Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 1:

CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

Authors: Thomas J. Thom, William B. Kannel, Halit Silbershatz, Ralph B. D'Agostino, Sr.

The large and long-term decline in mortality from the cardiovascular diseases accounted for almost 4 of the 5.6-year increase in life expectancy in the United States attained between 1965 and 1995.[1] The 55 percent decline in the age-corrected death rate for total cardiovascular disease between 1950 and 1996 indicates the extent to which these leading causes of death are subject to preventive and therapeutic measures. These diseases, however, still account for 41 percent of all deaths and are leading causes of morbidity and health care utilization. Control of these diseases should focus on prevention because of its inherent benefits, its apparent role in the mortality reductions, and its potential given the presence of modifiable risk factors in millions of Americans.

CARDIOVASCULAR DISEASES

Major Cause of Morbidity and Mortality

The most common cardiovascular diseases are hypertension and heart disease, but the basis for most cardiovascular diseases is atherosclerosis, which is almost universally present in U.S. adults and is manifest clinically as coronary heart disease (CHD), cerebrovascular disease (stroke), or peripheral arterial disease. The likelihood of developing one of these diseases is high, and they affect the health of nearly 59 million Americans.[2] In 1999, these diseases were projected to account for $178 billion in health care expenditures in the United States-2 percent of the gross domestic product (Fig. 1-1). These diseases also account for an estimated $108 billion in lost productivity due to illness and premature mortality. These expenditures and indirect costs are by far the largest for any diagnostic group.

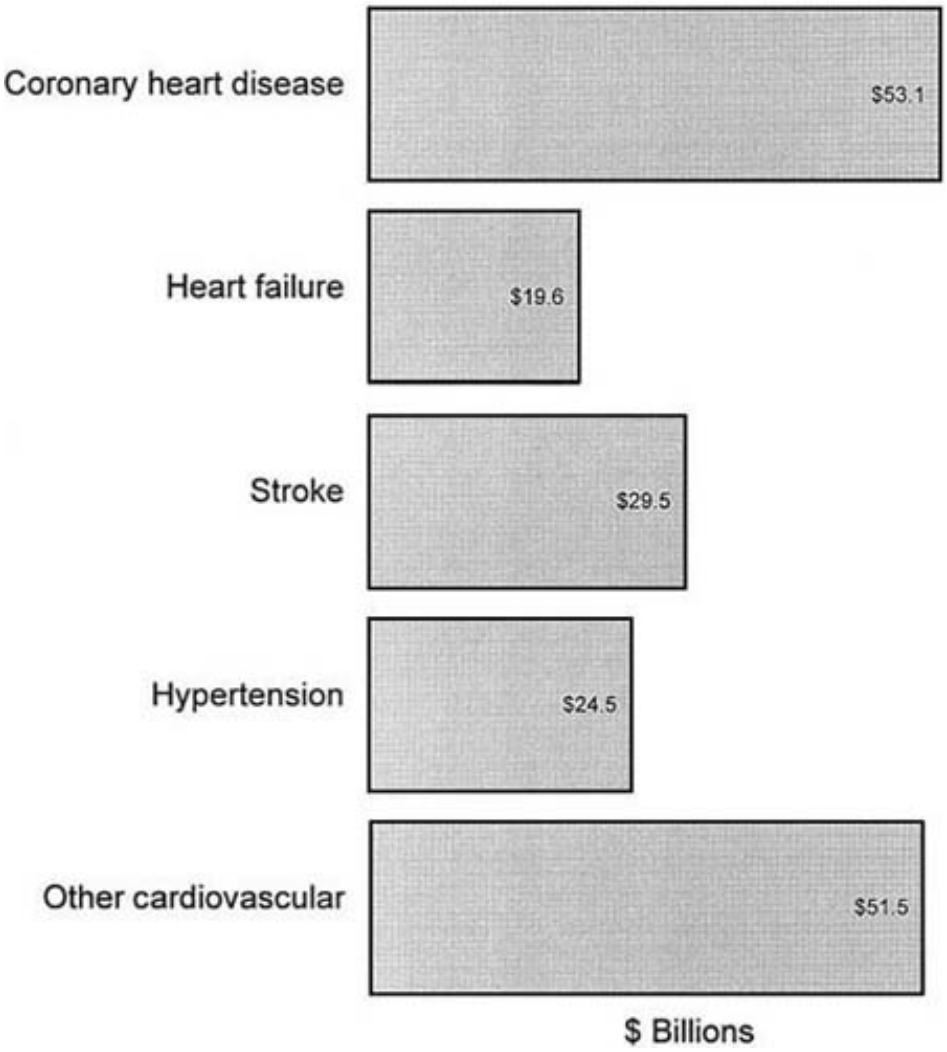

Figure 1-1: Health expenditures for cardiovascular diseases, United States, 1999 (includes expenditures for hospital, home, and nursing home care; physician and other professionals; and drugs). (From the American Heart Association and National Heart, Lung, and Blood Insitute.[2])

During the past 30 years, there have been major reductions in mortality rates for the various forms of cardiovascular disease (Fig. 1-2). Cardiovascular diseases, however, continue to be the most common threat to life and health. The lifetime risk of developing CHD after age 40 is 49 percent in men and 32 percent in women.[3] Even at age 70, the risk is 35 percent for men and 24 percent for women. CHD is the leading or second leading cause of death beginning at age 45 in men and in women.[4] An estimated 8 percent of the U.S. population, 20 million persons, have some form of heart disease.[5] About 50 million, 20 percent of the total population and one-fourth of the adult population, have hypertension, defined as a systolic blood pressure of 140 mmHg or greater, a diastolic blood pressure of 90 mmHg or greater, or normal blood pressure levels maintained by use of antihypertensive medication.[1,2] Thirty-two percent of persons with heart disease and 36 percent of those with stroke are limited in their usual activity by the condition.[6] Heart disease and hypertension, respectively, are the third and fourth most common chronic conditions causing limitation of activity.[1] Almost 60 percent of those with hypertension are under 65 years of age, and about 50 percent of persons with heart disease are under that age.[5] The prevalence and mortality from the cardiovascular diseases increase with decreasing levels of family income and education.[5,7] Between 1990 and 1992 in the United States, heart disease and hypertension accounted for an estimated 542 million days of restricted activity and 206 million bed days.[6] In 1997, there were an estimated 33 million days in short-stay hospitals, 60 million visits to physicians' offices, 5 million outpatient visits, and 616,000 patients receiving home health care (in

1996) for the cardiovascular diseases.[8-11]

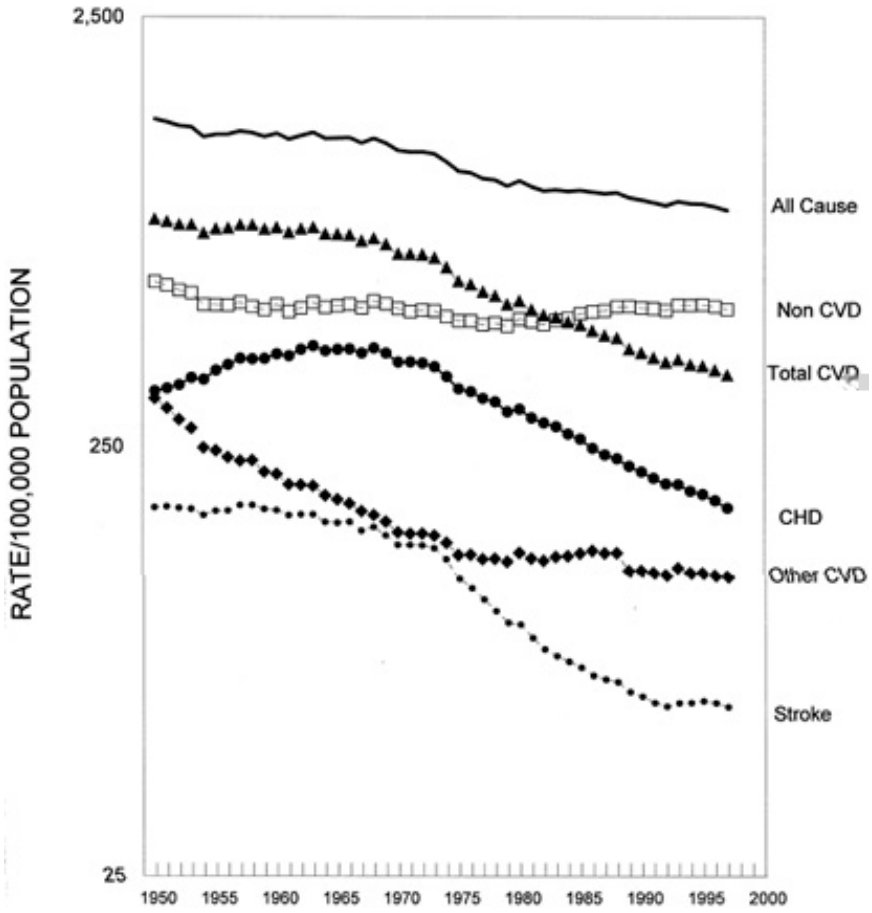

Figure 1-2: Age-adjusted death rates for selected causes of death; United States,1950-1997 (adjusted to U.S. population 2000) CVD, cardiovascular disease; CHD, coronary heart disease. (From *Vital Statistics of the United States*, National Center for Health Statistics.)

In 1997, cardiovascular diseases accounted for 41 percent of all deaths in the United States, a total of 952,000.[1] Largely because there are many more older women than older men in the U.S. population, the analogous percentage is higher in women (42 percent) than in men (39 percent), and the number of deaths from cardiovascular diseases is greater in women than in men.[4] Of all cardiovascular disease deaths, 36 percent occurred "prematurely," i.e., before 75 years of age. Atherosclerosis, when manifested as CHD, cerebrovascular disease, or peripheral arterial disease, accounted for 71 percent of all deaths from the cardiovascular diseases in 1997.[1] Heart disease is the leading cause of death in all racial groups.[4] Stroke ranks third highest in whites, blacks, and Asians in the U.S. population; fourth in Hispanics; and fifth in Native Americans.[12] Age-adjusted death rates for cardiovascular disease in 1997 were highest in black males, next highest in white males, and then followed by black females and white females.[2] Rates are not quite as high in Native Americans, Asian Americans, and Hispanic Americans.

Unfortunately, national incidence and case fatality data for the cardiovascular diseases do not exist. Data from the Framingham (Massachusetts) Heart Study, which began in 1948, and the Framingham Offspring Study provide reliable estimates for 44 years of follow-up of a defined population sample of men and women aged 35 to 94, the original cohort, and for 20 years of follow-up of their offspring. The average annual rates of first major cardiovascular events rose from 7 per 1000 men at ages 35 to 44 years to 68 per 1000 at ages 85 to 94 (Table 1-1). For

women, comparable rates are achieved 10 years later in life, with the gap narrowing with advancing age. CHD is the predominant cardiovascular event, comprising more than one-half of all such events in men and in women under age 75 (Table 1-2). The proportions of cardiovascular events due to CHD decline with age, as the proportions due to stroke and congestive heart failure (CHF) increase with age. Under age 75, there is a higher proportion of cardiovascular events due to CHD in men than in women and a higher proportion due to CHF in women than in men (see Tables 1-1 and 1-2).

Secular Trends

The trend in mortality from total cardiovascular disease has been downward since about 1940, with long-term declines for the three subgroups-rheumatic, cerebrovascular, and hypertensive diseases-and a decline for CHD since the mid-1960s.[1] The coronary decline antedates effective antithrombolytic and antihypertensive treatment. Prior to 1940, cardiovascular mortality increased and became the predominant cause of death because of control of infectious and parasitic diseases and an epidemic increase in fatal coronary attacks. Cardiovascular mortality declined just less than 1 percent per year in the 1950s and 1960s. The decline became more precipitous in the 1970s, with the rate falling 3 percent per year since then. For CHD, there has been more than a 58 percent decline in the age-adjusted death rate between the peak of mortality in 1963 and 1997; the current decline is 2 to 3 percent per year. For stroke, the rate of decline was 4 to 6 percent per year in the 1970s and early 1980s, but the decline slowed and has been less than 1 percent per year between 1990 and 1996.

The decline in cardiovascular mortality, including the steep rise and fall in CHD mortality, indicates that the major cause of mortality is controllable. Whether attributable more to beneficial changes in disease-promoting lifestyle or to better medical care of those already afflicted, it is clear that cardiovascular disease in most patients is not an inevitable burden of aging or genetic makeup. Although the causes of the decline in cardiovascular mortality are uncertain, the decline has been substantial, sustained, and real. The decline has coincided with increased efforts to achieve healthier living habits and with improvements in the ambient burden of cardiovascular risk factors.

Unfortunately, there are very few statistics on trends in morbidity, particularly incidence. Some, but not all, studies suggest that there have been declines in incidence and case fatality of CHD and stroke.[13,14] For myocardial infarction (MI), de- clines have been reported from most international sites in the MONICA (Monitoring Trends in Cardiovascular Diseases) studies.[15] This is important because reduction in mortality without a decline in the incidence rate would indicate that better medical care were responsible, whereas a reduction in both incidence and mortality would suggest that environmental influences and/or preventive measures have improved. If reduction in mortality continues, the size of the elderly population will continue to increase over and above increases due to demographic effects.

Risk Factors and Subclinical Disease

Observational studies in populations such as the Framingham Study have documented factors that increase the risk of cardiovascular diseases.[16,17] These include atherogenic attributes such as dyslipidemia, hypertension, glucose intolerance, and elevated fibrinogen; living habits that promote them; indicators of unstable lesions; and signs of compromised circulation, e.g., measures of subclinical arterial disease. Risk factors can be classified into the lipids, metabolic factors, hemostatic factors, blood pressure, and lifestyle factors. Some are modifiable. They promote cardiovascular disease in both sexes at all ages but with different strengths. Diabetes and high-density lipoprotein (HDL) cholesterol operate with greater power in women. Cigarette smoking is particularly influential in men, is noncumulative, and loses some of its adverse impact shortly

after quitting. Some risk factors, such as blood lipids, impaired glucose tolerance, uric acid, and fibrinogen, have smaller risk ratios in advanced age, but this lower relative risk is offset by a high absolute risk. In fact, most of the major risk factors remain relevant in the elderly. Obesity or weight gain promotes or aggravates all the atherogenic risk factors, and physical indolence worsens some of them and predisposes to cardiovascular events at all ages. Systolic blood pressure and isolated systolic hypertension are major risk factors at all ages in both sexes. The ratio of total to HDL cholesterol is used by many as a convenient lipid risk factor profile (see also Chap. 53).

Beyond age 65, women become nearly as vulnerable to cardiovascular mortality as men.[4] The predisposing modifiable risk factors for CHD, stroke, peripheral arterial disease, and cardiac failure are similar in the young and old in men and women.[16] An attenuated risk ratio for some risk factors at advanced age is offset by a greater incidence of cardiovascular disease. Consequently, the attributable risk and the potential benefit of treatment rise with age. In old age, average atherogenic total and low-density lipoprotein (LDL) cholesterol levels are considerably higher in women than in men. Cardiovascular risk profiles comprising the major risk factors predict CHD as efficiently in the elderly as in the young. This, and the fact that the decline in cardiovascular mortality has included the elderly, suggests the potential for intervention.

Evidence from the Framingham Study suggests that the presence of certain risk factors in women can attenuate their advantage in cardiovascular risk over that in men. The male-female gap in incidence closes with advancing age. After menopause, risk escalates two- to threefold, with more infarction and sudden death. A high total to HDL cholesterol ratio of 7.5 or greater virtually eliminates the female advantage. Diabetes has twice the relative impact on risk in women, almost canceling the female advantage. Electrocardiographic evidence of left ventricular hypertrophy has a greater relative impact on risk in women. The residual effect of triglycerides after consideration of HDL cholesterol appears to be greater in women than in men.

The major modifiable risk factors that contribute powerfully to cardiovascular disease are highly prevalent in the population. Trends in their prevalence and differences in their impact on the various atherosclerotic sequelae are noteworthy. Despite 30 years of appreciable decline in the percentage of persons who smoke cigarettes, one-fourth of adults, 49 million, still smoke.[2] Despite declining trends in mean total serum cholesterol level, more than 50 percent of American adults, 98 million, have blood cholesterol levels of 200 mg/dL or greater, and of these, 39 million have levels of 240 mg/dL or greater. Fifty million have hypertension, but fortunately, treatment and control of this condition improved considerably since the early 1970s.[1,2] Not improving is obesity. One-third of adults, 106 million, are overweight, defined as a body mass index greater than 25 kg/m2. An estimated 10 million persons are at increased risk of cardiovascular disease because they have diabetes.[2] Another highly prevalent risk factor is sedentary lifestyle. It plays a role in the prevalence of overweight, dyslipidemia, and hypertension and, thus, cardiovascular disease. There also are persons under 18 years of age who have one or more modifiable risk factors.[1,12]

More recent additions to the list of risk factors include homocystinemia. In the general population, 29 percent have deficient enough vitamin B intake to elevate homocystine to more than 14 μmol/L.[18] Inadequate intake of vitamins B_{12} and B_6 and folate account for 67 percent of the elevated homocystine encountered in the general population. An estimated 25 percent of the population have Lp(a) lipoprotein cholesterol values greater than 20 mg/dL.[19] Small, dense LDL (pattern B) occurs in 11.1 percent of the population and in 50 percent of patients with CHD.[20] Fibrinogen greater than 300 mg/dL occurs in 30 percent of the population. Other novel risk factors are leukocyte count, estrogen deficiency, factor VII, endogenous tissue plasminogen activator, plasminogen activator inhibitor type 1, D-dimer, C-reactive protein, and possibly *Chlamydia pneumoniae*.[16,17]

Very early asymptomatic cardiovascular disease can be diagnosed by noninvasive testing, such as magnetic resonance imaging (MRI) and computed tomographic (CT) scanning. Well-established clinical indicators include left ventricular hypertrophy, audible vascular bruits, a positive exercise electrocardiogram (ECG), absent arterial pulses in the limbs and neck, regional wall motion abnormality on the echocardiogram, reduced ankle-arm blood pressure ratio, sonographic evidence of carotid wall thickness, reduced left ventricular ejection fraction, and presence of coronary calcium.

No individual risk factor is essential or sufficient in the causation of cardiovascular disease; causation is multifactorial. Indeed, the risk posed by one factor is generally enhanced in the presence of another. Thus multivariate risk factor assessment gives the most useful measure of the joint effect of the risk factors.[16] Multivariate analyses help provide a better understanding of the pathogenesis of the disease and guidelines for prevention. Based on the absolute, relative, and attributable risks imposed by the various risk factors, the older concepts of *normal* have evolved to optimal values associated with long-term freedom from disease. As a consequence, acceptable blood pressures, blood glucose levels, and lipid values have been revised downward.[16] Multifactorial risk functions based on the Framingham Study data, composed of the major identified risk factors, have been shown to predict the rate of occurrence of coronary disease in a variety of U.S. population samples, suggesting that much of the cardiovascular disease in the population is attributable to these factors[21] (see also Chap. 41).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

CORONARY HEART DISEASE

CHD kills and disables people in their most productive years and in 1999 was estimated to account for $53 billion in medical care costs and $47 billion in indirect economic costs.[2] Each year there are more hospitalizations for CHD than for any broad diagnostic group, with the exceptions of births, all respiratory diseases, all digestive diseases, and all injuries.[8]

Prevalence

In the United States, an estimated 12 million people have CHD, about one-half of whom have acute MI and half have angina pectoris.[2] For men, prevalence of MI is 1 percent at ages 35 to 44 years and 16 percent at age 75 and over (Fig. 1-3). In women, the prevalence is less than 1 percent at ages 35 to 44 years and 13 percent at age 75 and over.

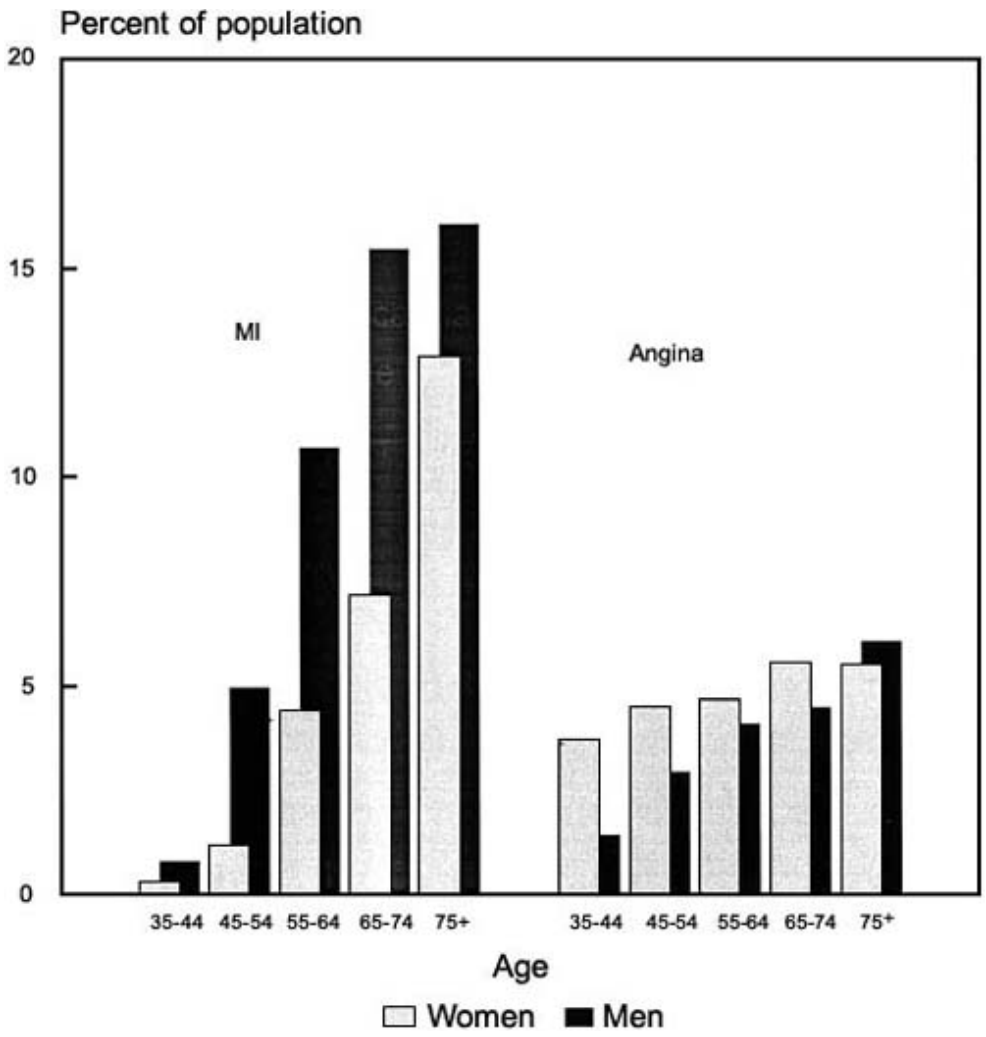

Figure 1-3: Prevalence of MI and angina pectoris by age and sex, United States, 1988-1994 (self-reported myocardial infarction and Rose angina from health interviews). MI, myocardial infarction. (From the

National Health and Nutrition Examination Survey, 1988-1994, National Center for Health Statistics.)

Incidence

In the United States, CHD causes about 650,000 new heart attacks each year and 450,000 recurrent attacks.[2] The incidence in women lags behind that in men by 10 years for total CHD and by 20 years for more serious clinical manifestations such as MI and sudden death (Tables 1-1 and 1-3). Male predominance is least striking for uncomplicated angina pectoris. The first coronary presentation for women is more likely to be angina, whereas in men it is more likely to be MI (Table 1-4). In men, more angina occurs after MI than before. Only 20 percent of coronary attacks are preceded by long-standing angina; the percentage is lower if the infarction is silent or unrecognized. In premenopausal women, serious manifestations of CHD such as infarction or sudden death are relatively rare. The incidence and severity of CHD increase with age in both sexes (see Table 1-3 and Table 1-4). There seems to be a more precipitous increase for women after menopause, with CHD rates in postmenopausal women two to three times those of women the same age who remain premenopausal.[21] This applies whether the menopause is natural or surgical and, in the latter case, whether or not the ovaries are removed. The sex ratio in incidence narrows progressively with advancing age.

Unrecognized MIs are common in the Framingham Study, numbering at least one in three infarctions (Fig. 1-4). Half the unrecognized infarctions are silent, and the rest are atypical so that neither the patient nor the physician entertains the possibility.[22] More than half these persons eventually develop some overt clinical manifestations of CHD and hence come under medical care. Angina is less frequent in individuals with unrecognized MI than in those with recognized symptomatic MI, either before or after the infarction occurs. Despite the apparent mild nature of unrecognized MI, t risk of subsequent mortality is nearly the same as in patients with recognized infarction. Diabetic men and hypertensive persons of both sexes are particularly susceptible to silent or unrecognized MIs.

Prognosis

In patients who survive the acute stage of an MI, the morbidity and mortality range from 1.5 to 15 times that of the general population, depending on the person's sex and clinical outcome (Table 1-5). The rates of occurrence of reinfarction, sudden death, angina pectoris, cardiac failure, and stroke are all substantial. The relative and absolute risks of these events are as great in women as in men after MI. Within 6 years following a recognized MI, 18 percent of men and 35 percent of women have a recurrent infarction, and 27 percent of men and 14 percent of women develop angina. About 22 percent of men and 46 percent of women are disabled with cardiac failure; 8 percent of men and 11 percent of women will have a stroke. Sudden death will be experienced by 7 percent of men and 6 percent of women. The prognosis is nearly as bad, sometimes worse, following an unrecognized MI (see Table 1-5).

Table 1-5: Six-Year Prognosis Following Myocardial Infarction: Framingham Study, 44-Year Follow-Up of Cohort and 20-Year Follow-Up of Offspring[a]

	MEN		WOMEN	
	Percent	Risk Ratio[b]	Percent	Risk Ratio[b]
Recognized

Mortality

CHD is the leading single cause of death in adults in the United States, accounting for 1 in 5 deaths.[4] In 1997, there were 466,000 coronary deaths. Mortality from this disease increases with age, but CHD is also a prominent cause of death in adults at the peak of their productive lives. Heart disease is the leading cause of death in men and women in every racial or ethnic group except Asian-American females.[2] The CHD death rate is almost three times higher in men than in women at ages 25 to 34, but this ratio declines to 1.6 by ages 75 to 84. The coronary death rate is more than 50 percent higher in blacks than in whites at ages 25 to 34, and this difference disappears by age 75. CHD mortality is not as high among the Hispanic population as it is among blacks and whites.

In a substantial number of CHD deaths, the progression from inapparent clinical disease to death is swift. Much of the premature mortality from CHD comes with little warning in a population prone to this disease. Sudden, unexpected, out-of-hospital coronary deaths that occur too rapidly to allow arrival alive at the hospital account for one-half of all coronary fatali- ties. The proportion of coronary deaths that are sudden deaths is lower in women than in men and lower in elderly men than in the young (Fig. 1-5). The percentage of sudden coronary deaths that occur without prior CHD, however, is much greater in women than in men (Fig. 1-6). In 50 percent of men and 63 percent of women who died suddenly, there was no prior overt evidence of coronary disease (see also Chap. 36).

There is a higher risk of death in patients with a prior coronary attack, yet most CHD deaths arise from the population who are still free of symptomatic CHD.[23] Hence primary prevention ultimately appears to offer more to society than secondary prevention. After MI, sudden death occurs at four to six times the rate in the general population. The first year following a recognized MI is especially dangerous, with 25 percent of men and 38 percent of women succumbing (Fig. 1-7). Long-term survival following unrecognized MI is only slightly better than for recognized MIs, and survival is better for women than for men (

Table 1-6). In men under age 65 with uncomplicated angina pectoris, the survival picture is nearly the same as it is for recognized MI and is much worse than the survival in women (see also Chap. 38).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

HYPERTENSION

Hypertension, present in 50 million Americans, is one of the most powerful contributors to cardiovascular morbidity and mortality: the 600,000 annual cases of stroke, 1.1 million annual heart attacks, 400,000 annual new cases of CHF, and most of the nearly 1 million annual deaths from cardiovascular and kidney diseases.[2,4]

Prevalence

In a 1988-1994 national survey of persons aged 20 to 74 years, the prevalence of hypertension, i.e., systolic blood pressure of 140 mmHg or greater or diastolic blood pressure of 90 mmHg or greater or on antihypertensive medication, was 24 per- cent in white men, 19 percent in white women, 35 percent in black men, and 34 percent in black women.[24] Prevalence in- creases with age and is highest among blacks and the elderly (Fig. 1-8). Isolated systolic hypertension is a common and distinctly hazardous condition in the elderly. There is evidence from the Systemic Hypertension in the Elderly Program (SHEP) and the Syst-Eur trial that treatment of this form of hypertension in the elderly is distinctly efficacious not only against stroke but also against coronary disease.[25,26] Persons with hypertension face serious excess risks of cardiovascular sequelae, and since much of this excess risk is attributable to mild hypertension, there is need for intervention through preventive lifestyle modification, if not through drug treatment. Because of the higher prevalence of milder hypertension, almost 60 percent of the excess mortality attributable to hypertension comes from this blood pressure range. The risks of cardiovascular sequelae are proportional to the blood pressure level at any age and in both sexes and are increased whether the elevation is systolic or diastolic. Approximately one-half of persons who suffer a first heart attack and two-thirds who suffer a first stroke have blood pressures greater than 160/95 mmHg.

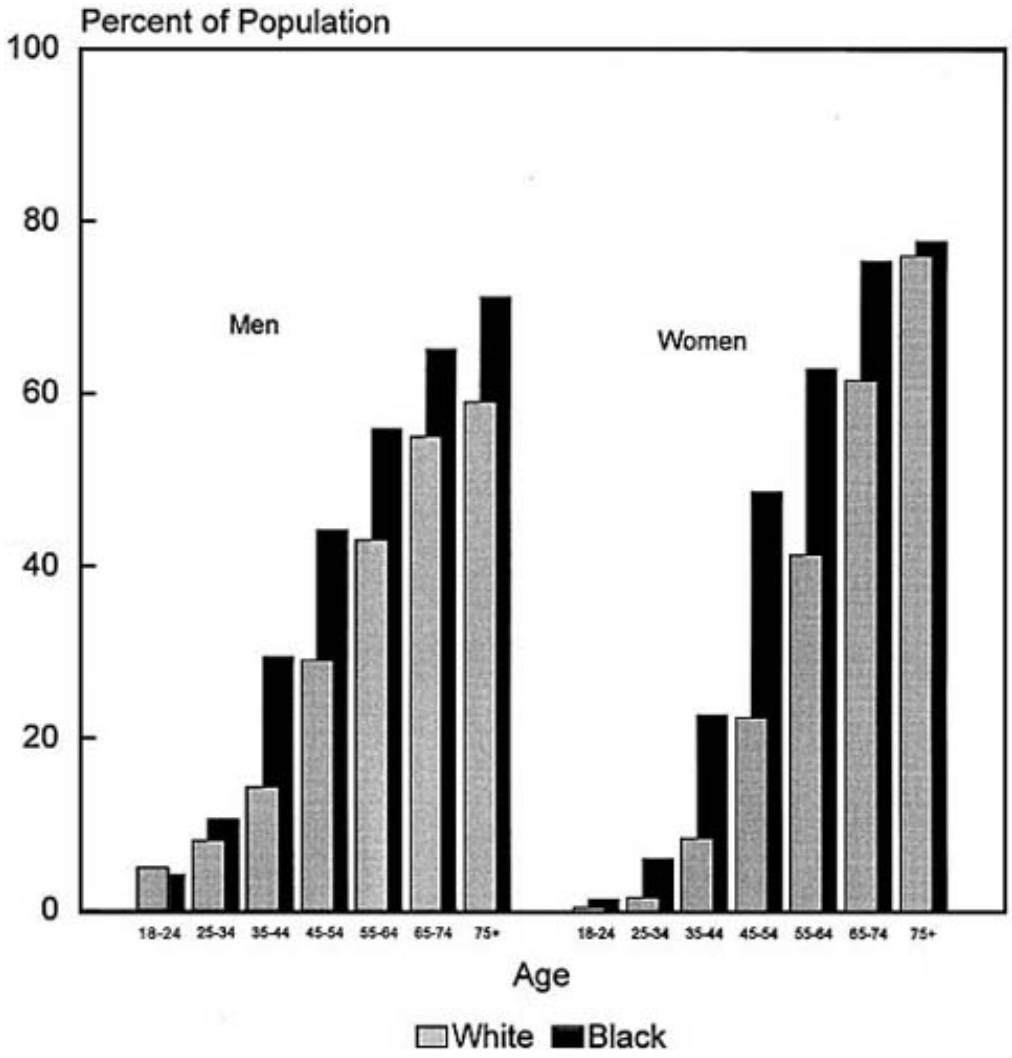

Figure 1-8: Prevalence of hypertension by age, race, and sex; United States, 1988-1994 (hypertension: 140/90 mmHg or greater or on antihypertensive medication). (From the National Health and Nutrition Examination Survey, National Center for Health Statistics.)

Although there is a rise in blood pressure with age in both sexes, in most affluent populations this is not universal, and it does not imply that blood pressure inevitably must rise with age or that in those whose pressures do rise it reflects a normal aging process. In the United States, there is about a 20 mmHg systolic and 10 mmHg diastolic rise in mean pressures from age 30 to age 64. Systolic pressures continue to rise in women into their eighties and in men into their seventies. Diastolic pressures level off earlier and in men decline beyond age 55. The pressures start lower in young-adult women and rise more steeply in middle age (50 and over), and they equal those of men in their fifties and then progressively exceed those of men in later life; this crossover is observed for both systolic and diastolic pressures. In some populations in the world, blood pressure does not rise with age.

For the following discussion, *hypertension* means that a patient has blood pressure of 160/95 mmHg or greater or is on antihypertensive medication; *under control* means that a patient is on antihypertensive medication and has blood pressure of less than 160/95 mmHg. Between the periods 1971-1972 and 1988-1994, there have been large improvements in the percentage of hypertensive patients who (1) are aware of their hypertension (from 51-88 percent), (2) are on antihypertensive medication (from 36-79 percent), and (3) are under control (from 16-65 percent).[1] Although an improving trend is also seen at the 140/90 mmHg and greater level of control, using this definition, 46 percent still do not have medication prescribed for their hypertension.[2]

Incidence

Longitudinal observation of blood pressures as people age reveals a different pattern than cross-sectional prevalence data. The reason for this difference is obscure. Diastolic pressures are essentially parallel in both sexes, with women's pressures consistently below those of men at all ages. In women, systolic pressures are initially lower than in men but subsequently rise more steeply with age. They converge at age0 with those of men but never exceed them. With advancing age in both genders, a progressive and disproportionate rise in systolic pressure occurs that is presumed to result from loss of arterial elasticity. Blacks have higher blood pressures than whites in most Western cultures.

Determinants

While genetic susceptibility plays a large role in hypertension, this may be only permissive, requiring one or more environmental cofactors such as salt intake, alcohol, or weight gain to bring on hypertension. Of all the identifiable determinants of hypertension, weight gain and adiposity, particularly abdominal in distribution, seem to be predominant. New underlying causes of hypertension are discovered every decade, but the causes of the vast majority of cases remain undetermined. Of the identifiable causes, chronic renal diseases, renovascular disease, and oral contraceptives head the list. Routine search for underlying causes not suggested by signs or symptoms is usually unrewarding and often counterproductive. Recent research suggests that insulin resistance occurring in association with obesity may play a fundamental role [27] (see also Chaps. 41 and 56).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

STROKE

Prevalence

Two percent of the U.S. adult population, 4.4 million people, have cerebrovascular disease (stroke).[2] More than 1 million of these individuals are limited in their usual activity.[6] Prevalence rises from 2 percent in men at 45 to 54 years to 12.5 percent for men aged 75 and over and from 1 to 10.7 percent in the respective age groups in women (Fig. 1-9). In the Framingham Study, the most common variety of complete stroke is atherothrombotic brain infarction, which accounts for 61 percent of all strokes (excluding transient ischemic attacks).[28] Next most common are cerebral embolus (24 percent), intracerebral hemorrhage, and subarachnoid hemorrhage. Intracerebral hemorrhage apparently has declined most in recent years (see also Chap. 98).

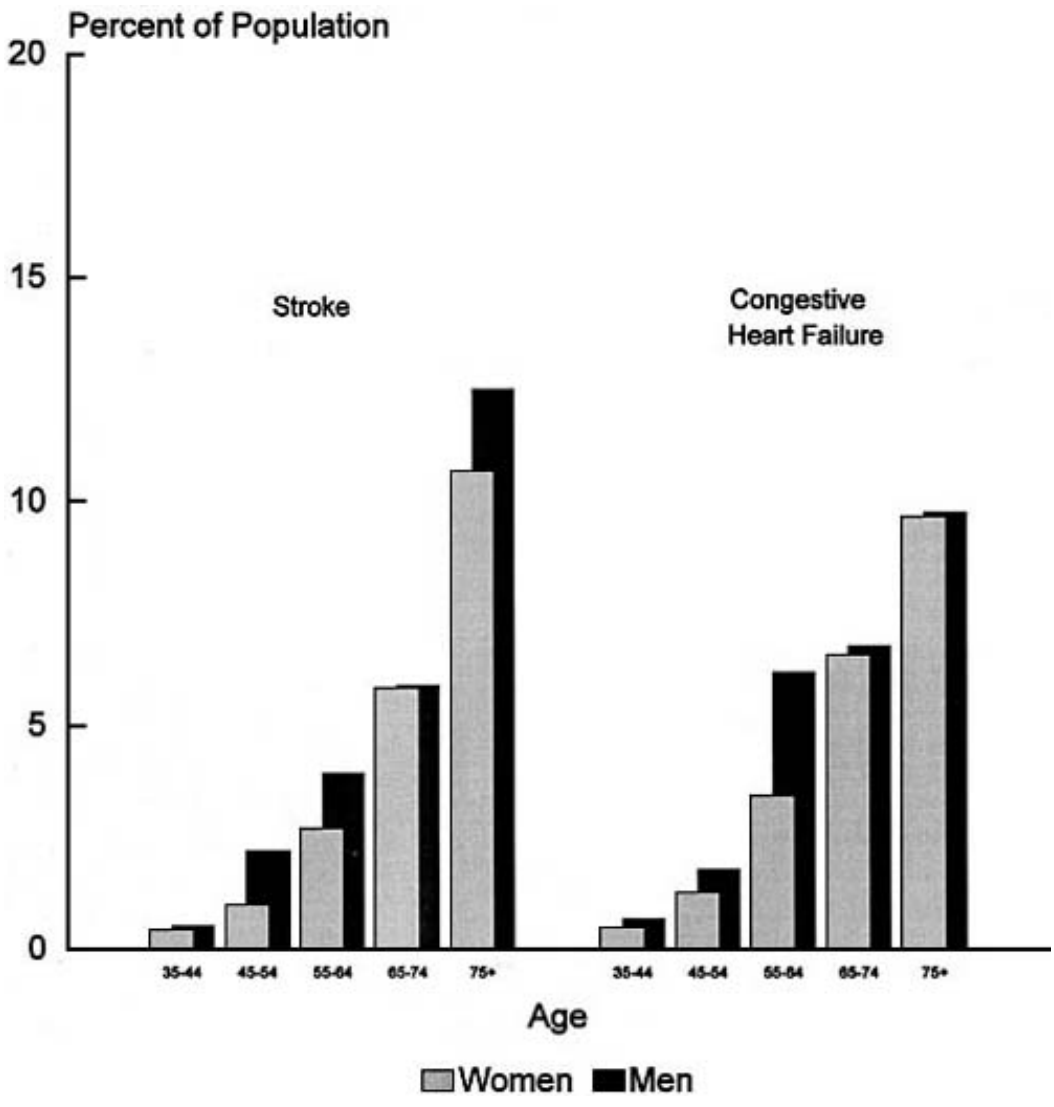

Figure 1-9: Prevalence of stroke and CHF by age and sex, United States, 1988-1994 (self-reported stroke and congestive heart failure from health interviews). (From the National Health and Nutrition Examination Survey, National Center for Health Statistics.)

Incidence and Disability

In the Framingham Study, the chance of having a stroke before age 70 was 5 percent for both sexes.[28] Annual incidence in the Atherosclerosis Risk in Communities Study was 5.3 per 1000 persons at risk in black men aged 45 to 64 years, 4.0 in black women, 2.0 in white men, and 1.5 in white women.[29] Of the incident events, 83 percent were ischemic strokes, 10 percent were hemorrhagic, and 7 percent were subarachnoid hemorrhage. Among the 54 percent classified as definite thrombotic brain infarctions, 38 percent were classified as lacunar, more than twice as many in blacks as in whites. The time course of functional recovery is strongly related to initial stoke severity.[30] Of survivors of an initial event, 50 to 70 percent return to functional independence, but 15 to 30 percent become permanently dependent. Institutional care is required by 20 percent at 3 months after onset.[31]

Stroke attacks have become less severe in recent years, but prevention is essential for dealing effectively with the problem of stroke because of the irreversibility of established ischemic brain damage and the neurologic deficit it induces. The underlying cerebrovascular disease is not a necessary consequence of aging. Modifiable contributing factors offer the possibility of prevention in identified stroke candidates. Stroke prevention requires early and sustained treatment of persons with hypertension, cardiac disorders (especially atrial fibrillation), and transient cerebral ischemic attacks.

Mortality

Cerebrovascular disease, the third leading cause of death, was responsible for 207,000 deaths in the United States in 1974, but by 1997, the number had declined to 160,000.[4,12] This decline is remarkable because the population of older persons increased substantially during that time. The age-adjusted death rate declined by more than 50 percent over this period, but the decline appears to have almost ended in the 1990s.[1] This disease still accounts for 7 percent of all deaths, and 44,000 of them occur in individuals younger than 75 years of age. Under age 65, the mortality rate is three times greater in blacks than in whites, largely as a result of the higher prevalence and increased severity of hypertension in the former. The proportion of strokes that result in death within 1 year is about 22 percent in men and 25 percent in women, less if the stroke occurs before age 65 (see Fig. 1-7). For men or women under age 65, however, only 50 percent survive past 8 years (see Table 1-6; see also Chap. 98).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

HEART FAILURE

Heart failure is the end stage of cardiac disease after the myocardium has used all its reserve and compensatory mechanisms. Once overt signs appear, half of patients die within 5 years despite medical management.[32] Heart failure is most often a consequence of hypertension, CHD, valve deformity, diabetes, or cardiomyopathy. The various etiologies tend to coexist. CHD, frequently accompanied by hypertension, is responsible in more than 50 percent of cases and has been increasing in prevalence among new cases of heart failure. Left ventricular hypertrophy, hypertension, and valvular diseases are diminishing determinants. The risk of cardiac failure is increased two- to sixfold with CHD, angina conferring half the risk compared with MI. The dominant cause continues to be hypertension, which precedes failure in 75 percent of patients.

An estimated 4.8 million Americans have CHF.[2] The prevalence increases with age to exceed 10 percent after age 60 (see Fig. 1-9). Each year there are an estimated 400,000 new cases.[2] In 1997, there were 43,000 deaths nominally classified to heart failure as the underlying cause and about another 200,000 where heart failure was listed on the death certificates as a secondary cause. The death rate increased in most years between 1968 and 1997. The rate of hospitalizations for heart failure increased between three and four times between 1970 and 1997 in patients aged 45 to 64 and 65 and over.[2,8] In 1997, heart failure was the first-listed discharge diagnosis in 957,000 hospital discharges and a secondary diagnosis in another 2.1 million discharges.[8] Twenty percent of all hospital discharges of patients aged 65 and over had heart failure as a primary or secondary diagnosis. The percentage of CHF patients who died in hospitals, however, decreased from 11.3 percent in 1981 to 5.0 percent in 1996.[1] Visits to physicians' offices for CHF increased from 1.7 million in 1980 to 3.2 million in 1995. The prevalence is similar in men and women, but it is higher in blacks than whites. It increased substantially as measured in national surveys in 1976-1980 and 1988-1994 (see also Chaps. 23 and 41).

Based on the Framingham Study, heart failure is equally frequent in men and women, and the annual occurrence approaches 10 per 1000 population after 65 years of age (see Table 1-1). Survival following the diagnosis of heart failure is worse in men than in women, but even in women fewer than 15 percent survive much longer than 8 to 12 years (see Table 1-6). The prognosis is not much better than for most forms of cancer. The 1-year fatality rate for heart failure is high, with one in five patients dying. Sudden death is a common mode of exitus, occurring at six to nine times the general population rate. With an increasing geriatric population, heart failure is a formidable problem.

There is little indication that the declines in death rates from heart disease in general and from CHD in particular in the United States have been accompanied by an improvement in the incidence of heart failure.[33] This cannot be readily explained. Some postulate that improved survival of patients with angina, MI, and hypertensive heart disease may result in an increased prevalence of chronic heart disease and ultimately heart failure. Data from the Framingham Study indicate very little improvement to date in the ominous outlook following the onset of CHF. The median survival of 652 incident cases of CHF was only 1.7 years in men and 3.2 years in women,[33] and the overall survival rates at 5 years were only 25 percent for men and 38 percent for women. The mortality increased with age in both sexes. If one adjusts for age, no significant

changes in the prognosis of CHF are evident over the past four decades despite improvements in treatment. Advances in treatment of hypertension, myocardial ischemia, and valvular heart disease have not resulted in dramatic improvements in survival once heart failure ensues.

Despite the availability of potent glycosides, diuretics, and antihypertensive agents, heart failure continues at a high incidence.[34] Because of the high attributable risk of hypertension and CHD, their prevention and effective treatment would appear to be required to make a significant impact on the incidence of congestive heart failure.

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

IDIOPATHIC CARDIOMYOPATHY

Reliable estimates of the prevalence and incidence of idiopathic dilated (congestive) and hypertrophic cardiomyopathies are unavailable because of their comparatively uncommon occurrence in the general population. The National Center for Health Sta- tistics data from 1996 assigned 27,501 deaths to cardiomyopathy, hypertrophic cardiomyopathy accounting for only 1 percent.[4,35] Alcoholic heart muscle disease (cardiomyopathy) appears to account for 8 percent of deaths due to cardiomyopathy. This condition appears to be 2.5 times as frequent in blacks as in whites. Mortality from cardiomyopathy was highest in older persons, men, and blacks. Death rates rose sharply in the 1970s and 1980s but for reasons that are unclear. This apparent increase could be an artifact of changes in diagnostic criteria and death certification practices. In 1997, cardiomyopathy was the primary diagnosis for 39,000 hospitalizations and 261,000 days of hospital care, but 443,000 hospitalizations had cardiomyopathy listed as a secondary diagnosis[8] (see also Chaps. 72 and 73).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

ARRHYTHMIAS

Arrhythmias are a major cause of morbidity in heart failure and rheumatic heart disease and are a contributor to half the mortality from CHD. Many such victims die suddenly, without warning. Together with heart failure, arrhythmias are often the final common pathways of terminal heart disease. Estimates of morbidity and mortality are difficult to obtain. There is good evidence, however, that atrial fibrillation is the most common of the serious arrhythmias and is responsible for substantial morbidity and mortality in the general population.[36] Although the true frequency of arrhythmias is not known, in 1997 there were an estimated 3.5 million hospital discharges with arrhythmias as the primary (635,000) or secondary diagnosis, with two-thirds being due to atrial fibrillation.[8] Between 1982 and 1995, the rate of hospitalization for atrial fibrillation about doubled.[1] In 1995, there were an estimated 3.3 million visits to physicians' offices for arrhythmias, more than due to the cerebrovascular diseases.

The Framingham Study reported estimates for atrial fibrillation. In that population, prevalence rose from 0.5 percent at ages 50 to 59 years to almost 9 percent at ages 80 to 89 years.[36] Between 1968 and 1989, age-adjusted prevalence tripled in men but did not change appreciably in women. These trends are unexplained. Incidence also doubles with each successive age decade, to reach almost 5 percent per year at ages 85 to 94 years.

Most cases of atrial fibrillation evolved following development of overt cardiovascular disease. Heart failure, MI, and valvular heart disease were the most powerful precursors, with the relative risks as much as sixfold. Hypertensive cardiovascular disease was the most common prior cardiovascular disease, largely because of its great frequency in the general population. Impaired glucose tolerance was the other major risk factor predisposing substantially to atrial fibrillation.

Atrial fibrillation is associated with increased risks of cardiovascular morbidity and mortality. After adjusting for various factors, there was a three- to fivefold increased risk of stroke, the chief hazard of atrial fibrillation. Atrial fibrillation decreases survival and is associated with a near doubling of the risk of mortality, after adjusting for associated cardiovascular conditions (see Chap. 27).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Rheumatic fever is a prominent cause of serious valvular heart disease. Acute rheumatic fever and subsequent rheumatic heart disease remain important cardiovascular problems in the tropical and subtropical developing countries of South America, Africa, the Middle East, and Asia, and there have been outbreaks in the United States in recent years.[37] Although preventable, rheumatic fever occurs more frequently because of overcrowding, the deceptive self-limited nature of symptoms in streptococcal pharyngitis, and the mild and often clinically inapparent nature of streptococcal infections. The availability of penicillin to treat these infections, living conditions that are less crowded than formerly, and evolution of different strains of *Streptococcus* have made rheumatic fever uncommon in the United States, although the incidence remains high in subgroups such as blacks, Puerto Ricans, Mexican Americans, and Native Americans (see Chap. 62). Because this disease has not been eradicated in this country, there is a need to define its incidence and prevalence more accurately as well as those of the infective endocarditis that may follow in order to pinpoint those at risk (see also Chap. 82).

An estimated 1.8 million persons have rheumatic heart disease in the United States, more than 6 per 1000 persons.[2] About 15 percent of these persons are limited in activity because of the resulting chronic carditis.[6] There is no national estimate of annual incidence. A study in Tennessee reported a range from 0.5 to 1.88 new cases per 100,000 school-aged children in 1977-1981, with the lowest rates in the affluent suburbs.[37] Occurrence tends to be concentrated in the lower socioeconomic subgroups, perhaps due to factors of nutrition, hygiene, and access to medical care. Rheumatic fever is rare before age 3, occurring most frequently between 5 and 15 years of age, when streptococcal infections are most frequent. During epidemics of streptococcal pharyngitis, the rheumatic fever attack rate may be 3 percent, whereas in endemic situations it is usually only 0.3 percent (see also Chap. 62).

With the decline in rheumatic fever in the United States, its clinical manifestations also have moderated so that carditis is detected in fewer than 20 percent of acutely affected patients.[38] The annual mortality has declined to about 5000 deaths per year. Because the cardiac sequelae of rheumatic fever are still seen in adults and adequate treatment can reduce attacks by 90 percent, rheumatic fever and rheumatic heart disease remain the two most preventable serious cardiovascular disorders. It seems clear that at least part of the decline in rheumatic fever was due to prompt antistreptococcal treatment by physicians. The decline in rheumatic fever, however, appears to have antedated the advent of antistreptococcal agents. We are currently unable to explain the reasons for the decline in rheumatic fever definitely, possibly because we do not fully understand its etiologic factors (see Chap. 62).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

OTHER VALVULAR DISEASE

In the two decades since mitral valve prolapse was described, the syndrome was thought to be a frequently diagnosed valvular deformity, more common in women. This assessment was based on studies that had patient selection bias and diagnostic criteria that were less specific than those used today. In a community population study, with false-positive results, false-negative results, and selection bias greatly minimized, the picture looks quite different.[39] The Framingham Study reports that prevalence is no more than 1 to 2 percent, no more common in women than in men, and diagnosis of associated cardiovascular sequelae is low. This assessment also has its limitations. Study results are based on a white population only, confidence limits around the prevalence estimates are large, results are subject to a survival bias, and patients with mitral valve prolapse that resulted in sudden death may not have been included in the cohort. The major importance of mitral valve prolapse may be the threat of endocarditis, which must be rare, and arrhythmias, which may be common (see Chap. 65).

Little information is available on the prevalence of valvular heart disease in the general population. Most prevalence estimates come from surgical studies and small numbers of patients referred for diagnosis. The Framingham Study has estimated prevalence of mitral, tricuspid, and aortic regurgitation in their population sample using color Doppler echocardiography routinely obtained on all participants.[40] Some degree of mitral and tricuspid regurgitation was seen in 19 and 15 percent of men and 19 and 18 percent of women, respectively. Aortic regurgitation was found in 13 percent of men and 8.5 percent of women.

Rheumatic heart disease is no longer the most frequent cause of valve disease. Mitral valve prolapse and degeneration of congenital aortic valve lesions are now the most common causes.[41] Aortic stenosis also may result from atherosclerotic degeneration of the valve in diabetes with dyslipidemia. It is the most common valve lesion in the elderly having valve replacement.[42] Aortic root or annular dilatation is responsible for most aortic regurgitation, of which 40 to 60 percent is of unknown cause.

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

CONGENITAL HEART DISEASE

About one million persons in the United States have congenital cardiovascular disease, and each year an estimated 32,000 babies, about 8 per 1000 live births, are born with this disease.[2,43] Of the new cases, 8 to 13 percent have atrial sepal defects, 6 to 11 percent have patent ductus arteriosus, and 20 to 25 percent have ventricular sepal defects. The prevalence of congenital heart disease at birth as determined during the infant's brief stay in the hospital is likely to be underestimated, and recognition of specific lesions may be inaccurate.[44] Most data are deficient for a diagnosis after the first week of life. Prevalence data based on autopsy findings are unreliable because they reflect a fraction of the deaths and relate only to fatal lesions. Most information comes from retrospective studies based extensively on referral practices.

Structural abnormalities of the heart or intrathoracic great vessels seem to affect 8 to 10 of every 1000 infants born alive in the United States. If bicuspid aortic valves and mitral valve prolapse manifested later in life are included, the rate may well exceed 1 percent of live births. About 1 newborn per 1000 live births has a cardiac birth defect that cannot be managed medically or surgically. Most infants who previously would have died now survive to adult life because of improved treatment, but 5 to 6 of these infants per 1000 live births require frequent medical or surgical attention shortly after birth or later in childhood.

Except for the recent unexplained twofold increase in ventricular sepal defects and the threefold increase in patent ductus arteriosus, the incidence of most congenital heart diseases has remained stable. Rubella vaccine has reduced rubella-caused congenital heart disease, and congenital heart defects associated with Down's syndrome are less common because older women are having fewer babies. Pregnancies may be terminated if prenatal screening reveals Down's syndrome. Preventive strategies are impeded by lack of knowledge of the cause of most congenital heart disease, although it is known that alcohol, trimethadione, and lithium can cause cardiac defects. The majority of congenital heart disease may involve complex genetic-environmental interactions that remain to be elucidated (see Chaps. 69 and 70).

About 75 of each 1000 live births in the United States are premature, with the infants weighing less than 2500 g.[12] Almost half of premature infants weighing less than 1750 g will maintain patency of their ductus arteriosus, possibly because their immature lungs do not properly metabolize prostaglandins that cause the ductus to remain open.[45] The growing number of teratogens identified appears to account for only 5 percent of all human malformations, and single mutant genes are said to be responsible for only 3 percent of cases.

In 1997, deaths in infancy from congenital cardiovascular disease occurred at the rate of 0.5 per 1000 live births, about one-half the rate that occurred in 1980.[8] The 1-year fatality rate among the estimated 32,000 new cases at birth each year was about 6.5 percent in 1997. About 25 percent of infants with congenital heart disease have a malformation incompatible with life beyond the first year; possibly half of these can be treated surgically to improve the quality of life, if not to produce a cure. About 2.5 per 1000 live-born infants require specialized services for diagnosis and treatment of congenital heart disease shortly after birth, and another 2.5 per 1000 will need these resources later in childhood.

With the exception of bicuspid aortic valve in older patients, ventricular septal defect is the most common variety, accounting for 30 percent of congenital heart disease. Some 75 percent of congenital heart disease in infants and children is encompassed by seven defects: ventricular sepal defect, pulmonary stenosis, patent ductus arteriosus, tetralogy of Fallot, aortic stenosis, coarctation of the aorta, and transposition of the great arteries. There is an excess of birth defects in blacks. The rate among siblings is 17 per 1000 compared with 2.6 per 1000 in the general population (see Chap. 70).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

PULMONARY THROMBOEMBOLISM

More than 95 percent of pulmonary emboli arise from deep venous thrombi in the legs (above the knee); the remainder arise from the right cardiac chambers or other veins. The majority of deaths occur suddenly and can be avoided only by prophylaxis. Patients who survive to reach the hospital for medical treatment generally have a good outlook, with little morbidity and resolution of the emboli.

Estimates of mortality from pulmonary embolism vary depending on the source and accuracy of data. Pulmonary emboli are probably directly responsible for 50,000 deaths annually in the United States. If untreated, recurrent episodes are frequent, and more than 25 percent will be fatal. More than 60 percent of fatalities occur within 1 hour of onset; hence pulmonary embolism is likely to be confused with sudden coronary death. It is estimated that pulmonary embolism is grossly underdiagnosed, since only 10 to 30 percent of autopsied cases with evidence of embolism had an antemortem diagnosis.[46]

Among the U.S. population, the age-adjusted death rate for pulmonary embolism decreased 33 percent between 1979 and 1997.[4] The decline was greater in whites than in blacks and greater in men than in women. The rate of hospital discharges with a primary or secondary diagnosis of pulmonary embolism declined 38 percent from 7 per 10,000 population in 1979 to 4.3 in 1997.[8] Death rates and hospital rates for pulmonary embolism increase with age and are higher in men than in women and in blacks than in whites.[4] It was listed on 115,000 hospital records in 1997.[8] The incidence is even more uncertain. Only 10 percent of cases occur in normal persons without predisposing factors such as chronic cardiopulmonary and malignant disease, estrogen therapy, orthopedic trauma, immobilization, operative procedures, obesity, pregnancy, or blood dyscrasias. The elderly are more vulnerable.

Postoperative pulmonary emboli alone produce 4000 to 8000 deaths annually.[47] It is a major cause of death postpartum and in patients hospitalized for orthopedic conditions. Evidence from Britain suggests that the annual mortality from pulmonary embolism has been increasing for several decades despite anticoagulant drugs. More than 5 million persons over age 45 undergo major surgery each year in the United States; 1 or 2 of each 1000 will die postoperatively from pulmonary embolism. The recent advent of low-dose heparin prophylaxis may reduce this risk substantially (see Chap. 60).

Chapter 1: CARDIOVASCULAR DISEASES IN THE UNITED STATES AND PREVENTION APPROACHES

PREVENTIVE IMPLICATIONS FOR THE 21ST CENTURY

Examination of the incidence, prevalence, mortality, natural history, and risk factors of cardiovascular disease suggests the greatest benefits will be from a preventive approach. Further innovations in diagnosis and treatment for cardiovascular disease undoubtedly will improve the outlook of patients surviving the initial attack, but this can have only a limited impact because of the high initial mortality. When the heart or brain is infarcted, no therapy can be expected to restore full function. If the initial presentation is sudden death, therapy is unavailing. A preventive approach involving correction of predisposing factors in advance of the overt clinical expression of the disease can be expected to have a greater impact. To date, application of preventive measures of proven efficacy has been suboptimal.[48] Their application in the next century, even for the growing elderly population, has immense potential for primary and secondary prevention. Evidence is accumulating that medical therapy (vigorous risk-factor control) may be at least as effective as surgical or invasive revascularization in preventing recurrence of MI, progression of angina to MI, and premature CHD mortality. The potential benefits for primary prevention of MI by modification of risk factors has been demonstrated by a meta-analysis and reviews of the larger and more rigorous epidemiologic studies.[49] A multifactorial approach to risk reduction offers the best opportunity for saving patients at high risk and preventing the development of high-risk status in the first place.[50]

CHD often strikes without warning: One in five coronary attacks presents as sudden death, and two-thirds of the deaths occur in the community too precipitously to be brought under medical attention. While some strokes may give warning by transient ischemic attacks, most do not. Even when they do, intervention at that stage does not necessarily avoid a permanently damaging stroke or prolong life. Heart valves damaged by degenerative and rheumatic heart disease and infective endocarditis can be repaired surgically or replaced by prosthetic appliances; this approach often requires potentially dangerous anticoagulants to prevent emboli, and valve failure and hemolysis are distressingly common. Although such patients live longer, more comfortable lives than formerly, their survival does not approach that of patients with rheumatic fever who have been kept from progressing to severe valve damage by antibiotic prophylaxis against recurrent disease. Hypertension that pro-gresses to target-organ involvement is less manageable than if vigorously treated prior to such manifestations. The first sign of target-organ involvement is often a stroke, MI, or sudden death. Half of such events occur before evidence of organ involvement is discovered on routine biennial examination. In some respects, the occurrence of symptoms more properly may be regarded as a medical failure rather than as the initial indication for treatment (see Chap. 58).

A major impact on cardiovascular morbidity and mortality in the 21st century should derive from the practice of preventive medicine, from public health measures to alter lifestyle to one more favorable to cardiovascular health, and from health education to inform people of what they must do to protect their cardiovascular health. Recent expansion and improvements in these measures have occurred, conceivably contributing significantly to the 36 percent decline in cardiovascular mortality during the past two decades, which is responsible for most of the decline in overall mortality.[2]

The epidemiologic and clinical trial evidence of the cardiovascular diseases in the 20th century

has set the stage for opportunities in the next century to direct research and public health activities that can substantially reduce the risk and impact of cardiovascular disease. Foremost among those opportunities is implementation of comprehensive preventive programs of government regulation, health education, and preventive medicine designed to control the major identified cardiovascular risk factors. This includes exploring further the underlying basis for clustering of atherogenic risk factors and the prevalence and impact of insulin resistance, promoting cardiovascular risk profiles to more efficiently target high-risk cardiovascular disease candidates for preventive measures, and finding better ways to implement preventive measures against obesity, insulin resistance, and cigarette smoking. The potential is large if physicians can be induced to more aggressively implement the proven measures recommended to prevent cardiovascular disease.

Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 2:

FUNCTIONAL ANATOMY OF THE HEART

Authors: Joseph F. Malouf, William D. Edwards, A. Jamil Tajik, James B. Seward

BACKGROUND

The study of the heart and great vessels has come a long way since the days of Andreas Vesalius, the great 16th-century anatomist who recognized the impact of anatomy on the practice of medicine.[1] During the European Renaissance, the tomographic approach to the study of cardiac anatomy became popular because of its artistic-based correlations. This is vividly depicted in the drawings of Leonardo da Vinci[2] (Fig. 2-1), who was called the first comparative anatomist since Aristotle. During the ensuing nearly four hundred years, however, interest in cardiac anatomy was very sporadic and limited to a few zealous and pioneering physicians, anatomists, and artists.

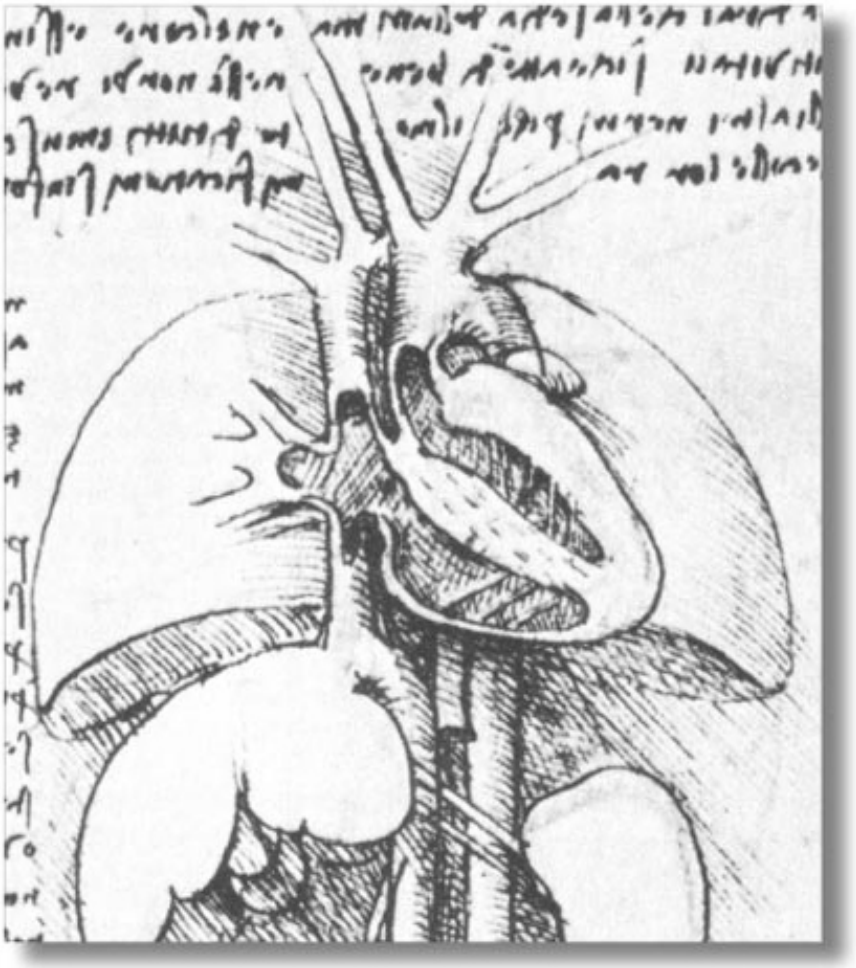

Figure 2-1: Four-chamber tomographic section of the heart as illustrated by Leonardo da Vinci. Note the thin-walled right ventricle and thick-walled left ventricle and detailed anatomic

connections. (From O'Malley and Saunders,[2] with permission.)

The 19th century ushered in the era of anatomic dissection for the study of physiologic and pathophysiologic processes. Virchow in 1885 described the *inflow-outflow method of cardiac dissection* that followed the direction of blood flow.[3] It was quick and simple and became the dissection method of choice. The works of Virchow and Osler paved the way to understanding the pathophysiologic basis of such diseases as pulmonary embolism, endocarditis, and heart failure.[4] Renewed interest in the study of cardiac anatomy and pathology was facilitated by the rise in autopsy rates in Europe and North America during the first half of the 20th century.[5] Herrick described the clinical features of coronary thrombosis.[5] Later, Blumgart, Schlesinger, and Zoll advanced our understanding of coronary artery disease through elegant clinicopathologic correlations.[5]

These achievements notwithstanding, however, they were limited to postmortem examinations. The advent of cardiac surgery in the 1950s, followed by coronary angiography, was a major impetus for promoting the study of in vivo clinicopathologic anatomic correlations. While cardiac surgeons were quick to appreciate the importance of having a detailed understanding of cardiac anatomy, clinical cardiologists were more interested in pathophysiology. However, with the introduction of noninvasive imaging techniques [echocardiography, computed tomography (CT), magnetic resonance imaging (MRI), and single-photon-emission computed tomography (SPECT)] over the past two decades, the perception of cardiac anatomy and pathophysiology radically changed for all of medicine in general and cardiology in particular.

With increasing use of tomographic techniques in the diagnosis and management of cardiovascular diseases, there has been a corresponding decrease in the use of autopsy for anatomic correlations. The reasons for this decrease are complex and controversial and include an increased confidence in technology, lack of reimbursement for the cost of autopsy, and rescinding the mandate for autopsies for hospital accreditation.[4] Nonetheless, autopsy still uncovers unexpected processes in about 15 percent of cases and is an invaluable tool for quality assurance programs.

Today, at the beginning of the 21st century, there is a resurgence in the clinicopathologic correlative approach to cardiovascular morphology. In particular, the tomographic presentation of cardiac structure, which had remained dormant for over a century, has become relevant because the diagnostic techniques used today are tomographic in nature.[6] The specialties associated with cardiovascular diseases have been quick to embrace these newer anatomic presentations. Echocardiography was brought into the operating room, and with the advent of transesophageal echocardiography, the cardiologist became an indispensable member of the surgical team.[7,8] Because of increasingly more sophisticated cardiac surgical techniques, coupled with closer interaction between the cardiac surgeon and the noninvasive cardiologist, there has been a growing demand for precise diagnostic tools with greater spatial and temporal resolution to guide the planning of surgical procedures and, therefore, to ensure their success.[7,8]

The interest in cardiac anatomy among cardiologists is by no means limited to those involved in imaging the heart. Over the past few years, there has been an explosion of interest in anatomically guided electrophysiologic mapping and ablation techniques, which are increasingly guided by intracardiac ultrasound.[9-13] It has thus become feasible to accurately pinpoint the anatomic location of the source of many arrhythmias[9-13] (Figs. 2-2 and 2-3). By providing the electrophysiologist with a real-time visual "road map," the "search and destroy" mission during an ablation procedure will be made much easier and results, as well as complications, recognized immediately.[9-13] By providing a new window to the heart, real-time anatomic-electrophysiologic correlations also may help to enhance our understanding of the mechanisms of propagation of various arrhythmias.

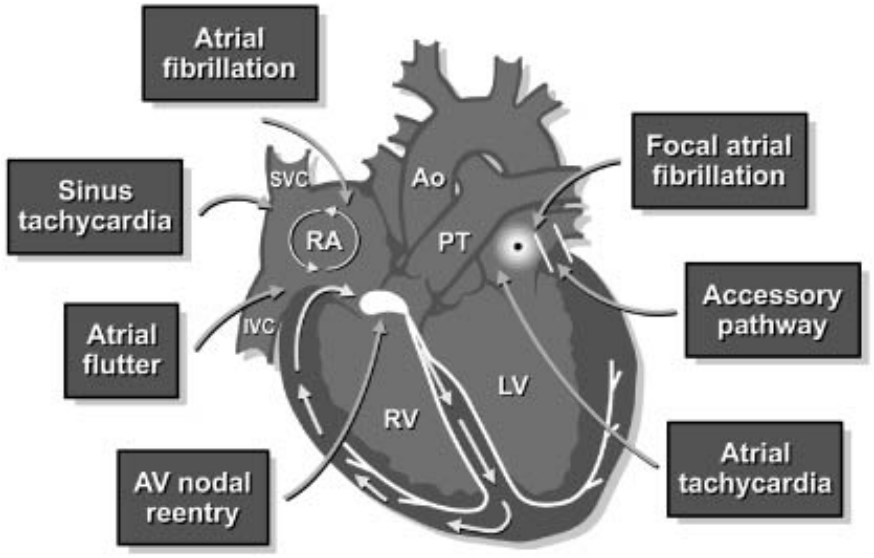

Figure 2-2: Anatomic considerations in the treatment of supraventricular arrhythmias. (Courtesy of Dr. Douglas L Packer, Mayo Clinic, Rochester, Minnesota.)

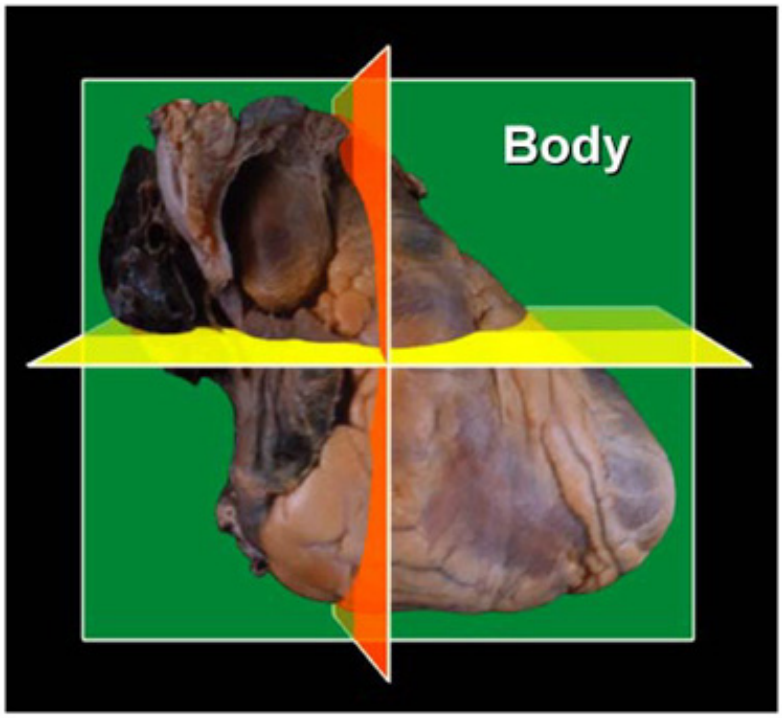
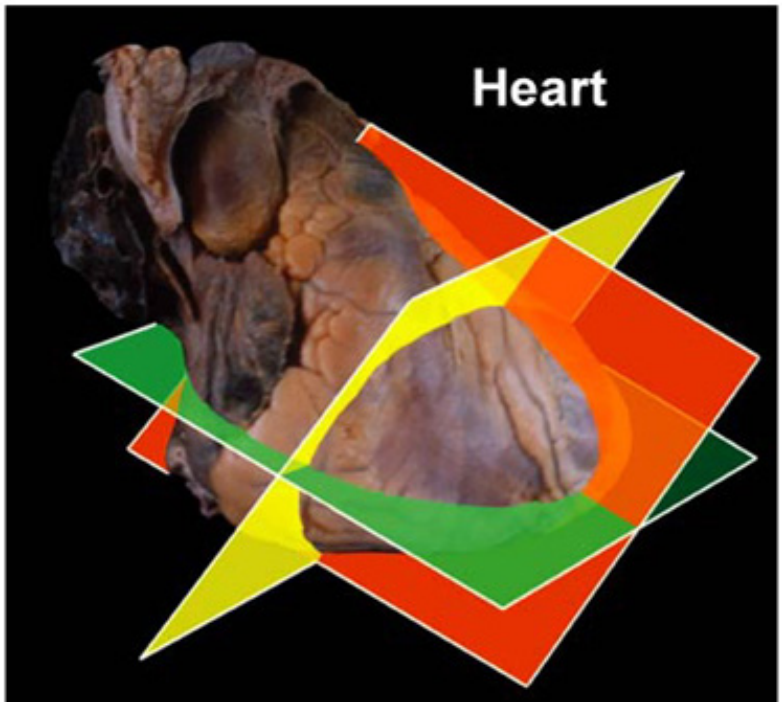
In this technologically driven era, a *new* appreciation of cardiac anatomy has emerged as the cornerstone for clinical cardiology. The purpose of this chapter is to describe the anatomy of the heart by principally using the tomographic format prevalent in current CT, MRI, and echocardiography, with special emphasis and focus on clinically relevant anatomic details. We will make only a passing note of the next generation of imaging techniques. The intent is to emphasize the important anatomic features of various cardiovascular disease processes relative to

diagnosis and management.

Orientation of the Heart Within the Thorax

The body may be viewed in three standard anatomic planes: (1) frontal (coronal), (2) horizontal (transverse), and (3) sagittal that are orthogonal to one another.[6,7] However, the three primary planes of the heart [short axis (transverse), four-chamber (frontal), and long-axis (sagittal)] do not correspond to the standard anatomic planes of the body[6,7] (Fig. 2-4, Plate 1). *Incorrect photographic or artistic orientation of surgical or autopsy specimens of the heart, presented out of context, can result in the display of two-dimensional images in nonanatomic positions and actually contribute to misconceptions regarding the position of the heart within the thorax*[6] (Fig. 2-5, Plate 2).





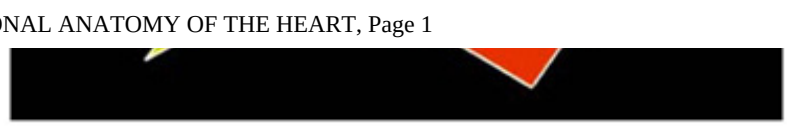


Figure 2-4: (Plate 1) The three primary planes of the body (*left*) and heart (*right*). Note that the planes of the body are aligned with vertical midline structures, such as the esophagus. In contrast, the major axis of the heart is oriented obliquely. Thus the heart's long and short axes do not lie in the same plane as the body's long and short axes. The body planes cut the heart obliquely and not in its primary planes. Conversely, the heart's primary planes cut the body obliquely.

Thus, first, when describing the orientation of a specific organ such as the heart, one must take into account both the position of the heart and the position of adjacent structures such as the thoracic aorta and esophagus. When interpreting two-dimensional images, clinicians must avoid making correlations that yield impossible anatomy[6] (Fig. 2-6). Accurate anatomic diagnoses require close interdisciplinary interactions between cardiovascular pathologists, clinicians, radiologists, anesthesiologists, and surgeons and emphasize a critical need for teamwork and a "common language" when describing cardiac anatomy and pathology.

Methods Used to Study Cardiac Anatomy

The two conventional approaches to the study of cardiac anatomy that have stood the test of time are (1) the inflow-outflow method (Fig. 2-7) and (2) the tomographic ventricular slice method[3,6] (Fig. 2-8, Plate 3). Although the inflow-outflow method readily demonstrates disease processes in a given cardiac chamber or valve, it does not allow simultaneous visualization of the effects of that process on contiguous structures.[6] Furthermore, the inflow-outflow method does not correspond well to clinical tomographic imaging modalities except possibly cavitary angiography.[6] With the ventricular slice technique (see Fig. 2-8), the ventricles are "bread sliced" perpendicular to the plane of the ventricular septum. This technique is ideal for the evaluation of ischemic heart disease but may need to be carried basally, well beyond the papillary muscle tips.[6]

Chapter 2: FUNCTIONAL ANATOMY OF THE HEART

TOMOGRAPHIC METHOD

Renaissance anatomists such as da Vinci used the *tomographic approach* principally because of its *artistic correlations*.[2] Modern anatomists and pathologists have resorted to this method because it correlates with conventional diagnostic tomographic-anatomic techniques. With this method, cardiac dissection involves bisecting the heart into two pieces using a single plane of section.[6] Anatomy contained within the depth of each section fosters a perception of three-dimensional anatomy. Commonly used planes bisect the heart perpendicular to the base-apex axis (*short-axis "transverse" views*) (Fig. 2-9, Plate 4) or parallel to it (*long-axis and four-chamber "frontal" views*)[6] (Fig. 2-10, Plate 5). Planes that bisect the heart parallel to the conventional body planes (frontal **"coronal", transverse "short-axis", and sagittal "long-axis" views**) (Fig. 2-11, Plate 6) replicate *body tomography*.[6,14]

The *short-axis tomographic planes*[6,7] of the heart (Fig. 2-12) are similar to the ventricular slice method but differ in two important respects. The "bread slicing" of the heart is continued to the base of the heart and great vessels, and the slices are oriented as though the heart were being viewed from the apex toward the base rather than in the opposite direction, as has been the case with the ventricular slice technique. Photographs should correspond with diagnostic tomographic scans.

The *long-axis and four-chamber planes* are orthogonal to the short-axis planes. The four-chamber planes of cardiac dissection (Fig. 2-13) involve sectioning the heart along both lateral walls, from apex to base, such that both ventricles and both atria are included in the plane of section.[6,7] The long-axis two-chamber method (Fig. 2-14) involves bisecting the heart from the left ventricular apex through the mitral orifice and into the left atrium.[6,7] The long-axis plane can cut through both the left ventricular inflow tract (including the left atrium and mitral valve) and the left ventricular outflow tract (including the ventricular septum, anterior mitral leaflet, and ascending aorta) (Fig. 2-15). This plane also cuts obliquely through the right ventricular outflow tract.[6,7]

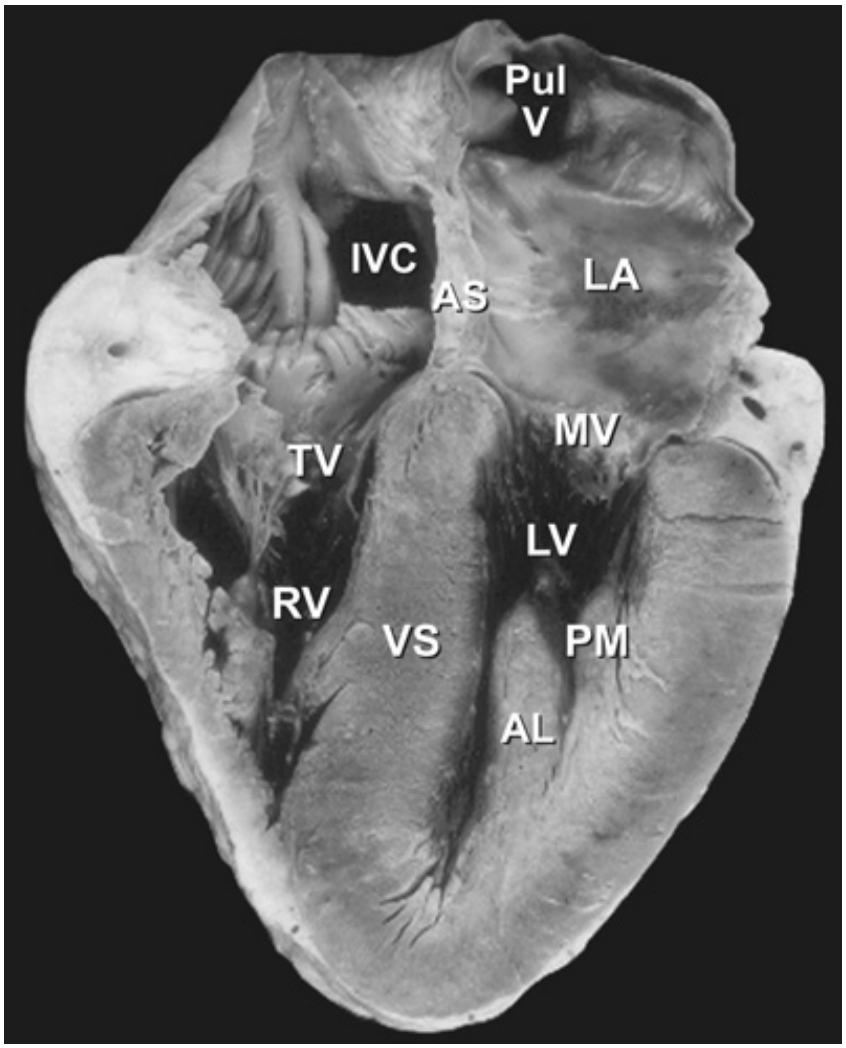

Figure 2-13: Tomographic cardiac dissection along the heart's primary fourchamber plane. The heart is viewed as though one were looking from the anterosuperior surface toward the posteroinferior surface. In the floor of the right atrium is the orifice of the inferior vena cava (IVC). The pulmonary veins (PulV) enter the posterior aspect of the left atrium. AL, anterolateral mitral papillary muscle; AS, atrial septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PM, posteromedial mitral papillary muscle; RV, right ventricle; TV, tricuspid valve; VS, ventricular septum.

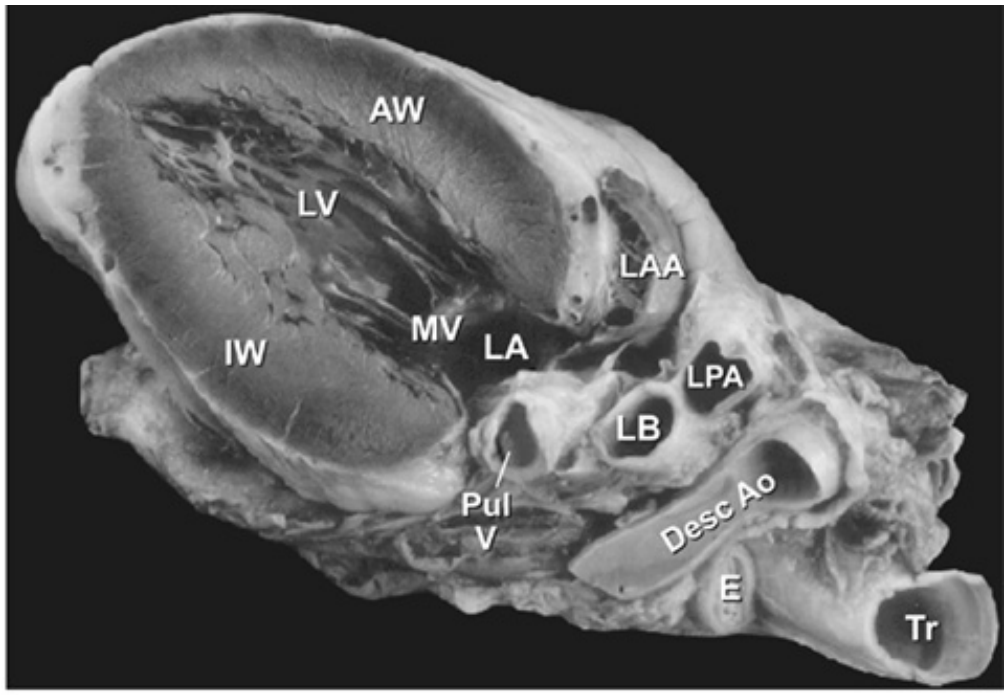
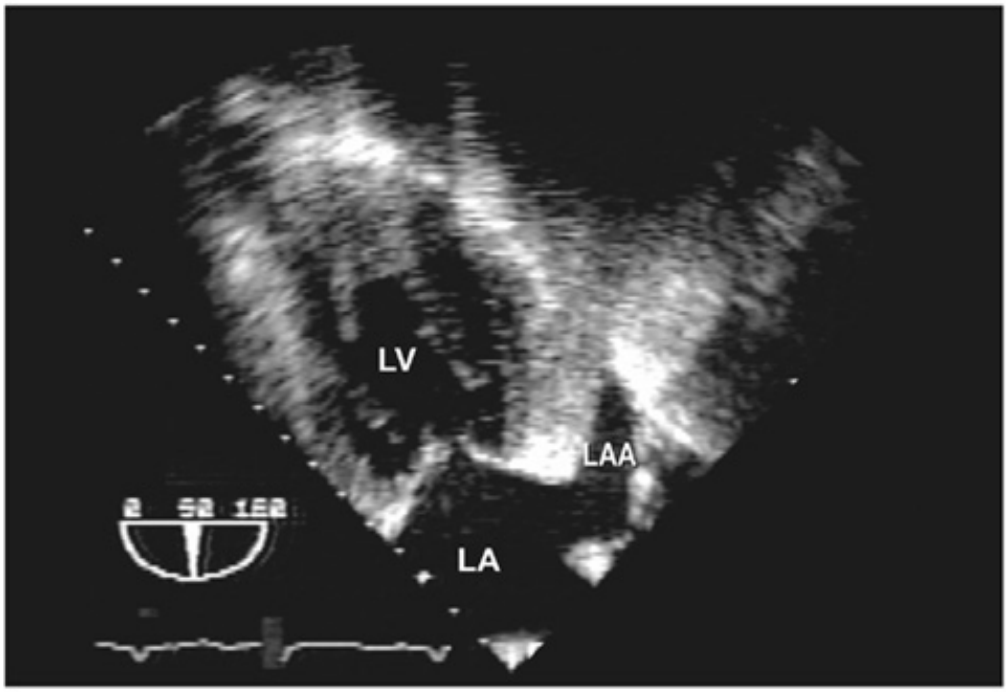


A



B

Figure 2-14: Tomographic cardiac dissection along the heart's primary long-axis plane. *A.* Tomographic section showing the left ventricle and left atrium. The mitral valve is also well demonstrated. The left atrial appendage is located anteriorly. The specimen is viewed as though one were looking from the tip of the left scapula toward the right nipple. *B.* Analogous two-chamber transesophageal view. AW, anterior wall; **Desc** Ao, **descending thoracic aorta;** E, **esophagus;** IW, **inferior wall**; LA, **left atrium;** LAA, **left atrial appendage;** LB, **left bronchus;** LPA, **left pulmonary artery;** LV, **left ventricle;** MV, **mitral valve;** PulV, pulmonary vein; Tr, trachea.

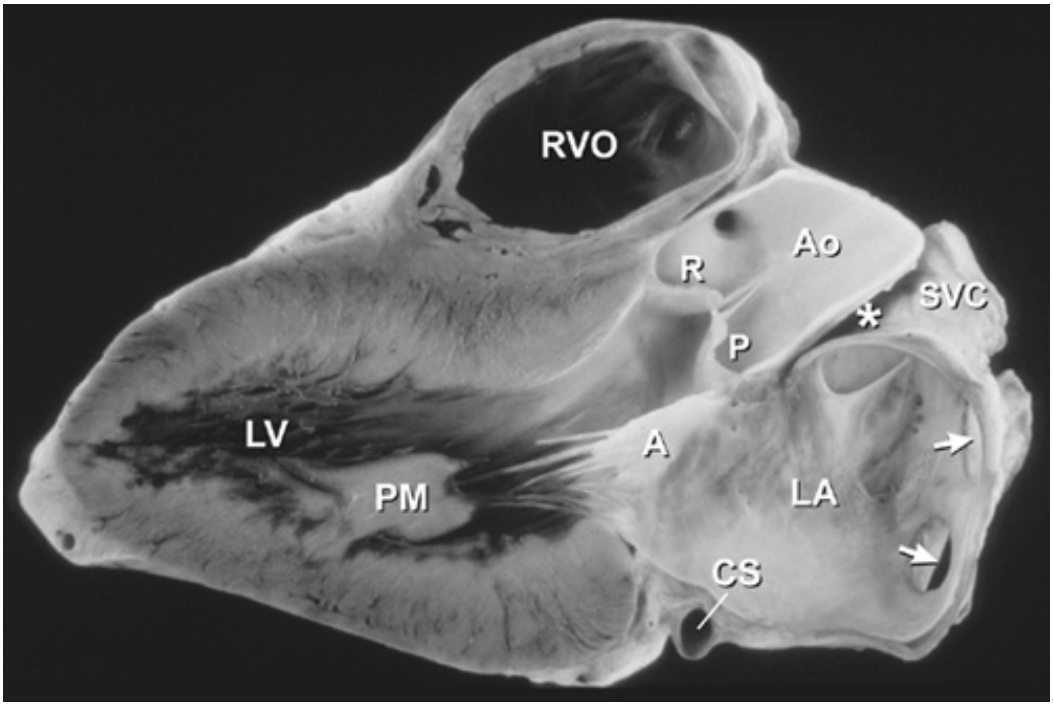


Figure 2-15: Left ventricular long-axis method of tomographic cardiac dissection (looking from left flank toward the midsternum). Continuity between mitral and aortic valves is clearly seen. The oblique sinus (*) abuts the wall of the left atrium. A, anterior mitral leaflet; Ao, ascending aorta; CS, coronary sinus; LA, left atrium; LV, left ventricle; P, posterior aortic cusp; PM, posteromedial mitral papillary muscle; R, right aortic cusp; RVO , right ventricular outflow; SVC, superior vena cava; arrows point to the right upper and lower pulmonary veins.

