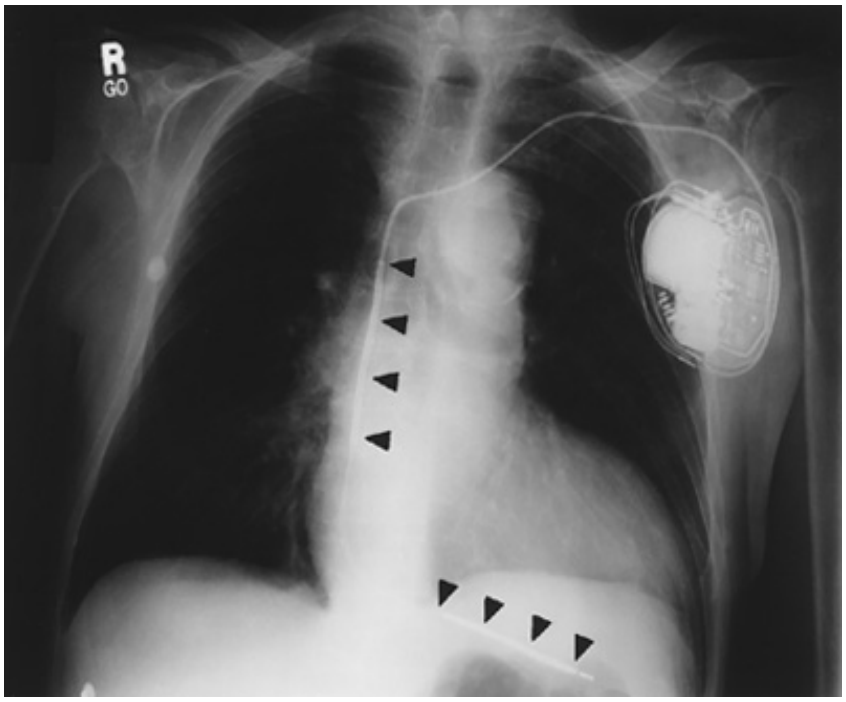

Figure 30-4: Posteroanterior chest x-ray of pectoral ICD device. A single integrated lead is inserted via the cephalic vein and positioned at the right ventricular apex. This is attached to a pulse generator implanted in the left pectoral region. ICDs are implanted using techniques similar to permanent pacemaker implantation. The integrated lead consists of right ventricular and superior vena cava defibrillation coils (*arrows*) and a tip electrode. In addition to the defibrillation coils, the titanium case of the pulse generator acts as a large-surface-area defibrillation electrode (active can). The defibrillation pathway in this patient is right ventricular coil to both superior vena cava coil and active can.

In dual-chamber devices, a separate atrial lead is inserted. Anesthesia may be local or general, with procedures performed under local anesthesia well tolerated in most patients.[33,34] In a retrospective analysis, patients who had their ICD placed under local anesthesia and intravenous sedation had higher intraoperative blood pressures and were discharged from hospital earlier than those who received general anesthesia.[35]

Pulse generator implantation may be prepectoral (subcutaneous) or subpectoral (submuscular). The prepectoral technique can be employed in patients with adequate subcutaneous tissue and the submuscular technique reserved for patients with a thin layer of subcutaneous tissue.[36] Implanting physicians should be familiar with both techniques. Prepectoral (subcutaneous) device implantation avoids deep subpectoral dissection, is associated with a shorter procedure time, may facilitate battery replacement, and has overall complication rates comparable to those for subpectoral implantation.[37]

In unipolar defibrillation systems, the titanium case of the pulse generator acts as a large-surface-area defibrillation electrode ("active can").[38] The defibrillation pathway in pectoral active-can implants is right ventricular coil to active can (with or without a superior vena cava coil). As a result, the position of the pulse generator affects the defibrillation wavefront and should, when possible, be implanted in the left pectoral region. Right-sided implantation results in significantly higher defibrillation thresholds (DFTs) than does left-sided implantation.[39]

Device Testing

The ability to reproducibly defibrillate VF is fundamental to the success of ICD therapy in preventing SCD. Accomplishing this goal requires meticulous testing at the time of implantation. Correct lead positioning usually involves advancing its tip as close as possible to the apex of the right ventricle. During sinus rhythm, R-wave amplitude, rate of change of the signal voltage (slew rate), pacing threshold, and lead impedances are assessed. The minimum acceptable R-wave amplitude is greater than 5 mV, to ensure satisfactory sensing during both sinus rhythm and VF.