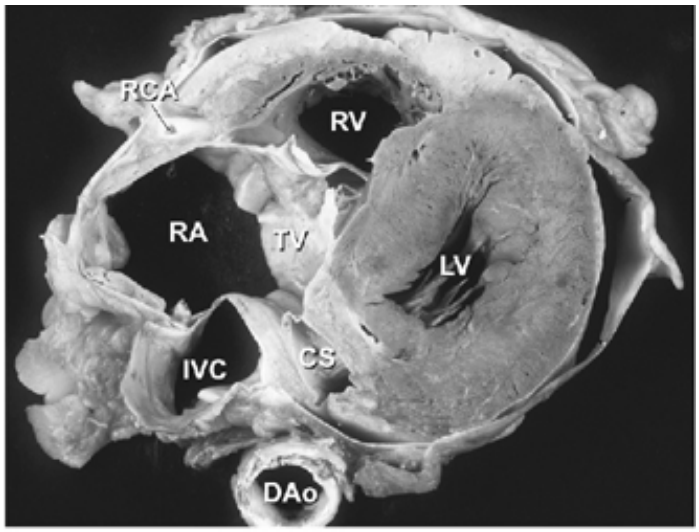
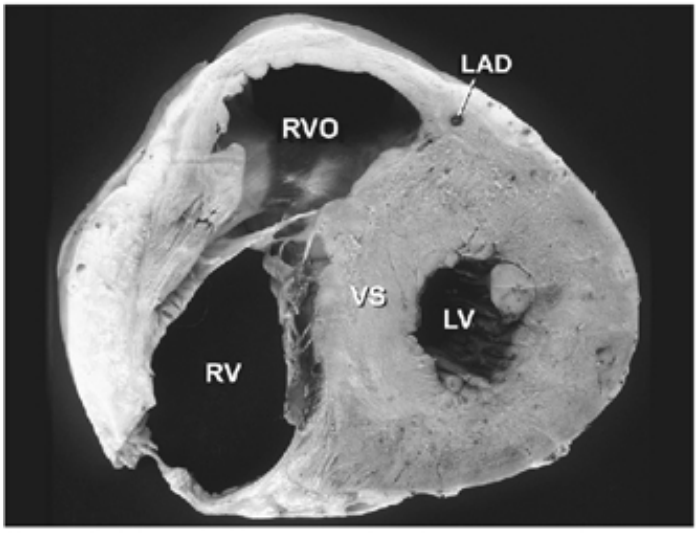
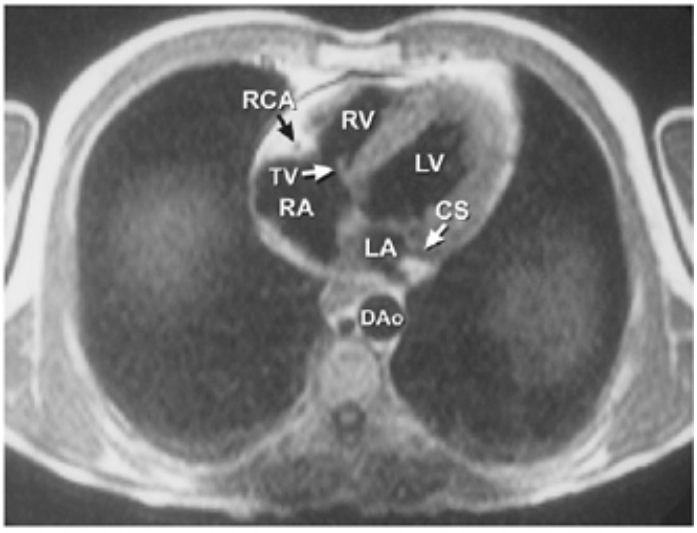
These three tomographic planes of the heart have been particularly useful in echocardiography. Serial sections within each plane produce a collage of anatomic slices (Fig. 2-16, Plate 7) that can be used for three-dimensional reconstruction, which is beyond the scope of this chapter. The tomographic planes of section can be tailored to the different imaging modalities. *Thus echocardiography and* SPECT *generally employ the primary planes of the* heart. *In contrast,* CT *and* MRI *use the primary planes of the* body. *The parasagittal or oblique planes of the body serve radionuclide angiography and left ventriculography.*[6] When the tomographic examination is not configured to the primary planes of the heart but rather to the planes of the body, the terms *short, long,* and *frontal* can be misleading (Figs. 2-17 and 2-18).



A



B



C

Figure 2-17: Tomographic sections of the heart in the transverse (*A*) and frontal (*B*) planes of the body. A tomographic section in the transverse plane of the body (*A*) results in a four-chamber view of the heart. *A* tomographic section along the frontal plane of the body (*B*) results in an oblique short-axis view of the heart. *C*. MRI image corresponding to *A*. CS, coronary sinus; DAo, descending thoracic aorta; IVC, inferior vena cava; LA, left atrium; LAD, left anterior descending

coronary artery; LV, left ventricle; RA, right atrium; RCA, right coronary artery; RV, right ventricle; RVO, right ventricular outflow; TV, tricuspid valve; VS, ventricular septum.

Pathologic lesions in both congenital and acquired heart diseases often involve contiguous chambers, valves, or vessels. The tomographic method is the optimal technique for demonstrating intracardiac relationships and is ideal for any disease that involves several cardiac chambers. The proliferation of noninvasive tomographic imaging techniques makes this method particularly ideal for clinicopathologic correlations.

Limitations of tomographic dissection can be overcome by photography, computer imagery, and interestingly, the use of glue. After each tomographic section has been produced and photographed, the bisected specimens can be glued back together using any cyanoacrylate glue such as Krazy **Glue or Superglue** and resectioned along a different tomographic plane.[6] A step-by-step photographic documentation is necessary, since once the specimen has been glued and recut, the preceding tomographic plane of section will be available only in the photograph and not in the actual specimen.

Chapter 2: FUNCTIONAL ANATOMY OF THE HEART

CORRELATIVE ANATOMY

This section in this chapter is an illustrated review of applied cardiac anatomy. The clinical significance of the anatomy described is highlighted in italics.

Pericardium

The fibrous (parietal) pericardium is a resilient sac that envelops the heart and attaches onto the great vessels.[15] Almost the entire ascending aorta and main pulmonary artery and portions of both venae cavae and all four pulmonary veins are intrapericardial (Fig. 2-19). *These are important anatomic landmarks to remember when evaluating diseases of the pericardium. Given the intrapericardial location of the ascending aorta, diseases such as localized aortic wall hematoma, aortic dissection, or aortic rupture can produce a rapidly fatal hemopericardium. Because the sac is collagenous, with little elastic tissue, it cannot stretch acutely. In patients with total anomalous pulmonary venous connection, the confluence of pulmonary veins is intrapericardial. In contrast, the right and left pulmonary arteries and ductal artery (ductus arteriosus) are extrapericardial structures.*[16]

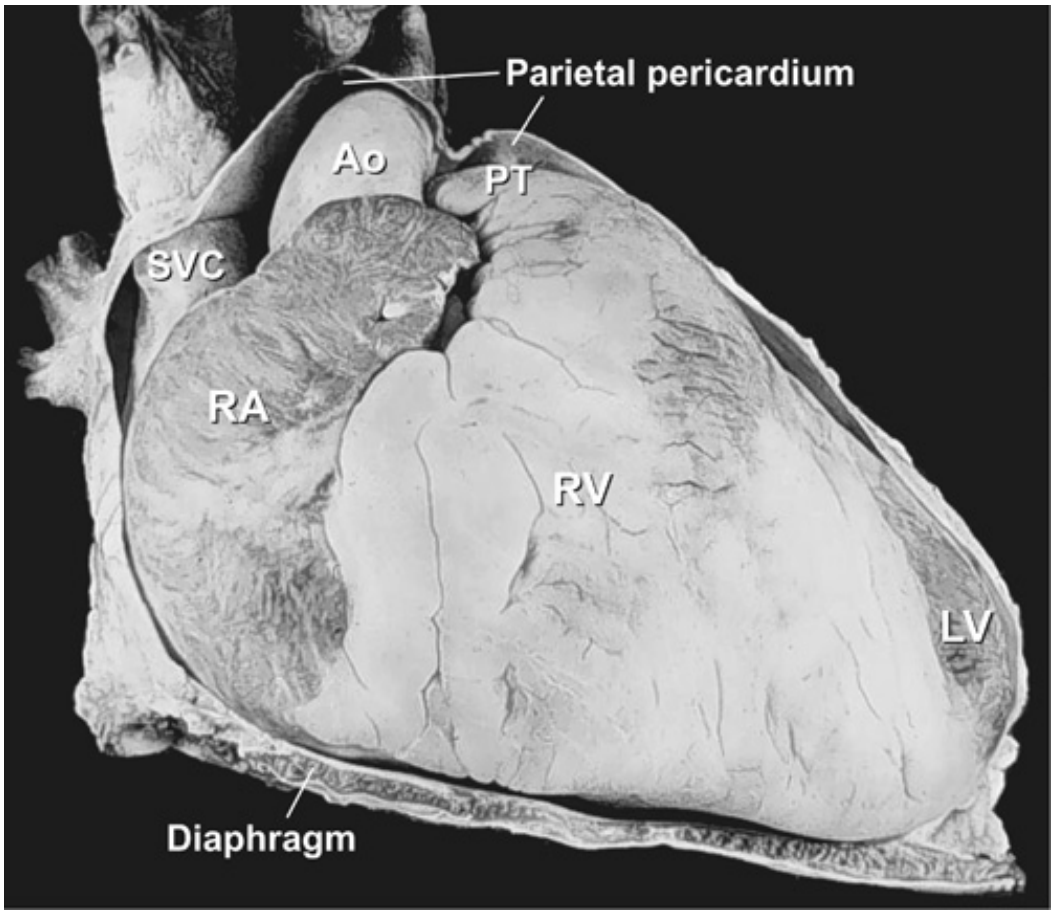

Figure 2-19: Anterior view of the heart. The anterior portion of the parietal pericardium has been

removed, exposing the intrapericardial portions of the superior vena cava (SVC), ascending aorta (Ao), and pulmonary trunk (PT). LV, left ventricle; RA, right atrium; RV, right ventricle.

The serous pericardium forms the delicate inner lining of the fibrous pericardium as well as the outer lining of the heart and great vessels (visceral pericardium). Over the heart, it is referred to as the epicardium, and it contains the epicardial coronary arteries and veins, autonomic nerves, lymphatics, and a variable amount of adipose tissue. The junctions between the visceral and parietal pericardium lie along the great vessels and form the pericardial reflections. The reflections along the pulmonary veins and vena cavae are continuous and form a posterior midline cul-de-sac known as the *oblique sinus*. Behind the great arteries, the *transverse sinus* forms a tunnel-like passageway (Fig. 2-20). *After open-heart surgery, localized accumulation of blood within the oblique sinus can produce isolated left atrial tamponade.*[16] *Similarly, a hematoma adjacent to the low-pressure right atrium can cause isolated right atrial tamponade*. With increasing age and with obesity, fat can accumulate within the parietal pericardium and epicardium.[16] *When imaging the heart, it is important not to misinterpret fat as an abnormal structure or a tumor*.

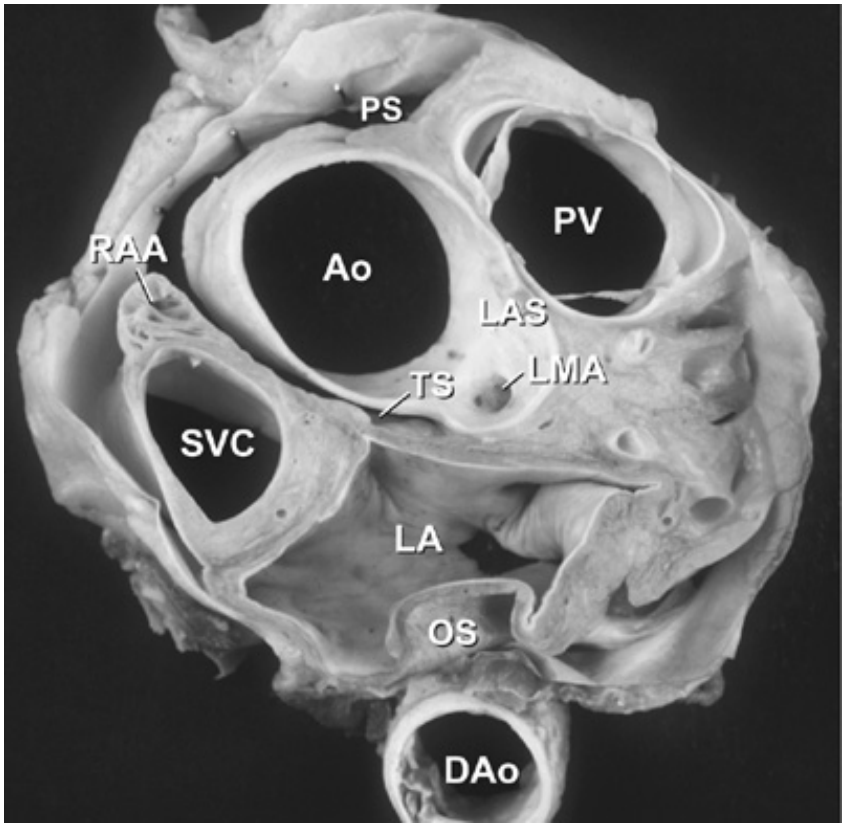

Figure 2-20: Tomographic section in the short-axis plane of the body, looking from apex toward the base, showing the oblique (OS) and transverse (TS) pericardial sinuses. Ao, ascending aorta; DAo, descending thoracic aorta; LA, left atrium; LAS, left aortic sinus; LMA, left main coronary artery: PS, pericardial sac; PV, pulmonary valve; RAA, right atrial appendage; SVC, superior vena cava.

Cardiac Skeleton

The four cardiac valves are anchored to their annuli, or valve rings. These fibrous rings, at the base of the heart, join to form the fibrous skeleton of the heart[16] (Fig. 2-21). The centrally located aortic valve forms the cornerstone of the cardiac skeleton, and its fibrous extensions abut each of the other three valves. The cardiac skeleton contains not only the four valve annuli but

also the membranous septum and the aortic intervalvular, right, and left fibrous trines. The fibrous trigones form the anatomic substrate for direct mitral-aortic continuity[16] (Figs. 2-21, Plate 8, and 2-22). The intervalvular fibrosa also forms part of the floor of the transverse sinus (see Figs. 2-22 and 2-33). *In patients with infective endocarditis of the mitral or aortic valves, the infection may burrow through the intervalvular fibrosa and produce fistulas betwn the left ventricle and the adjacent left atrium, ascending aorta, or transverse sinus.*[17]

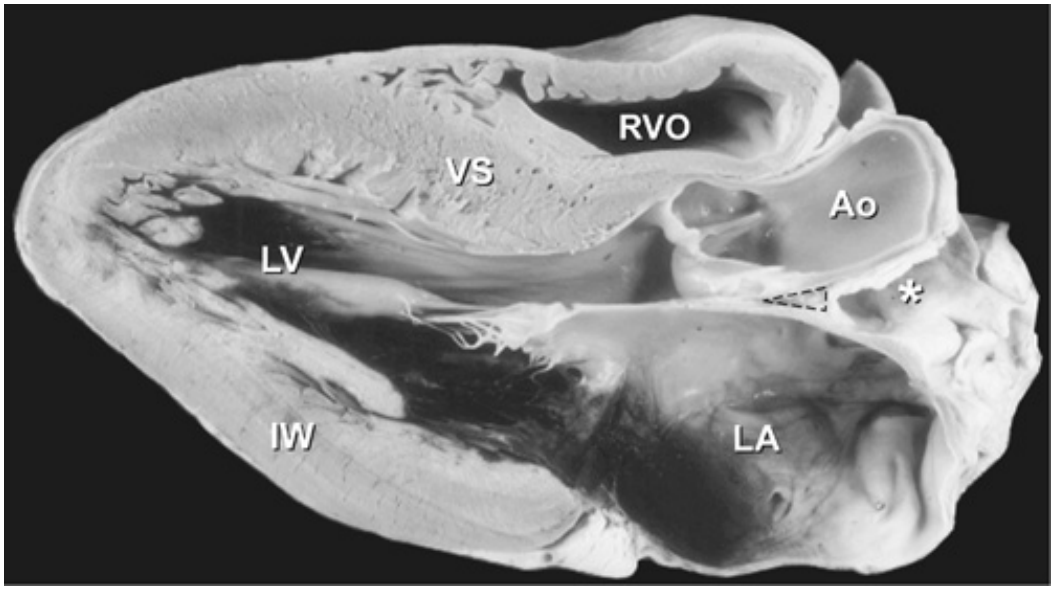

Figure 2-22: Long-axis section of the left ventricle. The intervalvular fibrosa (dashed triangle) lies between the anterior mitral leaflet and the posterior cusp of the aortic valve and abuts the floor of the transverse pericardial sinus (*). Ao, ascending aorta; IW, inferior wall; LA, left atrium; LV, left ventricle; RVO, right ventricular outflow; VS, ventricular septum.

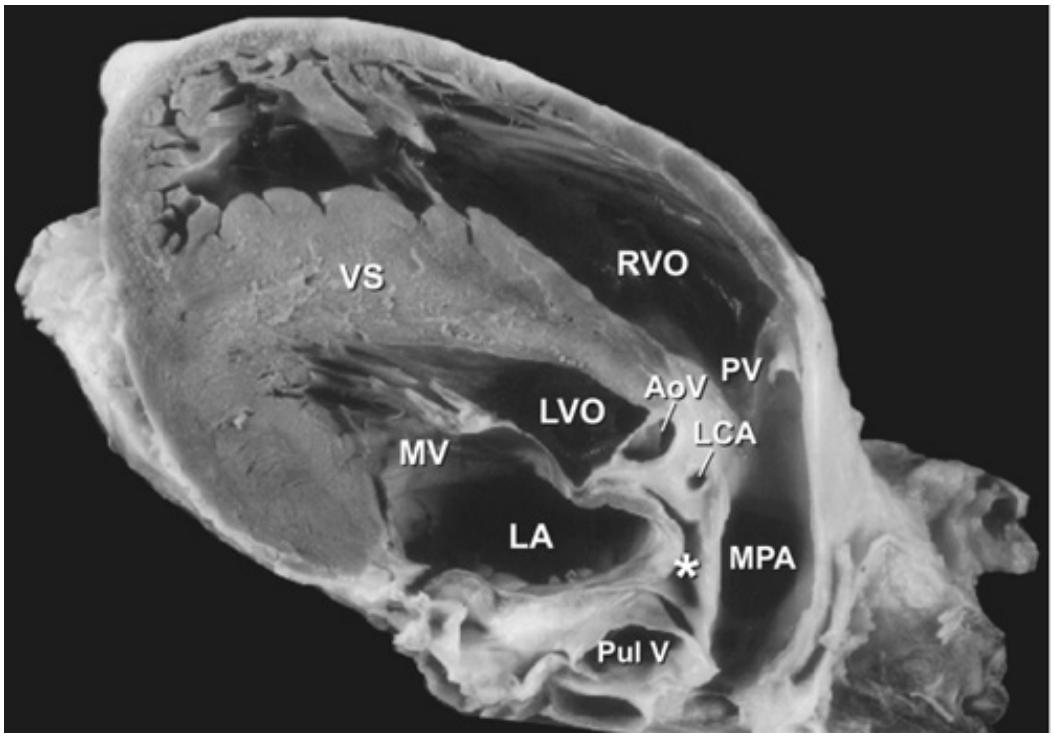

Figure 2-33: Long-axis view of the right ventricular outflow (RVO) tract showing the pulmonary valve (PV) and main pulmonary artery (MPA). AoV, aortic valve; LA, left atrium; LCA, left coronary artery; LVO, left ventricular outflow; MV, mitral valve; PulV, pulmonary vein; VS, ventricular septum; *, transverse sinus.

The right fibrous trigone, also known as the *central fibrous body*, welds together the aortic, mitral, and tricuspid valves and forms the largest and strongest component of the cardiac skeleton. It is through the right fibrous trigone that the atrioventricular (His) bundle passes. Otherwise, the fibrous cardiac skeleton serves to electrically isolate the atria from the ventricles. *Diseases or surgical alterations of one valve may affect the shape or angulation of adjacent valves (e.g., aortic valve replacement causing severe mitral regurgitation) and may affect the nearby coronary arteries or conduction tissue*.[17]

Tricuspid Valve

The tricuspid valve is comprised of five components (i.e., annulus, leaflets, commissures, chordae tendineae, and papillary muscles). The anterior tricuspid leaflet is the largest and most mobile and forms an intracavitary curtain that partially separates the inflow and outflow tracts of the right ventricle (Fig. 2-23). The posterior leaflet is usually the smallest. The septal leaflet is the least mobile because of its many direct chordal attachments to the ventricular septum. A distensible fibroadipose annulus is unique to the tricuspid valve.[17] Consequently, dilatation of the right ventricle commonly produces circumferential tricuspid annular dilatation that results in variable degrees of tricuspid valve regurgitation.[16]

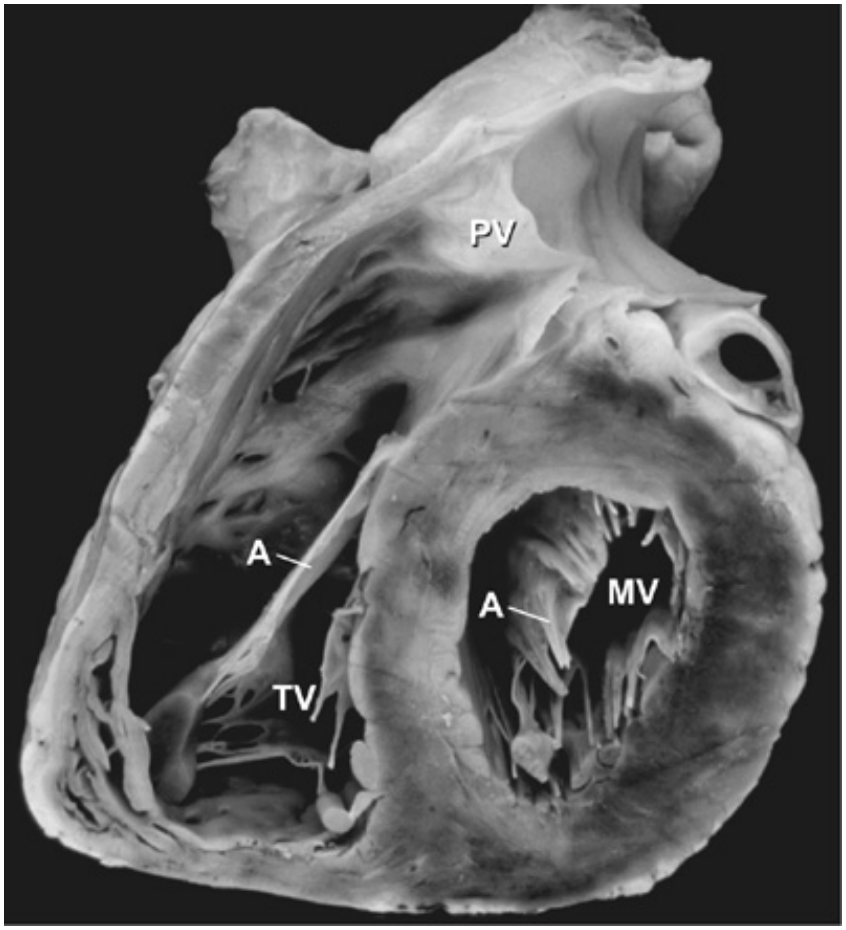

Figure 2-23: This oblique short-axis view of the heart shows the triangular-shaped tricuspid orifice (TV) and the elliptical mitral orifice (MV) at midleaflet level. The anterior tricuspid and anterior mitral leaflets (A) separate the inflow and outflow tracts of the right and left ventricles, respectively, and are parallel to one another. PV, pulmonary valve.

Mitral Valve

The mitral apparatus is comprised of the same five components as the tricuspid valve. Competent mitral valve function is a complex process that requires the proper interaction of all components, as well as adequate left atrial and left ventricular function. *Abnormalities of the mitral valve apparatus may involve any of these components or combinations thereof. The pattern of pathologic involvement often determines the feasibility of mitral valve repair (surgical or percutaneous)*.[18] The mitral valve annulus forms a complete fibrous ring that is firmly anchored along the circumference of the anterior leaflet by the tough fibrous skeleton of the heart[17] (see Fig. 2-21). Therefore, dilatation of the mitral valve annulus primarily affects the posterior leaflet. *All current operative mitral repair techniques are based on this principle of asymmetric annular dilatation. Mitral valve annuloplasty reduces the mitral valve inlet area by reducing the circumference of the posterior leaflet.*[17] *This is the rationale for using a partial posterior annuloplasty ring*.

Unlike the other cardiac valves, the mitral valve has only two leaflets. The anterior leaflet is large and semicircular, and it partially separates the ventricular inflow and outflow tracts (see Fig. 2-23). However, unlike its right-sided counterpart, it also forms part of the outflow tract. *In patients with hypertrophic obstructive cardiomyopathy, the anterior mitral leaflet may be drawn toward the basal anterior septum because of the Venturi effect, resulting in midsystolic outflow obstruction and mitral regurgitation*.[16] The posterior mitral leaflet is rectangular and usually is divided into three scallops. The middle scallop is the largest of the three in more than 90 percent of normal hearts. Occasionally, however, either the anterolateral or the posteromedial scallop is larger, and rarely there are accessory scallops[15,17] (Fig. 2-24, Plate 9). *Posterior mitral leaflet prolapse usually involves the middle scallop and may be associated with chordal rupture*. Both mitral leaflets are normally similar in area. The anterior leaflet is twice the height of the posterior leaflet but has half its annular length.[17] With advanced age, the mitral leaflets thicken somewhat, particularly along their closing edges.[15]

The commissures are cleftlike splits in the leaflet tissue that represent the sites of separation of the leaflets (Figs. 2-25 and 2-26*A*). Beneath the two mitral commissures lie the anterolateral and posteromedial papillary muscles, which arise from the left ventricular free wall (see Figs. 2-18*B* and 2-25). Commissural chords arise from each papillary muscle and extend in a fanlike array to insert into the free edge of both leaflets adjacent to the commissures (major commissures)[17] (see Figs. 2-24 and 2-26*A*, Plate 10) or into two adjacent scallops of the posterior leaflet (minor commissures) (see Figs. 2-24 and 2-25). *In contrast to congenital clefts, a true commissure is always associated with an underlying papillary muscle and an intervening array of chordae tendineae*.[17] The attachments of commissural chords precisely demarcate the commissure. *Because the commissural chords are seldom elongated, they serve as accurate reference points for determining the proper closing plane for the leaflets during surgical repair*.

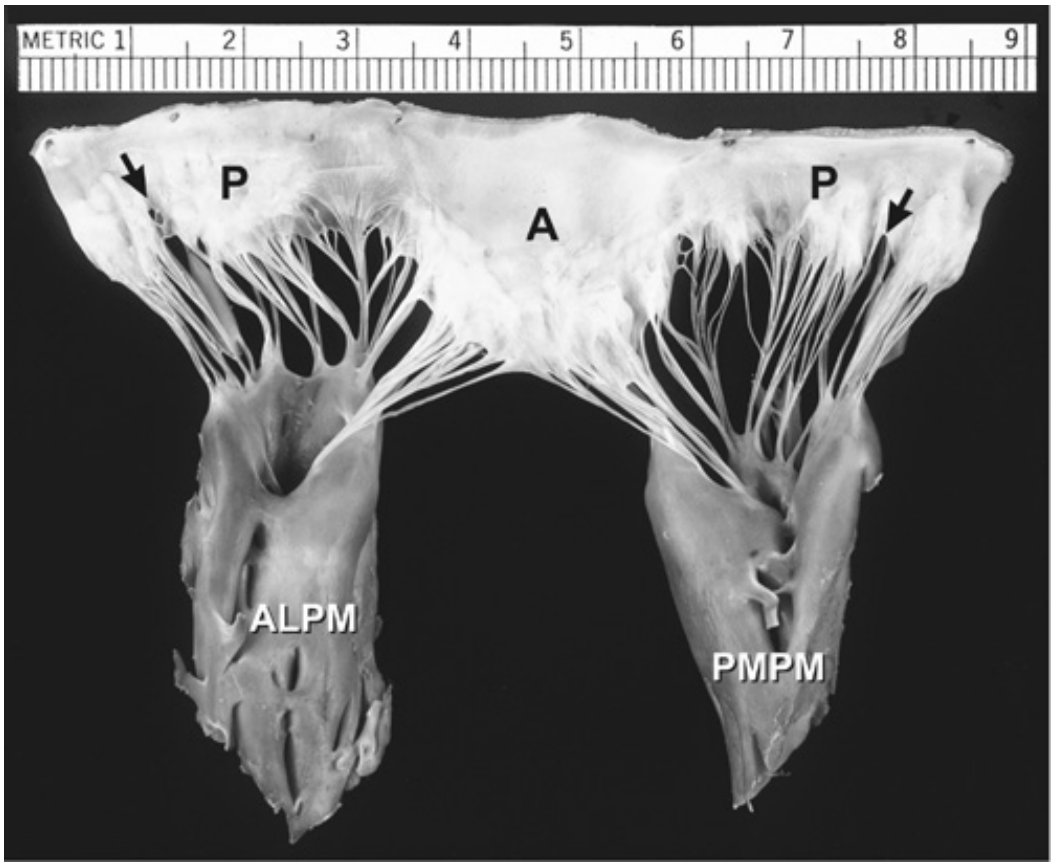

Figure 2-25: Gross anatomy of the mitral valve and papillary muscle-chordal apparatus, as demonstrated in an excised and unfolded valve. Each commissure overlies a papillary muscle. Arrows point to minor commissures. A, anterior leaflet; ALPM, anterolateral papillary muscle; P, posterior leaflet; PMPM, posteromedial papillary muscle.

The anterolateral papillary muscle is commonly single and usually has a dual blood supply from the left coronary circulation.[16] In contrast, the posteromedial papillary muscle usually has multiple heads and is most commonly supplied only by the right coronary artery.[16] Small left atrial branches supply the most basal aspects of the mitral leaflets.[17]

Papillary muscle contraction pulls the two leaflets toward one another and thereby promotes valve closure. The line of closure for either mitral leaflet is not its free edge but an ill-defined junction between a thin, clear zone and a thicker, rough zone[17] (see Fig. 2-26, Plate 10). The major chordae supporting a leaflet insert into its free edge and rough zone. The chordae tendineae anchor and support the leaflets and, by doing so, prevent leaflet prolapse during ventricular systole. Two particularly prominent rough zone chords, referred to as *strut chordae*, insert along each half of the ventricular surface of the anterior mitral leaflet and provide additional leaflet support.[17] They may contain cardiac muscle and tend to calcify with age. Unlike the tricuspid valve, the normal mitral leaflets have no chordal insertions into the ventricular septum.[16]

The functional orifice of the mitral valve is defined by its narrowest diastolic cross-sectional area. This may be at the annulus when there is extensive annular calcification or close to the papillary muscle tips in patients with rheumatic mitral stenosis.

Mitral valve prolapse is characterized by thickened and redundant leaflets, annular dilatation (with or without calcium), and thickened and elongated chordae tendineae (with or without rupture). Prolapse of the posterior leaflet occurs more frequently than that of the anterior leaflet. Rheumatic involvement of the mitral valve causes chordal shortening and thickening without annular dilatation. Rheumatic mitral stenosis is produced by chordal and commissural fusion,

often with calcification, whereas rheumatic mitral insufficiency results from scar retraction of leaflets and chords.[15] *Chronic postinfarction mitral regurgitation is associated with left ventricular dilatation and scarring of a papillary muscle and its subjacent ventricular free wall. Acute postinfarction mitral regurgitation may be associated with partial or complete rupture of a papillary muscle, usually the posteromedial one.*

Anatomically important structures during mitral valve surgery include the left circumflex coronary artery, which courses within the left atrioventricular groove near the anterolateral commissure, and the coronary sinus, which courses within the left atrioventricular groove adjacent to the annulus of the posterior mitral leaflet[17] (see Fig. 2-21A).

Aortic Valve

The aortic valve, like the pulmonary valve, is comprised of three components (i.e., annulus, cusps, and commissures). In contrast to the mitral and tricuspid valves, the two semilunar valves have no tensor apparatus (i.e., chordae tendineae or papillary muscles). The commissures form tall, peaked spaces between the attachments of adjacent cusps (Figs. 2-27 and 2-28) and attain the level of the aortic sinotubular junction, the ridge that separates the sinus and tubular portions of the ascending aorta (originally described by Leonardo da Vinci as the "suprortic ridge")[15] (see Fig. 2-28). The functional aortic valve orifice may be at the sinotubular junction or proximal to it.[17]

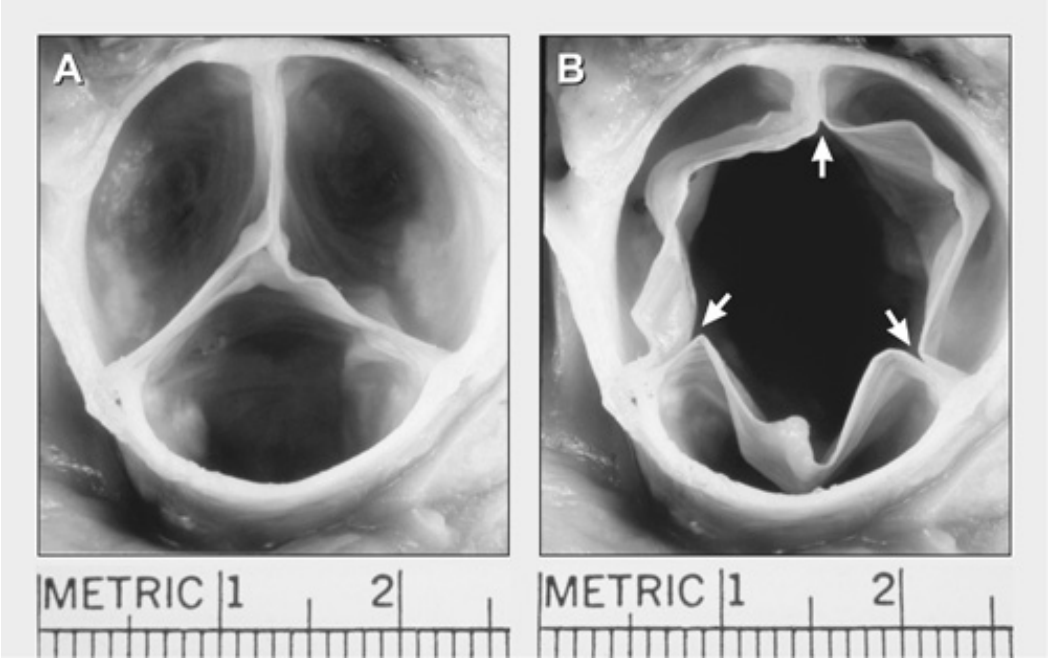

Figure 2-27: Each cusp of a semilunar valve is pocket-shaped. The aortic valve is viewed from above in simulated closed (*A*) and open (*B*) positions, showing the three commissures (arrows). Note that the length of the closing edge exceeds the straight-line distance between the commissures.

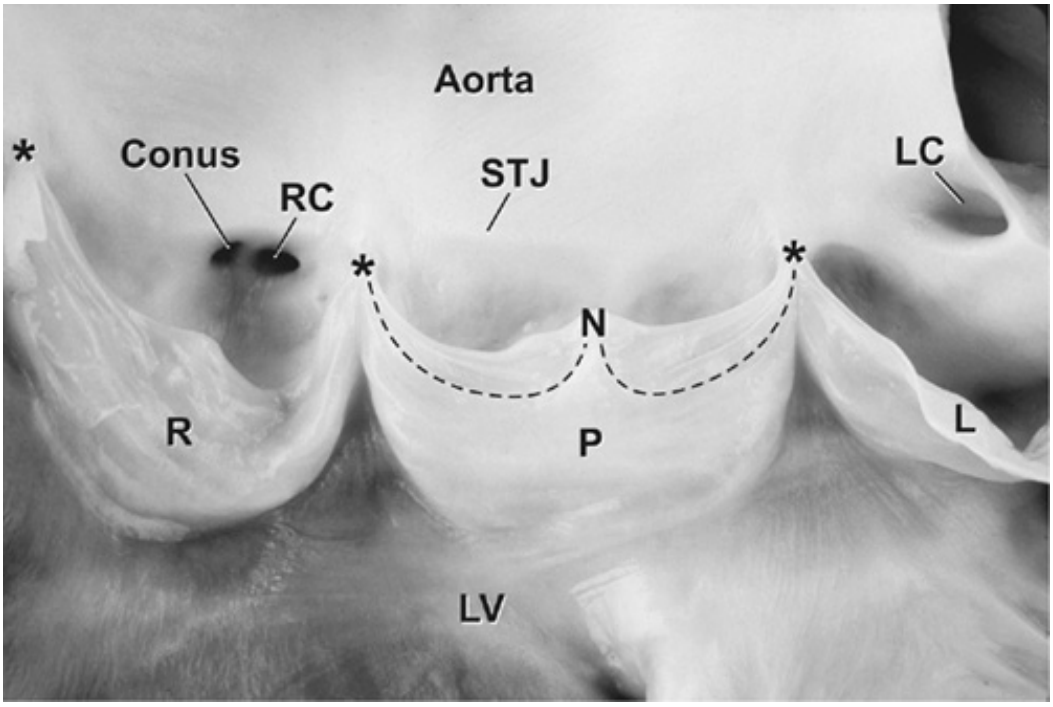

Figure 2-28: An opened aortic valve shows the right (R), left (L), and posterior (P) cusps. The dashed line marks the closing edge. Between the free and closing edges of each cusp are two lunular areas, representing the surfaces of apposition between adjacent cusps during valve closure. The commissures (*) attain the level of the aortic sinotubular junction (STJ). Conus, conus coronary ostium; LC, left coronary ostium; LV, left ventricle; N, nodule of Arantius; RC, right coronary ostium.

The three half-moon-shaped (semilunar) aortic cusps form pocket-like tissue flaps that are avascular. In only about 10 percent of hearts are they truly equal in size. In two-thirds of hearts, either the right or posterior cusp is larger than the other two.[17] Just below the free edge of each cusp is a ridgelike closing edge (see Fig. 2-28). At the center of each cusp the closing edge meets the free edge and forms a small fibrous mound, the *nodule of Arantius*[15] (see Fig. 2-28). Between the free and closing edges, to each side of the nodule, are two crescent-shaped areas known as the *lunulas* that represent the sites of cusp apposition during valve closure.[15] Lunular fenestrations, near the commissures, are common and increase in size and incidence with age[15] (Fig. 2-29). However, owing to their position distal to the closing edge, they rarely produce valvular incompetence.[17] When viewed from above, the linear distance along the closing edge of a cusp is much greater than the straight-line distance between its two commissures[15] (see Fig. 2-27). This extra length of cusp tissue is necessary for nonstenotic opening and nonregurgitant closure of the valve.[15] Normally, the diameter of the aortic annulus at the hinge points of the aortic valve is about equal to the diameter of the ascending aorta at the sinotubular junction.[8]

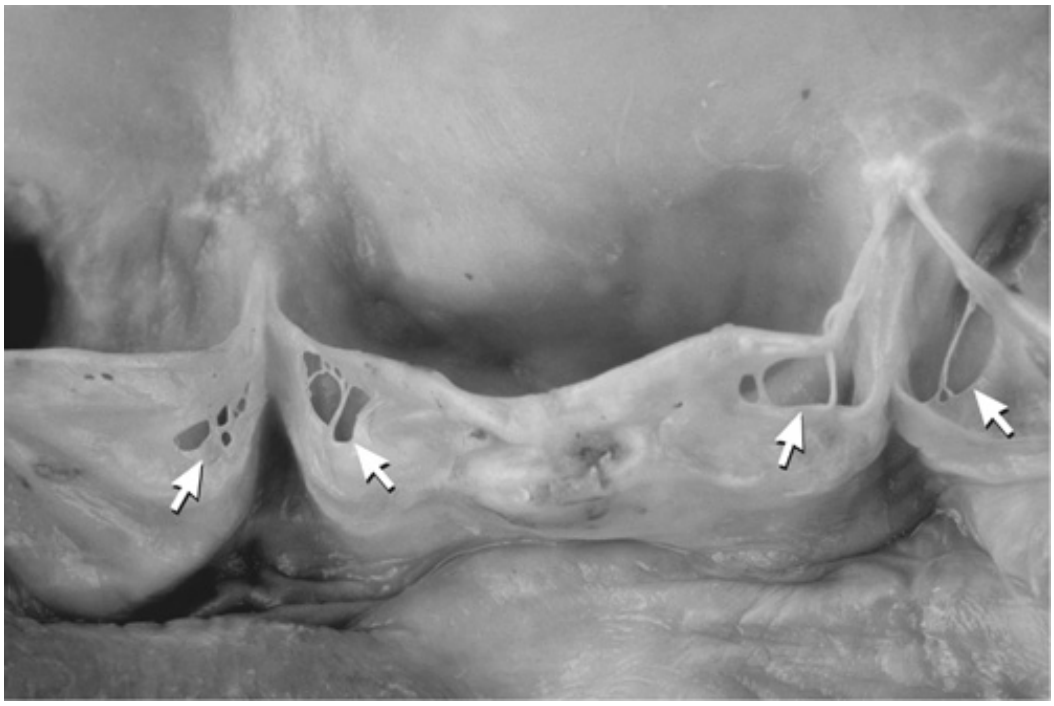

Figure 2-29: Aortic cusp fenestrations (arrows) occurring in the lunular regions near the commissures. This is a common age-related degenerative finding and normally accounts for little or no aortic valve regurgitation.

These are important anatomic details in patients undergoing aortic valve repair. In hearts from adults with bicuspid valves and other congenital aortic valve disease, the annular diameter is usually enlarged. In contrast, patients with normal aortic cusps and central aortic regurgitation show enlargement at the level of the sinotubular junction.[7]

A prebypass intraoperative transesophageal long-axis view of the left ventricular outflow tract is used to measure the aortic valve annular diameter prior to replacement by a homograft. By doing so, precious bypass time is saved while the homograft is being prepared.[8] *Disease processes that produce commissural fusion such as rheumatic valvulitis or which decrease cusp mobility such as fibrosis or calcification may lead to aortic stenosis.*[15] *In contrast, those disorders which decrease cusp size such as rheumatic valvulitis or which cause aortic root dilatation may lead to aortic regurgitation.*[15] *Combinations of these processes may produce combined stenosis and regurgitation.*

The commissure between the right and posterior aortic cusps overlies the membranous septum (Fig. 2-30) and contacts the commissure between the anterior and septal leaflets of the tricuspid valve (see Fig. 2-40). The commissure between the right and left aortic cusps contacts its corresponding pulmonary commissure and overlies the infundibular septum (see Fig. 2-12D). The intervalvular fibrosa, at the commissure between the left and posterior aortic cusps, fuses the aortic valve to the anterior mitral leaflet.[15,17]

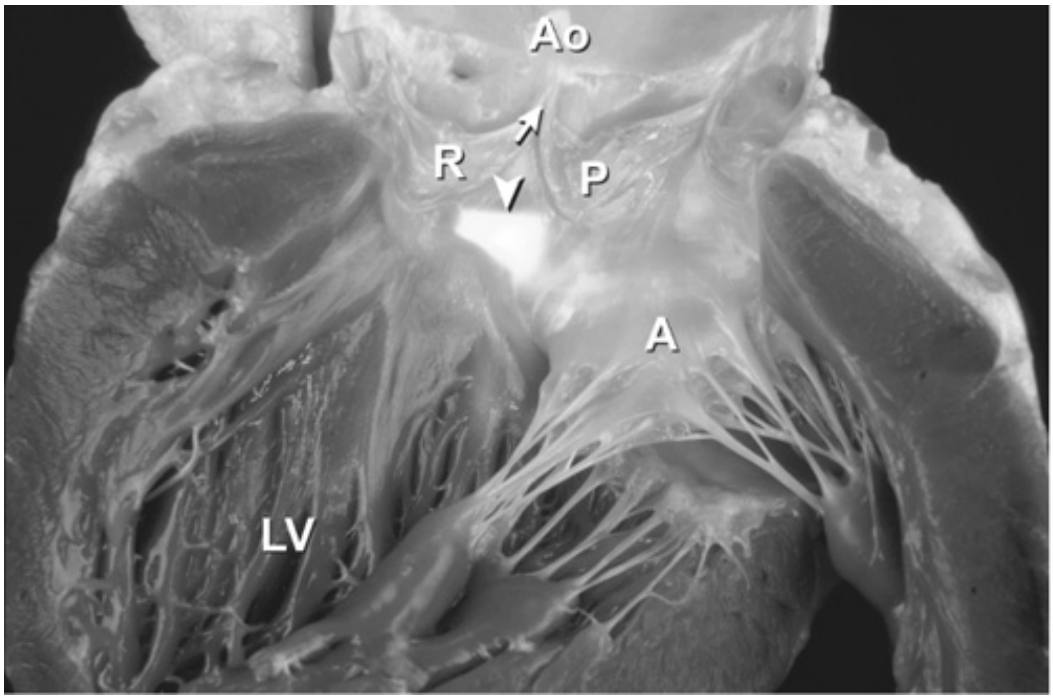

Figure 2-30: The commissure between the right and posterior aortic cusps (arrow) overlies the transilluminated membranous septum (arrowhead). A, anterior mitral leaflet; Ao, ascending aorta; LV, left ventricle; P, posterior aortic cusp; R, right aortic cusp.

During aortic valve replacement, the anterior mitral leaflet, left bundle branch, or coronary ostia may be injured inadvertently.[17] *Annular abscesses due to infective endocarditis involving the aortic valve may burrow into adjacent structures and thereby produce endocarditis of the other valves, conduction disturbances with septal involvement, aortoatrial, aortopulmonary artery, or aortoventricular fistulas, pericarditis, or fatal hemopericardium.*[15]

Pulmonary Valve

The pulmonary valve is virtually identical in design to the aortic valve.[17] The pulmonary artery sinuses are partially embedded within the muscle bundles of the right ventricular infundibulum, particularly adjacent to the right and left sinuses.[16,19] *In pulmonary valve atresia with an intact ventricular septum, hypertrophy of the muscle bundles and the narrow right ventricular outflow tract accentuate this relationship.*[19] Also, unlike the aortic valve, which is continuous with the mitral valve, the pulmonary and tricuspid valves are separated by infundibular muscle.[17]

Age-Related Valve Changes

Several age-related changes in the cardiac valves may have clinical significance.[20] In normal hearts, the thickness of the aortic and mitral leaflets increases progressively with each decade, particularly along their closure margins.[20] Probably the most common clinical manifestation of these changes is aortic valve sclerosis, characterized by valve thickening without hemodynamic dysfunction.[20] However, age-related degenerative calcification of an otherwise normal-appearing tricuspid aortic valve may result in progressive aortic stenosis.[20]

Age-related thickening along the nodule of Arantius and closing edges may be associated with the formation of whisker-like projections called *Lambl's excrescences*. These fine fibrous-like strands also can develop on the mitral valve.[17] *They are readily detected by echocardiography and have been associated with cardioembolic stroke.*[21] *Larger clusters, having the appearance of a sea anemone, are considered to be either neoplastic or reactive and are known as* papillary

fibroelastomas.[22]

The circumferences of all four cardiac valves increase with age in normal hearts. This is particularly evident in the semilunar valves.[20] Age-related annular dilatation of the aortic valve can result in aortic regurgitation.[20] Mitral annular calcification is rare before age 70 but is present in 40 percent of women over age 90.[20] Mitral annular calcification almost invariably only involves the posterior leaflet and forms a C-shaped ring of annular and subannular calcium.[17] *Mitral annular calcification may impede subannular ventricular contraction, thereby resulting in mitral regurgitation. Because of the proximity of the posteromedial commissure to the atrioventricular (His) bundle, mitral annular calcification may be associated with atrioventricular block.*[20] *With the increasing size of the aging population, degenerative calcific aortic disease is increasing in frequency*.[20]

Cardiac Grooves, Crux, and Margins

The atrioventricular groove encircles the heart and defines its base. It separates the atria from the ventricles (Fig. 2-31). The two ventricles are separated by the anterior and posterior (inferior) interventricular grooves, which define the plane of the ventricular septum (see Figs. 2-5*A* and 2-31).

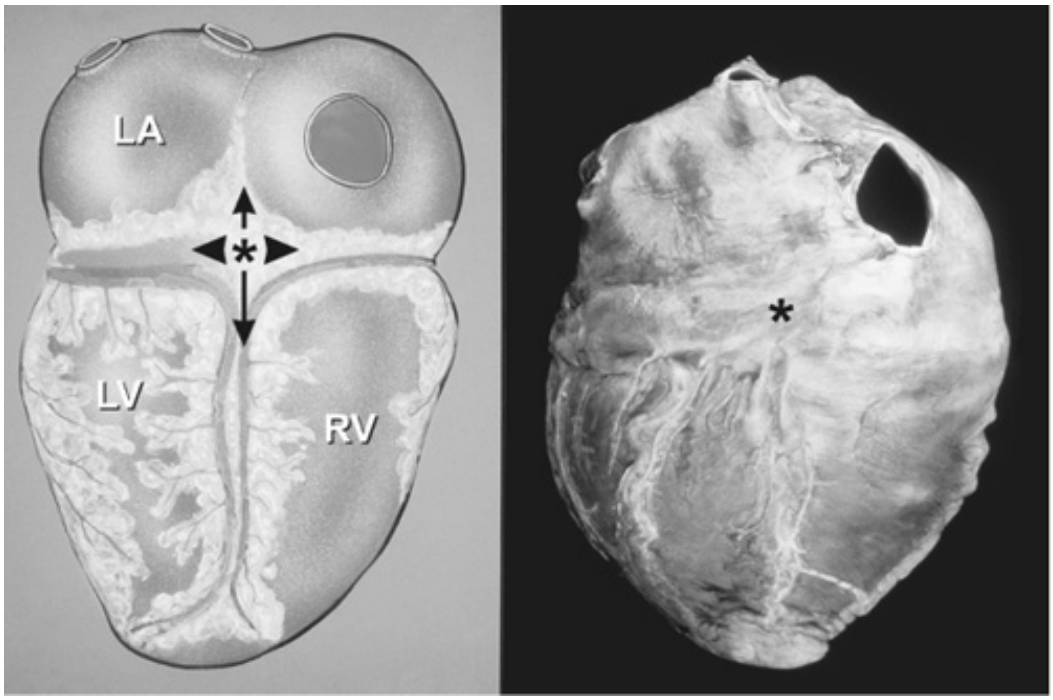

Figure 2-31: View of the diaphragmatic aspect of the heart shows the intersection of the atrioventricular (arrowheads), posterior interventricular (long arrow), and interatrial (small arrow) grooves at the external cardiac crux (*). (*Left*) Diagram. (*Right*) Cardiac specimen. LA, left atrium; LV, left ventricle; RV, right ventricle.

With age, fat tends to accumulate in increasing amounts in the epicardium, particularly in the atrioventricular grooves.[20,23] *Increased epicardial fat deposits may be associated with increased risk of cardiac rupture after acute transmural myocardial infarction*.[23] Excess fat in the atrial septum is called *lipomatous hypertrophy* and may result in a thickness that exceeds that of the ventricular septum. Fat in the right ventricular free wall is difficult to detect accurately clinically; its excess accumulation may be associated with increasing age, obesity, or arrhythmogenic right

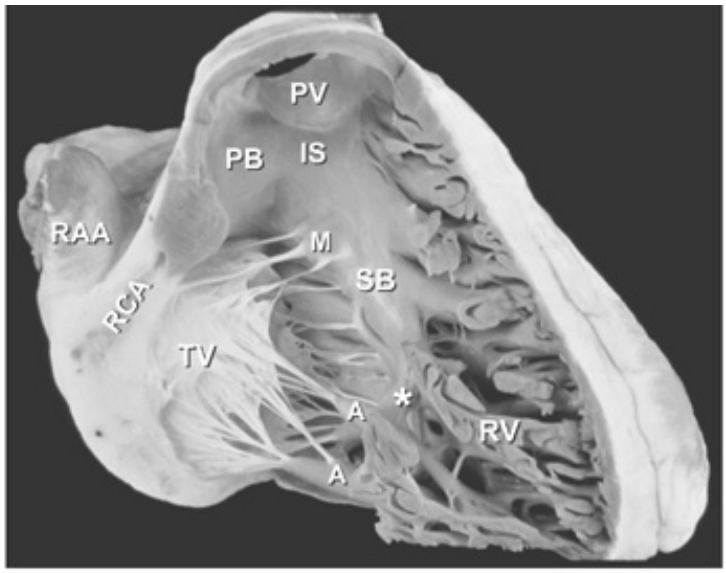
ventricular cardiomyopathy.[24]

Along the surface of the heart, the right and circumflex coronary arteries travel in the right and left atrioventricular grooves, respectively, and the left anterior and posterior descending coronary arteries course along the anterior and posterior (or inferior) interventricular grooves, respectively (see Figs. 2-5*A* and 2-31). The external cardiac crux is the cross-shaped intersection between the atrioventricular, posterior interventricular, and interatrial grooves (see Fig. 2-31). Its internal counterpart (the internal crux) is the posterior intersection between the mitral and tricuspid annuli and the atrial and ventricular septa (see Figs. 2-16*B* and 2-34, Plate 11).

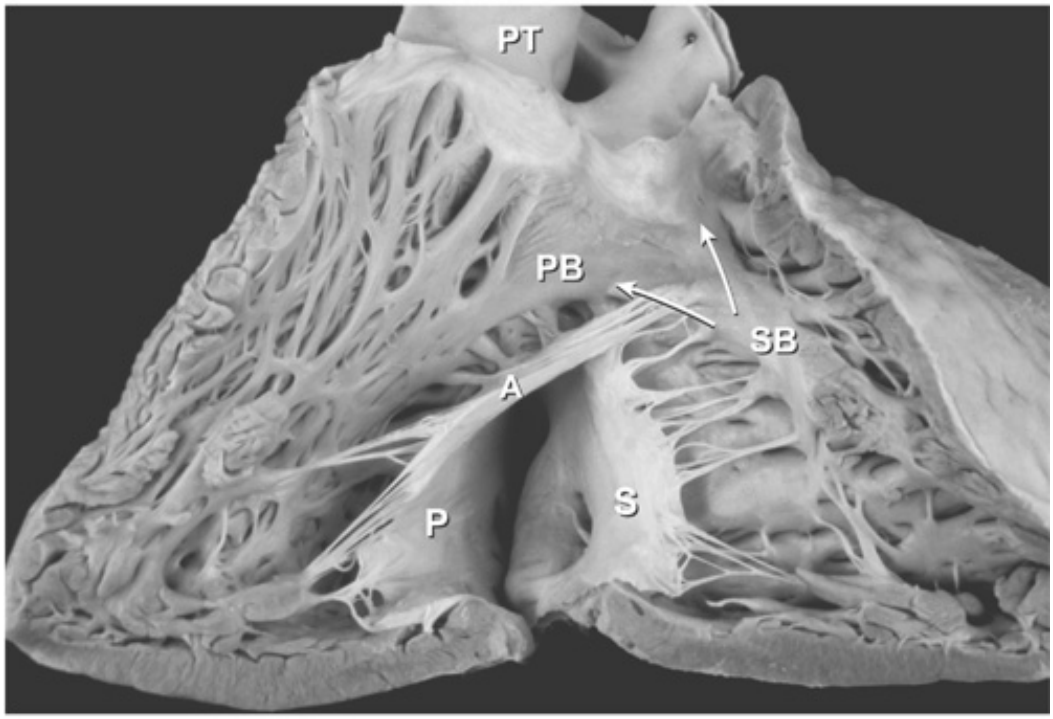
The junction between the anterior and inferior free walls of the right ventricle forms a sharp angle known as the *acute margin*. The rounded lateral wall of the left ventricle forms the *obtuse margin*.[15]

Right Ventricle

The right ventricle is a right-anterior structure. It is comprised of an inlet and trabecular and outflow segments[15] (Fig. 2-32). The inlet component extends from the tricuspid annulus to the insertions of the papillary muscles. An apical trabecular zone extends inferiorly beyond the attachments of the papillary muscles toward the ventricular apex and about halfway along the anterior wall.[15] *This muscular meshwork is the site of insertion of transvenous ventricular pacemaker electrodes. During right ventricular endomyocardial biopsy, tissue generally is obtained from the trabeculated apex. Disruption of a portion of the tricuspid support apparatus is a potential complication of right-sided heart instrumentation (e.g., right ventricular endomyocardial biopsy).*[17] The outflow portion, also known as the conus (meaning "cone") or *infundibulum* (meaning "funnel"), is a smooth-walled muscular subpulmonary channel[15,17] (see Fig. 2-32).



A



B

Figure 2-32: Right ventricle. *A*. The right ventricular free wall has been removed to show the archlike crista supraventricularis, which consists of the parietal band (PB), infundibular septum (IS), and septal band (SB). The moderator band (*) joins the septal band to the anterior tricuspid papillary muscle (*A*). The anteroapical portion of the chamber is heavily trabeculated. M, medial tricuspid papillary muscle; PV, pulmonary valve; RAA, right atrial appendage; RCA, right coronary artery; TV, tricuspid valve. *B*. The right ventricle has been opened by the inflow-outflow method to show the parietal band (PB) separating the tricuspid and pulmonary valves, as well as the two upper limbs (arrows) of e septal band (SB). *A*, anterior leaflet of the tricuspid valve; P, posterior leaflet of the tricuspid valve; PT, pulmonary trunk; S, septal leaflet of the tricuspid valve; other abbreviations as in *A*.

A prominent arch-shaped muscular ridge known as the *crista supraventricularis* separates the tricuspid and pulmonary valves. It is made up of three components (i.e., parietal band, infundibular septum, and septal band) that may appear as distinct structures or may merge

together[15,17] (see Fig. 2-32). The parietal band is a free-wall structure, whereas the adjacent infundibular septum is intracardiac and separates the two ventricular outflow tracts beneath the right and left cusps of both semilunar valves[15,17] (Figs. 2-12D and 2-33). The septal band forms a Y-shaped muscle, the two upper limbs of which cradle the infundibular septum. From this branching point of the septal band emanates the medial tricuspid papillary muscle[15,17] (see Fig. 2-32). The moderator band forms an intracavitary muscle that connects the septal band with the anterior tricuspid papillary muscle (see Fig. 2-32*A*).

Left Ventricle

The left ventricle, like the right ventricle, is made of an inlet portion comprised of the mitral valve apparatus, a subaortic outflow portion, and a finely trabeculated apical zone.[17] The left ventricular free wall is normally thickest toward the base and thinnest toward the apex, where it averages only 1 to 2 mm in thickness, even in hypertrophied hearts.[17] Structurally, the left and right ventricles differ considerably.[15,17] Normally, the left ventricular free-wall and septal thicknesses are three times the thickness of the right ventricular free wall. The mitral and aortic valves share fibrous continuity, whereas the parietal band separates the tricuspid and pulmonary valves. Whereas the mitral valve has an elliptical orifice and no septal attachments, the tricuspid valve has a triangular orifice and numerous direct septal attachments (see Fig. 2-23). The right ventricular apex is much more trabeculated than its counterpart on the left (see Figs. 2-9*B* and 2-18*C*). *The distinctive differences in apical trabeculations persist even in markedly hypertrophied or dilated hearts*.[17]

The annular attachment of the septal leaflet of the tricuspid valve inserts more apically than that of the anterior mitral leaflet, allowing distinction between the right and left ventricles by four-chamber imaging (Fig. 2-34). *Exceptions include partial atrioventricular septal defects and double-inlet ventricles in which the two valve annuli are at the same level. Ebstein's anomaly is characterized by exaggeration of apical displacement of the septal and posterior tricuspid leaflets resulting in an atrialized portion of the right ventricular chamber*.[16,17] *Morphologic differentiation of the right and left ventricles is particularly important in congenital heart disease*. The morphologic tricuspid valve virtually always connects to a morphologic right ventricle, whereas the morphologic mitral valve connects to a morphologic left ventricle.[15,16] Because of the rightward bulging of the ventricular septum, the left ventricular chamber appears circular in cross section, whereas the right ventricular chamber has a crescentic appearance (see Fig. 2-23). Tomographic segmental left ventricular anatomy will be reviewed in the section on coronary arteries.

Left ventricular false tendons, also referred to as *pseudotendons* or *bands*,[25] are discrete, thin, cordlike fibromuscular structures that connect two walls, the two papillary muscles, or a papillary muscle to a wall, usually the ventricular septum (Fig. 2-35). However, false tendons, as the name implies, are not attached to the mitral leaflets. *Chordal attachments between the mitral leaflets and the ventricular septum are abnormal and are usually associated with atrioventricular septal defects or straddling atrioventricular valves*.[16] False tendons are common anatomic variants of the normal left ventricle, occurring in 50 percent of hearts, and may become calcified with age (Fig. 2-36, Plate 12). They are more frequently observed in men, but their incidence does not appear to be age-related.[25] *It has been suggested that they may be the cause of innocent systolic musical murmurs*.[25] *Although they are readily detectable by echocardiography, they may be misinterpreted by the inexperienced sonographer as pathologic structures such as ruptured chords, mural thrombi, or vegetations*.[17,25]

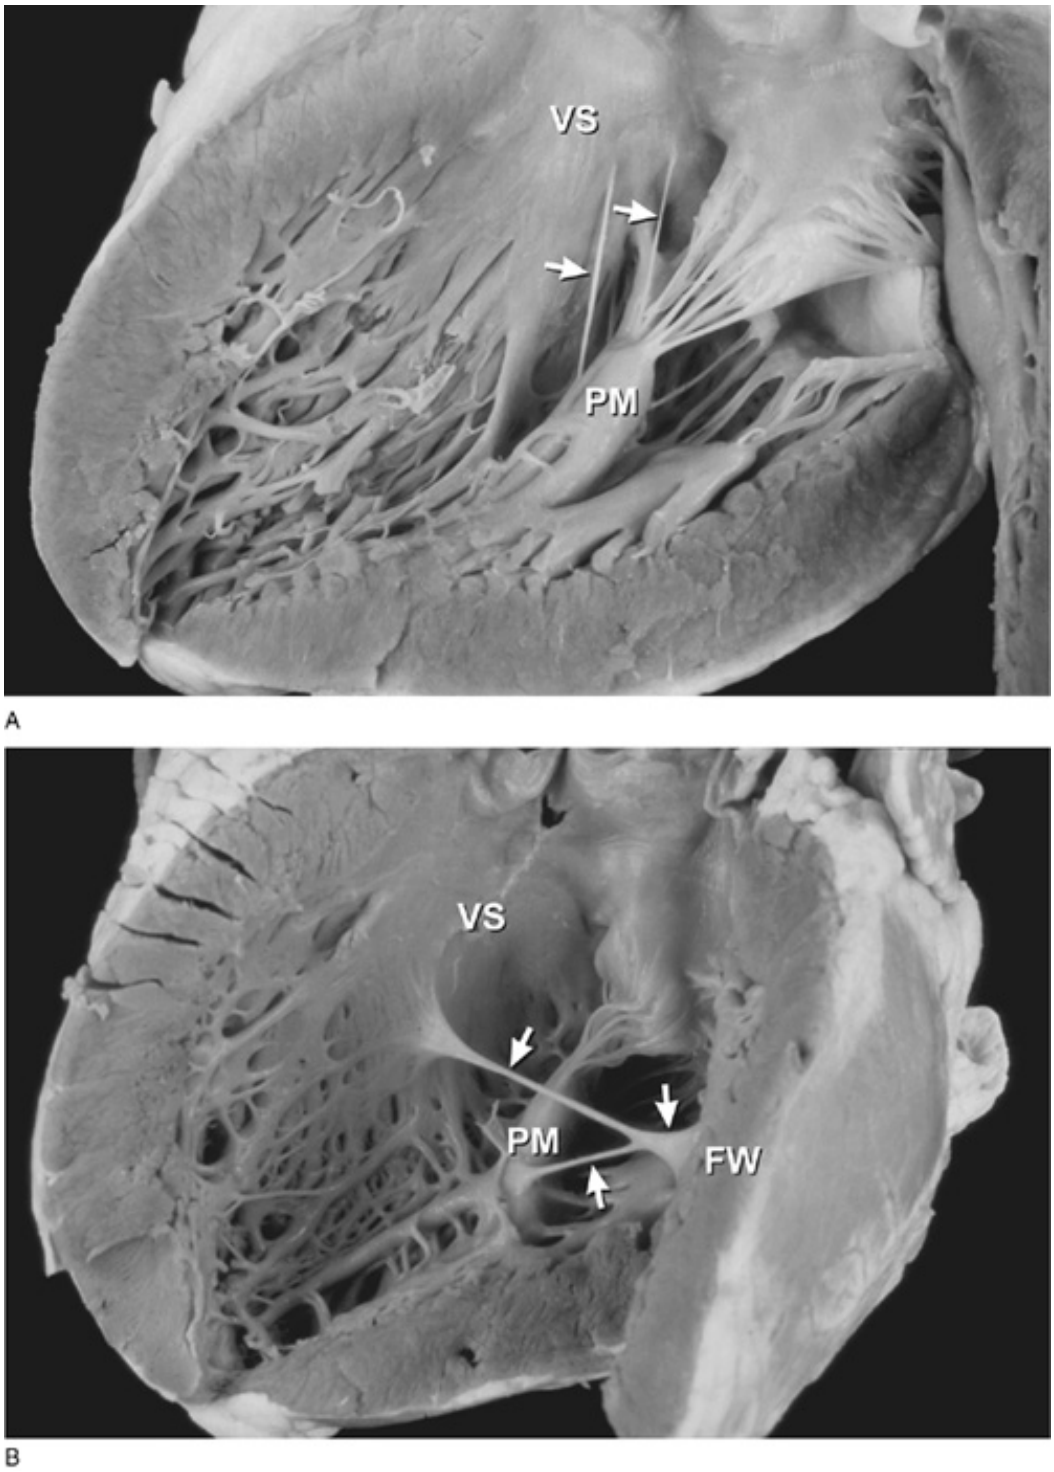


Figure 2-35: Various locations of left ventricular false tendons. *A.* Two false tendons (arrows) from posteromedial mitral papillary muscle (PM) to ventricular septum (VS), representing the most common location. *B.* Complex branching false tendon (arrows) with origin from the left ventricular free wall (FW) and insertions into the ventricular septum (VS) and base of posteromedial mitral papillary muscle (PM).

Prominent left ventricular trabeculations[26] are another common anatomic normal variant that may be an even greater source of misinterpretation by two-dimensional echocardiography in patients with suspected mural thrombus. They are defined as discrete, thick muscle bundles that generally connect the free wall to the septum (Fig. 2-37). Less common attachments include papillary muscle to the septum, septum to septum, or free wall to free wall. *In noncompaction of the left ventricular myocardium,*[27,28] *also known as* **spongy myocardium**, *there is persistence of multiple*

prominent ventricular trabeculations and deep intertrabecular recesses caused by arrest in the normal in utero process of myocardial compaction. The associated clinical manifestations and age at onset of symptoms (i.e., typically a dilated cardiomyopathy) are highly variable.

Figure 2-37: Prominent left ventricular trabeculations. Multiple large muscle bundles extend from the anterior free wall to the septum (probes). A single muscle bundle extends from the posteromedial mitral papillary muscle to the posterior septum (probe with white arrow), and one bundle extends from one portion of the posterior septum to another (probe with black arrow). Such trabeculations become even more prominent in noncompaction of the left ventricular myocardium.

Ventricular Septum

The ventricular septum is a complex intracardiac partition that can be considered to comprise four parts: inlet, trabecular, membranous, and infundibular. The plane of the infundibular portion (see Figs. 2-12*D* and 2-33) is different from that of the three other portions. *This anatomic relationship is important in many forms of congenital heart disease in which the infundibular septum is dissociated from the remainder of the ventricular septum (e.g., malalignment forms of ventricular septal defects in tetralogy of Fallot and in double-outlet right ventricle).*[15-17]

The ventricular septum also may be divided into muscular and membranous portions[15-17] (Figs. 2-38, Plate 13, and 2-39). The membranous septum lies beneath the right and posterior (noncoronary) aortic cusps (see Fig. 2-30) and contacts the mitral and tricuspid annuli (Fig. 2-40, Plate 14). The membranous septum in conjunction with the right fibrous trigone with which it is continuous fuses the commissure between the right and posterior aortic cusps to the commissure between the anterior and septal tricuspid leaflets (see Fig. 2-21*B*). *The majority of clinically significant ventricular septal defects involve the membranous septum.*[17] Owing to normal angulation between the infundibular septum and remaining ventricular septum, the septal surface follows the course of an inverted S (moving from apex to aortic valve). The basal half of the ventricular septum is smooth-walled, while the apical half is characterized by numerous small and irregularly arranged **trabeculations**.[15-17]

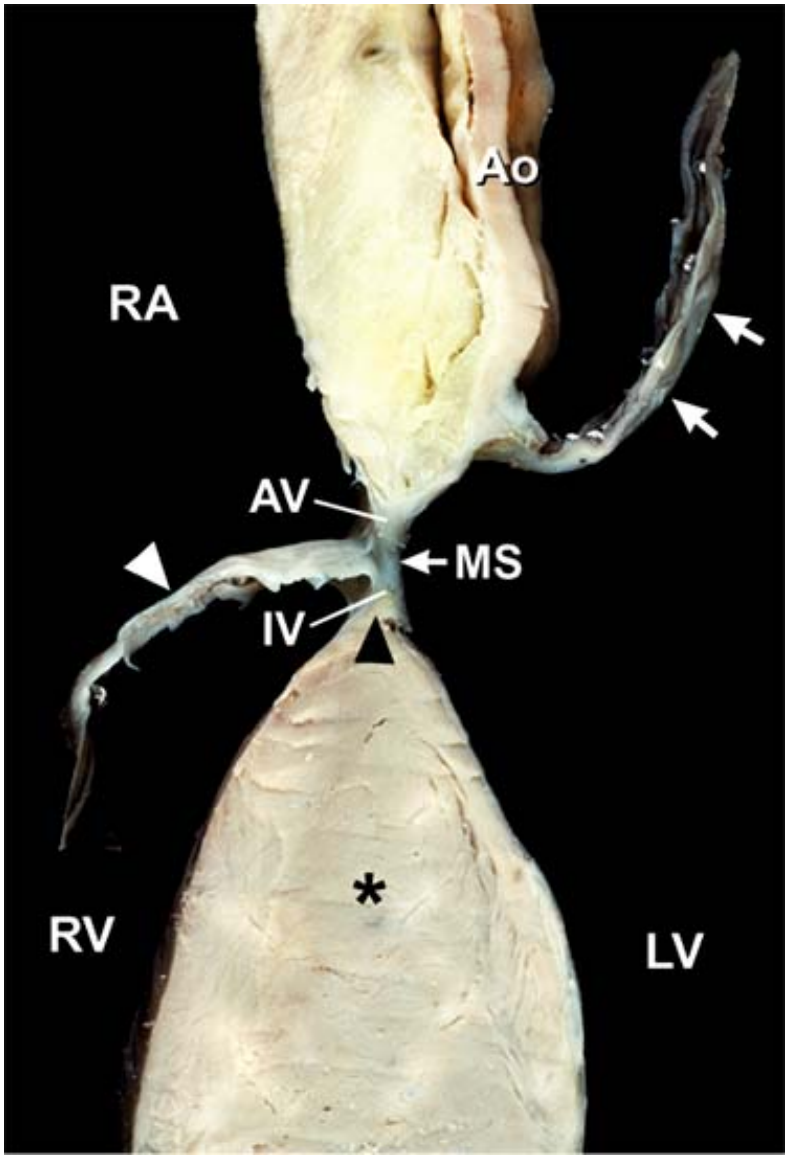

Figure 2-38: (Plate 13) Four-chamber tomographic slice through the aortic root (Ao) and aortic valve (arrows) showing the small membranous (MS) and large muscular (*) portion of the ventricular septum. The membranous septum is divided into atrioventricular (AV) and interventricular (IV) components by the septal tricuspid leaflet (white arrowhead). Black arrowhead points to the expected location of the AV (His) bundle. LV, left ventricle; RA, right atrium; RV, right ventricle.

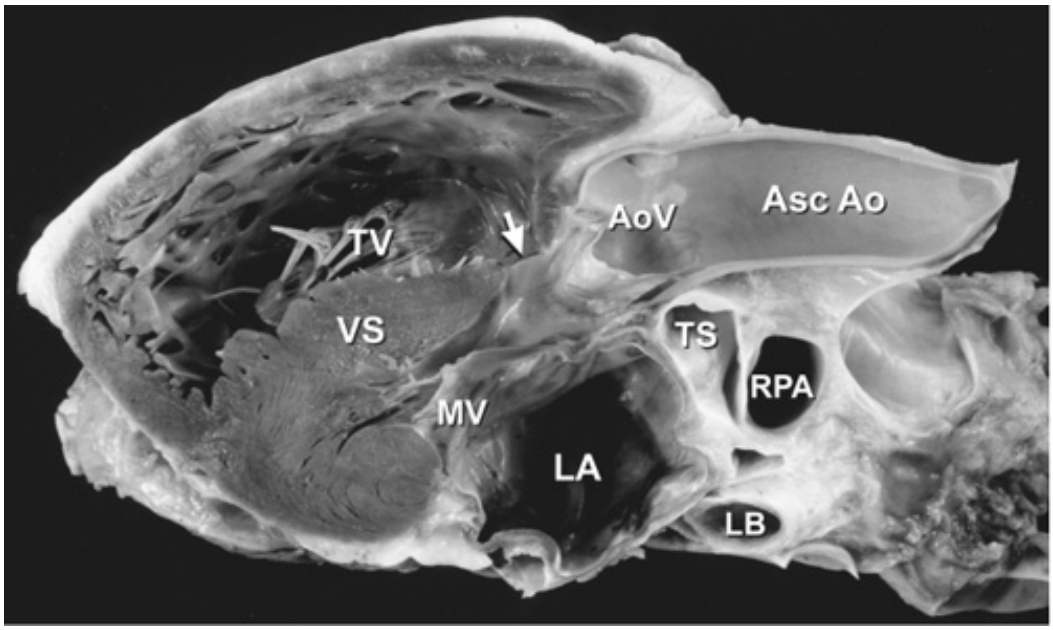

Figure 2-39: Tomographic section of the heart along a long-axis plane of the body. The aortic root lies in this plane. The left ventricle and aortic valve are cut obliquely. The membranous ventricular septum (arrow) lies beneath the right and posterior aortic cusps. AoV, aortic valve; Asc Ao, ascending aorta; LA, left atrium; LB, left bronchus; MV, mitral valve; RPA, right pulmonary artery; TS, transverse sinus; TV, tricuspid valve; VS, muscular ventricular septum.

Clinically relevant age-related anatomic changes include a disproportionate increase in ventricular septal thickness regardless of gender and in the absence of a history of hypertension.[20] This is associated with an appreciable increase in the ratio of ventricular septal to left ventricular free-**wall thickness** often exceeding 1.3 in patients older than **age** 60[20] (Fig. 2-41, Plate 15). This may be due in part to accentuation of the sigmoid shape of the basal septum[15,20] (Fig. 2-42). *Age-related ventricular septal angulation may have clinical importance because it may mimic certain features of hypertrophic cardiomyopathy,*[15,20] *particularly if complicated by the indiscriminate use of diuretics or afterload-reducing agents.*

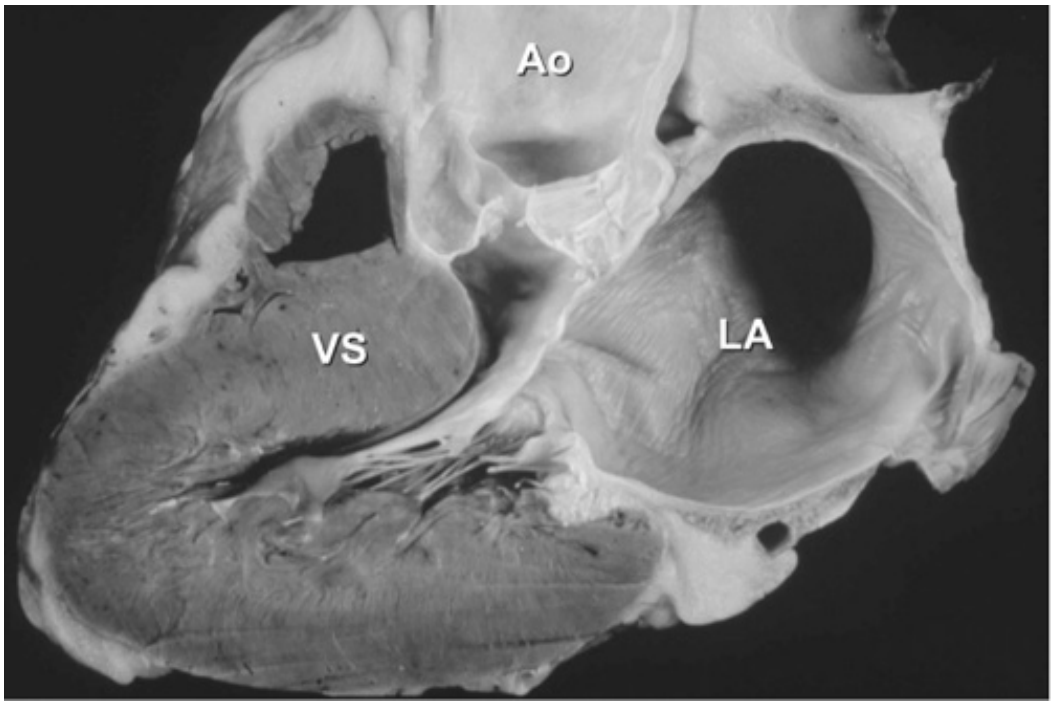

Figure 2-42: Age-related changes in the left-sided cardiac structures. Normal heart from an 84-year-old man demonstrates shortening of the base-to-apex (long-axis) dimension, decreased internal left ventricular dimension, aortic root dilatation, left atrial enlargement, and sigmoid-shaped septum. (Compare with Fig. 2-15 from an 18-year-old man.) Ao, ascending aorta; LA, left atrium; VS, ventricular septum.

Atrial Septum

When viewed from its right aspect, the atrial septum is comprised of interatrial and atrioventricular regions[16,17] (see Fig. 2-34). The interatrial portion is characterized by the fossa ovalis, which is the anatomic hallmark of a morphologic right atrium (Fig. 2-43*A*). Its outer muscular rim is a horseshoe-shaped limbus, and its central depression is the valve of the fossa ovalis[16,17] (see Fig. 2-43*A*). The potential interatrial passageway between the limbus and the valve (which is patent throughout fetal life) is the foramen ovale (Figs. 2-43*B* and 2-44). When viewed from the left atrium, the atrial septum is entirely interatrial, since the atrioventricular component lies below the mitral annulus, between the left ventricle and right atrium. Likewise, the limbus of the fossa ovalis is completely covered by its opaque valve and is not directly visible from the left atrium.[15]

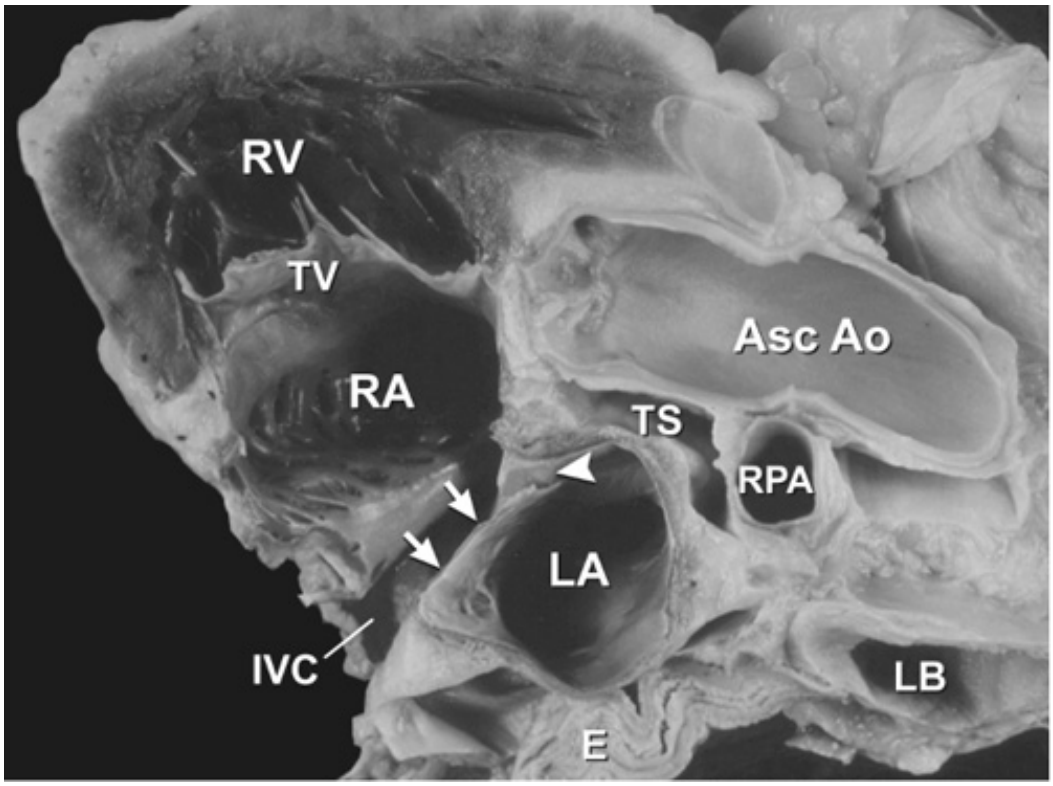

Figure 2-44: Tomographic section of the heart along a long-axis of the body. The valve of the fossa ovalis (arrows) and a patent foramen ovale (arrowhead) are seen in this view. Asc Ao, ascending aorta; E, esophagus; IVC, inferior vena cava; LA, left atrium; LB, left bronchus; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; TS, transverse sinus; TV, tricuspid valve.

The foramen ovale is anatomically closed in about two-thirds of adults, but in the remaining one-third it remains patent and, therefore, a potential source for shunts and paradoxical embolism. Stretching of the atrial septum, when the atria are markedly dilated, can transform a patent foramen ovale into an acquired atrial septal defect. The posterior aortic sinus abuts against the interatrial septum (see Fig. 2-12*D*). *During transseptal procedures, care must be taken to stay within the confines of the valve of the fossa ovalis in order to avoid perforation of an aortic sinus.*[16] *Echocardiography may help guide transseptal puncture during balloon mitral valvuloplasty or closure of an atrial septal defect with an occluder device.*[13] *Fenestrations of the valve of the fossa ovalis are the most common cause of congenital atrial septal defects. Redundant valve tissue may form an aneurysm of the valve of the fossa ovalis.*

The atrioventricular (AV) portion of the atrial septum is made of major muscular and minor membranous components and separates the right atrium from the left ventricle[16,17] (see Figs. 2-34 and 2-38). *This explains why there is a potential for left-ventricular-to-right-atrial shunts.*[16,17] *The AV septum corresponds roughly to the triangle of Koch, an important anatomic surgical landmark because it contains the AV node and proximal portion of the AV (His) bundle. Thus, during tricuspid annuloplasty procedures and patch closures of membranous ventricular septal defects, care must be taken to avoid injury to the conduction system.*[16,17] The muscular component of the AV septum is interposed between the membranous septum anteriorly and the internal cardiac crux posteriorly.

When defects occur in the muscular atrioventricular septum, the mitral annulus usually drops to the same level as the tricuspid annulus, so the defect becomes primarily interatrial (primum atrial septal defect), and the AV conduction tissues are displaced inferiorly. Lipomatous hypertrophy of the atrial septum is characterized by excessive accumulation of adipose tissue within the limbus of

the fossa ovalis but always sparing the valve of the fossa[7,15-17] (Fig. 2-45, Plate 16). Lipomatous hypertrophy of the atrial septum occurs commonly but not exclusively in older and obese persons.[15-17] *Although readily detected by echocardiography, it may be misinterpreted as a thrombus or tumor*.[7]

Right Atrium

A prominent internal muscle ridge, the crista terminalis (Fig. 2-46), separates the right atrial free wall into a smooth-walled posterior region that receives the venae cavae and coronary sinus and a muscular anterior region that is lined by parallel pectinate muscles and from which the right atrial appendage emanates.[15-17] *Pectinatus* is Latin for "comb," and the pectinate muscles and crista terminalis resemble the teeth and backbone of a comb, respectively.[17] The right atrial appendage abuts the right aortic sinus and overlies the proximal right coronary artery (see Fig. 2-52). *The right atrial free wall is paper thin between pectinate muscles and therefore can be perforated easily by stiff catheters*.[15-17]

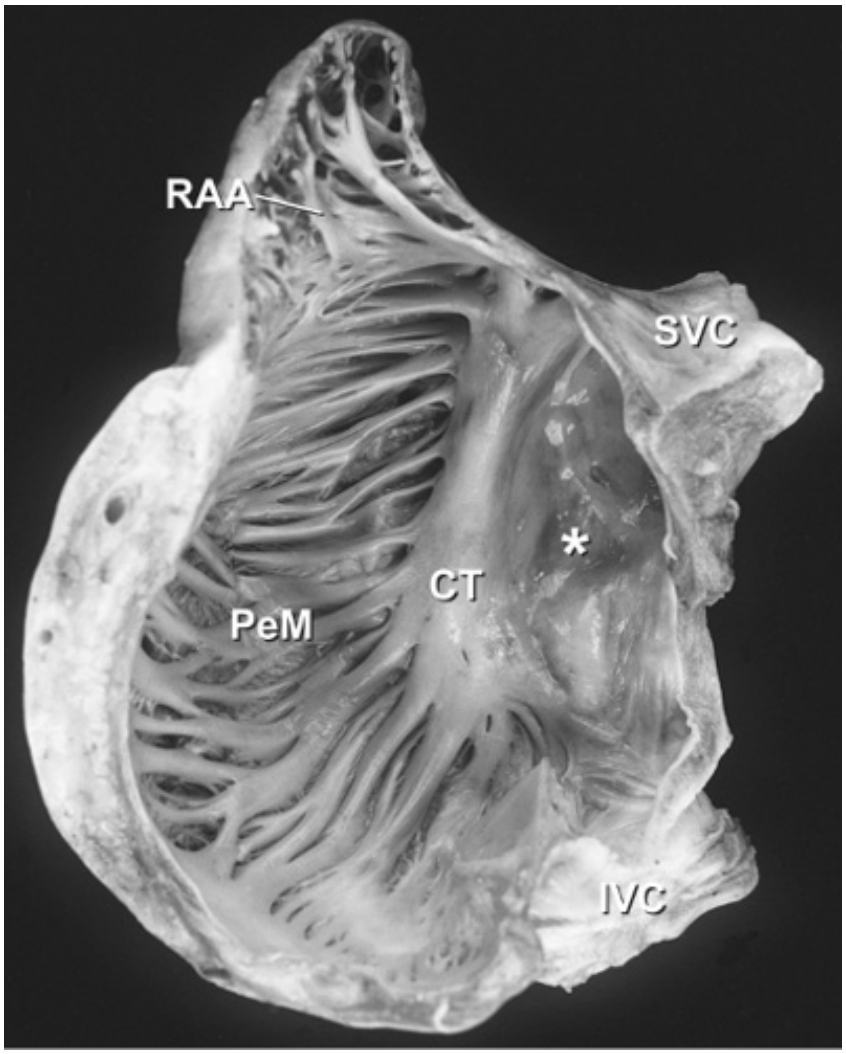

Figure 2-46: Right atrial free wall showing separation of the posterior smooth-walled (*) portion from the anterior muscular portion with its pectinate muscles (PeM) and right atrial appendage (RAA) by the crista terminalis (CT). IVC, inferior vena cava; SVC, superior vena cava.

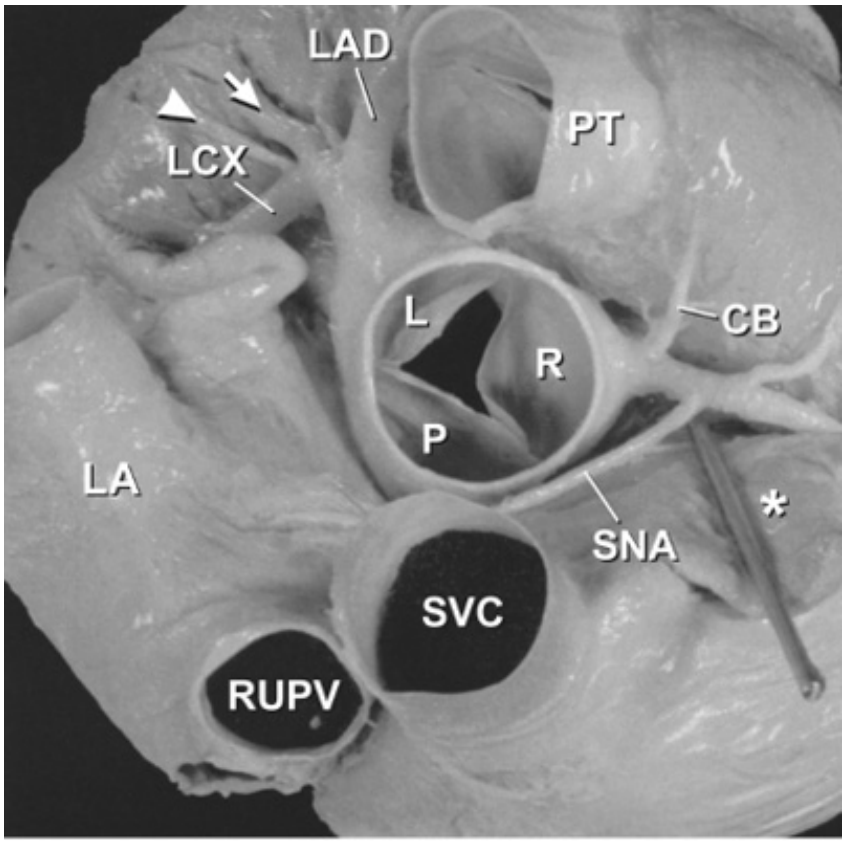

Figure 2-52: The right coronary artery gives rise to the conus branch (CB). A rod retracts the right atrial appendage (*) to disclose the sinus node artery (SNA). Arrow points to an intermediate left coronary artery; arrowhead points to a circumflex marginal branch. L, left aortic cusp; LA, left atrium; LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery; P, posterior aortic cusp; PT, pulmonary trunk; R, right aortic cusp; RUPV, right upper pulmonary vein; SVC, superior vena cava. (From McAlpine,[30] with permission.)

Inferior vena caval blood flow is directed by the eustachian valve toward the foramen ovale, and superior vena caval blood is directed toward the tricuspid valve[15] (Fig. 2-47, Plate 17). *Thus transseptal cardiac catheterization is more easily accomplished via the inferior vena cava, whereas instrumentation of the right ventricular apex (e.g., endomyocardial biopsy, placement of ventricular pacemaker lead) is more easily accomplished via the superior vena cava.*[15]

Left Atrium

The pulmonary vein orifices lie on the posterolateral (left pulmonary veins) and posteromedial (right pulmonary veins) aspects of the left atrial cavity. The left and right upper pulmonary veins are directed anterosuperiorly, whereas the lower veins enter the left atrium nearly perpendicular to the posterior atrial wall[15-17] (Figs. 2-15 and 2-48). *Left atrial muscle extends some distance within the pulmonary veins. The resultant cuff of muscle acts as a sphincter during atrial systole and may be the source of focal atrial fibrillation that is amenable to catheter ablation*[9-13] (see Fig. 2-2).

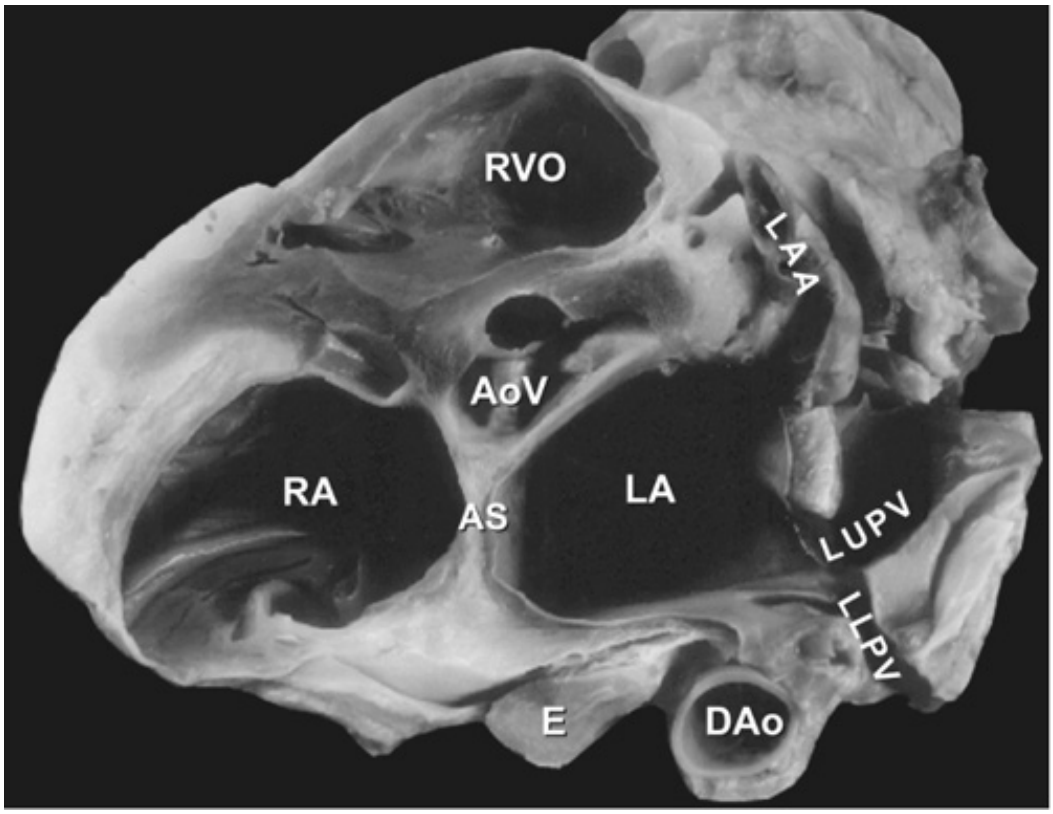

Figure 2-48: Oblique, short-axis cut at the base of the heart. The esophagus (E) is posterior and adjacent to the left atrium (LA) and adjacent to the descending thoracic aorta (DAo). The left upper pulmonary (LUPV) and left lower pulmonary vein (LLPV) are clearly seen. The right ventricular outflow tract (RVO) is anterior. AS, atrial septum; AoV, aortic valve; LA, left atrium; LAA, left atrial appendage; RA, right atrium.

The atrial appendage arises anterolaterally and lies in the left atrioventricular groove atop the proximal portion of the left circumflex coronary artery and, in some individuals, the left main coronary artery[16] (see Figs. 2-21*A* and 2-48). The left atrial appendage is smaller, more tortuous, and less pyramidal than its right atrial counterpart.[15-17] At least 80 percent are multilobed (up to four lobes, but the most frequent finding is two lobes)[29] (Fig. 2-49, Plate 18). There are also age- and sex-related differences in the dimensions of the appendage.[20] *With increasing use of transesophageal echocardiography to search for a cardiac source of embolism and to guide cardioversion and percutanous balloon valvuloplasty procedures, a thorough appreciation of the variations in normal left atrial appendage morphology has become important because a thrombus may be missed if all lobes in the appendage are not visualized.* In contrast to the right atrial free wall, the left has no crista terminalis and no pectinate muscles outside its appendage.[15-17]

The coronary sinus travels along the posterior wall of the left atrium within the left atrioventricular groove (see Fig. 2-21*A*). *In patients with persistent left superior vena cava, which most commonly drains into a dilated coronary sinus, the left-sided cava courses between the left atrial appendage and the left upper pulmonary vein.*[17] *The venous structure can be misinterpreted as the descending thoracic aorta, a mass, or a pathologic cavity.*

The esophagus and descending thoracic aorta are in contact with the posterior left atrial wall (see Figs. 2-20 and 2-48). *Accordingly, esophageal carcinomas may compress, infiltrate, or perforate the left atrium, and descending thoracic aortic aneurysms may compress this chamber.*[15] *A large hiatal hernia also can abut against the left atrium and resemble a mass.*

The marked increase in the incidence of atrial fibrillation from the fourth to the ninth decades of life may be due in part to the age-associated dilatation of the left atrium.[20]

Coronary Arteries and Veins

A detailed description of the spectrum of coronary artery anatomy including the many variations in the number and size of branches and course of the different arteries is beyond the scope of this chapter. The interested reader is referred to the elegant anatomic work by McAlpine published almost 25 years ago.[30] The focus of the discussion that will follow, therefore, is to introduce the reader to the clinically relevant anatomy of the coronary circulation, with special emphasis on tomographic analysis of regional blood flow.

From the right and left aortic sinuses arise the right and left coronary arteries, respectively, and their ostia normally originate about two-thirds the distance from the aortic annulus to the sinotubular junction and about midway between theaortic commissures[15-17] (Figs. 2-28 and 2-50, Plate 19). Whereas the right coronary artery arises nearly perpendicularly from the aorta, the left arises at an acute angle[15] (Fig. 2-51). Rarely, the anterior descending and circumflex arteries arise separately from a double-barrel left coronary ostium.[15-17] *Ostial stenosis most commonly results from atherosclerosis and degenerative calcification of the aortic sinotubular junction, which often overlies the right aortic sinus.*[17] *Less often it is due to aortic dissection or to aortitis associated with syphilis or ankylosing spondylitis. Stenosis of the right coronary ostium is much more frequent than that of the left. Iatrogenic ostial injury may complicate coronary angiography, intraoperative coronary perfusion, or aortic valve replacement.*[15-17] *Atherosclerosis or thrombosis of the most proximal portion of either coronary artery may mimic true ostial stenosis.*

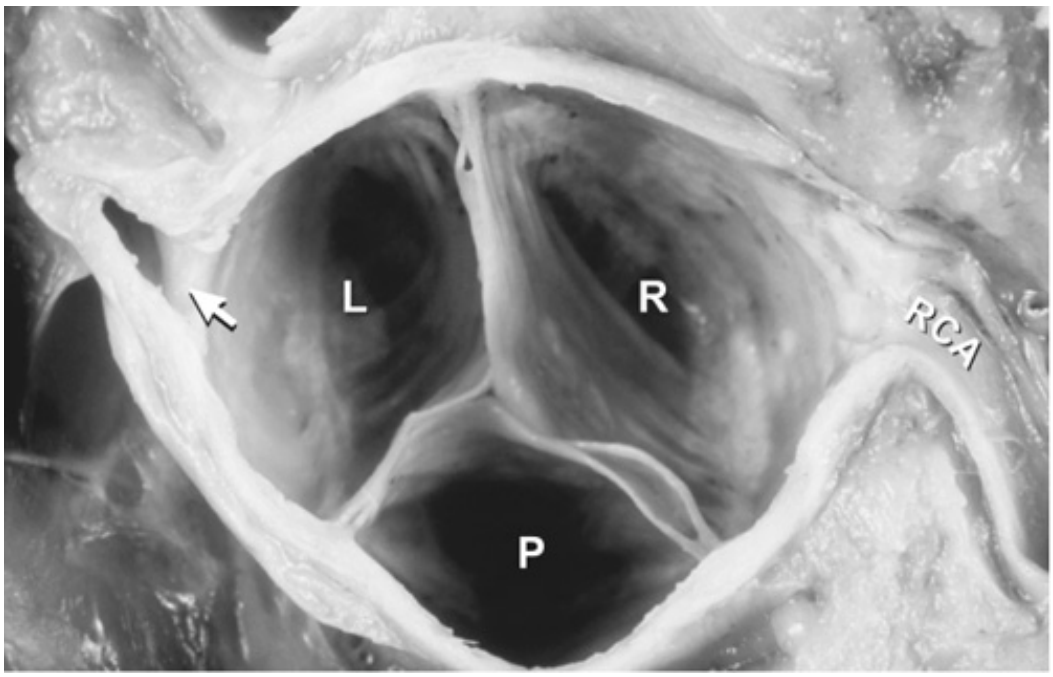

Figure 2-51: Differences in angulation at the origins of the right (RCA) and left main (arrow) coronary arteries. L, left aortic cusp; P, posterior aortic cusp; R, right aortic cusp.

The right coronary artery is embedded in adipose tissue throughout its course within the right atrioventricular groove. *Tricuspid annuloplasty or replacement may be complicated by injury to the right coronary artery.*[17] In 50 to 60 percent of persons, its first branch is the conus artery (Fig.

2-52), which supplies the right ventricular outflow tract and forms an important collateral anastomosis (circle of Vieussens), just below the pulmonary valve, with an analogous branch from the left anterior descending coronary artery.[15-17] In about a third of patients, the conus artery arises independently from the aorta[17] (see Fig. 2-28). The infundibular septum is supplied by the descending septal artery, which usually originates from the proximal right or conus coronary artery.[15-17] Among the numerous marginal branches of the right coronary artery that supply the remainder of the right ventricular free wall, the largest branch travels along the acute margin from base to apex[15-17] (see Fig. 2-50). In at least 70 percent of human hearts, the posterior descending artery arises from the distal right coronary artery (see Fig. 2-50). The posterior descending and distal posterolateral branches of a dominant right coronary artery supply the basal and middle inferior wall, basal (inlet) inferior septum, right bundle branch, AV node, AV (His) bundle, posterior portion of the left bundle branch, and posteromedial mitral papillary muscle.[17]

The left main coronary artery travels for a very short distance along the epicardium between the pulmonary trunk and left atrium (see Figs 2-50 and 2-52). It then divides into anterior descending and circumflex arteries (see Figs. 2-50 and 2-52). An intermediate artery also may arise at this division, thus forming a trifurcation rather than a bifurcation, and follows the course of a circumflex marginal branch[15-17] (see Fig. 2-52).

The left anterior descending coronary artery (LAD) courses within the epicardial fat of the anterior interventricular groove, wraps around the cardiac apex, and travels a variable distance along the inferior interventricular groove toward the cardiac base. Its septal perforating branches supply the anterior septum and apical septum. The first septal perforating branch supplies the AV (His) bundle and proximal left bundle branch[17] (Fig. 2-53, Plate 20). *In patients with symptomatic hypertrophic obstructive cardiomyopathy, nonsurgical septal reduction by percutaneous transluminal occlusion of septal branches of the* LAD *is a new therapeutic approach aimed at reducing the outflow gradient.*[31] *The long-term effects of this procedure are currently unknown.* The epicardial diagonal branches of the LAD supply the anterior left ventricular free wall, part of the anterolateral mitral papillary muscle, and the medial one-third of the anterior right ventricular free wall.[15-17] Although short segments of the LAD may travel within the myocardium (covered by a so-called myocardial bridge) (Fig. 2-54), the resulting systolic luminal narrowing is probably benign in the vast majority of people.[17] *However, whereas the prevalence of myocardial bridging is only 0.5 to 1.6 percent in the general population, it is reported to be 28 percent in children and 30 to 50 percent in adults with hypertrophic cardiomyopathy.*[32] *More important, myocardial bridging appears to be associated with a poor prognosis (higher incidence of myocardial ischemia and sudden death) in patients with hypertrophic cardiomyopathy regardless of age.*[32]

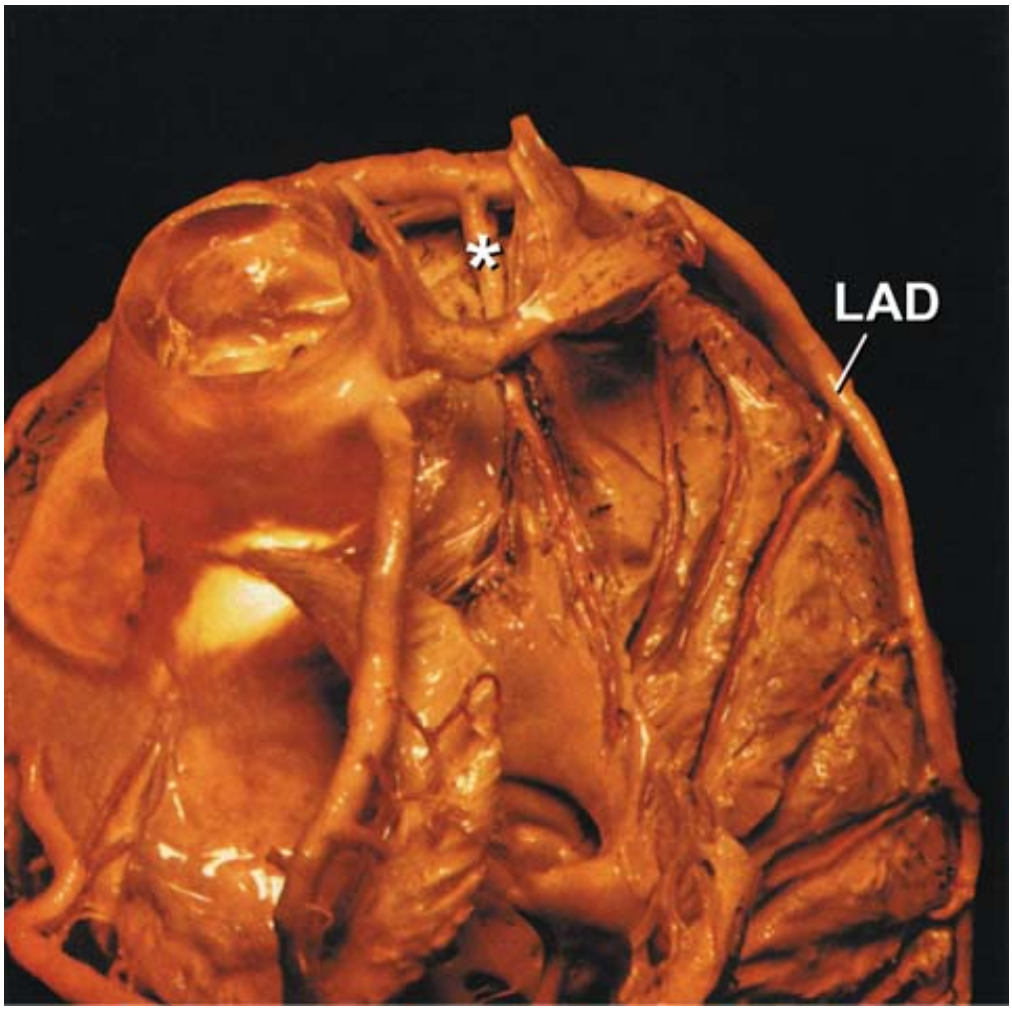

Figure 2-53: (Plate 20) Septal branches of the left anterior descending coronary artery (LAD); * points to the first septal perforator. (From McAlpine,[30] with permission.)

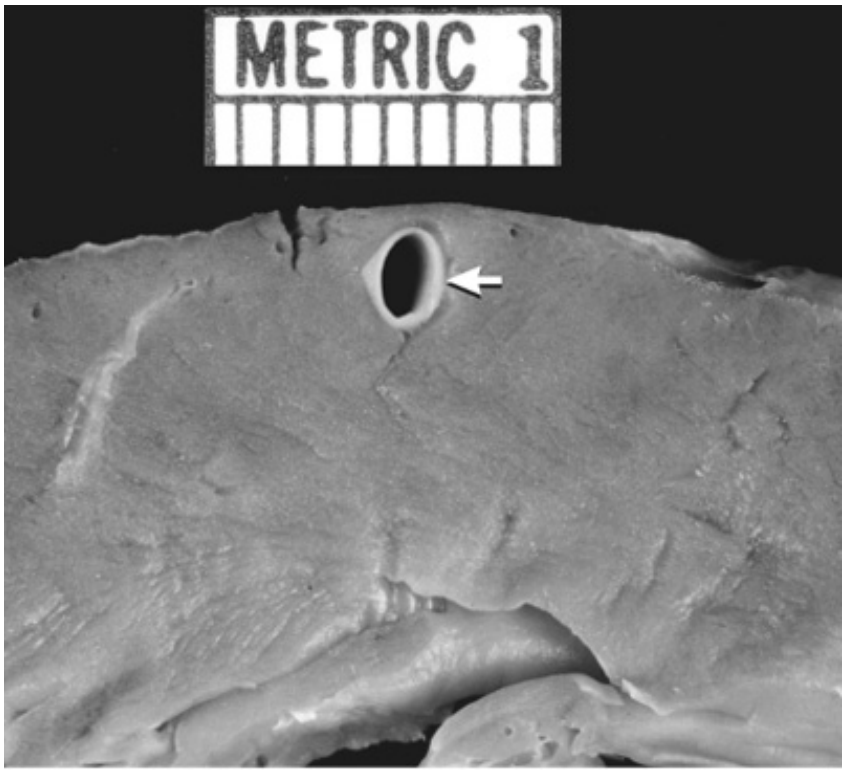

Figure 2-54: Intramyocardial course of the left anterior descending coronary artery (arrow).

The left circumflex coronary artery courses within the adipose tissue of the left atrioventricular groove (see Fig. 2-21*A*) and commonly terminates just beyond its large obtuse marginal branch (see Fig. 2-50). It supplies the lateral left ventricular free wall and a portion of the anterolateral mitral papillary muscle.[15-17]

Along the inferior surface of the heart, the length of the right coronary artery varies inversely with that of the circumflex artery. The artery that crosses the cardiac crux and gives rise to the posterior descending branch represents the dominant coronary artery. Dominance is right in 70 percent of human hearts, left in 10 percent, and shared in 20 percent.[15-17] *In patients with a congenitally bicuspid aortic valve, the incidence of left coronary dominance is 25 to 30 percent.*[17]

The coronary venous circulation is comprised of coronary sinus, cardiac veins, and thebesian venous systems[15-17] (Fig. 2-55, Plate 21). The great cardiac vein travels in the anterior interventricular groove beside the left anterior descending coronary artery and in the left atrioventricular groove beside the left circumflex artery.[15-17] The great cardiac vein and other cardiac veins, such as the left posterior and middle cardiac veins, drain into the coronary sinus, which courses along the posteroinferior aspect of the left atrioventricular groove and empties into the right atrium[15-17] (see Fig. 2-21*A*). The ostium of the coronary sinus is guarded by a crescent-shaped valvular remnant, the thebesian valve. Rarely, the coronary sinus drains directly into the left atrium.[17]

During cardiac operations, cardioplegic solution may be administered retrogradely into the coronary sinus. In patients with the Wolff-Parkinson-White preexitation syndrome and left-sided bypass tracts, the ablation catheter during electrophysiologic studies can be positioned within the coronary sinus and great cardiac vein adjacent to the mitral valve ring in order to localize the aberrant conduction pathway.[17] *The coronary veins, via the coronary sinus, provide access to percutaneous epicardial mapping and pacing of the ventricles and ablation of subepicardial arrhythmogenic foci*[33] (Fig. 2-56, Plate 22). *Some patients with ischemic cardiomyopathy may be poor candidates for conventional revascularization procedures (e.g., coronary artery bypass graft*

surgery or angioplasty) because their epicardial coronary arteries are diffusely diseased. Since in virtually all people the coronary veins run parallel to the entire course of coronary arteries, alternative percutaneous revascularization methods that use the coronary veins as a bypass conduit for coronary arterial flow are being explored.[34-36] *Myocardial revascularization is achieved by either connecting the coronary artery proximal and distal to a stenosis to its companion coronary vein (similar to a conventional bypass graft) or by retroperfusion through the venous microvasculature if the artery and vein are only connected proximal to the stenosis. Coronary veins, unlike saphenous veins, are not removed, thus preserving their adventitia and blood supply.*[34-36]

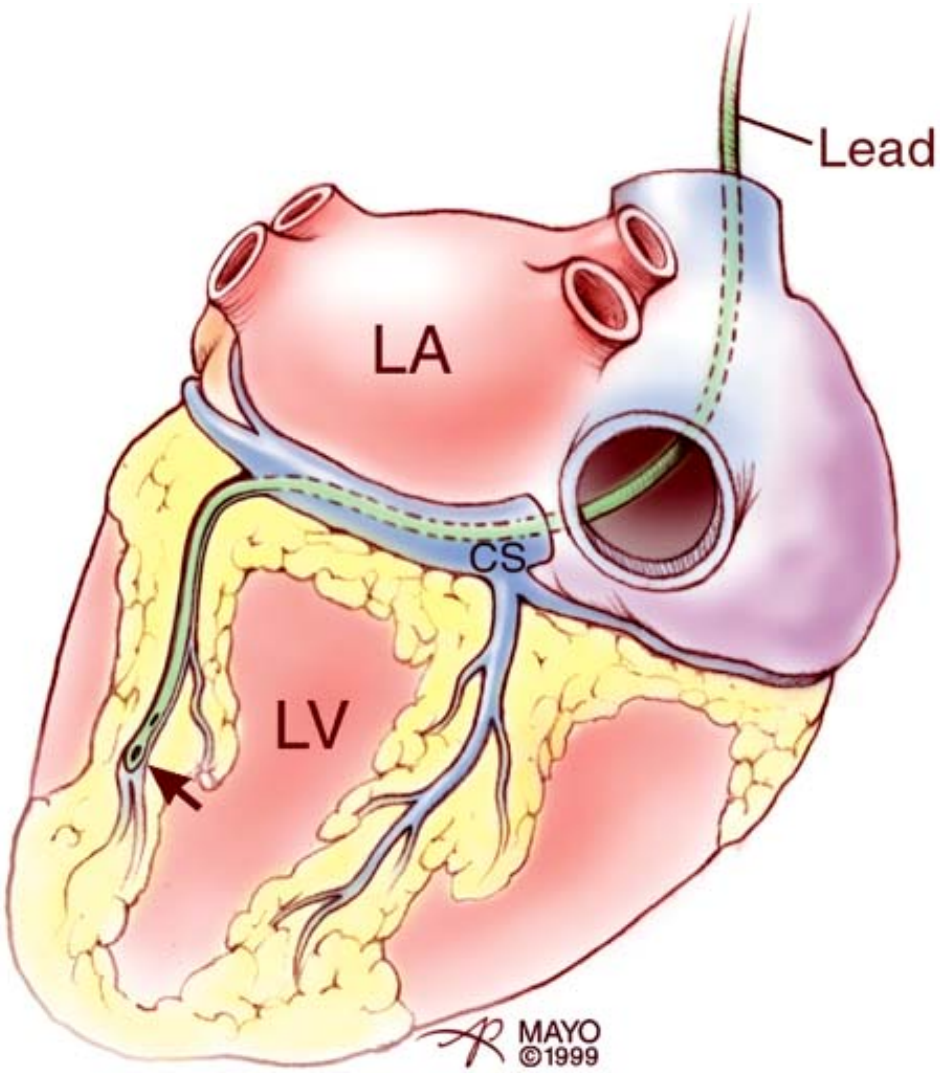

Figure 2-56: (Plate 22) Schematic diagram shows placement of the tip of a pacing/mapping catheter within a coronary vein (arrow) via the coronary sinus (CS). LA, left atrium; LV, left ventricle.

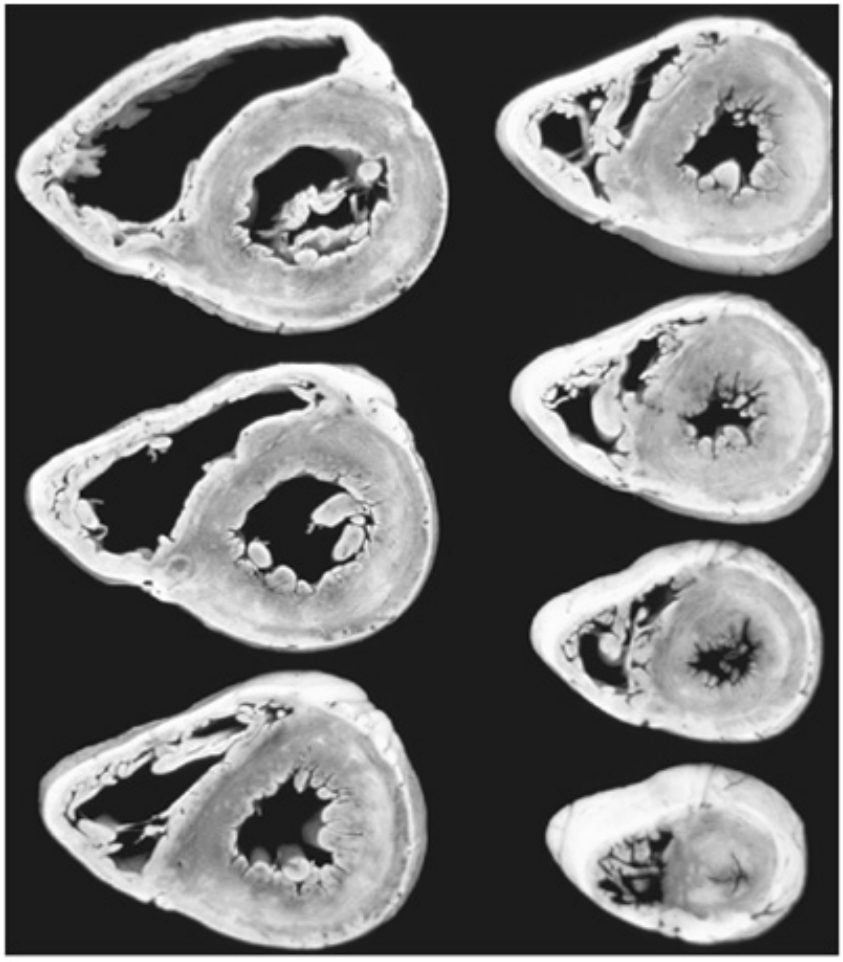
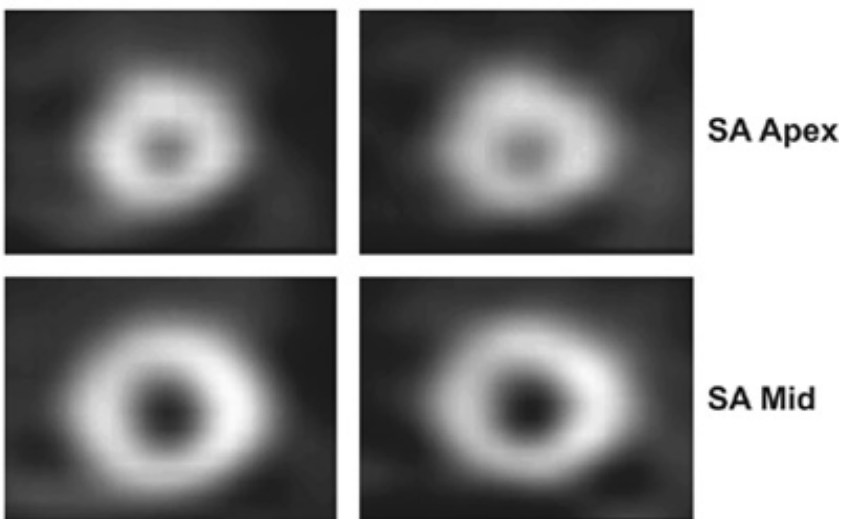
Coronary artery disease is associated with regional abnormalities in ventricular structure and function. Because analysis of segmental myocardial perfusion or contractility is the cornerstone of tomographic imaging techniques [stress echocardiography, SPECT imaging, positron emission tomography (PET), and MRI], for clinicopathologic correlations (Fig. 2-57), a combination tomographic and segmental approach to coronary artery anatomy is recommended.[17,37,38] Ventricular mass is made of the left and right ventricular free walls and the partitioning

ventricular septum. Three levels (i.e., basal, midventricular, and apical) are used to divide the base-apex length of the left ventricle into thirds (Fig. 2-58). The basal third includes that portion between the mitral annulus and the tips of the papillary muscles. The midventricular third is from the papillary muscle to the most apical insertion point of these muscles into the left ventricular free wall. The apical third includes the remainder of the ventricle, from the insertion of the papillary muscles to the left ventricular apex. A similar approach can be applied to the right ventricle.[15-17,37] The ventricular septum can be divided into anteroseptal, septal, and inferoseptal segments, and the left ventricular free wall is divided into anterior, lateral, and inferior segments at the basal and midventricular levels (see Fig. 2-58). The left ventricular apical level consists of four segments (i.e., septum, inferior, lateral, and anterior) (see Fig. 2-58).



A



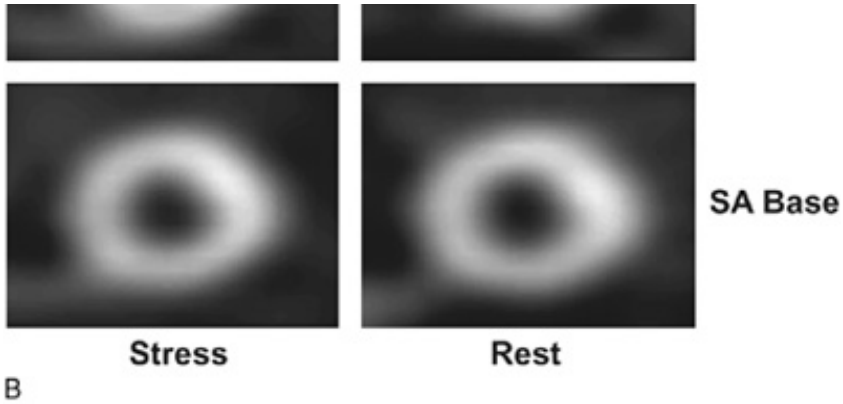


Figure 2-57: Short-axis views. A. Collage of anatomic sections obtained by "bread slicing" the heart in its short-axis plane, corresponding to the tomographic sections obtained by echocardiography and SPECT imaging, viewed from the apex toward the base of the heart. B. Comparable sestamibi SPECT images of the left ventricle showing normal myocardial perfusion at rest and with exercise. SA, short axis.

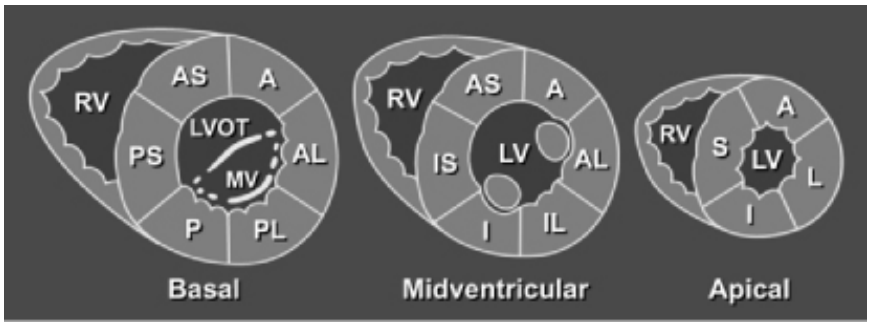

Figure 2-58: Schematic diagram of the three levels of short-axis tomographic views used in echocardiography for 16-segment wall motion analysis. A, anterior; AL, anterolateral; AS, anterior ventricular septum; I, inferior; IL, inferolateral; IS, inferior ventricular septum; L, lateral; LV, left ventricle; LVOT, left ventricular outflow tract; P, posterior; PL, posterolateral; PS, posterior ventricular septum; RV, right ventricle; S, septum. The most basal segment of the inferior wall is the anatomically true posterior segment. At this level, the adjacent ventricular septum is commonly referred to as either the *basal posterior septum* or the *basal inferior septum* and the adjacent lateral wall as either the *basal posterolateral wall* or the *basal inferolateral wall*.

This regional approach is not arbitrary and has been verified by studies of normal, dilated, and hypertrophied hearts. According to this system, there are 16 left ventricular segments that can be evaluated for regional abnormalities. This regional approach also can be used to assess transmural infarct size, because the percentage of left ventricular mass contributed by any particular region is not altered in any significant manner by symmetric hypertrophy or dilatation.[17]

Regional Coronary Artery Supply

The ventricular regions described tend to correlate well with common patterns of coronary arterial distribution[15-17] (Figs. 2-59 and 2-60, Plate 23). Any specific epicardial coronary artery generally will supply a certain cluster of regions. For example, in a typical right-dominant system, the left anterior descending coronary artery would supply the midventricular and basal segments of the anterior and anterolateral walls and anterior septum and all apical segments. The left circumflex artery would supply the midventricular and basal inferolateral segments, and the right coronary artery would supply the midventricular and basal inferior wall and inferior septum (see

Fig. 2-60). However, because the patterns of coronary distribution are so highly variable, these correlations between coronary blood flow and regional anatomy are not precise. For example, a hyperdominant right coronary artery may supply the apex, and a large, obtuse marginal branch of the circumflex artery may supply the anterolateral or inferior wall. Also, any given myocardial region may, in some people, receive its blood supply from the branches of two independent major epicardial arteries.[15-17] In old age, the coronary arteries become dilated and tortuous (Fig. 2-61).

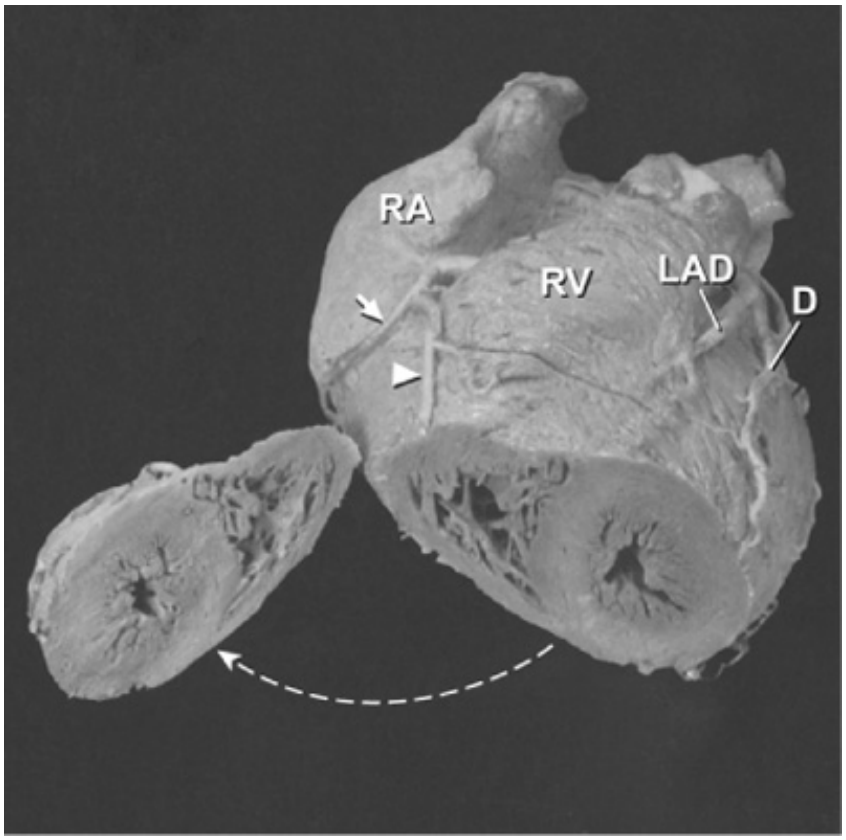

Figure 2-59: Regional coronary flow, with a short-axis slice of the heart. A large diagonal branch (**D**) of the left anterior descending coronary artery (LAD) supplies the lateral wall, and an acute marginal branch (arrowhead) of the right coronary artery (arrow) supplies the anterior right ventricular free wall. The distal segment of the LAD is intramural. RA, right atrium; RV, right ventricle. (From McAlpine,[30] with permission.)

Figure 2-61: Tortuous coronary arteries (arrow) typically seen in the elderly with nondilated hearts. Ao, ascending aorta; PT, pulmonary trunk.

Coronary Collaterals and Microcirculation

Collateral channels provide communication between the major coronary arteries and their branches.[17] If stenosis of an epicardial coronary artery produces a pressure gradient across such a vessel, the collateral channel may dilate with time and provide a bypass avenue for blood flow beyond the obstruction. Such functional collaterals may develop between the terminal extensions of two coronary arteries, between the side branches of two arteries, between branches of the same artery, or within the same branch (via the vasa vasorum). These are most common in the ventricular septum (between septal perforators of the anterior and posterior descending arteries), in the ventricular apex (between anterior descending septal perforators), in the anterior right ventricular free wall (between anterior descending and right or conus arteries), in the anterolateral left ventricular free wall (between anterior descending diagonals and circumflex marginals), at the cardiac crux, and along the atrial surfaces (between the right and left circumflex arteries).[17]

The intramural coronary vessels form the microcirculation. There are age-related variations in the

pattern of distribution of the coronary microcirculation.[39] *Angina-like chest pain in some patients with angiographically normal epicardial coronary arteries (i.e., syndrome X, or microvascular angina) may be secondary to abnormal vasodilator reserve or vasoconstriction of the coronary microcirculation.*[40] *Abnormal flow reserve of the coronary microcirculation is seen in both dilated and hypertrophied hearts. In the latter, structural changes in the coronary arterioles can be found on histologic examination of the myocardium.*[41-43] *In patients with symptomatic hypertrophic cardiomyopathy without angiographic evidence of epicardial coronary artery disease, myocardial tissue obtained during surgical myectomy may show smaller than normal coronary arteriolar lumina.*[43] *Postmortem analysis of hearts with hypertrophic cardiomyopathy also has revealed coronary arterioles with abnormally thick walls.*[43] *With contrast echocardiography, it may be possible to noninvasively visualize intramyocardial arterioles and study coronary flow reserve.*[44] *Demonstration of an intact microvascular circulation in akinetic myocardium following acute myocardial infarction, using PET or SPECT imaging or contrast echocardiography, is evidence of viability of the affected segment.*[44] *The creation of intramyocardial channels with CO_2 laser transmyocardial revascularization has been associated with augmentation of collateral flow to ischemic myocardium through angiogenesis.*[45]

Cardiac Lymphatics

The myocardial lymphatics drain toward the epicardial surface, where they merge to form the right and left lymphatic channels, which travel in retrograde fashion with their respective coronary arteries. These two lymphatic channels travel along the ascending aorta and merge before draining into a pretracheal lymph node beneath the aortic arch. This single lymphatic channel then travels through a cardiac lymph node, between the superior vena cava and innominate artery, and finally empties into the right lymphatic duct. Metastatic tumor obstruction of epicardial lymphatics can produce a pericardial effusion.[15-17]

Great Vessels

The subclavian and internal jugular veins merge bilaterally to form the right and left innominate veins (Fig. 2-62). Valves in the subclavian and internal jugular veins, near their junctions with the innominate veins, are important anatomic structures that help maintain unidirectional antegrade blood flow not only in the normal state but also in the setting of elevated right-sided heart filling pressures.[46] Subclavian and internal jugular venous valves are absent in 2 and 6 percent of people, respectively, and venous valves may be damaged by catheter-induced trauma or by age.[46] *Absent or malfunctioning valves may interfere with the success of closed-chest cardiopulmonary resuscitation and contribute to the development of brain edema during such a procedure.*[46]

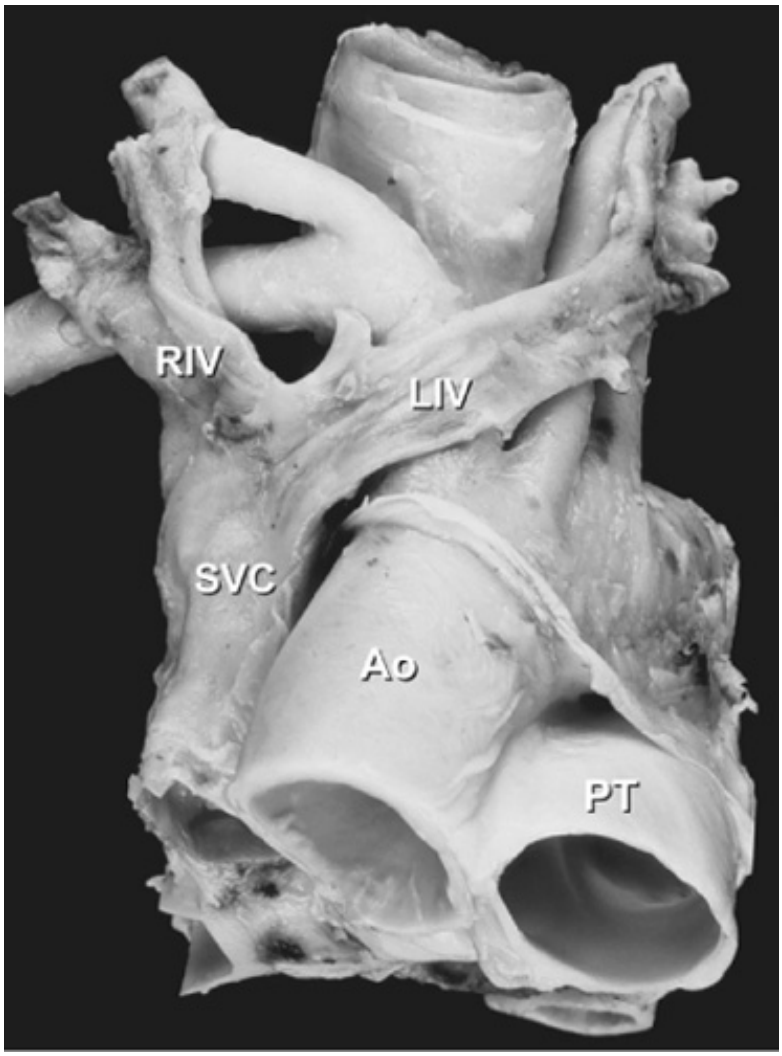

Figure 2-62: The longer left (LIV) and shorter right (**RIV**) innominate veins normally join to form the right superior vena cava (SVC). Ao, ascending aorta; PT, pulmonary trunk.

The left innominate vein is two to three times the length of its right-sided counterpart. It travels anteriorly to the aortic arch along the right anterolateral border of the ascending aorta, where it joins the shorter right innominate vein to form the superior vena cava[15-17] (see Fig. 2-62). *Transesophageal echocardiographic imaging of the upper ascending aorta may show a double lumen (i.e., aorta and adjacent innominate vein) that can be misinterpreted as aortic dissection by an inexperienced echocardiographer.*[7]

The superior vena cava lies anterior to the right pulmonary artery (Fig. 2-63) and receives the azygos vein posteriorly before draining into the superior aspect of the right atrium, just posterior to the atrial appendage[15-17] (see Figs. 2-46, 2-47, and 2-63). *The vein of Marshall forms the terminal connection between a persistent left superior vena cava and the coronary sinus. Its vestigial remnant in normal adults is the ligament of Marshall* (Fig 2-64, Plate 24). *Both vein and ligament are a potential source of arrhythmias*. The ostium of the inferior vena cava is guarded by a crescent-shaped, often fenestrated flap of tissue, the eustachian valve[15-17] (see Fig. 2-16*A*), that is readily seen by echocardiography. Although generally small, the eustachian valve may become so large that it can produce a double-chambered right atrium.[16] Also, when either the eustachian or thebesian valve is large and fenestrated, it is referred to as a *Chiari net*.[15-17] *By echocardiography, a Chiari net may be misinterpreted as a mass*.

The thoracic aorta arises at the level of the aortic valve and is divided into three segments:

ascending aorta, aortic arch, and descending thoracic aorta (Fig. 2-65). The ascending aorta consists of sinus and tubular portions, which are demarcated by the sinotubular junction (Figs. 2-28 and 2-66). *This is the site at which supravalvular aortic stenosis is often most severe*.[15-17]

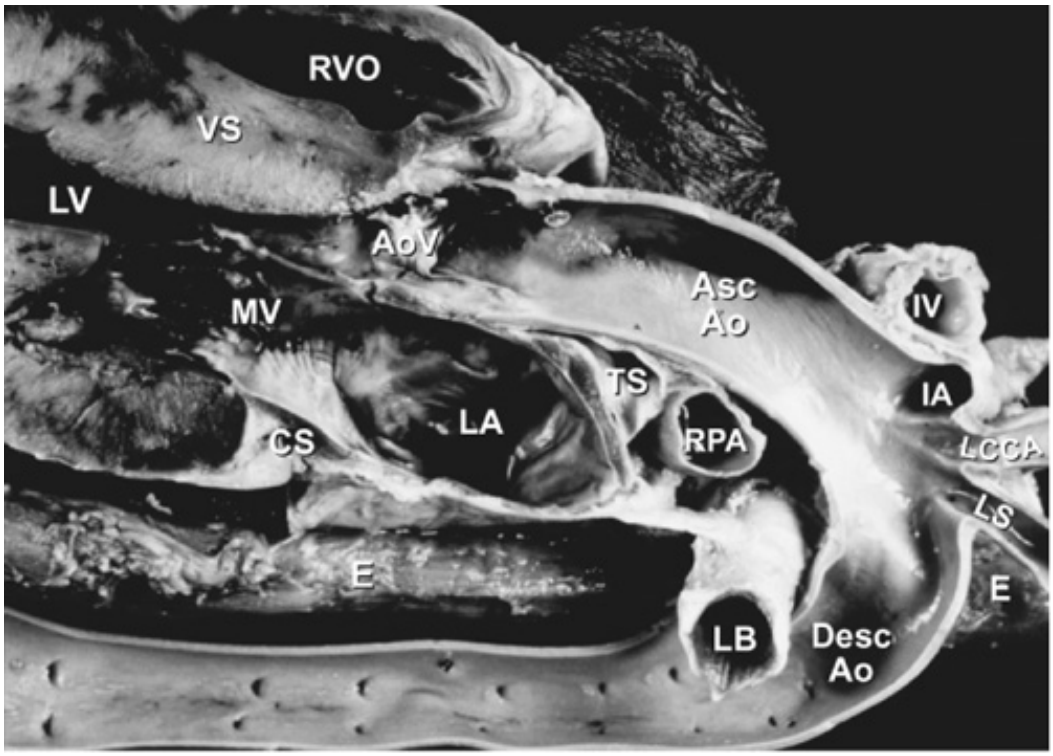

Figure 2-65: Thoracic aorta. The entire thoracic aorta has been cut in a tomographic manner. The aortic arch travels over the left bronchus and the right pulmonary artery. Asc Ao, ascending aorta; AoV, aortic valve; CS, coronary sinus; Desc Ao, descending thoracic aorta; E, esophagus; IA, innominate artery; IV, innominate vein; LA, left atrium; LB, left bronchus; LCCA, left common carotid artery; LS, left subclavian artery; LV, left ventricle; MV, mitral valve; RPA, right pulmonary artery; RVO, right ventricular outflow; TS, transverse sinus; VS, ventricular septum.

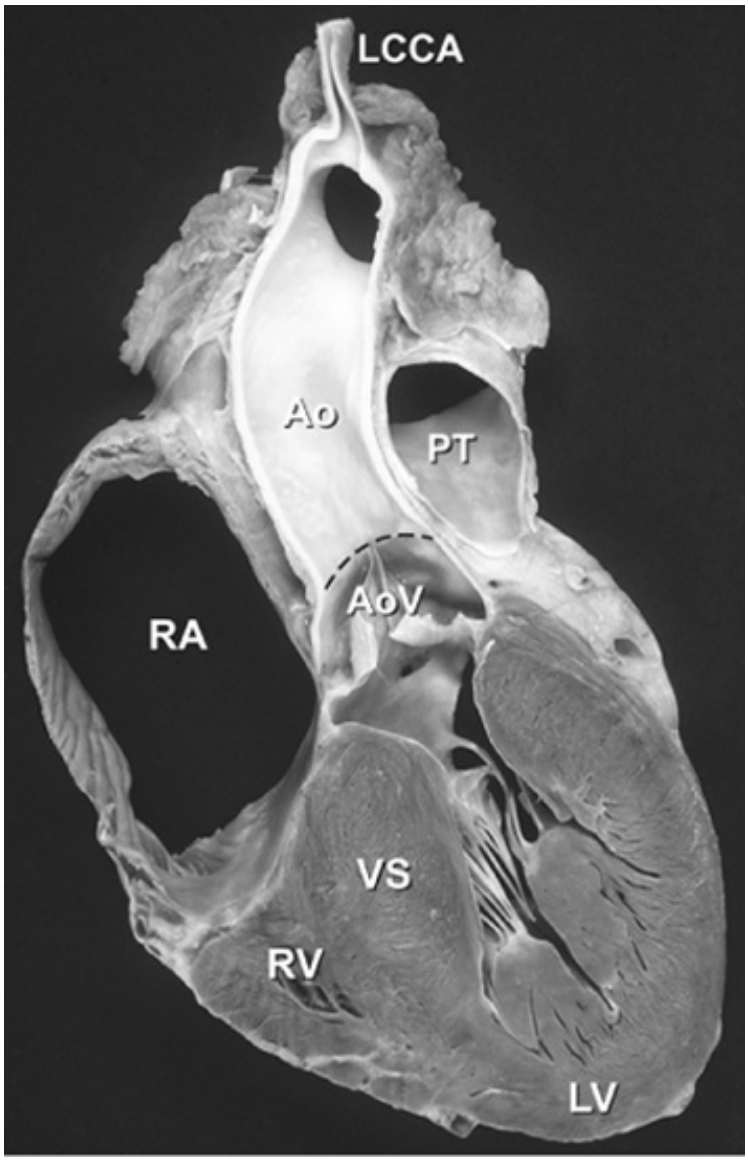

Figure 2-66: Tomographic section of the heart in the frontal plane of the body showing the aortic sinotubular junction (dashed line). Ao, ascending aorta; AoV, aortic valve; LCCA, left common carotid artery; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; LV, left ventricle; VS, ventricular septum.

Behind the aortic valve cusps are three outpouchings, or sinuses (of Valsalva). The right aortic sinus abuts against the ventricular septum and right ventricular parietal band and is covered in part by the right atrial appendage (see Figs. 2-30 and 2-52). In contrast, the left aortic sinus rests against the anterior left ventricular free wall and a portion of the anterior mitral leaflet, abuts the left atrial free wall, and is covered in part by the pulmonary trunk and left atrial appendage (see Figs. 2-20 and 2-21*A*). The posterior (noncoronary) aortic sinus overlies the ventricular septum and a part of the anterior mitral leaflet, forms part of the transverse sinus, abuts the atrial septum, and indents both atrial free walls[15-17] (see Figs. 2-12*D* and 2-22). *Rupture of the right and posterior aortic sinuses of Valsalva may result in a communication with the right ventricular outflow tract or right atrium, whereas rupture of the left aortic sinus of Valsalva leads to a communication with the left atrium or left ventricular outflow tract. Annuloaortic ectasia is associated with hypertension, aortic medial degeneration, and advanced age and may produce aortic regurgitation, ascending aortic aneurysm, or aortic dissection.*[15-17]

The aortic arch gives rise to the innominate, left common carotid, and left subclavian arteries in

that order (see Fig. 2-65). In about 10 percent of people, the innominate and left common carotid arteries share a common ostium, and in 5 percent of people, the left vertebral artery arises directly from the aortic arch, between the left common carotid and left subclavian arteries.[17] The ligamentum arteriosum (ductal artery ligament) represents the vestigial remnant of the fetal ductal artery, which when patent connects the proximal left pulmonary artery to the undersurface of the aortic arch.[17] *Most coarctations occur just distal to the left subclavian artery* (see Fig. 2-69). *When thoracic aortic dissection does not involve the ascending aorta (Debakey type III and Stanford type B), the intimal tear is commonly near the ligamentum arteriosum or the ostium of the left subclavian artery*.[17] *Nonpenetrating deceleration chest trauma, as may occur in motor vehicle accidents, commonly involves the aorta in the region between the aortic arch and descending thoracic aorta and may be associated with aortic transection or pseudoaneurysm formation*.[17]

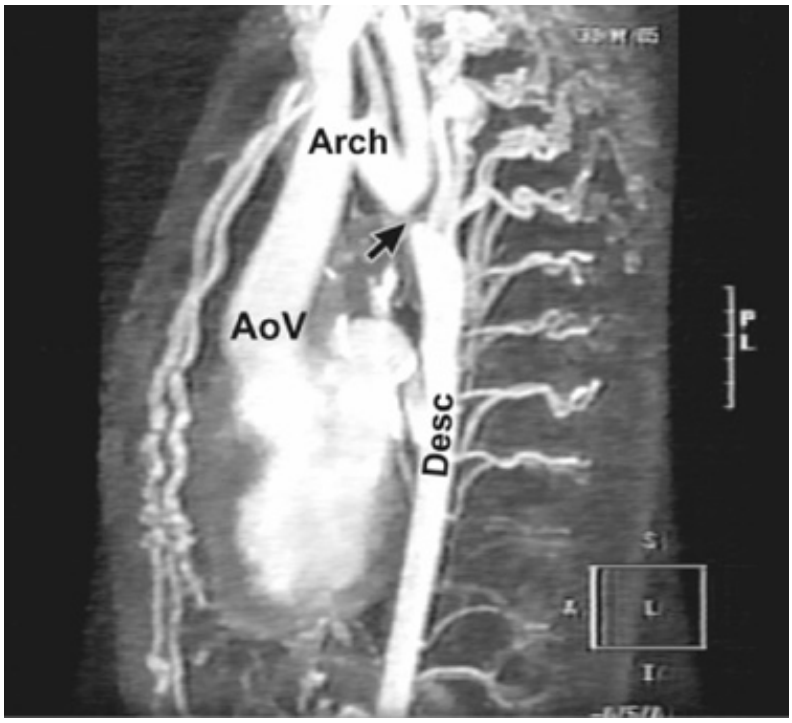

Figure 2-69: Real-time three-dimensional CT reconstruction of the thoracic aorta in a patient with coarctation (arrow) distal to the left subclavian artery. AoV, aortic valve. Desc, descending thoracic aorta.

The descending thoracic aorta lies adjacent to the left atrium, esophagus, and vertebral column. The pulmonary trunk (or main pulmonary artery) emanates from the right ventricle and travels to the left of the ascending aorta. As it bifurcates, the left pulmonary artery courses over the left bronchus, whereas the right pulmonary artery travels beneath the aortic arch and behind the superior vena cava (see Figs. 2-11*A* and 2-63). Thus the *left* bronchus and the *right* pulmonary artery normally travel beneath the aortic arch.

Cardiac Conduction System

The cardiac conduction system consists of the sinus node, internodal tracts, AV node, AV (His) bundle, and right and left bundle branches[15-17] (Fig. 2-67, Plate 25). The sinus node is located sub-epicardially in the terminal groove, close to the junction between the superior vena cava and right atrium. The sinus node artery arises from the right coronary artery in 55 percent of

people. Its course may place it in contact with the base of the right atrial appendage and the superior vena cava-right atrial junction (see Fig. 2-52). When the sinus node artery arises from the left circumflex artery (45 percent), it may course close to the left atrial appendage. *During such surgical operations as the Mustard and Fontan procedures, the sinus node and its artery are susceptible to injury*.[16,17]

By light microscopy, there are no morphologically distinct conduction pathways between the sinus and AV nodes.[17] However, electrophysiologic studies support the concept of functional preferential pathways that travel along the crista terminalis and atrial septum including the limbus but not the valve of the fossa ovalis.[17] *Internodal conduction disturbances therefore are not expected as a result of transseptal procedures. With the Mustard operation for complete transposition of the great arteries, there may be severe disturbance of internodal conduction because the entire septum is resected, and the surgical atriotomy may disrupt the crista terminalis*.[17] *Lipomatous hypertrophy of the atrial septum may interfere with internodal conduction and induce a variety of atrial arrhythmias. Ventricular preexcitation is most commonly associated with aberrant bypass tracts that span the annulus of the tricuspid or mitral valve* (see Fig. 2-2).

The AV node, in contrast to the sinus node, is a sub*endo*cardial structure that is located within the triangle of Koch[15-17] (Fig. 2-68, Plate 26). The triangle of Koch is bordered by the coronary sinus ostium posteroinferiorly and the septal tricuspid annulus anteriorly. *Because of its right atrial location near the tricuspid annulus, the AV node is susceptible to injury during tricuspid annuloplasty and during plication procedures for Ebstein's anomaly*.[15-17]

The AV (His) bundle arises from the distal portion of the AV node and travels along the ventricular septum adjacent to the membranous septum[15-17] (see Fig. 2-68). *The AV conduction tissue is generally remote from the defect in the outlet, inlet, and muscular forms of ventricular septal defect but travels along the inferior margin of a membranous ventricular septal defect*. The AV bundle travels through the central fibrous body (right fibrous trigone) and therefore is closely related to the annuli of the aortic, mitral, and tricuspid valves. *Thus, during operative procedures involving these valves or a membranous ventricular septal defect, care must be taken to avoid injury to the His bundle. Whereas in normal hearts the AV bundle courses along the posteroinferior rim of the membranous septum, it courses along the anterosuperior rim of the membranous septum in hearts with AV discordance*. The AV bundle receives a dual blood supply from the AV nodal artery and the first septal perforator of the left anterior descending coronary artery.[17]

The right bundle branch emanates from the distal portion of the AV bundle and forms a cordlike structure that travels along the septal and moderator bands toward the anterior tricuspid papillary muscle (see Fig. 2-67). In contrast, the left bundle branch represents a broad fenestrated sheet of subendocardial conduction fibers that spread along the septal surface of the left ventricle[15-17] (see Fig. 2-67). The right and left bundle branches receive dual blood supply from the septal perforators of the left anterior descending coronary artery and posterior descending coronary arteries.[17] Left ventricular pseudotendons may contain conduction tissue from the left bundle branch.[17] *Following right ventriculotomy for reconstruction of the right ventricular outflow tract, the ECG shows a pattern of right bundle-branch block even though the right bundle is not disrupted*.[16]

Chapter 2: FUNCTIONAL ANATOMY OF THE HEART

NEW DEVELOPMENTS AND FUTURE CHALLENGES

The future holds promise for an integrated multidimensional approach to the study of cardiac anatomy that incorporates static three-dimensional data, the elements of time (the fourth dimension) and motion, and physiologic (pressure and perfusion) and metabolic parameters.[47-49] Until recently, the geometric fusion of anatomy and function was not possible without physically invading the body. With the currently available imaging techniques, multidimensional anatomy and physiology are mentally reassembled from the sequential tomographic images using echocardiography, MRI or CT, or multiple scintigraphy, as with SPECT imaging.[47] With the advances made in medical technology propelled by the rapid developments in computer technology, digital imaging, and data-storage techniques, it has become possible to electronically perform virtual dissection and reconstruction of the heart and cardiovascular system[47-49] (Fig. 2-69). Furthermore, multidimensional imaging allows continued study of any human organ of interest because of the ability to permanently store anatomic images and physiologic features for retrieval, comparison for change, and ultimately, physical replication.[47-49]

The potential realization of virtual anatomy notwithstanding, standardization of the various tomographic approaches to image acquisition in a manner that conforms with anatomic correctness remains a major challenge that has to be overcome if multidimensional cardiac imaging is to become a clinical reality. There is current progress in this direction. Real-time three-dimensional reconstruction of the heart using identical CT and two-dimensional tomographic sectioning of the heart is now possible. Virtual vivisection may soon become reality. It will allow virtual surgery (dry runs prior to the actual operation) and dissection of the heart into its various functional components, be it anatomic, physiologic, or metabolic, either separately or in various combinations. Because of these advances in multimedia technology, the centuries-old great divide between physiologists and anatomists has been relegated to the history books.

Chapter 2: FUNCTIONAL ANATOMY OF THE HEART

ANATOMY NOT ADDRESSED AND QUANTUM COMPUTING

Fine-detailed anatomy such as that of the conduction system and microvasculature is not available to the usual anatomic dissection. Additionally, tissue histology or molecular biologic assessment is not obtained routinely by the dissectionist. At the other end of the spectrum, three-dimensional gross anatomic dissection of contiguous structures is also normally not available. How does metastatic cancer throughout the system relate to a primary tumor in the gut?

These and other desirable anatomic and histologic dissections await the future of increasing computer technology. Both pathologic and living tissues someday will be dissected and analyzed not by destructive cutting but by digital imagery. Today's computers have introduced the information era. Information has become a commodity expanding our ability to access useful data. Within the next two decades, however, we will have evolved to the quantum era where all that has been discussed in this chapter plus gross and microscopic anatomy will be possible within an electronic environment. Reality will be broken down into its base parts or characteristics and then re-formatted relative to the desired information. Gross anatomy, physiology, tissue characteristics, and even histopathology can be dissected and presented as a quantifiable geometric image.

Chapter 2: FUNCTIONAL ANATOMY OF THE HEART

List of Figures

Figure 2-10: (Plate 5) Bisected cardiac specimen in the four-chamber view parallel to the base-apex axis of the heart. (*Left*) The bisected specimen has been partially opened to show the relative relationship of the bisected halves. (*Right*) The two components of the bisected specimen are opened completely. Note the positions of the pulmonary veins posteriorly and the positions of the atrial appendages at the atrioventricular groove. AL, anterolateral papillary muscle; AS, atrial septum; IVC, **inferior vena cava**; LA, left atrium; LAA, left atrial appendage; LV, left ventricle; MV, mitral valve; PM, posteromedial papillary muscle; PulV, pulmonary vein; RA, right atrium; RAA, right atrial appendage; RV, right ventricle; TV, tricuspid valve; VS, ventricular septum.

Figure 2-11: Tomographic cardiac dissection along the body primary planes. *A*,*B*. Transverse sections (looking from head toward feet) at the level of the great vessels (*A*) or the cardiac chambers (*B*). The aortic arch travels over the left bronchus and the right pulmonary artery. *C*,*D*. Frontal sections (looking from anterior to posterior) through both ventricles (*C*) or left ventricle and right atrium (*D*). *E*,*F*. **Parasagittal sections looking from right** (*E*) **to left** (*F*). Ao, **ascending aorta;** CS, coronary sinus; E, **esophagus;** IA, innominate artery; IVC, **inferior vena cava;** LA, **left atrium;** LAA, **left atrial appendage;** LB, left bronchus; LCX, left circumflex **coronary artery;** LIV, left innominate vein; LLPV, left lower pulmonary vein; LPA, left pulmonary artery; LUPV, left upper pulmonary vein; LSA, left subclavian artery; LV, **left ventricle;** MS, membranous ventricular septum; MV, **mitral valve;** PS, pericardial sac; PT, **pulmonary trunk;** PV, pulmonary valve; RA, **right atrium;** RAA, **right atrial appendage;** RPA, right pulmonary artery; RUPV, right upper pulmonary vein; RV, **right ventricle**; RVO, right ventricular outflow; SVC, **superior vena cava;** TV, **tricuspid valve.**

Figure 2-12: *A*-*D*. Tomographic cardiac dissections along the heart's primary short-axis plane. This method of tomographic dissection shows the crescentic right ventricle (RV) and circular left ventricle (LV). The atrioventricular valves are sectioned at the level of their papillary muscles (in *A*), chordae tendineae (in *B*), atrioventricular valve leaflets (in *C*), and their annuli and the semilunar valves (in *D*). The infundibulum septum (IS) separates the pulmonary and aortic valves. The atrial septum (AS) separates the tricuspid and mitral valves and abuts the posterior (noncoronary) cusp of the aortic valve. LA, left atrium; MV, mitral valve; RA, right atrium; RVO, right ventricular outflow; TV, tricuspid valve.

Figure 2-13: Tomographic cardiac dissection along the heart's primary fourchamber plane. The heart is viewed as though one were looking from the anterosuperior surface toward the posteroinferior surface. In the floor of the right atrium is the orifice of the inferior vena cava (IVC). The pulmonary veins (PulV) enter the posterior aspect of the left atrium. AL, anterolateral mitral papillary muscle; AS, atrial septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PM, posteromedial mitral papillary muscle; RV, right ventricle; TV, tricuspid valve; VS, ventricular septum.

Figure 2-14: Tomographic cardiac dissection along the heart's primary long-axis plane. *A*. Tomographic section showing the left ventricle and left atrium. The mitral valve is also well demonstrated. The left atrial appendage is located anteriorly. The specimen is viewed as though one were looking from the tip of the left scapula toward the right nipple. *B*. Analogous two-chamber transesophageal view. AW, anterior wall; **Desc** Ao, **descending thoracic aorta;** E, **esophagus;** IW, **inferior wall**; LA, **left atrium;** LAA, **left atrial appendage;** LB, **left bronchus;** LPA, **left pulmonary artery;** LV, **left ventricle;** MV, **mitral valve;** PulV, pulmonary vein; Tr, trachea.

Figure 2-15: Left ventricular long-axis method of tomographic cardiac dissection (looking from left flank toward the midsternum). Continuity between mitral and aortic valves is clearly seen. The oblique sinus (*) abuts the wall of the left atrium. A, anterior mitral leaflet; Ao, ascending aorta; CS, coronary sinus; LA, left atrium; LV, left ventricle; P, posterior aortic cusp; PM, posteromedial mitral papillary muscle; R, right aortic cusp; RVO , right ventricular outflow; SVC, superior vena cava; arrows point to the right upper and lower pulmonary veins.

Figure 2-16: Collage of four-chamber tomographic sections cutting from inferior wall to anterosuperior wall showing coronary sinus (*A*), internal cardiac crux (*) (*B*), and aortic valve (*C*). Ao, ascending aorta; CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; arrow in *A* points to a fenestrated eustachian valve.

Figure 2-17: Tomographic sections of the heart in the transverse (*A*) and frontal (*B*) planes of the body. A tomographic section in the transverse plane of the body (*A*) results in a four-chamber view of the heart. *A* tomographic section along the frontal plane of the body (*B*) results in an oblique short-axis view of the heart. *C*. MRI image corresponding to *A*. CS, coronary sinus; DAo, descending thoracic aorta; IVC, inferior vena cava; LA, left atrium; LAD, left anterior descending coronary artery; LV, left ventricle; RA, right atrium; RCA, right coronary artery; RV, right ventricle; RVO, right ventricular outflow; TV, tricuspid valve; VS, ventricular septum.

Figure 2-18: Oblique methods of tomographic cardiac dissection. *A, B.* Right anterior oblique sections, viewed from the right, are taken parallel to the ventricular and atrial septa, may include the right side of the heart (*A*) or the left side of the heart (*B*), and are similar to the two-chamber tomographic sections. *C,D.* Left anterior oblique sections, viewed from the apex toward the base, may be taken at various levels and are similar to the short-axis tomographic sections. Ao, aorta; CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LAA, left atrial appendage; LV, left ventricle; MV, mitral valve; PT, pulmonary trunk; PV, pulmonary valve; RA, right atrium; RV, right ventricle; RVO, right ventricular outflow; SVC, superior vena cava; TV, tricuspid valve.

Figure 2-19: Anterior view of the heart. The anterior portion of the parietal pericardium has been removed, exposing the intrapericardial portions of the superior vena cava (SVC), ascending aorta (Ao), and pulmonary trunk (PT). LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 2-20: Tomographic section in the short-axis plane of the body, looking from apex toward the base, showing the oblique (OS) and transverse (TS) pericardial sinuses. Ao, ascending aorta; DAo, descending thoracic aorta; LA, left atrium; LAS, left aortic sinus; LMA, left main coronary artery: PS, pericardial sac; PV, pulmonary valve; RAA, right atrial appendage; SVC, superior vena cava.

Figure 2-21: (Plate 8) Base of heart. *A.* Section through the base of the heart, looking from base toward apex, with the atria and great arteries removed, shows all four cardiac valves. *B.* A comparable schematic diagram of the fibrous cardiac skeleton. The centrally located aortic valve forms the cornerstone of the cardiac skeleton. Its fibrous extensions anchor and support the other three valves. *A*, anterior; AoV, aortic valve; AV, atrioventricular; CS, coronary sinus; IV, interventricular; L, left; LCX, left circumflex coronary artery; MV, mitral valve; P, posterior; PV, pulmonary valve; R, right; RCA, right coronary artery; S, septal; TV, tricuspid valve.

Figure 2-22: Long-axis section of the left ventricle. The intervalvular fibrosa (dashed triangle) lies between the anterior mitral leaflet and the posterior cusp of the aortic valve and abuts the floor of the transverse pericardial sinus (*). Ao, ascending aorta; IW, inferior wall; LA, left atrium; LV, left ventricle; RVO, right ventricular outflow; VS, ventricular septum.

Figure 2-23: This oblique short-axis view of the heart shows the triangular-shaped tricuspid orifice (TV) and the elliptical mitral orifice (MV) at midleaflet level. The anterior tricuspid and anterior mitral leaflets (A) separate the inflow and outflow tracts of the right and left ventricles, respectively, and are parallel to one another. PV, pulmonary valve.

Figure 2-24: (Plate 9) Mitral valve, viewed from left atrial aspect. Minor commissures (*) divide the posterior leaflet into four scallops (arrows). A, anterior; C, major commissures; P, posterior.

Figure 2-59: Regional coronary flow, with a short-axis slice of the heart. A large diagonal branch (**D**) of the left anterior descending coronary artery (LAD) supplies the lateral wall, and an acute marginal branch (arrowhead) of the right coronary artery (arrow) supplies the anterior right ventricular free wall. The distal segment of the LAD is intramural. RA, right atrium; RV, right ventricle. (From McAlpine,[30] with permission.)

Figure 2-60: (Plate 23) Coronary distribution using a 16-segment model. **D**, diagonal branch of the left anterior descending coronary artery; LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery; LMA, left main coronary artery; OM, obtuse marginal branch of the circumflex coronary artery; PD, posterior descending coronary artery; RCA, right coronary artery; RM, right marginal branch; other abbreviations as in Fig 2-58.

Figure 2-61: Tortuous coronary arteries (arrow) typically seen in the elderly with nondilated hearts. Ao, ascending aorta; PT, pulmonary trunk.

Figure 2-62: The longer left (LIV) and shorter right (**RIV**) innominate veins normally join to form the right superior vena cava (SVC). Ao, ascending aorta; PT, pulmonary trunk.

Figure 2-63: Long-axis view of the superior vena cava (SVC) and inferior vena cava (IVC). The specimen is viewed from the left looking toward the free wall of the right atrium. The right atrium (RA) and its appendage (RAA) are anterior. This is a commonly used tomographic plane in transesophageal echocardiography. AS, atrial septum; LA, left atrium; LB, left bronchus; RPA, right pulmonary artery.

Figure 2-64: (Plate 24) Schematic diagrams showing the ligament/vein of Marshall in normal hearts (*left*) and persistent left superior vena cava (LSVC) (*right*). CS, coronary sinus; LA, left atrium; LAA, left atrial appendage; LV, left ventricle; RA, right atrium; RSVC, right superior vena cava.

Figure 2-65: Thoracic aorta. The entire thoracic aorta has been cut in a tomographic manner. The aortic arch travels over the left bronchus and the right pulmonary artery. Asc Ao, ascending aorta; AoV, aortic valve; CS, coronary sinus; Desc Ao, descending thoracic aorta; E, esophagus; IA, innominate artery; IV, innominate vein; LA, left atrium; LB, left bronchus; LCCA, left common carotid artery; LS, left subclavian artery; LV, left ventricle; MV, mitral valve; RPA, right pulmonary artery; RVO, right ventricular outflow; TS, transverse sinus; VS, ventricular septum.

Figure 2-66: Tomographic section of the heart in the frontal plane of the body showing the aortic sinotubular junction (dashed line). Ao, ascending aorta; AoV, aortic valve; LCCA, left common carotid artery; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; LV, left ventricle; VS, ventricular septum.

Figure 2-67: (Plate 25) Schematic diagram of the cardiac conduction system. (*Left*) The right side of the heart showing the sinus node, atrioventricular (AV) node, AV (His) bundle, and right bundle branch. (*Right*) The left side of the heart showing incomplete anatomic separation of the left bundle into antero and posterior fascicles. Ao, ascending aorta; AV, atrioventricular; CS, coronary sinus; CT, crista terminalis; FO, fossa ovalis; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; PV, pulmonary valve; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Figure 2-68: (Plate 26) The atrioventricular node (AVN) lies within the triangle of Koch (dashed triangle), and the AV (His) bundle (AVB) travels through the tricuspid annulus to rest along the summit of the ventricular septum. CS, coronary sinus; FO, fossa ovalis; IVC, inferior vena cava; S, septal leaflet of the tricuspid valve; SVC, superior vena cava.

Figure 2-69: Real-time three-dimensional CT reconstruction of the thoracic aorta in a patient with coarctation (arrow) distal to the left subclavian artery. AoV, aortic valve. Desc, descending thoracic aorta.

Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 3:

NORMAL PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

Authors: Martin M. LeWinter, George Osol

The cardiovascular system functions to deliver oxygen, nutrients, and other essential molecules to the tissues and carry waste products (e.g., carbon dioxide, metabolic end products) to the organs responsible for their elimination (i.e., lungs, liver, kidney). To accomplish these functions, a system with two separate circulations in series has evolved. The pulmonary circulation is a low-resistance, high-capacitance vascular bed specialized for bidirectional gas exchange with the environment. The systemic circulation consists of multiple, relatively high resistance vascular beds specialized for the delivery of oxygen and nutrients to tissues and extraction of carbon dioxide and metabolic waste products. Blood is a solvent that dissolves and transports the substances required for and produced by metabolic processes. It travels sequentially through the two circulations and is pumped by two highly adapted pumps in series. The latter are combined in one organ, the heart, that is under coordinated local and neurohumoral control. Each side of the heart is composed of two chambers, a thin-walled atrium that accepts venous blood from its respective circulation and also has a booster pump function and a thicker-walled ventricle that pumps the blood to its respective circulation.

A key aspect of the cardiovascular system is that it must function under a wide variety of demands. Thus, during the stress of exercise, the amount of blood pumped, the *cardiac output* (CO), must increase fourfold or more.[1,2] Extremes of temperature (e.g., during exercise) require that the cardiovascular system function to maximize heat loss or conservation. Beat-to-beat variations in loading of the heart related to normal functions such as respiration require exquisitely fine tuning of the stroke volume (SV) produced by each side of the heart. Moreover, the system has little or no room for error; even a slight, sustained mismatch of left- and right-sided SV would result in a catastrophe. This chapter reviews the cellular and organ-level cardiac and vascular mechanisms nature has devised to accomplish these tasks.

CARDIAC FUNCTION

The Cardiac Cycle

As a departure point, we begin this section by considering the sequence of events that occur at the organ level during the course of a single heartbeat, or cardiac cycle (Fig. 3-1, Plate 27). Before mechanical activity begins, an electric signal is delivered to the myocardium (see Chaps. 11 and 23). Electrical signaling is accomplished by specialized conduction system tissue that controls heart rate (HR) by responding to a variety of influences (especially sympathetic and parasympathetic stimulation), provides a normal sequence of activation of the heart chambers that in turn maximizes efficient contraction and filling, and at the cellular level, initiates the biochemical processes that underlie contraction. With respect to HR, conduction system cells have the general property of undergoing spontaneous electrical depolarization and thereby functioning as pacemakers that control the rate of beating. The sinus node, located in the right atrium (RA) near the superior vena caval junction, is the component of the conduction system that has the fastest rate of spontaneous depolarization and therefore provides normal control of HR. It is under the direct influence of the autonomic nervous and neuroendocrine systems, which modulate beat-to-beat and longer-term variations in HR.

At the body surface, activity of the specialized conduction system and spread of the electric impulse is represented by the electrocardiogram (ECG), which is caused by electrical potential differences generated by the heart (see Chap. 11). At the cellular level, electrical excitation consists of transmission of a membrane-based depolarizing and then repolarizing current called the *action potential* (AP) that is propagated through the cardiac chambers via the specialized conduction system, ultimately reaching

individual atrial and ventricular myocytes.

The electric signal (AP) begins in the sinoatrial node and then traverses specialized conduction tissue in both atria, spreading to atrial myocytes and causing atrial contraction (the P wave of the ECG). The atrial conduction system tissue then converges at the atrioventricular node region, consisting of the atrioventricular node itself and the more distal His bundle. These structures are located in the junctional tissue where interatrial and interventricular septa meet. The atrioventricular node is an area of relatively slow conduction that is responsible for most of the normal delay between atrial and ventricular contraction (the PR interval of the ECG). A properly timed delay maximizes the booster pump function of the atria and also protects the ventricles from excessively rapid stimulation. From the His bundle, electrical excitation spreads through large, intraventricular fascicles, the left and right bundles. The left bundle branches into two smaller branches, the left anterior and posterior fascicles. Both bundle-branch systems then ramify within the ventricular myocardium. The smallest branches of the specialized conduction tissue are Purkinje system fibers. The electric signal is transmitted from the Purkinje fibers to individual ventricular myocytes, which contract following a series of cellular events described below. Depolarization of ventricular myocardium accounts for the QRS complex of the ECG. Within the myocardium, the AP spreads from myocyte to myocyte through specialized structures called *intercalated disks,* which contain low-resistance gap junctions across which current flows preferentially. The left ventricle (LV), most massive of the cardiac chambers, is the largest source of electrical potential differences. Electrical activation of the LV begins in the interventricular septum, spreads toward the anteroapical region, and reaches the posterobasal portion last. Activation of the right ventricle (RV) begins slightly after the LV.

This pattern of normal electrical activation causes a coordinated sequence of contraction and relaxation of the cardiac chambers, resulting in ejection of blood by the ventricles into the aorta and pulmonary artery (PA), followed by relaxation and filling. The fact that interference with the normal electrical activation sequence almost always adversely affects cardiac function is strong evidence that normal activation is also the most efficient.

By convention, the mechanical cycle (see Fig. 3-1) is considered to begin at ventricular end diastole (ED), the instant just before systole, when the ventricles begin to actively generate tension as signaled by a sudden, rapid rise in intraventricular pressure. Soon after ventricular systolic pressure begins to rise, it exceeds atrial pressure, at which time the mitral and tricuspid valves close. Ventricular pressures then continue to rise rapidly until aortic (Ao) and PA pressures are exceeded, resulting in opening of the Ao and pulmonic valves and onset of the period of *ejection* of blood into the systemic and pulmonary circulations. Between mitral/tricuspid valve closure and Ao/pulmonic valve opening, ventricular volume is constant. This phase of the cycle is termed *isovolumic* or *isovolumetric contraction*. As ejection proceeds, ventricular and Ao/PA pressures rise and then fall together. The Ao and pulmonic valves close, and ejection ends when ventricular pressure falls below Ao and PA pressure. This event is signaled by the *dicrotic notch* of the respective arterial pressures. In the LV, a period then ensues during which pressure continues to fall rapidly until it drops below left atrial (LA) pressure, when the mitral valve opens. Since Ao and mitral valves are closed during this period, volume is constant, and it is termed *isovolumic* or *isovolumetric relaxation*. Although pulmonic valve closure and tricuspid valve opening are shown as separated significantly in time in Fig. 3-1, the point at which RV pressure falls below PA pressure is actually so low (slightly above the point at which it falls below RA pressure) that the RV isovolumic relaxation period is almost nonexistent.[3]

The time when ventricular pressure falls below atrial pressure signals the onset of the *ventricular filling period*. (There is disagreement as to the best conceptual definition of the *onset of diastole*. One is that contraction and relaxation should be viewed as linked events. Diastole therefore does not begin until relaxation is complete. As will be seen, ventricular filling begins *before* relaxation ends. A second is that diastole begins when ventricular filling commences. A third is that diastole begins when the ventricular myocardium begins to relax, i.e., at about the time ventricular systolic pressure begins to fall. Each definition has merit, and there is no need to take sides in the debate.) Immediately after the atrioventricular (AV) valves open, there is rapid inflow of blood into the ventricles. The latter is caused by an AV pressure gradient (typically several millimeters of mercury) that develops immediately after the AV pressure crossover (Fig. 3-2). Ventricular pressure normally declines by at least several millimeters of mercury immediately after the onset of filling and then rises rapidly after reaching its minimum value. Following

this initial *rapid filling phase*, ventricular pressure plateaus, the AV gradient diminishes markedly, and filling slows and actually may come to a complete halt (*diastasis*). Slow filling is immediately succeeded by the final filling event, contraction of the atria, which results in a second increase in the AV gradient and injection of an additional bolus of blood into the ventricle. The increase in pressure caused by atrial contraction is the *a wave*. Because of its brief duration, it has relatively little effect on *mean* atrial pressure. Thus normal atrial pump function augments ventricular filling with little risk of an excessive increase in atrial pressure and attendant circulatory congestion. With a normal PR interval, ventricular contraction begins during atrial relaxation.

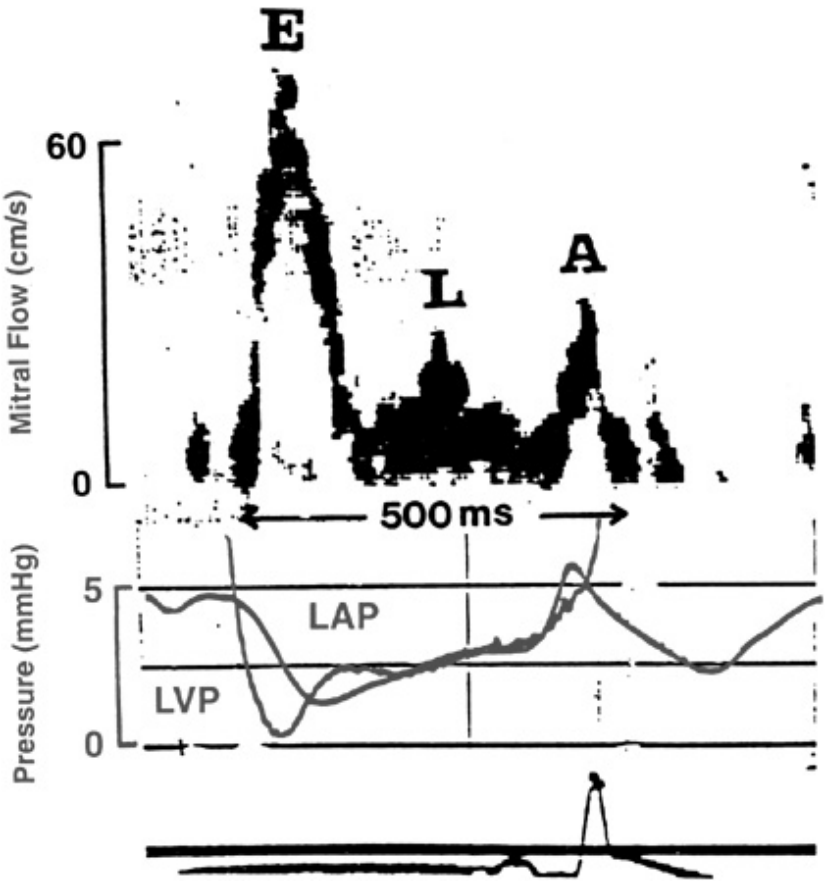

Figure 3-2: Mitral flow recorded with a Doppler probe in the mitral annulus and simultaneous LA (LAP) and LV (LVP) pressures in a dog. Note initial gradient immediately after LV pressure crosses LA pressure. As shown here, when recorded with high-fidelity manometers, this is typically followed by a brief reversal of the gradient and then, following the slow-filling phase, by atrial contraction and a second increase in the gradient. Note rapid, early transmitral mitral flow (E wave) and smaller contribution of atrial contraction (A wave). The record also reveals a middiastolic increase in flow (L wave) that is occasionally observed. (From Yellin EL, Nikolic SD. Diastolic suction and the dynamics of LV filling. In: Gaasch WH, LeWinter MM, eds. *LV Diastolic Dysfunction and Heart Failure*. Philadelphia: Lea & Febiger, 1994:92. Reproduced with permission of the publisher.)

Ventricular volume changes as a function of time are similar on the right and the left sides, except for the virtual absence of isovolumic relaxation on the right (see Fig. 3-1). Systolic pressure waveforms, of course, differ. The thick-walled LV generates a much higher pressure than the RV, reflecting the high-resistance systemic vascular bed. Pressure waveforms during filling are qualitatively similar in both ventricles but normally on the order of a few to as many as 7 to 8 mmHg higher in the left, reflecting the less distensible, thicker-walled LV chamber. Table 3-1 is a listing of hemodynamic values in normal adult human subjects.

Table 3-1: Hemodynamic Values in Normal Recumbent Adults

Measurement	Range	Mean
Cardiac index, liters/min per m^2	2.8-4.2	3.4
SV, mL/beat	30-65	47
Arteriovenous oxygen difference, mL per liter of blood	30-48	38
Intravascular pressure,[a] mmHg		
Brachial artery		
Systolic	90-140	-
Diastolic	60-90	-
Mean	70-105	85
LV		
Systolic	90-140	-
ED	5-12	-
LA or PA wedge		
Mean	5-12	-
PA		
Systolic	15-28	-
Diastolic	5-16	-
Mean	10-22	16
RV		
Systolic	15-28	-
ED	0-8	-
RA		
Mean	0-8	-
LV volume index (mL/m^2)		
ED	50-90	-
ES	15-25	-
Resistance, $dyn \cdot s/cm^5$		
Total systemic	900-1400	1150
Systemic arteriolar	600-900	850
Total pulmonary	150-250	200
Pulmonary arteriolar	45-120	70

[a]Baseline for pressure measurements one-half of anteroposterior chest diameter. 1 mmHg = 133.332; Pa = 0.133 kPa.