VF is induced by the device either by a critically timed T-wave shock or very rapid burst ventricular pacing. The relationship between defibrillation energy and success is best described as a sigmoidal dose-response curve, the probability of success increasing steadily with each increase in energy until a 100 percent success plateau is reached (Fig. 30-5). The measured DFT is defined as the minimum energy producing defibrillation success and may be significantly lower than the lowest energy required for consistent defibrillation success (E_{99}). In clinical practice, various defibrillation threshold testing protocols are described.[41,42] To ensure future efficacy, even if there is a temporary or chronic rise in DFT, an adequate safety margin (at least 10 J) must exist between the measured DFT and the maximum energy output of the device. Today it is relatively uncommon to encounter DFTs so high that implantation criteria are not met. Boriani et al. achieved a safety margin of greater than or equal to 10 J and successfully implanted a single-lead unipolar system with a maximum energy output of only 29 J in 54 of 55 patients (98 percent).[43] If high DFTs are encountered at implantation, repeat testing can be performed after repositioning the lead (usually by attempting to get as close to the right ventricular apex as possible); changing the lead polarity, pulse duration, or waveform; adding additional defibrillation electrodes; or changing to a higher-energy-output device. In addition, in unipolar systems, a pneumothorax can greatly increase the high voltage impedance, resulting in high DFTs.[44] Finally, the role of antiarrhythmic drugs should be considered. When high DFTs are found at the time of implantation in patients who have been taking chronic oral amiodarone, we recommend completing the procedure and repeating DFT testing after a 4-week drug-washout period.

Predischarge Testing and Programming

Prior to discharge, the pace-sense characteristics of the ICD system are assessed in all patients and posteroanterior and lateral chest x-rays are reviewed to rule out lead dislodgment. Modern ICD systems employ integrated lead technology that combine both pace-sense and defibrillation functions. Changes in lead position that can potentially result in failure to detect or terminate VF invariably result in a change in pace-sense variables relative to implant values.[45] It is our practice

to reserve predischarge arrhythmia induction testing for select patients with marginal implant characteristics or in whom routine testing raises the possibility of a device malfunction.

The characteristics of induced VT correlate poorly with those of subsequent spontaneous VT episodes due to the frequent induction of faster, "nonclinical" VTs.[46] Fortunately, empirically programmed ATP successfully terminates VT in over 90 percent of cases.[47] In addition, even in VF survivors, the most common tachyarrhythmia recorded during follow-up is monomorphic VT.[48] Therefore, in the majority of ICD recipients, empiric programming of a VT zone should be considered prior to discharge.

Chapter 30: THE IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

LONG-TERM FOLLOW-UP

Routine Patient Follow-up

Patients are reviewed routinely every 3 months to assess the pace-sense and impedance characteristics of the ICD system, to assess the charge times, and to diagnose the cause of any delivered therapy. Radiographs of the ICD system are obtained annually. Fortunately, careful regular follow-up will identify the majority of asymptomatic problems. If routine assessment reveals a significant alteration in the pace-sense or impedance characteristics of the system and if no defibrillation shock was recently administered, DFTs are rechecked noninvasively under intravenous sedation to confirm an adequate defibrillation safety margin. Tokano et al. performed serial DFT testing in 31 patients who received biphasic defibrillation systems. After 2 years' follow-up 5 patients, (15 percent) had an increase in defibrillation energy requirements of 10 J or more, and 1 patient (3 percent) required surgical revision of the system.[49]