LA and RA pressure waveforms are also similar (see Figs. 3-1 and 3-2). Mean LA pressure is normally higher than RA pressure (upper limit of mean RA pressure is ~7 mmHg; LA, ~12 mmHg). The positive *a* wave resulting from atrial contraction is followed by a decline in pressure (the *x* descent) as the atria relax, during which time ventricular contraction begins. There is often an additional small positive wave, the *c wave*, superimposed on the *x* descent. Following the ventricular-atrial pressure crossover at the beginning of ventricular systole, atrial pressure initially continues to decline as atrial relaxation continues but then rises progressively during ventricular ejection, reaching a peak at time of the ventricular-atrial pressure crossover signaling the onset of AV valve opening and ventricular filling. This second positive atrial wave is the *v* wave, caused by passive filling of the atria while the AV valves are closed. Normally, the *a* wave is larger than the *v* wave in the RA, with the reverse in the LA. The *v* wave is followed by a second pressure decline, the *y* descent, that begins with AV valve opening and is more gradual than the simultaneous decline in ventricular pressure occurring at the onset of filling (see Fig. 3-2).

The most important beat-to-beat variation in loading of the cardiac chambers is caused by normal respiration. The inspiratory decrease in intrathoracic pressure causes a substantial *increase* in venous return to the right side of the heart and pooling of blood in the pulmonary circulation in association with a small decrease in venous return to the left side of the heart. As a result of the relative changes in left- and right-side heart filling during inspiration, RV SV increases in relation to LV SV. This prolongs RV ejection time and delays pulmonic valve closure, accounting for the inspiratory increase in splitting of the second heart sound (see Chap. 10).

The Cellular Basis of Cardiac Contraction

Cardiomyocytes may be considered to consist of three systems: (1) a sarcolemmal excitation system that participates in spread of the AP and functions as a switch initiating the intracellular events giving rise to contraction, (2) an intracellular excitation-contraction coupling (ECC) system that amplifies and converts the electric excitation signal to a chemical signal that, in turn, activates the (3) contractile system, a molecular motor based on formation of chemical crossbridges between two proteins, actin and myosin (Fig. 3-3).

EXCITATION SYSTEM

This system is also discussed in Chap. 23. The cellular AP consists of a transient, local transsarcolemmal depolarizing current that raises the transmembrane potential from its normal resting value of negative 80 to 90 mV to slightly positive values, followed by a depolarizing current that returns the potential to its resting value[4-6] (Fig. 3-4). The AP is initiated within the specialized conduction tissue and is propagated to individual myocytes. It results from a series of coordinated changes in the conductance of specific ionic species through variably gated sarcolemmal channels. The earliest and largest component of membrane depolarization is caused by a rapid, inward Na current. The resting potential is established and maintained by the transsarcolemmal Na-K-ATPase, which uses energy from ATP hydrolysis to pump Na ions out of the cytoplasm.

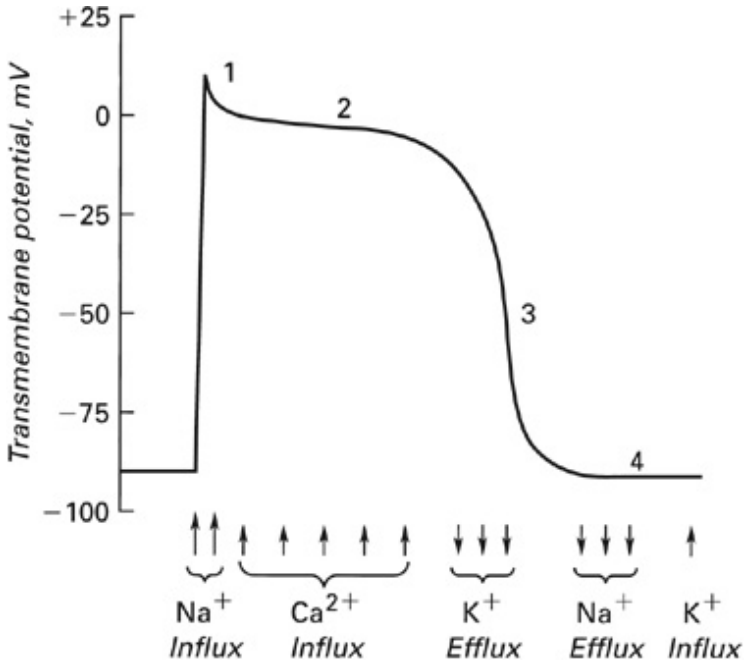

Figure 3-4: Phases of cellular AP and major associated currents in ventricular myocyte. Initial phase zero spike (not labeled) and overshoot (1) is caused by rapid inward Na current, the plateau phase (2) by slow inward Ca current through L-type Ca channels, and repolarization (phase 3) by outward K current. Phase 4 resting potential (Na efflux, K influx) is maintained by the Na-K-ATPase. Na-Ca exchanger is mainly responsible for Ca extrusion. In specialized conduction system tissue, there is spontaneous depolarization during phase 4 until the voltage resulting in opening of the Na channel is reached.

With respect to initiation of contraction, the most important component of the AP is a relatively *slow, inward Ca current* through voltage-sensitive, L-type (for long-lasting) Ca channels[5,7,8] (Ca^{2+} influx in Fig. 3-4). These channels open, and the current begins when transmembrane potential reaches -35 to -20 mV and, because of its slow kinetics, continues well after the Na current has ceased. The Ca current is mainly responsible for the AP plateau phase. It ceases when L-type channels become inactivated, and regenerative currents (mainly K efflux) begin the repolarization process. L-type channels, also termed *dihydropyridine (DHP)receptors,* are concentrated in invaginations of the sarcolemma called the *transverse-tubule system,* in close proximity to sarcoplasmic reticulum membrane-associated *ryanodine receptor* (RyR) Ca release channels (discussed below).

The AP results in a net movement of Ca ions into and a net movement of Na ions out of the cytoplasm. Ionic balance is restored mainly by another sarcolemmal ion-transport mechanism, the *Na-Ca exchanger*.[7,9-11] The exchanger is a shuttle that moves one Ca ion out of the cell against its concentration gradient while using energy from the Na gradient to move one Na ion into the cell. The exchanger also can function in so-called reverse mode, moving a Ca ion into the cytoplasm and a Na ion out.[9-11] Normally, the reverse mode does not contribute significantly to inward movement of Ca ions.

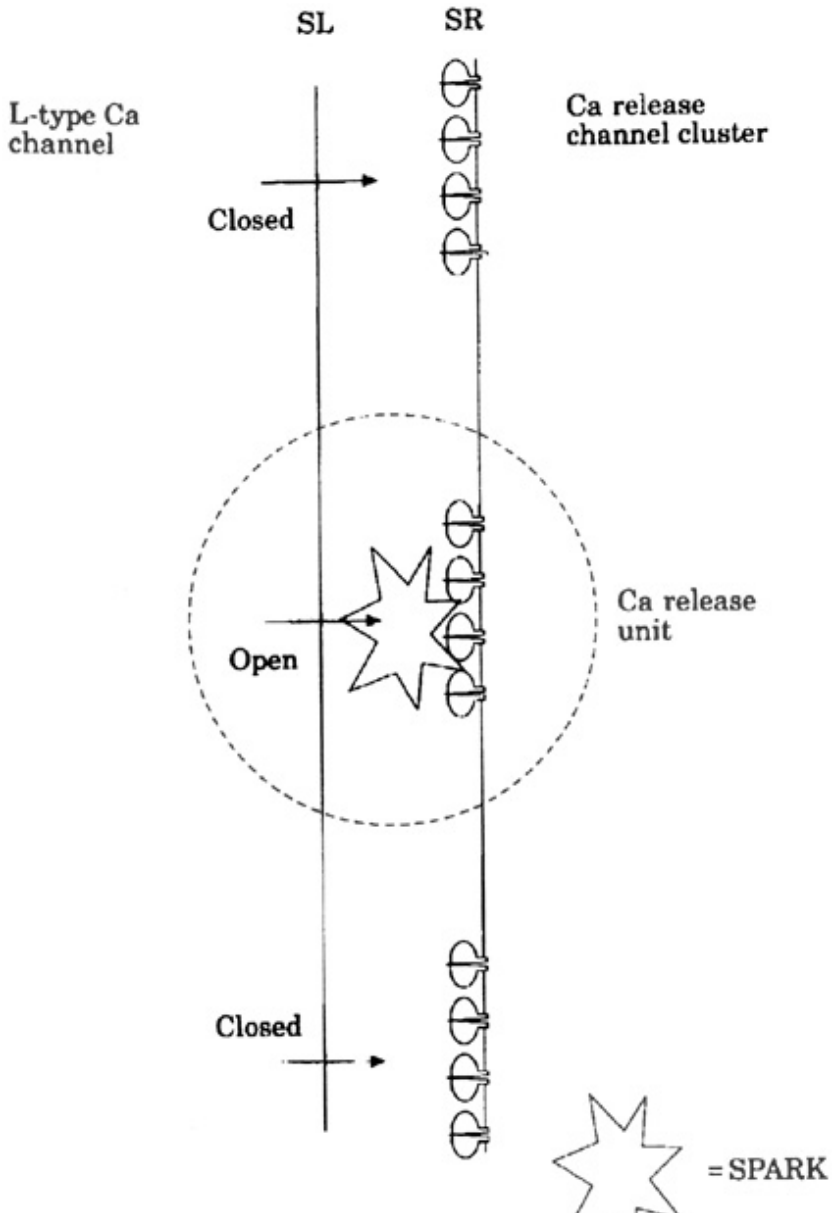
EXCITATION-CONTRACTION COUPLING SYSTEM

ECC is accomplished by the *sarcotubular system,* an arrangement of specialized sarcolemmal and intracellular membranes that functions to control and amplify the ability of the AP to switch the activity of the contractile system on and off. It does so by creating electrochemical signals between the sarcolemma and intracellular organelles; these signals occur much more rapidly than would be possible by simple diffusion of the signaling molecule (in this case, Ca ions).

The sarcotubular system consists of two main components, transverse or T-tubules and the sacroplasmic reticulum (SR)[7,12,13] (see Fig. 3-3). T-tubules are transverse invaginations of the sarcolemma that are concentrated at the Z line of the sarcomere (see below). The SR is a longitudinally oriented system of intracellular membranous sacs and tubules consisting of collar-like structures encircling the contractile

filaments at 1- to 2-μm spacings and forming repeating closed compartments that extend along the length of each myofibril from cross striation to cross striation. At the end of each collar is a bulge (*cistern*) that closely abuts a T-tubule, creating a *dyad* or sometimes a *triad* structure. The gap between the cistern and nearby T-tubule is bridged by structures called *feet*.

The SR contains a large store of Ca ions that are released into the cytoplasm as a result of a process termed *Ca-induced Ca release* (CICR)[7,8,14-21] that takes place within or near the dyad. At any point in time, the bulk of Ca ions within the SR is associated with binding proteins, for example, calsequestrin. The details of CICR have been illuminated by Ca "spark" studies employing Ca concentration-sensitive bioluminescent intracellular dyes in conjunction with confocal microscopy[17-21] (Fig. 3-5). As indicated earlier, DHP receptor Ca channels are concentrated in the T-tubule region forming the dyad. The adjacent SR membranes in the dyad contain Ca release channels (RyRs)[7,8,16,25] that bridge the cisternal membrane near the foot proteins of the dyad. When the AP depolarizes the cell membrane in the dyad region, the voltage-sensitive DHP receptor channel gate opens, allowing movement of Ca from the extracellular space across the sarcolemma into the gap region of the dyad. Nearby RyR channels are activated (opened) by the local rise in Ca concentration in the dyad,[7,25] resulting in very rapid release of much larger amounts of Ca ions from the SR cisternae into the cytoplasm (causing the intracellular Ca "spike" or transient[26] detectable with bioluminescent dyes) (Fig. 3-6). This large amount of Ca ions in turn activates the contractile system (see below).



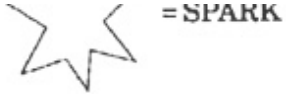


Figure 3-5: Schematic of Ca-induced Ca release from SR resulting in a Ca "spark." Opening of sarcolemmal (SL) L-type Ca channel results in movement of a relatively small amount of Ca ions into the cell. The latter causes opening of a number of nearby RyR channels (Ca release unit) with local release of a large amount of Ca ions from the SR and appearance of a "spark," as bioluminescent dye responds to change in local Ca concentration. (From Williams.[8] Reproduced with permission of the publisher.)

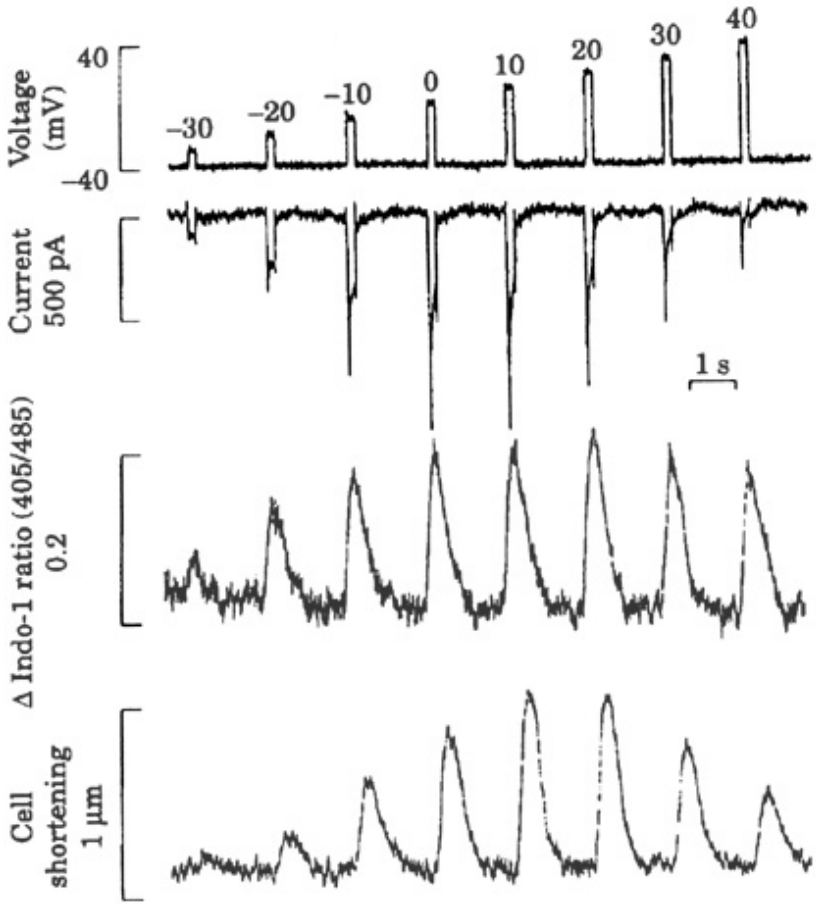

Figure 3-6: Intracellular Ca transient obtained with the bioluminescent dye Indo-1 is shown in the middle of this figure. It reflects the average instantaneous intracellular Ca ion concentration. The L-type Ca channel current modified by voltage clamping is shown in the top panel, and myocyte shortening is shown in the bottom panel. Note the voltage dependence of the Ca current and the parallel changes in both the Ca transient and shortening. (From Williams.[8] Reproduced with permission of the publisher.)

The amplification of Ca release inherent in CICR occurs because each DHP release channel induces release of Ca from more than one RyR channel (the exact number is unknown) and because of the very large Ca concentration gradient between the SR and the cytoplasm.[7,8,16,25] CICR results in an increase in the intracellular Ca concentration from a diastolic value of approximately 0.1 µ*M* to 1 to 10 µ*M* at the peak of the Ca transient. However, the actual amount of Ca released per beat constitutes only a small amount of the total stored (due to the binding proteins). The increase in intracellular Ca concentration is very transient because free Ca ions rapidly bind to the contractile proteins and are also removed from the cytoplasm by the Na-Ca exchanger and a specialized pump, the SR Ca ATPase (SERCA2).

In order for contraction to be turned off (i.e., for relaxation to occur), Ca ions bound to the contractile proteins must be returned to their storage sites in the SR, and the relatively small number that enter during the AP must be transported back to the extracellular space. As indicated earlier, the Na-Ca exchanger is

primarily responsible for extrusion of Ca out of the cytoplasm. There is also a sarcolemmal Ca pump that uses energy from ATP hydrolysis, but this does not appear to be an important means of Ca extrusion. The most important mechanism of reuptake of Ca ions by the SR is pumping by SERCA2, a SR membrane-spanning protein[7,13,27] (see Fig. 3-3). SERCA2 uses energy from ATP hydrolysis to rapidly pump the bulk of Ca ions released during CICR back into the SR. It competes with the contractile proteins and other potential uptake sites (Na-Ca exchanger, sarcolemmal ATPase, mitochondria) for Ca ions. Pump stoichiometry is two Ca ions for each ATP hydrolyzed. Functionally, Ca ions pumped back into the SR initially enter a "reuptake pool" and then move to a "release" pool.

The SERCA2 pump is partially self-regulating, since its speed increases in proportion to free Ca concentration (see below). It is also regulated by a closely associated SR protein, phospholamban (PLB), a key modulator of cardiac responses to adrenergic signaling.[28-33] PLB is a 52-amino-acid protein with a hydrophobic domain anchored in the SR membrane and a hydrophilic domain containing three phosphorylation sites. PLB inhibits SERCA2 activity, as exemplified by transgenic PLB knockout mice with increased basal cardiac contractility due to increased Ca cycling per beat but blunted adrenergic responses.[30,31] β-Adrenergic stimulation results in phosphorylation of PLB by activation of cyclic AMP-dependent protein kinase A (PKA). This reduces the inhibitory effect of PLB on SERCA2, resulting in increased Ca cycled per beat and an increased reuptake rate. These effects increase the rate and force of contraction as well as relaxation rate. (In addition to PLB phosphorylation, adrenergic stimulation of PKA also causes phosphorylation of L-type Ca channels,[8,15,34] resulting in increased transsarcolemmal Ca current and increased CICR via RyR channels.)

CONTRACTILE SYSTEM

The basic building block of the contractile system is the sarcomere[12] (Fig. 3-7), a recurring arrangement of the proteins responsible for mechanical activity. Adult myocytes are capable of increasing the numbers and changing the arrangement of sarcomeres in response to physiologic or pathologic changes in demands. An increase in sarcomeres in parallel increases force-producing capacity; an increase in series increases shortening capacity. Each sarcomere is composed of two bundles of longitudinally oriented filaments.[12] *Thick filaments*, approximately 1.6 μm long, are composed of myosin molecules in a trigonal array at the center of the sarcomere's length. Cardiac myosin is a member of a large family of myosins that function in various molecular motors. In addition to myosin, two other proteins are associated with the thick filament, titin and myosin-binding protein C. At each end of this array, a set of approximately 1-μm-long *thin filaments* composed of actin and the proteins tropomyosin (Tm) and troponin (Tn) interdigitates with the thick filaments. The other ends of the thin filaments extend to the ends of the sarcomere, where they attach to a transverse structure, the *Z-line*. The distance between sequential Z-lines is the sarcomere length. At a length of 2.2 μm (length at which maximal force is produced), the central end of each thin filament overlaps 0.7 μm of the distal ends of the thick filaments (the *overlap zone*). The 0.3-μm length of nonoverlapped thin filaments extending to the Z-line and the corresponding 0.3 μm of nonoverlapped thin filaments in the adjacent sarcomere constitute the *I-band*. The centrally positioned thick filaments constitute the *A-band*. Alternating A- and I-bands are responsible for the *striated* appearance of cardiac muscle. Thick filaments are joined at the *M-line* in the middle of the sarcomere.

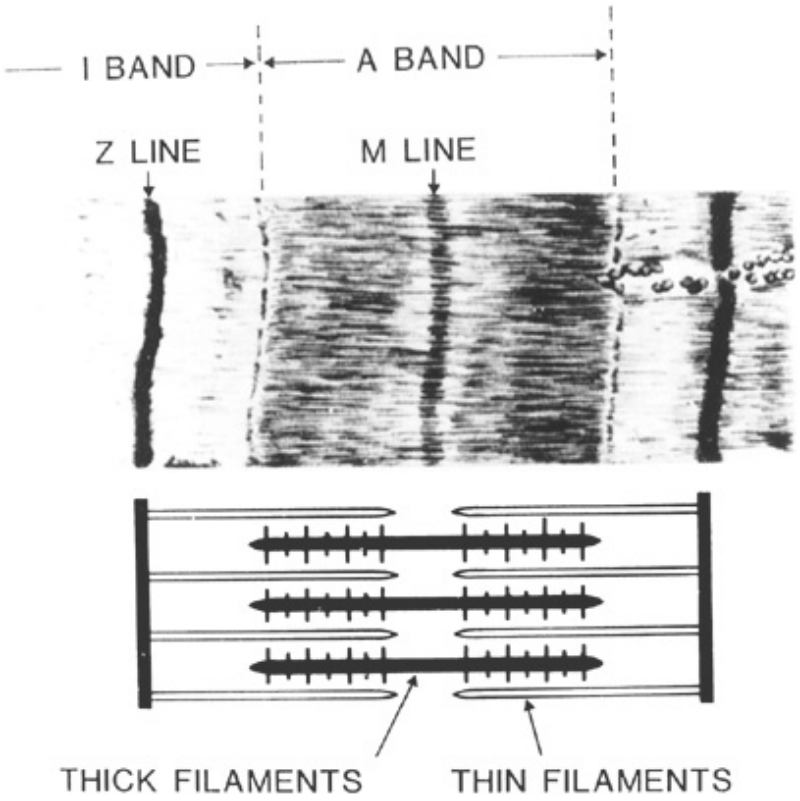

Figure 3-7: (*Top*) Electronmicrograph of sarcomere. (*Bottom*) Schematic (see text). (From Woledge et al.[58] Reproduced with permission of the publisher.)

As just indicated, a portion of each myosin molecule is oriented longitudinally to form the thick filament. In addition, a portion of the molecule protrudes from the thick filament surface and can move freely in the space between the thick and thin filaments (Fig. 3-8, Plate 28). This protruding portion includes the myosin *heavy chain* that forms the crossbridge, the molecular structure that interacts with actin and is responsible for conversion of chemical energy (high-energy phosphate bonds) to mechanical energy (force and motion).[35,36] The crossbridge head (myosin heavy chain) is a complex protein containing a domain that binds with actin and a site of ATPase activity.[37,38] Two auxiliary proteins (*light chains*) that have a role in maintaining the structural requirements for force generation (*essential light chain*) and providing fine control of force and motion (*regulatory light chain*) are adsorbed to the surface of the heavy chain. In mammalian cardiac muscle, myosin heavy chain exists primarily as two isoforms, alpha and beta.[37] The alpha isoform has higher ATPase activity and more rapid rates of crossbridge formation and velocity than beta and is dominant in adult small mammals.[38-42] The beta isoform is dominant in adult large mammals, including humans. Titin is a giant protein anchored in the Z-line on one end and closely associated with myosin on its other end.[43] A segment of titin has springlike properties and is an important determinant of the passive viscoelasticity of the myocyte[43,44] and, in turn, the ventricle. When cardiac muscle contracts below its slack, or unstressed, length, titin is compressed and recoils to its rest length.[43,44] This *restoring force* may have a role in diastolic suction (see below). Myosin-binding protein C is bound to both myosin and titin. It appears to have a role in sarcomere assembly and also may modulate myosin ATPase activity by virtue of variations in its phosphorylation.[45]

Actin monomers are arranged in a double helix to form the core of the thin filament[46-48] (Figs. 3-8, '3-9"">Plate 28, and). Tm is adsorbed longitudinally along the thin filament. Each molecule spans seven actin monomers, with a short overlap segment at the ends of adjacent Tms. Tn, composed of three subunit proteins, TnC, TnI, and TnT, is adsorbed on Tm, also in a ratio of 1 per 7 actin monomers. TnC contains a Ca-binding site, TnI variably binds to Tm and TnC (depending on activation), and TnT links Tn to Tm at the overlap zone. The combined Tm-Tn complex is responsible for the ability of Ca ions, binding to TnC, to act as a switch initiating crossbridge formation. TnI and TnT, the myosin regulatory light chain, and myosin-binding protein C all have phosphorylatable sites (mainly serines and threonines).[48,49] Phosphorylation of these contractile proteins, especially TnI and TnT, modulates the activity of myosin

ATPase, as described below.

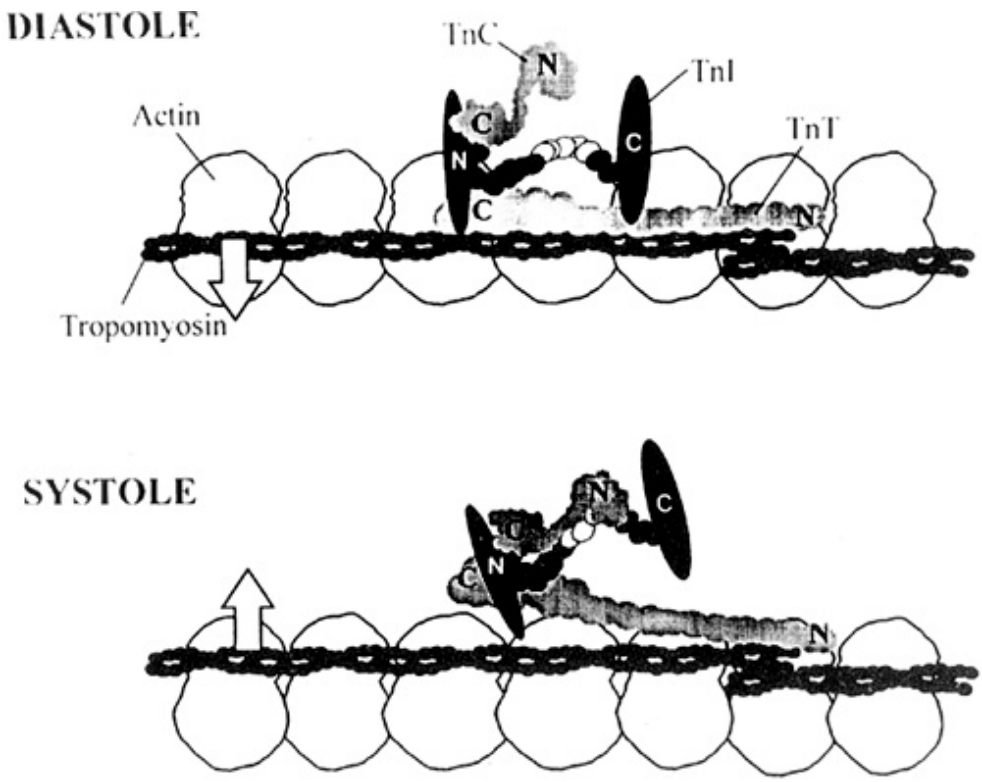

Figure 3-9: Cartoon of the thin filament with actin and regulatory proteins, Tm and Tn complex, showing conformational differences between inactive state (diastole) and activation (systole). C, COOH terminus; N, NH_2 terminus. (From Solaro and Rarick.[48] Reproduced with permission from the publisher.)

The sequence of events that ensues when the contractile system is activated by Ca ions entering the cytoplasm as a result of CICR may be summarized as follows[46-48] (see Fig. 3-9): In diastole, with low Ca concentration, Tm occupies a position on actin that inhibits interaction between actin and myosin. Strong binding between TnI and Tm appears to be responsible for maintaining this position. In the *steric blocking* model of Huxley,[50] it was hypothesized that in diastole Tm physically blocks any actin-myosin interaction; i.e., crossbridges are detached. It now appears that the situation is more complex.[48,51,52] At diastolic Ca concentrations, crossbridges exist in both a truly detached or *blocked* state and a weakly attached, non-force-producing state. Moreover, it is proposed that weakly attached crossbridges exist in two states, *closed* and *open*, depending on variations in the position of Tm on actin. With activation, Ca ions bind to TnC and cause a complex rearrangement of the Tn complex, with the most important element probably being a switch to strong binding of TnI to TnC rather than to Tm. The latter, in turn, causes a change in the position of Tm on actin that releases inhibition of actin-myosin interaction and, in addition, probably directly influences the kinetics of crossbridge formation by increasing the rate of transitions from the various non-force-producing to force-producing states.

Two other factors appear to be important in this process of *thin filament activation*. One is *nearest-neighbor interactions*[47,48] along the actin monomers, such that binding of Ca to Tn causes the process of crossbridge formation to spread down the thin filament (perhaps to as many as 12 to 14 adjacent monomers). This property appears to be related to activation-induced structural changes in TnT and Tm. The second is strong binding of actin to myosin,[48,53,54] which begins to occur once inhibition of the actin-myosin reaction is relieved. In and of itself, strong binding seems to encourage additional thin filament activation. Under most physiologic conditions, systolic Ca concentration does not achieve a level resulting in maximum force and/or shortening; i.e., the muscle is *submaximally* activated. Cardiac muscle is also highly cooperative; i.e., the relation between Ca concentration and force/shortening between diastolic and maximally activated

levels is very steep (Fig. 3-10). This property is thought to be due to both nearest-neighbor interactions and strong actin-myosin binding. Functionally, this means that contractile reserve can be recruited with modest changes in Ca concentration.

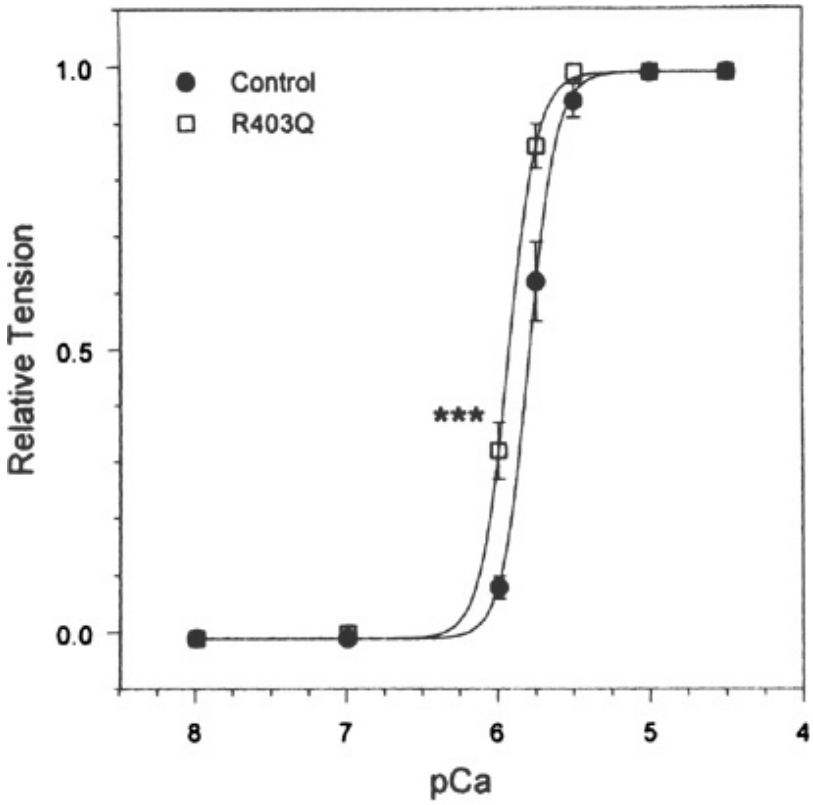

Figure 3-10: Relation between log Ca concentration (pCa) and isometric tension in detergent-treated ("skinned") strips of mouse cardiac muscle. R403Q indicates a transgenic animal with a mutation causing hypertrophic cardiomyopathy; control is wild type. Skinning results in loss of integrity of the sarcolemma and all intracellular membranes, leaving sarcomeric proteins intact. In skinned strip, the ionic milieu of the contractile proteins can be manipulated and their behavior studied in isolation from the excitation and ECC systems. Note very steep relation between isometric tension and pCa between relaxing (pCa >7) and fully activating Ca concentrations (pCa 5) in both strips. The relation is shifted to the left in R403Q mice. (From Blanchard E, Seidman C, Seidman JG, et al. Altered crossbridge kinetics in the αMHC403/+ mouse model of familial hypertrophic cardiomyopathy. *Circ Res* 1999; 84:475. Reprinted with permission of the publisher.)

Regardless of the details of thin filament activation, when Ca binds to TnC, the crossbridge cycle is switched on, and actin and myosin undergo a chemical reaction powered by ATP hydrolysis in which a series of transitions are made from detached/weakly bound states to force-producing states and back.[35,36,38,55-59] ATP hydrolysis actually occurs in conjunction with the transition from force production back to detached/weakly bound states. Energy released from hydrolysis of one high-energy phosphate bond is stored in the form of a molecular conformational change in the head of the crossbridge. While the myosin head is strongly bound to actin on the activated thin filament, conformational energy is released, causing the myosin head to rotate slightly as would the oar of a rower seated on the actin filament (Fig. 3-11). This motion generates a force propelling the thin filament along the thick filament toward the center of the sarcomere. The essential light chain appears to function as a lever arm between the thick and thin filaments. This process occurs repeatedly and randomly at millions of actin-myosin crossbridges, causing large-scale force and/or motion generation.

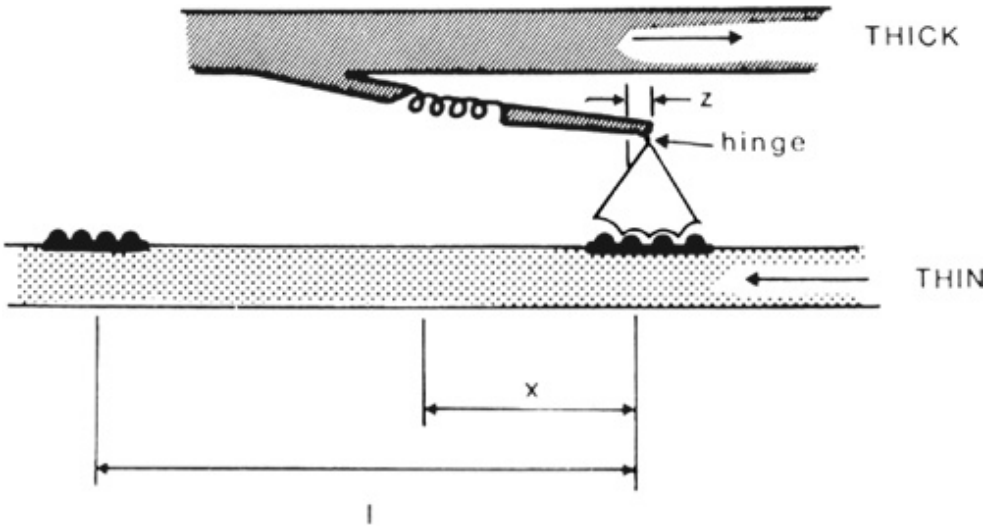

Figure 3-11: Schematic of the mechanical interaction between the myosin head (triangular structure) and actin located on the thin filament. Letter *z* denotes the distance moved by the thick filament as a result of rotation of the head region (see text). (From Woledge et al.[58] Reproduced with permission of the publisher.)

The amount of force and/or shortening that occurs as a result of crossbridge formation is related to the restraints, or *load*, placed on the muscle.[58-60] If no external restraining force is applied (i.e., *afterload* is zero), crossbridges propel the filaments at the maximum speed their chemical reactions permit, and a maximum amount of displacement and work are performed with no force generation. This is termed *unloaded shortening*. If shortening is opposed by an external load, such as during a physiologic contraction, crossbridge motion is slowed, allowing time for force to develop and more crossbridges to find binding sites on the thin filaments. At the other extreme, an *isometric* contraction in which the muscle is so restrained that there is no external shortening or work (i.e., afterload is greater than can be overcome by the ability to shorten), crossbridge energy is used almost exclusively for force development. This tradeoff between force and motion is reflected in the hyperbolic shape of the force versus velocity relation and the parabolic shape of the power or work versus load relation determined in isolated cardiac muscle (Fig. 3-12). There is also a reciprocal relation between load on the muscle and crossbridge cycling rate.[58-60] That is, the speed of the chemical reactions driving crossbridge attachment and detachment is sensitive to load and/or the resulting strains or displacements within the sarcomere. The mechanism of this relationship is uncertain, but it is a fundamental property of cardiac muscle that is required for normal function.

Another key determinant of mechanical performance of an activated sarcomere is its initial length, as reflected by the initial length of the muscle (its *preload*)[48-50,61,62] (Fig. 3-13). Force (or shortening) is maximal at an initial sarcomere length of approximately 2.2 μm and falls off very rapidly below approximately 2 μm. The ascending length-active tension/force relation is mainly caused by changes in activation of crossbridges as a function of sarcomere length.[61,62] This is most likely related to the fact that because the sarcomere maintains a constant volume, thick and thin filaments move farther apart at shorter sarcomere lengths.[63] The resulting change in geometry causes a decrease in the effective activation at any concentration of Ca; i.e., fewer crossbridges are formed. This *length-dependent activation* is the primary mechanism at the sarcomere level of the Frank-Starling law of the heart, i.e., the increase in contractile performance as ventricular preload increases. Previously it was thought that the Frank-Starling relation was best explained by changes in thick and thin filament overlap,[35,55] but the latter is probably a modest contributor at best. Although a *descending limb* of the length-tension relation is evident in isolated muscle, it does not appear to be present in the intact ventricle.

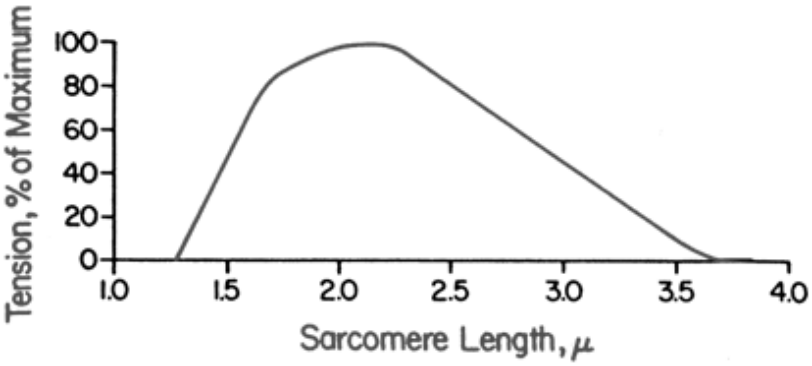

Figure 3-13: Schematic of relation between sarcomere length and developed tension (or force). Note fall in tension at lengths below approximately 2.2 μm. At very long sarcomere lengths, thick-thin filament overlap is reduced, resulting in descending limb of relation (not observed in ventricle). (Modified from Braunwald E, Ross J Jr, Sonnenblick EH, eds. *Mechanisms of Contraction of the Normal and Failing Heart*. Boston, Little, Brown, 1976:77.)

MYOCYTE RELAXATION

Myocyte relaxation is a complex process whose rate is determined by three main factors: the kinetics of crossbridge cycling (particularly the rate at which the crossbridges transition from a force-producing to a non-force-producing state), the affinity of Ca ions for TnC, and the activity and affinity of the main Ca reuptake and extrusion mechanisms.[64,65] All else being equal, slower kinetics of crossbridge cycling, increased Ca affinity for TnC, and reduced activity of SERCA2 and/or the Na-Ca exchanger slow relaxation. Relaxation is also modulated by the load on the myocyte, at least in part because of the aforementioned dependence of crossbridge cycling kinetics on load. As noted previously, relaxation also may be influenced by restoring forces generated by compression of titin.

ENERGY METABOLISM AND MECHANOENER-GETICS

Myocytes are heavily dependent on oxidative metabolism and endowed with large numbers of mitochondria. Under basal conditions, myocytes preferentially take up and oxidize fatty acids to generate ATP.[66-68] During stress, however, glucose uptake, glycogenolysis, and glycolysis become increasingly important. Certain ion pumps, e.g., SERCA2, may be especially dependent on glycolytic ATP.[69] Nitric oxide (NO) generated by vascular endothelium decreases myocardial oxygen consumption (VO_2) due to a direct effect on mitochondrial respiration, and may have a significant role in normal control of energy production and utilization.[70-72]

The processes that account for the great majority of myocardial energy consumption are crossbridge cycling (myosin ATPase), Ca reuptake by the SR (SERCA2), and basal metabolism.[59] Each crossbridge cycle consumes one high-energy phosphate bond, although at very rapid cycling rates it may be possible for one ATP to fuel more than one cycle. SERCA2 uses one high-energy phosphate bond for every two Ca ions pumped. As indicated earlier, the rate of energy consumption is heavily dependent on loading conditions and resulting work and power generation.[58,59] The thermodynamic efficiency of heart muscle, its total mechanical energy output divided by its total chemical energy input, is uncertain, in large measure because of difficulties in quantifying *total* energy output. A more conventional approach is estimation of efficiency of external work production.[58] External work efficiency is heavily dependent on loading conditions, ranging from a maximum under unloaded conditions to zero for an isometric contraction. Additional mechanoenergetic concepts are discussed below under ventricular function.

Cellular Control of Contractility

This section is divided into intrinsic and extrinsic control systems. *Intrinsic control* includes adaptive mechanisms that are components of the normal mechanical behavior of cardiac muscle. *Extrinsic control* includes both adaptive mechanisms that require the elaboration/secretion of a cardioactive substance by the myocyte or some other cell type and classic neurohumoral modulation of myocyte function.

INTRINSIC CONTROL SYSTEMS

The most obvious is the *length-dependent activation* underlying the Frank-Starling relation. This allows heart muscle to adjust its performance on a beat-to-beat basis, e.g., with respiration and changes in body position, and is discussed further under ventricular function.

Another important intrinsic control mechanism is the *force-frequency relation* (FFR)[73-75] (Fig. 3-14). At a basal rate of 60 per minute, the duration of the myocardial twitch contraction is such that relaxation would be incomplete at rates achieved during exercise and cause impaired diastolic filling. Therefore, the myocardium must have mechanisms that automatically speed contraction and relaxation at rapid rates. In conjunction with this abbreviation of contraction, the strength of contraction is markedly enhanced, allowing maintenance of SV even though less time is available for filling and emptying. The mechanism of the positive FFR involves increased and more rapid Ca cycling per beat as frequency increases.[8,59,76-79] Factors contributing to this include the direct effect of a greater number of APs per unit time, causing intracellular accumulation of Ca ions, as well as increases in SR Ca pumping. Thus Ca entry increases directly with more frequent opening of L-type Ca channels and indirectly when the Na-Ca exchanger extrudes excess Na ions arising from the increased frequency of sarcolemmal Na channel opening. Operating in isolation, these factors would risk elevation of diastolic Ca concentration. However, SR Ca pump speed increases concomitantly, increasing relaxation rate and abbreviating the contraction. In addition to PLB, SERCA2 activity is under the control of another protein, *Ca-activated calmodulin kinase*, which increases SERCA2 activity in response to increased Ca concentration and has built-in frequency sensitivity. Slight, transient increases in Ca ions, even if insufficient to directly activate the kinase, are held in binding sites long enough so that repeated increases are summated. This averaging process results in increased speed of the SERCA2 pump in response to increased average and instantaneous Ca concentration.

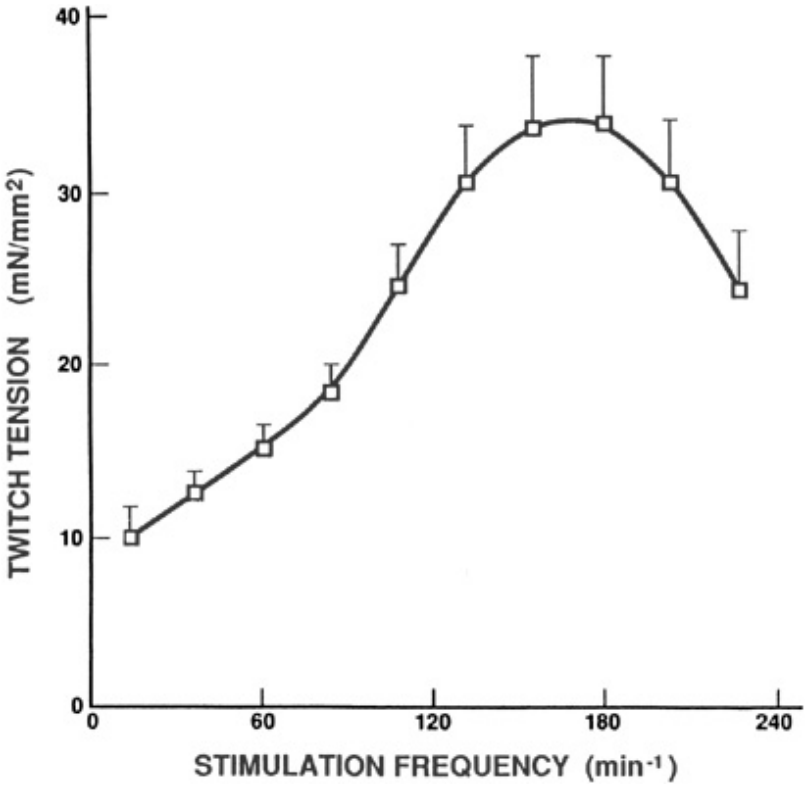

Figure 3-14: Example of average relation between developed force and stimulation frequency in strips of human myocardium obtained by epicardial biopsy from a group of patients undergoing coronary bypass surgery, all with normal LV contraction patterns. Note the marked increase in force as contraction frequency increases from typical basal level of 60 per minute to a value of 170 to 180 per minute, at which force is maximal (see text).

The FFR appears to depend on the intactness of multiple elements of Ca handling, as evidenced by the fact that it is depressed in a number of conditions in which the myocardium is diseased and/or subjected to chronic stress.[73,74,76,80] The ratio of SERCA2 pumps to PLB protein has been proposed as an important determinant of its magnitude.[77] Moreover, the FFR is markedly amplified by increased β-adrenergic stimulation.[75] Thus, during stress, increased adrenergic stimulation not only increases HR but also increases the magnitude of FFR occurring in response to the increase. This amplification appears to be related to cyclic AMP-mediated phosphorylation of PLB.[30]

EXTRINSIC CONTROL SYSTEMS

The best understood, most extensively characterized and important extrinsic control mechanism is modulation of contractility by adrenergic and cholinergic neural discharge and circulating catecholamines.[75,81-85] Increased adrenergic stimulation markedly increases contractile strength, relaxation, and HR. These effects on the myocardium may be explained as follows: Normal myocytes contain predominantly β_1 receptors, with a minority of β_2 receptors. Agonist binding to β_1- or β_2-adrenergic receptors on the surface of the cell membrane results in an interaction between membrane-associated G protein and guanosine triphosphate (GTP) in which GTP combines with active subunit G_s, which activates enzymatic conversion of ATP to cyclic AMP by *adenylate cyclase* on the cytoplasmic side of the receptor complex. Cyclic AMP in turn activates PKA, which phosphorylates both the L-type Ca channel, altering its gating to allow more Ca ion entry per AP, and PLB, which increases SERCA2 pumping. This results in more rapid removal of Ca from the contractile proteins (faster relaxation), a larger amount of Ca cycled per beat (increased activation), and potentiation of the FFR. PKA also phosphorylates TnI, resulting in decreased Ca affinity for TnC, an effect that also facilitates relaxation. Increased cholinergic stimulation decreases contractility, possibly by activation of nitric oxide synthase-3 (NOS-3) (see below). Cholinergic stimulation, though, has a much weaker influence on contractile performance than adrenergic stimulation. Cholinergic responses are important modulators of HR, however.

A number of other naturally occurring substances modulate myocyte function. These include circulating neurohormones as well as molecules produced by myocytes themselves and vascular endothelium. Alterations in these substances and their effects on myocardial function may be critically important in disease. The normal physiologic roles of these substances have been variably and in no case fully delineated, but they are almost certainly less important than the intrinsic and extrinsic control systems already discussed. Accordingly, some but not all will be discussed briefly. These substances and their complex signaling pathways are also discussed in Chaps. 5 and 6.

NO is produced in endothelial cells in proximity to cardiac myocytes and in myocytes themselves.[70-72,86,87] NOS-3 is the predominant form of nitric oxide synthase in the myocyte. NOS-3 is Ca-sensitive and is activated by levels of intracellular Ca achieved during normal beating and by muscarinic cholinergic agonists. NO produced in the myocyte or in adjacent endothelium has a negative inotropic effect, mediated via cyclic GMP.[72,86,88] The mechanism appears to involve myofilament desensitization to Ca, possibly via protein kinase G phosphorylation of TnI. NOS-3 activation also blunts catecholamine responses. Inflammatory cytokines also activate NOS-3,[88] an observation that may be important in disease. Endothelial-derived NO may have somewhat different effects than myocyte-derived NO. Thus endothelial-selective, NO-dependent vasodilators cause early and somewhat accelerated relaxation with only a modest negative inotropic effect. Although effects of NO on contractile performance have been observed in normal humans, their physiologic significance is uncertain. *Atrial natriuretic peptide* (ANP) and *brain natriuretic peptide* (BNP) produced in atria and ventricles, respectively, are naturally occurring vasodilators and diuretics. These substances appear to have effects on myocyte function similar to endothelial-derived NO. While increased secretion of these hormones has great significance in heart failure, their role in normal physiologic control of myocyte function also has not been defined.

A number of agonists, including α_1-*adrenergic agonists*,[89] *endothelin-1* (ET-1),[90-92] and *angiotensin II* (ATII),[93-95] influence myocyte function through activation of phospholipase with resulting production of inositol triphosphate (IP_3) and diacylglycerol (DAG).[96-98] (It is now well established that the heart has its

own ATII-generating system.[93-95]) IP_3 increases the release of intracellular Ca during contraction through as yet poorly understood mechanisms. DAG appears to be more importantly involved in myocyte functional responses. Its effects are mediated through activation of protein kinase C (PKC).[96-100] The effects of DAG and PKC activation have been somewhat controversial. This may be related to the fact that the effects of DAG or its analogs administered intracellularly (the normal "route") differ from those when they are administered extracellularly.[98] On balance, activation of PKC by the preceding agonists appears to result in a complex, slowly appearing, sustained positive inotropic effect. Mechanisms that may account for this effect are increased intracellular Ca due to phosporylation of L-type Ca channels and PLB. In addition, phosphorylation of the sarcolemmal Na-H exchanger may increase contractility by increasing intracellular pH. However, activation of PKC also has distinctive and contrasting effects on the contractile proteins via phosphorylation of both TnT and TnI.[47,48,101] The result is a reduction in myofibrillar ATPase activity with attendant decreases in crossbridge cycling rate, an effect that by itself would reduce measures of contractility such as rate of tension development or shortening, as well as relaxation rate. The integrated response to agents such as ET-1 is a net positive inotropic effect that may be relatively economical with respect to energy consumption because of the concomitant effects on crossbridge cycling.

Structure and Function of the Ventricles

ARCHITECTURE

The human LV is a thick-walled chamber (average approximately 1.0 cm at ED) with a truncated ellipsoid shape composed of spiraling, sheetlike layers of myocyte bundles (Fig. 3-15). The orientation of the bundles changes from subepicardium to subendocardium, progressing from relatively longitudinal (in relation to the long axis of the ellipsoid) to roughly circumferential fibers occupying about the middle two-thirds of the wall to longitudinal fibers once again in the subendocardium.[102] Regional wall thickness parallels the local radius of curvature. Near the apex, where the radius is small, thickness is relatively small. Variations in thickness may function to equalize regional wall stress.

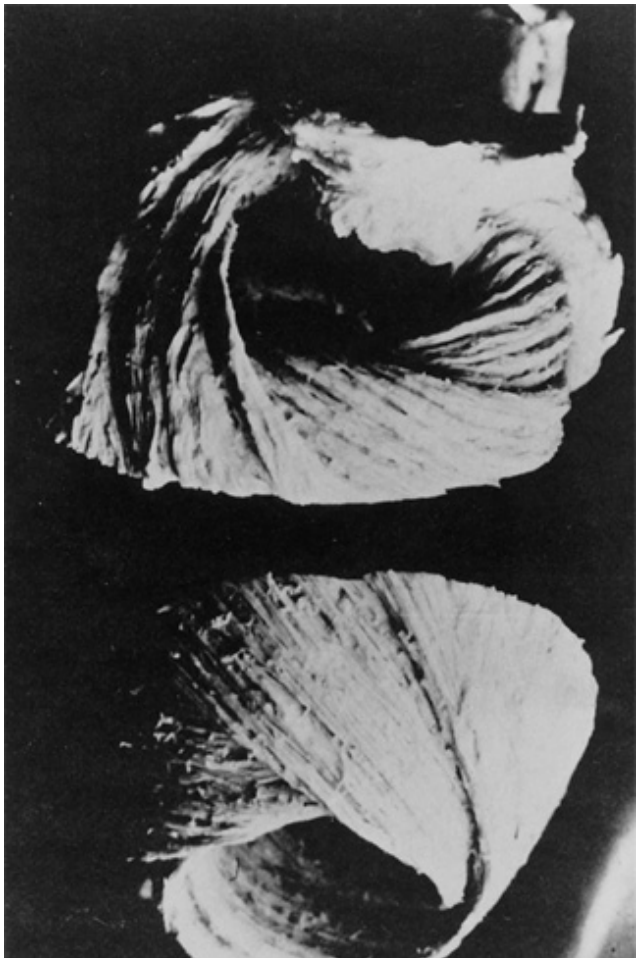

Figure 3-15: Three-dimensional architecture of LV, illustrating spiraling bundles of myofibers (see text). (From Streeter.[102] Reprinted with permission of the publisher.)

Contraction of the LV is associated with a wringing motion, or torsion, characterized by a counterclockwise rotation that progressively increases from base to apex.[103] Torsion is important for normal ejection and is an inherent feature of the normal spread of excitation and the connections between the fiber bundles.[104] It also is likely a storage mechanism for potential energy generated during systole that is converted to kinetic energy during diastole, assisting filling by suction.[105] This complex architecture results in efficient conversion of the shortening of individual myocytes and fibers to wall thickening, which is ultimately responsible for ejection of blood. Thus, even though individual fibers shorten only about 10 percent, the normal LV ejects about two-thirds of its ED volume. Interventricular septal fibers have a similar orientation and are continuous with those of the LV free wall. As a result, the septum normally functions as a part of the LV; i.e., during contraction, its endocardial surface undergoes more or less symmetric inward movement toward the center of the LV.

In line with the high-capacitance/low-resistance nature of the pulmonary vascular bed, the RV is much thinner-walled than the LV (3 to 4 mm in an adult human) and appears crescentic in cross section.[102] Its contraction has been likened to that of a bellows. The RV inflow and outflow portions are functionally distinct, with inflow contraction preceding outflow contraction.[106] A significant fraction of the mechanical output of the RV appears to be related to energy transfer from the LV through the interventricular septum (systolic ventricular interaction).[107] This is supported by the observation that destruction of much of the free wall of the RV is remarkably well tolerated.

Ventricular myocardium also has a well-developed connective tissue matrix.[108-110] Cardiac collagen is organized into a weave of fibers that forms a netlike structure around the myofibers (groups of six or more myocytes), as well as connections that link adjacent myofibers and strutlike projections connecting to adjacent blood vessels. The latter may function to help maintain vessel patency during contraction. The collagen network of the ventricles is an important determinant of their passive filling properties (see discussion below). The last major component of the ventricles is the vascular bed, described below.

THE VENTRICLE AS A PUMP

Normal pumping of the ventricles requires that they deliver appropriate amounts of blood to the tissues at acceptably low filling pressures (FPs). Thus the most physiologically relevant means of characterizing the pump is to construct a *function curve* relating FP to a measure of mechanical output (SV, minute volume, work, power). Ventricular function curves display a prominent *Frank-Starling effect*, manifest as a curvilinear relationship between FP and output (once again, there is no descending limb in the normal ventricle) (Fig. 3-16). As discussed earlier, at the myocyte level, the Frank-Starling effect is mainly caused by increased myofilament Ca sensitivity at longer sarcomere lengths. Thus a function curve relating ED *volume* (ventricular *preload*) to mechanical output is a more accurate representation of the ventricular Frank-Starling effect. However, in the clinical setting, FP (pulmonary capillary wedge or RA pressure) is usually more readily available than volume. Whether FP or volume is employed, changes in intrinsic contractile performance result in upward or downward shifts of the ventricular function curve. However, characterization of ventricular performance in terms of function curves relating FP to output is a "black box" approach; alterations in diastolic compliance (see below) produce effects that are indistinguishable from alterations in contractile performance.

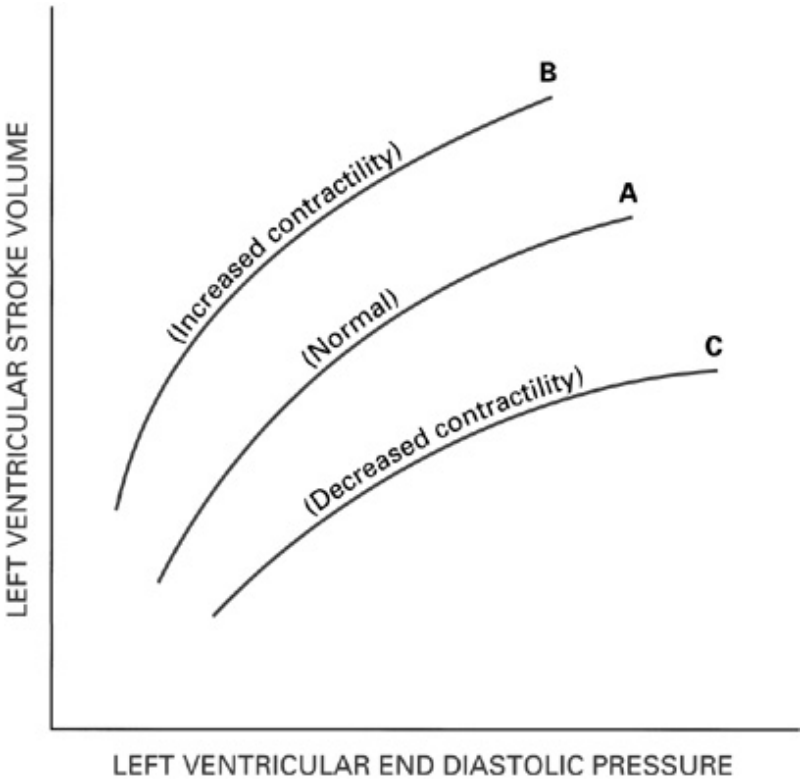

Figure 3-16: LV function curves relating SV to ED pressure (see text). *A*. Normal function. *B,C*. Augmented and depressed contractility, respectively, as occur with increases or decreases in adrenergic stimulation. Because ED pressure is plotted, identical shifts could be observed with altered diastolic compliance.

The normal heart can pump adequate amounts of blood to meet the needs of the body under the most stressful conditions. Indeed, maximal CO normally is not limited by pumping capacity but by the ability of the systemic circulation, via venoconstriction and the systemic venous system of valves and muscular pumps, to return blood to the heart.[111] Under pathologic conditions, pumping capacity may limit CO.

THE VENTRICLE AS A MUSCLE

For convenience, it is useful to consider contraction (systolic performance) as distinct from relaxation and filling (diastolic performance). This distinction is arbitrary, however. The two aspects of function overlap and interact.

Systolic Function

Systolic performance of the ventricle traditionally is characterized in terms of loading conditions (preload, afterload) and contractility.[112] Although *contractility* is a term that is employed frequently and often perfectly reasonably, it is difficult to define. We use it here as a *comparative concept* to connote differences in the intrinsic level of contractile performance either before or after some intervention *in the same heart* or *between different hearts* that cannot be accounted for by differences in loading conditions. Thus one way to define a change or difference in contractility is as a change or difference in contractile performance when loading conditions are unchanged or can be accounted for, e.g., increased shortening despite increased afterload. Unfortunately, this is often impossible in the intact heart, especially in the clinical setting. Further, any definition of contractility that attempts to neatly separate it from loading conditions inevitably encounters the fundamental problem that the two are not really separable. A good example of this problem is the Frank-Starling relation, in which *preload* influences *intrinsic* contractile performance by modulating myofilament Ca sensitivity. Similarly, afterload, by influencing shortening, determines instantaneous length and myofilament Ca sensitivity during the course of contraction. Thus, while contractility is a useful concept, the notion that it is possible to define *load-independent* contractility indices is not entirely realistic.

Loading Conditions and Contractile Performance

In classic, isolated muscle experiments,[58,60] a force in the form of a weight is applied to one end of a quiescent, quasi-linear muscle (e.g., a cardiac papillary muscle) whose other end is tethered (Fig. 3-17). This force is the *preload*, which stretches the muscle to some initial length preceding contraction. The muscle is then simulated electronically to contract and lift an additional weight, the *afterload*. Once stimulated, the muscle develops tension or force until it just meets and then slightly exceeds the opposing force of the afterload. At this point in time, the muscle can begin to lift the afterload, and shortening commences. In this system, once shortening begins, the developed force and afterload are constant (*isotonic* contraction). Force or afterload is reciprocally related to the magnitude and velocity of shortening; muscle performance is often characterized as the force-velocity or force-shortening relation (see Fig. 3-12), with upward or downward shifts reflecting changes in contractility. If both ends of the muscle are tethered, or if the afterload simply exceeds the force-generating capacity of the muscle, an *isometric* contraction ensues, in which tension is generated, but no shortening occurs. By varying the preload, the Frank-Starling effect (see Fig. 3-13) can be delineated by relating the initial length to shortening (isotonic contraction) or developed tension or force (isometric contraction).

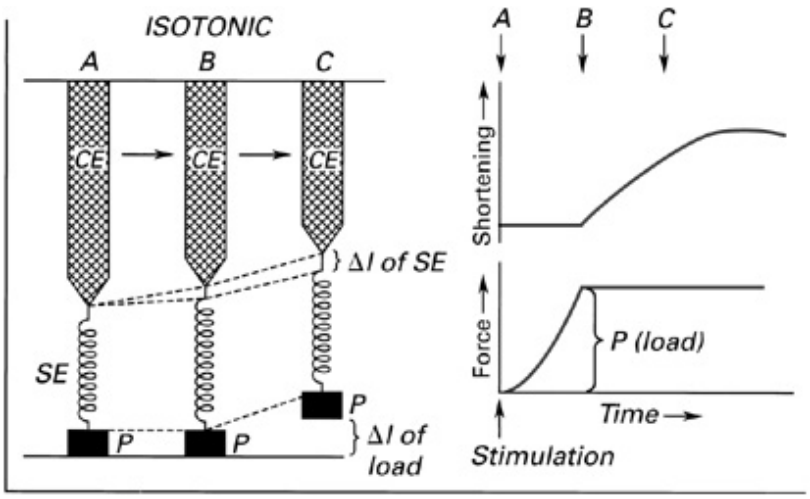

Figure 3-17: Schematic illustrating concept of preload and afterload during isotonic contraction. (*Left*) Linear muscle is depicted as consisting of contractile element (CE) (i.e., thick and thin filaments) and spring in series (SE). (*Right*) Shortening and force are depicted. *A*. Muscle is at rest, with one end tethered and the other connected to a weight (P). P is supported, however, so that muscle is only subjected to a fraction of weight (or load). This relatively small load is the preload, which stretches the muscle to the initial, resting length. *B*. Muscle begins to contract. In order to shorten, it must lift the entire weight P, which is the afterload. Initially, force increases but is insufficient to lift the weight. During this period, the CE shortens and reciprocally lengthens the SE, while total muscle length remains constant. Eventually, the developed force just exceeds the afterload, and the muscle begins to shorten (*C*). Once shortening begins, force is constant and essentially equal to the afterload. In an isometric contraction, the muscle cannot lift the load and therefore does not shorten (although the CE shortens and SE lengthens by the same amount).

In isolated muscle, load also can be expressed as *stress* (force normalized to cross-sectional area). Normalization allows comparison of muscles of different size. Normalization for stress can be transferred to the ventricle, most easily the LV because of its relatively symmetrical shape. Estimation of LV wall stress can be accomplished by using the LaPlace relation.[113] For a relatively thick-walled sphere, the LaPlace relation states that the average wall stress equals (pressure × internal radius) divided by twice the wall thickness. Variants of this equation can be employed to account for the actual shape of the LV, fiber orientation, and other geometric and structural features. Thus, for an ellipsoid, the ratio of the long to short axis (a measure of how ellipsoidal the shape is) modifies the stress; as shape changes from less to more spherical, wall stress increases.

Use of the LaPlace relation allows an estimate of the stress "seen" by the myofibers as the ventricle fills and

then contracts against its afterload. In diastole, the stress applied to the myofibers constitutes their preload and determines initial length at the beginning of the next contraction. During contraction, the stress resulting from both the preload and the afterload (or systolic load) determines the velocity and extent of ejection. Total systolic load presented to the LV by the vascular system has two components, a resistive load determined at the level of small systemic arteries and arterioles by microvascular tone and a smaller capacitive load determined by the properties of the large arteries, which absorb a certain amount of blood pumped via expansion of their walls.[114] As mentioned earlier, a component of vascular load is caused by reflection of pressure waves back to the heart from the periphery. In contrast to classic, isolated muscle experiments, during ventricular contraction, both afterload and developed wall stress vary.

Estimates of *systolic* stress using the LaPlace relation are helpful clinically in assessing and comparing contractile performance.[115] This can accomplished by relating some measure of shortening [e.g., ejection fraction (EF), defined as SV/ED volume] or shortening velocity [e.g., mean velocity of circumferential fiber shortening (V_{cf}); see discussion below] to a measure of systolic stress [e.g., peak, end-systolic (ES), or mean]. The ventricle behaves in a qualitatively similar fashion as isolated muscle; i.e., afterload (wall stress) is reciprocally related to shortening. As shown in Fig. 3-18, the stress-shortening relation can be characterized in a normal population with single data points obtained invasively or using noninvasive techniques such as echocardiography and cuff sphygmomanometry. If the value in a given patient falls above or below the normal range, this may indicate an alteration in intrinsic contractile performance.

Clinically, the most commonly employed index of ventricular contractile function is the EF (from angiography, echocardiography, or radionuclide ventriculography). Fractional shortening (minor axis diameter shortening/ED minor axis diameter) is calculated routinely from the echocardiogram and is interchangeable with EF, provided there are no regional wall motion abnormalities. Both these shortening measurements are sensitive to alterations in preload and afterload.[112] Thus normal values are indicative of normal intrinsic contractile function only if loading conditions are also normal.

Elastance Concepts in the Assessment of Ventricular Contractile Function

As an alternative to characterization of systolic function in terms of stress and shortening, Suga and Sagawa proposed an elastance approach.[116-118] This is based on the empirical observation that during systole the ventricle behaves like a spring with a time-varying elastance (or stiffness) that increases from a minimum at ED to a maximum at ES (Fig. 3-19). The elastance of a spring is the slope of the linear relation between the stress or force applied to stretch it and its length normalized to its unstressed or rest length. A "stiffer" spring requires a larger stress to extend it by a given length. By analogy, ventricular elastance is the relation between pressure and volume at any time during systole normalized to a volume at which the pressure is zero (*dead volume*, V_0 or V_d).

At any time during contraction, elastance can be estimated by varying loading conditions and generating a series of pressure-volume loops with varying ES volumes. In their original studies, Suga and Sagawa used isolated, perfused canine ventricles with controlled loading conditions and volumes.[116,117] Analysis of such a series of pressure-volume loops (see Fig. 3-19) reveals that at any time *t* during *each of the series of variably loaded contractions* (e.g., 100 ms after the start of contraction), the relation between pressure and volume is linear, and its slope reaches a maximum (maximal elastance) at ES, or t_{max}. (The volume axis intercept can be measured directly or extrapolated from the linear pressure-volume relation at any time *t*.) Elastance then decreases as the ventricle relaxes. The slope (E_{max}) of the end-systolic pressure-volume relationship (ESPVR) changes with acute positive and negative inotropic interventions. Specifically, E_{max} increases with positive inotropic interventions and decreases with negative inotropic interventions, whereas V_0 usually does not change. Based on these observations and initial studies suggesting that ED volume did not influence the ESPVR, it was thought initially that E_{max} offered the possibility of an index of contractility that was "load independent." Subsequent studies, especially those performed in the in situ heart and circulation, have modified these original conclusions.[118] Thus the ESPVR is often significantly curvilinear, especially with augmented or depressed contractility. Furthermore, as expected based on the concept of length-dependent activation, it is influenced to some extent by preload (ED volume) and also can be modified by the way in which afterload is varied (e.g., resistive versus capacitive load change).

Systolic interaction also can modify the ESPVR.[119] E_{max} must be used with caution in comparing different hearts because of difficulties in normalizing ES relationships for size and variable curvilinearity. To overcome these problems, the ESPVR has been modified by calculating ES myocardial stiffness based on wall stress estimates, and comparative analyses have been devised that take curvilinearity into account.[115,120-123] Last, the pressure-volume approach does not include rate of change of these parameters and therefore does not capture power output,[58,112] an important aspect of performance.

Despite the aforementioned cautions, the ESPVR has proven to be a useful conceptual approach to assessment of contractile function in the experimental laboratory and the clinic. Measurements have been made in hearts as small as that of the mouse,[124] whereas estimation of ES pressure and/or stress-volume relations can be obtained in patients.[115,125] Although it corresponds to only a single point on the ESPVR, the ratio of systolic arterial pressure (as a surrogate for ES pressure) to ES volume determined *noninvasively* using cuff sphygmomanometry and echocardiography also has been used as an index of ventricular function. Moreover, despite the empirical nature of the original observations, the elastance approach has been shown to be very consistent with the molecular physiology of ECC and crossbridge cycling.[126]

Two extensions of elastance theory have proven valuable in understanding ventricular function. The first is its application to ventricular *mechanoenergetics*.[127] The main determinants of VO_2 traditionally have been considered HR, afterload, and contractility (basal metabolism accounts for a significant fraction of VO_2 but is not subject to much variability). HR is obviously a critical determinant of energy consumption per unit time. However, the difficulty in even defining contractility was discussed earlier. Moreover, it is not obvious how contractility or afterload is related *quantitatively* to the two major energy-consuming processes in heart, ECC and crossbridge cycling.

As proposed by Suga,[127] use of elastance theory to quantify mechanoenergetics is based on quantification of the *total mechanical energy* of contraction. Total mechanical energy consists of two components (Fig. 3-20, top), *external work* (EW), which can be quantified as the area enclosed within the pressure-volume loop of a contraction, and *potential energy* (PE), which is dissipated as heat during relaxation and possibly also converted to kinetic energy used for filling the ventricle by suction (see below). To understand PE in this context, consider an isovolumic contraction, which can be produced experimentally. Such a contraction obviously generates mechanical energy, but none of it is EW; i.e., it is all PE. As afterload is reduced and shortening and work increase, the ratio of EW to PE increases. The novelty of elastance theory in quantifying total mechanical energy is that it provides a basis for quantifying PE. In elastance theory, the PE stored in a spring is the area under its elastance relationship between its rest length and its actual length. Correspondingly, in the ventricle, PE for any beat can be considered the area under the ESPVR between its ES point and V_0 (see Figs. 3-19 and 3-20). The sum of EW and PE is total mechanical energy and is termed *pressure-volume area* (PVA). The relation between PVA and VO_2 requires knowledge of the ESPVR and can be delineated by widely varying loading conditions while measuring LV VO_2. This is done most easily in isolated, perfused heart preparations.[123,127,128] PVA has a remarkably high linear correlation with VO_2 in several species, under a variety of loading conditions, and in both normal and abnormal hearts[123,124,127,128] (see Fig. 3-20, bottom).

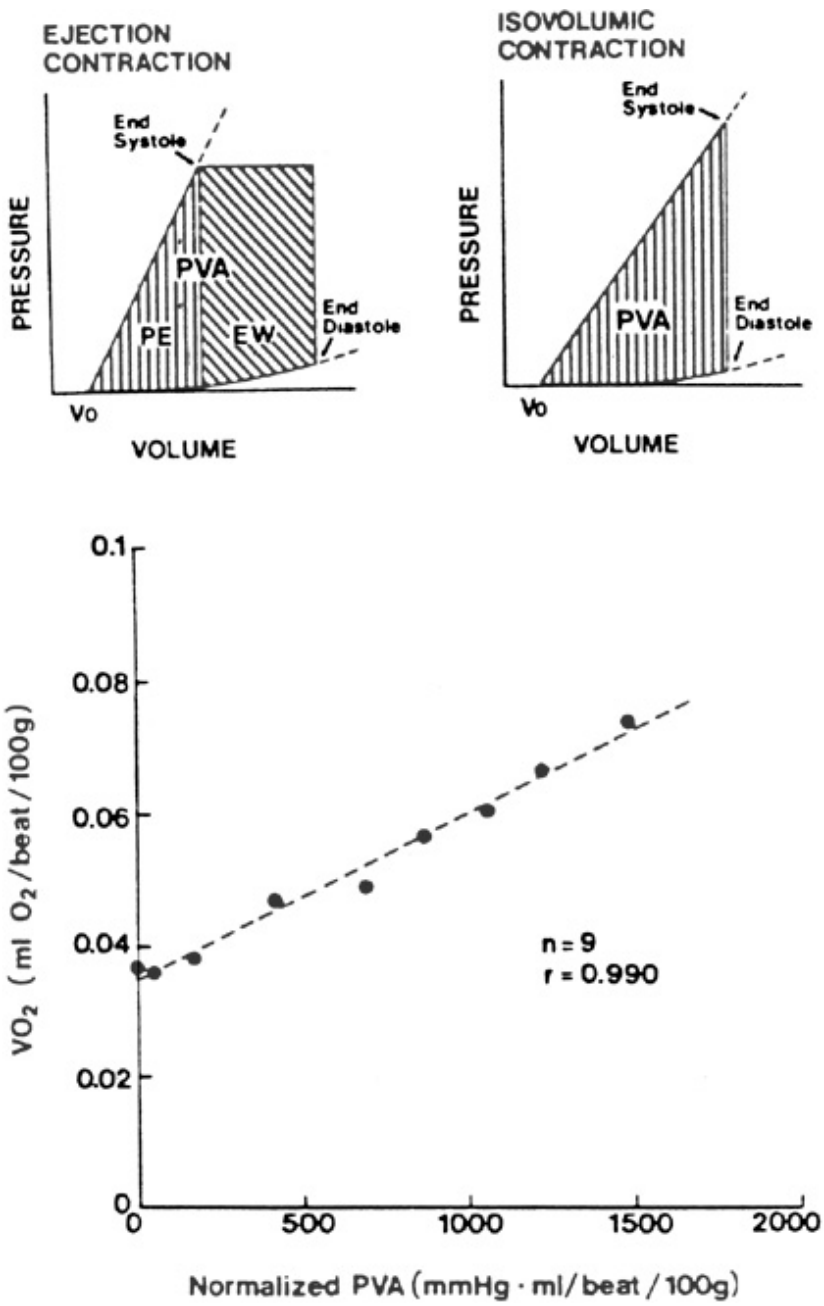

Figure 3-20: (*Top*) Schematic of VO_2-PVA concept (see text). In ejecting contraction, PVA = EW + PE; in isovolumic contraction, PVA = PE only. (*Bottom*) Correlation of PVA with VO_2. (From Goto et al.128 Reproduced with permission of publisher.)

The linear VO_2-PVA relation has a positive VO_2 axis intercept (see Fig. 3-20), unloaded VO_2, or O_2 consumption at zero PVA, when virtually no mechanical energy is produced. Unloaded VO_2 is largely accounted for by basal metabolism and Ca pumping by SERCA2, which continue under unloaded conditions. Subtraction of unloaded VO_2 from total VO_2 provides an estimate of VO_2 used by the contractile machinery, or PVA-dependent VO_2. Since VO_2 can be converted to units of energy, the ratio of PVA to PVA-dependent VO_2 (total mechanical energy output divided by total chemical energy input), or simply the inverse slope of the linear VO_2-PVA relation, is an estimate of the *efficiency* of conversion of O_2 to mechanical energy by the contractile machinery. Variations in myosin ATPase activity modulate efficiency assessed in this fashion.[124,129]

Based on the preceding analyses, it can be understood how changes in afterload and contractility as well as preload can alter myocardial energy demands and consumption (see Fig. 3-20). Assuming no change in ED volume or afterload, increased contractility increases E_{max}, resulting in a smaller ES volume and increased

EW at any preload. Even though ES volume is smaller, which in and of itself decreases PE, this is at least partially compensated by increased E_{max}, which serves to increase the area under the ESPVR. The net result is increased PVA in association with more energy used for crossbridge cycling by the contractile machinery. Most positive inotropic interventions increase the amount of Ca cycled per beat and, in turn, energy consumption by SERCA2, resulting in increased unloaded VO_2. Increased afterload increases the level of pressure at which the pressure-volume loop intersects the ESPVR, increasing PE with variable effects on EW but a net increase in PVA. In the whole LV, increases in preload have not been considered to markedly alter myocardial energy demands. Assuming constant contractility (ESPVR) and afterload, it is evident that changes in ED volume (preload) should modify EW and therefore PVA and VO_2 in direct proportion to the magnitude of the change. However, it is likely that under basal conditions the LV operates at an ED volume not too far from the point at which the diastolic pressure-volume relation becomes relatively steep. Thus there is not a great deal of room for the LV to acutely increase its preload (although its FP certainly may increase considerably). This may explain the modest effect of preload on VO_2.

A second application of elastance theory is ventricular-vascular coupling.[130,131] Just as the ventricle can be considered in terms of an elastance relationship, systemic arteries also can be characterized by an elastance relationship. Arterial elastance is largely a function of the properties of the large arteries. There exists an optimal relationship between ventricular and arterial elastance at ES such that energy transfer from the heart to the periphery is most efficient; i.e., the largest possible proportion of total mechanical VO_2 is converted to EW. In essence, this merely states that arterial loading influences the point at which the pressure-volume loop intersects the ESPVR and therefore the proportion of PVA converted to EW. The normal heart and vascular system operate at nearly optimal ventricular-vascular coupling. Vasoactive drugs can influence ventricular-vascular coupling. Moreover, in heart failure, coupling is adversely affected, resulting in less efficient transfer of energy from the heart to the vascular system.[132]

Other Approaches to Assessment of Systolic Ventricular Performance

Following is a sampling of a number of indexes that have been proposed to assess systolic function. Maximal rate of pressure rise (max *dP/dt*) is very sensitive to changes in intrinsic contractile performance but also varies somewhat with preload.[133,134] It is not markedly influenced by changes in afterload. Max *dP/dt* is especially useful in quantifying acute changes in contractility. Its use for comparisons between different patients is limited by large interindividual variations. *Mean circumferential fiber shortening* velocity (V_{cf})[135,136] is LV internal minor axis shortening ÷ (ejection time × ED minor axis dimension). It is readily calculated from echocardiograms. Although quite sensitive to changes in afterload (as is any shortening measurement), it is a useful measure of intrinsic contractile performance if afterload is normal or can be accounted for. *Maximal ventricular power index*[137] is attractive because of its physiologic importance; i.e., it takes into account both the work done by the ventricle and the time over which it is generated. This index has been normalized to minimize effects of loading and has the potential for noninvasive determination. Two empirical indexes have been devised that appear to be relatively afterload-insensitive. One of these is preload recruitable stroke work,[138] the relationship between ED volume (or strain) and stroke work. The other is the relationship between ED volume and max *dP/dt*.[139,140] Both are linear and in essence representations of the Frank-Starling relation; by incorporating ED volume, length-dependent activation is an intrinsic component of these indexes.

Diastolic Function

In addition to meeting widely varying physiologic demands for blood flow, the heart must do so at levels of FP that do not result in circulatory congestion. This requires a normal sequence of relaxation and filling. Ventricular relaxation begins at about ES (defined as the time of maximal elastance, slightly before Ao valve closure), continues through isovolumic relaxation, and does not reach completion until after AV valve opening. Before filling commences, several factors combine to determine relaxation rate, represented by isovolumic pressure decline (Fig. 3-21). After filling begins, but before relaxation is complete, other factors related to the level of ventricular volume and/or the rate of ventricular volume change also influence ventricular diastolic pressure. Once relaxation is complete, the so-called passive properties of the ventricle dominate the relation between pressure and volume as filling continues through ED.

During isovolumic relaxation, pressure falls exponentially. The rate of isovolumic pressure fall (a measure of relaxation rate) therefore has been quantified as a time constant (τ)[141,142] or simply the time to reach one-half of some starting value ($T_{1/2}$, typically measured beginning at peak negative *dP/dt*).[143] Peak negative *dP/dt*, maximal rate of pressure fall, also has been used but is less accurate. The determinants of the rate of isovolumic pressure fall are as follows:[65,141,142,144] First, as discussed earlier, myocyte relaxation rate is determined by the balance between the avidity of the contractile proteins for Ca and the rate at which SERCA2 and other uptake and extrusion mechanisms remove Ca from the contractile proteins and restore the cytoplasmic concentration to normal diastolic levels. In some pathologic conditions, e.g., certain types of ischemia, diastolic Ca may not be restored to normal.[145] Relaxation is therefore incomplete, and crossbridge cycling continues during diastole, resulting in increased diastolic tension. Isovolumic relaxation is also modulated by the load on the myocardium.[141,142,144,146150] Increased afterload through all of systole or beginning early in systole (*a contraction load*) results in delayed relaxation. Changes in load occurring late during systole (*a relaxation load*) cause opposite effects. Although changes in relaxation load may be considered to be of theoretical interest only, this may not be the case. Normal arterial waves reflected from the periphery return to the ventricle at about ES and may function to accelerate relaxation. When arteries become noncompliant, e.g., with aging, reflected waves return earlier and therefore may be converted to a contraction load, with delay of relaxation. Last, a normal temporal and spatial activation sequence results in the most rapid relaxation rate.[151]

As soon as ventricular pressure falls below atrial pressure, filling commences. As noted earlier, the magnitude and rate of ventricular filling are determined by the instantaneous AV pressure gradient (see Fig. 3-2). It is self-evident that the gradient is determined by properties of both ventricle and atrium. Immediately after AV valve opening, the rapid period of filling begins in association with a gradient of several millimeters of mercury (see Fig. 3-2). This corresponds to the E wave of mitral inflow measured with echocardiographic-Doppler techniques. During rapid filling, both ventricular and atrial pressures initially fall, but ventricular pressure falls faster than atrial pressure. Ventricular pressure soon reaches a minimum and then increases throughout the rest of diastole. The peak AV gradient occurs at or near the time of minimum ventricular pressure. (As noted earlier, it is common to observe a brief period of gradient reversal during the latter portion of rapid filling. Due to inertial effects, there is no retrograde mitral flow.) Rapid filling is succeeded by the variable slow filling phase during which the AV gradient is small to negligible. During this phase, a small, secondary increase in inflow (the L wave) is observed occasionally. The length of the slow filling phase is markedly dependent on HR, being maximal at slow rates and disappearing at rapid rates. Atrial contraction increases the AV gradient once again and injects an additional volume of blood into the ventricle.

The ventricular properties that determine pressure and the AV gradient during filling are as follows: As indicated earlier, relaxation continues past the time of AV valve opening. Therefore, the same factors (Ca reuptake, load) that modulate *isovolumic* pressure fall also influence pressure *after filling begins*. However, effects of load on relaxation rate may differ somewhat once filling begins.[144,148,150]

In addition to the ongoing process of relaxation, *restoring forces* generated during contraction also influence ventricular pressure during the early, rapid filling phase.[152,154] By a restoring force, we mean PE generated during contraction in the form of a deformation(s) of the myocyte and/or the ventricle that can be converted into kinetic energy during diastole, accelerating flow of blood from atrium to ventricle. Restoring forces are caused by functional springs whose compression during contraction is converted to elastic recoil during diastole and filling by *suction*. When present, this active, energy-requiring driving force for filling results in lowering of ventricular pressure relative to atrial pressure and a larger AV gradient. Restoring forces are probably generated by two interrelated mechanisms. One is contraction of the ventricle to an ES volume below equilibrium volume (V_{eq}), the volume at which, in the *fully relaxed* state, the pressure inside and outside the chamber is equal (transmural pressure = 0). With contraction below V_{eq}, the fully relaxed intracavitary pressure is negative with respect to the outside, and the chamber may be considered to be under compression. If allowed to fill, the PE stored in the walls results in elastic recoil and filling until V_{eq} is reached. As noted earlier, titin appears to be the site of a restoring force in the myocyte. The second mechanism involves complex, contraction-dependent three-dimensional deformations that are normally dissipated (by elastic recoil) during isovolumic relaxation and the early phase of ventricular filling. One of

these is torsional rotation. The magnitude of these deformations increases as ES volume decreases;[103-105,155] hence they parallel compressive forces related simply to contraction below V_{eq}. As a corollary, whether and how much of a restoring force is present are critically dependent on the ES volume in relation to V_{eq}. The *sine qua non* of suction is a negative transmural pressure early during diastole, but this is rarely observed because filling is occurring rapidly and is driven simultaneously by the atrial pressure. Thus the presence of suction is ordinarily obscured. However, suction appears to be important at diastolic volumes within the physiologic range and especially during the stress of exercise, when ES volume decreases.[103,104] A second myocardial property that theoretically influences ventricular pressure during rapid filling is *viscous resistance to stretch*, i.e., intrinsically greater stiffness at high lengthening rates due to elements that behave like dashpots.[156] This property does not appear to be significant under normal physiologic conditions, however.

Relaxation and the generation of restoring forces are dynamic aspects of filling whose influence varies with time. Underlying these time varying properties is the passive ventricular pressure-volume relationship, the exponential relation between pressure and volume in the fully relaxed state.[157] We will refer to this as the *end-diastolic pressure-volume relationship* (EDPVR) (Fig. 3-22). (Although usually considered only at positive transmural pressures, as discussed earlier and as shown in Fig. 3-21, the EDPVR has a negative-pressure portion. The volume at zero transmural pressure is once again V_{eq}.) Passive *chamber compliance* is the ratio of change in volume to change in pressure at any point on the EDPVR. Because the EDPVR is exponential, passive compliance is inversely related to volume. The inverse of chamber compliance is *passive chamber stiffness*. The EDPVR is determined mainly by the geometry of the ventricular chamber, especially the chamber volume to wall thickness ratio, and the intrinsic stiffness of the myocardial tissue itself. Thus, all else being equal, increases in wall thickness or myocardial stiffness increase its slope. Intrinsic stiffness is the change in stress (force normalized to cross-sectional area) occurring in association with a given change in strain (extension of the tissue above some initial length or area). Passive myocardial stiffness is largely accounted for by the properties of titin[43,44] at relatively low volumes and by connective tissue at larger volumes. Throughout all of relaxation and filling, a portion of the pressure in the ventricle is dictated by its position on its EDPVR. Early during filling, the relation between ventricular pressure and volume is determined by relaxation and elastic recoil (when present), superimposed on the EDPVR; the EDPVR alone is the prime determinant of ventricular pressure once relaxation is complete.

The EDPVR is modified by external restraints. The most important is the parietal pericardium.[158] The pericardial sac has a relatively small reserve volume; at total heart volumes in the physiologic range, the pressure in the sac is very low in relation to left-side FPs. However, with relatively modest increments in volume above the physiologic range, the *pericardial* pressure-volume relation becomes quite steep (noncompliant), and the pressure rises rapidly. This external pressure acting on the surface of the heart is transmitted to the chambers and serves to restrain further filling; i.e., it decreases chamber compliance. Even under physiologic conditions, however, pericardial pressure is significant in relation to right-side FPs, which are normally lower than left-side FPs. Thus effective pericardial pressure is normally responsible for a significant fraction of right-side FP. Restraint to filling by the pericardium becomes quite important when the heart dilates rapidly, e.g., after RV myocardial infarction. The interventricular septum constitutes about one-third of the LV wall; diastolic pressure in the RV is therefore also an external restraint to filling of the LV (and vice versa). That is, a component of LV diastolic pressure is transmitted from the RV, an effect termed *diastolic interaction*.[158] Diastolic interaction is normally modest but can become important when RV diastolic pressure is elevated, often in conjunction with augmented pericardial restraint.

An additional factor that influences the EDPVR is the volume of blood in the myocardial vascular bed, or myocardial *turgor*.[159] A significant component of pressure in the fully relaxed ventricle is accounted for by turgor. This component is almost certainly reasonably constant under normal physiologic conditions because coronary blood volume is more or less constant. The significance of turgor is evident from the substantial drop in diastolic pressure that occurs when coronary flow is terminated abruptly.[159]

Following rapid filling and the variable period of slow filling, atrial contraction injects additional blood into the ventricle (typically one-quarter to one-third of the SV). During atrial systole, ventricular pressure and

volume track the EDPVR.[157]

Atrial properties are also a key determinant of the AV gradient that drives filling.[160] During ventricular systole, the atria fill continuously. Therefore, atrial pressure at the instant of AV valve opening is determined directly by atrial compliance; the lower the compliance, the higher is the pressure and the larger is the gradient. The relationship between ventricular pressure and volume as diastolic filling proceeds is also influenced by the properties of the atrium, as well as the pulmonary veins (for the LV). This is so because the ventricle, atrium, and pulmonary veins are an open system when the mitral valve is open. The ventricles, being much stiffer, are much more important determinants of the ventricular diastolic pressure-volume relation than the atria. Last, the contractile strength of the atrium is obviously a determinant of the gradient during atrial systole.

SHORT-TERM MODULATION OF VENTRICULAR FUNCTION

Heart Rate

The ventricle has a positive FFR with an optimal frequency that parallels the myocardial FFR.[74,75] As indicated earlier, this is an important means of modulating ventricular function that is intimately connected with changes in adrenergic stimulation. Changes in contraction frequency also influence relaxation and filling. There is some shortening of relaxation in conjunction with the positive FFR even without concurrent increases in adrenergic stimulation.[73] Moreover, with increased HR, diastole is shortened much more than systole, especially the slow-filling phase.

Paracrine Modulation of Ventricular Function

This has been discussed previously in the section on cellular control of contractility. It is important to emphasize that the significance of these factors with respect to *normal* ventricular function is not established. In the ventricle, these factors tend to have more prominent effects on relaxation than on contraction.[161] NO and endothelial-dependent vasodilators cause very modest depression of systolic function and an earlier onset of ventricular relaxation. Substances whose effects are mediated by the IP_3 second-messenger system (ET-1, α-adrenergic agonists) have more or less opposite effects.

Neurohumoral Responses

The most important short-term neurohumoral modulation occurs as a result of variations in sympathetic and parasympathetic stimulation caused by both cardiac neural activity and circulating catecholamines. Stimulation of β-adrenergic receptors results in increased HR and contractility and more rapid relaxation. These effects are due to the influence of adrenergic stimulation on the sinus node and specialized conduction system and, within the myocyte, activation of adenyl cyclase with increases in cyclic AMP. Increases in HR also allow the heart to use the FFR. Adrenergic stimulation interacts with the FFR not only by increasing HR but also by increasing the gain of the relationship.[75] There are many other myocyte cell surface receptors (e.g., α-adrenergic, dopaminergic, histaminergic, angiotensin II, and endothelin receptors), but none has a clearly delineated, significant role in normal, short-term modulation of ventricular function. Vagal stimulation, of course, has profound HR slowing effects as well as modest negative effects on contractility. Correspondingly, vagal withdrawal is an integral component of HR responses during exercise and other stresses.

The heart participates in a number of reflexes that modulate HR and ventricular function in the short term.[162-165] These typically result in coordinated changes in parasympathetic and sympathetic stimulation. Thus the heart is a component of the efferent limb of arterial baro- and chemoreceptors. Acute increases in systemic arterial pressure result in slowing of HR due to increased vagal stimulation and decreased sympathetic neural stimulation with attendant effects on contractility; the reverse occurs with decreased arterial pressure. Vagal responses occur very rapidly, on a beat-to-beat basis, whereas changes in sympathetic neural stimulation take somewhat longer to take effect. Pulmonary stretch receptors are largely responsible for normal sinus arrhythmia. Atrial stretch receptors also may modulate HR via the Bainbridge

reflex, resulting in tachycardia with increased intravascular volume. Ventricular mechanoreceptors that discharge with deformation are activated when volume decreases. Discharge results in vagally mediated bradycardia and hypotension and appears to be involved in vasovagal syncope. Chemoreceptors on the ventricular epicardium also connect to vagal efferents and may discharge in response to prostaglandins secreted into the pericardial sac.

Ventricular Interaction

Diastolic ventricular interaction has been discussed previously. The ventricles also interact during systole. Left-to-right systolic interaction was mentioned earlier. There is also a modest amount of right-to-left interaction.[119] As a result, an abrupt increase in PA pressure results in a small increase in LV contractile performance. Both diastolic and systolic ventricular interaction function as internal feedback mechanisms that modulate SV on a beat-to-beat basis to ensure that left- and right-side heart outputs remain equal over time. Obviously, even tiny differences in output summated over time would have disastrous consequences.

Coronary Perfusion

Changes in coronary perfusion pressure and/or flow per se can influence ventricular function.[166,167] Increases augment systolic performance and may cause some decrease in passive compliance. Modest decreases insufficient to cause myocardial ischemia likely have opposite effects. A component of the influence of coronary perfusion on ventricular function is related to turgor. In addition to modulation of diastolic compliance, stretching of myocardial tissue due to increased turgor appears to augment the Frank-Starling effect. It is also possible that stretch-activated Ca channels[168] open as turgor increases with resulting increased activation of the myocardium. Because of *coronary autoregulation*, these effects of coronary perfusion are probably of minor importance under normal physiologic conditions.

LONG-TERM MODULATION OF VENTRICULAR FUNCTION

Chronic nonphysiologic stresses modulate ventricular function by causing pathologic hypertrophy. Chronic alterations in the demands placed on the cardiovascular system within the physiologic range can cause modest changes in cardiac mass.[169,170] However, measurable changes require very substantial changes in demand. Thus endurance athletes develop modest, physiologic hypertrophy characterized by increased ventricular chamber volume with little or no increase in wall thickness. This adaptation allows for a greater SV.

Chapter 3: NORMAL PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

THE PERIPHERAL CIRCULATION

The essence of normal *vascular* function lies in adjusting total and regional peripheral resistance, as needed, to accommodate the metabolic demands of various organs and in ensuring adequate venous return to the heart. The goal of this section is to first provide an understanding of transcapillary exchange, the process by which tissues are nourished and normal fluid balance maintained, and to then consider the underlying physiologic mechanisms responsible for changes in regional and total peripheral resistance.

Physiology of the Peripheral Circulation

PRINCIPLES OF CAPILLARY EXCHANGE

The exchange of gases, nutrients, water, and waste material occurs at the capillary level and is governed by the interplay of two opposing but balanced forces. At the proximal end of a capillary, intravascular pressure slightly exceeds tissue pressure. The gradient in hydrostatic pressure results in hydraulic *ultrafiltration*, a process characterized by the movement of fluid through the capillary wall and into the extracellular compartment. Composed of a single layer of endothelial cells, the capillary acts as a selective filter. The degree of selectivity varies with the physical properties of the endothelium in different tissues. Passage of relatively large molecules (e.g., proteins) is largely impeded, although some leakage occurs with subsequent reabsorption into lymphatic vessels and a return to the circulation. As a result of ultrafiltration, the concentration of solute (plasma osmolarity) increases along the length of a capillary, and the associated force (termed *oncotic pressure*) acts to pull extracellular fluid back into the capillary lumen through a process of *reabsorption*. This fundamental concept was first described by Ernest Starling in 1896 and is therefore known as the *Starling hypothesis*, mathematically expressed as follows:

$$Q_f = k[(P_c + \pi_i) - (P_i + \pi_p)]$$

where Q_f is fluid movement across the capillary wall, P_c is capillary hydrostatic pressure, π_i is interstitial fluid oncotic pressure, P_i is interstitial fluid hydrostatic pressure, π_p is plasma oncotic pressure, and k is a filtration constant for capillary membrane.

A positive Q_f value indicates net filtration, whereas a negative value connotes net reabsorption. In general, if filtration exceeds reabsorption, an edematous state develops; conversely, if reabsorption exceeds filtration, plasma volume expands (primarily on the venous side), and cellular/extracellular volume decreases. It should be noted, however, that not every capillary behaves in the idealized fashion predicted by the Starling hypothesis. For example, in the renal glomerulus, hydrostatic pressures are elevated along the entire length of the capillary; hence filtration predominates. In the intestinal mucosa, the elevated oncotic forces result primarily in reabsorption, with little or no filtration.

Transcapillary exchange is modulated by a series of integrated mechanisms ranging from central neural control of CO and total peripheral resistance (the primary determinants of blood pressure) to local mechanisms within the microcirculation that modulate capillary pressure and regional blood flow. During the last decade, our appreciation of the latter has increased substantially, and it is now clear that metabolic and myogenic factors within the microcirculation play a major role in determining upstream resistance and, hence, pressure within a capillary bed.

The presence of actin and myosin in some endothelial cells, particularly those of postcapillary venules (also a site of fluid exchange), argues for the existence of a cytoskeletal mechanism for governing the geometry of interendothelial pores or clefts.[171] The state of the cytoskeleton is, in turn, regulated by physical and chemical signals that impinge on the capillary. A number of molecules, such as histamine, adenosine, and

NO, are able to alter the permeability characteristics of the endothelium and lead to rapid and significant changes in permeability. For example, *vascular endothelial growth factor* (VEGF) is a peptide that binds to receptors on the endothelium and initiates a series of intracellular signal-transduction events that result in greatly augmented permeability. Recent observations suggest that this pathway involves a receptor tyrosine kinase that is coupled to phospholipase C, an enzyme whose activation leads to the generation of second messengers that modulate both enzymatic and ionic events within the endothelial cell, including activation of protein kinase C, generation of NO, and changes in the endothelial cytoskeleton.[172] Finally, in some organs such as the brain or kidney, transcapillary exchange may be subject to modulation by pericytes, specialized cells that encircle the capillary endothelium and contribute to permeability/barrier functions by mechanisms that are as yet poorly defined. Under normal conditions, it is essential that the vascular resistance upstream of the capillary bed be regulated in such a way so as to maintain capillary pressure at levels at which normal fluid exchange may occur. The remainder of this section therefore is devoted to reviewing the principal mechanisms by which the cells of the arterial and arteriolar wall regulate arterial tone and hence vascular resistance and capillary pressure.

PERIPHERAL RESISTANCE AND ITS DETERMINANTS

Pressure, flow, and resistance are related most often through Poiseuille's equation, which was first formulated in 1842. Based on a series of careful observations of water flowing through rigid tubes, Poiseuille demonstrated that the resistance to flow R through a tube is proportional to tube length L and fluid viscosity η and inversely proportional to the tube radius to the fourth power (r^4). These variables can be related to each other in the following way:

$$R = 8\eta L/\pi r^4$$

Poiseuille's equation applies to the behavior of Newtonian fluids flowing in a nonpulsatile, nonturbulent (laminar) manner through rigid tubes. Although the vascular system satisfies none of these parameters, the equation is useful because it predicts that flow Q is proportional to r^4 (and inversely proportional to resistance: $Q \propto r^4$, or $Q \propto 1/R^4$, where r is radius and R is resistance), i.e., given the same initial pressure, doubling the inner radius of a tube will result in a sixteenfold (2^4) increase in flow. Estimates from intact vascular networks suggest that this may be an overestimation and that a third-power equation ($Q \propto r^3$) may be more accurate.[173] Nevertheless, it is clear that relatively minor changes in arterial caliber can produce large changes in resistance and flow.

The relationship between vascular resistance and blood flow may be defined by an equation that is analogous to Ohm's law for the flow of electrons, where flow = perfusion pressure/resistance. The complete formulation includes the main determinants of resistance (labeled as above in Poiseuille's equation) and is called *Poiseuille's law:*

$$Q = PP\pi r^4/8\eta L$$

where Q is flow, PP is perfusion pressure, and the determinants of resistance (inverted during the simplification of the quotient) are signified as above. Although flow resistance also can be affected by the viscosity of the blood (η) and the length of the vessel (L), as predicted by the Poiseuille formula, these parameters are normally relatively invariant within the adult cardiovascular system. For this reason, lumen diameter is the single most powerful determinant of vascular resistance (and blood flow) under physiologic conditions. Its control is the primary end point for a variety of physiologic mechanisms.

Most of the pressure drop between large conduit arteries and capillaries occurs in vessels having lumen diameters of a few hundred microns or less. For this reason, small arteries and arterioles are considered to be of primary importance in regulating and determining peripheral resistance. These muscular vessels have a high wall-thickness to lumen diameter ratio and usually contain one to three layers of circumferentially oriented vascular smooth muscle cells. They also normally possess some degree of basal tone and are capable of diameter changes that range from fully open to virtually closed. Hence their potential to affect resistance is considerable. In contrast, large conduit arteries such as the aorta only constrict by 10 to 20 percent. Unless they become diseased, they are of minor importance to peripheral resistance and blood flow control. The relationship between blood pressure, blood flow velocity, and total cross-sectional area in

various blood vessels of the systemic circulation is summarized in Fig. 3-23.

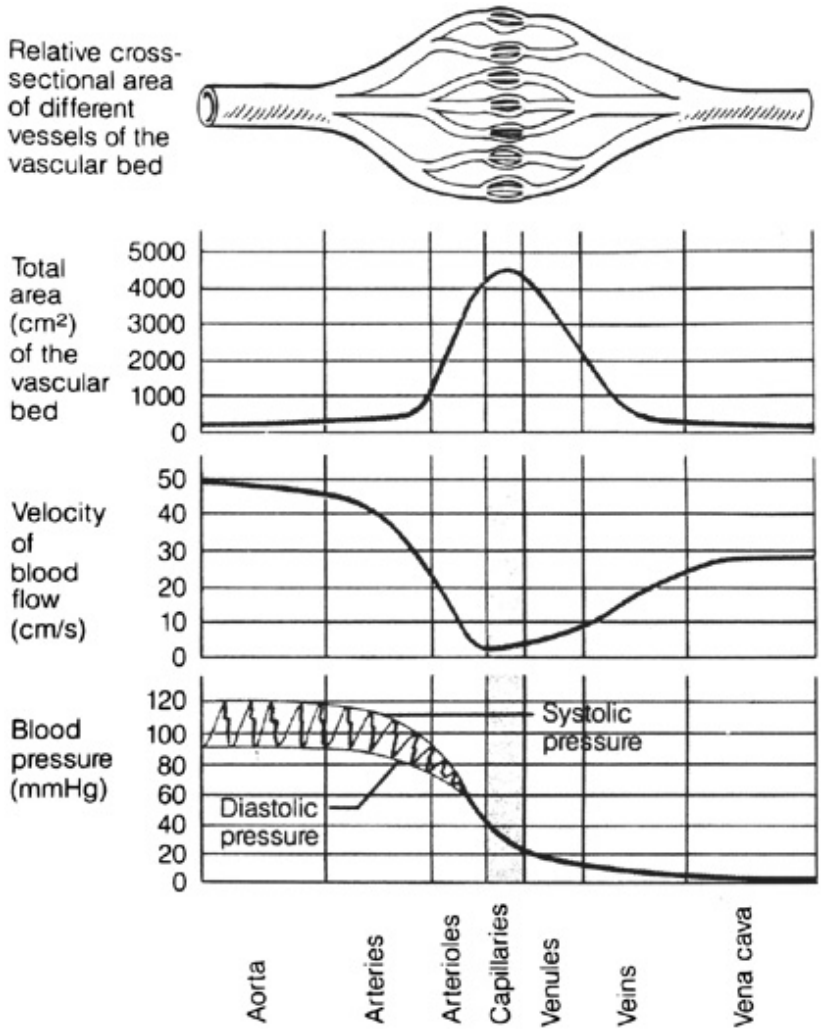

Figure 3-23: Relations between total cross-sectional area of the vascular bed (cm2), velocity of blood flow (cm/s), and blood pressure (mmHg) in various vessels in systemic circulation. (From Marieb EN. *Human Anatomy and Physiology*. Redwood City, CA: Benjamin/Cummings; 1989:629. Reproduced with permission of the publisher.)

Larger vessels do contribute significantly to resistance in some organs, such as the brain,[174] primarily due the more linear geometry of the arterial vasculature. In a *serial arrangement* of tubes, total resistance R_t is the sum of individual resistance elements ($R_t = R_1 + R_2 + R_3$, etc.). Conversely, in regional circulations in which vessels are highly and sequentially branched, resistance tends to be localized to smaller (<50 μm) arteries. This occurs because a greater number of *parallel elements* lowers the overall resistance of the array. This makes sense because, given the same driving pressure, there are more tubes to conduct flow, and in this case, total resistance is defined by a reciprocal relationship ($1/R_t = 1/R_1 + 1/R_2 + 1/R_3$, etc.). These concepts are shown in Fig. 3-24.

SYSTEMIC HEMODYNAMICS

In healthy adults, 15 percent of the blood is contained within the systemic arterial system. The remainder is distributed between capillaries (5 percent), veins (66 percent), heart (6 percent), and pulmonary circulation (8 percent). The peripheral circulation distributes CO throughout the various tissues and organs of the body. The elasticity of large conduit arteries such as the aorta serves to absorb and dampen the highly pulsatile and discontinuous flow from the heart (the Windkessel effect). As a result, the amplitude of pressure

pulsations is diminished in smaller vessels and capillaries and is virtually absent in the venous circulation. Mean pressure also decreases from a value of 90 to 95 mmHg in large arteries to about 30 mmHg in capillaries and less than 20 mmHg in veins. The peripheral circulation must adapt rapidly to changes in arterial pressure and variations in end-organ metabolic demands. Even actions we take for granted, such as getting out of bed, challenge the cardiovascular system. Thus, owing to gravitational forces, cerebral perfusion pressure and venous return are suddenly reduced, leading to transient feelings of dizziness in some individuals (orthostatic hypotension). At the same time, capillary pressures in the ankles may rise to exceed 90 or 100 mmHg. As another example, the metabolic demands of exercise require major redistribution of CO to increase perfusion of coronary, pulmonary, and skeletal muscle circulations, diminish splanchnic flow, and still maintain cerebral blood flow (Table 3-2). Regulatory mechanisms therefore must be bidirectional, i.e., allow blood flow to either increase or decrease on demand. For this to occur, the venous circulation must be able to adjust its capacitance and modulate venous return, and the arterial vasculature must operate at a point from which it can either dilate or constrict to increase or decrease flow. Because it is impossible to dilate a vessel that is already fully relaxed, some portion of the arterial circulation must operate in a state of partial constriction or tone. This theoretical supposition is supported by experimental studies in which the infusion of vasodilators into the afferent vasculature results in substantial increases in blood flow, demonstrating a dilator "reserve" (Fig. 3-25) that can only be accounted for by the presence of basal tone.

Table 3-2: Distribution of Tissue Blood Flow during Exercise

	TISSUE BLOOD FLOW (mL/min)		
Organ	Rest	Light Exercise	Strenuous Exercise
Skeletal muscle	1200	4500	12,500
Heart	250	350	750
Brain	750	750	750
Skin	500	1500	1,900
Kidney	1100	900	600
Abdominal viscera	1400	1100	600
Miscellaneous	600	400	400
TOTAL CO	5800	9500	17,500

Integration of Circulatory Mechanisms: Blood Flow Autoregulation

Minute-to-minute control of the peripheral circulation involves a complex interplay between several physiologic mechanisms, mainly neural, myogenic, and endothelial. Metabolites released from adjacent tissues also impinge on the vascular wall (metabolic regulation). The importance of each varies with ambient conditions. Under resting conditions, skeletal muscle arteries and arterioles operate in a highly constricted state, and perfusion is relatively low. Physical activities such as running or swimming result in

manyfold increases in skeletal muscle blood flow due to a combination of increased CO and arterial dilation. The proportion of CO directed to skeletal muscles increases from 20 to more than 70 percent, and total blood flow is increased by as much as tenfold (see Table 3-2).

During exercise, dilation of skeletal muscle arteries and arterioles occurs due to metabolic factors such as adenosine and potassium and hydrogen ions that diffuse from adjacent myocytes into the vascular wall and induce hyperpolarization and relaxation of vascular smooth muscle either directly or indirectly by stimulating the release of endothelial factors such as NO and prostacyclin.[175] Increased flow itself serves as a stimulus for further vasodilation, presumably through shear stress-induced release of vasoactive substances from the endothelium.[176] The degree of local circulatory control can be quite remarkable. This is perhaps best illustrated by studies of cerebral blood flow using inhaled isotopes such as xenon in combination with scanning devices that produce a topographic map of cortical flow.[177] These studies show that when an individual begins to play the piano with his or her right hand, cerebral blood flow increases markedly, but only in the opposite hemisphere in the area of the motor cortex that controls finger and hand movements. Similarly, the act of speaking increases blood flow to the speech areas, solving mathematical equations augments flow to the frontal lobe, visual stimuli to the occipital cortex, and so on. At the same time, global cerebral flow is unaltered in the face of changing blood pressure, a phenomenon called *autoregulation*.

Autoregulation is the ability of an organ to maintain a constant blood flow despite changes in systemic arterial pressure. Although most organs can autoregulate blood flow, this phenomenon is particularly well developed in the cerebral, coronary, and renal circulations and is principally effected by adjustments in the caliber of smaller arteries and arterioles. Autoregulatory effectiveness is determined by the ability of the arteries to constrict to increased and dilate to decreased pressure so as to keep total flow relatively constant. This involves an interaction between several mechanisms, myogenic, endothelial, neural, and metabolic; others, such as tissue pressure or tubuloglomerular feedback, may occur within the cranium and kidneys, respectively.

Autoregulation occurs over a range of pressures with both upper and lower limits. If perfusion pressure falls below a certain point, tissue hypoperfusion will ensue. Transmural pressures above the upper limit of autoregulation, on the other hand, result in a "breakthrough" phenomenon in which forced dilatation of arteries occurs, leading to loss of vasomotor tone. Large increases in organ blood flow, transmission of high intravascular pressures to capillaries and veins, and vessel leakage and rupture potentially may result. Forced dilatation is thought to be important in the development of hypertensive encephalopathy, a condition characterized by increases in cerebral blood flow and extravasation of fluid and protein from the microcirculation. Experimental studies have shown that leakage occurs initially in postcapillary venules, although arteriolar damage and changes in permeability have been documented as well.[178] The ability to autoregulate flow must be reserved for some organs (e.g., brain, heart, and kidney) but not all; if increased blood pressure stimulated arterial constriction throughout the body, total peripheral resistance would increase, raising pressure further via a positive-feedback mechanism that could have dire consequences. An equally dangerous situation would occur with a fall in blood pressure and potentially lead to vascular collapse. Thus simultaneous and opposite changes in arterial and arteriolar tone and/or adjustments in venous capacitance and plasma volume (driven by nervous and endocrine systems) must occur to prevent the development of either hyper- or hypotension.

Cellular Mechanisms Involved in the Regulation of Blood Flow

VASCULAR TONE AND ITS DETERMINANTS

Vascular tone generally increases with decreasing arterial size and is greatest in the smaller arteries and arterioles that play a primary role in determining peripheral resistance and regulating regional blood flow.[179] The level of tone at any time reflects an integration of multiple excitatory and inhibitory pathways that converge on the ultimate effector, vascular smooth muscle (VSM), to "set" the level of tone. Changes in the physical forces impinging on the vascular wall (shear stress, transmural pressure), neurotransmitter release from nerves (most often located at the medial-adventitial junction), or the concentration of metabolites released from surrounding tissues all modulate the set point to either increase or decrease arterial tone, lumen diameter, and resistance. VSM itself is capable of constricting in response to pressure

or stretch. Because this occurs in isolated arterial segments that have been denuded of endothelium and in the absence of metabolic or neural factors, it appears to be a pure response of VSM to pressure or stretch and therefore is termed *myogenic tone* (see ref.[179] for review).

The endothelium, situated at the interface between blood and VSM, is also an important modulator of tone via release of a number of vasoactive factors having both inhibitory (e.g., NO, prostacyclin) and excitatory (e.g., ET-1, thromboxane) effects on VSM.[180] Moreover, in many arteries the endothelium is coupled to VSM through numerous myoendothelial junctions-areas where membranes of endothelium and VSM are in close contact.[181] The nature of the contact varies but may occur through low-resistance gap junctions that allow bidirectional transfer of information and propagation of dilatation or constriction. Spontaneous vasomotion and, in some cases, upstream ("ascending") vasodilatation have been observed in vivo in several circulatory beds and may involve cooperativity between endothelium and VSM in determining network resistance.[182]

MYOGENIC PROPERTIES OF VASCULAR SMOOTH MUSCLE

Arterial constriction to increased perfusion pressure was first described by Bayliss in 1902. Since then, myogenic responses have been documented in arteries, arterioles, and veins. The fundamental question of how a vessel is able to sense intravascular pressure and/or flow has proven difficult to answer. The identity of the myogenic sensor-the structure(s) that convert physical force into VSM contraction-has thus far eluded investigators. Some putative candidates are integrins (molecules embedded in the membrane that link the extracellular matrix with the cytoskeleton) and stretch-activated cation channels.[183] Recent studies have elucidated many of the intracellular signal-transduction pathways involved in myogenic tone. Myogenicity appears to involve a cooperativity between ionic and enzymatic mechanisms, with Ca entry and activation of the phospholipase C/protein kinase C cascade being central among them. Transmural pressure leads to depolarization of the VSM membrane and activation of L-type Ca channels that allow extracellular Ca to enter the VSM cell. Ca entry activates a variety of enzymes and promotes contraction through calmodulin-mediated myosin light chain phosphorylation that initiates actomyosin ATPase activity and crossbridge (actin and myosin) cycling. At the same time, membrane enzymes such as phospholipase C and protein kinase C become activated; many of these enzymes are Ca-dependent. Enzyme activation leads to kinase-induced phosphorylation of a number of other intracellular enzymes and ion channels (e.g., K channels) located in the membrane, as well as modulation of intracellular Ca stores through phosphoinositides such as IP_3.[179,183] Although Ca is required for constriction (inhibition of entry with channel blockers eliminates myogenic tone), enzymatic activity may "sensitize" the contractile proteins to the effects of Ca. Tone is thus controlled by a combination of mechanisms that (1) regulate VSM Ca levels (Ca entry and extrusion) and (2) modulate the effect of Ca on the contractile proteins (Ca sensitivity).

The feedback mechanisms for myogenic behavior are poorly understood but may involve Ca-induced activation of K channels whose opening facilitates K efflux and membrane hyperpolarization, opposing the depolarizing effect of transmural pressure and stabilizing membrane potential at the appropriate level.[184] An intriguing concept, first reported in cardiomyocytes,[185] invokes control of a subset of K channels that have been implicated in basal tone (KCa, or Ca-activated K channels) by highly localized intracellular "hot spots" of Ca, i.e., Ca sparks.[186] In this scenario, Ca is released from the SR in a discrete fashion that leads to localized concentrations of Ca within the cytoplasm. The proximity of the SR release site to the KCa channels, which are proteins embedded in the plasma membrane, leads to their activation. The resulting outward K current produces membrane hyperpolarization that, in turn, inhibits voltage-sensitive Ca channels, decreasing Ca entry and leading to vascular relaxation. Hence Ca sparks produce vasodilation indirectly by activating KCa channels but have little direct effect on spatially averaged intracellular Ca concentration, which regulates contraction.

ENDOTHELIAL INFLUENCES ON VASCULAR SMOOTH MUSCLE CONTRACTILITY

Although the importance of the endothelium as a nonthrombogenic surface has been known for some time, its role in modulating arterial tone was unrecognized until the early 1980s, when Furchgott and Zawadski[187] observed that this cell type was obligatory for the relaxation response to acetylcholine. Although cholinergic vasodilation in vivo had been recognized, its mechanism was difficult to study

because the event rarely could be reproduced in vitro. In their landmark paper, Furchgott and Zawadski[187] reported that endothelial denudation abolished relaxation to acetylcholine and hypothesized that cholinergic stimulation led to the release of a substance that relaxed VSM. This compound, initially called *endothelium-derived relaxing factor* (EDRF), was subsequently shown to be NO. NO is a gas produced during the conversion of the amino acid L-arginine into L-citrulline by the enzyme NO synthase.[188] In addition to its vasodilatory actions, NO is now known to be an important cytotoxic molecule used by the immune system, a neurotransmitter, a modulator of cell division,[189] and, as discussed earlier, a modulator of myocardial function and energy metabolism.

It is now clear that the endothelium performs a variety of chemo- and mechanotransduction functions and releases a host of vasoactive molecules in response to physical and chemical stimulation.[180] In addition to NO, the latter include ET-1[190] and dilator and constrictor prostaglandins (e.g., prostacyclin and thromboxane, respectively). There is also experimental evidence for a non-NO factor that hyperpolarizes VSM. This substance has been termed *endothelium-derived hyperpolarizing factor* (EDHF).[191] Endothelial secretions diffuse to adjacent VSM to activate a variety of signal-transduction mechanisms that alter intracellular concentrations of cyclic AMP (induced by prostaglandins), cyclic GMP (via NO), phospholipase C (ET-1), and membrane potential (EDHF). Release of endothelium-derived vasoactive molecules is controlled by a variety of factors, both chemical and physical. The endothelium is exposed to much higher levels of shear stress than most other tissues. Shear is thought to be an important stimulus for a number of endothelial events, including hyperpolarization (opening of K channels), Ca influx, up- and down-regulation of mRNA for many proteins (e.g., adhesion molecules, tissue plasminogen activator, heat shock proteins), induction of G proteins and a number of kinases (protein kinase C, mitogen activated protein kinase), cytoskeletal rearrangement, and release of cytokines and growth factors.[176] There is also evidence that shear stress modulates arterial growth and remodeling through an endothelium-dependent mechanism.[192] Altered small artery endothelial function (most often characterized by diminished release of vasodilator substances) has been reported in vascular diseases such as hypertension and diabetes.[193,194] In larger arteries, abnormal flow patterns (turbulence, eddy currents) associated with reduced shear stress may lead to metabolic derangements in endothelial function and accelerate the development of atherosclerotic lesions.

Autonomic Regulation of Peripheral Blood Flow

Most arteries and veins receive direct sympathetic innervation. Sympathetic tone contributes to maintenance of arterial and venous pressure under normal and stressful conditions. Sympathetic efferent activity is determined by a complex interaction of neurons in the spinal cord, medulla, pons, hypothalamus, limbic system, and portions of the forebrain and, as discussed earlier, by feedback signals arising from cardiovascular mechano- and chemoreceptors localized in discrete baroreceptor centers in the carotid sinuses, aortic arch, and the heart. The two central nervous system (CNS) areas that appear to be of principal importance in regulating sympathetic outflow are the nucleus tractus solitarius (NTS) and the rostral ventral lateral medulla (RVLM). The influence of the NTS on the RVLM is inhibitory: In animals, bilateral lesions lead to malignant hypertension. Sympathetic denervation produces widely varying effects on organ blood flow. Cerebral and coronary circulations are virtually unaffected, most likely as a result of the dominance of intrinsic autoregulatory mechanisms, whereas denervation of the skin or skeletal muscle produces substantial increases in blood flow. During intense sympathetic activation, large amounts of epinephrine (and, to a lesser extent, norepinephrine) are released from the adrenal medulla in response to activation of sympathetic preganglionic afferents. Blood pressure increases markedly, and significant redistribution of CO occurs (e.g., simultaneous increased perfusion of skeletal muscle and decreased splanchnic flow). Moreover, stimulation of the venous circulation increases venous return, thereby augmenting CO.

The efferent fibers of the cranial division of the parasympthetic system innervate the blood vessels of the head and viscera; those of the sacral division supply the vasculature of the large bowel, bladder, and genitalia. Resistance vessels are not thought to receive parasympathetic innervation, and the effect of the parasympathetic system on total resistance is minor. The parasympathetic system generally produces effects opposite those of the sympathetic division, i.e., decreased cardiac rate and output and vascular relaxation, but is thought to be of secondary importance in peripheral vascular regulation.

Chapter 3: NORMAL PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

THE CORONARY CIRCULATION

Anatomic and Mechanical Considerations

The right and left main coronary arteries (CAs) arise at the root of the aorta and provide the blood supply to the myocardium. The right CA normally supplies the inferior surface of the LV, the RV and RA, whereas the left CA divides into circumflex and anterior descending branches that perfuse the rest of the LV and the LA. In about 10 percent of cases the left circumflex branch rather than the right CA supplies the inferior LV. Branches from the main CAs ramify and penetrate the myocardium, forming dense capillary beds. Most venous blood returns to the RA via the coronary sinus; there is also communication between the cardiac chambers and myocardium via arteriosinusoidal channels. Delivery of blood to the myocardium is complicated by compression of intramyocardial vessels during systole, which induces retrograde flow in epicardial CAs.[195-201] As a consequence, the bulk of coronary flow occurs during diastole, and the upstream perfusion pressure is the Ao *diastolic* pressure. The subendocardial layer of the myocardium is more susceptible to hypoperfusion because ventricular diastolic pressure opposes the driving pressure for flow. Moreover, compression of microvessels during systole is more prominent in the subendocardium. There has been some uncertainty about the actual driving pressure for nutrient flow, in particular whether the downstream pressure should be considered RA/coronary sinus pressure or a higher value related to tissue forces that cause collapse of the microcirculation (i.e., a critical closing pressure).

Modulation of Coronary Vasomotor Tone and Flow

The distribution of coronary vascular resistance is complex and dependent on type of vessel, region, and specific vasomotor stimuli.[198,200] Arterioles clearly comprise the main component of resistance, but small arteries and venules also contribute in a coordinated fashion to control flow to specific regions. Some vasodilators and contrictors preferentially dilate small arteries rather than arterioles. Resistance in subendocardial microvessels appears to be significantly lower than in the subepicardium. Modulation of coronary vascular resistance is exceedingly complex, and only a brief discussion will be undertaken here (see ref. 200 and Chap. 37 for additional details). As the heart varies its mechanical performance over a wide range of physiologic demands, the coronary circulation must keep pace. For example, nutritive coronary flow increases by as much as 400 percent during exercise. Since upstream Ao diastolic pressure does not change markedly during exercise (or even decreases), this requires an ability to markedly dilate coronary resistance vessels. The most potent mechanism of modulation of coronary resistance and flow is endogenous autoregulation. As discussed earlier, this is the ability of the coronary circulation to maintain flow constant over a wide range of perfusion pressures and/or alter flow in response to increased metabolic demands by changing its resistance.[198,200] Autoregulation occurs at the level of small arteries, arterioles, and venules and appears to be due to both *myogenic* and *metabolically mediated* responses.[198,200,201] As discussed earlier, a myogenic response is the ability of vessels to alter tone as a direct response to changes in pressure and/or flow. This is most prominent in arterioles and results in constriction when perfusion pressure is increased and dilatation when pressure is reduced. Although myogenic responses play a role in autoregulation, the most important factors are those related to changes in the washout of metabolites. (Of course, changes in perfusion pressure and flow themselves alter metabolite concentration.) The actual metabolites

and effector mechanisms responsible for autoregulation are incompletely defined, but the effects are most prominent in small arterioles. There is much evidence that local release of adenosine (a potent coronary dilator) under conditions of increased metabolic demand is a key mediator of autoregulation.[198,200,202,203] However, other endogenous vasoactive mechanisms also contribute. For example, local release of K and activation of ATP-sensitive K channels in small arteries and arterioles also may have a role.[204] Moreover, adenosine release itself may activate ATP-sensitive K channels. NO appears to have a significant role in autoregulation as well (see below).

Neurohumorally mediated responses also play a role in modulation of coronary vascular resistance.[198,200] Their importance under *normal physiologic conditions* is uncertain. α-Adrenergic responses are well documented in the coronary circulation. α-Adrenergic agonists constrict large epicardial and small coronary arteries/arterioles (>100 μm in diameter) and dilate smaller arterioles. At physiologic perfusion pressure, the main effect appears to be constriction of small arteries. While there is evidence of α-adrenergic activity under physiologic conditions, endogenous mechanisms mask and/or counteract this vasoconstrictive influence. Thus endothelial release of NO occurs concomitant with α-adrenergic activity. β-Adrenergic receptors are present in coronary vessels and cause dilation of large arteries and resistance vessels. However, this influence is difficult to distinguish from and likely of minor importance compared with autoregulation.

Constrictive and dilatory substances produced by the endothelium play a key role in many, if not all, of the changes in coronary tone occurring in response to a variety of physiologic stimuli, including autoregulation in general and adenosine, serotonin, acetylcholine, and adrenergic stimulation.[198,200,205,206] These endothelial-derived substances include prostaglandins, ET-1, endothelium-derived hyperpolarizing factor,[207] and NO.[198,200,204-209] At present, there is considerable information about the physiologic role of NO, but relatively little is known about the others. Although NO is a coronary vasodilator, it produces somewhat heterogeneous effects and may have quantitatively different influences on large arteries versus resistance vessels. NO appears to be the key effector of autoregulatory responses to normal physiologic stimuli, including tachycardia and vasodilation during exercise,[208-210] and is intimately connected to responses to the endothelial-derived substances mentioned earlier, as well as a variety of vasoactive drugs.

The response of the coronary circulation to changes in demand requires the coordination of the multiple modulatory mechanisms discussed earlier. The integrated response consists of heterogeneous effects that depend on the type of vessel and the region of the myocardium, which together increase nutritive flow. A scheme illustrating the complex interactions involved in the response to an increase in demand is shown in Fig. 3-26.

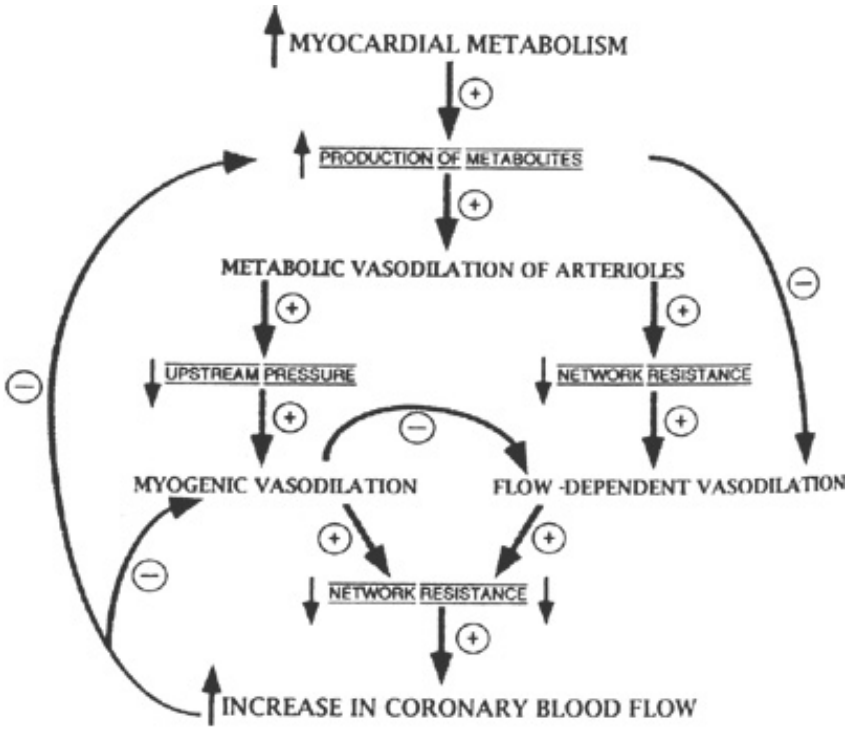

Figure 3-26: Schematic diagram of integrated response of metabolic, myogenic and flow-mediated regulation of coronary vascular resistance and flow during increase in metabolic demand. Plus sign indicates vasodilatory feed-forward steps in response to initial increase in demand. Minus sign indicates negative-feedback processes that limit vasodilation. Events marked by lines ("Production of Metabolites") occur as a reaction to metabolic or vascular changes. Bolded items are metabolic or vasoactive adjustments. Chapter 3: NORMAL PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

INTEGRATION OF THE CARDIOVASCULAR SYSTEM: THE RESPONSE TO DYNAMIC EXERCISE

Integrated functioning of the heart and peripheral and coronary circulations is exemplified by responses to dynamic exercise, especially isotonic activities such as walking, running, and swimming that entail repetitive shortening of skeletal muscle against relatively low loads. The coordinated response maximizes flow to working skeletal muscle and the heart; minimizes flow to nonworking muscle, visceral organs, and the kidneys; and ensures that flow to the brain is not compromised (see Table 3-2). In the periphery, local vasodilatory influences reduce resistance in vascular beds of working muscle. Cutaneous beds also dilate in order to facilitate heat transfer. In contrast, neurohumorally mediated responses cause vasoconstriction in nonworking skeletal muscle, abdominal viscera, and the kidneys. With isotonic exercise involving large muscle groups, there is usually a decrease in total systemic vascular resistance.

O_2 delivery to the myocardium is augmented by increased coronary flow caused by autoregulatory vasodilatation in response to increased metabolic demands. In addition to increased O_2 delivery, O_2 consumption is augmented by increased extraction, with lowering of coronary sinus O_2 saturation. Myocardial use of glycolytic metabolism increases, and NO produced in the coronary endothelium may facilitate shifts in mitochondrial respiration that tend to minimize increases in energy demands.

As noted earlier, in the normal circulation the ability to return blood to the heart is the limiting factor for increases in CO during exercise. In order to increase venous return, systemic venoconstriction decreases the volume of blood in venous reservoirs, resulting in a shift of blood volume to the arterial circulation and the heart. Working skeletal muscles in conjunction with venous valves themselves function as pumps to return blood to the heart, and increased respiratory rate causes the intrathoracic pressure to be negative a larger proportion of the time, which directly assists venous return to the right side of the heart.

In the heart itself, increased adrenergic stimulation caused by the coordinated effects of increased central nervous outflow and circulating catecholamines, along with parasympathetic withdrawal, results in increased HR (as much as three- to fivefold at maximum exercise), accelerated AV conduction, and enhanced contractility. Increased force and velocity of contraction are achieved through the effects of adrenergic stimulation (via cyclic AMP) and the FFR on Ca delivery to the myofilaments. Their effects on Ca reuptake and myofilament Ca sensitivity speed myocardial relaxation so that increased HR does not occur at the expense of incomplete relaxation. During upright exercise, ED volume remains relatively constant; during supine exercise, it increases somewhat.[211] Reflecting increased contractility, the ESPVR shifts leftward, and ES volume decreases. The combination of relatively constant or modestly increased ED volume and reduced ES volume results in a variable increase in SV and EF. With respect to augmenting CO, however, the increase in HR is considerably more important than the increase in SV.

The combination of increased HR and SV with resulting marked shortening of diastole means that ventricular filling must occur much more rapidly than under resting conditions. This is partly accomplished by the aforementioned increase in relaxation rate. However, it is likely that an increase in the generation of restoring forces due to the smaller ES volume as well as increased

deformations such as torsion result in increased suction. Thus the same mechanisms causing increased force of contraction (adrenergic stimulation, FFR) also result in more rapid diastolic filling at lower ventricular pressures.

Systolic systemic arterial pressure increases substantially during dynamic exercise as a result of increased contractility and SV, while diastolic arterial pressure decreases because systemic resistance decreases. Obviously, pulse pressure increases. Minimum ventricular diastolic pressure decreases (more rapid relaxation, increased suction) with little or no change in ED pressure. Finally, coordinated changes in arterial elastance may function to optimize ventricular-vascular coupling and efficiency of conversion of chemical energy to EW by the contractile machinery.

Predominantly isometric exercise involving relatively brief bursts of skeletal muscle shortening against a heavy load (e.g., weight lifting, handgrip) evoke different responses. This type of exercise does not require a marked and/or sustained increase in CO with selective distribution to working muscles and heart. Thus many of the complex, integrated responses present during sustained isotonic exercise are unnecessary. However, isometric exercise does elicit reflex-mediated increases in sympathetic stimulation causing increased systemic vascular resistance and arterial pressure, HR, and cardiac contractility. The increases in systolic blood pressure are comparable with those during isotonic exercise, whereas the increases in HR are much smaller in magnitude.

Chapter 3: NORMAL PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

List of Figures

Figure 3-17: Schematic illustrating concept of preload and afterload during isotonic contraction. (*Left*) Linear muscle is depicted as consisting of contractile element (CE) (i.e., thick and thin filaments) and spring in series (SE). (*Right*) Shortening and force are depicted. *A*. Muscle is at rest, with one end tethered and the other connected to a weight (P). P is supported, however, so that muscle is only subjected to a fraction of weight (or load). This relatively small load is the preload, which stretches the muscle to the initial, resting length. *B*. Muscle begins to contract. In order to shorten, it must lift the entire weight P, which is the afterload. Initially, force increases but is insufficient to lift the weight. During this period, the CE shortens and reciprocally lengthens the SE, while total muscle length remains constant. Eventually, the developed force just exceeds the afterload, and the muscle begins to shorten (*C*). Once shortening begins, force is constant and essentially equal to the afterload. In an isometric contraction, the muscle cannot lift the load and therefore does not shorten (although the CE shortens and SE lengthens by the same amount).

Figure 3-18: Relation between EF and circumferential stress (with 95 percent confidence intervals) in human subjects with normal ventricular function (control, filled squares) and mitral regurgitation (MR, open circles) (see text). Some MR patients fall below confidence intervals. (From Starling et al.[115] Reproduced with permission of publisher.)

Figure 3-19: Schematic of elastance concept (see text). *A*. Series of variably loaded pressure-volume loops. Filled circles connected by straight lines occur at same time *t* during contraction. E_{max} is line connecting points at ES. *B*. Elastance *E(t)* increases at each time *t* during contraction until it reaches maximal value at ES. Increased contractility increases slope at any time *t*, including ES (E_{max}); vice versa for decreased contractility. *C,D*. The concept that the ventricle behaves like a spring of increasing stiffness (increased slope of elastance relations) during contraction. (From Suga H, Takaki M, Matsubara H, Goto Y. Energy costs of PVA and E_{max}: Constancy and variability. In: LeWinter MM, Suga H, Watkins MW, eds. *Cardiac Energetics: From E_{max} to Pressure-Volume Area.* Boston, Kluwer, 1996:2. Reprinted with permission of publisher.)

Figure 3-20: (*Top*) Schematic of VO_2-PVA concept (see text). In ejecting contraction, PVA = EW + PE; in isovolumic contraction, PVA = PE only. (*Bottom*) Correlation of PVA with VO_2. (From Goto et al.128 Reproduced with permission of publisher.)

Figure 3-21: Determinants of relation between LV diastolic pressure and volume during filling. Solid line, LV pressure during isovolumic relaxation, filling, and isovolumic contraction; dashed line, positive and negative portions of passive pressure-volume relation. V_{ES}, ES volume; V_0, equilibrium volume or zero pressure intercept of passive pressure-volume relation (which is not same as dead volume of ESPVR); V_{ED}, ED volume. (From Gilbert JC, Glantz SA. Determinants of LV filling and of the diastolic pressure-volume relation. *Circ Res* 1989; 64:828. Reproduced with permission of publisher.)

Figure 3-22: (*Left*) EDPVR in two ventricles with differing passive diastolic properties. Chamber stiffness is *dP/dV* at any point on the EDPVR. Chamber compliance is its inverse. Stiffer chamber (left) has steeper overall slope. (*Right*) Same data plotted as pressure versus chamber stiffness. Because of exponential nature of EDPVR, result is a straight line. Its slope (k_c) is a chamber-stiffness constant that characterizes the overall slope of the EDPVR. (From Gaasch.157 Reprinted with the permission of the publisher.)

Figure 3-23: Relations between total cross-sectional area of the vascular bed (cm2), velocity of blood flow (cm/s), and blood pressure (mmHg) in various vessels in systemic circulation. (From Marieb EN. *Human Anatomy and Physiology*. Redwood City, CA: Benjamin/Cummings; 1989:629. Reproduced with permission of the publisher.)

Figure 3-24: Illustration of principle of resistance elements arranged in series versus parallel. (*Top*) If the driving pressurer (ΔP) across each series resistance is 3 mmHg, and flow (Q) is 1 mL/min, each resistance (R) would be $\Delta P/Q$, or 3 mmHg/mL per minute, and total resistance (R_t) would be 9 mmHg/mL per minute. (*Bottom*) In parallel resistances, if driving pressure (ΔP) is 3 mmHg, and flow (Q) is 1 mL/min, total resistance is $1/R_1 + 1/R_2 + 1/R_3$, or 1 mmHg/mL per minute. When three resistances are in parallel, total resistance is only one-ninth that with resistances in series, so it would take a ΔP of only 1 mmHg to produce a 1 mL/min flow. (From Smith JJ, Kampine JP. *Circulatory Physiology: The Essentials*. Baltimore: Williams & Wilkins, 1990:20. Reprinted with permission of the publisher.)

Figure 3-25: Regional blood flow at rest (shaded areas) and at maximal dilatation (stippled areas) per organ and per 100 g tissue, illustrating the concept of arterial/arteriolar vasodilator reserve. (From Mellander S, Johansson B. Control of resistance, exchange and capacitance functions in the peripheral circulation. *Pharmacol Rev* 1968; 20:117. Reprinted with permission of the publisher.)

Figure 3-26: Schematic diagram of integrated response of metabolic, myogenic and flow-mediated regulation of coronary vascular resistance and flow during increase in metabolic demand. Plus sign indicates vasodilatory feed-forward steps in response to initial increase in demand. Minus sign indicates negative-feedback processes that limit vasodilation. Events marked by lines ("Production of Metabolites") occur as a reaction to metabolic or vascular changes. Bolded items are metabolic or vasoactive adjustments. Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 4:

PRINCIPLES OF MOLECULAR CARDIOLOGY

Author: Robert Roberts

Application of the techniques of recombinant DNA to cardiovascular disorders appears to be essential and appropriate to overcome several of the major obstacles to immediate and future progress.[1-3] The heart exhibits three characteristic adaptive responses to changes in its environment: the constitutive adaptive mechanism-namely, myofibril stretch that regulates cardiac output on a beat-to-beat basis (Starling's law)[4]; modulation of excitation contraction coupling through intramyofibril calcium leading to increased heart rate and force of contraction; and the long-term adaptation of compensatory growth (see Chap. 5). The first two adaptations were characterized extensively in the 20th century through the development, refinement, and application of hemodynamic techniques. In the 21st century, the molecular basis for the growth response will be elucidated and will include deciphering the basis for cardiac differentiation and development. This will be necessary if one desires to therapeutically modulate growth. Similarly, elimination of restenosis after angioplasty probably will require disruption of smooth muscle migration and proliferative response.[5] Unraveling the molecular basis of hereditary cardiac disorders is well underway, and with completion of the Human Genome Project within the next couple of years, this will be accelerated considerably[6,7] (see Chap. 62).

We have already entered the era of genetically engineered drugs such as recombinant tissue plasminogen activator (rt-PA),[8] which initiated a paradigmatic shift in the therapy of myocardial infarction, resulting in an acute mortality of only 6 percent.[9] The era referred to as *pharmacogenomics* is rapidly approaching, in which therapy will be individualized on the basis of a patient's genotype.[10]

HISTORICAL PERSPECTIVE OF MOLECULAR BIOLOGY

In 1953, Watson and Crick[11,12] proposed the double-helix model for DNA structure based on the results of x-ray defraction studies by Franklin and Wilkins.[13,14] The implications of DNA being a double helix, in which each strand is a mirror image of the other, were evident, namely, that one strand could serve as a template for the synthesis of a daughter strand, thus providing the means whereby genetic information could be perpetuated from parent to offspring. In 1957, Kornberg[15] described DNA polymerase, the enzyme necessary for the synthesis of DNA that was essential to recombinant DNA technology. Marmor and colleagues showed that the double helix of DNA, when subjected to high temperatures,[16,17] could be separated into its separate strands (denatured), and decreasing the temperature resulted in the reannealing, or hybridizing, of the strands, thus returning them to their previous double-stranded nature. This specific hybridization, or "base pairing" of complementary nucleotide strands, provides both the rationale and the practical basis for much of recombinant DNA technology. Crick had suggested correctly that the genetic code would be written in codons of three nucleotides for each amino acid.[12] The specific combination of three nucleotides that code for each amino acid was unraveled by Leder and Nirenberg[18] and Nishimura et al.[19] Several other necessary components were discovered subsequently, including the enzyme DNA ligase, which joins DNA fragments together.[20] All this information was known in the 1960s, as was the complete DNA code, as well as messenger RNA and the cytoplasmic

ribosomal RNA for protein synthesis, but recombinant technology was not yet born and, in fact, for the next few years did not appear promising.

Many important discoveries, including those from the 1950s, played a role in recombinant technology, but four that really brought it to fruition and made possible modern molecular biology occurred between the years of 1970 and 1977. A major obstacle to the manipulation of DNA was its large size with no means to cut it into smaller pieces of known specific size. This obstacle was overcome by the discovery of restriction endonucleases that made it possible to cut DNA into smaller pieces in a predictable fashion.[21,22] These endonucleases, more commonly referred to as *restriction enzymes*, recognize specific sequences of DNA consisting of anywhere from four to eight nucleotides and specifically cut the DNA molecules at their recognition sites, making it possible to use and manipulate DNA fragments in a variety of procedures and reactions. In 1972, the enzyme reverse transcriptase was discovered by Baltimore[23] and Temin and Mizutani[24] simultaneously, making it possible to translate messenger RNA (mRNA) into its complementary DNA (cDNA). Shortly after the first molecule was cloned,[25] recombinant DNA techniques were born, as was modern molecular biology. In 1975, Sanger and Coulson[26] and Maxim and Gilbert[27] developed techniques for the rapid sequencing of DNA. In addition to these four developments, polymerase chain reaction (PCR), a more recently developed technique to rapidly amplify small amounts of DNA or RNA several million-fold, is also having a revolutionary effect on medicine and other fields.

Chapter 4: PRINCIPLES OF MOLECULAR CARDIOLOGY

NUCLEIC ACIDS

The Essentials of Nucleic Acids

The human genome is known to contain about three billion base pairs, which contain information that would more than fill a 500,000-page textbook. The DNA is contained in 46 chromosomes consisting of 44 autosomal and 2 sex chromosomes, but each chromosome is one continuous DNA molecule around which is wrapped several proteins. The smallest chromosome, 21, has more than 50 million base pairs, whereas chromosome 1, the largest, has over 250 million base pairs. There is enough DNA to form several hundred thousand genes; however, it is estimated that only about 67,000 genes encode for a human being. This would indicate that less than 5 percent of DNA is used to code for protein. The remainder of the DNA is used to provide spacing, structure, regulatory information, and other as yet unknown functions.

DNA consists of four building blocks referred to as *nucleotides* or merely as *bases*. A nucleotide consists of a nitrogenous base, a 5-carbon sugar (deoxyribose), and a phosphate group (Fig. 4-1). There are two purine bases (adenine and guanine) and two pyrimidine bases (cytosine and thymine) (Fig. 4-2). The triphosphate molecule is bonded to the 5′ carbon of the sugar, and the base is bonded to the 1′ carbon of the sugar. Each DNA molecule consists of millions of nucleotides joined together in a linear fashion through the phosphate group, which forms a bond with the hydroxyl group of the 3′ carbon of the next sugar. The phosphate groups form the backbone of the molecule, but because they are water-soluble, they face outward. Attached to the inner side of the sugar is the hydrophobic base, which faces inward to shield it from the aqueous environment. The molecule forms a right-sided spiral coil with a turn every 10 nucleotides (3.4 nm), referred to as a *right-sided α-helix*, and pairs with its complementary strand to form the so-called double helix (Fig. 4-3). The center of the molecule consists of the bases that face inward and are opposite to each other. This arrangement provides for the hydrogen bonding between the bases that keeps the two strands together. The hydrogen bonds are perpendicular to the helical axis. The directionality of the strands is referred to as *5′ to 3′* or *3′ to 5′*, which is based on the position of the carbons in the sugar. The end of the molecule with a phosphate or hydroxyl group on the 5′ carbon is termed the *5′ end*, whereas the end with a free terminal 3′ carbon is referred to as the *3′ end*. It is important to distinguish the two ends because the enzyme DNA polymerase always initiates replication of DNA from the 5′ end and proceeds to the 3′ end. There seems to be no constraints on which bases can be adjacent to each other; however, the hydrogen binding between the bases of the two chains is highly specific, since adenine (A) always pairs with thymine (T), and guanine (G) always pairs with cytosine (C). The sugars and the phosphate groups are always the same, whereas the sequence of the bases varies and determines the nature of the hereditary information to be passed onto the progeny. The specificity of this "base pairing" is the basis of the ability of DNA to replicate itself and pass on the genotype characteristics and also forms the basis for the specificity of essentially all the procedures used in recombinant DNA technology. During the process of DNA replication, the strands separate, and new strands form complementary to the original strands, resulting in two additional identical molecules.

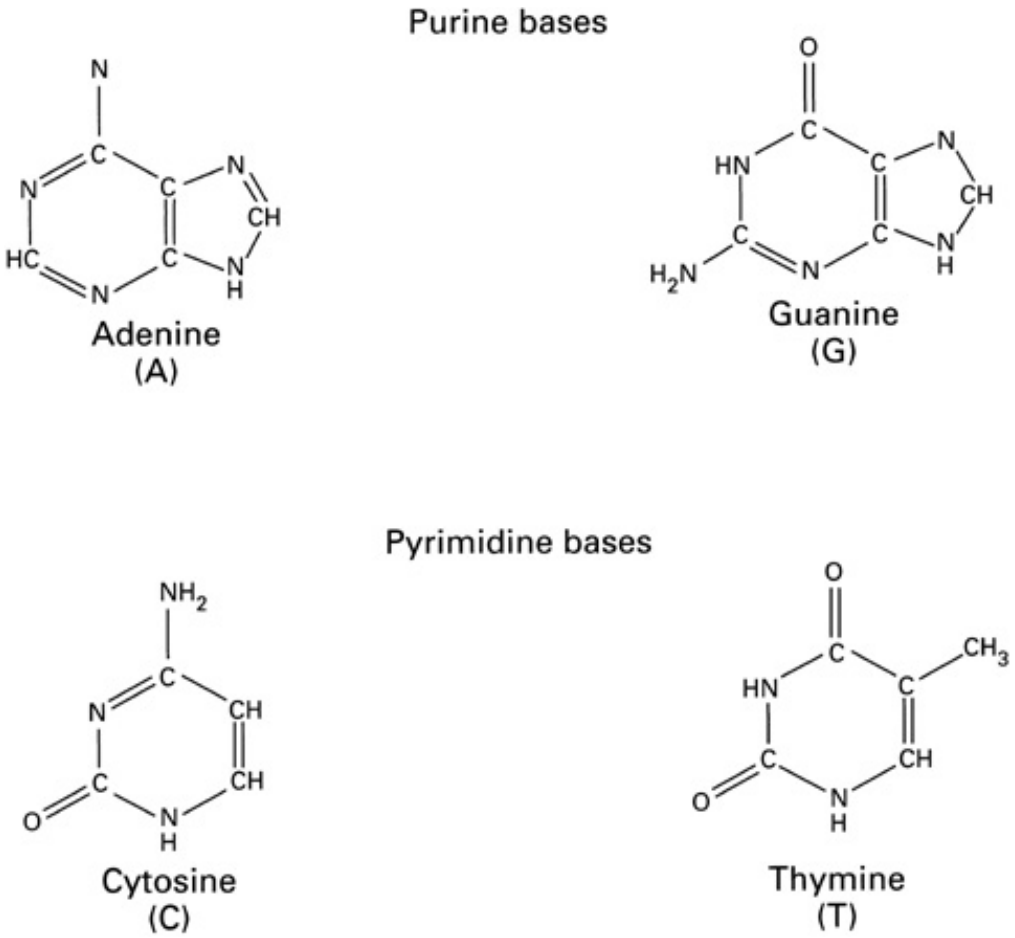

Figure 4-2: The common purine and pyrimidine bases found in DNA. Uracil is substituted for thymine in RNA. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

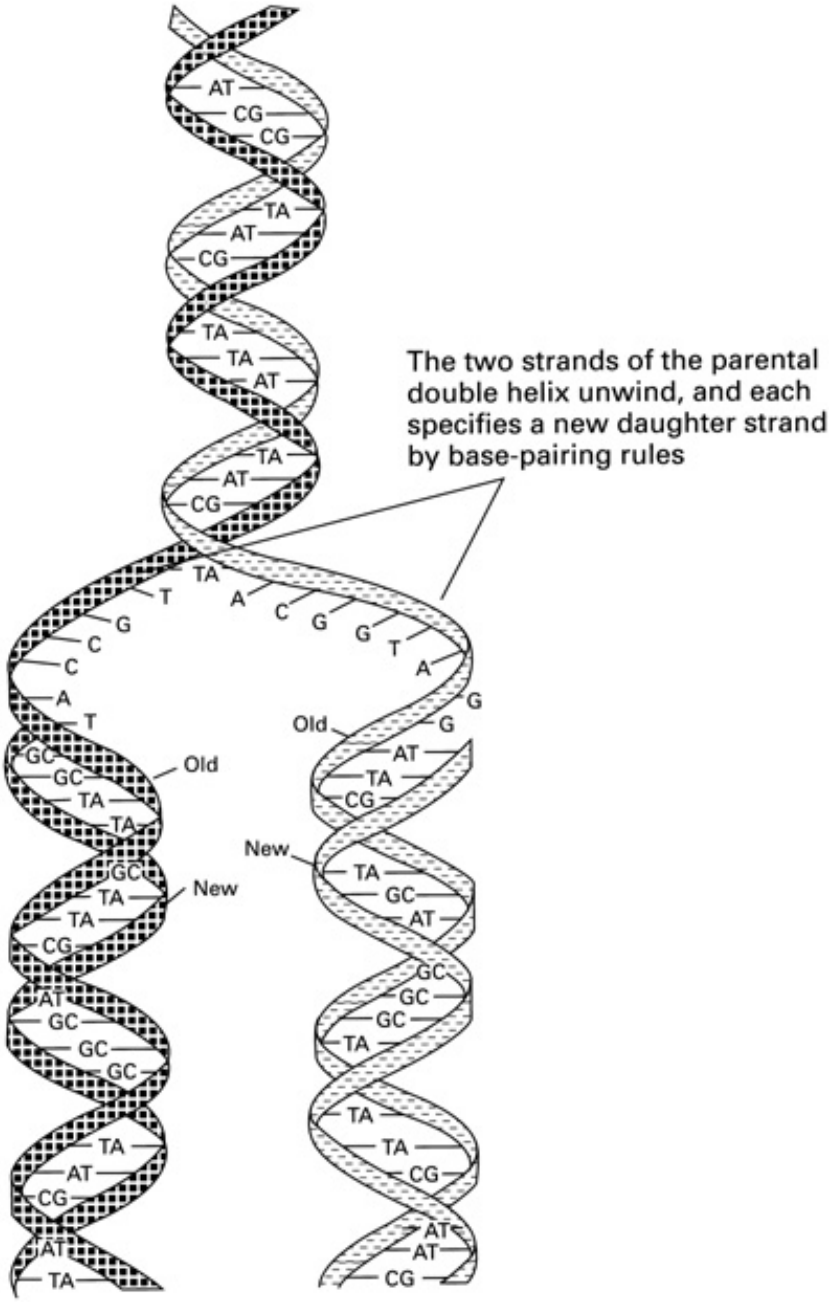

Figure 4-3: DNA replication conserves the nucleotide sequence. DNA is a double-stranded helical molecule bound together by the nucleotide bases contained on each individual strand. During cell division, two identical copies of the original parental strand are made by unwinding the DNA and then synthesis of a complementary second strand to make two identical new daughter strands.

Transcription (from DNA to RNA)

The central dogma of molecular biology is that DNA produces RNA, which in turn produces a polypeptide, the latter being the molecules that make up proteins that provide the cell structure and perform the functions of the cell (Fig. 4-4). The genetic information inherited by each individual is encoded by the sequence of the bases of the DNA (the genotype), which is translated into proteins and provides the observable characteristics of the individual (the phenotype). This overall process from DNA to protein, however, must first go through the intermediary step of RNA. The process whereby mRNA is synthesized using DNA as the template is referred to as *transcription* (Fig. 4-5). Transcription and the processing of mRNA occur in the nucleus of the cell, separated by the nuclear membrane from the cytoplasm of the cell. The process of

transcription is initiated by attachment of the enzyme RNA polymerase II to specific recognition sites where the DNA is double-stranded, but on activation by the enzyme, the strands now selectively unwind and separate (Fig. 4-6). The binding site of RNA polymerase II is always located on the 5′ end of the gene, and the enzyme remains attached to a single strand of DNA as it travels in the 3′ direction. The DNA immediately in front of it separates into two strands with just one strand of DNA (antisense) acting as a template for the synthesis of mRNA. Thus, in contrast to DNA, mRNA is a single-stranded polynucleotide. Messenger RNA also differs from DNA in that deoxyribose, the sugar found in DNA, is replaced by ribose. Moreover, uracil (U) replaces thymine (T), and like thymine, uracil pairs exclusively with adenine (A). Thus, by this mechanism, each adenine (A) of DNA pairs with uracil (U) of RNA, each cytosine (C) of DNA pairs with guanine (G) of RNA, each thymine (T) of DNA pairs with adenine (A) of RNA, and each guanine (G) of DNA pairs with cytosine (C) of RNA.

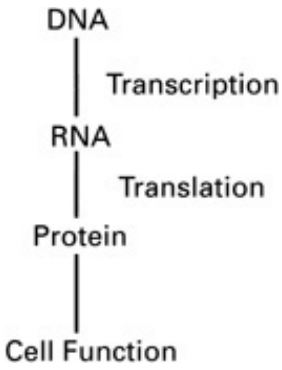

Figure 4-4: Central dogma of molecular biology.

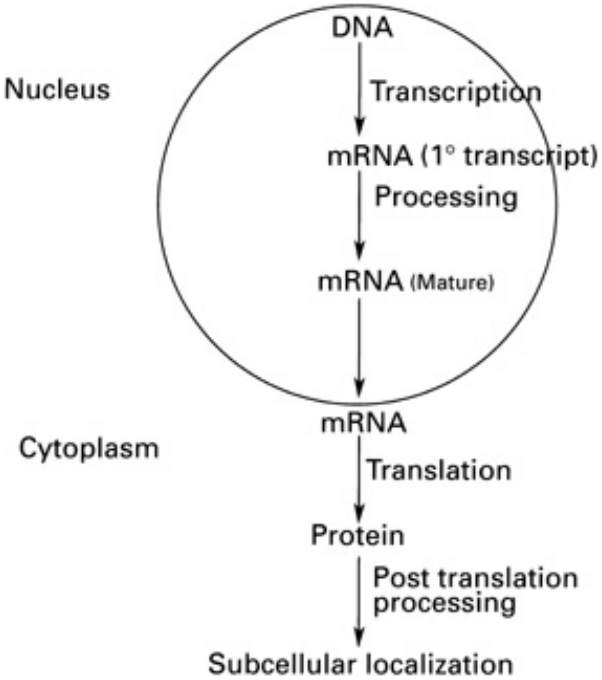

Figure 4-5: Schematic localization of the processes of transcription and translation.

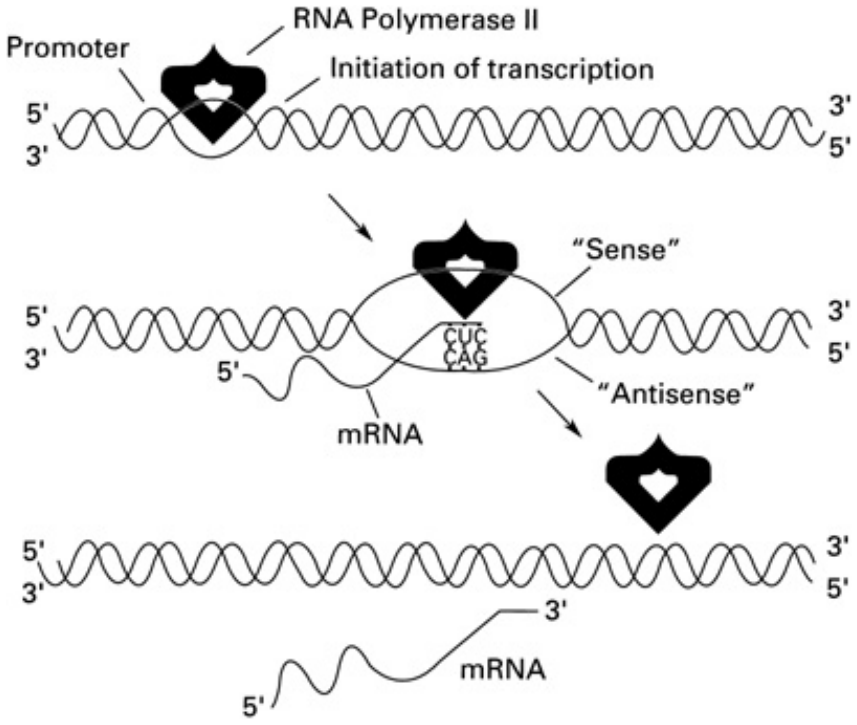

Figure 4-6: Illustration of how RNA polymerase II interacts with DNA and the promoter to generate a single-stranded mRNA. RNA polymerase II attaches to the initiation site promoted by the 5′ promoter sequence. mRNA is synthesized in the 5′ to 3′ direction from just one strand, the antisense strand. The specificity of base pairing between mRNA and the antisense strand provides for an mRNA with sequences complementary to that of the antisense strand and identical to that of the sense strand.

The mRNA, as transcribed from the DNA, is referred to as the *primary transcript*, or sometimes as *immature mRNA*, and is a complementary copy of the DNA (Fig. 4-7). Since protein synthesis occurs in the cytoplasm, the mRNA must exit the nucleus, but prior to transport, it undergoes extensive posttranscriptional processing primarily through three main events: (1) addition of a methylated guanosine (4-methylguanosine residue) to the 5′ end, referred to as a *cap*, which is important for the initiation of translation; (2) addition of a long tail of repeated adenine nucleotides, called the *poly(A) tail*, to the 3′ region of the mRNA, which is essential for stability of the message in the cytoplasm; and (3) the primary transcript, which contains introns and exons, undergoes a specific splicing process whereby the introns are removed and the exons are properly respliced together prior to exit from the nucleus as mature mRNA. The process of splicing is, in part, performed by molecules referred to as *small nuclear ribonucleoproteins* (snRNPs), which consist of RNA molecules tightly associated with a group of about 10 different proteins. Exons survive the mRNA processing and exit the nucleus (hence the name) as part of the mature mRNA. The mRNA consists of three distinct regions. The exons of the 5′ end are not translated into protein but signal the beginning of mRNA translation and contain sequences that direct the mRNA to the ribosome in the cytoplasm for protein synthesis. The exons in the second region, referred to as the *coding region*, contain the information that determines the amino acid sequence of the protein. The exons of the 3′ end do not code for protein but for signals that terminate translation and direct the addition of the poly(A) tail. Introns are portions of the gene included in the primary mRNA transcript but which are spliced out of the mature mRNA. The process of splicing out introns and rejoining exons is an important means of introducing genetic diversity, since one mRNA may provide several different mRNAs that code for different polypeptides (this will be discussed further under gene regulation). The primary transcript undergoes extensive shortening such that the mature mRNA often represents only 10 percent of the primary transcript. The mature mRNA exits the nucleus through nuclear pores, enters the cytoplasm, and attaches to a ribosome to initiate protein synthesis.

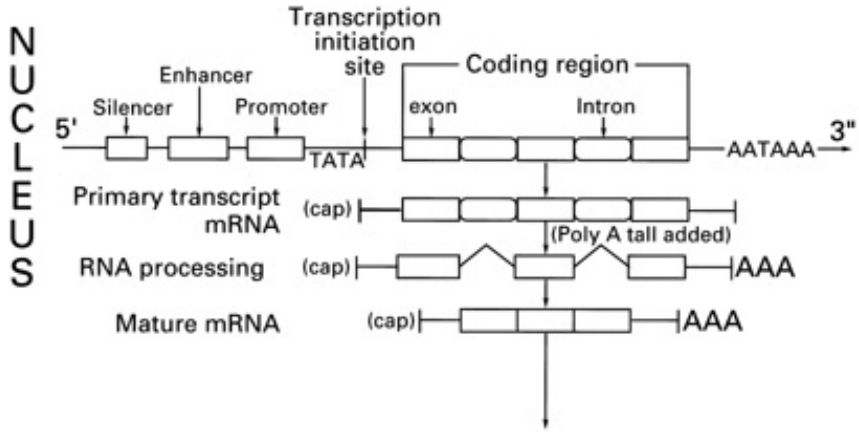

Figure 4-7: Transcription. Transcription occurs in the nucleus, producing mRNA that is processed into mature mRNA and transported to the cytoplasm. In the cytoplasm, translation occurs, with the mRNA coding for specific amino acids that are linked together to form a polypeptide and ultimately to form a mature protein. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

Translation

The final process whereby the nucleic acids of the mRNA code for a specific polypeptide is referred to as *translation*. This process is the most complex of the various processes that occur in the flow from genomic DNA (gene) to mature protein. The alphabet of the DNA or its single-stranded complementary mRNA is that of the four nucleotides (bases), whereas that of the protein is the 20 amino acids. Crick in 1961,[11] while trying to determine the code for translation from DNA to protein, showed that the genetic code was written in triplets of bases, with each amino acid being encoded by three base pairs referred to as a *codon* and specific amino acids determined by the sequence of the codon. The mRNA codons dictate which amino acids are to be selected, and the order of the codons dictates the sequence of the amino acids in the protein. Determination of the codons for each amino acid was completed in 1966. There are four different nucleotides to form the triplets; thus the number of combinations (4^3) is 64, but there are only 20 amino acids. There is considerable redundancy, referred to as *degeneracy,* and this results in most of the amino acids having more than one codon. In addition to codons for each amino acid, there is also the codon AUG, which is the start codon that initiates protein synthesis and also codes for methionine. To stop translation, there are three codons, UAA, UAG, and UGA, that signal the end of a particular polypeptide. Translation into protein requires two other RNA species, ribosomal RNA (rRNA) and transfer RNA (tRNA). The mRNA, after exiting the nucleus, recognizes the ribosome, which is the site of protein synthesis. The ribosome moves along an mRNA molecule, translating each of its codons in a 5′ to 3′ direction to assemble the polypeptide from its amino (N-terminal) to its carboxy (C-terminal) ends (Fig. 4-8).

The mRNA does not interact directly with amino acids but rather through adaptor molecules-referred to as transfer RNA (tRNA)-to which amino acids are covalently joined by a highly specific enzyme (aminoacyl tRNA synthetase) using ATP. There is at least one tRNA species corresponding to each of the 20 naturally occurring amino acids. The aminoacyl tRNA synthetase performs a special function of activating the amino acids and ensuring that each amino acid is joined to its tRNA and to no other. The structure of tRNA is now known in great detail, and its specificity is attributed to the sequence of three nucleotides complementary to the codon exposed at one end of the folded tRNA molecule, which, on the tRNA, is referred to as the *anticodon*. The

amino acid receptor site is exposed at the other end. Amino acids thus are specified at two recognition steps: one in which a specific enzyme joins the amino acid to a specific tRNA and the other in which the tRNA serving as an adaptor molecule joins the amino acid to the ribosomal-mRNA complex through a codon-anticodon specific-base-pairing interaction between the mRNA and the tRNA. Once the process of protein synthesis is initiated, the ribosome moves along the mRNA joining the amino acids via peptide bonds in the sequence specified by the mRNA to form the mature polypeptide. The process of protein synthesis from this complex of mRNA and ribosome involves over 100 enzymes. The steps involved consist of initiation, elongation, and termination of the polypeptide, with each process having its own enzymes.

The mature polypeptide consists of amino acids joined together by peptide bonds; the mature protein, however, often consists of multiple covalently bound polypeptides, and many undergo other modifications referred to as *posttranslational changes*. A more detailed analysis of protein synthesis is given in Chap. 5. Encoded in the polypeptide are other features that have been determined by the mRNA, namely, leader sequences that will direct the protein to either intracellular membranes, the plasma membrane, or organelles such as the mitochondria. There is also considerable proteolytic activity following entry of the molecule into its organelle, or membrane, as the leader sequences are removed. There are also the processes whereby disulfhydryl bonds are formed or glycosylation occurs (in the Golgi apparatus) (see Fig. 4-8). The mRNAs generally are not long-lived due to their rapid degradation by RNAses and so may last from only a few minutes to many hours. A single mRNA may code for only a few copies of the polypeptide or several thousand. The average estimate is 1400. In contrast, rRNAs and tRNAs are much less rapidly degraded and therefore have acquired the name *stable RNAs*. Their relative concentration in the cell, in large part, reflects their stability, with more than 80 percent being rRNAs, 15 percent being tRNAs, and less than 5 percent being mRNAs.

Gene Structure, Expression, and Regulation

The concept that one gene leads to one protein remains basic to the central dogma of molecular biology but does, in some cases, need to be modified slightly in view of recent observations. In the classic sense, a gene consists of a discrete unit of DNA that encodes for a specific polypeptide. Two observations must be noted: First, transcription produces two end points-ribonucleic acid (RNA) and protein. The products, or rRNA, tRNA, and small nuclear RNA (snRNA), do not get translated into protein but rather perform functions during posttranscription and translation that are pivotal to expression of the mRNA that does code for protein. The polymerases necessary for transcription of these genes are of three types, polymerase I for rRNA, polymerase II for mRNA, and polymerase III for tRNA and some other snRNAs. Second, in part because of snRNA and certain proteins, alternative splicing of the exons in the primary mRNA can lead to different mature mRNAs that each code for a slightly different polypeptide. The forms generally are isoforms of the same protein, however, such as multiple forms of tropomyosin from the same gene. The genes that do encode for proteins do so only through mRNA. The following discussion will address the regulation of those genes which encode for proteins.

The anatomy of a protein-coding gene is composed of introns and exons. The average exon is about 300 base pairs long, whereas introns are much larger and are spliced out of the mature mRNA and, thus, do not code for protein. A typical mRNA has three regions: the 5′ untranslated region that contains the cis-acting sequences that regulate translation; the central portion, referred to as the *coding region*, that codes for protein; and the 3′ untranslated end, which also has regulatory sequences and coding signals for stability of the mature mRNA. The first nucleotide to be transcribed is given the +1 number, and everything 5′ to it is referred to as *upstream* or *proximal* and is numbered with the first base pair as -1, etc. The initiation site for transcription is always upstream from the 5′ untranslated region. The 5′ regulatory untranslated region has variable sequences, but there are several consistent sequences present in the same position in most human genes. Polymerase II has no affinity for DNA and can only bind after several transcription

factors have bound. The site of transcription and its direction are determined by a TATA box, which has a consensus sequence of TATAA(T)AA(T) and is found at base pairs -25 to -30 upstream from the start site. A large complex of transcription factors (more than 25 proteins) binds to the TATA box in preparation for RNA polymerase II binding and transcription. Collectively, these transcription factors are referred to as *transcription factors for polymerase II* (TFII), with letters designating the different factors. TFIID binds first, then TFIIB, followed by RNA polymerase II, followed by several TFII factors such as E, F, G, H, and J, etc. TFIIH has kinase activity and phosphorylates RNA polymerase II, which now, independent of transcription factors, can initiate transcription. In addition, in many human genes, located at about base pair -200 upstream is the GGGCG box to which SP1 binds, and this is felt to be a regulator of housekeeping genes (Fig. 4-9).

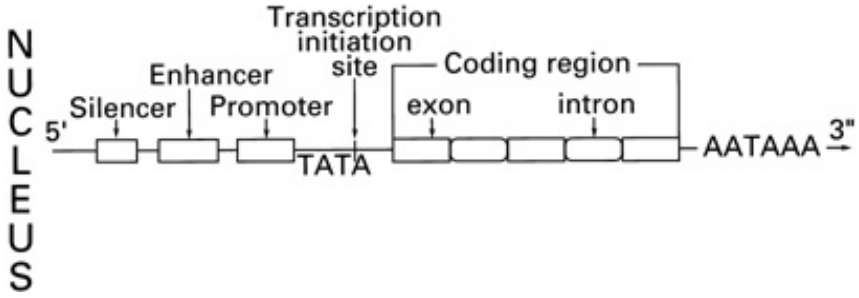

Figure 4-9: Structure of a gene. These small functional units within the nucleus contain the coding information for the synthesis of a polypeptide and on their 5′ ends have regulatory sequences that include silencers, enhancers, and promoters. The coding region consisting of exons (code for protein) as well as intervening noncoding sequences (introns) is followed by a 3′ noncoding region that is translated into the mRNA. The 3′ end appears important for exit of the mRNA from the nucleus and its stability in the cytoplasm but does not code for protein. The TATA is the initiation site for polymerase and is present in most eukaryotes at about 10 to 30 base pairs 5′ from the start codon (TAC) of the coding region. The AATAA will become the recognition site on the mRNA to which attaches an enzyme that cleaves the 3′ region and replaces the distal portion with a poly(A) tail. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

Gene expression refers to all the processes required to go from DNA to protein, from the initial unfolding of the nuclear chromatin in preparation for transcription to the mature protein emerging following completion of posttranslational changes. Regulation of this process occurs at all levels in response to signals both from within the cell and from the environment. The latter mechanism is of particular interest because it represents one of the major areas of research in molecular biology and cardiology, and it is also an area that has great potential for therapeutic intervention. The cell maintains its integrity and responds to external stimuli through signals that activate receptors (generally in the cell membrane). These in turn use signaling proteins to transfer their message to the cytoplasm or nucleus, which in some way modifies gene expression. Delineation of the receptor, the signaling proteins, and where and how gene expression is altered are of prime importance.

The most fundamental level of gene regulation involves cell differentiation (discussed later). The body contains at least 200 different types of cells that have been programmed by their genes to perform highly specialized functions. All cells have the same DNA and the same genes, but only those genes which are expressed determine the cell's phenotype. Cardiac myocytes, for example, are characterized by a set of proteins that specialize in contractile activity, whereas hepatocytes specialize in the synthesis and catabolism of proteins. Selective gene expression is the basis of cell

differentiation. Cell growth and replication occur in what is termed the *undifferentiated cell* but, through complex mechanisms, give rise to cells that cease to replicate and are programmed to take on specialized functions (cell differentiation). In the process of cell differentiation, genes-particularly those concerned with cell proliferation and undifferentiated functions-are down-regulated, whereas those genes coding for the proteins that perform the specialized functions are up-regulated. Once cells are differentiated, protein synthesis, however, remains a dynamic process to maintain cell integrity. Most of gene regulation is concerned with the maintenance of cellular integrity, and the genes responsible for this basal function are referred to as *housekeeping genes.* Housekeeping genes are constitutively regulated, as opposed to genes responsible for cell differentiation and growth, which are developmentally regulated. It is estimated that organs use about 10,000 genes (constitutive) to maintain their integrity, with one exception-the brain, which is estimated to use around 20,000 genes. Gene regulation may be classified under the following headings: pretranscription, transcription, posttranscription, translation, and posttranslation.[28]

Pretranscriptional regulation refers to the decompaction of the DNA and exposure of the region about to undergo transcription. The total DNA of a single cell would measure about 1 m in length, yet in the nucleus it is markedly compacted and is folded around specific proteins, the dominant class being histone. The coiling of the DNA appears to be in domains that can be exposed when transcription is activated. It is also at this level that methylation plays a part. Heavily methylated genes, made insensitive to digestion by the enzyme DNAse, tend not to be transcribed, whereas other areas sensitive to digestion appear to be very active in transcription. The precise mechanisms involved with chromatin conformational changes or exposure of the gene for transcription are, at present, relatively unknown. There is evidence, however, that methylation is involved in regulating cell differentiation.

The role of transcriptional control is a major rate-limiting step to gene expression. While transcription is catalyzed by the enzyme RNA polymerase II, the enzyme by itself cannot initiate transcription and acts only with the help of additional transcriptional factors. In addition to the promoter sequences previously described (TATA box and CG box), several DNA sequences in conjunction with their DNA-binding proteins act as either promoters, enhancers, or silencers of transcription and will be defined subsequently (see Fig. 4-9). The 5′ upstream region, immediately adjacent to the transcription initiation site and including the area that binds RNA polymerase II, is referred to as the *promoter region*. This region contains sequences that are specific binding sites for proteins referred to as *transacting factors,* or *transcriptional factors*. The protein-binding sites are often referred to as *cis-acting sequences* because they are on the same DNA molecule on which they act. The transcription factors (also referred to as *DNA-binding proteins*) are referred to as *transacting factors* (acting at a distance) because they are encoded by genes that may even be on another chromosome. The average promoter binding site consists of several hundred base pairs grouped into motifs of 4 to 10 base pairs.[29] It is hypothesized that all the motifs have to be bound by transcription factors of the appropriate nature and in the appropriate sequence for transcription to occur.

The promoter sequences and their corresponding DNA-binding proteins may act ubiquitously or may be tissue-specific. Promoters often increase transcription of a class of genes rather than a single gene. Another type of DNA sequence that increases transcription is referred to as an *enhancer* (see Fig. 4-9). Enhancers differ from promoter sequences in that they may be upstream or downstream from the coding region and be separated by as many as hundreds of thousand base pairs and are effective in either the 5′ to 3′ or 3′ to 5′ direction. An extreme example is the DNA sequence that enhances expression of the gene for hemoglobin, which is located more than 1 million base pairs from the transcription initiation site. These enhancers, like promoters, consist of several small motifs of 4 to 10 base pairs, and when bound by their corresponding DNA-binding proteins (transcription factors), they have a positive influence on gene transcription. Another regulatory DNA sequence that is similar to enhancers in size and location but exerts a negative influence on transcription is referred to as a *silencer* or *repressor*. It is believed that enhancer and

silencer sequences, when bound by transcription factors, communicate with promoters by DNA looping that is induced by the binding. This DNA binding that brings the enhancer, silencer, and promoter in close proximity is the mechanism responsible for the action-at-a-distance phenomenon seen in human gene regulation.

The genes that encode proteins regulating cardiac growth are many: growth factors, growth factor receptors, intracellular signaling proteins that relay growth signals from the extracellular milieu, and ultimately, transcription factors that regulate RNA polymerase and selectively induce or down-regulate gene expression.[30] Several DNA-binding proteins are recognized (transcription factors) ( Fig. 4-10), including the zinc-finger, leucine-zipper, helix-loop-helix, MADS domain, and helix-turn-helix proteins. The zinc-finger type of protein is used by developmental genes called *GATA factors* and the receptors for circulating hormones, including the glucocorticoids, progesterones, androgens, mineralocorticoids, estrogen, thyroxine, vitamin D_3, and retinoic acid. These hormones, which are lipophilic, penetrate the cell membrane and activate an intracellular receptor or nuclear receptor, which, in turn, activates gene expression through the zinc-finger transcription proteins. Many of the growth-related signaling proteins, such as c-fos, jun-B, and c-jun, dimerize through leucine-zipper proteins prior to binding to DNA. For example, c-fos dimerizes with c-jun and subsequently binds to DNA.[31] Transcription factors such as the *myo-D* family genes, which are the master genes for inducing differentiation of skeletal muscle, contain a helix-loop-helix motif. The MADS domain proteins include myocyte enhancer factor 2 (MEF2) and the serum response factor (SRF). The helix-turn-helix proteins include homeodomain-containing proteins that are important in the development of prokaryotes and eukaryotes.

Another level at which gene expression may be regulated is that of mRNA processing, whereby the introns are removed and the exons spliced together to provide the mature mRNA. In the majority of instances, each exon present in the gene is incorporated into a mature mRNA via ligation of consecutive pairs of exons and removal of all introns. This constitutive splicing process produces a single gene product from each transcriptional unit, even when the coding sequence is split into many separated exons. In other instances, however, nonconsecutive exons are joined in the processing of some gene transcripts, and this alternative pattern of primary mRNA splicing can exclude individual exons from mature mRNA in some transcripts and include them in others. The use of such differential splicing patterns creates mRNAs that generate a variety of proteins from a single gene. Differential splicing is particularly prevalent in genes of muscles and has been shown to occur in three of the eight major sarcomeric proteins studied thus far-myosin heavy chains, tropomyosin, and troponin T (skeletal and cardiac).

The 3′ non-protein-coding region of the mature mRNA contains the poly(A) tail, which is essential for message stability. It is believed that protein synthesis is, in part, regulated on the basis of alterations in message stability. The precise mechanism whereby an mRNA is induced to remain stable and encode several thousand polypeptides as opposed to being extremely unstable and encoding only a few molecules is not well understood. Nevertheless, it is likely to be an important step in regulating the response to cytoplasmic signals that require rapid synthesis of a particular polypeptide. Synthesis of a polypeptide initiated via transcription is estimated to take several minutes, whereas synthesis of a protein initiated through translation requires only seconds. Regulation of gene expression also occurs at the translational and posttranslational levels. Proteins are often translated as precursors that must undergo proteolytic cleavage. Others must undergo cleavage of leader sequences that are attached to direct them to their particular subcellular compartment. Other posttranslational modifications include protein glycosylation, the addition of polysaccharides and lipids, and the formation of disulfide bonds. Finally, polypeptides often polymerize with similar or different polypeptides to form complex tertiary structures that make up the mature proteins. The folding of polypeptides into mature proteins is guided by a group of genes that encode for so-called chaperone genes. Regulation of gene expression at the protein synthesis level is more fully discussed in Chap. 5.

Molecular Biology and the Basis for Recombinant DNA Technology

Modern molecular biology, initiated in the 1970s,[27,32] was in part due to four pivotal discoveries or inventions: restriction enzymes, reverse transcription, cloning, and DNA sequencing. Since DNA consists simply of four nucleotides joined together, it is a monotonous, repetitive molecule that, at first glance, offers no landmarks to recognize that a particular segment of DNA codes for a particular mRNA. The discovery of the restriction endonucleases provided the genetic scalpel to cut DNA into smaller pieces of predictable size that could be used in a variety of procedures. The unique feature of these enzymes is that each recognizes a specific sequence of DNA of 4 to 8 base pairs and cleaves the molecule at that particular site. Thus one knows precisely where the enzyme cuts, and using a number of different enzymes, one can identify the site and number of recognition sites for each enzyme in a fragment of DNA of interest and develop what is referred to as a *restriction map*. These enzymes also made it possible to cut DNA from different sources in a predictable manner in preparation for ligating them together into a recombinant molecule. Restriction endonucleases are obtained from bacteria, and enzymes have been purified that recognize more than 100 different cleavage sites. A restriction endonuclease is named after the bacterium from which it was isolated, taking the first letter of the genus of the bacterium, the first two letters of the species, and the first letter of the strain. An example of this would be an enzyme from *Haemophilus influenzae* referred to as *Hind-III*. The III simply refers to the third restriction endonuclease enzyme isolated from that particular species of bacteria. Thus the availability of restriction endonucleases made it possible to digest DNA into smaller molecules that could be manipulated and used in a variety of reactions and to develop a restriction map as well as develop chimeric DNA molecules, the latter being the essence of recombinant DNA technology.

The discovery that retroviruses contain an enzyme that catalyzes the formation of DNA from RNA, referred to as *reverse transcriptase,* revolutionized molecular biology. The resulting so-called complementary DNA (cDNA) (represented by the appropriate complementary bases for the mRNA, except, of course, with thymine replacing uracil) binds to the nucleotide sequences from which the particular mRNA was originally derived (Fig. 4-11). Messenger RNA, as discussed previously, codes for a specific polypeptide and is derived from a discrete, specific unit of DNA referred to as a *gene*. Reverse transcriptase reverses this process so that a cDNA is generated from an mRNA (coding part of the gene) and can be used as a gene to express the protein. The cDNA is reinserted into the genome of a vector (virus or plasmid) and subsequently replicated in an appropriate host, such as a bacterium, which made possible the first cloning of the gene. Radioactive labeling of a cDNA provides an extraordinarily powerful tool to develop known chromosomal landmarks and to isolate and identify particular genes. The labeled cDNA, referred to as a *probe,* or *indicator molecule,* is a routine, essential tool used to identify and isolate DNA or RNA fragments of interest. Development of rapid-sequencing techniques made it possible to sequence several thousand of bases per day. It is expected that a by-product of the Human Genome Project will be technology to sequence millions of bases per day.

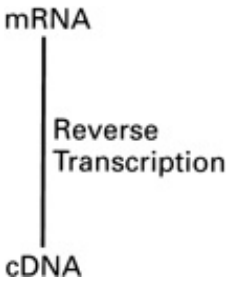

Figure 4-11: Generation of a complementary DNA (cDNA). Taking advantage of the enzyme reverse transcriptase, mRNA is converted to DNA, referred to as *complementary DNA* (cDNA). The DNA is single-stranded and complementary to the sequence of RNA, except thymine now

replaces uracil. Using DNA polymerase, one can then make the single-stranded DNA into double-stranded cDNA. The cDNA can be used as a probe to identify specific sequences or genes of the genomic DNA, or it can be inserted into vectors to be cloned or expressed in a variety of hosts.

Two features essential to all techniques of recombinant DNA technology need to be highlighted: The first is the ability of DNA to denature and anneal, or hybridize. The double-stranded DNA, held together by hydrogen bonding of the corresponding complementary bases, will, on exposure to high temperatures (95°C), separate into two strands, but under appropriate conditions (55°C), the complementary strands will again anneal precisely as originally and return to their normal double-stranded state. The process of separating into separate strands is referred to as *denaturation*, and the recombining process is known as *annealment*, or *hybridization*, with the latter term preferred if the two DNA fragments are from different sources. Second, the strands come together identically to the parent molecule because of complementary base pairing, whereby A must bind to T and C to G.

Unique Features of Recombinant DNA Technology

The techniques of recombinant DNA are unique and are not limited by some of the restrictions imposed on other scientific techniques.[3] Some of these are the abilities (1) to perform the structure-function analysis of a selected molecule or a portion thereof in the intact living cell or organism, (2) to isolate and identify genes responsible for hereditary diseases, (3) to unravel the molecular basis for the regulation of growth (including the heart), and (4) to generate large quantities of protein present only in trace amounts that otherwise would not be available, as well as the opportunity to genetically engineer proteins for maximum benefit with the least side effects. The techniques routinely used in molecular biology consist of electrophoresis, Southern and Northern blotting, DNA cloning, polymerase chain reaction (PCR), electrophoretic mobility shift assay, and the development of gene libraries. Techniques related to vessel wall biology and gene transfer are discussed in Chap. 8.

Isolation of DNA

Since the DNA of all human tissues is the same, practically any tissue can be used to obtain a DNA sample. It requires only a microgram for most procedures. In humans, lymphocytes are commonly used because they are very accessible and the DNA can be extracted easily. Lymphocytes are also used because they can be transformed by Epstein-Barr virus into an immortal cell line that can provide a continuous, renewable source of DNA. The cells can be grown in culture, frozen for years (from which samples can be obtained), thawed, and regrown, providing a renewable source of DNA for several decades. A sample of 10 to 15 mL of whole blood typically would yield about 50 to 100 μg of genomic DNA. If one's interest is restricted to the DNA sequences that are expressed, one would isolate mRNA and, using it as a template, employ reverse transcriptase to derive its cDNA. cDNA molecules represent the expressed form of a gene and thus can be used as probes to select the specific genomic DNA segments from which the mRNA was transcribed. Myocardial biopsies obtained under appropriate conditions provide adequate tissue for most DNA or RNA analyses.

Digestion and Electrophoretic Separation of DNA

One of the important physical properties of the DNA molecule is that each individual nucleotide possesses a net negative charge resulting from the phosphate group. Thus fragments of different sizes exposed to an electric field tend to migrate toward the positive electrode at differential rates depending on their size, with small fragments migrating faster than larger ones. This process of separation based on electric charge is called *electrophoresis*.[33] The DNA sample, after being digested into fragments of different size by a restriction endonuclease, is added to a gel matrix such as agarose or acrylamide. After separation by electrophoresis, the pattern of the DNA can be

visualized under an ultraviolet lamp with a fluorescent dye such as ethidium bromide (Fig. 4-12). Agarose gel electrophoresis will separate fragments from 1000 to 60,000 base pairs (60 kb) in size, and polyacrylamide gels effectively separate fragments smaller than 1000 base pairs (1 kb). The recent development of pulse-field gel electrophoresis (PFGE) made possible the separation of DNA fragments even up to 2000 kb in size. In this technique, the electric field is alternated in different directions, forcing the molecules of DNA to reorient between each pulse of electric current. Thus this technique is particularly suitable for isolating and characterizing large segments of DNA, such as to identify a known gene.

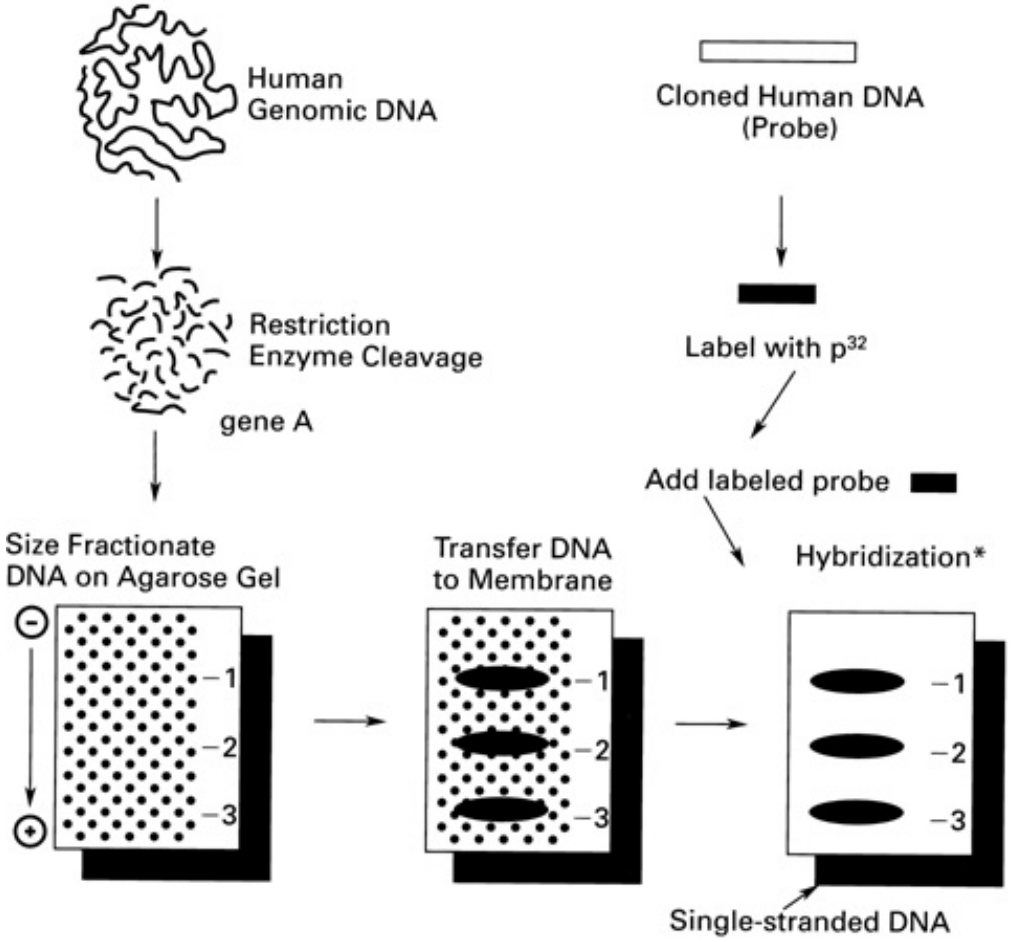

Figure 4-12: Southern blotting technique. The DNA is cleaved with an appropriately selected restriction endonuclease. The digested fragments are separated by electrophoresis on agarose gel, and the fragments of gene A are located at positions 1, 2, and 3 but cannot be seen against the background of many other randomly occurring DNA fragments. The DNA is denatured and transferred to a membrane in an identical pattern to what it was on the agarose gel. It is difficult to manipulate anything on a soft gel or to remove it. Once transferred to the membrane (filter), a solid support system, the DNA is much easier to handle. A DNA probe (cDNA) that has been labeled with 32P is hybridized to its cDNA and visualized after exposure of the nylon membrane to an autoradiograph. The transfer of the DNA from the gel to the membrane developed by Southern was a major innovation illustrated in the next figure. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

As noted previously, prior to electrophoresis, the DNA must be digested with one of the restriction endonucleases. The size of the fragments resulting from digestion will depend on the type of restriction endonuclease used, i.e., whether they recognize sequences of 4, 5, 6, or 8 base

pairs. Enzymes recognizing a 4-base-pair sequence will cut the DNA into much smaller fragments than one that recognizes an 8-base-pair sequence.

Development of a DNA Probe

A nucleic acid probe is a fragment of nucleic acid to which has been attached a label such as a radioisotope or a fluorescent compound, making it possible to easily detect and recognize the desired fragment among other native DNA molecules. The fragment labeled is usually cDNA or a synthetic oligonucleotide, although it could be RNA. It is now possible to synthesize DNA fragments of up to 30 to 40 base pairs, referred to as *oligonucleotides*, that, with an attached label, can be used as probes to identify cDNA in the human genome or mRNA. This takes advantage of the fact that at high temperatures, the double-stranded DNA probe and the native DNA will break into separate strands. On recombining at random, the labeled DNA probe can bind with either its original complementary strand or the native DNA that is complementary to the probe and thus provide a means of isolating a fragment of native genomic DNA. A probe is necessary in most recombinant DNA procedures to detect the molecule of interest following electrophoresis.

Southern, Northern, and Western Blotting

A procedure to separate and detect specific DNA fragments, referred to as *Southern blotting*, is named after E. M. Southern, who developed it in 1975.[34] Genomic DNA is isolated and digested into small fragments with restriction enzymes, and the fragments are separated by gel electrophoresis as described previously. Following separation, DNA fragments are denatured chemically into single-strand fragments. It is very difficult to handle gels and even more impractical to store them. Southern developed a technique whereby these separated single-strand fragments in the gel could be transferred by capillary action to a solid support medium (nylon or nitrocellulose membrane) and fixed permanently by heating. The pattern on the membrane reflects identically the pattern induced by electrophoresis on the gel. The process used to produce a Southern blot is illustrated schematically in Fig. 4-12. The nylon membrane and its attached single-strand DNA fragments are then incubated with a radioactively labeled complementary probe. The hybridized, radioactive double-strand product, on exposure to x-ray film (autoradiography), will exhibit the pattern of the radiolabeled DNA fragments (Fig. 4-13). In summary, the electrophoretic separation of DNA followed by its transfer to a nylon membrane for subsequent identification by radioactive hybridization is referred to as *Southern blotting*, and the autoradiogram as a *Southern blot*. The same approach to detect mRNA is referred to as *Northern blotting*. This procedure also can be used for detection of proteins, in which case it is referred to as *Western blotting* (Table 4-1). The only significant difference in detecting protein versus nucleic acid by this procedure is the probe, which is an antibody rather than an oligonucleotide, or cDNA. However, as in Southern and Northern blotting, the probe may be labeled with a radioactive isotope, a fluorescent tag, or some visual colorimetric substance.

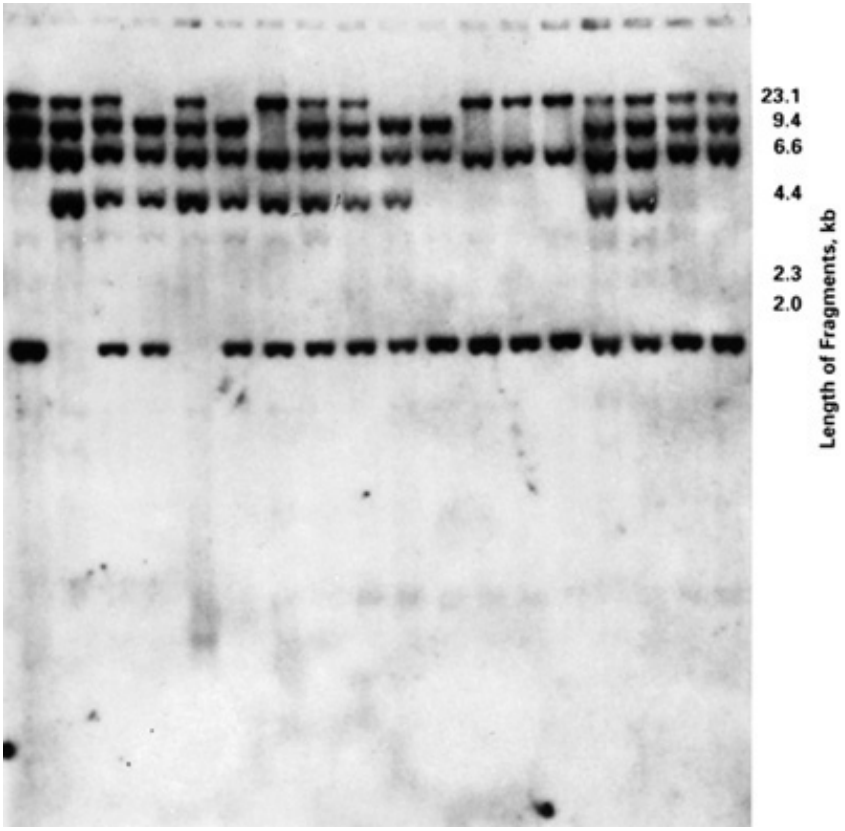

Figure 4-13: A typical Southern blot with distinct bands. Each vertical lane consists of DNA from a separate individual. All the individual DNAs were digested with the same restriction endonuclease. Following separation on electrophoresis and transfer to a nylon membrane, hybridization was performed with the selected radioactive probe, and thus only those fragments complementary to the probe are visualized. This is an analysis of a family with hypertrophic cardiomyopathy, and the different patterns reflect restriction fragment length polymorphisms (RFLPs) characteristic of the marker locus, which is linked to the disease locus. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

Procedures	Molecule	Labeled Probe
Southern blotting	DNA	DNA or cDNA
Northern blotting	RNA	DNA or cDNA
Western blotting	Protein	Antibody

Cloning of a Gene

DNA cloning is a technique used to produce large quantities of a specific DNA fragment of interest.[35] It generally is quite feasible to produce a billion copies of a DNA fragment by routine bacterial cloning techniques. The DNA fragment of interest (insert) is inserted into the DNA of a vector, and the vector is amplified in an appropriate host cell. The host provides amplification of the DNA of both the vector and the foreign insert. The prerequisites for cloning are (1) isolation of the DNA fragment of interest, (2) a vector, which is often an extrachromosomal segment of DNA

with the ability to propagate independently of the host DNA, (3) a restriction endonuclease to digest both the insert and the vector so the DNA ends will be compatible for ligation (as illustrated in Fig. 4-14), (4) a DNA ligase to ligate the insert into the vector, (5) a means to introduce the vector into the host cell, and (6) a means to differentiate the host cells that have incorporated the vector from those which have not. Standard vectors used in cloning have circular DNA and fall into three classes: (1) plasmids harvested from bacterial cells (a *plasmid* is an extrachromosomal segment of DNA present in bacteria that is self-replicating and on which are located certain genes that express resistance to ampicillin or other antibiotics), (2) bacteriophages (commonly referred to merely as *phages*, they are viruses that invade and multiply in bacterial cells), and (3) an artificially developed vector (referred to as a *cosmid*). The insert and vector are enzymatically ligated together by DNA ligase into circular DNA, and the recombinant product (hence the name *recombinant*) is incorporated into a host such as a bacterium or a mammalian cell for amplification (Fig. 4-15). In order to identify whether or not the particular DNA of interest has been replicated in the host, a so-called selection gene, such as one responsible for ampicillin resistance, is incorporated into the vector. The bacteria are grown in media containing ampicillin so that only those with the resistance gene will survive. Since the resistance gene is attached to the DNA fragment of interest, it indicates that colonies (bacteria) or plaques (phage) that survive must contain the gene of interest. The size of the insert is a limitation in cloning. Plasmids can only accommodate inserts up to approximately 15,000 base pairs, phages up to 25,000 base pairs, and cosmids up to 45,000 base pairs. Recently, a new vector has been developed, namely, bacterial artificial chromosomes (BACs), that accommodates DNA fragments of up to 200,000 base pairs. The yeast artificial chromosome (YAC),[36] developed several years ago, accommodates DNA inserts of up to 2 million base pairs but is extremely difficult to work with on a routine basis; in contrast, the BACs are as convenient as plasmids or phages. This has markedly accelerated the cloning of large fragments of DNA. Cloning, as discussed, is performed to obtain multiple copies of DNA, and unless specifically designed, the DNA is neither transcribed into mRNA nor translated into protein. If one desires to express a particular DNA fragment or gene, one must then use what is referred to as an *expression vector*. It is imperative to provide a promoter element that is appropriate for the host, and the gene must contain the appropriate 5′ untranslated region for binding to the ribosome as well as the appropriate 3′ region for stability of the message. An example would be the expression of rt-PA in mammalian cells, whereby the protein is expressed and secreted to be harvested and processed commercially for use as a thrombolytic agent.

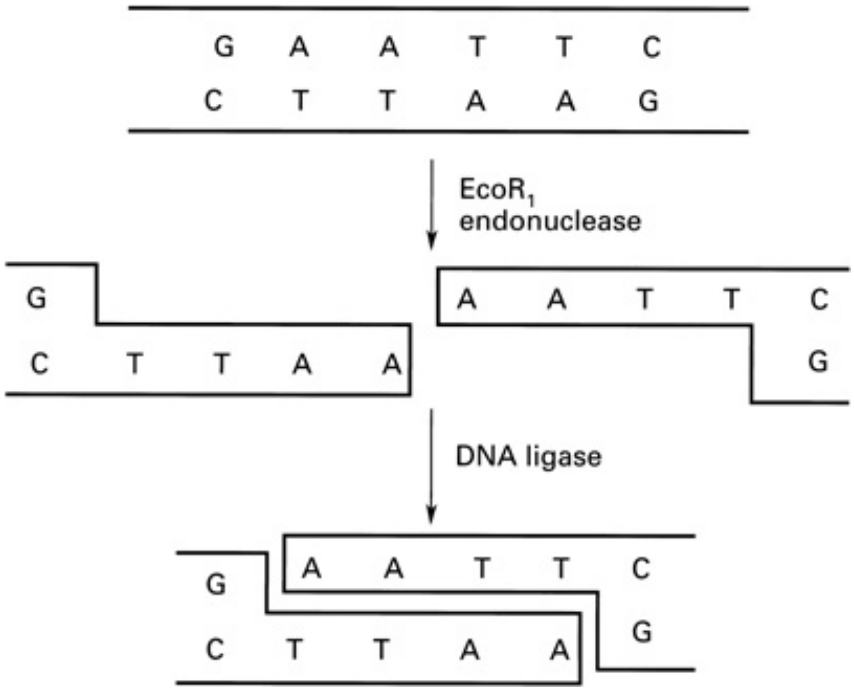

Figure 4-14: Restriction endonucleases recognize specific sequences and cut in a specific manner. The sequences recognized may be anywhere from 3 to 8 base pairs long and may cut to give a blunt end or a staggered end (EcoR1). Enzymes that provide staggered ends (cohesive or sticky ends) have unpaired bases that are easy to ligate together because they are complementary to each other, as shown in this illustration. This feature is exploited in cloning or in the formation of any recombinant DNA molecule. For cloning purposes, the fragment of DNA to be inserted is digested with the same restriction enzyme as is used to digest the DNA of the vector into which it will be inserted. Thus the sticky ends of the DNA insert and the vector will be complementary and easy to ligate together in the presence of the enzyme DNA ligase, as illustrated in Fig. 4-15.

Development of Gene Libraries

Gene libraries are usually called either genomic or cDNA libraries. A *genomic library* refers to one made from genomic DNA. A library is a collection of DNA fragments that have been cloned in an appropriate vector and grown in a particular host, usually bacteria. A major difference between a genomic and a cDNA library is that a genomic library contains DNA fragments composed of introns and exons, whereas a cDNA library is made from mRNA that represents genes expressed in a particular organ and does not have introns. The cDNA library contains genes specifically expressed in a particular tissue only. In contrast, a genomic library, whether derived from the heart or another tissue, will have the same genes. To make a human genomic library, one must first isolate the whole genome of a cell, cut it into fragments with a restriction enzyme, and insert the fragments into a vector replicated in an appropriate host, usually bacteria.[37] To increase the odds that enough fragments are cloned to represent the whole genome, certain calculations are necessary. It is assumed that the recognition site for a particular restriction enzyme occurs at random. For the restriction enzyme EcoR1, with a 6-base-pair recognition site, the average size of each fragment will be $4^6 = 4096$ base pairs. In contrast, if the recognition site involves 4 base pairs, each fragment would be $4^4 = 256$ base pairs long. If the 6-base-pair cutter were used for the human genome, the result would be the 3 billion base pairs of the human genome divided by 4096 to produce roughly 750,000 fragments requiring 750,000 colonies or clones. However, the recognition sites are not evenly or randomly distributed. Thus some fragments are larger and others are smaller, so to be certain, at least 1 million colonies would be required. Other factors also must be considered, such as the choice of vector with respect to insert size. Any part of the library that is used can be replaced by regrowing it, and thus the library is a permanent, renewable source of DNA. cDNA libraries of the whole heart and specific structures of the heart such as the Purkinje system are now available. To isolate a particular gene or fragment of DNA or cDNA from a library generally requires a radioactive cDNA probe.

Polymerase Chain Reaction

The PCR has revolutionized application of the techniques of molecular biology. This technique was not developed until 1985,[38,39] but its impact already has been felt throughout medicine and biotechnology. This procedure, conveniently and without the tedium of cloning, can provide 1 million copies of a DNA fragment in 3 to 4 h and 1 billion copies within 24 h. PCR simply and ingeniously takes advantage of the natural DNA replication process. One must know the sequence of the two ends of the DNA fragment that is to be amplified, but short sequences of 15 to 30 base pairs are adequate, and fragments in between these sequences as large as 20 kb can be amplified. The sequence is used to make two oligonucleotides, referred to as *primers*, with one for each end of the DNA fragment. The sequence of one primer is complementary to the sense direction, and the sequence of the other is made complementary to the antisense direction. The primers are used to prime the synthesis of cDNA strands and are designed such that the DNA between the primers is the fragment of interest to be amplified. If mRNA is to be amplified, it is first converted to a cDNA using the enzyme reverse transcriptase. The primers (oligonucleotides) and the necessary bases are added in excess, together with the enzyme Taq DNA polymerase (which catalyzes DNA synthesis) and a sample containing the DNA to be amplified. There are three steps to each cycle.

Initially, one must denature the DNA (separate the primers and the native DNA) into separate strands, which is done by increasing the temperature to 95°C. The temperature is then decreased to 50°C so that the primers and native DNA will reanneal to their complementary base sequences. The native DNA strands will bind not only to each other but also to the primers. The temperature is now increased to 65°C for synthesis of the new DNA fragments. Synthesis in the presence of Taq1 polymerase is initiated at the 5′ end, and further nucleotides are added in the 5′ to 3′ direction to provide the desired double-stranded DNA fragment. Taq1 DNA polymerase, isolated from *Thermus aquaticus,* is thermostable, which is of tremendous advantage in performing the PCR reaction. Since the high temperatures of up to 95°C do not destroy this polymerase, it negates the need to add DNA polymerase between each cycle. Furthermore, since Taq polymerase has an optimal activity at around 70°C, one can significantly accelerate DNA synthesis. The cycle is then repeated, and after about 30 cycles over 3 h, one should have about 1 million copies. There are many clinical applications for PCR. To make a diagnosis of viral myocarditis, for example, one can use PCR to amplify from a myocardial biopsy any specific viral RNA or DNA for which primers can be made. The sensitivity of most conventional techniques is inadequate to detect molecules unless present in 50,000 to 100,000 copies per cell. In contrast, only one copy of RNA or DNA is needed for detection by PCR, and in 3 to 4 h, up to 1 million copies can be generated, which is adequate abundance for detection by most conventional techniques. PCR offers exquisite diagnostic sensitivity and specificity for determining the etiology of cardiac disorders such as myocarditis, and in patients undergoing cardiac transplantation, it is used for detecting infection or immunologic rejection. Another application of PCR is to detect and amplify mutations associated with hereditary disorders. One also can sequence DNA directly from PCR without the need for cloning.

Electrophoretic Mobility Shift Assay (Band-Shift Assay)

This technique is used routinely to study transcriptional factors. On gel electrophoresis, DNA exhibits a certain migratory pattern owing to the large fragments moving more slowly and thus being detected as the stained bands closer to the negative electrode. If a transcription factor is bound to its DNA-binding site, migration is slowed, and the decreased mobility will be detected as a shift in the migrating band through the gel (hence the name). Using an antibody to the protein, one also can study the protein specifically. It was this technique that identified a unique family of DNA- and RNA-binding proteins that are specific for the triplet repeat CTG (or CUG) and are thought to play a role in the pathogenesis of myotonic dystrophy.[40]

Chapter 4: PRINCIPLES OF MOLECULAR CARDIOLOGY

THE SARCOMERE AND CARDIAC CONTRACTION

Cardiac myocytes are large cells of up to 120 μm in length.[41] They are joined together in a syncytium. The sarcolemma surrounding the myocyte through the intercalated disk joins to adjacent cells and invaginates into the myofibril through the T-tubules. Cardiac muscle is composed of fibers, which in turn are composed of myofibrils. The myofibril has a periodicity imparted to it by the sarcomere, which is the working unit of contraction. The sarcomeres are joined in series with each other via the Z-lines. The sarcomere is composed of many proteins, with myosin and actin being the predominant proteins comprising the thick and thin filaments, respectively. Two regulatory proteins are attached to the actin filament-tropomyosin and the troponins C, T, and I-and two myosin light chain molecules are attached to the myosin heavy chains. The sarcomeres comprise about 50 percent of the mass of the cardiac myocyte and, depending on the state of contraction, vary from 1.6 to 2.2 μm in length, as shown in Fig. 4-16. The specific molecular functions of the proteins that comprise the sarcomere are now beingcarefully elucidated by the discovery of mutations that are responsible for inherited diseases, particularly familial hypertrophic cardiomyopathy (FHCM). It is now recognized that FHCM is essentially a disease of the sarcomere, with eight sarcomeric genes having being identified exhibiting over 100 mutations that cause hypertrophic cardiomyopathy (HCM).

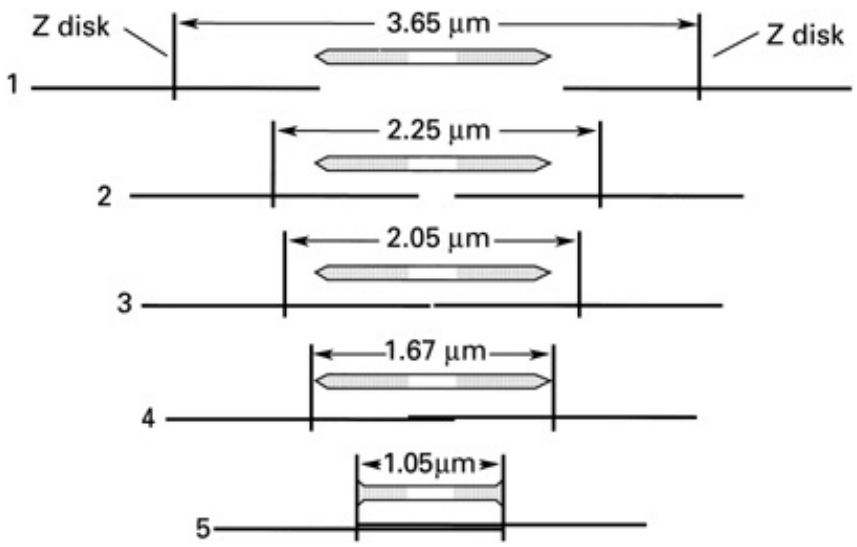

Figure 4-16: Relationship of sarcomere length and tension generated during isometric contraction of striated muscle. Maximum tension is generated at sarcomere lengths that allow maximum interaction of myosin heads and actin filaments (positions 2 and 3). If the sarcomere length is too short (positions 4 and 5), actin filaments overlap one another and prevent optimal interaction with myosin heads. (From Darnell J, Lodish H, Baltimore D, eds. *Molecular Cell Biology*. New York: Scientific American Books, W. H. Freeman; 1990. Reproduced with permission from the publisher.)

The Contractile Proteins

The proposed mechanism whereby the actin filaments slide over the myosin filaments and induce shortening or contraction is illustrated in Fig. 4-17. Cardiac contraction and relaxation are regulated in part by calcium. The sarcoplasmic reticulum (SR) induces contraction by releasing calcium and induces relaxation by sequestering it. Hydrolysis of ATP at a rate of one molecule per myosin head is required for each cycle, as the actin filament moves a distance of about 7 nm. In the relaxed state, myosin is prohibited from binding to actin by the presence of tropomyosin and troponin, which block the binding site for myosin. Myosin has minimal ATPase activity in the absence of actin; nevertheless, it does induce some hydrolysis of ATP to ADP and P_i. Systolic contraction is induced by calcium. Calcium released from the SR binds to troponin C, which induces a slight movement of tropomyosin that exposes the binding site on actin for myosin. The resulting binding of actin to myosin increases the ATPase activity of myosin by about 200-fold, which hydrolyzes the ATP to ADP. The ADP is released from the head of the myosin, which further enhances the binding of myosin to actin. The head of the myosin, which is oriented at a 90° angle to the actin, flexes to a 45° angle and in so doing moves the actin filaments closer together. Subsequently, the calcium is again sequestered by the SR, and ATP binds to the myosin head, which inhibits binding to the actin, relaxes the sarcomere, and reinitiates diastole (Fig. 4-18). Using high-intensity x-ray from a synchrotron, it has been possible to follow the changes in muscle-diffraction patterns during muscle contraction. The increase in cytosolic calcium and tropomyosin movement occur 17 ms after a muscle is stimulated. The myosin head attaches to actin after about 25 ms, and the tension is generated after about 40 ms (see also Chap. 5).

Chapter 4: PRINCIPLES OF MOLECULAR CARDIOLOGY

CYTOSKELETAL PROTEINS

The cell *cytoskeleton* refers to the fibrous proteins that are present in the cytoplasm. The cytoskeletal fibers give the cell strength and rigidity and control movement within the cell. For example, the microtubules provide the tracks along which vesicles are transported by tubulin-binding molecules. These cytoskeletal proteins form three major classes subdivided according to size into microfilaments,[42] microtubules, and intermediate filaments.[43] The microfilaments are polymers of the protein subunit actin; the microtubules are polymers of the subunits of α- and β-tubulin, and the intermediate filaments are polymers of five different rod-shaped protein subunits. The polymerization and depolymerization of these fibers are closely regulated by the cell. Just as FHCM is essentially a sarcomeric disease, it appears that familial dilated cardiomyopathy (FDCM) is a disease of cytoskeletal proteins. Mutations in dystrophin,[44] α-dystroglycan,[44] α-sarcoglycan,[45] metavinculin,[46] actin,[47] and desmin[48] have all been shown to be associated with FDCM.

Microfilaments

In addition to the actin thin filaments of the sarcomere, which help to generate the force of contraction, actin filaments are distributed throughout the cytoplasm of essentially all cells and serve to transmit force. To serve its role as a transmitter of force, actin is linked to several other proteins. The dual function of actin is exemplified in the thin sarcomere filaments that generate force by mutations that induce FDCM,[47] whereas other mutations in the portion of the molecule that transmits force induce FHCM.[49] Titan, which binds myosin to the Z-line, is essential to the velocity and force developed by myosin-actin interaction, as is nebulin, which attaches actin to the Z-line. Dystrophin is the protein encoded by the gene responsible for Duchenne muscular dystrophy and is known to be a subsarcolemmal protein with the function of anchoring actin to the plasma membrane. Spectrin, which binds actin to the plasma membrane, has several isoforms, one of which is specific to the heart.[50]

Microtubules

Microtubules are about 24 nm in diameter, varying widely in length from a fraction of a micrometer to tens of micrometers. The microtubule wall is made up of globular subunits about 4 to 5 nm in diameter, and these subunits are arranged in 13 longitudinal rows encircling the hollow-appearing center. This basic design is present in practically all microtubules. Colchicine, which inhibits microtubule assembly, does so by binding to the tubulin. Microtubules are involved in movement and organization of cell organelles.

Intermediate Filaments

In contrast to actin and tubulin, which are widely distributed among cell types, the rather insoluble intermediate filaments are tissue- and cell-specific. Actin and tubulin are globular, and the polymers they form are rather like beads on a string. In contrast, intermediate filament subunit proteins are extended molecules that form ropelike polymers. The intermediate filament proteins include desmin, vimentin, neurofilaments, glial fibrillary acid protein, and the keratins. In cardiac myocytes, desmin filaments connect the desmosomes from one muscle cell to another and form the scaffold for both the Z-disk and the myofibrils. The desmin filament plays a role in the

transmission of the stress and strain of contractile force between cardiac myocytes. It also connects the nucleus to the plasma membrane. Recently, it was shown that a mutation in the tail region of desmin causes FDCM.[48] Mutations in the rod region induce a phenotype exhibiting skeletal and cardiac manifestations, whereas mutations in the tail region exhibit only a cardiac phenotype.[48] The restriction of the phenotype to cardiac tissue suggests a specific cardic function for the tail domain.

Chapter 4: PRINCIPLES OF MOLECULAR CARDIOLOGY

MOLECULAR BASIS FOR CELLULAR GROWTH

Patterns of Growth (Hyperplasia, Hypertrophy, and Constitutive)

The molecular genetic basis for growth is somewhat distinct,[51,52] depending on when in the life of the organism it occurs, and may be divided into four phases: the embryonic phase of development and cellular differentiation (to be discussed later) occurring in utero, the rapidly growing phase prior to and during puberty, the normal constitutive maintenance growth throughout life, and compensatory growth in response to stimuli such as exercise or injury. Growth may be associated with an increase in the number of cells (hyperplasia) or just an increase in the size (hypertrophy) or just replacement of proteins as they are catabolized with no change in the number of cells, their size, or function (constitutive growth). During early development in the fetal and embryonic stages, practically all cells proliferate as well as increase in size and are said to be in cell cycle (Fig. 4-19). Throughout this process, certain cells drop out of cell cycle, cease proliferating, and undergo the process of differentiation. At birth or within weeks thereafter, certain cells of organs, such as the heart and brain, lose their ability to proliferate, and growth is restricted to the constitutive or hypertrophic type. Some cells undergo programmed cell death, called *apoptosis*. Many of the genes responsible for embryonic development subsequently downregulate after birth. Conversely, genes that code for proteins serving specialized functions in the differentiated cell are inhibited in the proliferating, undifferentiated cell and are only expressed on differentiation. For example, the muscle cell, on differentiation, downregulates the gene that encodes for BB creatine kinase and upregulates the gene that encodes for MM creatine kinase. Similarly, upregulation occurs for the genes that encode for myosin, actin, and other sarcomeric proteins essential to the contractile performance of the cell. It is estimated that the human body has a total of 10^{14} cells but only about 200 different types defined by their specific function. The specialized functions of a cell are determined by the repertoire of genes expressed in that particular cell.

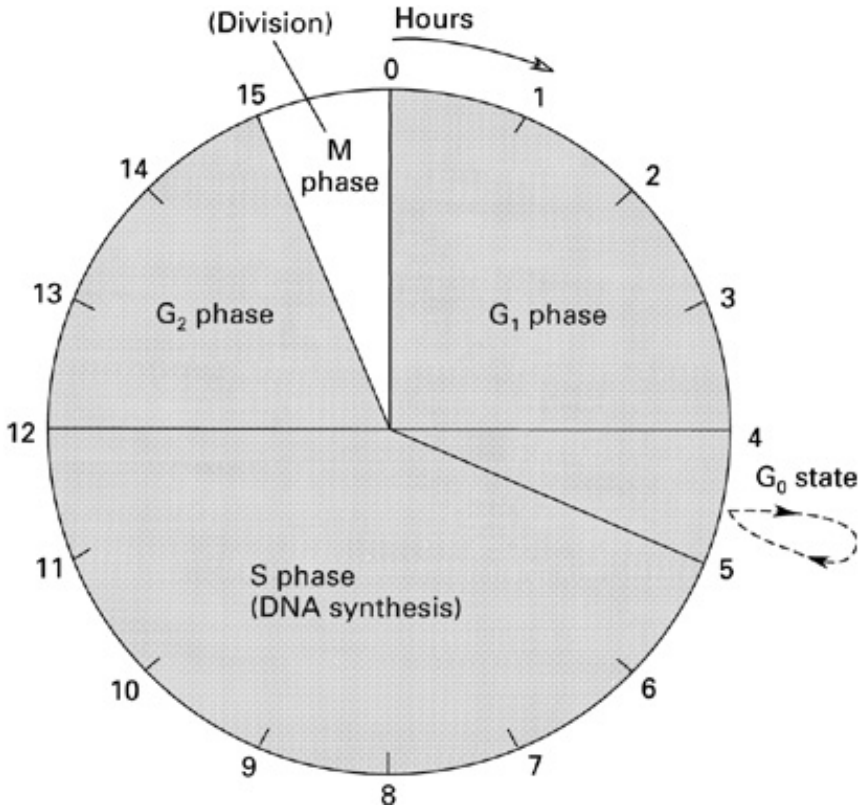

Figure 4-19: The cell cycle in a mammalian cell having a generation time of 16 h. The three phases spanning the first 15 h or so-the G1 (first gap) phase, and S (synthetic) phase, and the G2 (second gap) phase-make up the interphase, during which DNA and other cellular macromolecules are synthesized. The remaining hour is the M (mitotic) phase, during which the cell actually divides.

In the adult heart, most of normal growth is constitutive. It is estimated that most of the proteins of the heart are replaced every 5 days, except collagen, which replaces itself every 120 days; with hypertrophy, however, the half-life of collagen is only 17 days. Thus, in humans, the heart is replaced about every 3 weeks. It is estimated that all human functions are determined by about 67,000 genes, and about 10,000 genes (proteins) are required to maintain basal cellular integrity of a particular organ, except the brain, which requires about 20,000 genes. Thus, maintaining normal cellular homeostasis is a dynamic growth process. For example, in every second of a human being's life, more than a million trillion hemoglobin molecules are synthesized.

Growth Factors and Receptors Underlying the Growth Response

Normal and pathologic growth is initiated by multiple factors. Several of the circulating hormones, such as growth hormone, thyroxine, mineralocorticoids, glucocorticoids, and angiotensin II, act as growth factors. Growth factors such as transforming growth factor beta (TGFβ) and the fibroblastic growth factors (FGFs) are produced locally, released into the immediate environment, and mediate their effect on growth through what is termed *paracrine* or *autocrine mechanisms. Paracrine* refers to a growth factor that is secreted and affects the growth of adjacent cells. *Autocrine* refers to a growth factor that binds to the receptors of the same cell from which it was produced and secreted. *Intracrine* refers to a growth factor that induces growth in the same cell from which it was produced without being secreted. An external stimulus that influences growth is detected by a receptor that usually sits on the cell's surface as an intramembrane receptor and is relayed through several signaling or transducing proteins to the nucleus of the cell, where the ultimate effector molecule is a transcription factor (Table 4-2). The effector molecule also may affect growth through regulation of translation. The latter, however, is usually more transient, whereas a sustained change in growth almost always is mediated through

transcription. The signaling proteins usually involve kinases and phosphatases, which through phosphorylation transfer ATP to amplify the signal and by dephosphorylation decrease it or in some way alter it (Fig. 4-20). Regulation of protein synthesis also may result from altered stability of mRNA. The growth response to circulating hormones or locally produced growth factors occurs several hours after the initial stimulation and is more likely to occur if two or more growth factors have been activated (see Chap. 5). In the case of the heart, a common signal is increased intraventricular pressure, which results in compensatory hypertrophy (see Chap. 5).

Chapter 4: PRINCIPLES OF MOLECULAR CARDIOLOGY

THE CARDIAC GROWTH RESPONSE

The growth response of the myocardium to injury, whether it be myocardial infarction, hypertension, or valvular disease, is a major determinant of morbidity and mortality. Growth is the major long-term adaptive mechanism of the heart (see Chap. 5). In hypertrophy, the sarcomeres are added in parallel, which gives rise to thickened walls of the cardiac chambers.[53] In contrast, in cardiac dilatation, the growth is achieved by adding sarcomeres in sequence.[54] It remains to be determined whether dilated cardiomyopathy occurring as a pathologic entity is a normal compensatory response or represents abnormal growth or an inadequate growth response.

Developmental growth in utero or during prepuberty and puberty is associated with orchestrated stimuli from a variety of hormones such as growth hormone. This is in sharp contrast to the restricted cardiac growth observed in the adult in response to injury. For example, in aortic constriction, the left ventricle responds with increased mass, while the right ventricle is not affected. Hammond et al.[55] in 1979 demonstrated that the growth stimulus was indeed localized to the affected organ. Left ventricular hypertrophy was induced by aortic coarctation in the dog. Supernatants of the homogenized, hypertrophied left ventricle from dogs with aortic coarctation and normal dogs were used to perfuse a normal canine heart. Messenger RNA of the perfused heart was increased by extracts from the hypertrophied left ventricle but not from the normal myocardium, indicating the presence of a growth factor in the hypertrophied ventricle. This established the presence of a localized cellular stimulus acting through autocrine, paracrine, or intracrine mechanisms to induce cardiac hypertrophy. This was confirmed by Imamura et al.[56] in 1990; they showed that hypertrophy occurs in the left ventricle in response to aortic coarctation without growth in other chambers of the heart, while banding the pulmonary artery induced hypertrophy of the right ventricle without involvement of the left ventricle. Similarly, hypertrophy induced by volume overload, myocardial infarction,[57] or other forms of injury is restricted to the cardiac chamber involved. Despite the myocyte not increasing in number in the adult heart during hypertrophy, certain other features are interesting and unique. Cardiac myocytes, during their normal growth response, exhibit DNA synthesis (multiple nuclei)[58] and the reexpression of several fetal proteins otherwise expressed only in embryonic cells.[59] The rational basis for the reexpression of fetal protein is not obvious. The response has been referred to as *adaptive*, *maladaptive*, or part of a *triggered program response*.[28] The atrial natriuretic factor gene is expressed in the atria and ventricles in the embryonic state but not in the normal adult ventricle. It is reexpressed in the ventricle during hypertrophy.[60] Calcium ATPase, an enzyme essential to cardiac contractility, is decreased in the hypertrophied human ventricle.[61] It is well documented in the developing mammalian heart in utero that the initial actin gene expressed is that of smooth muscle type, followed by that of skeletal muscle and finally cardiac muscle.[62] The functional significance, if any, of the reexpression of fetal genes when the cardiac growth program is turned on in the adult heart is unknown. It is possible that the growth response can only be activated through expression of a family of genes. The master gene controlling expression of such a family could be triggered by a growth factor stimulated by pressure overload; this could result in a cascade of genes expressed, most of which are incidental rather than adaptive or maladaptive. For example, in skeletal muscle there is a master gene, *myo-D*,[63] that triggers the differentiation of skeletal muscle. When this occurs, a cascade of genes is downregulated, and another cascade of genes is upregulated. *Myo-D* is not expressed in cardiac muscle, and no such triggering factor has been found for cardiac myocyte differentiation (see Chap. 9).

Chapter 4: PRINCIPLES OF MOLECULAR CARDIOLOGY

List of Figures

Figure 4-9: Structure of a gene. These small functional units within the nucleus contain the coding information for the synthesis of a polypeptide and on their 5′ ends have regulatory sequences that include silencers, enhancers, and promoters. The coding region consisting of exons (code for protein) as well as intervening noncoding sequences (introns) is followed by a 3′ noncoding region that is translated into the mRNA. The 3′ end appears important for exit of the mRNA from the nucleus and its stability in the cytoplasm but does not code for protein. The TATA is the initiation site for polymerase and is present in most eukaryotes at about 10 to 30 base pairs 5′ from the start codon (TAC) of the coding region. The AATAA will become the recognition site on the mRNA to which attaches an enzyme that cleaves the 3′ region and replaces the distal portion with a poly(A) tail. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

Figure 4-10: Types of transcription factors that affect gene activation. Schematic representation of the shapes of four types of protein transcription factors that bond to DNA and influence gene activation. Helix-turn-helix is a protein with two α-helices separated by a β-turn. Leucine zippers are protein dimers with entering leucine amino acids. Zinc fingers have a peptide loop connected at the base by a zinc ion tetrahedran between cysteine and/or histidine in amino acids. The helix-loop-helix consists of α-helix but uses leucine zippers and has a loop between the α-helices. The darkened areas are believed to be the regions of the protein that interact with the DNA to modulate transcription.

Figure 4-11: Generation of a complementary DNA (cDNA). Taking advantage of the enzyme reverse transcriptase, mRNA is converted to DNA, referred to as *complementary DNA* (cDNA). The DNA is single-stranded and complementary to the sequence of RNA, except thymine now replaces uracil. Using DNA polymerase, one can then make the single-stranded DNA into double-stranded cDNA. The cDNA can be used as a probe to identify specific sequences or genes of the genomic DNA, or it can be inserted into vectors to be cloned or expressed in a variety of hosts.

Figure 4-12: Southern blotting technique. The DNA is cleaved with an appropriately selected restriction endonuclease. The digested fragments are separated by electrophoresis on agarose gel, and the fragments of gene A are located at positions 1, 2, and 3 but cannot be seen against the background of many other randomly occurring DNA fragments. The DNA is denatured and transferred to a membrane in an identical pattern to what it was on the agarose gel. It is difficult to manipulate anything on a soft gel or to remove it. Once transferred to the membrane (filter), a solid support system, the DNA is much easier to handle. A DNA probe (cDNA) that has been labeled with 32P is hybridized to its cDNA and visualized after exposure of the nylon membrane to an autoradiograph. The transfer of the DNA from the gel to the membrane developed by Southern was a major innovation illustrated in the next figure. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

Figure 4-13: A typical Southern blot with distinct bands. Each vertical lane consists of DNA from a separate individual. All the individual DNAs were digested with the same restriction endonuclease. Following separation on electrophoresis and transfer to a nylon membrane, hybridization was performed with the selected radioactive probe, and thus only those fragments complementary to the probe are visualized. This is an analysis of a family with hypertrophic cardiomyopathy, and the different patterns reflect restriction fragment length polymorphisms (RFLPs) characteristic of the marker locus, which is linked to the disease locus. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

Figure 4-14: Restriction endonucleases recognize specific sequences and cut in a specific manner. The sequences recognized may be anywhere from 3 to 8 base pairs long and may cut to give a blunt end or a staggered end (EcoR1). Enzymes that provide staggered ends (cohesive or sticky ends) have unpaired bases that are easy to ligate together because they are complementary to each other, as shown in this illustration. This feature is exploited in cloning or in the formation of any recombinant DNA molecule. For cloning purposes, the fragment of DNA to be inserted is digested with the same restriction enzyme as is used to digest the DNA of the vector into which it will be inserted. Thus the sticky ends of the DNA insert and the vector will be complementary and easy to ligate together in the presence of the enzyme DNA ligase, as illustrated in Fig. 4-15.

Figure 4-15: DNA cloning. The basic objective of cloning is to provide multiple copies of a DNA fragment of interest. The fundamental principles for in vitro cloning of specific DNA fragments are as follows: (1) The human genome DNA of interest is isolated after digested by a restriction endonuclease, which is often referred to as the *DNA insert*. (2) A DNA vector is selected (shown on the right); the vector is a plasmid that has circular DNA and contains the necessary replication site and the reporter gene (drug resistance gene) to subsequently recognize which host has the insert. The vector and the DNA fragment to be inserted are digested with the same restriction endonuclease so that the ends are complementary for ligation. (3) DNA ligase ligates compatible insert and vector ends together. (4) Finally, host cells are transformed by incorporating vectors containing insert fragments and are identified by characteristics encoded by resident genes on the vector. Some of the clones will be viable and others not. (From Mares A Jr, Towbin J, Bies RG, Roberts R. Molecular biology for the cardiologist. *Curr Probl Cardiol* 1992; 17:9-72. Reproduced with permission from the publisher and authors.)

Figure 4-16: Relationship of sarcomere length and tension generated during isometric contraction of striated muscle. Maximum tension is generated at sarcomere lengths that allow maximum interaction of myosin heads and actin filaments (positions 2 and 3). If the sarcomere length is too short (positions 4 and 5), actin filaments overlap one another and prevent optimal interaction with myosin heads. (From Darnell J, Lodish H, Baltimore D, eds. *Molecular Cell Biology*. New York: Scientific American Books, W. H. Freeman; 1990. Reproduced with permission from the publisher.)

Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 5:

MOLECULAR AND CELLULAR BIOLOGY OF THE NORMAL, HYPERTROPHIED, AND FAILING HEART

Author: Richard A. Walsh

INTRODUCTION

Growth of the heart is a dynamic process that occurs during embryogenesis, postnatal development, maturity, and senescence and in response to changing environmental and pathologic conditions. Cardiac growth occurs at the cellular level as a consequence of the interplay between *hyperplasia* (increase in cell number) and *hypertrophy* (increase in cell size) or a combination of both processes. The relative importance of each of these two mechanisms depends upon the cell type, developmental stage, and the nature of the growth stimulus. These two forms of cell growth are variably modulated by *apoptosis*, or programmed cell death.[1,2] This phenomenon is of importance in the determination of heart shape and chamber formation during cardiogenesis and may contribute to altered cardiac chamber geometry in response to pathologic stimuli. Physiologic and pathologic cardiovascular growth are generally mediated by developmental programs, mechanical deformation, and injury in various combinations. These processes stimulate a repertoire of biochemical signals that alter the cardiovascular phenotype. The application of molecular and cell biological approaches to this problem is rapidly defining the precise factors responsible for normal and pathologic growth of the heart and the mechanisms responsible for altered cardiac function.

Chapter 5: MOLECULAR AND CELLULAR BIOLOGY OF THE NORMAL, HYPERTROPHIED, AND FAILING HEART

CARDIAC GROWTH AND HYPERTROPHY

Cardiac hypertrophy is a process wherein there is an increase in chamber mass produced largely by an increase in the size of terminally differentiated cardiomyocytes. Although cardiomyocytes make up only one-third of the total cell number, they are responsible in aggregate for over 70 percent of cardiac volume. Cardiac hypertrophy may be reasonably categorized as either physiologic or pathologic (Fig. 5-1).

Physiologic Hypertrophy

Physiologic hypertrophy includes cardiogenesis during embryonic development, postnatal cardiac growth, a modest additional increase in heart size that evolves during senescence, and the increase in heart size that occurs in response to athletic conditioning. The earliest stage of cardiac growth in utero depends on a genetically determined developmental program, since it can occur in the absence of contractile activity. Subsequently, mechanical forces become increasingly important in the development of the normal cardiac phenotype. Throughout the embryonic period and for a few weeks after birth, cardiac growth occurs as a consequence of hyperplasia and hypertrophy of myocytes (see Chap. 9). Classically, adult myocytes have been described as terminally differentiated-that is, incapable of reentering the cell cycle. This issue is currently undergoing reexamination. It is critical to make a distinction between DNA synthesis and cell division. In the adult cardiomyocyte, DNA synthesis may clearly result in either multinucleation or polyploidy (an increase in the DNA content of a single nucleus). By contrast, there is little evidence that cardiomyocytes are capable of division under normal conditions after the early postnatal period.[3,4] The capacity to reactivate hyperplasia in the terminally differentiated cardiomyocyte is an area of intense research interest, with potentially important therapeutic implications in the hypertrophied and failing heart.[5]

From birth to maturation, the mammalian heart undergoes a sixfold increase in mass. The normal heart/body weight ratio is species-specific. The largest hearts relative to body size occur in animals with survival requirements that depend on sustained exercise rather than on burst activity.[6] In humans, intense, prolonged exercise training can produce an increase in cardiac mass. Isotonic exercise, such as running, produces *eccentric hypertrophy*, characterized by a normal ratio of wall thickness to dimension, whereas isometric exercise, such as weight lifting, stimulated *concentric hypertrophy*, associated with an increased ratio of wall thickness to dimension.[7] Senescent animals and humans free of organic heart disease develop mild concentric left ventricular hypertrophy as a consequence of age-related decreases in the distensibility of the peripheral vasculature.[8] The molecular, biochemical, and physiologic changes associated with physiologic hypertrophy differ both qualitatively and quantitatively from those that occur during pathologic hypertrophy. Physiologic studies in animal models and humans have demonstrated no substantial alterations in isolated muscle or intact heart function. There is also little evidence of alterations in the molecular determinants of excitation-contraction coupling. Most importantly, epidemiologic data fail to demonstrate adverse risk associated with the modest hypertrophy that occurs as a consequence of athletic conditioning. It is, therefore, important clinically to distinguish physiologic hypertrophy from hypertrophic cardiomyopathy in athletes (see Chap. 67).

Pathologic Hypertrophy

Pathologic hypertrophy is an important adaptive response to abnormal global or regional increase in cardiac work. Initially, the increase in cardiac mass serves to normalize wall stress and permit normal cardiovascular function at rest and during exercise in *compensated hypertrophy*. If the stimulus for pathologic hypertrophy is sufficiently intense or prolonged, *decompensated hypertrophy* and heart failure ensue. Pathologic hypertrophy may be caused by pressure overloading, as in systemic or pulmonary arterial hypertension, left ventricular outflow obstruction, or aortic coarctation. Pressure overloading produces an increase in systolic wall stress and results in concentric ventricular hypertrophy. Volume overloading, as occurs in mitral or aortic regurgitation or as a result of arteriovenous fistulas, also produces pathologic hypertrophy. These latter conditions induce an increase in either diastolic wall stress (mitral regurgitation) or both systolic and diastolic wall stress (aortic regurgitation and arteriovenous fistulas) and result in eccentric left ventricular hypertrophy. Regional hypertrophy that occurs in viable myocardium adjacent to and remote from an area of infarction has the characteristics of eccentric hypertrophy.

There are exceptions to the principle that pathologic hypertrophy occurs as a result of excessive increases in external work. For example, hypertrophic cardiomyopathy is produced by point mutations of the sarcomeric proteins, in particular the β-myosin heavy chain. These mutations result in massive asymmetric or concentric hypertrophy in the absence of augmented peripheral hemodynamic requirements (see Chap. 62). It is possible that the massive myofibrillar disarray that characterizes this genetic form of hypertrophy increases internal cardiac work, which, in turn, increased cardiac mass.[9,10] Genetically engineered mice with cardiac-specific postnatal overexpression of the β_2 adrenergic receptor[11] or targeted ablation of the phospholamban gene[12] have enhanced cardiac function throughout life but no significant increase in cardiac mass. By contrast, similar cardiac overexpression of the sarcoplasmic reticulum-binding protein calsequestrin in mice results in hypofunction of the heart, with decreased external work and substantial cardiac hypertrophy.[13] Finally, tachycardia-induced heart failure in animal models and humans is associated with increased external cardiac work, decreased cardiac function, and no alteration in cardiac mass. These recent observations suggest a critical reexamination of the primary role of mechanotransduction in the etiology of pathologic hypertrophy.

Mechanisms for the Development of Cardiac Hypertrophy

STIMULI AND SIGNAL TRANSDUCTION PATHWAYS

Stretch-Induced Growth Factors

Dynamic or static stretch of neonatal or adult cardiomyocytes, papillary muscle, isolated heart, or intact heart produces increased cardiac protein synthesis and resultant cellular hypertrophy.[14] The process by which stimuli in the physical domain activate intracellular growth-signaling pathways is known as *mechanotransduction*.[15] There is evidence that this process may be accomplished in the cardiomyocyte by stretch-activated sarcolemmal ion channels, G protein-coupled receptors, NA^+/H^+ antiporters, tyrosine kinase-containing receptors, and/or an extracellular matrix-integrin linked pathway. These cell-surface mechanotransducers then activate cytosolic signal transduction pathways that initiate gene transcription and translation of increased quantities of protein (Fig. 5-2). Important signal transduction pathways that are clearly activated by mechanical deformation include protein kinase C (PKC), mitogen activated protein (MAP) kinases, stress-activated protein kinase, and possibly cyclic adenosine monophosphate (cAMP)-dependent protein kinase.[16] In particular, stretch of neonatal cultured cardiomyocytes produces G protein-mediated activation of membrane-bound phospholipase C, which, in turn, hydrolyzes phosphatidylinositol bisphosphate (PIP_2) to inositol trisphosphate (IP_3) and diacylglycerol (DAG). Diacylglycerol then activates PKC.[17,18] Phosphorylation of downstream cytosolic and nuclear proteins and transcription factors by PKC is known to be of critical importance for growth in a

number of cell types, while inositol triphosphate is an important modulator of cytosolic calcium homeostasis by the interaction with its receptor on the sarcoplasmic reticulum. Angiotensin II receptor coupling appears to play a critical role in the activation of phospholipase C;[19,20] however, α_1-adrenergic and endothelin receptor stimulation can also activate this pathway, with resultant hypertrophy in the neonatal cardiomyocytes and in transgenic mice.[21-23]

Current information suggests that mechanotransduction and a number of interrelated autocrine, paracrine, and endocrine effects of hormones and growth factors mediate cardiac hypertrophy[24] (Fig. 5-2). The resultant activation of multiple signal transduction pathways, which have demonstrable cross talk and considerable redundancy, provides a powerful mechanism by which the heart can respond to changing chronic hemodynamic requirements. A point of downstream convergence of multiple signal transduction pathways in the heart and noncardiac systems appears to be the phosphorylation of mitogen-activated protein kinase [MAPK, also known as extracellular signal regulated kinase (ERK)].[25] Mammalian MAPKs are serine-threonine protein kinases that are activated by signal transduction pathways coupled to both phosphatidylinositol hydrolysis/PKC activation and receptor protein tyrosine kinases (Fig. 5-2). Of particular importance to cardiac hypertrophy is the observation that important transcription factors (c-*jun*, c-*myc*, $p62^{TCF}$) are known substrates of MAPK phosphorylation. Recently, transfection of an antisense nucleotide to MAPK was shown to prevent hypertrophy in cardiomyocytes. Information from noncardiomyocyte cell systems, neonatal and adult myocytes, and genetically engineered mice has demonstrated considerable complexity, redundancy, and cross talk among these and other intracellular signaling pathways in the development of the cardiac hypertrophy phenotype in response to stretch and other stimuli.[26] In particular, ischemia, hypoxia, oxidative stress, neurohormones, and cytokines can activate downstream signaling and resultant nuclear transcriptional events, including cardiomyocyte hypertrophy and fibroblast hyperplasia.

Non-Stretch-Induced Growth Factors

Gαq-coupled receptors-which include angiotensin II, phenylephrine, endothelin, prostaglandin F2α, and thrombin-can induce hypertrophy of neonatal cardiomyocytes in culture in the absence of altered mechanical forces and in vivo in genetically engineered mice when the receptor is overexpressed.[27]

Cytokines

Cytokines were initially characterized by their pleiotropic effects upon the cellular components of the immune system. They have recently been implicated in normal and pathologic cardiac growth by a variety of in vitro and in vivo animal studies and by clinical investigation. Cytokines of the interleukin-6 and cardiotrophin family activate the gp130 cardiomyocyte transmembrane receptor and rapidly stimulate cytoplasmic Janus kinases (JAK); these, in turn phosphorylate other cytoplasmic proteins called signal transducers and activators of transcription (STAT). Various components of gp130 and JAK-STAT pathways have induced hypertrophy in vitro and in vivo when overexpressed in transgenic mice.[28] By contrast interleukin-1 and tumor necrosis factor alpha (TNF-α) use a distinct pathway that involves activation of a phosphatidylcholine-specific phospholipase C with generation of diacylglycerol.[29] These cytokines are elevated in the plasma of patients with congestive heart failure, and inhibition of their effects is a current therapeutic target for clinical heart failure. There is increasing evidence that stimulation of cell-surface tyrosine-kinase receptors can elicit a hyperplastic or hypertrophic response in neonatal cardiomyocytes. Both acidic and basic fibroblast growth factors (FGFs), which act as ligands for tyrosine-kinase receptors, can induce myocyte growth.[30] Acidic FGF produces a hyperplastic response, whereas basic FGF stimulates an increase in protein synthesis with resultant hypertrophy.[31] In contrast to its role in vascular smooth muscle growth, transforming growth factor beta (TGF-β) does not induce a growth response under these conditions.[32]

In addition to FGF and TGF-β, insulin-like growth factor 1 (IGF-1) is expressed in the myocardium in response to pressure overload hypertrophy.[33] These and other peptide growth factors [neural growth factor (NGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and insulin] bind to receptor tyrosine kinases (RTK). These receptors undergo ligand-mediated homodimerization with resultant autophosphorylation of tyrosine residues on the cytoplasmic domain. These tyrosine complexes recruit signaling molecules such as the monomeric GTP-binding protein P21 ras to the membrane, where transient complexes stimulate downstream signaling to the nucleus. Increasing evidence using loss of function and gain of function in in vitro studies of neonatal myocytes implicates this signaling molecule and its downstream effector raf-1 as potential mediators of cardiac growth.[34]

Hormones

Thyroid hormone is generally considered the classic hormonal mediator of cardiac hypertrophy. Administration of excess thyroid hormone to experimental animals produces increased heart weight that is associated with transcriptionally mediated alterations in the myosin heavy chains (MHCs), calcium-cycling proteins, and other functional constituents of the cardiomyocyte in small animals and primates.[35] Thyroid hormone-induced hypertrophy appears to be an indirect effect of the T_3-mediated increased oxygen consumption and resultant augmentation of cardiac work. For example, heterotopic transplantation of a nonworking rat heart into the abdominal aorta of the hyperthyroid animal is unassociated with hypertrophy, despite the presence of the transcriptionally mediated effects of the hormone in the transplanted organ and hypertrophy and typical transcriptional events in the native working heart.[36,37]

In addition to the indirect effects of thyroid hormone on cardiac growth, other endocrine mediators of hypertrophy have been examined. Growth hormone, which mediates its effects in large part though IGF-1, may be a mediator of physiologic hypertrophy. By contrast, there is preliminary evidence that retinoic acid and vitamin D may inhibit cardiac growth.[38,39]

Calcium Signaling

Increases in intracellular calcium have been associated with hypertrophic cardiomyocyte growth in vitro (see Figs. 5-2 and 5-3).[40,41] For example, use of the calcium ionophore BAYK8644 enhances while application of a membrane-permeable calcium chelator inhibits the cellular hypertrophic response by affecting calcium-calmodulin-dependent protein kinase. In addition, calcineurin, a phosphatase activated by intracellular calcium, dephosphorylates nuclear factor for activation of transcription (NFAT), which translocates to the nucleus, where it activates numerous transcription factors such as GATA-4. In vitro and in vivo studies using genetically engineered mice have demonstrated that augmented levels of activity of calcineurin, NFAT, or both can initiate a hypertrophic response. However, the relative role of this pathway in normal and pathologic growth of the heart is unclear at this time.[42,43]

Chapter 5: MOLECULAR AND CELLULAR BIOLOGY OF THE NORMAL, HYPERTROPHIED, AND FAILING HEART

PROTEIN CONTENT AND ISOFORM DIVERSITY

The hallmark of cardiac hypertrophy is a net increase in protein synthesis above protein degradation. Under normal circumstances, these two processes are matched and result in nitrogen balance. Since the average half-life of cardiac proteins is 5 days, the composition of the adult heart is regenerated approximately every 3 weeks. The more rapid rate of cardiac growth in response to increased hemodynamic load could result from an augmentation in either the efficiency or the capacity of protein synthesis or a combination of the two.[44,45] Efficiency of protein synthesis is usually measured as moles of amino acid incorporated per milligram of cellular RNA per hour; capacity is assessed by determining the number of milligrams of RNA per gram of tissue. Experiments in a variety of systems indicate that the critical determinant for cardiac hypertrophy is an increased capacity for protein synthesis, which is mediated by augmented ribosomal content. Protein degradation appears to be modestly increased in cardiac hypertrophy and may play a critical role in the distinctive geometry of the ventricles in response to pressure or volume overloading, regression of hypertrophy, and cardiac atrophy.[46,47] The mechanisms for protein degradation in the heart involve the activation of both lysosomal and cytosolic proteases. Posttranslational processes are increasingly being recognized as important factors in the production of the cardiac phenotype in cardiac hypertrophy and failure.[35,48]

In addition to increased total protein content, cardiac hypertrophy is characterized by alterations in the relative abundance and isoform composition of the cardiomyocyte contractile, regulatory, and calcium-cycling proteins and other subcellular constituents. These processes provide an additional degree of plasticity for the heart to adapt to changing functional requirements. It is clear that there is considerable species specificity in the capacity for isoform switching. In small mammals with rapid heart rates, such as mice and rats, imposition of a pressure overload produces a transcriptionally mediated shift from the α- to the β-MHC and from cardiac to skeletal α-actin.[49-51] α-Myosin has a three- to sevenfold greater ATPase activity than β-myosin. The greater abundance of β-MHC in response to pressure overload in small animals increases the efficiency of force development by producing the same absolute muscle tension at a slower rate.[52] Despite identical cardiac muscle mechanics in response to hypertrophy, large animals with slower heart rates, including humans, possess β-MHC almost exclusively throughout embryogenesis and postnatal development.[53] It is possible that, in higher mammalian species, altered myosin ATPase in response to pressure-overload hypertrophy may be mediated in part by a posttranslationally produced low-molecular-weight variant of the β-MHC or isoform shifts in other myofibrillar proteins. For example, cardiac isoforms exist for essential and regulatory light chains, troponin (I, C, and T), tropomyosin, and the sarcolemmal Na^+, K^+-ATPase. Isoform switching of each of the components of the cardiomyocyte has been reported in hypertrophy and failure, but the functional significance of this has been unclear. The ability to ablate or overexpress these isoforms in genetically engineered mice will more clearly elucidate their role in the normal and hypertrophied heart.

Extracellular Matrix and the Cytoskeleton

Although cardiomyocytes make up the bulk of cardiac mass by volume, they are tethered in an extensive extracellular network of collagen and other structural proteins, including fibronectins and proteoglycans. The extracellular and intracellular myofibrillar scaffolding is a critical

determinant of cardiac shape during normal and pathologic cardiac growth.[54-56] Collagen is synthesized principally by fibroblasts but also by vascular smooth muscle cells in response to a variety of pathologic stimuli, including increased oxidative and mechanical stress, ischemia, and inflammation. Most of the molecules and signal transduction pathways operant in cardiomyocyte growth play a role in hyperplasia of fibroblasts and in the elaboration of collagen. The resultant fibrosis produces altered myocardial stiffness and arrhythmogenesis in ischemic heart disease, cardiac hypertrophy, and congestive heart failure. Collagen synthesis is continuously and variably offset by extracellular matrix resorption mediated by matrix metalloproteinases (MMPs). The activity of these enzymes is increased in dilated cardiomyopathy. Conversely, the activity of a class of enzymes known as tissue inhibitors of matrix metalloproteinases (TIMPs) is reduced in this setting. The resultant excessive collagenolyses may induce myofibrillar slippage and contribute to the dilated thin-walled chamber geometry that characterizes acute and chronic heart failure. This process has been termed *chamber remodeling* by clinicians.[57]

Cardiomyocytes are tethered to the extracellular matrix by membrane-spanning proteins called *integrins.* The extracellular portion of these molecules binds to fibronectins in the extracellular matrix while the cytoplasmic domain is associated with a nonreceptor tyrosine kinase called focal adhesion kinase (FAK).[58] Downstream targets for FAK phosphorylation are the SRC kinases src and fyn. This pathway is differentially activated by mechanical stretch ischemia and oxidative stress in the myocardium and provides an additional mechanism for altered growth during pathologic conditions.[59] Perimyocyte extracellular proteins such as dystrophin and dystrophin-related proteins contribute to normal cardiogenesis; when altered in abundance, they can produce a cardiomyopathy in Duchenne's muscular dystrophy and some familial cardiomyopathies, respectively (see Chap. 62).

The cardiomyocyte cytoskeleton is the intracellular scaffolding that provides a framework for the orderly arrangement of sarcomeres in striated cardiac and skeletal muscle. Titin-the third most abundant protein in the heart-desmin, and vinculin have differing intracellular spatial distributions that contribute to resting tension of cardiac muscle. The amount and polymerization status of the proteins that make up the microtubular network of the cardiomyocyte cytoplasm (tubulin and β actin) are important determinants of the viscous properties of heart muscle and contribute to altered cardiac function in pathologic states.[60,61]

Cardiac hypertrophy and failure are associated with changes in the relative abundance of the various intra- and extracellular structural proteins. All forms of cardiac hypertrophy are associated with increased collagen deposition in the extracellular matrix, which contributes to the observed alterations in passive chamber and muscle properties. Pressure overload (but not volume overload) hypertrophy has been associated with changes in the levels of the cytoskeletal proteins titin, desmin, and tubulin. Depolymerization of tubulin with colchicine reversed abnormalities in cardiac function in feline right ventricular hypertrophy but not in guinea pig left ventricular hypertrophy.[60,61]

Excitation-Contraction Coupling and Calcium Homeostasis (see Fig. 5-3)

Cardiomyocyte membrane depolarization is initiated by the intracellular movement of sodium through its ion channel, while repolarization is achieved by the extracellular movement of potassium via a family of sarcolemal K^+ channels. Membrane depolarization enhances the transmembrane conductance of calcium through a dihydropyridine-sensitive *l*-channel. The resultant increase in cytosolic calcium concentration permits binding of this cation to the ryanodine receptor on the surface of the sarcoplasmic reticulum. This process results in release of calcium from sarcoplasmic reticulum stores and further elevation of cytosolic calcium concentrations. The resultant hundredfold elevation of calcium permits binding to the myofilament regulatory protein troponin C. Calcium binding to troponin C promotes a steric movement of troponin I away from the actin binding site on the myosin molecule. This permits

actin-myosin cross-bridge formation and resultant tension development. The activity of troponin I can be modulated via phosphorylation by protein kinase A and C, while the affinity of troponin C for calcium is altered by intracellular pH. These processes may result in substantial alteration of myofilament calcium. Energy for cross-bridge cycling is produced by hydrolysis of ATP via myosin ATPase. Calcium is released from troponin C and resequestered into the sarcoplasmic reticulum by a specific SR-ATPase. The activity of this enzyme is inhibited by the phosphoprotein phospholamban. Phosphorylation of phospholamban by cAMP (PKA)-dependent protein kinases, protein kinase C, or calcium-calmodulin-dependent protein kinase results in disinhibition and resultant enhancement of calcium uptake in the SR. Steady-state sarcoplasmic reticulum calcium content is determined by the abundance of the anionic storage proteins calsequestrin and calreticulum. Reequilibration of cytosolic sodium and potassium levels produced by the depolarization and repolarization cycle is facilitated by the activity of the sarcolemmal Na^+,K^+-ATPase. Extrusion of transarcolemmal mediated calcium influx is mediated by the coordinated interplay between the membrane situated Na^+-H^+ and Na^+-Ca^{2+} exchangers. Isolated changes in the stoichiometry between the sarcoplasmic reticulum ATPase and its inhibitor, phospholamban, have been demonstrated to have functional significance in genetically engineered mice. Targeted ablation of phospholamban enhanced cardiac inotropic and lusitropic function, whereas cardiac-specific overexpression produced the opposite result.[62,63]

Chapter 5: MOLECULAR AND CELLULAR BIOLOGY OF THE NORMAL, HYPERTROPHIED, AND FAILING HEART

CARDIAC FUNCTION OF THE HYPERTROPHIED HEART

The phenotypic consequences of the increased cardiac mass and altered protein abundance and composition of the hypertrophied heart are considerable and depend upon the model utilized; the animal species; and the nature, intensity, and duration of the hypertrophic stimulus. Taken together, available clinical and animal studies suggest that functional alterations evolve along a continuum from normal chamber and myocyte function to abnormal chamber and normal myocyte function to abnormalities of both chamber and myocyte function (Fig. 5-1).

Electrical Properties

The most typical electrical abnormality of the hypertrophied heart is prolongation of the duration of the action potential.[64] Recent studies using the single-cell voltage-clamp technique have begun to elucidate the ionic mechanisms responsible for this phenomenon. In mild hypertrophy, increases in calcium and calcium-activated currents (including the NA^{+}/Ca^{2+} exchanger) appear to be important. In severe hypertrophy, prolongation of the action potential is also determined importantly by a reduction in the potassium currents Ik*l* and Ito. The relations between these changes in membrane current properties of hypertrophied hearts and altered mechanical behavior at the myocyte and whole-heart level are not clearly understood at present. Hypertrophied myocardium is more likely than normal tissue to precipitate arrhythmias. The mechanisms for arrhythmogenesis are multifactorial and are operant at the tissue and cardiomyocyte levels. Increased dispersion of refractoriness and slowed conduction results from myocyte loss and fibrosis. Prolongation of the duration of the action potential increases the likelihood of early afterdepolarizations, which may result in triggered arrhythmias. Reduced coronary artery flow reserve and accelerated atherosclerosis of epicardial coronary vessels predispose toward ischemia-induced arrhythmias.[65] In concert, these mechanisms contribute to the finding of cardiac hypertrophy as the most powerful predictor of cardiovascular mortality in the Framingham Study (see Chap. 1).

The application of molecular biological and molecular genetic approaches is providing increasing insight into the cellular mechanisms of arrhythmogenesis. Normal cardiomyocyte excitation and arrhythmogenesis involve voltage-dependent ion channels, mechanosensitive channels, sarcolemmal electrogenic transporters, and gap junctions. The latter are two channels or connexins that enable ion current flow between and among cardiomyocytes. Connexons are composed of a class of molecules called *connexins*. Isoform diversity of the connexins are determinants of ion conductance and sensitivity.[66,67] The genes for each of the cardiomyocyte ion channels, transporters, and connexins have been cloned. Structure-function relations are being defined in vitro using site-directed mutagenesis and in vivo using loss of function or gain of function mutations in genetically engineered mice. In parallel, the abundance and/or function of the molecular determinants of excitability and arrhythmogenesis are beginning to be elucidated in animal models and human cardiovascular disease (see Chap. 23).

Genetic linkage analysis of familial arrhythmias and resultant identification of culprit gene defects of cardiomyocyte ion channels or channel modulators has provided complementary insight into the cellular mechanisms of arrhythmogenesis. The long-QT syndrome is now known to result from mutations in genes responsible for various outwardly rectifying potassium channels and the

cardiomyocyte sodium channel.[68-70] Analyses of other inherited arrhythmias are under way.

Mechanical Properties

Mechanical function of the hypertrophied heart has been studied at the isolated myocyte, muscle, and chamber levels and in the intact circulation.[71-73] The results of these studies have revealed variable alterations in the rate and extent of contraction and relaxation, in the amount of force development, and in resting muscle and chamber properties. In the intact circulation, altered systolic and diastolic function is a composite result of subcellular changes in the myocyte, changes in the extracellular matrix, altered chamber geometry and mass, altered ventricular-vascular coupling, and the modulatory effects of neural and hormonal influences.

The earliest changes in mechanical performance observed in isometrically contracting papillary muscles extracted from hypertrophied hearts consist of a prolongation of time to peak tension and relaxation, despite normal peak twitch tension normalized for cross-sectional area of the muscle.[74] Afterloaded isotonically shortening papillary muscle preparations from hypertrophied hearts of a variety of animal species typically reveal a decrease in the force-velocity relationship and a depression of V_{max} (the extrapolated maximal unloaded shortening velocity).[75] V_{max} has been directly related to the calcium-activated myosin ATPase activity. Both myosin and myofibrillar ATPase activity are typically depressed in hypertrophied myocardium. In small rodents, this is due to the transcriptionally mediated switch from α- to β-MHC. In higher mammals including humans, the decreased myosin ATPase activity of the hypertrophied heart may be due to alterations in the troponin isoform composition[76] or the posttranslational generation of a lower molecular variant of the β-MHC.[48]

The dissociation between depressed rate-dependent indices of contraction and relaxation and normal maximal force development and extent of shortening in early cardiac hypertrophy has also been demonstrated in isolated cardiomyocytes and in the intact circulation of the nonhuman primate.[71,73] *These results suggest the rate of cross-bridge cycling is reduced but that the effective number of active cross bridges per unit of myocardium is preserved in compensated cardiac hypertrophy.* In decompensated hypertrophy, reduced absolute levels of force development and diminished contractility ultimately ensue.

In addition to alteration in excitation-contraction coupling and relaxation, the increased cardiac mass and changes in geometry significantly affect passive muscle and chamber properties of the hypertrophied heart. Concentric hypertrophy is characterized by an increased resting muscle and chamber stiffness, which results in an increase in pulmonary venous pressure for any given left ventricular volume. The resultant pulmonary congestion at rest or with exercise is an important determinant of symptoms in patients with hypertensive left ventricular hypertrophy or hypertrophic cardiomyopathy and normal or elevated ejection fraction. Pure volume overload hypertrophy, as occurs with mitral regurgitation, is typically associated with no change or a decrease in passive muscle or chamber stiffness. As a result, patients with chronic volume overload may remain asymptomatic for long periods despite appreciable increase in regurgitant fraction (see also Chaps. 56 and 57).

Coronary Circulation

Clinicians have long recognized that myocardial blood flow may be abnormal in the hypertrophied heart, since such patients may have exertional angina, resting or exercise-induced electrocardiographic or perfusion abnormalities, or pathologic evidence of subendocardial fibrosis, despite the presence of angiographically normal epicardial coronary arteries.

Morphologic studies of hypertrophied hearts from experimental animals and patients with

pressure-overload hypertrophy demonstrate that the ratio of capillaries to myocytes remains unchanged.[77] Since myocyte cross-sectional area is increased, there is a resultant increase in nutrient diffusion distance in the hypertrophied heart. This anatomic change results in a reduced vasodilatory reserve in response to various stimuli in experimental and clinical studies.[78] Myocardial blood flow and oxygen consumption per unit of myocardium are normal in compensated pressure overload-left ventricular hypertrophy, where wall stress has been normalized by an increase in wall thickness. The impairment in vasodilatory reserve produces evidence of ischemia during increased myocardial oxygen demand. In right ventricular pressure-overload hypertrophy, differences in perfusion between the ventricles result in increased right ventricular blood flow per unit of myocardial mass at rest and no increase in minimum coronary resistance of hypertrophied right ventricular myocardium.[79]

Few data are available regarding changes in the coronary circulation in experimental or clinical volume-overload hypertrophy. Most studies have reported normal resting flow values per unit of myocardial mass. In contrast to pressure overload, volume-overload hypertrophy has been associated with normal or mildly increased minimum coronary resistance and normal or mildly decreased coronary reserve.[80] The coronary circulatory abnormalities associated with cardiac hypertrophy appear to be reversible with removal of the hypertrophic stimulus and resultant decreased chamber mass.[81]

Important recent studies have begun to elucidate the molecular and cellular mechanisms responsible for reversible functional consequences of ischemia and ischemia reperfusion. The syndrome of *myocardial stunning,* which refers to the variable period of regional or global myocardial hypofunction consequent to ischemia and reperfusion, is believed to involve two mechanisms. Either hydroxy-free radical generation, calcium overload, or both may be involved.[82] Downstream effects of these two pathologic processes include activation of protein kinase C, tyrosine kinases, and stress-activated kinases. In addition, proteolytic degradation of troponin I has been observed and is associated with uncoupling of excitation from contraction due to reduced myofilament calcium sensitivity. Transgenic overexpression either of a PKC isoform or the proteolytic degradation product of troponin I in mice produces both myocardial dysfunction and reduced myofilament calcium sensitivity responsiveness.[83]

Brief repetitive periods of ischemia and reperfusion also produce a powerful cardioprotective effect against myocardial necrosis. This process, called *ischemic preconditioning,* is also associated with activation of similar signal transduction pathways. The precise mechanism(s) for reduced myocyte cell death from necrosis, apoptosis, or both are presently unclear. *Hibernation* or myocardial hypofunction associated with reduced steady-state coronary blood flow may, in fact, result from repetitive periods of stunning.

Chapter 5: MOLECULAR AND CELLULAR BIOLOGY OF THE NORMAL, HYPERTROPHIED, AND FAILING HEART

MECHANISMS FOR THE TRANSITION FROM COMPENSATED HYPERTROPHY TO HEART FAILURE

In contrast to hypertrophied skeletal muscle, chronically increased work eventually results in depressed contractility and relaxation of the hypertrophied heart. Compensated hypertrophy, which is characterized by abnormal chamber function but preserved muscle and myocyte function, evolves into a decompensated phase characterized by abnormal chamber, muscle, and myocyte function (Fig. 5-1). Attempts to elucidate the underlying mechanisms for this transition have involved multidisciplinary studies of clinical end-stage heart failure, longitudinal studies in experimental animals, and characterization of cardiovascular function in genetically engineered mice, where attempts are made to mimic human disease (Fig. 5-4).[84]

Current information suggests that decompensated hypertrophy may result from a number of mechanisms that are both intrinsic and extrinsic to the cardiomyocyte. These include necrosis; apoptosis;[85,86] altered growth secondary to altered signal transduction pathways; alterations in cardiomyocyte contractile, regulatory, calcium-cycling, and structural proteins; alterations in the extracellular matrix, and remodeling (Fig. 5-4). Because of the complex combinatorial alterations that occur in human heart failure and conventional animal models of hypertrophy, studies in genetically engineered mice in which a protein of interest is either overexpressed or ablated using homologous recombination hold particular promise in determining the relative importance of various candidate genes. For example, mice bearing the mutation in the β-MHC that occurs in familial cardiomyopathy have many features of the human disease.[87] Overexpression of the α subunit of the G protein that couples to the β-adrenergic receptor has produced dilated fibrotic hearts with altered cardiovascular function.[88] Overexpression or ablation of genes involved in cardiomyocyte calcium-cycling proteins has been associated with altered heart function and abnormal calcium kinetics. It is of interest that, with few exceptions,[89] the resultant cardiac phenotype has failed to reproduce completely human decompensated hypertrophy and failure. This observation further supports the multifactorial nature of the condition and the importance of genetic background on the phenotype observed after loss-of-function or gain-of-function genetic engineering.

A common prominent feature of many experimental and clinical studies of decompensated hypertrophy and failure is a derangement of cardiomyocyte calcium homeostasis (Fig. 5-3). Studies of human cardiomyocytes extracted from the hearts of patients with end-stage heart failure have revealed elevated diastolic calcium levels with either no change or a reduction in the amplitude of the calcium transient.[90-93] Longitudinal studies of hypertrophy in experimental animals have revealed depression of steady-state mRNA levels[94] and sarcoplasmic reticulum ATPase and phospholamban proteins in decompensated, but not compensated, pressure-overload hypertrophy.[72] These changes were associated with distinctive contractile depression of isovolumically contracting heart function, increases in the EC_{50}, and decreases in the V_{max} for sarcoplasmic reticular membrane uptake of calcium. Transgenic overexpression of the sarcoplasmic reticulum ATPase inhibitor phospholamban depressed cardiomyocyte function and calcium kinetics, whereas targeted ablation of the phosphoprotein produced the opposite result. Whether altered levels of the calcium-cycling proteins occur by transcriptional, translational, or posttranslational levels is currently unknown. In addition to altered levels of the various calcium-cycling proteins in hypertrophy and heart failure, there is evidence that abnormal spatial

organization of the *l*-channel and SR may be contributory. Specifically, increased distance between the *l*-channel and the ryanodine receptor may contribute to abnormal calcium cycling.[95]

In addition to altered calcium homeostasis, there is increasing evidence that abnormal signal transduction plays a critical role in the development of cardiac hypertrophy and failure. In vitro studies with neonatal myocytes have demonstrated that phenylephrine, endothelin, and angiotensin II cause cardiomyocyte hypertrophy. These vasoactive peptides have cognate receptors that signal via the α subunit of the Gq protein (see Fig. 5-2). Cardiac-specific overexpression of Gαq produced cardiac hypertrophy, apoptosis, and contractile depression in transgenic mice.[96,97] By contrast, overexpression of a protein inhibitor of Gαq in a similar manner prevented cardiac hypertrophy due to pressure overload.[98] Transgenic overexpression of receptors that couple through Gαq, such as α_1 and angiotensin II, produces a similar phenotype: cardiac-specific postnatal overexpression of the calcium-sensitive PKC isoform B produced cardiac hypertrophy and failure. Pretreatment of mice overexpressing PKC B with a highly specific inhibitor prevented or reversed this hypertrophy-heart failure phenotype.[99] Part of the contractile depression observed with excess PKC B activity was due to phosphorylation of troponin I and resultant reduced myofilament calcium sensitivity.[100] Augmented PKC activity and elevated levels of the calcium-sensitive PKC α and β isoforms, but not Gαq, were found in human end-stage cardiomyopathic heart failure.[101,102] It is also known that PKC may be stimulated by pathophysiologic levels of stretch[103] and ischemia-reperfusion and directly by oxidative stress.[33] Taken together, these lines of evidence suggest that *PKC mediated signal transduction plays a critical role in the development of cardiac hypertrophy and failure.*[104]

A variety of studies with end-stage human cardiomyopathic heart tissue, conventional animal models, and genetically engineered mice suggest that apoptosis may contribute to the heart failure phenotype.[105] The key issue that remains unclear is the quantitative importance of the phenomenon. This problem is further complicated by the fact that a number of signaling molecules (e.g., Gαq and TNF-α) produce both hypertrophy and apoptosis. By contrast, gp130 heterodimerizes with LIF (leukemia inhibitory factor) receptor to permit binding of the interleukin-6 family of cytokines, such as cardiotrophin 1. Receptor binding stimulates the hypertrophic response while inhibiting apoptosis. Elimination of the gp130 by loss of function mutations of the gene results in mice that have structurally normal hearts. However, when a pressure overload is imposed, a rapidly progressive dilated cardiomyopathy ensues, which is associated with massive apoptosis.[106] The application of molecular genetic and biological approaches to elucidate mechanisms responsible for myocardial hypertrophy, cardiac failure, arrhythmogenesis, and ischemic dysfunction will permit improved diagnostic and therapeutic approaches to congenital and acquired heart diseases.[107]

Chapter 5: MOLECULAR AND CELLULAR BIOLOGY OF THE NORMAL, HYPERTROPHIED, AND FAILING HEART

List of Figures

calcium channel, leading to increased calcium entry, by phosphorylating phospholamban and resultant enhanced SR ATPase activity, and by phosphorylating regulatory proteins of the myofilament leading to decreased calcium sensitivity. The net enhancement of intracellular calcium concentration is restored by the coordinated activity of the Na+-H+ and Na+-Ca2+ exchangers (Ex).

Figure 5-4: Schematic diagram of the mechanisms responsible for the development of the anatomic and functional cardiac phenotypes in physiologic and pathologic hypertrophy. Abnormalities at one or multiple levels in this putative closed-loop system may be responsible for the transition between compensated and decompensated hypertrophy.

Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 6:

MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

Authors: Kathy K. Griendling, David G. Harrison, R. Wayne Alexander

It has become apparent that a diverse number of pathologic processes all contribute to common vascular diseases such as atherosclerosis and hypertension. During the past several years, these pathologic events have been defined with increasing clarity at a cellular and molecular level, and strategies are emerging to treat these primary processes rather than simply treating the secondary manifestations of vascular disease. Because of this, understanding normal function of vascular cells and how these are altered by various vascular insults has become essential for both basic investigators and clinicians caring for patients with peripheral vascular disease, coronary artery disease, and hypertension. This chapter is designed to introduce important concepts in vascular biology and to emphasize how fundamental aspects of vascular control are altered by common disease conditions.

STRUCTURE OF THE VESSEL WALL

Arteries consist of three layers: the innermost intima, the media, and the outermost adventitia. The intima is comprised of a single layer of endothelial cells embedded in an extracellular matrix. The internal elastic lamina separates the intima from the media. The media consists of smooth muscle cells, elastic laminae, bundles of collagen fibers, and elastic fibrils, all embedded in an extracellular matrix. The adventitia is the most variable layer, containing dense fibroelastic tissue, nutrient vessels, and nerves.

The actual composition of each of these layers varies with the type of blood vessel. Large, conduit arteries are typically referred to as *elastic arteries*, because of their high ratio of elastic laminae to smooth muscle cells. Muscular arteries are generally smaller and have a prevalence of smooth muscle cells, whereas arterioles consist of only one to two layers of smooth muscle cells. Capillaries are the smallest vessels, made up of a single layer of endothelial cells that are occasionally apposed to pericytes-smooth muscle-like cells that serve a contractile and synergistic nutritive function. The venous system has a similar architecture to that of the arterial system, the main difference being the orientation and mass of the smooth muscle cells within the wall.

Physiologically, the two best understood cell types in the vascular system are the endothelial and vascular smooth muscle cells (VSMCs). The endothelial cell is generally oriented with the direction of blood flow parallel to the main axis of the vessel. Endothelial cells are held together by junctional complexes that regulate permeability and control cell-to-cell communication. The smooth muscle cell is a spindle-shaped cell whose orientation varies with the type of artery, but is generally helical in large, elastic arteries and concentric in muscular arteries. Vascular smooth muscle cells contain three types of filaments: thick (myosin), thin (actin), and intermediate. The proteins that form these filaments undergo phosphorylation upon exposure to certain vasoactive agonists, thus altering their orientation and interactions and supporting force development (see below). In normal arteries, the smooth muscle cells are primarily in the aforementioned *contractile* phenotype. In contrast, in response to vascular insults such as hyperlipidemia or angioplasty, smooth muscle cells lose their contractile phenotype and acquire a so-called *synthetic* phenotype. This is characterized by a loss of contractile proteins, a rounded shape, and a dramatic change in biochemical properties. This change in phenotype and function is thought to be

important in the genesis of the myointimal cell that populates the atherosclerotic subintimal space.

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

PHYSIOLOGY OF THE ENDOTHELIAL CELL

Normal endothelial cell function is crucial to homeostasis in the vascular system. During the past decade, it has become apparent that diseases such as atherosclerosis are ultimately manifestations of endothelial dysfunction. The endothelium has three major functions: (1) it is a metabolically active secretory tissue; (2) it serves as an anticoagulant, antithrombotic surface; and (3) it provides a barrier to the indiscriminant passage of blood constituents into the arterial wall. The implications of these physiologic properties for vascular biology will be considered separately.

Endothelial Cell Metabolism and Secretion of Vasoactive Factors

As discussed in more detail below, endothelial cells secrete vasoactive substances that play a major role in the control of vascular tone. These molecules include vasodilators such as prostacyclin, endothelial-derived relaxing factor (EDRF), and endothelial-derived hyperpolarizing factor (EDHF).[1-3] In addition, the endothelium produces vasoconstrictor substances, including endothelin[4] and vasoconstrictor prostanoids.[5]

Endothelial cells also manufacture and secrete substances such as factor VIII antigen, von Willebrand's factor, tissue factor, thrombomodulin, and tissue plasminogen activator, which are all involved in coagulation/fibrinolytic pathways. Structural components of the extracellular matrix synthesized by these cells include collagen, elastin, glycosaminoglycans, and fibronectin.[6,7] The composition of the extracellular matrix is dynamically modulated by matrix metalloproteinases, enzymes that degrade matrix protein and participate in its remodeling. These enzymes are secreted by both endothelial and smooth muscle cells.[8,9] In addition, endothelial cells synthesize and secrete heparans and growth factors that regulate smooth muscle cell proliferation.[10-13] Finally, endothelial cells are able to clear and metabolically alter bloodborne and locally produced substances, including plasma lipids and lipoproteins,[14] adenine nucleotides and nucleosides,[15] serotonin, catecholamines, bradykinin, and angiotensin I.[16]

Endothelial cells are involved in the metabolism of plasma lipids in several ways. Lipoprotein lipase, an enzyme that hydrolyzes triglycerides into constituent fatty acids, is bound to the endothelial cell surface by heparan sulfates.[17] The interaction of this enzyme with chylomicrons or very low density lipoprotein (VLDL) particles results in the release of free fatty acids, which can then cross the subendothelial space to the underlying smooth muscle or inflammatory cells in atherosclerosis. In addition, endothelial cells possess receptors for low-density lipoprotein (LDL),[18] which regulate the transport and modification of LDL. Normally, LDL receptors are downregulated because receptor processing is inhibited in the nonproliferating monolayer.[18] There are, however, two other pathways for uptake of LDL. First, LDL can be transported across the endothelium by an unknown, active, receptor-independent mechanism.[19] Second, modified, or oxidized LDL can be taken up by "scavenger" LDL receptors,[20] the expression of which is unaffected by the growth state of the endothelial cells. These cells also have the capacity to modify LDL,[21] thus enhancing its uptake and ultimately leading to an increase in cholesterol esters in the vessel wall and, importantly, facilitating LDL uptake by inflammatory cells in disease.

The Endothelial Cell and Thrombosis

Quiescent endothelial cells normally present an antithrombotic surface that resists platelet adhesion and does not activate coagulation. (For a more detailed discussion of thrombosis, see Chap. 44.) The continuity of the endothelium is essential to this function, and nonthrombogenicity has been attributed in part to the negative charge on the surface of these cells.[22] Endothelial cells are, however, capable of synthesizing and secreting prothrombotic factors, especially when stimulated with cytokines or other inflammatory agents. The endothelium thus represents a functional antithrombotic-thrombolytic/thrombotic balance. Potent anticoagulants elaborated by the endothelium include prostacyclin, which inhibits platelet aggregation,[23] heparin-like molecules,[24] and thrombomodulin, which activates protein C.[25] In addition, antithrombin III binds to the surface-bound heparin-like molecules and serves as a clearance (via internalization) molecule for thrombin, as well as a thrombin inhibitor.[26] These cells also produce tissue plasminogen activator (tPA) and plasminogen activator inhibitor I (PAI-I), and can bind plasminogen on their surface via fibronectin and thrombospondin.[27] The relative amounts of tPA and PAI-I can be upregulated or downregulated, respectively, by thrombin, angiotensin II, and other vasoactive substances to control clot lysis.[28]

As alluded to earlier, the endothelium, under conditions of injury or inflammation, may become prothrombotic (Fig. 6-1). On stimulation with inflammatory cytokines, endothelial cells increase the surface expression of tissue factor[29] and leukocyte adhesion molecules,[30] and decrease the expression of thrombomodulin.[29] Thrombin itself stimulates further production of von Willebrand's factor,[31] which, along with thrombospondin and fibronectin, participates in the thrombotic response. Furthermore, endothelial cells can bind factor IX,[32] which, when tissue factor is expressed, can be activated by tissue factor VIIa complex, leading to activation of factor X in the presence of factor VIII. Activated factor X (Xa) can then promote assembly of the prothrombinase complex. Thus, under inflammatory conditions, endothelial cells can amplify the prothrombotic response. Not all of the factors controlling the expression of pro- and antithrombotic/fibrinolytic molecules are known, but it is clear that the endothelium functions as a major regulator of hemostasis.

Barrier Function and Endothelial Cell Permeability

There are three ways that the endothelium regulates influx of macromolecules into the arterial wall: intercellular tight junctions, vesicles and/or transendothelial channels, and the lipid phase of the endothelial membrane. These pathways enable the intact endothelium to serve as a barrier, preventing or impeding highly mitogenic, thrombotic, or vasoactive substances from coming into direct contact with the underlying vascular smooth muscle. Each route has both active and passive components, and the extent to which they are utilized depends to a certain degree on the location of the endothelial cells. Thus, capillaries and postcapillary venules respond to vasoactive agents, some of which (histamine, prostaglandins) are secreted by the endothelial cell itself, with increased flux through tight junctions.[33] The tight junctions found in arteries tend to be more occlusive, but may also be influenced by hypertension[34] and various agonists. Vesicular transport is mainly utilized by the cell to transfer water-soluble macromolecules from the luminal surface to the abluminal surface, but the permanence of such structures and whether they form transendothelial channels is a matter of debate. It has recently been shown that caveolae, vesicles containing the structural protein caveolin that are pinched off from the plasma membrane, are involved in transendothelial transport of macromolecules. Multiple such vesicles may link together to form functional pores from the luminal to abluminal surface.[35,36] Lipid-phase transport has been proposed as a mechanism whereby lipid-soluble molecules (e.g., free fatty acids) could be transferred to the abluminal surface of the endothelial cell.[37] These molecules could enter the outer leaflet of the membrane from the circulation and diffuse along the lipid bilayer to be released or bind to extracellular matrix components in the subintimal area.

Another major mechanism modulating endothelial barrier formation occurs via contraction of these cells in a fashion analogous to smooth muscle contraction. This occurs in response to a variety of agonists, including thrombin, histamine, and ionomycin, and results in cell shape change that opens gap junctions between cells. It is likely that this contractile response is a major mechanism for edema formation in response to histamine and bradykinin and is also involved in solute transport. This phenomenon is mediated by a series of intracellular signaling events, including activation of protein kinase C, myosin light chain phosphorylation, activation of tyrosine kinases, and stimulation of the small G-protein Rho.[38-40]

Thus, the endothelium has both passive and active roles in the control of vascular permeability by acting as a physical permeability barrier and by modulating the expression of cell surface and secreted agonists and molecules that are capable of altering permeability.

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

PHYSIOLOGY OF THE VASCULAR SMOOTH MUSCLE CELL

The smooth muscle cell normally responds to hormonal stimulation with contraction or relaxation. In certain disease states, however, growth and/or hypertrophy and migration to the intima are the predominant responses. Some of the biochemical signals generated by these vasoactive agonists are similar for both types of responses, with the final physiologic response dictated by the phenotype and environment of the cell, and the exact biochemical pathways activated. Thus, in normal arteries, growth factors can act as vasoconstrictors[41] while, in modulated smooth muscle cells, vasoconstrictors can stimulate hypertrophy or hyperplasia.[42]

Second Messengers Traditionally Associatedwith Contraction

Some of the earliest signals generated within the cell following stimulation with calcium-mobilizing vasoactive agonists involve hydrolysis of a specific class of membrane lipids: the phosphoinositides.[43] There are three major inositol phospholipids in the plasma membrane that serve as substrates for a class of enzymes called phospholipase Cs. Phospholipase C cleaves phospholipids to liberate the water-soluble head group and the lipophilic molecule, diacylglycerol (Fig. 6-2). The water-soluble head group that is most important for signal generation is inositol trisphosphate (IP_3), which has been shown to release Ca^{2+} from intracellular stores.[44] Ca^{2+}, in turn, activates a cascade of enzymes leading to contraction or growth (see below). Diacylglycerol is a potent activator of protein kinase C, a Ca^{2+}- and phospholipid-dependent enzyme that phosphorylates numerous cellular proteins.[45] Diacylglycerol can be further metabolized to phosphatidic acid or to glycerol, fatty acids, and, ultimately, eicosanoids and leukotrienes that may themselves modulate tone. Additionally vasoconstrictor agents cause a sustained intracellular alkalinization[46] and an influx of extracellular Ca^{2+},[47] both of which serve to sustain and enhance vasoconstriction.

Contraction Cascade

Contractions induced by various vasoactive hormones differ not only in magnitude and time course, but also differ between vessels. In general, there is an initial, rapid component of force generation and a more sustained phase of contraction. Some agonists, such as angiotensin II, induce only a transient constriction of many vessels, whereas others, including norepinephrine and vasopressin, nearly always cause a sustained contraction. The initial phase of force development has been shown to depend on the formation of actin-myosin cross-bridges, but the mechanisms underlying the sustained phase of contraction are less clear.

A sliding-filament mechanism similar to that found in skeletal muscle is thought to regulate phasic contraction of smooth muscle. Force generation is accomplished by attachment of the myosin heads (or cross-bridges) to actin filaments. This attachment catalyzes ATP hydrolysis to generate tension and occurs in a cyclic manner for the duration of the stimulus. Smooth muscle has a relatively greater content of actin and a lower content of myosin than does skeletal muscle and, in contrast to skeletal muscle, the major site of calcium regulation of smooth muscle actomyosin is on the myosin molecule. Smooth muscle myosin consists of two large subunits, each with a molecular weight of 200 kDa, and two small subunits of 20 and 16 to 17 kDa, known as the *myosin light chains*. Force generation in smooth muscle is regulated by the phosphorylation/dephosphorylation of the 20-kDa protein (Fig. 6-3). Once phosphorylation

occurs, actin-activated Mg^{2+}ATPase activity is stimulated, resulting in cross-bridge cycling. Myosin light chain phosphorylation is mediated by an enzyme known as myosin light chain kinase (MLCK). This protein associates with calmodulin, a calcium-binding protein required for activation of numerous cytoplasmic enzymes. Thus, when Ca^{2+} increases within the cell in response to hormonal stimulation, it binds to calmodulin, which, in turn, associates with MLCK, converting it from an inactive to an active form. MLCK then phosphorylates the myosin light chain, enabling actin activation of the Mg^{2+}-ATPase ultimately resulting in cross-bridge formation. When the intracellular Ca^{2+} concentration drops below about 100 nM, Ca^{2+} dissociates from calmodulin, calmodulin detaches from MLCK, and MLCK becomes inactive. Myosin light chain phosphatase activity then predominates, myosin is dephosphorylated, and cross-bridge cycling ceases. During sustained contraction, however, the intracellular Ca^{2+} concentration is low, and energy consumption is reduced, suggesting the development of a latch-bridge, or of a low cycling state.[48] Alternatively, the sensitivity of the contractile apparatus to Ca^{2+} may be increased, a response posited to be regulated by protein kinase C.[49]

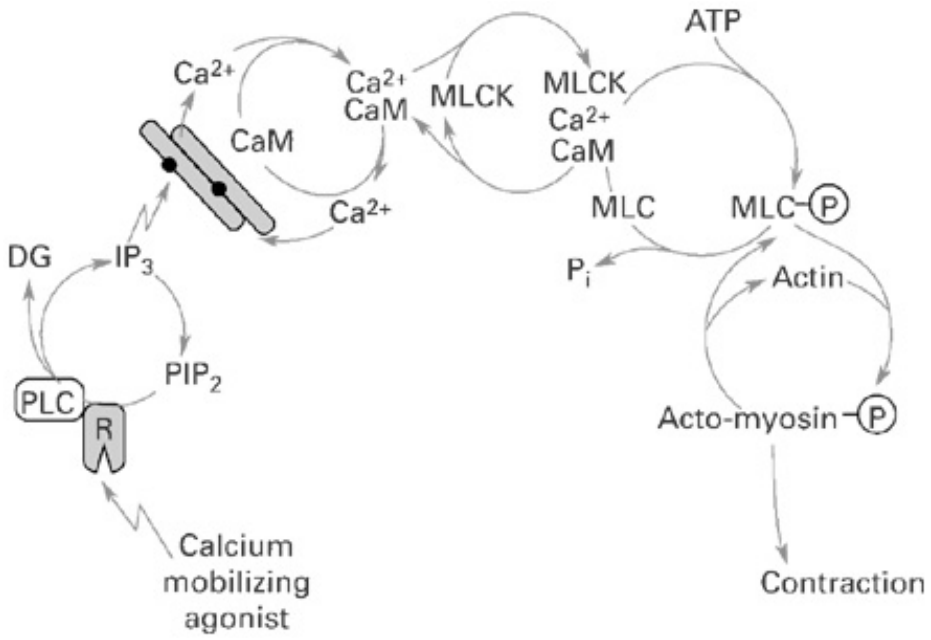

Figure 6-3: Contraction cascade. Activation of smooth muscle by a vasoconstrictor hormone leads to a cascade of biochemical signals, ultimately resulting in phosphorylation of actomyosin, cross-bridge formation, and force generation. The release of Ca2+ from intracellular stores is one of the major initiating events, since Ca2+ combines with calmodulin to activate myosin light chain kinase. This enzyme phosphorylates the myosin light chain, which is then able to interact with actin. ABBREVIATIONS: R = receptor; PLC = phospholipase C; DG = diacylglycerol; PIP_2 = phosphatidylinositol 4,5-bisphosphate; IP_3 = inositol trisphosphate; CaM = calmodulin; MLCK = myosin light chain kinase; MLC = myosin light chain; P = phosphate. (Courtesy of Bernard Lassègue, Ph.D.)

Biochemical Signals Traditionally Associatedwith Proliferation

Classic growth factors, such as platelet-derived growth factor (PDGF), activate many of the same signaling pathways as do vasoconstrictors: phosphoinositide hydrolysis, Ca^{2+} mobilization and influx, Na^+/H^+ exchange and intracellular alkalinization. Receptors for these growth factors are intrinsic tyrosine kinases, leading to the tyrosine phosphorylation of numerous proteins that are essential for growth. The importance of tyrosine phosphorylation in mediating the growth

response is shown by the observation that mutant PDGF receptors, which lack the normal, intrinsic tyrosine kinase domain, are incapable of mediating proliferation in response to PDGF.[50] In addition, tyrosine kinase inhibitors have been shown to inhibit growth.[51] There is also increasing evidence that tyrosine phosphatases can counteract the mitogenic effects of growth factors by inhibiting tyrosine phosphorylation of specific substrates.[52]

A complex of substrates becomes associated with activated growth factor receptors and subsequently activates multiple signaling cascades leading to the final cellular response.[53] Some proteins, such as phospholipase C-γ, the tyrosine kinase c-Src, and phosphatidylinositol-3-kinase, bind directly to receptor tyrosine kinases, whereas others, including the tyrosine kinase Pyk-2 and the cytoskeletal protein paxillin, associate with the receptor via linker proteins such as Grb and Shc. Upon addition of growth factors, the receptors dimerize and auto-tyrosine phosphorylate, and each of the aforementioned proteins is phosphorylated on tyrosine, presumably leading, either directly or indirectly via association with the activated receptor, to their activation. In addition, Shc and Grb2 link these receptors to Ras, a ubiquitous GTPase that initiates a kinase cascade that includes mitogen-activated protein kinase (MAP kinase) and ultimately leads to growth. Recent evidence suggests that many of these proteins are also activated by seven-transmembrane-spanning G-protein-coupled receptors,[54] an observation that may partially explain the growth-promoting properties of some vasoconstrictor hormones.

An additional pathway that is activated under some conditions by growth factors and vasoactive agonists is phospholipase D-mediated hydrolysis of plasma membrane phosphatidylcholine.[55] In this reaction, phosphatidic acid and choline are released. This pathway is receiving increasing attention because phosphatidic acid may have a role in mediating the growth response[56] and because phospholipase D activation seems to be required for the proliferative response.[57]

Growth

Vascular smooth muscle cell growth occurs via two processes: hypertrophy and hyperplasia. In general, hypertrophy occurs in response to long-term stimulation with vasoconstrictor-type agents, whereas hyperplasia occurs in response to the classic growth factors. Hypertrophy is characterized by an increase in smooth muscle cell mass due to increased protein synthesis and has been shown to occur in response to angiotensin II[58] and thrombin[59] and in large vessels during hypertension. Hyperplasia is characterized by cell replication and is stimulated by growth factors such as PDGF and fibroblast growth factor (FGF)[60-62] following vascular injury. The biochemical processes leading to hypertrophy and hyperplasia are currently under investigation. It is clear that the aforementioned tyrosine kinase pathways are important in both types of growth.[53,54] In addition, generation of reactive oxygen species, including superoxide and hydrogen peroxide, serves to transduce the growth signal by activating specific proteins such as p38 mitogen-activated protein kinase and Akt/protein kinase B.[63,64]

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

THE EXTRACELLULAR MATRIX

The extracellular matrix is a major component of the vessel wall. It is the medium through which nutrients are transported, a repository for products secreted by the cells of the vascular wall, the site of accumulation of cell debris, and a substrate for migration and proliferation of endothelial cells, monocytes, and vascular smooth muscle cells. The matrix consists of several proteins that have distinct functions in maintaining the integrity of the wall (Table 6-1).

Table 6-1: Components of the Extracellular Matrix

Matrix Component	Function
Proteoglycans	Resistance to deformation
	Arterial permeability, filtration, ion exchange
	Transport and deposition of plasma elements
	Regulation of cellular metabolism
Collagens (types I and III)	Mechanical strength
Collagens (types IV, V, and VI)	Attachment of vascular cells to the matrix
	Components of the basal lamina
	Linking collagens to noncollagenous structures
Elastin	Regulation of vascular elasticity
Fibronectin	Cell-cell adhesion
	Cell-substrate adhesion
	Cell motility
	Specific binding of collagen, heparin
Laminin	Attachment of endothelial cells to type IV collagen

Extracellular matrix degradation and reformation is an extremely important biological process with profound clinical implications. It is impossible for vascular cells to hypertrophy, proliferate, or migrate without an initial degradation of the matrix. One of the earliest events in angiogenesis is the degradation of the extracellular matrix to enable tube (capillary) formation. Vascular cells, including endothelial cells, VSMCs, resident macrophages and fibroblasts, may secrete matrix metalloproteinases (MMPs), enzymes that selectively digest the individual components of the matrix. In addition, these cells elaborate tissue inhibitors of metalloproteinases (TIMPs).[8]

MMPs belong to three main groups: the type IV collagenases (also called gelatinases), the stromelysins, and interstitial collagenase. The characteristics of these proteins are described in Table 6-2. MMPs are produced as inactive zymogens that can be activated by plasmin.[9] The activity of MMPs is also regulated by cytokines at transcriptional and posttranslational levels, as well as by the relative levels of TIMPs. MMP-

2 is usually found complexed with its specific inhibitor, TIMP-2.

Table 6-2: Matrix Metalloproteinases and Inhibitors

Class	Nomenclature	Molecular Weight[a]	Vascular Cell Type	Expression
Interstitial collagenase	MMP-1	~45	VSMC, EC, microvascular EC	Inducible by PDGF, PMA, IL-1, VEGF
Type IV collagenase	MMP-9, gelatinase B, type V gelatinase	92	VSMC, EC	Inducible by IL-1α, PMA; inhibited by retinoic acid
	MMP-2, gelatinase A, type IV gelatinase	72	VSMC, wounded EC, microvascular EC	Constitutive, ↑ by TNF-α, IL-1α (VSMC); ud by retinoic acid (EC)
Stromelysin	MMP-3	50	VSMC, EC, microvascular EC	Inducible by IL-1 (VSMC); TNF-α, PMA (EC)
TIMP-1	Inhibits MMPs	30	VSMC, EC, microvascular EC	Constitutive
TIMP-2	Inhibits MMP-2	~20	VSMC, EC, microvascular EC	Constitutive, ↑ by retinoic acid (EC)

[a]The molecular weight of MMP-1 and MMP-3 depends on the species.
ABBREVIATIONS: EC = endothelial cell; IL = interleukin; MMP = matrix metalloproteinase; PDGF = platelet-derived growth factor; PMA = phorbol 12,13-myrisate acetate; TIMP = tissue inhibitor of metalloproteinase; TNF = tumor necrosis factor; VEGF = vascular endothelial growth factor; VSMC = vascular smooth muscle cell.

In venous or microvascular endothelial cells, MMP-1 (interstitial collagenase), MMP-2 (72-kDa gelatinase), and TIMPs-1 and 2 are constitutively expressed. Although MMP-3 is only weakly expressed, it can be induced synergistically by incubation of the cells with the cytokine tumor necrosis factor α (TNF-α) and phorbol ester tumor promoters.[8] This treatment also induces MMP-9 expression. Since MMP-2 and TIMP-2 are unaffected by TNF-α, cytokine activation of endothelial cells can change the complement of metalloproteinases produced. In VSMCs, MMP-2 is constitutively expressed, whereas MMP-1, MMP-9 (92-kDa gelatinase), and MMP-3 (stromelysin) are induced by cytokines such as interleukin 1 and TNF-α.[9] Cytokines can also activate MMP-2 zymogen.[65] Thus, cytokine stimulation increases the range of active metalloproteinases secreted by smooth muscle cells to encompass proteases capable of degrading all the major matrix components. In contrast, although TIMP-1 and TIMP-2 are constitutively expressed by vascular smooth muscle, their expression is unaffected by cytokines.[9] The net effect of cytokines on the vascular wall may be to tip the balance between the production of MMPs and TIMPs in favor of extracellular matrix degradation and remodeling.

Of particular importance, several reactive oxygen species have been shown to stimulate both activation and expression of MMPs, in particular MMP-9.[66,67] This is likely to be very important in diseases like atherosclerosis and hypertension, where vascular oxidant stress is increased. Activated macrophages accumulate at shoulder regions of the atherosclerotic plaque and secrete both MMPs and reactive oxygen species,[66,68] contributing to plaque rupture in this region.

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

ENDOTHELIAL CELL-VASCULAR SMOOTH MUSCLE INTERACTIONS

Endothelial Control of Vascular Tone

The endothelium serves a dual function in the control of vascular tone (Fig. 6-4). It secretes relaxing factors such as nitric oxide and adenosine, and constricting factors such as the endothelins. Vessel tone thus depends on the balance between these factors, as well as on the ability of the smooth muscle cell to respond to them. The most important regulatory molecules are discussed separately.

ENDOTHELIUM-DERIVED RELAXING FACTOR/NITRIC OXIDE

An EDRF was first described by Furchgott and Zawadzki,[2] who observed that aortic rings dilated in response to acetylcholine only when the rings maintained an intact endothelium. The predominant form of EDRF, derived from L-arginine by the action of the enzyme nitric oxide synthase (NOS), is nitric oxide (NO), or a closely related nitroso compound.[62]

Many factors have been shown to regulate the release of EDRF/NO[69] by increasing intracellular Ca^{2+}. These include hormones such as acetylcholine, norepinephrine, bradykinin, thrombin, ATP, and vasopressin; the platelet-derived factors, serotonin and histamine; fatty acids; ionophores; and physical forces. NO easily crosses the smooth muscle cell membrane and binds to the heme moiety of the soluble guanylate cyclase, thereby enhancing the formation of cyclic GMP. Cyclic GMP, in turn, reduces intracellular Ca^{2+} concentrations leading todephosphorylation of the myosin light chain and relaxation.[70] It should be noted that the drug nitroglycerin exerts its vasodilator effects by being converted to NO, thus substituting for a natural product. Deficiency in release of active NO is an important contributing factor leading to vasospasm.

NO is produced by the action of the enzyme NOS, which oxidizes the guanidino nitrogens of L-arginine to form citrulline and NO. This enzyme has been cloned from brain (nNOS, for neuronal NOS, type I),[71] macrophages (iNOS, for inducible NOS, type II),[72] and endothelial cells (eNOS, for endothelial NOS, type III).[73] The three isoforms of NOS share important consensus sequences for NADPH, flavin adenine dinucleotide, and flavin mononucleotide cofactor-binding sites, as well as a Ca^{2+}-calmodulin-binding site. During the past several years, a great deal has been learned about how these enzymes function.[74] All NO synthases function as homodimers, and each subunit consists of a carboxy-terminal reductase domain and an amino-terminal oxygenase domain, connected by a calmodulin-binding region. The NADPH- and flavin-binding sites reside in the reductase domain, where electrons derived from NADPH are stored by the flavins. For both the neuronal and endothelial isoforms of the enzymes, increases in intracellular calcium lead to calmodulin binding to the calmodulin-binding site, which in turn enables electrons to flow from the reductase domain to the amino-terminal oxygenase domain. This region contains binding sites for heme, tetrahydrobiopterin, and L-arginine. Electrons transferred from the reductase domain are initially bound by the ferrous iron in the prosthetic heme group. The precise role of tetrahydrobiopterin remains unknown, although it appears critical in allowing electrons to be transferred from the heme to the guanidino nitrogens of L-arginine, resulting in the formation of NO. Interestingly, when tetrahydrobiopterin or L-arginine is absent, the electron flows to molecular oxygen, resulting in the formation of the superoxide anion.[75] This phenomenon has been termed *uncoupling* of NOS, and there are substantial data that this may occur in a variety of disease states, perhaps because of oxidation of tetrahydrobiopterin.

Although increases in intracellular calcium clearly activate eNOS via stimulation of calmodulin, there are additional ways that the enzyme is activated that seem independent of calmodulin or calcium. For example, shear stress acutely stimulates the release of NO from the endothelium, and this depends only on calcium

during the first few seconds of the response.[76] The continued activation of eNOS in response to several minutes or hours of shear seems independent of calcium and calmodulin. Phosphorylation of eNOS is almost certainly important in this calcium-independent stimulation.[77] Recently, specific sites of the enzyme have been identified that are phosphorylated in response to shear.[78] Phosphorylation by the kinase Akt leads to a calcium-independent activity of the enzyme.[79] Other phosphorylation sites have also been implicated.

Although expression of the endothelial enzyme (eNOS) was originally thought to be constitutive, it is now clear that its expression is highly regulated. Increases in shear stress rather markedly enhance expression of eNOS.[80] Likewise, low shear is associated with a decrease in eNOS expression. Exercise training dramatically increases eNOS expression in endothelial cells, likely because of the increased shear stress caused by the high cardiac output that accompanies sustained exercise.[81] In contrast, inflammatory cytokines such as TNF-α decrease eNOS expression.[73] This is caused by destabilization of eNOS mRNA, rather than by decreasing the rate of eNOS transcription.[82] Several other conditions and stimuli seem to alter eNOS expression by changing the half-life of mRNA. These include exposure to oxidized LDL,[83] hypoxia,[84] and changes in endothelial cell growth state.[85] The mechanisms underlying regulation of eNOS mRNA stability are incompletely understood, but are the focus of intense investigation.

ENDOTHELIUM-DERIVED HYPERPOLARIZING FACTOR

Shortly after the identification of the EDRF, it was suspected that the endothelium could release more than one relaxing factor, depending on the vessel size, the stimulus, and the species studied. Initial studies showed that some vasodilators produce hyperpolarization of the vascular smooth muscle membrane in an endothelium-dependent manner. It is now clear that this is due to the release of a hyperpolarizing factor from the endothelium that is almost certainly different than NO.[86] Its production is stimulated by many of the same stimuli that evoke the release of NO and depends on intracellular calcium. Although there is some debate regarding the nature of this factor, increasing evidence suggests that it is a cytochrome P450 metabolite of arachidonic acid and perhaps other fatty acids.[87] This epoxide, when released from the endothelium, opens calcium-activated potassium channels in the adjacent vascular smooth muscle, resulting in vasodilation.[88] It has also been shown that these epoxides have important anti-inflammatory effects.[89]

PROSTACYCLIN

Prostacyclin, or prostaglandin I_2 (PGI_2), which is a prostanoid derived from the action of cyclooxygenase on arachidonic acid, is released by the endothelium and relaxes vascular smooth muscle by increasing its intracellular content of cyclic AMP.[90] Prostacyclin is also platelet suppressant and antithrombotic, and reduces the release of growth factors from endothelial cells and macrophages.[23] Among the agonists that stimulate prostacyclin synthesis are bradykinin (one of the most potent), substance P, platelet-derived growth factor and epidermal growth factor, and adenine nucleotides,[23] whereas aspirin has been shown to inhibit it transiently. Therapeutically, the debate about the appropriate dose of aspirin in ischemic coronary syndromes revolves around finding a dose that will inhibit platelet function without inhibiting endothelial PGI_2 synthesis.

ADENOSINE AND RELATED COMPOUNDS

Both adenine nucleosides (adenosine) and nucleotides (ADP and ATP) are released by the endothelium in response to such stimuli as thrombin[91] and flow.[92] Adenine nucleosides bind to P1 purinergic receptors that activate cyclic AMP leading to relaxation, whereas adenine nucleotides stimulate P2 receptors that are coupled to phosphoinositide hydrolysis. Stimulation of P2 receptors in endothelial cells results in an increase in intracellular Ca^{2+} and release of EDRF/prostacyclin,[93] whereas P2 receptors on vascular smooth muscle mediate contraction.[94] Thus, depending on the relative amounts of adenosine, ATP, and ADP in the vessel wall, and the presence of a functional endothelium, these compounds can have a net dilatory or constrictor effect on vascular smooth muscle. Additionally, the endothelium possesses an extracellular ectonucleotidase enzymatic system that mediates the conversion of ATP or ADP to adenosine, thereby regulating the local levels of these compounds.[15] These systems are important in determining the vascular response to ADP released from platelets at the site of thrombus formation.

ENDOTHELIN

The endothelins are a family of closely related peptides made and secreted by endothelial cells in some, but not all, vascular beds. There are three endothelins (ET-1, 2, and 3), all of which are 18 amino acid peptides. Endothelins are initially synthesized as preproendothelin, which undergoes preprocessing to big-endothelin. Big-endothelin is released and is converted to active endothelin by the endothelin-converting enzyme. The vascular effects of endothelin are mediated by endothelin receptors, of which three subtypes have been identified (ET-A, B, and C). The receptors have differing specificity for the individual endothelin peptides and activate somewhat different signaling pathways. In the vessel, the ET-A receptor is predominantly found on vascular smooth muscle, whereas the ET-B receptor resides on endothelial cells. Activation of the former stimulates potent vasoconstriction, whereas activation of the latter stimulates release of NO and thus favors vasodilation.[95]

The slow, intense, and sustained contraction caused by ET-1 appears to be the result of activation of the phosphoinositide/protein kinase C signaling pathway, as well as of opening voltage-dependent L-type calcium channels.[96] Importantly, even low, subthreshhold concentrations of ET-1 enhance vasoconstriction to a variety of other vasoconstrictor agents, including serotonin, angiotensin II, and α-adrenergic agonists, seemingly via activation of protein kinase C. This has been suggested to contribute to the *rebound phenomenon* that occurs after nitroglycerin has been administered for several days and suddenly discontinued.[97]

ET-1 is also a potent growth factor for smooth muscle,[98] is a chemoattractant for monocytes,[99] and plays a role in nitroglycerin tolerance.[97] Importantly, angiotensin II has been shown to stimulate the production of ET-1 by VSMCs in culture[100] and, in vivo, some of the hypertensive effect of angiotensin II is mediated by endothelin.[101]

ANGIOTENSIN-CONVERTING ENZYME

Endothelial cells synthesize and express on their surface angiotensin-converting enzyme (ACE),[102] the protein that converts angiotensin I to the potent vasoconstrictor angiotensin II and degrades and inactivates bradykinin. Of note, vascular cells contain almost all components of the renin/angiotensin system, and thus local production of angiotensin II can contribute importantly to vascular function. This local production of angiotensin II can explain why ACE inhibitors and angiotensin receptor antagonists are often effective even when the circulating levels of renin or angiotensin II are not elevated.

Endothelial Control of Vascular Growth

As with vascular tone, the endothelium also exerts a dual effect on vascular growth (Fig. 6-5). Both growth-promoting and growth-inhibitory factors are made and secreted by endothelial cells, making them pivotal in the control of smooth muscle responsiveness. Endothelial cells are involved in two types of vascular growth: angiogenesis and abnormal growth of smooth muscle during disease.

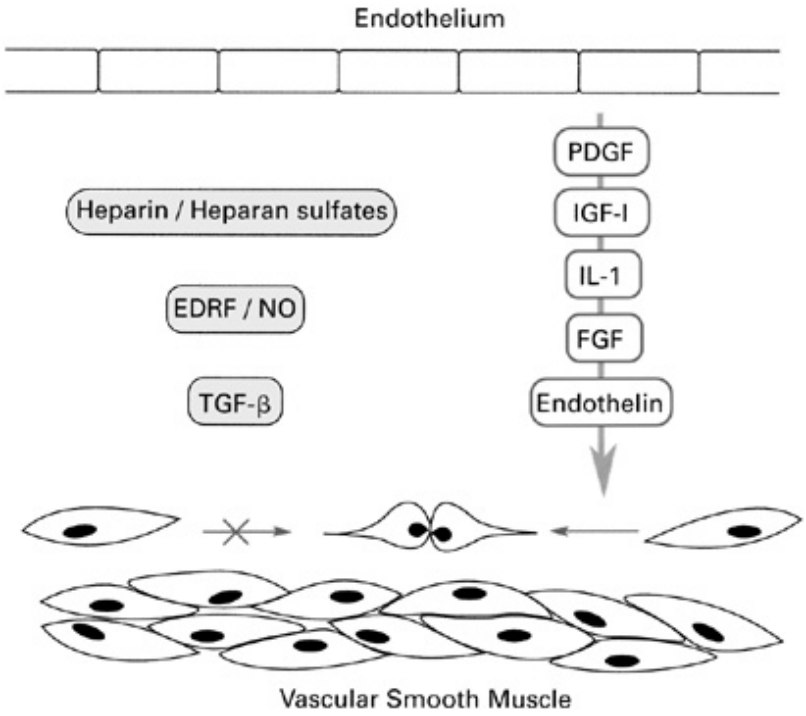

Figure 6-5: Endothelial control of vascular growth. As with vasoactive substances, endothelial cells make and secrete both growth-promoting (*white boxes*) and growth-inhibitory (*colored boxes*) compounds. Under normal conditions, the net effect of the endothelium is growth inhibitory. ABBREVIATIONS: EDRF = endothelial-derived relaxing factor; NO = nitric oxide; TGF-β = transforming growth factor-β; PDGF = platelet-derived growth factor; IGF-I = insulin-like growth factor-I; IL-1 = interleukin-1; FGF = fibroblast growth factor. (Courtesy of Bernard Lassègue, Ph.D.)

ANGIOGENESIS

Angiogenesis in vivo occurs during normal wound healing and during the vascularization of solid tumors. It is a complex process involving degradation of the basement membrane, the migration and proliferation of endothelial cells, and tube formation. Several factors have been shown to stimulate angiogenesis, including FGF, vascular endothelial growth factor (VEGF), transforming growth factor α (TGF-α), angiogenin, transforming growth factor-β (TGF-β), TNF-α,[103] and insulin-like growth factor 1 (IGF-1).[104] Their properties are summarized in Table 6-3. Some of these factors stimulate angiogenesis by inducing endothelial cell migration and proliferation (FGF and VEGF); others appear to do so by stimulating endothelial cell differentiation (TGF-β and TNF-α) or by activating a secondary cell type to produce angiogenic factors (angiogenin, TGF-β, and TNF-α). Angiogenesis may be negatively regulated by both naturally occurring and synthetic compounds. It can be inhibited by the combination of heparin and cortisone,[105] thrombospondin, platelet factor IV, and γ-interferon. Many of these agents bind to heparin, suggesting that they exert their growth-inhibitory effects by blocking the action of heparin-binding growth factors, such as FGF. It is likely that the control of angiogenesis rests on the maintenance of a balance between the stimulatory and inhibitory factors, the regulation of which is not yet fully understood.

Table 6-3: Angiogenic Stimulators and Inhibitors

	Angiogenesis	Origin	Release	Endothelial Cell Proliferation	Endothelial Cell Chemotaxis	Tubule Formation
FGF	+	Endothelial cells	Cell lysis	+ +	+ (EC)	+
VEGF	+	Endothelial cells	Secreted	+ +	+	+
TGF-α	+	Transformed fibroblasts, macrophages (adenocarcinoma cells)	Secreted	+ +		
Angiogenin	+	Lymphocytes, liver	Secreted	0	-	
TGF-β	+	Endothelial cells	Secreted	-	-(EC)+ (Monocytes)	+
TNF-α	+	Activated macrophages, tumor cells	Secreted	-	+	+
Angiostatic steroids	-	Synthetic	-	-		
Thrombospondin	-	Platelets	Secreted	-		
Platelet factor IV	-	Platelets	Secreted	-		
?-Interferon	-	Activated T cells, macrophages	Secreted	-		

ABBREVIATIONS: EC = endothelial cell; FGF = fibroblast growth factor; TGF = Transforming growth factor; TNF = tumor necrosis factor; VEGF = vascular endothelial growth factor.

ENDOTHELIAL-DERIVED INHIBITORS OF SMOOTH MUSCLE CELL GROWTH

Normally, smooth muscle cells are relatively refractory to growth stimuli and are maintained in a quiescent, differentiated state. It has been proposed, based on at least two lines of evidence, that the endothelium is important in maintaining this smooth muscle phenotype. First, removal of the endothelium experimentally allows initiation of the mitogenic response and, second, regrowth of normal endothelium inhibits further proliferation.[106] One mechanism by which such a tonic inhibitory influence on smooth muscle cell growth could be effected is the secretion by endothelial cells of specific inhibitors of cell proliferation. Alternatively, the endothelium could be an effective barrier limiting access of bloodborne growth factors to vascular smooth muscle. Attention so far has focused on heparin and other glycosaminoglycans (including heparan sulfate) as possible candidates for endothelial-derived growth-inhibitory factors. Heparin inhibits VSMC mitogenesis and migration in vivo and in vitro, and reduces neointimal proliferation if administered during the first 3 days after vascular injury.[107] However, the inhibition is not complete, and it seems likely

that other endothelial cell factors may be involved. Another possibility is NO, which is usually associated with vascular relaxation. NO is released tonically from the endothelium of large arteries, which have a relatively minor role in the control of vascular tone, suggesting that it may have an additional function in these vessels. Studies on cultured VSMC have shown that pharmacologic agents such as sodium nitroprusside and 8-bromo-cyclic GMP, which mimic the effect of NO on vascular smooth muscle G kinase, can inhibit mitogenesis.[108] This raises the possibility that NO may have an important role in maintaining the normal artery in a state refractory to mitogens. It is of interest that the myointimal proliferation in response to balloon injury can be inhibited by overexpression of NO synthase using gene transfer techniques.[109,110] Finally, endothelial cells have been shown to make and secrete TGF-β,[12] which is subsequently activated by smooth muscle cells. This growth factor inhibits smooth muscle growth directly[111] and alters PDGF secretion,[112] as well as extracellular matrix composition. The extracellular matrix may itself have a very important influence on smooth muscle proliferation.

The response of VSMCs to growth factors depends on the balance of the hormonal and environmental influences to which the cells are subjected. For example, intact arteries are relatively unresponsive to FGF, only showing a proliferative response when the endothelium has been damaged or removed.[61] This raises the possibility that the cellular mechanism of action of factors secreted by the endothelial cells is to induce a protein or factor in smooth muscle cells that makes them refractory to mitogenic stimulation. One candidate for such a protein is a tyrosine phosphatase. As already noted, most growth factors activate a cascade of tyrosine kinases as an initial step in the mitogenic stimulus. The level of tyrosine in cellular proteins is also controlled by tyrosine phosphatases, enzymes that remove phosphates from tyrosine residues. Thus, in cells with very active tyrosine phosphatases, tyrosine kinases may be unable to induce a sustained phosphorylation of proteins on tyrosine, theoretically inhibiting the growth response. Evidence for such a mechanism of growth control is only now becoming available, with the discovery that somatostatins act as growth inhibitors in neoplastic cells through activation of a tyrosine phosphatase.[52] Angiopeptin, a somatostatin analog, has been shown to inhibit neointimal proliferation after balloon injury,[113] suggesting that activators of tyrosine phosphatases may be important in growth control in the vasculature. These observations raise the possibility that one of the mechanisms by which endothelial cells help to maintain smooth muscle quiescence is by the induction of tyrosine phosphatase activity in the smooth muscle cells.

ENDOTHELIAL-DERIVED STIMULATORS OF SMOOTH MUSCLE CELL GROWTH

Endothelial cells have the capacity to secrete several factors that are thought to be involved in the abnormal smooth muscle cell growth seen during atherogenesis and hypertension. As noted previously, the most well studied of these factors is PDGF, so named because it was originally isolated from platelets. PDGF is a dimer, composed of two distinct peptide chains (designated A and B chains), and can be produced as an AB heterodimer or as an AA or BB homodimer. Endothelial cells contain the mRNA for both peptides,[112] although the precise form in which PDGF is secreted is unclear. Release of PDGF from the endothelium is regulated by second messengers such as cAMP and activators of protein kinase C; other growth factors including TGF-β, FGF, and TNF; circulating factors; and locally produced factors such as thrombin.[112] A second growth factor made and secreted by endothelial cells is IGF-1,[13] which is a progression factor that facilitates movement of cells through the cell cycle but, by itself, is not a particularly strong mitogen. In vitro, it enhances the mitogenic effect of PDGF on smooth muscle.[114] IGF-1 production by endothelium has been shown to be regulated by PDGF and has been shown to be a major player in vascular hypertrophy and hyperplasia.[115]

Other factors made by the endothelium that are able to alter smooth muscle proliferation include interleukin 1 (IL-1), FGF, and endothelin. IL-1 is an inflammatory cytokine that has numerous vascular effects in addition to mitogenesis, including the stimulation of procoagulant activity,[116] induction of leukocyte adhesiveness (see below), and inhibition of contraction.[117] IL-1 regulates its own expression,[118] and, in addition, its production is regulated by TNF-α,[103] lipopolysaccharide, and γ-interferon.[118] As already noted, basic FGF has been detected in endothelial cells[17] and acts as a potent smooth muscle mitogen, particularly after denuding injury.[61] FGF does not contain the signal peptide that usually provides a mechanism for transporting proteins out of cells and thus may not be secreted by endothelial cells. It is, however, present

and stored in the subendothelial matrix and may be released on cell lysis or death.[119] FGF released from VSMCs may be particularly important in the growth response induced by injury to the arterial wall after balloon angioplasty. FGF bound to the matrix can be released by heparin and proteinases,[120] suggesting that the matrix may serve as a store for rapidly mobilizing this growth factor. Finally, the vasoconstrictor endothelin has also been shown under certain circumstances to act as a smooth muscle mitogen,[121] possibly by increasing PDGF-A chain secretion in the smooth muscle cells themselves.

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

ENDOTHELIAL CELL-LEUKOCYTE INTERACTIONS

Endothelial cells participate actively in the development of inflammatory reactions. They are central to the recruitment of leukocytes to sites of inflammation by secreting chemotactic molecules and expressing adhesion molecules that interact with surface proteins on leukocytes.

Inflammatory cytokines increase synthesis of vasodilators by the endothelium, which causes increased blood flow to the injured area. Histamine, which is released at the site of vascular inflammation, also contracts endothelial cells in certain areas, thus increasing permeability.[122] Cytokines stimulate endothelial secretion of leukocyte chemoattractant proteins (interleukin 8) and monocyte chemotactic protein 1 (MCP-1), and expression of adhesion molecules such as intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2), endothelial leukocyte adhesion molecule 1 (E-selectin), vascular cell adhesion molecule 1 (VCAM-1), and GMP-140, which are important regulators of leukocyte accumulation on the vascular surface.[123] E-selectin and GMP-140 bind resting, but not activated, neutrophils; VCAM-1 binds to the VLA-4 antigen on monocytes and T lymphocytes; and ICAM-1 and 2 bind to the LFA-1 integrin receptor on B lymphocytes.[123] The expression of these molecules appears to be differentially regulated by cytokines, thrombin, and histamine,[123] so that their surface expression determines the type of leukocytes attached to the endothelial monolayer. It has been suggested that the sequential accumulation of different leukocyte classes at sites of inflammation can be explained by the differential induction of these endothelial cell adhesion molecules.[124] Leukocyte adhesion molecules and chemoattractant proteins are also likely to be important in atherogenesis (see below).

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

ENDOTHELIAL RESPONSES TO HEMODYNAMIC INFLUENCES

In addition to being influenced by the interaction of circulating blood cells, VSMCs, and matrix, the endothelium responds to the physical forces of pressure, stretch, and shear stress imposed by the hemodynamics of the circulation. Flow-mediated, endothelium-dependent vasodilation has been described in many vascular beds,[125] and shear stress has been proposed to play a role in controlling endothelial cell proliferation.[126] Elevated pressure, stretch of the vessel wall, and shear stress have all been shown independently to affect endothelial cell morphology and/or function. Pressure alone appears to have a role in the generalized hypertrophy of the vessel wall that occurs during hypertension. Studies in cultured cells have shown that stretching endothelial cells leads to changes in cell shape, intracellular signal generation with an increase in calcium concentration, and proliferation.[126] Shear stress has numerous effects on endothelial cells. Initially, it was found that exposure of endothelial cell monolayers to elevated shear stresses in vitro caused them to align in the direction of flow. This reorientation was accompanied by changes in the cytoskeleton of the cells, including reorganization and alignment of the actin filaments and microtubules (Fig. 6-6). Similar mechanisms presumably also account for the orientation of endothelial cells parallel to the longitudinal axis in areas of laminar flow in the arterial system. The function of endothelial cells is also altered by shear stress: a K^+ current is activated; secretion of vasoactive and growth factors, including NO, endothelin, prostacyclin, and basic FGF (bFGF) is increased; tissue factor expression is increased; uptake of LDL is elevated; and tPA secretion is increased.[126]

The importance of these observations lies in the variation in hemodynamic forces throughout the circulation. High pressure, such as that which occurs in hypertension, causes changes in the morphology and function of the vessel wall.[127] In addition, the areas of the vasculature exposed to low shear stress (branch points and curvatures) exhibit a predilection to the formation of atherosclerotic lesions.[128] It is thus clear that the hemodynamic environment of the endothelium and underlying smooth muscle is a potentially powerful regulator of vascular function.

The mechanism(s) by which the endothelial cell can sense and transduce mechanical signals has not been defined definitively. Possibilities include signaling through focal adhesion complexes, a surface mechanoreceptor, a flow-sensitive ion channel, changes in cytoskeletal stress due to deformation, and flow-dependent gradients of bioactive substances along the surface of the cell. Recent data have implicated heterotrimeric G-protein activation.[129] Furthermore, caveolae, which are budding, membrane vesicular structures as described previously, are rich in signaling molecules such as G proteins and may be involved in signal generation in response to shear stress.[130]

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

ENDOTHELIAL DYSFUNCTION AND VASCULAR SMOOTH MUSCLE ABNORMALITIES

In general, the normal endothelium is in an inhibitory mode-inhibiting contraction, thrombosis, white cell adhesion, and vascular smooth muscle growth (Figs. 6-4 and 6-5). *Endothelial dysfunction* is one of the important concepts that has developed in vascular biology over the last decade. Implicit in the term is the recognition that the fundamental or normal functions of the endothelium are not fixed, but are mutable. Thus, the endothelium in a given area may lose its vasodilator predominance, become prothrombotic or less thrombolytic, begin to support leukocyte adherence (which may be a normal response in the inflammatory process), or stimulate rather than inhibit smooth muscle migration and proliferation. *It is likely that endothelial dysfunction accounts ultimately for a large portion of cardiovascular diseases*.

Oxidative Stress and Vascular Disease

In the past several years, it has become clear that vascular cells, including endothelial, vascular smooth muscle, and adventitial cells, can produce reactive oxygen species (ROS). These include superoxide anion, hydrogen peroxide, NO, and peroxynitrite. In numerous pathophysiologic conditions, the production of ROS in the vascular wall is increased, resulting in a situation commonly referred to as *oxidant or oxidative stress*. Several enzyme systems have been implicated in production of ROS.

Recent studies suggest that an NADH/NADPH-driven oxidase is a major source of ROS in endothelial and vascular smooth muscle cells. This oxidase is a multisubunit enzyme that has only partial similarity to the neutrophil respiratory burst oxidase. For example, in VSMCs, the subunit p22phox has been shown to be critical for its function, whereas the gp91phox subunit appears to be absent.[131] In endothelial cells, the existence of all of the neutrophil subunits has been demonstrated, although it is not clear that they function together to produce ROS as they do in the neutrophil.[132] The adventitia also contains fibroblasts and macrophages that express multiple oxidase subunits.[133] Importantly, the NADH/NADPH vascular oxidase is activated by several pathophysiologic stimuli, including angiotensin II, mechanical stretch, cytokines, and thrombin.[134-137]

A second source of ROS is eNOS. As discussed previously, in the absence of tetrahydrobiopterin or L-arginine, this enzyme becomes "uncoupled" so that it produces hydrogen peroxide and superoxide, rather than NO.[75,138] Importantly, this uncoupling process seems to occur in several common disease states, including hypercholesterolemia,[139] hypertension,[140] and diabetes, although the mechanisms responsible for this process are poorly understood.

An important source of radicals in the vasculature is the lipoxygenases and in particular 12,15-lipoxygenase. These do not form superoxide, but react directly with unsaturated fatty acids (e.g., linoleic or arachidonic acid) to form a lipid radical ($L_{\bullet}$), which in turn can react with molecular oxygen to produce alkoxy radicals ($LO_{\bullet}$) and lipid peroxy radicals ($LOO_{\bullet}$). These lipid radicals are biologically very active and can stimulate gene expression, consume NO, oxidize NADH, and serve as a source of other radicals.[141]

Other sources of ROS in vascular cells are xanthine oxidase, cytochrome P450, cyclooxygenase, and mitochondrial electron transport.[141] There is now substantial interest in the role of these various sources of ROS and how they contribute to vascular oxidant stress.

In the next several paragraphs, we consider how endothelial dysfunction and vascular smooth muscle abnormalities contribute to several vascular diseases. A recurring theme in these conditions is that ROS play a central role. For example, superoxide rapidly reacts with NO, forming the strong oxidant peroxynitrite. The latter can oxidize lipids, damage lipid membranes, deplete cellular thiols, and alter function of several enzymes.[142] This inactivation of NO alters vasomotion and can predispose one to or even cause hypertension.[143] A substantial component of VSMC hypertrophy caused by angiotensin II is mediated by hydrogen peroxide.[144] ROS also contribute to vascular inflammation by stimulating expression of adhesion molecules in endothelial cells.[145] These issues discussed in the context of several vascular diseases.

Atherosclerosis

Atherosclerosis is the prototypical disease characterized by endothelial dysfunction, which may explain many of its cardinal features. Thus, mononuclear and lymphocytic infiltration, hypercontractility, LDL modification, smooth muscle cell growth, and intimal migration are likely related to abnormalities of the endothelium induced by hyperlipidemia, hypertension, smoking, and unknown hereditary factors. The pathogenesis of atherosclerosis viewed as a disease of endothelial dysfunction is depicted in Fig. 6-7. (For a more detailed discussion, see Chap. 41.)

Clinically, endothelial dysfunction in atherosclerosis has primarily been defined by impairment of endothelial-dependent relaxation.[146] This defect, which likely accounts for the vasospastic tendency of diseased arteries, appears to be attributable to defective generation or delivery of active EDRF/NO.[147] Coronary endothelial-dependent vasodilator function is impaired in patients with risk factors such as hypercholesterolemia, prior to angiographically demonstrable coronary disease.[148] As previously discussed, increased inactivation of NO by the superoxide anion is likely one cause of this abnormality.[147,149] Other causes may include "uncoupling" of the eNOS enzyme, altered calcium signaling of eNOS, and diminished expression of the eNOS enzyme, which clearly occurs late in the atherosclerotic process.[150] Of note, LDL and cytokines have been shown to downregulate eNOS by destabilizing the eNOS mRNA. This is prevented by HMG-CoA reductase inhibitors even without lowering of cholesterol. New evidence suggests that this process involves the lipid modification of the small GTPase Rho by the attachment of a geranylgeranyl and lipid moiety, which facilitates its localization to the cell membrane, suggesting a new target for the HMG-CoA reductase inhibitors.[151]

A second manifestation of a dysfunctional endothelium that is apparent very early after initiation of cholesterol feeding in animals is the recruitment of monocytes and macrophages into the vessel wall.[152] This recruitment is likely the result of induction of VCAM-1 expression,[153] as well as secretion of MCP-1.[154] The molecular linkage between hyperlipidemia and MCP-1/adhesion molecule expression is unknown, but may reflect in part the oxidative stress imposed by this change in milieu. Inflammatory cytokines are also important mediators of adhesion molecule expression,[155] and their production by the endothelium and inflammatory cells in the vessel wall may also contribute to adhesion molecule expression in both the early and the late stages of the disease.

The intimal proliferation observed in atherosclerotic lesion formation results from migration and hyperplasia of VSMCs[156] and accumulation of extracellular matrix.[157] Proliferation has been attributed to growth factors such as PDGF, FGF, and IGF-1. Since these growth factors can be

produced by the endothelium in vitro, it is very likely that the dysfunctional endothelium in atherosclerosis also produces growth factors while shifting from a growth-inhibitory to a growth-promoting mode. Furthermore, there is evidence that products of oxidative metabolism may also release growth factors and activate matrix metalloproteinases,[67] thus contributing to intimal lesion formation on multiple levels.

The recent advances in our understanding of vessel wall biology provide insight into the biological mechanisms responsible for the pathogenesis of atherosclerosis. A unifying concept of the disease has arisen that revolves around endothelial dysfunction mediated by changes in oxidative metabolism. Oxidative stress and oxidatively modified LDL thus assume central roles in atherogenesis (Fig. 6-7). As discussed previously, a major source of lipid oxidation is lipoxygenase. Recently, the 12,15-lipoxygenase gene has been deleted in mice. When these animals were crossed with apolipoprotein E-deficient mice (which spontaneously develop atherosclerosis), atherosclerotic lesion development was strikingly reduced.[158] These data indicate that 12- and 15-lipoxygenases are almost certainly involved in the atherosclerotic process. The role of oxidized LDL is discussed more completely in Chap. 35, and the relationship of the cell biology of atherosclerosis to coronary ischemic syndrome is discussed in Chap. 41.

Hypertension

Hypertension is characterized by dysfunction of both endothelium and vascular smooth muscle. In chronic hypertension, endothelium-dependent relaxations are impaired in both conduit and resistance arteries.[159-162] Relaxations to some platelet factors are also altered, but have been found to be augmented or diminished, depending on the hypertensive model studied.[163] Furthermore, the endothelium-dependent constrictor activity is increased in some models of hypertension.[163] These alterations in endothelial function would tend to increase the tone of hypertensive vessels. The mechanism responsible for this effect is not entirely clear. Data from experimental animals make it seem likely that the alterations in endothelium-dependent responses in hypertension result from a combination of altered endothelial and VSMC function.

Hypertension is also characterized by an increase in vessel wall mass. In the aortas of spontaneously hypertensive and Goldblatt hypertensive rats, this increase can be attributed to an increase in the size of the existing smooth muscle cells.[164,165] Hypertrophy is accompanied by an increase in ploidy; that is, an increased DNA content per cell.[164,165] In contrast, resistance vessels from these same animals appear to increase their mass by hyperplasia of the smooth muscle cells.[166] The stimuli responsible for these changes in the hypertensive vascular wall are unknown. Vascular remodeling appears to have two stages: (1) an initial, reversible intense vasoconstriction mediated by neural or endogenous signals, followed by (2) a remodeling of the vessel wall characterized by increased smooth muscle mass and narrowing of the vessel lumen. There is some evidence that this response is dependent on the presence of the endothelium.[127]

Vasospasm

When the endothelium becomes dysfunctional as in atherosclerosis, the underlying smooth muscle cells often become hyperreactive to certain vasoconstrictor stimuli, including serotonin and ergonovine.[167] Coronary spasm leading to myocardial infarction is one of the most clinically relevant problems arising from this phenomenon. Proposed mechanisms underlying this vasoconstrictor abnormality that can result in total occlusion include supersensitivity of the smooth muscle cells to constrictor stimuli and loss of endothelial-dependent relaxing mechanisms. The increased tendency toward thrombus formation in dysfunctional endothelium, due to a loss of the normal anticoagulant properties, also promotes the release of thrombus-related factors (serotonin, thromboxane A_2, ADP, thrombin, and PDGF) in the vicinity of the smooth muscle cells, which can promote vasoconstriction.[168]

Restenosis

Restenosis is the development of a neointima that occurs following angioplasty, often leading to reocclusion of the initial lesion. The response of the arterial wall to the injury induced by angioplasty (removal of the endothelium and stretching of the vessel wall) involves several distinct events (Fig. 6-7). Removal of the endothelium not only alters the paracrine hormonal environment in which VSMCs exist, but it also exposes a thrombogenic surface to which platelets and other circulating factors can adhere, resulting in the formation of a thrombus. In addition, injury to the underlying smooth muscle may release factors such as FGF, which have mitogenic effects on the remaining smooth muscle cells. Finally, infiltration and subsequent activation of macrophages into the denuded vessel wall bring an additional set of hormonal influences to bear on the vascular smooth muscle. The pathophysiologic consequences of these complex events include migration and proliferation of smooth muscle cells into the intimal area, resulting in the formation of a neointima over a period of weeks to months.

Balloon injury has been extensively studied in several animal models, including pigs, rabbits, rats, and baboons. In the rat carotid artery, the events following injury can be divided into three stages: initial (injury to 48 h), migratory (3 to 7 days), and proliferative (7 days to 3 to 4 weeks). During the initial response to injury, growth-related genes in the smooth muscle cells are induced, including c-fos, PDGF-A, PDGF-β receptor,[169] and MCP-1.[170] It also appears that deep injury to smooth muscle cells results in an outpouring of FGF, a potent smooth muscle mitogen.[119] This initial response does not appear to depend on platelet factors, but does appear to be directly related to the removal of the endothelium.[106] During the migratory phase, a large increase of thymidine incorporation in the vessel wall occurs, accompanied by further increases in the mRNA encoding IGF-I[171] and the PDGF-β receptor.[169] This phase of the response can be modulated by platelet factors and inhibited by the endothelium.[106] Finally, the proliferative phase is characterized by marked intimal thickening, with a decreased percentage of thymidine-labeled cells. Some of the increased area is due to deposition of extracellular matrix, and the majority of the proliferative activity occurs at the luminal surface of the vessel. This proliferative phase seems ultimately to be inhibited by regrowth of normal-functioning endothelium.

Thus, during the process of restenosis after angioplasty, both the loss of endothelium and the transformation of smooth muscle cells appear to contribute to neointimal formation. At least two lines of evidence implicate the endothelium as having a crucial role in the response of the vessel wall to injury. First, removal of the endothelium allows initiation of the mitogenic response and, second, regrowth of normal endothelium inhibits further proliferation. Furthermore, gentle denudation with a nylon loop, accompanied by rapid regeneration of endothelium, results in significantly less neointimal proliferation.[172] In addition, proliferating smooth muscle cells have characteristics distinct from the differentiated smooth muscle cells in the medial layer. Their cytoskeleton is similar to that found in cultured cells. It seems likely, therefore, that two of the most important causes of restenosis are the loss of endothelium-derived growth-inhibitory factors and the transformation of smooth muscle cells into a phenotype able to respond to platelet- and endothelial-derived factors with proliferation.

ROS are not only thought to be centrally involved in the pathogenesis of atherosclerosis, but very likely are major mediators of the proliferative, hypertrophic, and fibrotic responses that frequently occur in arteries after percutaneous transluminal coronary angioplasty (PTCA) resulting in renarrowing or restenosis of the lumen (see Chap. 45). Migration and growth of VSMCs into the intima contribute significantly to restenosis, and intracellular signaling pathways mediating growth, hypertrophy, and migration are stimulated by ROS.[173,174] As discussed previously, both proinflammatory pathways and matrix metalloproteinases, which facilitate vascular remodeling, involve redox-sensitive controlling mechanisms. The apparent broad role for oxidative signaling mechanisms in the vascular wall led to testing of the concept that antioxidants might inhibit

restenosis. The production of superoxide is increased in vessels following balloon injury and, in the porcine model of restenosis, vitamins E and C have been shown to reduce neointimal development.[175,176] Further, several clinical studies have shown that the potent antioxidant probucol reduces late lumen loss after balloon angioplasty.[177-179] Larger clinical trials are under way to test the hypothesis that antioxidants are effective in inhibiting the vascular remodeling processes leading to post-PTCA restenosis.

Chapter 6: MOLECULAR AND CELLULAR BIOLOGY OF BLOOD VESSELS

FUTURE DIRECTIONS

Defining the molecular and cellular basis for dysfunction of the arterial wall in vascular diseases provides information critical to developing clinical strategies for patient management, as well as new therapeutic targets. It is now clear that both endothelial function and smooth muscle function are compromised by a variety of risk factors for vascular disease, due in part to oxidative stress. Further research is required to determine at a more basic level the molecular events that link these risk factors to these diseases. In the near future, the human genome will be fully sequenced, and via the use of bioinformatics, it will be possible to identify genetic profiles that predispose people to the development of vascular pathologies. Clinical trials in the future will be targeted to these populations in new and powerful ways, and basic research will address the roles of these newly identified genes in vascular physiology and pathophysiology.

Figure 6-6: Effect of shear stress on endothelial cells. In bovine aortic endothelial cells grown in static conditions, F-actin filaments assume a random orientation as visualized by rhodamine-labeled phalloidin staining (*left*). Upon exposure to shear stress (30 dynes/cm2, 24 h), these filaments align (*right*). Bars = 100 μm. (Courtesy of Lula Hilenski, Ph.D.)

Figure 6-7: Theoretical initiating events in vascular lesion formation. *Non-denuding injury:* Low-density lipoprotein (LDL) enters the subendothelial space where it is converted to oxidized LDL (ox-LDL), which induces monocyte chemoattraction and endothelial dysfunction. Dysfunctional endothelial cells (ECs) express cell adhesion molecules (ICAM, ELAM, and VCAM), leading to increased monocyte adhesion and movement into the vessel wall. Monocytes in the vessel wall differentiate into macrophages, take up lipids, and remain locally as foam cells, subsequently evolving into fatty streaks. The foam cells in the fatty streak and the overlying endothelium express monocyte chemotactic protein 1 (MCP-1), resulting in further enhanced monocyte chemoattraction and adhesion. Dysfunctional ECs may synthesize less nitric oxide synthase (NOS) or superoxide dismutase (SOD, an enzyme that metabolizes oxygen radicals that have been shown to inactivate NO). This decreases endothelial-derived relaxing factor (EDRF) release/activity. The loss of EDRF together with the direct effects of ox-LDL, or growth factors secreted by the foam cells or endothelium, act on the quiescent contractile smooth muscle cells in the vessel wall, giving rise to the proliferative phenotype, with division and migration into the intima. *Denuding injury:* Loss of endothelium leads to platelet deposition, tissue factor-mediated activation of extrinsic coagulation to generate thrombin, cleavage of fibrinogen to fibrin, and the formation of thrombus. Thrombin gives rise to endothelial expression of adhesion molecules and consequent monocyte attachment, together with secretion of platelet granular constituents. Monocytes enter the thrombus and differentiate into phagocytic macrophages expressing tissue factor and MCP-1. This leads to further monocyte chemoattraction into the vessel wall. Smooth muscle cell proliferation is produced by (1) thrombin generation at the site of denuding injury, (2) platelet-derived growth factor (PDGF) or other growth factors released from platelets in the thrombus, (3) factors secreted by the macrophages ingesting the thrombus, and (4) the loss of EDRF activity caused by endothelial dysfunction. *Proliferative response:* Modulated smooth muscle cells (SMCs) proliferate and synthesize factors that promote plaque development. SMCs synthesize (1) PDGF and other growth factors that cause self-perpetuating autocrine or paracrine stimulation of SMC proliferation, (2) tissue factor (TF) and plasminogen activator inhibitor 1 (PAI-1) that act locally to produce thrombin or inhibit fibrinolysis of the fibrin network used to facilitate cell migration, and (3) MCP-1, which increases monocyte chemoattraction into the lesion, thereby leading to lesion development. (We thank Drs. Laurence Harker, Josiah Wilcox, and Bernard Lassègue for their creative and intellectual development of this figure.)

Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 7:

UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

Authors: Robert Roberts, Richard Lifton

THE HUMAN GENOME

The term *genome* refers to all of the DNA, including the genes, responsible for an organism. The term *proteome* refers to all of the proteins responsible for an organism. The genes exert all of their influence through the proteins they produce. In general, the dogma is still true that each gene produces a unique protein, although it is preferable to refer to the end product as a polypeptide, since some proteins are made of two or more polypeptides and occasionally certain genes, through alternative splicing, may produce more than one polypeptide. The human genome is contained in 23 pairs of chromosomes. Twenty-two of these pairs are homologous chromosomes (one from the father and one from the mother), referred to as autosomes, and the remaining pair contain the sex chromosomes, which in the male consists of an X and a Y chromosome and in the female of two X chromosomes. Only a small portion of the X and Y chromosomes are homologous which is referred to as the pseudoautosomal region. Each pair of autosomal homologous chromosomes carries the same set of genes, with one inherited from each parent. Despite their homology and potentially identical function, some of the genes have a slightly different DNA sequence from that of the corresponding gene on their homologous partner, which may slightly or markedly alter their function. For example, the gene encoding for angiotensin-converting enzyme (ACE) has three forms (alleles): D, DI, and II. Thus, the chromosome from the mother may have the D form and the homologous chromosome from the father the I form; nevertheless, both genes encode for ACE and convert angiotensinogen to angiotensin II. However, there is increased plasma enzyme activity associated with the D form, leading to an exaggeration of ACE function. Studies suggest that individuals who are homozygous for the DD gene are predisposed to develop cardiac hypertrophy.[1,2] These minor differences give rise to individual's genetic distinguishing features and in some instances predispose to the disease.

It is estimated that the difference in the DNA sequence among all humans is about 0.1 percent, which means that 99.9 percent of the DNA sequence is identical. However, there is a difference in over 3 million bases of the DNA sequence. Each chromosome is a long molecule made of DNA. DNA is made up of only four bases: **adenine (A), guanine (G), cytosine (C), and thymidine (T). If one visualizes a chromosome, it consists of repetitions of these four bases and is extremely monotonous. Nevertheless, the sequence of these four bases determines all of one's inherited characteristics. The average length of a chromosome is about 135,000,000 base pairs. The longest chromosome, chromosome 1, has over 250,000,000 base pairs. The smallest, chromosome 21, has only 50,000,000 base pairs. The 23 chromosomes together contain a total of 3 billion base pairs (Table 7-1). Genes themselves are discrete units with a start and stop point and vary in size from 10,000 to 2,000,000 base pairs. The estimated average is about 20,000 base pairs. Despite the fact that the whole of the human genome has 3 billion base pairs, it is estimated that only about 3 percent is used to make genes.[3] Genes themselves do not participate in specific functions, but function through an intermediary, their single-stranded templates, referred to as messenger RNA (mRNA). The mRNA leaves the nucleus and goes to the ribosome in the cytoplasm, where it provides the template for protein synthesis. It is estimated there are between 50,000 and 100,000 genes.[3]

Table 7-1: The Human Genome

Base pairs	3 billion
Genes estimated	50,000-100,000
Percent of DNA contained in genes	<3%

The intervening DNA sequences between the genes that do not exit the nucleus are referred to as introns, and the DNA sequences transcribed into mRNA that exits the nucleus to form the template for protein synthesis are referred to as exons. The function of the introns is largely unknown. A small proportion of the introns has the important regulatory function of determining when and how often the gene make, mRNA. Another function of the introns is, presumably, maintaining the structure and integrity of the DNA molecule. On a simple mathematical basis, the introns also offer some protection of the genes from mutations. The natural mutation rate is 1 every 200,000 years per gene. The mutation rate is higher in the introns, but, since the intron is not expressed in the protein, they are benign and nondisease producing. The DNA used to make genes consists of just one copy of each gene per chromosome. However, the introns not infrequently have many repeating units of the same sequence throughout the genome. The most frequent example of this is the ALU repeats, which consists of a 300-base pair repeat with over 500,000 copies scattered throughout the human genome. The role of these repeat sequences is also not known, but they may play a role as replication or initiation sites for duplication of DNA. While foreign DNA is usually destroyed, some, such as the genomes of retroviruses, does get incorporated into the human genome. It is estimated that 35 percent of the human genome is composed of DNA from evolutionary relics of mobile DNA elements transposed into the human genome with no known function.[4] Mutations that induce single-gene diseases inherited as Mendelian disorders occur at a frequency of less than 1 percent. In contrast, mutations that induce more subtle changes (genes that predispose to polygenic diseases; e.g., DD versus II) or none at all may be located in exons or introns and occur more frequently, in the range of 10 to 20 percent. One form of these polymorphisms, single-nucleotide polymorphisms,[5,6] which occur every 1000 base pairs, is discussed subsequently as the most promising marker for identifying genes responsible for polygenic diseases.

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

THE HUMAN GENOME PROJECT

The Human Genome Project is the first large international effort in the history of biological research.[7] The overall objective of the Human Genome Project was to determine the sequence of the bases throughout each chromosome of the human genome, which is a total of 3 billion bases. The Human Genome Project was initiated on October 1, 1990, to be completed in the year 2005.[8] The National Institutes of Health and the Department of Energy in the United States are expected to produce 60 to 70 percent of the sequences, with the remainder from the Sanger Institute, at Cambridge, England, and other international partners.[7] However, with improvements in technology and increasing demands, the timetable has been accelerated. Initially, the Human Genome Project announced that it would have all of the genes sequenced by the year 2003, and most recently it was announced that a rough draft of 90 percent of the human sequences will be available by the spring of 2000.[7] At least two commercial enterprises involved in sequencing human genes have claimed they will have all of the human genes sequenced by the year 2001.[9] Regardless of the precise timetable and whether every gene is to be identified as indicated, it is now evident there will be an avalanche of genes available to the cardiologist within the next 2 to 3 years. At the end of 1999, only one-third of the human genome was sequenced, and there were less than 1000 human genes available in GenBank. There will be at least 20,000 to 30,000 genes, if not more, available within the first couple of years of the new millenium. It is part of the policy of the Human Genome Project that all of these genes will be available to the public. As it is sequenced, each gene is entered into a publicly accessible database and available at no cost. In the United States, GenBank (accessible at http://www.ncbi.nlm.nih.gov) run by the National Center for Biotechnology Information, serves as the public repository of sequence information. The results of the efforts of the publicly funded Human Genome Project consist not only of DNA sequences of the various genes but also of the intervening sequences. In addition, each sequence is anchored to one of the known genetic markers, integrating the physical and genetic maps. The first chromosome to be sequenced was chromosome 22, which was announced in November 1999. Investigators from Great Britain, the United States, and Japan teamed up to sequence 32,000,000 bases. While there remain some gaps, there is general agreement that essentially all of the genes of chromosome 22, together with most of the intervening sequences, have been sequenced.[10]

Charles Delisi, of the Department of Energy, in commenting on the initiation of the Human Genome Project, stated that the goal was to decipher the blueprint for the development of a single fertilized egg into a complex organism of more than 10^{13} cells. The blueprint is written in a coded message given by the sequence of nucleotide bases-the As, Cs, Gs, and Ts-that are strung along the DNA molecules in the human genome. The goal was to sequence from one end to the other and then to try to decipher all of the instructions included in this massive coding sequence. In 1990, the best of the laboratories were probably sequencing only a few hundred bases per day; at that rate, it would have required centuries to complete the human genome. However, technological improvements have enabled some laboratories engaged in the Human Genome Project to sequence more than 1 million bases per day. While the overall objective was to sequence the human genome, other goals completed along the way markedly accelerated the efforts of all investigators involved in biological or medical research. The first goal was to develop a genetic map. This meant developing markers along each chromosome that would be readily identifiable and highly informative signposts for the identification of nearby genes. This goal has now been achieved. Investigators in France and the United States published 6000 markers spaced less than 1 million

base pairs apart throughout the entire human genome.[11] Thus, a complete set of genetic markers is now available for each chromosome. This provided the necessary tool for widespread application of genetic linkage analysis, a technique that has led to the mapping of numerous genes responsible for disease of the cardiovascular system (Chap. 62) and other organs.

The next goal was to develop a genomic physical map. This map would involve sequence tagged sites (STSs) throughout the genome that has been completed.[12] Over 50,000 STSs were given their approximate chromosomal location which made it possible to relate them to the location of a locus genetically linked to a disease of interest.[13] The next goal was to develop a physical map of that part of the DNA that is expressed as genes. These markers are referred to as expressed sequence tags (ESTs) and contain short sequences of 200 to 300 base pairs. These sequences are unique and believed to represent a specific gene. If, indeed, each one of these ESTs represents a gene, we are at present in the position of having available 60,000 genes to be identified.[14] One may wonder how it is possible to obtain such ESTs and be certain that they represent only sequences that are expressed in genes. As indicated previously, all genes are first synthesized as single-stranded mRNA that leaves the nucleus to travel to the ribosome in the cytoplasm, where it serves as a template for its unique protein product. Thus, if one extracted all of the RNA in the cell, it would include all of the mRNAs and, thus, at that moment in time, all of the genes expressed in that cell. This is, in fact, the approach for obtaining ESTs: mRNA is isolated from cells of all organs in the body, and collectively they represent all of the body's expressed genes. The mRNA is then converted to complementary deoxyribonucleic acid (cDNA) with the enzyme reverse transcriptase, and sequences from these cDNAs are amplified by polymerase chain reaction. From these amplified sequences, unique sequences are selected and entered into GenBank as ESTs. These ESTs are cloned in vehicles such as bacteria and, thus, provide a library of human ESTs. Many of these ESTs are now being mapped to their chromosomal location to be used as markers to find genes responsible for disease. The ultimate aim is to have an EST every 100,000 base pairs evenly distributed throughout the 23 chromosomes. The development of the genetic map and that of the physical map, which followed, were great contributions that have tremendously accelerated the efforts of all investigators throughout the world in identifying genes responsible for disease.

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

FUNCTIONAL GENOMICS (PROTEOMICS)

One of the great accomplishments-and perhaps the greatest of the twenty-first century or even the new millenium-will be the identification of all the genes responsible for humankind. This development is often compared to another great landmark in physics, namely, the identification of the table of physical elements. This analogy emphasizes a very important point for the future. The table of physical elements (periodic table) provided the physicists with the tools to determine the composition of the earth, to understand many natural phenomena, and also to create artificial constructs, many that were essential to modern civilization and others that were destructive, such as the atomic bomb. Identification of the genes will be to the biologist or physician what discovering the physical elements was to the physicist. Leroy Hood refers to the human genetic map as the "periodic table of life." The identification of all human genes provides the tools for the first step: determining gene function and how to manipulate genes to benefit humankind. Determining the function of known and unknown genes was addressed at a recent workshop in Cold Spring Harbor, New York.[15] At present, we know of only about 2000 proteins. Thus, we do not know the protein composition of most genes and so would not be expected to know their function. It was estimated that determining the function of 100,000 genes by conventional techniques-namely, eliminating the gene from the mouse by homologous recombination or overexpressing the gene (transgenic mouse)-would take a century. The theme of Human Genome Project II will undoubtedly be determining functions of the proteins, and the project has been referred to by several names emphasizing function, such as The Proteome, Gene Health and Disease, or Functional Genome II. It is imperative that the efforts to determine the functions of human genes receive a boost from improved technology and increased awareness. New approaches are already emerging from the Human Genome Project to address this issue.

In parallel with the progress for sequencing the human genome has been the success of efforts to sequence simpler genomes of single-cell organisms. The first organism for which the genome was sequenced and the genes identified was *Haemophilus influenzae,* in 1995, consisting of 1.4 million base pairs and 1740 genes. Within 3 years of this initial effort, the genomes of over 40 single-cell organisms were completely sequenced and all of the genes identified. Several notable organisms were sequenced: *Saccharomyces cerevisiae,*[16] which is the cause of vaginitis, and spirochete *Treponema pallidum,*[17] which causes syphilis. These organisms, many of which are bacterial, offer the potential for the diagnosis and treatment of human infectious diseases, whether they affect the heart or other organs. Identification of the genes responsible for these various organisms has ushered in a new era for antibiotics based on a variety of molecular mechanisms made possible through the identification of genes and the various pathways they regulate. A significant step forward in our understanding of the function of human genes came with the sequencing of the genome responsible for *Caenorhabditis elegans* (*C. elegans*).[18] This was the first multicellular organism for which the genome and all of its genes have been sequenced. *C. elegans,* although a tiny worm that is not visible to the naked eye, has 959 cells, all of which have been identified and characterized. Its genome consists of over 97,000,000 base pairs, with a total of over 19,000 genes. This represents one-fifth of the number of genes present in the human genome. The more important features are, however, that 36 percent of the genes in *C. elegans* are virtually identical to human genes, with many others having homologous consensus. The *C. elegans* is a transparent worm, and, thus, it is possible under the microscope to observe development from a single cell to a multicellular organism and now to do so with the armamentarium of knowing all the genes. Thus, it should be possible, by determining the function of many genes in *C. elegans* homologous

to human genes, to learn of their approximate function in humans. Several other multicellular organisms are being sequenced, including the fruit fly (*Drosophila*)[19] and the mouse, which will provide an immense opportunity for determining the function of human genes with similar functions.[20] This will considerably accelerate our efforts to determine the function of human genes and how to utilize them to diagnose, prevent, and cure disease.

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

COMPUTERIZED GENE BANK NETWORKS AND BIOINFORMATICS

It became evident to investigators and physicians involved with genetics that the amount of information to be derived from unraveling the genome would be exhaustive. It was thus necessary to develop a computerized network of gene databases in which information would be rapidly entered worldwide and available worldwide at no cost. GenBank, a computerized network of gene banks, was established in the United States, Britain, and Japan, and all investigators have agreed to input their data daily. This database resource has been invaluable to medical scientists throughout the world. Information on DNA and genes from all species is entered into this network and cataloged for readily accessible use. Over 2 billion DNA bases have been collected from over 39,000 species, and that number is rapidly expanding on a daily basis. There are over 500,000 queries per day for information from GenBank alone. The information in GenBank provides available access to all investigators identifying genes.

The storage of gene sequences is likely to directly contribute to the determination of gene function. The functions of certain genes are often first determined in simple organisms, such as single-cell bacteria or viruses. It is also well recognized that certain genes, because of their function, have been conserved through evolution. Thus, when a DNA sequence is identified in the human genome with consensus sequence to one of the genes of known function in simpler organisms, one immediately has an important clue to the function of that sequence in humans. Such comparative genomic techniques are expected to significantly accelerate our search for the function of genes. A DNA sequence from the human genome with unknown function can be entered into a gene bank network such as GenBank (http://www.ncbi.nlm.nih.gov) and a consensus sequence sought. It is possible with GenBank to travel back in time over 1 billion years to very simple organisms of which much more is known of the function of their genes. Although the human genome may contain 100,000 genes, it is highly likely that many of these genes can be grouped into families that have a common function, such as the genes that encode for kinases. These proteins all have a common function: the transfer of high-energy phosphate from one compound to another. Therefore, genes encoding for kinases will share this common functional motif. This common motif can be used to group unknown genes that have the motif in their sequences to encode for kinases. It is estimated there are over 3000 genes encoding for various kinases. Thus, in addition to computerized comparative genomics, another function of bioinformatics is to cluster based on common functional motifs. Another emerging contribution from bioinformatics is the grouping of genes that have in common a functioning pathway, whether it be that of metabolism or message signaling. Several such signaling pathways have been identified, including the map kinases, the inositol phosphatases, and the tyrosine kinases. It is expected that several metabolic pathways, such as glycolysis, the Kreb's cycle, the hexosmonophosphate shuttle, and others, will have a common group of genes. The cascade of signaling proteins responsible for growth and development of the heart is likely to be very similar across the invertebrate, vertebrate, and mammalian cardiac genetic systems. It is of note that all mammals have a similarly sized genome of 3 billion bases with an estimated 100,000 genes. Similarly, the network of molecules that process the electrical activity to decipher and analyze messages in the brain is likely to have common genetic pathways. It is anticipated that information on human disease-causing genes available from GenBank will be transmitted to nursing stations and made available to all personnel, including physicians, nurses, genetic counselors, and others. Determining the function of genes through such bioinformatics techniques as comparative genomics and gene clustering is likely to contribute greatly to our understanding of the role of

genes in human physiology and disease.

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

THE DNA CHIP TECHNOLOGY

A major obstacle in applying the progress made in molecular genetics to the practice of medicine is inability to detect mutations rapidly and accurately. At the turn of the millenium, there were already 1000 genes in GenBank known to cause disease, with over 25,000 mutations. To perform genetic screening for known mutations and determine individuals at risk for disease is still a formidable task at an unacceptable cost. The various techniques for detecting mutations are time consuming, expensive, and, ideally, require confirmation by DNA sequencing. Technologies to perform these tasks on a daily basis with results available within a reasonable time from hours to days are essential. Several technologies are evolving, the most promising being the DNA microarray chip.[21] Several thousand genes are attached to glass or plastic, and each base is color coded to detect mismatches in hybridization (mismatch mutations; Fig. 7-1). This technique has the potential for robust high-throughput detection of thousands of mutations within hours. Other techniques include high-pressure liquid chromotography and mass spectrometry, both of which also have the potential for high-throughput analysis. Genetic testing of individuals, for example, with familial hypertrophic cardiomyopathy (FHCM) or arrhythmogenic right ventricular dysphasia could prevent the death of thousands of individuals each year in competitive sports. Another use of the DNA chip technology is in the field of pharmacogenomics, or genoptying to individualize therapy. This technique could also provide screening for multiple genes that are up- or down-regulated during the response of a particular organ to various physiologic or pathologic stimuli.

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

RESTORATIVE BIOLOGY

It is highly likely that, within the first decade of the new millenium, significant progress will be made in our ability to generate organs. While the average human has over 200 trillion cells, it is estimated there are only about 206 distinct cells as defined by a unique function. These cells are derived from stem cells that are pluripotent, which means that with appropriate stimulation they can develop into any kind of cell. There are two types of stem cells: embryonic and adult.[22,23] Embryonic stem cells have not yet specialized into any type of cell and are obtained from two sources: (1) fetal tissues from miscarriages or abortions, and (2) in vitro embryos discarded by fertility clinics that cannot be implanted. Adult stem cells are committed to develop into a specific cell but have some limited capacity to be directed to develop into some other cell. At present, investigators have been relatively unsuccessful in obtaining stem cells from most organs in adults. Stem cells in limited numbers have been obtained from bone marrow, liver, and skeletal muscle. These stem cells, exposed to the appropriate cardiac growth factor, would be expected to develop into cardiac myocytes.[24] There are already considerable preliminary data to show that fibroblasts can be transformed into skeletal muscle.[25,26] The key gene that commits a cell to become a skeletal muscle cell has been identified, namely, MyoD. Transfection with MyoD has been shown to induce the phenotype of skeletal muscle in fibroblasts and several other cells.[26] Myocardial infarction may be thought of as a myocyte deficiency disease in which a part of the myocardium is replaced by fibrous scar tissue. Myoblast, an adult skeletal muscle stem cell, has been transplanted with some success into the heart of a rat that had undergone a previous myocardial infarction.[27] Bone marrow stem cells are being used with some degree of success in regenerating bone marrow in the treatment of leukemias. The National Institutes of Health has already developed goals to begin the pursuit of research to repair or regenerate human organs (http://www.bioethics.gov). Extensive research will be required to understand the molecular factors necessary to convert stems cells into a pretargeted, specific cell. Nevertheless, this research has great potential for diseases such as myocardial infarction.

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

A NEW ERA FOR UNRAVELING POLYGENIC DISORDERS

The extraordinary similarities in the height, weight, body habitus, and facial features of identical twins underscore the extremely limited variation in physical features of individuals who share complete genetic identity. The wide variation that is seen in these features among unrelated individuals in the general population strongly implies that much of this variation is attributable to variation in DNA sequence. Therefore, it comes as no surprise that this same principle applies to variation in disease susceptibility and that virtually all human diseases have an inherited component. In some cases, referred to as Mendelian diseases, mutation in a single gene is sufficient to produce disease in a high proportion of individuals inheriting that mutation. For other diseases, the inherited contribution is more subtle, requiring inheritance of variants in a number of genes, with disease development also being influenced by environmental factors. In this setting, inheritance of a particular genetic variant may be neither necessary nor sufficient for disease development. These genetically complex diseases thus have multifactorial determination.

With the development of complete genetic maps of the human genome, a new approach to identifying genes contributing to Mendelian diseases, called positional cloning, became available.[28] Positional cloning proceeds in several stages: (1) the collection of families' segregating traits of interest; (2) determination of the chromosomal location of disease genes by comparing the inheritance of chromosome segments to the inheritance of disease in families; (3) refinement of the interval containing the disease gene and identification of genes in the disease interval; and (4) screening genes in the interval for mutations that alter the structure or expression of the encoded protein. In the Mendelian paradigm, independent mutations that alter the encoded protein and segregate specifically with the disease in families constitute proof that the disease gene has been identified. This approach has to date resulted in identification of nearly 1000 human disease genes, of which over 100 are associated with cardiac diseases, and almost all have been identified within the last decade. While these Mendelian disorders are typically uncommon or rare, they have in many cases provided fundamental new insight into disease biology that has proved relevant to more common forms of disease.

Nonetheless, the truly common diseases of mankind, such as coronary artery disease, stroke, diabetes, and hypertension, are believed to be generally multifactorial in nature. For these diseases, the positional cloning paradigm that has been so successful for Mendelian diseases may have limited power, since, even within single families, affected individuals may have different combinations of inherited and acquired risk factors; moreover, the number of factors and the magnitude of the impact of any single risk locus is unknown. These barriers to identifying the genes underlying common diseases are formidable. Evidence that these diseases have an inherited component come from a variety of studies, including studies of twins, demonstrating that monozygotic twins, who share 100 percent of their genes, are more concordant in disease status than are dizygotic twins, who share only 50 percent of their genes, and studies of familial aggregation, showing that diseases recur within families more often than expected from their prevalence in the general population. A relatively simple means of assessing recurrence risk in families is determination of the so-called ō sib, defined as the risk of disease recurrence in a sibling of a patient with the disease divided by the prevalence in the general population.[29] A ō sib of 1.0 would indicate no familial contribution to disease risk, while a ō sib of 10 would indicate that all familial factors together increase the risk of disease tenfold. It is important to note that, while these approaches can provide strong evidence for the impact of inheritance on disease risk,

none indicates how many genes underlie the inherited disease risk, their mode of transmission, or the magnitude of the effect imparted by any single locus. For example, the same tenfold familial increase in disease risk could be determined by the effects of two genes, each imparting fivefold increased risk, or, alternatively, 50 genes, each imparting 1.2-fold increased risk. The best study design for identifying underlying disease genes is considerably confounded by this imprecise knowledge.

There are a number of potential approaches to unraveling the inherited contribution to these complex disorders. One is to simplify the analysis by identifying sub- or intermediate phenotypes in which the genetic contribution is more homogeneous or contributes to a larger fraction of disease risk. For example, the considerable etiologic heterogeneity of coronary artery disease can be reduced by focusing on cases sharing diabetes, hypertension, or hypercholesterolemia as contributing factors. Similarly, further refinement of these subgroups might define physiologic subsets with more homogeneous genetic contribution, potentially defining Mendelian subsets to which the power of Mendelian genetics can be applied.[30]

Despite this potential, few useful intermediate phenotypes have been defined for common diseases, often requiring investigation of non-Mendelian traits. In this setting, linkage approaches like those used for Mendelian diseases might be successful if any single locus imparts a relatively large effect on disease risk, and collecting large extended kindreds may be worthwhile. In the absence of evidence of a substantial Mendelian component, a modification of the linkage approach analyzing large numbers of sibling or relative pairs concordant or discordant for disease has potential advantages. In this approach, one scans the genome for chromosome segments that are shared among phenotypically concordant siblings more often than expected by chance. This approach has the advantage that can detect linkage despite complications in which a disease locus does not contribute to disease in every affected individual and not all individuals inheriting a disease allele develop disease. Nonetheless, success with this approach requires that individual risk loci impart relatively large effects on disease risk.[31]

Another approach that will become increasingly used for complex trait analysis is identification of risk alleles by study of patients and control subjects. As indicated above, there are estimated to be approximately 3 million common single nucleotide polymorphisms (SNPs) in the human genome (Table 7-2). A fraction of them will ultimately prove to underlie multifactorial traits by altering the expression or function of the gene in which they reside. The ability to identify and genotype these SNPs motivates their use for genetic studies. It is anticipated that the vast majority of common SNPs in human populations will be identified in the next 5 years and that many of the alleles contributing to common diseases will be found among them. If one tested a SNP whose variation contributes to, for example, coronary artery disease, comparison of SNPs allele frequencies in patients with the disease and in a matched cohort of control subjects free of disease would demonstrate a significantly different distribution of allele frequencies. This approach has substantially higher power than does linkage to detect variants with small effects on disease risk.[31] This case-control approach is associated with a number of important caveats, however. First, patients and control subjects must be well matched for genetic background. If they are not, many SNPs will show a false-positive association with disease. This is a current and serious problem with case-control studies. Unless disease associations are highly reproducible using the same SNP alleles and the same clinical phenotype, their significance should be regarded with caution. One means of eliminating this vexing problem is to collect the parents of affected individuals to permit use of transmission disequilibrium.[32] If a SNP allele contributes to disease risk, it ought to be transmitted from a heterozygous parent to an affected offspring more often than the expected Mendelian proportion of 0.5. This test thus eliminates the problem of poorly matched cases and control subjects and holds considerable promise for the investigation of complex genetic traits. Proof that a disease-associated SNP is itself a functional variant contributing to disease may be problematic, since some of these SNPs may well be common alleles in the population. Proof can be pursued by clinical studies of the physiology of individuals with and without the disease allele,

biochemical studies of the wild-type and variant gene and gene product in vitro, and construction and investigation of animal models based on the variant gene.

Table 7-2: Single Nucleotide Polymorphisms

SNPs per human genome	3 million
SNPs per 1000 base pairs	1
SNPs in typical human genome involving amino acid substitutions	24,000-40,000

A second caveat regarding this SNP approach is that at present we have a limited number of SNPs for examination and also a limited capacity for SNP genotyping. As a result, we cannot readily perform comprehensive genome-wide searches for disease variants with this approach, instead being limited to investigation of candidate genes. While this approach may prove successful, we are currently largely limited to implicating genes in pathways we can already associate with disease. There are two approaches to extending this case-control approach to a genome-wide analysis. One is to investigate populations that have been established from a small number of founders in relatively recent times. In such cases, one expects relatively long ancestral chromosome segments to be preserved in the present-day population such that genetic markers at considerable distance from one another remain in *linkage disequilibrium*. Thus, one may be able to screen for the chromosome location of disease susceptibility loci using a relatively modest number of SNPs distributed across the genome; proceeding from initial map location would be analogous to the positional cloning paradigm for Mendelian traits. Alternatively, with identification of complete SNP maps of the human genome, we will have many or all of the common SNPs in hand; one can contemplate performing extremely high-density SNP genotyping in outbred populations to identify disease susceptibility alleles. In order to retain analytic power, this approach may require performance of 10^9 to 10^{10} genotypes; such a study is clearly beyond the capacity of present implemented technology but is not inconceivable in the future.[31]

Ultimately, one can envision that alleles that contribute to susceptibility to common disease will be identified. These findings will have important consequences for clinical medicine. First, these findings will permit identification of individuals with specific inherited disease susceptibility before disease has become manifest, affording new opportunity for targeted lifestyle or pharmacologic intervention in individual patients. Second, identification of these susceptibility alleles will define the physiologic pathways that contribute to disease, providing "validated targets" whose altered activity can be predicted with high likelihood to alter disease development; these will highlight opportunities for development of new therapies. Third, we currently treat multifactorial diseases as though they are of homogeneous causation, with largely empiric therapies. The ability to identify specific risk alleles in individual patients may afford the opportunity to tailor treatment in individual patients to the specific inherited abnormalities underlying their disease susceptibility.

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

BIOETHICAL IMPLICATIONS AND GENETIC COUNSELING

Molecular genetics will soon be part of routine clinical practice. While most genetic screening currently performed for cardiovascular disease is done as part of a research protocol, many diseases, such as the familiar cardiomyopathies or those associated with the long Q-T syndrome, will soon enter the realm of routine genetic screening and diagnosis. It is estimated that less than 5 to 10 percent of cardiologists have any understanding of genetic testing and that even fewer are capable of interpreting the results of genetic testing. It is well recognized that there are too few genetic counselors and medical geneticists to meet present demands, let alone the demands within a few years, following the exposition of the human genome.[33] It was realized from the very beginning of the Human Genome Project that, in parallel with the scientific effort, there had to be a formal initiative to plan for the ethical, legal, and societal implications (ELSI) of this new paradigm. The National Institutes of Health have allocated 5 percent of the budget of the Human Genome Project for ELSI and the U.S. Department of Energy has allocated 3 percent of the HGP budget. A detailed review of the Human Genome Project and the ELSI have been prepared by the U.S. Department of Energy and the Human Genome Project and made available on the internet (http://www.ornl.gov/hgmis/tko/index.html).

The working group for ELSI developed an agenda with the following main goals: (1) stimulate research on issues through grant making; (2) refine the research agenda through workshops, commissioned papers, and invited lectures; (3) solicit public input; (4) provide massive education through multiple media, including the internet; and (5) encourage international collaboration. A major objective would be to develop policies regarding professional, institutional, governmental, and societal levels to ensure that genetic information would be used to maximize benefit to individuals and society. Three issues were identified as particularly important: privacy of genetic information, safety and efficacy of new testing options, and fairness in the use of genetic information.

The Hereditary Susceptibility Working Group of the National Action Plan on Breast Cancer (NAPBC), coordinated by the Public Health Service Office on Women's Health, recently joined with the National Institutes of Health/Department of Energy ELSI group to address the issue of genetic information in the workplace. The working group recommendations are as follows:

1. Employment organizations should be prohibited from using genetic information to affect the hiring of an individual or to affect the terms, conditions, privileges, benefits, or termination of employment unless the employment organization can prove that this information is job related and consistent with business necessity.
2. Employment organizations should be prohibited from using genetic information or requiring collection or disclosure of genetic information prior to a conditional offer of employment, and, under all other circumstances, employment organizations should be prohibited from requesting or requiring collection or disclosure of genetic information unless the employment organization can prove that this information is job related and consistent with business necessity, or otherwise mandated by law. Written and informed consent should be required for each request, collection, or disclosure.
3. Employment organizations should be restricted from access to genetic information contained in medical records released by individuals as a condition of employment, in

claims filed for reimbursement of health care costs, and other sources.

4. Employment organizations should be prohibited from releasing genetic information without prior written authorization of the individual. Written authorization should be required for each disclosure and include to whom the disclosure will be made.
5. Violators of these provisions should be subject to strong enforcement mechanisms, including a private right of action.
6. The task force recommends genetic testing be made available to individuals in the context of clinical investigation and research; however, the information obtained must remain available only to the patient, physician, and investigator. Information must not be made available to any other party or individual.

In regard to genetic diagnosis and screening, there is as yet no consensus on who should undergo genetic testing, how to protect the privacy of the results, or how this information should be applied in the routine practice of medicine. Most genetic testing in cardiology at present is performed as part of research and as such is regulated by Recombinant Regulatory Committee (RRC) and the local institutional review board. In a recent Bethesda, Maryland, conference of the American College of Cardiology on Bioethics and Molecular Genetics,[33] there was a consensus that certain rules must be followed in the routine use of genetic testing: (1) informed written consent must be obtained prior to obtaining the sample; (2) every effort should be made to provide the necessary education in terms understandable to the concerned individual, and (3) genetic testing must not be performed unless accompanied with counseling. The Bethesda conference offered the following guidelines, recognizing that they will continue to evolve and are as yet not definitive:[34]

1. The use of genetic testing and diagnosis as a research tool should continue along the guidelines outlined for research.
2. Genetic testing (usually prenatal) for devastating fetal disease or early-onset disease, such as Down's syndrome, is performed routinely and should be continued. It has been shown that, if the results are positive, whether the parents seek an abortion or not, the information provided is considered beneficial.
3. Use of genetic testing in someone with a phenotype to confirm or exclude a genetic cause should be permitted. An example would be FHCM with concomitant hypertension.
4. In families with a known history of a familial disease, genetic testing when sought by a family member should be performed. Testing of other members of the family should be performed only at their request.
5. Testing at birth or during childhood for asymptomatic disorders that develop later in life remains investigational until more data are available.

It has been customary not to perform genetic screening in high school students unless there is an immediate medical benefit. However, recent studies[35] from Montreal and Hong Kong show that genetic screening during high schoool has successfully decreased the incidence of Tay-Sachs disease and β-thalassemia. A major issue associated with the cardiovascular disorder FHCM, the most common cause of sudden death in the young, particularly in the athlete, is whether athletes at the high school and college level with a family history or suspected HCM phenotype should be screened prior to participating in competitive sports.[36]

Chapter 7: UNRAVELING THE HUMAN GENOME AND ITS FUTURE IMPLICATIONS FOR CARDIOLOGY

A NEW PARADIGM FOR MEDICINE

The genetic revolution that has already begun will usher in the beginning of a new paradigm in the diagnosis and treatment of cardiac disorders. Physicians traditionally have been taught to diagnose and treat disease. Cardiology in the past 50 years has advanced more than perhaps in the previous 2000 years.[37] Nevertheless, despite our ability to diagnose, we seldom know the precise molecular defect or pathogenesis of a particular phenotype. In the near future, a single blood sample will make available to the physician 100,000 etiologies with their multiple mutations. This represents a new era in which specific etiologies will be looking for their respective diseases. This will further challenge the physician to attempt to associate genes with physiological functions and mutations with disease. The physician will be well positioned to advance functional genomics through translational research at the bedside. In fact, until recently, physicians who saw individuals without complaints were often questioned as to the appropriateness of their practice. We are now entering an era of prevention, and thousands of genetic risk factors will soon be available on which to base comprehensive and effective preventive therapies. In the near future, physicians will yearn to assess individuals early in life in the hope of aborting major disease, such as atherosclerosis, hypertension, cancer, and osteoporosis. This, too, will represent a new paradigm for all physicians. It will stimulate changes in health care delivery as well as means to finance such programs. The developent of an electronic medical record will be essential, and protection of the individual's rights and privacy will be paramount.[34]

List of Figures

Figure 7-1: Illustrated here is the means of detecting genes or their mutations. Oligonucleotides are single short strands of DNA of about 15 to 30 bases artificial synthesized to have the sequence of the desired gene. These oligonucleotides are bound to glass with each of the four bases labeled with a distinct fluorescent color. The DNA extracted from the patient's white blood cells is denatured into separate strands and brought in contact with the artificial oligonucleotides DNA. If the sequence in the patients DNA is complementary to the oligonucleotide, hybridization will occur and the laser beam will detect the appropriate colors. If there is a mutation present, there will be a mismatch and a different color will be exhibited by the laser indicating where the mutation is.

Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 8:

CARDIOVASCULAR TISSUE MODIFICATION BY GENETIC APPROACHES

Authors: Elizabeth G. Nabel, Victor J. Dzau

The field of cardiovascular gene therapy had its origins in the mid-1980s as a result of rapid advances in the molecular genetics of the cardiovascular system. The cloning of genes important for the development and function of the cardiovascular system increased our understanding of the normal biology and pathology of cardiac diseases. In turn, this genetic information provided new opportunities for novel therapeutics using gene-transfer approaches.

Somatic gene transfer is the introduction of recombinant genetic material (DNA or RNA) into host cells such that gene expression within the host cell is altered to achieve a therapeutic effect. The genetic material includes eukaryotic genes (often with transcriptional regulatory elements) and RNA that encodes intracellular or secreted gene products. *Vectors* are used commonly to introduce the genetic material into cells (Table 8-1). These vectors include replication-incompetent viruses and biochemical substances. The genetic material can be delivered directly into vascular or myocardial cells in vivo, referred to as *direct gene transfer*, or into tissues, such as a venous bypass graft ex vivo that in turn is returned to the host. This latter approach is termed *indirect gene transfer*. Local delivery catheters are required for the introduction of vectors and cells (Fig. 8-1).

Adeno-associated virus	DNA plasmid vectors

This chapter reviews our current understanding of genetic therapies, including stem cell biology, for cardiovascular diseases. This discussion will examine vector systems for delivering genes, disease targets and preclinical animal models, recent results of clinical trials, and new, emerging opportunities for cell transplantation with pluripotent stem cells.

VECTORS FOR GENE TRANSFER

Viral Vectors

RETROVIRAL VECTORS

Retroviruses were the first viruses adapted for use as vectors owing to the simplicity of their genomes and their capacity to stably integrate their genome into the host chromosome. A retroviral vector is constructed in several steps.[1,2] First, the structural genes required for viral replication are deleted to render the vector nonreplicating. After insertion of the exogenous gene of interest into the viral backbone, the recombinant retrovirus contains the exogenous gene, regulatory sequences, and packaging signals but lacks the actual structural genes required to produce a complete virion. It requires a helper cell to produce infectious viral particles. Nabel et al. demonstrated the feasibility of transfecting blood vessels with foreign DNA in vivo by transfecting pig iliofemoral arteries with a recombinant amphotropic retroviral vector containing a β-galactosidase gene.[3,4] Several cell types in the vessel wall were transduced, including endothelial and vascular smooth muscle cells. Using a β-galactosidase retroviral vector to modify endothelial cells, Wilson et al.[5] demonstrated β-galactosidase expression up to 5 weeks after transfection in prosthetic vascular grafts seeded with the genetically transformed cells. Retroviral vectors have not been effective vectors for cardiovascular applications because they require actively dividing cells for integration and expression of the viral genome. Since most myocardial and vascular cells are not dividing, transfection efficiency with retroviral vectors in these cells has been low.

ADENOVIRAL VECTORS

Adenoviral vectors are widely used for cardiovascular gene transfer because adenoviruses infect nondividing cells and do not integrate into the host genome. Adenoviruses are double-stranded linear DNA viruses that in their wild type cause a self-limited respiratory tract infection in humans.[6] The wild-type adenovirus genome is a 36-kDa DNA molecule that is divided into 100 map units. The majority of adenoviral vectors are derived from adenovirus serotypes 2 and 5. These vectors are constructed by deletion of the E1 region (map units 1-9) of the genome that normally encodes E1A and E1B motifs that are required for the expression of late viral genes and for the induction of the lytic phase of the virus. Without the E1 region, the virus cannot replicate. This region is replaced with the transgene of interest, up to 7.5 kb in size. Because the E1 deletion renders them replication-incompetent, adenoviral vectors are propagated in a helper cell line that expresses E1 protein in transfection. These vectors can be produced in high titers for in vivo delivery.[7] Adenoviral vectors enter mammalian cells by receptor-mediated endocytosis and α2β3 integrins.[8] Aortic smooth muscle cells[9] and cardiac myocytes[10] were transfected successfully using replication-defective adenovirus carrying the β-galactosidase or chloramphenicol acetyltransferase reporter gene, respectively. In vivo transfection by adenoviral vectors was demonstrated in vascular tissue by direct infusion into vessels,[9,11,12] in myocardial tissue by direct injection into the myocardium,[10,13] and in the circulation after adenoviral infection of skeletal muscle.[14] Limitations of the first-generation adenoviral vectors include transient gene expression and host inflammatory and immune responses against the transgene[15] and viral antigens.[16,17] These limitations are being overcome by the development of "gutted" adenoviral vectors.[18] These vectors retain viral coat proteins for receptor attachment and internalization but lack other viral proteins that are immunogenic.

ADENO-ASSOCIATED VIRAL VECTORS

Adeno-associated virus (AAV) is a defective human parvovirus that is not able to replicate unless a helper virus, such as adenovirus, is also present.[19] There are several features that make AAV an attractive vector. The virus can be prepared at high titer, is not pathogenic in humans, and infects a broad range of cell lines.[20] Wild-type AAV integrates in a site-specific manner in a 7-kb region of human chromosomes.[20,21] The AAV genome is a single-stranded, linear, 5-kb DNA molecule.

The genome is flanked by two 145-bp inverted terminal repeats (ITRs) that contain the sequences required for packing, integration, and DNA replication. The coding region contains two open reading frames (ORFs). Either of these ORFs can be replaced with the transgene and regulatory elements to construct an AAV vector. The ORF can only accept a transgene of 4 to 5 kb, thus limiting the size of the transgene insert. Propagation of AAV vectors requires AAV Rep and Cap proteins and five adenoviral proteins: E1A, E1B, E2A, E4, and VA. These are complex packaging requirements, and thus it has been difficult to construct a packaging cell line. Instead, AAV vectors are propagated by cotransfection of the AAV vector with a plasmid wild-type or mutant helper adenovirus. AAV vectors have been used very successfully when injected into skeletal muscle to produce proteins secreted into the circulation, such as factor IX for hemophilia B.[22] Cardiovascular applications include cardiac myocytes, where Svensson et al. have demonstrated stable expression.[23] Whether AAV vectors can be adapted to efficiently transduce vascular endothelial cells and smooth muscle cells is not known.

Nonviral Vectors

CATIONIC LIPOSOMES

The encapsulation of DNA in artificial lipid membranes (i.e., liposomes) can facilitate its uptake and cellular transport. Cationic liposomes have been used for cellular delivery of DNA[24] and antisense oligonucleotides.[25] The activity of cationic liposomes is postulated to be mediated by (1) spontaneous capture of the negatively charged polynucleotides with cationic lipids by a condensation reaction, (2) increased cellular uptake due to interaction of positively charged complexes with negatively charged biologic membranes, and (3) membrane fusion (or transient membrane destabilization) with the plasmalemma or the endosome to achieve delivery into the cytoplasm while avoiding degradation in the lysosomal compartment. Recent data indicate that movement of DNA from the cytoplasm to the nucleus and successful dissociation of DNA from the lipid complex appear to be important variables for lipid-mediated gene transfer.[26] Expression of recombinant genes after cationic lipid-mediated gene transfer has been demonstrated in vivo in several animal models.[27-29] Gene expression after liposome-mediated arterial gene transfer may be augmented in the presence of ongoing proliferation (e.g., intimal proliferation after balloon injury).[30]

FUSIGENIC LIPOSOMES

This method uses a combination of fusigenic proteins of the Sendai virus (hemagglutinating virus of Japan) and neutral liposomes. Hemagglutinating virus of Japan (HVJ) is an RNA virus that belongs to the paramyxovirus family, which has HN and F glycoproteins on its envelope. HN binds with glycol-type sialic acid and degrades the receptor by its own neuraminidase activity. F glycoprotein is cleaved to generate a hydrophobic fusion peptide by proteases, and the activated F protein can interact directly with the cellular lipid bilayer and induces fusion. A nuclear protein, namely, high-mobility group 1 (HMG-1), that binds DNA enhances the integration of transfected DNA into the nucleus.[31] HVJ liposomes consist of neutral liposomes complexed with ultraviolet (UV) light-inactivated HVJ virus. It is postulated that after fusion of the liposome complex with the cell membrane, the DNA is released directly into the cytosol without undergoing endocytosis, thereby reducing lysosomal destruction of the DNA construct and facilitating the nuclear uptake.[32] HVJ liposome methods have been employed successfully for gene transfer in vivo to liver,[31] kidney,[33] and vasculature.[34,35]

PLASMID DNA

Direct injection of plasmid DNA in cardiac or skeletal muscle results in stable transfection of a

small percentage of cells.[36] Following direct injection to the heart muscle, expression of a reporter gene was demonstrated for up to 4 weeks.[37] Expression of injected genes can be targeted to specific cell types in vivo (e.g., cardiac muscle cells) and can be modulated by the hormonal status of the animal.[38]

SYNTHETIC OLIGONUCLEOTIDES

Antisense oligonucleotides (ASOs) are short, 10- to 30-bp, chemically synthesized DNA molecules that are designed to be complementary to the coding sequence of a target RNA. ASOs can be introduced into cells simply by diffusion or complexed with liposomes, such as HVJ.[32] Inside the cell, ASOs form double-stranded complexes with their complementary RNA and decrease translation of RNA. Mechanisms of antisense inhibition include interference with ribosome binding and processing of mRNA, interference with mRNA conformation or mRNA splicing, and RNase-H activation of mRNA digestion.[39,40]

ASOs are attractive agents for in vivo gene therapy. They can be chemically synthesized in large quantities, and they do not require a viral component for in vivo delivery. However, there are several limitations to their use in vivo. ASOs have a short half-life in vivo due to nuclease degradation. Chemical modifications, such as substitution of sulfur for one of the nonbridging oxygens of a phosphate group (phosphorothiorates), renders ASOs more stable to degradation in serum.[41] Several nonspecific effects of ASOs have been noted that account in part for their biologic effect.[39,42] ASOs can have nonspecific cytotoxic effects due to binding to intracellular and cell surface proteins. Some ASOs affect the expression of multiple genes in addition to the gene of interest. This effect is sequence-specific and cannot be controlled for by scrambled oligonucleotides. ASOs containing C_pG dinucleotides have been shown to have nonantigen activation of the humoral immune system.[43] Despite these relative limitations, ASOs are well suited to the treatment of diseases where transient reductions in gene expression are required. ASOs theoretically can be used to specifically reduce the expression of one or more genes. The uptake of ASOs can be enhanced by complexing the oligonucleotide with cationic liposomes[25] or HVJ liposomes.[34,35]

Synthetic double-stranded oligonucleotides containing binding sites for transcription factors serve as "decoys" to block the binding of nuclear factors to promoter regions of targeted genes, resulting in the inhibition of gene transactivation.[41,44] Morishita et al.[45] have shown that a single administration of an E2F decoy (containing the E2F cis element) that binds the transcription factor E2F inhibits smooth muscle cell hyperplasia in a rat carotid balloon injury model[45] (Fig. 8-2). The binding of E2F prevents it from transactivating the gene expression of cell cycle regulatory proteins such as PCNA, c-myc, and cdk2, thereby inhibiting vascular smooth muscle cell proliferation and subsequent neointimal formation in vivo.

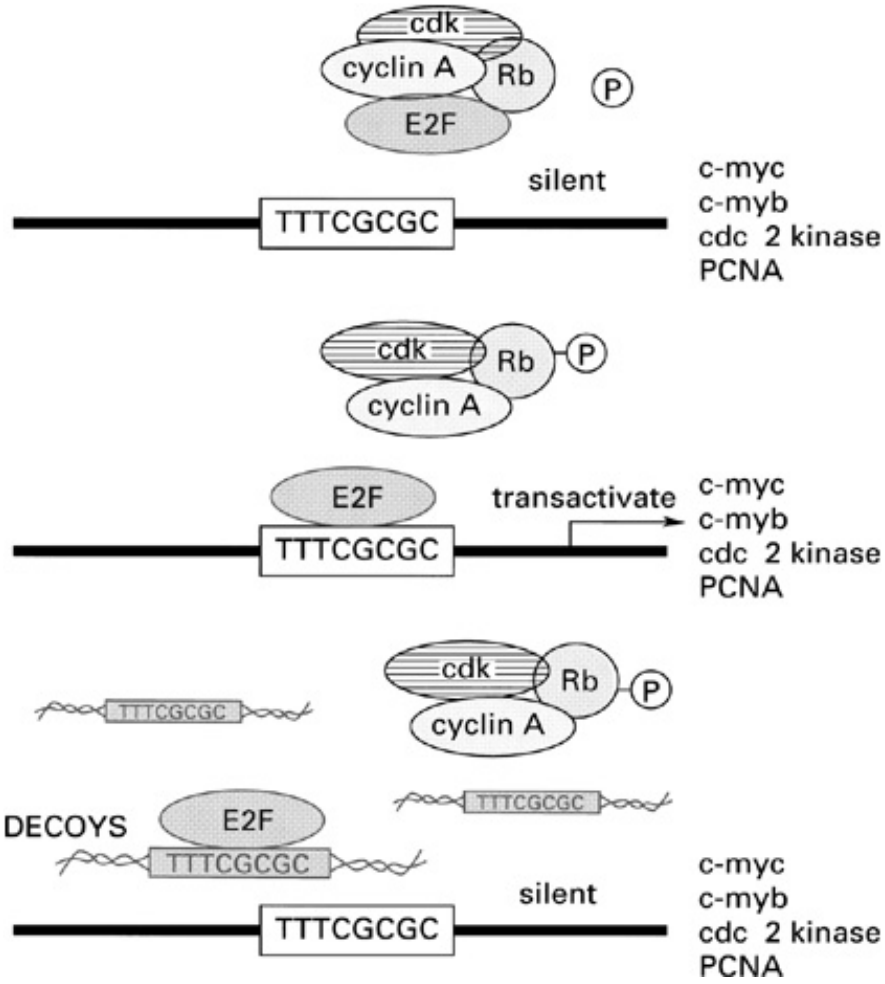

Figure 8-2: Principal of E2F "decoy" strategy. TTTCGCGC is the consensus sequence for the E2F binding site. In the quiescent cell state, the transcription factor E2F is complexed with Rb (retinoblastoma gene product), cyclin A, and the cyclin-dependent kinase cdk2 (*top*). Phosphorylation of Rb releases free E2F, which binds to cis elements of the cell cycle regulatory genes, resulting in the transactivation of these genes (*middle*). The E2F decoy cis-element double-stranded oligonucleotide binds to free E2F, preventing E2F-mediated transactivation of cell cycle regulatory genes (*bottom*). (From Morishita et al.,[45] with permission.)

Chapter 8: CARDIOVASCULAR TISSUE MODIFICATION BY GENETIC APPROACHES

CELLULAR TRANSPLANTATION

The implantation of cells expressing recombinant genes into the heart or vasculature is termed *ex vivo gene transfer*. Nabel et al.[3] demonstrated a cell-based vascular gene-transfer technique. By reimplanting endothelial cells transfected ex vivo with a retroviral β-galactosidase vector on the surface of balloon-injured porcine iliofemoral arteries, genetically modified cells could be detected up to 2 to 4 weeks following reimplantation. Wilson et al.[5] demonstrated expression of a reporter gene from endothelial cells implanted on a Dacron graft and placed in the carotid arteries of dogs. In addition to endothelial cells, ex vivo-transfected smooth muscle cells have been introduced in the vasculature.[46] Lynch et al.[47] reported the seeding of smooth muscle cells transfected with the adenosine deaminase gene into endothelium-denuded blood vessels. Another application of ex vivo gene transfer is the engineering of vascular grafts seeded with endothelial cells previously transfected in a culture dish.[48] Seeding of vascular grafts with soluble vascular cell adhesion molecules (sVCAMs) (see Chap. 5) using adenoviral ex vivo gene transfer was reported by Chen et al.[49]

Implantation of genetically modified myoblasts or fibroblasts into skeletal muscle is an attractive gene-transfer method because the gene product can be delivered systemically. Indeed, several investigators have reported successful gene delivery using these approaches.[50-52] In a mouse model, myoblasts were transplanted and supported sustained delivery of functionally active erythropoietin to correct anemia associated with renal failure.[53] The myoblast method potentially could provide an approach for the delivery of insulin (diabetes), atrial natriuretic peptide (hypertension or heart failure), or apolipoprotein AI (atherosclerosis).

Chapter 8: CARDIOVASCULAR TISSUE MODIFICATION BY GENETIC APPROACHES

GENE TRANSFER AND VASCULAR DISEASE

Gene transfer into the vasculature has been used to investigate the pathophysiology of vascular diseases and to develop novel therapies for these diseases. This field has expanded rapidly in the past decade. A number of models in the mouse, rat, rabbit, dog, and pig have been created to dissect vascular pathophysiology in peripheral, coronary, renal, pulmonary, and cerebral blood vessels. A full discussion of these animal models is beyond the scope of this chapter, and the reader is guided to pertinent reviews.[54-58]

Experimental Applications of ASOs

INTIMAL HYPERPLASIA

Simons et al.[59] reported that the administration of ASOs against c-myb applied by pluronic gel to the adventitial layer of rat carotid arteries inhibited neointimal hyperplasia in response to balloon injury. Data from Morishita et al.[34] demonstrated that a single HVJ liposome-mediated administration of ASOs against proliferating cell nuclear antigen (PCNA) and cdc2 kinase inhibited neointimal lesion formation after balloon injury for at least 8 weeks after transfection. The combination of antisense cdc2 kinase and cdk2 kinase oligonucleotides also resulted in almost complete inhibition of neointima formation.[35] Bennett et al.[60] showed an inhibition of vascular smooth muscle cell proliferation by administration of c-myc ASOs to the adventitial surface of injured carotid arteries in a pluronic gel solution. Two other studies reported inhibition of neointima formation after application of ASOs. Delivery of antisense PCNA oligonucleotides by pluronic gel (in a rat carotid model) and of antisense c-myc oligonucleotides by direct application through a porous balloon (in a porcine coronary artery model) resulted in significant inhibition of neointimal hyperplasia.[61,62]

VEIN GRAFT DISEASE

Autologous vein grafts remain the most commonly used conduits for surgical revascularization of the heart and lower extremities. Given the failure of traditional therapies at improving long-term vein graft function, gene therapy offers a new opportunity for reducing the morbidity and increased costs associated with the current limitations on functional graft survival. The vein graft offers an unusual opportunity for combining intact tissue in vivo gene-transfer techniques with the increased safety of an ex vivo application of the transfection medium. Manipulation of transfection conditions, including increased exposure time and controlling components of the transfection medium, also can be more easily achieved. Some researchers have begun to explore the possibility of ex vivo virus-mediated gene transfer in autologous vein grafts. Chen et al.[49] demonstrated the expression of the marker gene β-galactosidase along the luminal surface and in the adventitia of porcine vein grafts infected with a replication-deficient adenoviral vector at the time of surgery. In this same study, short-term expression of soluble VCAM-1 was documented after transfection of vein grafts.

The Dzau laboratory hypothesized that genetic engineering could alter the ability of the grafts to mount a hyperplastic response to acute injury while leaving intact their ability to respond to chronic hemodynamic stress via a hypertrophic response, such as that seen in arteries exposed to

hypertension. This group used HVJ liposomes to deliver a combination of ASOs to cdc2/PCNA to rabbit veins at the time of grafting into the carotid artery and observed a greater than 90 percent inhibition of smooth muscle cell (SMC) proliferation during the first postoperative week[63] (Fig. 8-3). This blockade of cell cycle progression resulted in a near-complete inhibition of neointimal hyperplasia. Instead, the vein graft wall was shifted to an adaptive process of medial hypertrophy. Having redirected the genetically engineered grafts away from neointimal hyperplasia and toward medial hypertrophy as an adaptation to the arterial environment, the susceptibility of these ASO-treated grafts to accelerated atherogenesis was tested. Control ASO-treated and untreated grafts placed in cholesterol-fed rabbits developed significant foam cell lesions and plaque within 6 weeks after surgery. ASO-treated grafts that had remained free of neointima formation, however, resisted macrophage invasion and the development of macroscopic plaque. This inhibition of cell cycle progression is likely to have effects on the phenotypes of the vascular cells undergoing remodeling after vein grafting, and these changes are likely to affect the proatherogenic environment of the normal graft wall. For example, the endothelium of ASO-treated grafts retained more of its capacity to produce nitric oxide and resist monocyte adhesion in comparison with untreated or control ASO-treated grafts.[64]

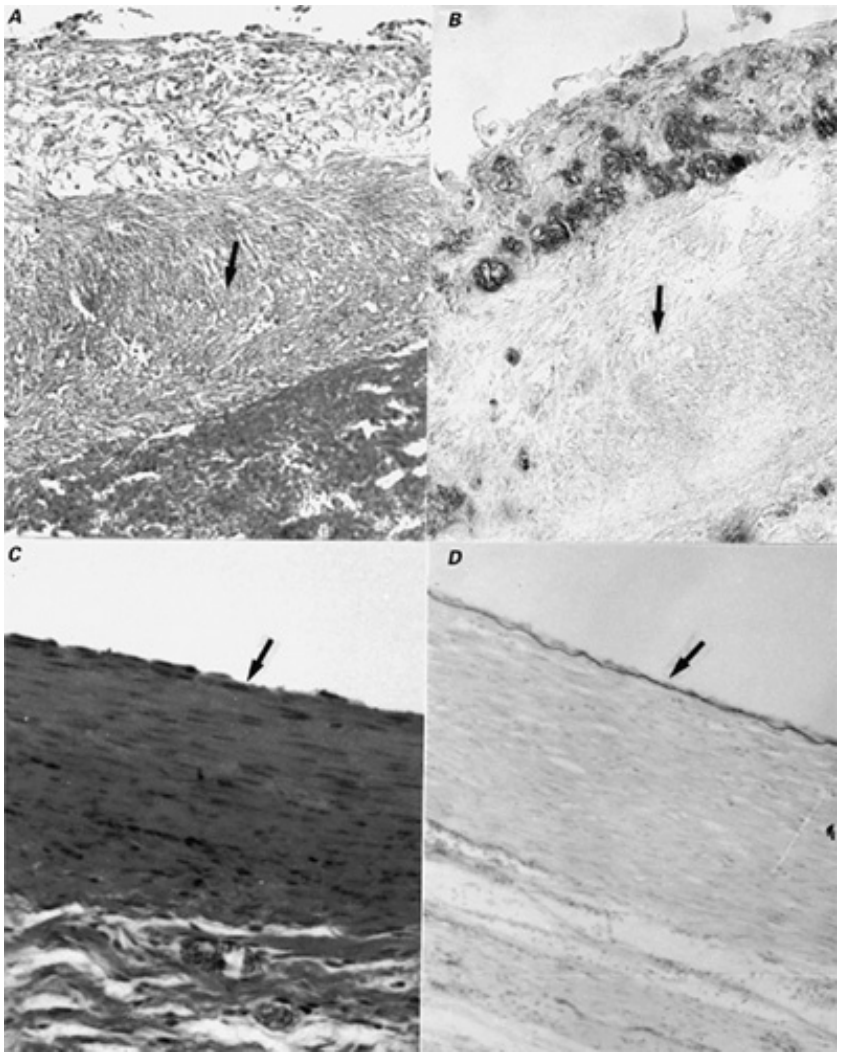

Figure 8-3: Control oligonucleotide-treated (*A* and *B*) and ASO (against cdc2 kinase/PCNA)-treated vein grafts (*C* and *D*) in hypercholesterolemic rabbits 6 weeks after surgery (×70). Sections of 5 mm were stained with hematoxylin/van Gieson (*A* and *C*) and a monoclonal antibody against rabbit macrophages (*B* and *D*). Arrows indicate the location of the internal elastic

lamina. (From Mann et al.,[63] with permission.)

Gene Transfer and Vascular Remodeling

Molecular cardiovascular research has resulted in significant gains in the knowledge of disease processes at cellular and molecular levels and has led to the characterization of expressed genes in diseased blood vessels. These gene products play autocrine and/or paracrine roles in vascular pathophysiology.

Nabel et al.[65] overexpressed an expression vector encoding a secreted form of fibroblast growth factor 1 (FGF-1) in porcine arteries. FGF-1 expression was associated with intimal thickening of the transfected vessels together with neocapillary formation in the expanded intima. These findings suggest that FGF-1 induces intimal hyperplasia in the arterial wall in vivo, and through its ability to stimulate angiogenesis in the neointima, FGF-1 could stimulate neovascularization of atherosclerotic plaques. In the same porcine model, the overexpression of transforming growth factor β1 (TGF-β1) in normal arteries resulted in substantial production of extracellular matrix accompanied by intimal and medial hyperplasia.[65] These findings demonstrated that TGF-β1 differentially modulates extracellular matrix production and cellular proliferation in the arterial wall and plays a reparative role in response to arterial injury. The increased production of extracellular matrix that accompanied the intimal and medial hyperplasia was not observed following expression of other growth factor genes in the vessel wall, including genes for platelet-derived growth factor (PDGF-BB)[27,66] or the secreted form of FGF-1.[62] Porcine arteries transfected with human PDGF-BB demonstrated intimal hyperplasia with increased numbers of intimal smooth muscle cells. An increased deposition of procollagen, however, as seen in TGF-β1-transfected vessels, was not observed. By stimulating the formation of extracellular matrix, it is possible that TGF-β1 could promote healing following vascular injury, limiting the extensive cellular intimal hyperplasia observed with PDGF-BB.[66]

The pathogenesis of vascular diseases such as hypertension involves a process of vascular remodeling associated with increased vascular hypertrophy and activation of the local angiotensin system. Angiotensin II has been shown to stimulate the growth and proliferation of vascular smooth muscle as well as collagen biosynthesis in vitro. Its in vivo role has been inferred from experiments using angiotensin converting enzyme (ACE) inhibitors. Since these drugs produce hemodynamic effects, a direct role of local angiotensin in vascular remodeling was not clear. To study the local effects of angiotensin, Morishita et al.[67] overexpressed ACE within the vascular wall. Immunoreactive ACE activity was noted in medial vascular smooth muscle cells as well as in intimal endothelial cells. Vascular ACE activity was associated with increased DNA synthesis and vascular protein content via the local production and action of vascular angiotensin II without changes in systemic blood pressure. Parallel to these biochemical changes, medial thickening of ACE-transfected vessel segments was noted, without changes in luminal diameters, implying medial wall hypertrophy by local production of angiotensin II. In a subsequent study, Nakajima et al.[68] demonstrated that overexpression of the type 2 angiotensin II (AT2) receptor in balloon-injured rat carotid arteries exerts an antiproliferative effect, counteracting the growth action of AT1 receptors.

One approach to the treatment of vascular diseases that are characterized by excessive cell proliferation is to overexpress a gene that inhibits cellular proliferation. It is important that expression of the gene proceed during the time period when intimal cells undergo proliferation following vascular injury. This may vary between animal models, and it is likely that in humans, cell proliferation following angioplasty, stent placement, or bypass graft surgery may proceed over a longer period of time than in animal models. Nonetheless, several gene products have proven efficacious in appropriate animal models of vascular injury. Most of these approaches are

based on arresting vascular cells in G1 or S phase of the cell cycle (Fig. 8-4). One approach is to express the herpes simplex virus thymidine kinase gene (*HSVtk*). *HSVtk* encodes for the enzyme thymidine kinase that phosphorylates the nucleoside analog ganciclovir or acyclovir into a metabolite that disrupts replication of DNA during S phase of the cell cycle. A by-product of this biochemical reaction is diffusible to adjacent cells, where it is incorporated in replicating cells, leading to inhibition of cell replication. This property is termed a *bystander effect* and allows for inhibition of replication in a greater number of cells than transfected. This model was established initially in a pig peripheral artery model of vascular injury, where intimal hyperplasia was decreased by 50 percent.[69] Subsequent investigations in the rat, rabbit, and a transplant model also demonstrated reductions in cell proliferation and lesion formation by about 50 percent.[70-73] This approach is currently being investigated in a model of in-stent restenosis. Chang et al.[74] demonstrated that localized arterial infection with a replication-defective adenovirus encoding a nonphosphorylatable, constitutively active form of the retinoblastoma gene product at the time of angioplasty significantly reduced SMC proliferation and neointima formation in both the rat carotid and porcine femoral artery models of restenosis. The cyclin-dependent kinase inhibitors p21 and p27 that arrest smooth muscle cells in G1 phase of the cell cycle are also potent negative regulators of lesion formation after vascular injury.[75-78] Ras proteins are key transducers of mitogenic signals from the cell membrane to the nucleus. The local delivery of vectors expressing *ras* transdominant negative mutants, which interfere with ras function, reduced neointimal lesion formation in a rat carotid artery balloon-injury model.[79]

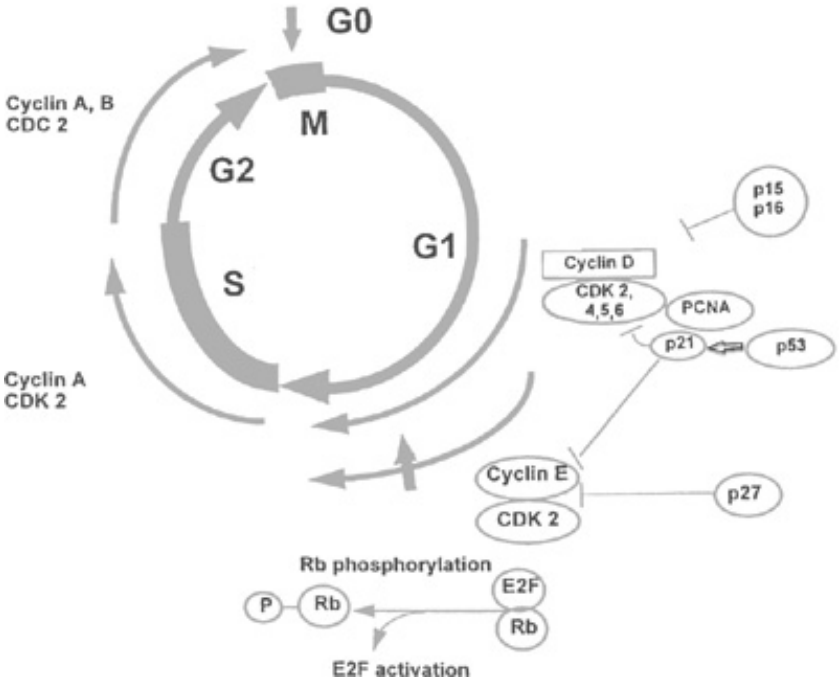

Figure 8-4: Regulation of the cell cycle. Progression through the G1 phase of the cell cycle is regulated by the assembly and phosphorylation of cyclins and cyclin-dependent kinases (CDKs). The cyclin-CDK complexes are inhibited by cyclin-dependent kinase inhibitors (CKIs), of which p21 and p27 are examples. These CKIs lead to G1 arrest. Inhibition of Rb phosphorylation, inactiviation of E2F, or inhibition of cyclin A and B also lead to disruption of DNA synthesis and inhibition of cell proliferation. (From Tanner et al.,[96] with permission.)

To assess the effect of endothelial cell nitric oxide synthase (ecNOS) on vessel lesion formation, a DNA vector encoding ecNOS was expressed in a rat model of arterial injury[80] (Fig. 8-5). Four methods were used to verify ecNOS expression: transgene protein expression by Western blot, localization of enzyme expression by in situ histochemical staining, enzymatic activity of the

transgene product, and vascular reactivity in response to the transgene. Overexpression of ecNOS led to vasorelaxation and 70 percent inhibition of neointima formation after balloon injury. This same approach has been investigated in a pig coronary model.[81] The loss of ecNOS may play a fundamental role in the pathogenesis of vascular diseases, including atherosclerosis. The overexpression of ecNOS may be useful for gene therapy of neointimal hyperplasia and associated local vasospasm after vascular injury.

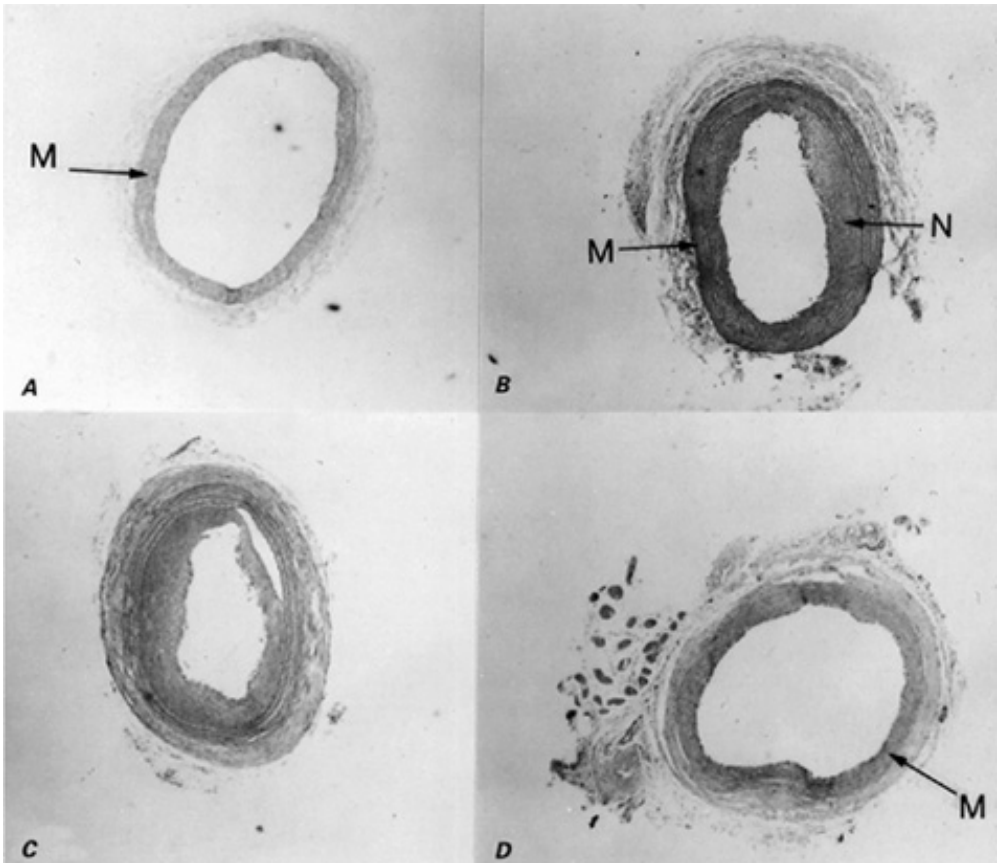

Figure 8-5: Inhibition of neointimal hyperplasia by in vivo gene transfer of endothelial cell nitric oxide synthase (ecNOS) in balloon-injured rat carotid arteries. *A*. Normal artery. *B*. Injured, untransfected artery. *C*. Injured, control vector-transfected artery. *D*. Injured, ecNOS-transfected artery. M, media; N, neointima. (From von der Leyen et al.,[80] with permission.)

Angiogenesis

Angiogenic growth factors may be useful to augment collateral artery development in animal models of myocardial and hind limb ischemia. Initial studies using intramuscular injections of angiogenic proteins, including basic fibroblast growth factor (bFGF) and acidic fibroblast growth factor (aFGF) into the hind limbs of rabbits with surgically induced ischemia lead to increased capillary densities and augmented blood flow.[82,83] These findings have been extended to gene-transfer approaches using vascular endothelial growth factor (VEGF). Following gene transfer of VEGF via a hydrogel balloon, increased numbers of capillary vessels also were observed in a rabbit model of hind limb ischemia, and improvement of resting and maximum flow was achieved that was comparable with that of a single administration of VEGF protein.[84] Intracoronary delivery of a recombinant adenovirus that encodes FGF-5 has been shown to induce collateral blood flow and restore myocardial function in a pig model of myocardial ischemia.[85] While the studies are encouraging, our understanding of the process by which VEGF, angiopoietin, and

other angiogenic proteins lead to blood vessel formation and maturation is still incomplete.

Chapter 8: CARDIOVASCULAR TISSUE MODIFICATION BY GENETIC APPROACHES

MYOCARDIAL GENE TRANSFER

Direct injection of DNA into myocardial tissue has been shown to be effective in local delivery of a transgene to the heart. Lin et al.[37] reported in vivo expression of β-galactosidase in cardiac myocytes for at least 4 weeks after direct injection into the left ventricle. Direct injections of a major histocompatibility complex (*MHC*) gene and the reporter gene *luciferase* under the control of an MHC promoter also resulted in the regulated expression of these genes.[38] Subsequent studies also showed increased gene expression after myocardial injection of adenoviral vectors.[10,13]

Healing and remodeling of the ventricle after myocardial infarction remain as important clinical problems. Some candidate genes (e.g., those for TGF-β1 and myogenin) may enhance the healing and recovery of myocytes after injury associated with infarction. The induction of neovascularization or angiogenesis in ischemic myocardium after coronary artery occlusion using gene transfer may salvage myocardium at risk by enhancing blood supply to the ischemic areas. Indeed, intracardiac myoblast grafts stably transfected with an inducible TGF-β1 construct were associated with increased DNA synthesis in vascular endothelial cells, consistent with a sustained angiogenic response.[86] The success of intracardiac grafting with genetically modified cardiomyocytes depends on the ability of grafts to couple with host myocytes. Soonpaa et al.[87] demonstrated that fetal cardiomyocytes isolated from transgenic mice carrying a fusion protein of the cardiac α-MHC promoter with a β-galactosidase reporter gene were connected to the host myocardium by nascent intercalated disks formed after grafting. Chronic heart failure is accompanied by a reduction in the number of myocardial β-adrenergic receptors and inotropic responsiveness. Cardiac-specific overexpression of a β_2-adrenergic receptor in a transgenic animal model with subsequent increased myocardial function suggests a potential gene-therapy approach to heart failure.[88]

CLINICAL TRIALS

Clinical trials in cardiovascular gene therapy have gone forward in two areas: vascular proliferative diseases and angiogenesis. The results of a Phase I/II randomized study of a cell cycle inhibitor have been reported recently.[89] In this study, cell cycle blockade by ex vivo gene therapy of experimental vein grafts was accomplished with a dominant negative transcription decoy, E2F, that leads to G1 arrest and inhibition of cell proliferation. The investigators hypothesized that this transcription decoy would inhibit the neointimal hyperplasia and subsequent accelerated atherosclerosis that lead to human bypass graft failure. This hypothesis was tested in a prospective, randomized, controlled trial to investigate the safety and biologic efficacy of intraoperative gene therapy in patients receiving bypass vein grafts. Patients undergoing infrainguinal bypass grafting were randomized to decoy oligodeoxynucleotide (which binds and inactivates E2F), scrambled oligodeoxynucleotides, or no treatment. Oligonucleotide was delivered to grafts intraoperatively by ex vivo pressure-mediated transfection. Since this was a Phase I/II study, the primary end points were safety and inhibition of target cell cycle regulatory genes and of DNA synthesis in the grafts. The investigators found that the E2F decoy treatment reduced proliferating-cell nuclear antigen and c-myc mRNA concentrations as well as cell proliferation indices. Twelve months later, there were fewer clinical complications in the E2F treatment group, defined as fewer graft occlusions, revisions, or severe lesions. The investigators concluded that the intraoperative transfection of human bypass vein grafts with E2F decoy oligodeoxynucleotide was not only safe and feasible but also achieved inhibition of cell cycle genes and cell replication.[89]

Several protocols have now been initiated to promote angiogenesis for myocardial and peripheral ischemia. These studies have administered recombinant protein, plasmid DNA, or adenoviral vectors encoding bFGF, VEGF, aFGF, or FGF-4 by direct injection into the heart or limb muscle or by direct intracoronary infusion. Thus different genes, vectors, routes of delivery, and tissues are being examined. These studies to date have been Phase I (i.e., safety and toxicity) studies in which clinical efficacy is not an end point due to the small number of patients. Some of these Phase I protocols have been completed and reported. In a study to treat myocardial ischemia, recombinant aFGF was injected directly into the anatomosis site of the left internal mammary artery (LIMA) and into the left anterior descending artery (LAD) of patients undergoing coronary bypass surgery.[90] Patients with peripheral ischemia have been treated with direct injections of plasmid DNA encoding VEGF.[91] These Phase I studies are promising. The treatments to date have been safe, with no substantial toxicities. Progression to Phase II/III studies in which dose escalation, double-blind randomization, and measurements of clinical efficacy are performed is warranted.

Chapter 8: CARDIOVASCULAR TISSUE MODIFICATION BY GENETIC APPROACHES

STEM CELL BIOLOGY

Recently, pluripotent human stem cells have been discovered or derived from human embryos.[92] These stem cells have the potential to differentiate into any kind of cell and thus may be used to treat or cure many diseases, including heart disease, diabetes, Parkinson's disease, Alzheimer's disease, and others.[93] There are two types of stem cells: embryonic and adult stem cells. Embryonic stem (ES) cells have not become differentiated and hence are pluripotent. Adult stem cells have undergone differentiation, and their potential to regenerate damaged tissue is limited. There is controversy surrounding stem cell research with regard to funding for the derivation of human embryonic stem cells and for research on ES cells once derived.

The following scenario could be envisioned. ES cells are derived by culturing a several-day-old human embryo or blastocyst. The trophoblast will form the placenta, while the inner cell mass will form the embryo. The inner cell mass is isolated. This tissue contains ES cells that have the potential to differentiate into any kind of tissue. The ES cells are cultured in media to grow colonies of cells. Special factors can be applied to encourage differentiation. Subpopulations of cells can be separated, i.e., bone marrow cells, cardiac myocytes, neurons, etc. The differentiated cells are then engineered to be an immunologic match with the patient and then can be administered. For example, ES cells that have differentiated into cardiac myocytes can be injected into a patient having sustained a myocardial infarction or heart failure.

SUMMARY AND FUTURE DIRECTIONS

Since the 1980s, there has been remarkable progress in the design of vectors, the enhancement of gene expression by optimizing regulatory units, the development of animal models, and the translation of basic science studies into clinical applications. Despite this progress, there are significant hurdles and challenges that must be met if the promise of gene therapy is to be fulfilled. There is a persistent need for improved vectors that increase transgene expression and program expression specifically to cardiovascular tissues. Cell-specific promoters are being studied. Improved catheters are needed to deliver vectors and transgenes to vascular and myocardial tissues.[94] A better understanding of the pathways leading to cardiovascular diseases will permit more careful delineation of candidate target genes. There is no doubt, however, that enthusiasm and optimism remain high that this technology can lead to successful cardiovascular therapies.

Part 1: BASIC FOUNDATIONS OF CARDIOLOGY
Chapter 9:

MOLECULAR DEVELOPMENT OF THE HEART

Authors: Bradley B. Keller, Andy Wessels, Robert J. Schwartz, Robert Roberts, Roger R. Markwald

The wide spectrum of congential cardiovascular anomalies that present from the prenatal period into adulthood has challenged clinicians and scientists for centuries.[1,2] Equally daunting historically have been the complex and varied descriptions of cardiac embryology and the pathogenesis of congenital cardiovascular malformations.[3-6] Fortunately, scientific advances, including the availability of cell-specific immunohistochemistry, rapid advances in molecular biological techniques, expansion of investigations into integrated embryonic cardiovascular physiology, and dramatic improvements in the three-dimensional imaging of the embryonic cardiovascular anatomy, make the specific determination of pathogenesis for most cardiovascular anomalies a realistic goal in the next decade (Fig. 9-1).[7-11]

This chapter will discuss current ideas about normal development of the heart and vasculature and illustrate how this knowledge can help one understand the pathogenesis of congenital cardiovascular malformations. As with all complex developmental events, cardiovascular morphogenesis must be defined in a stepwise fashion, and this chapter details some of these pivotal developmental events. Although many of the mechanisms that lead to the development of the fully septated, four-chambered vertebrate heart are interdependent (e.g., the formation of the muscular ventricular septum and the membranous portion of the atrioventricular septum), many of these events are discussed in separate sections for clarity. It needs to be emphasized, however, that none of these remodeling events are isolated processes (e.g., formation of the outflow tract and closure of the interventricular foramen). The information presented in this chapter focuses on human development. However, a rapidly growing number of animal models generated by using sophisticated molecular biological techniques are becoming available and will accelerate the investigation of a wide variety of aspects related to normal and aberrant cardiovascular morphogenesis.

MOLECULAR DEVELOPMENT OF THE HEART TUBE

Embryo Patterning

Morphogenesis of the heart begins with the initial patterning of the embryo that determines the three axes of the embryo: anterior-posterior, dorsal-ventral, and left-right. These axes are imprinted onto the cellular program as cell populations expand to form the embryo and extraembryonic tissues. Specific genes have been identified that alter axis determination in a range of species, including the mouse.[12,13] After determination of the embryo axes, subpopulations of cells are programmed in a segmental body plan. Much of the current understanding of the body plan comes from developmental studies of *Drosophila*, an insect with a head, thorax, and abdomen.[14] In mammals, maternal gene products control the cell through the first two cell cycles and then control switches to the embryonic genome. These patterning (homeobox) genes are arranged along the anterior-posterior axis of the embryo.[15] Structural asymmetry is apparent at the blastodisc stage, when the primitive streak defines the anterior-posterior axis and the dorsal-ventral axis is defined by the position of the yolk sac. Myocyte commitment in the chick embryo

occurs in the early blastula stage, followed by clonal expansion in the bilateral heart-forming regions located in the lateral splanchnic folds after gastrulation. Molecular studies also have confirmed the segmental patterning of the cardiac tube, linking gene products with morphologic boundaries between segments that eventually integrate to form the future atria, ventricles, and outflow tract in chick, mouse, and human hearts.[16]

The process of mesoderm formation is integral to the organization of the primary axis of the embryo and the differentiation of the right and left sides. At the blastodisc stage of development, there are two primitive germ layers-endoderm and ectoderm-and then the endoderm layer splits into splanchnic and visceral layers with interposed mesodermal cells (Fig. 9-2). Mesoderm is formed as ectodermal cells migrate through the primitive streak coursing adjacent to Hensen's node (organizer). Hensen's node contains retinoic acid and serves as an embryonic organizer that may confer positional information on the mesodermal cells.[17] At this critical phase in cell determination, exogenous retinoic acid is extremely teratogenic. Interestingly, retinoic acid has a gradient-like effect on the determination of the heart tube, with the greatest effect at the arterial pole and the smallest effect at the venous pole.[18] After migration, this crescent of mesodermal cells forms the precardiac region from which the heart and the precursor cells of the great vessels originate.

Molecular Factors Involved in Cardiogenesis

Defining the molecular basis that underlies the establishment and maintenance of cardiac muscle differentiation has presented a fundamental challenge in developmental biology and molecular genetics. Despite the shared expression of numerous contractile protein genes by both cardiac and skeletal striated muscles, the molecular mechanisms for cell determination, differentiation, and tissue patterning are quite distinct. The following section presents some of the current, relevant information on molecular cardiogenesis, as defects in these molecular mechanisms have been shown to be associated with structural and/or functional heart diseases in children and adults (Fig. 9-3).

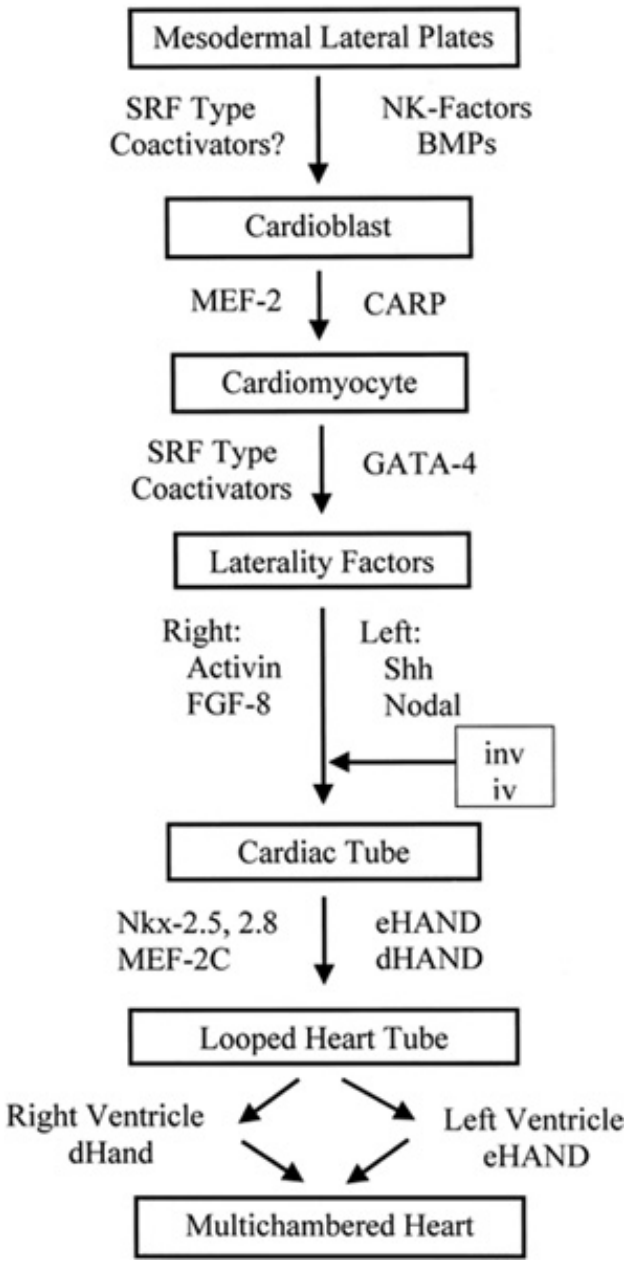

Figure 9-3: A lateral plate of mesoderm on each side of the midline forms the progenitor for the development of the heart and portions of the great vessels. The NK-Factor homeobox genes, such as *Nkx2.5*, in combination with multiple other genes, such as the serum response factor (SRF), are responsible for activating commitment of these undifferentiated cells to cardioblasts. Myocyte enhancer factor (MEF) has a binding site in practically all muscle genes and is essential to the development of cardiac myocytes. The CARP gene is downstream of *Nkx2.5* in the cardiac lineage. The genes responsible for the fusion of the two lateral mesodermal plates into a single tube are unknown, but experiments show that GATA-4 is necessary, along with SRF and many other genes yet to be identified. Genes involved in laterality include *Activin*, *FGF-9*, *Shh*, and *nodal*. The cardiac tube that forms a loop to the right requires *Nkx* genes and the *eHAND* and *dHAND* as well as *inv* (inversion of embryonic turning) and *iv* genes. The *dHAND* gene is responsible for the formation of the right ventricle, and the *eHAND* for that of the left ventricle.

Basic Helix-Loop-Helix Factors and Muscle Development

One of the initial, critical discoveries related to muscle development was the observation that a specific transcription factor, Myo-D, expressed in myoblasts[19] is sufficient to convert a variety of mesodermal and nonmesodermal cell types to stable myoblasts with active muscle-specific gene

expression. Using Myo-D as a probe, several additional regulatory factors that specify skeletal muscle cell lineage in fibroblasts have been identified: myogenin,[20,21] Myf5,[22] MRF4-herculin, and Myf6.[23-25] These factors share extensive homology within a basic region and an HLH motif that mediate DNA binding and dimerization, respectively.[26] HLH proteins share the ability to recognize the DNA consensus sequence CANNTG, known as an *E-box*, which first was identified with the immunoglobulin enhancer[26] and subsequently was found in regulatory regions of most muscle-specific genes. Thus, the regulatory paradigm for skeletal muscle differentiation is centered on the bHLH myogenic regulatory factors, but Myo-D, myogenin, Myf5, MRF-4, and Myf6 are not expressed in the heart.[27]

In the heart, there are other basic HLH factors. dHAND and eHAND are two bHLH transcription factors that share high homology in their bHLH regions and show segment-specific expression patterns.[28] In the mouse, HAND expression coincides with that of other cardiac transcription factors. dHAND expressed in the endocardium is maintained throughout the straight heart tube but is restricted to the conotruncus and the future right ventricle as the heart tube forms a loop. eHAND expressed in the myocardium rapidly becomes restricted to the conotruncus and the left ventricle.[29] Expression of dHAND and eHAND precedes separation of the two ventricles, representing early chamber specification. In addition to cardiac expression, dHAND (HAND1) is expressed in early trophoblast tissue and is required for the nutritional support of the developing mouse embryo.[30] It is of interest that *Nkx-2.8* has an expression pattern that overlaps eHAND, being restricted to the rostral and caudal regions of the heart tube after looping and being expressed in the endoderm of the pharyngeal arches. The deletion of dHAND by gene targeting showed that dHAND expression is necessary for the formation of the right ventricle.[29,31] Thus, it appears that dHAND may specify the right ventricle, and eHAND the left ventricle. In addition, dHAND and eHAND specify right ventricle (RV) and left ventricle (LV) specific morphology independent of situs.[32] Expression of cardiac-specified genes *αMHC, MLC2A, MLC2V, ANF,* and *Nkx-2.5* was not affected by elimination of the dHAND gene. GATA-4 in the myocardium was downregulated by dHAND-deficient hearts and appears to be a downstream target of dHAND.

Drosophila tinman Is Required for Insect Heart Development

The identification of molecular mechanisms involved specifically in heart development has depended on the investigation of simpler biological models, including the fly *Drosophila*. Homeotic genes are genes that determine a change in structure and have in common a domain that codes for 60 amino acids. Genes with this sequence, referred to as homeobox (*Hox*) genes, generally are upregulated during early differentiation and appear in a time-dependent sequence. Homeobox genes have been studied extensively in *Drosophila,* where they are involved in the commitment of cells to specific developmental pathways and play an important role in pattern formation.[33]

Recently, the NK homeobox family of genes (*NK-1/S59*, *NK-2/vnd, NK-3/bagpipe*, and *NK-4/msh-2/tinman* and *H6*) was identified in the mouse.[34] Nkx-2 factors are DNA-binding proteins (transcriptional factors) that are capable of activating transcription; their 60-amino-acid homeodomain includes three helices, in which helix II and helix III form a helix-turn-helix motif.[35] Helix III fits across the AT-rich major groove of the DNA binding site. *Nkx-2.5* has been shown to bind to novel NKE sites,[36] certain serum response elements of the cardiac alpha-actin promoter,[37] and the NKE sites in the cardiac atrial natriuretic factor promoter.[38] Gajewski and associates[39] showed that two NKE promoter sites direct *Drosophila* MEF2(dMEF2) expression in response to *tinman*. Mutations in the *tinman* gene result in loss of heart formation in the *Drosophila* embryo.[40] In addition, *tinman* is known to regulate NK-3/bagpipe expression in the visceral mesoderm[41] and the expression of dMEF2.[39] These observations suggest that *tinman* may be involved in cardiac mesoderm patterning and make it a likely marker for cardiac mesoderm induction.

Tinman and Other Related NK-2 Genes Are Required for Vertebrate Heart Morphogenesis

Homeobox genes of the NK class also may function in early cardiac development in vertebrates. The murine NK-2 homeobox gene *Nkx-2.5/Csx* is expressed in early cardiac progenitor cells before cardiogenic differentiation and continues through adulthood.[42,43] Superimposed on the appearance of *Nkx-2.5* in cardiac progenitor cells is the sequential expression of the cell type-restricted cardiac alpha-actin and MHC genes.[42] The *Nkx-2.5* factors identified in other vertebrates, such as zebrafish,[44] *Xenopus*,[45] and chickens,[46] were highly related in sequence and expression pattern to the mouse gene and to cardiac development.

The similarity in expression patterns between *Nkx-2.5*, *XNkx-2.5*, *ceh-22*, *tinman*, and *bagpipe* suggested that the function of these genes might be conserved. Another member of the Nkx-2 family, *Nkx-2.8*, which was recently isolated from avian species, is closely related to *Xenopus*, chicken, and zebrafish *Nkx-2.5* homeoboxes and is expressed in the developing embryo in the lateral plate mesoderm and underlying pharyngeal endoderm.[47] An attractive hypothesis is that these homeodomain factors function in phylogenetically conserved myogenic pathways occurring in muscle types that do not utilize the Myo-D family. Whether the vertebrate *Nkx-2.5* or other Nkx-2-related genes expressed in the early heart play a role in heart specification or whether they are downstream regulators of cardiac gene expression remains to be determined. In this respect, it is interesting to note that although it does not inhibit formation of the cardiac tube, homologous recombination knockouts of the endogenous murine *Nkx-2.5* gene do result in cardiac dysmorphogenesis at the looping stages of development and embryonic lethality.[48]

The partially overlapping expression pattern of *Hox* genes in embryos has led to the concept of a "*Hox* code."[49] The term *Hox code* means that a particular combination of *Hox* genes is functionally active in a region and thus specifies the developmental fate of this region. The existence of eight Nkx-2 family members, their overlapping DNA-binding specificities, and, most important, their partially overlapping patterns of expression raise the possibility of an "Nkx code."[47] Overexpression of *Nkx-2.5* in a zebrafish embryo results in an enlarged heart.[44] Thus, inactivation of the Nkx genes by homologous recombination and their overexpression as transgenes offer promise in addressing the functional significance of the expression domains and thus also of the Nkx code. As is mentioned below, patients with secundum atrial septal defect have been identified to have specific mutations in the human homolog to the *Nkx2.5* gene.[49]

Cardiac-Restricted Ankyrin Repeat Protein Gene

The cardiac-restricted ankyrin repeat protein (*CARP*) gene encodes a nuclear coregulator for cardiac gene expression which lies downstream of the cardiac homeobox gene *Nkx 2.5* and is an early marker of the cardiac muscle cell lineage.[50] The expression of the *CARP* gene is developmentally downregulated and dramatically induced as part of the embryonic gene program during cardiac hypertrophy. A distinct 5′ cis regulatory element directs heart segment-specific expression, such as atrial versus ventricular and left versus right. In addition, a 213-base-pair sequence element of the gene confers conotruncal segment-specific expression.[50] In addition, an essential GATA-4-binding site is present in the proximal upstream regulatory region of the gene and cooperative transcriptional regulation is mediated by *Nkx2.5* and GATA-4. This cooperative regulation is dependent on the binding of GATA-4 to its cognate DNA sequence in the promoter, which suggests that *Nkx2.5* controls CARP expression, at least in part, through GATA-4.[50]

SRF and MEF2, MADS Box Factors Involved with Cardiogenesis

Serum response factor generally was presumed to be a ubiquitous and constitutive trophic factor[51] but was later shown to be highly expressed in the embryonic heart.[52] Serum response factor (SRF) represents an ancient DNA-binding protein whose relatives shared a highly conserved DNA-

binding/dimerization domain of 90 amino acids, termed the *MADS box*. SRF-related proteins that are capable of binding to sites found in the regulatory regions of both nonmuscle- and muscle-specific genes also belong to the MADS box family of trophic factors.[53] SRF-related proteins are capable of binding MEF2 sites, CTA(A/T)4TAG, which can be found in the regulatory regions of both nonmuscle- and muscle-specific genes.[54,55] Like SRF, MEF2 factors contain a MADS box and an adjacent MEF2 box. Expression and mutagenesis studies in *Drosophila* have shown that MEF2 proteins are necessary for myogenic differentiation during development[56,57] and are activated by *tinman*.[39]

In the mouse embryo, MEF2 genes are highly expressed in the early heart and skeletal muscle progenitor cells before the induction of cardiac and skeletal muscle structural genes, implicating MEF2 as key regulator of cardiac and skeletal muscle differentiation programs.[58-60] Four MEF2 genes have been isolated in vertebrate species and are referred to as MEF2A-MEF2D.[60,61] The four MEF2 gene products are highly homologous in the MADS box domain but are divergent in the carboxy termini, arising from alternative splicing mechanisms. MEF2C shows a tissue-restricted expression pattern, being expressed exclusively in skeletal muscle, brain, and spleen, and is induced by myogenin in fibroblasts during myogenic differentiation in tissue cultures.[62]

Transactivation of the Cardiac Alpha-Actin Gene by Nkx-2.5 and SRF

Gilman and coworkers[63,64] showed that human SRF interacts with a novel human homeodomain protein, Phox, which shows similarity to the homeodomains of two murine Pax genes. The highest similarity is to a partial murine cDNA termed S8[65] and to MHox, a novel homeodomain protein expressed in mesoderm.[66] Phox interacts with SRF to enhance the exchange of SRF with its binding site in the *c-fos* gene. It has been shown that *Nkx-2.5* transactivates the cardiac alpha-actin gene by binding to SRF, but only after SRF has bound to DNA.[67]

The Role of the GATA Family in Cardiogenesis

The GATA family of proteins has been subdivided, with GATA-1/2/3 being linked to hematopoiesis and GATA-4/5/6 thought to be involved with cardiac, gut, and blood vessel formation. Each of the six GATA proteins contains a highly specific DNA-binding domain consisting of two C4 zinc fingers that bind to the DNA sequence element (A/T)GATA(A/G) and that may be able to interchange with each other. GATA-4 and 6 have been found to be expressed in a developmentally and lineage-specific pattern within cardiac mesoderm and gut epithelium.[68-70] GATA-5 expression is restricted to the endocardium. Experiments have shown that GATA-4 regulates the expression of cardiac-specific genes such as cardiac troponin C[71] and alpha-MHC.[72] Mice without the GATA-4 gene display a severe defect in the formation of the cardiac tube. Several studies have demonstrated that the GATA-4 transcription factor plays an important role in regulating cardiac-specified genes and appears to be downstream to the *Nkx-2.5* gene.

Cardiogenesis, an Nkx-2-Dependent Paradigm

An attractive hypothesis from the analysis of these NK-2 homologues is that these homeodomain factors function in phylogenetically conserved pathways in muscle cell types that do not utilize the Myo-D family. Expression of *Nkx-2.5* in fibroblasts demonstrated that downstream targets such as the cardiac alpha-actin gene are not directly activated by *Nkx-2.5* alone but require the collaboration of additional factors, such as SRF.[37,67] Whether the vertebrate *Nkx-2.5* or other Nkx-2-related genes with SRF are sufficient to play the primary role in heart specification and serve as regulators of other downstream cardiac genes remains to be determined. It is reasonable to postulate that the vertebrate MEF2C genes and the GATA-4 factor are high in the hierarchical order of regulatory factors that, in combination with *Nkx-2.5* and SRF, specify the cardiac cell

lineage.

Role for Bone Morphogenic Proteins in Initiating Early Myocardial Cell Differentiation

One type of signaling molecule responsible for cardiogenic commitment was identified to be composed of the bone morphogenic proteins (BMPs), which are members of the transforming growth factor-beta family of signaling molecules. BMP-2 and -4 appear to be capable of inducing the cardiac regulatory factors *Nkx-2.5* and GATA-4 when ectopically applied to regions of chick embryos that usually are not specified to become heart tissue.[46] In mice with the BMP-4 gene eliminated (knockout mice), there was little or no mesoderm differentiation. Some of the mice deficient for BMP-2 gene that lacked *Nkx-2.5* expression also failed to develop beyond the early stages of looping.[73] Thus, BMPs appear to have an early influence on cardiogenesis and *Nkx-2.5* expression.

Laterality of the Cardiac Tube

Correct laterality is fundamental to the developing embryo, and situs solitus has the lowest risk of congenital cardiovascular malformations.[74] The first grossly asymmetric feature to develop is the heart tube, which forms from the fusion of cardiac primordia at the midline (see Fig. 9-2). Subsequently, the initially symmetric heart acquires a dextral loop. The tubular heart initiates rhythmic contractions at about day 23 in humans and then undergoes rightward looping. This pattern of left-right asymmetry occurs in all vertebrate internal organs as a result of a signaling cascade present before gastrulation. On the right side of Hensen's node, the secreted morphogen activin represses Sonic hedgehog (Shh) expression and induces expression of the genes for the activin receptor and fibroblast growth factor 8. On the left side, Shh induces Nodal expression in lateral plate mesoderm and subsequent left-sided expression of the bicoid-like homeobox gene *Pitx2*. The homeobox gene *Nkx3.2* is asymmetrically expressed in the anterior left lateral plate mesoderm (LPM) and head mesoderm in the chick embryo.[75] Misexpression of the normally left-sided signals Nodal, Lefty2, and Shh on the right side or ectopic application of retinoic acid results in upregulation of *Nkx3.2* contralateral to its normal expression on the left. FGF8 is an important negative determinant of asymmetric *Nkx3.2*, and ectopic application of FGF8 on the left side blocks *Nkx3.2* expression, whereas an FGF receptor-1 antagonist implanted on the right side results in bilateral *Nkx3.2* expression in the LPM.[75]

There is a genetic basis for left-right asymmetry, as several types of unlinked mutations affecting left-right laterality exist in mice and humans. For example, in the offspring of *iv* mice (lacking the *iv* gene), 50 percent have situs inversus.[76] The *iv* gene has been mapped to mouse chromosome 12 and has been identified to code for the structural protein dynein. The *inv* (inversion of embryonic turning) gene mapped to chromosome 4 causes complete reversal of left-right symmetry and cardiac looping.[77,78] *Nkx3.2* expression also was found to be asymmetric in the mouse LPM, but unlike in the chick, it was expressed in the right LPM. In the inversion of embryonic turning (inv) mouse mutant, which has aberrant left-right (L-R) development, *Nkx3.2* was expressed predominantly on the left side. Thus, *Nkx3.2* transcripts accumulate on opposite sides of mouse and chick embryos, although in both the mouse and the chick, *Nkx3.2* expression is controlled by the L-R signaling pathways.

Myocardial Expansion and Differentiation

Retrovirus labeling studies have demonstrated that the ventricular myocardium expands by a process of clonal expansion of the epitheliod myocytes of the cardiac tube (see Figure 9-7).[79,80] The regulation of myocyte specification and differentiation is complex and probably involves cell adhesion molecules, including N-cadherin, extracellular proteases, and morphogenetic signals from the transforming growth factor-beta (TGF-beta) and FGF families of growth and

differentiation factors.[80-84]

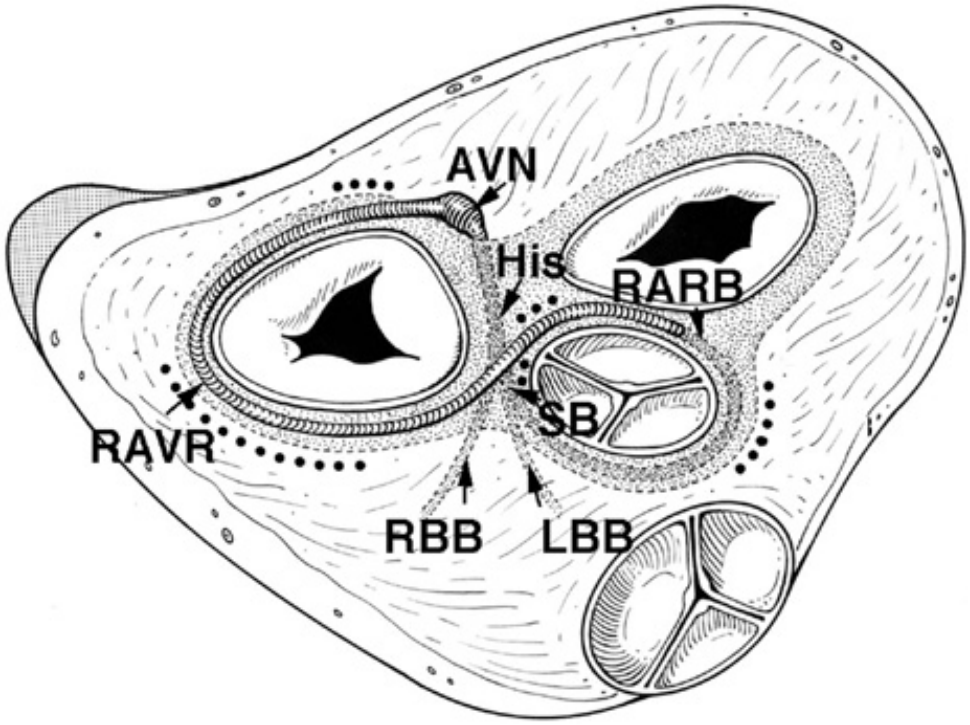

Figure 9-7: Schematic representation of the localization of remnants of the primary ring in the neonatal human heart. The ring is projected on a superior view of the aortic mitral fibrous unit of the adult heart. The black dots indicate the areas in which remnants of the ring are detected in a series of neonatal hearts. 1 = anterolateral part of the right atrioventricular ring; 2 = posteromedial part of the right atrioventricular ring; 3 = "dead-end" tract of the conduction axis; 4 = lateral part of the retroaortic rootbranch; 5 = posterior part of the retroaortic rootbranch. AVN = atrioventricular node; AoV = semilunar valve of the aorta; LBB = left bundle branch; mi = mitral valve; PuV = semilunar valve of the pulmonary trunk; Rbb = right bundle branch; SB = septal branch; tri = tricuspid valve. (Adapted from Wessels et al.[126])

The Neural Crest and Cardiac Development

The cardiac neural crest is an important migratory cell population that contributes to cardiovascular morphogenesis. The cardiac neural crest arises from the dorsal margin of the neural tube before fusion and migrates ventrally to form the autonomic ganglia, melanocytes, and Schwann cells. The crest cells move in waves through the branchial arches during the first 4 weeks of human development. The eventual fate of the neural crest cells likely is determined long before the initial phenotypic expression of a heart tube by activation of the cellular gradients of *Hox* genes and other morphoregulating factors.[85,86] The cranial neural crest region defines a developmental field that includes the heart, hindbrain, face, and branchial arch derivatives.

Experimental disruption of cranial neural crest produces a spectrum of abnormalities. In a series of elegant ablation and chick quail chimera studies, Kirby and Waldo defined the range of cardiac neural crest that is integral to the septation of the conotruncal region of the heart and branchial arch derivatives, including facial abnormalities, thymus, parathyroid, and autonomic derivatives.[85] These neural crest cells are site-specific and carry information for the formation of structures appropriate to their origin rather than being defined at the destination of migration.

Several genes have been identified as important in the proper migration and differentiation of the

cardiac neural crest. The Splotch mutant mouse is characterized by a mutation in the *Pax-3* gene.[87] Homozygote Splotch mutants have a complete neural crest ablation phenotype, including persistent truncus arteriosus and aortic arch anomalies,[88] similar to the CV phenotype of neural crest ablation in the chick embryo.[86,89] *Hox* gene abnormalities also are associated with defects in the derivatives of cranial neural crest. A transgenic murine model of *Hox* 1.1 overexpression has neural crest ectomesenchymal tissue abnormalities, including cleft palate, nonfused pinnae, and open eyes. *Hox* 1.5-deficient mice have features of DiGeorge's syndrome.[86] In humans, DiGeorge's syndrome, velo-cardio-facial syndrome, and conotruncal anomaly face syndrome are associated with chromosomal deletions in the 22q11 region on the long arm of chromosome 22.[90-93] Recent studies have indicated a number of candidate factors in the pathogenesis of these syndromes (referred to as catch22 syndrome). In addition, retinoic acid is a potent teratogen in humans and produces a syndrome involving all the derivatives of the cranial neural crest.[94]

Myocyte Differentiation

In the human embryo, the heart begins to contract at day 17 as the machinery of contraction and relaxation becomes functional. These functional units include the sarcomere, composed of the contractile elements; the mitochondria, containing the enzymes for energy production and modulation; and the sarcolemma, the cell envelope with specialized components of the t tubular system linked to the sarcoplasmic reticulum. In the mature myocardium, sarcomeres are organized parallel to the lines of peak systolic stress. In the embryonic myocyte, myofibrils initially appear disarrayed and become aligned as development proceeds.[95] Despite this disordered appearance, the contraction pattern of the early embryonic heart is isotropic.[96]

The temporal and spatial expression of contractile proteins in the developing heart is under intense investigation. At the precardiac tube stage, smooth muscle alpha-actin is the only isoform present. With formation of the cardiac tube, there is progressive expression of the cardiac form of sarcomeric actin with the onset of cardiac pumping. The alpha smooth muscle actin may act as a scaffolding during assembly of the sarcomere.[97,98]

Mitochondria multiply concurrently with the myofibrils in the differentiating myocyte. In the mature heart, mitochondrial enzymes are the major source of high-energy phosphate necessary for contraction and probably begin this function during embryonic development. In the chick, the mitochondria account for about 10 percent of myocyte volume.[95] In the rat embryo, total volume increases from 22 to 34 percent between days 6 and 10, and the mitochondria also change morphologically with development, becoming larger with more cristae and a denser matrix.[99] The myocyte mitochondrial volume fraction correlates directly with heart rate and oxygen consumption among animals.[100]

Maturation of the sarcoplasmic reticulum and the apparatus for excitation-contraction coupling occurs coincident with the structural morphogenesis of the embryonic heart. The sarcolemma contains ion pumps, channels, and exchangers that maintain chemical and charge differences between extracellular and intracellular spaces.[101] During maturation of the heart, the resting potential increases (becomes more negative) in both birds and mammals [102,103] Ca^{2+} influx through Ca^{2+} channels may play a relatively important role in transsarcolemmal Ca^{2+} influx in the immature heart. However, peak Ca^{2+} current density is actually decreased compared with that measured in mature cells.[104,105] Although Ca^{2+} influx by way of the Na^{+}-Ca^{2+} exchanger is less important for excitation-contraction coupling in mature myocardium, Na^{+}-Ca^{2+} exchange may play an important role in myocytes from relatively immature rabbit hearts.

Relaxation, an active process by which the myocardium returns to steady state after contraction, depends on rapid removal of Ca^{2+} from troponin C. This is mediated primarily by active transport of Ca^{2+} back into the sarcoplasmic reticulum (SR). The SR Ca^{2+} pump ATPase (SERCA2a)

usually couples hydrolysis of adenosine triphosphate (ATP) to active Ca^{2+} transport. The rate of SR Ca^{2+} uptake correlates well with the observed rate of myocardial relaxation. Regulation of SR Ca^{2+} pump activity is mediated by the intrinsic SR protein phospholamban. Ca^{2+} also is removed from the myofilaments by extrusion across the cell membrane. In the steady state, the amount of Ca^{2+} removed from the myocyte equals the amount entering through the Ca^{2+} channels.[106]

Segmental Basis of Heart Tube Formation

Formation of the cardiac tube is a complex morphogenetic event. The primitive, bilateral heart tubes each contain an inner layer of endocardium, a middle layer of cardiac jelly, and an outer layer of myocardium. At the cephalic end of the embryo (on each side of the midsagittal plane), myocytes within a section of each heart tube acquire contractile elements, and the position of the heart tubes shifts first to be parallel and close to each other within the cephalic part of the developing body cavity (intraembryonic coelom), ventral to the foregut, followed by fusion of the heart tubes in the ventral midline to form the linear or straight heart tube.[4,5107-109]

It is important to note that the primitive linear heart tube does not contain all the segments present in the mature heart. During morphogenesis, the proximal portion of the aortic sac is incorporated into the outflow tract of the right ventricle (along with migrating neural crest cells) and the sinus venosus is incorporated into developing atria. Thus, each "segment" of the mature heart arises at a unique time during embryogenesis.[110] One critical aspect of this segmental assembly and maturation of the heart is that there likely are both temporal and spatial "windows" that are developmentally regulated, and this may explain why similar morphogens such as retinoic acid produce a wide spectrum of teratogenic effects depending on the time in gestation of exposure. Another aspect of this segmental paradigm is the concept that cardiac morphogenesis depends on molecular and cellular as well as mechanical interactions between the respective segments in the developing heart.[110]

Cardiac Jelly

Prior to looping, the acellular space between the myocardium and the endocardium in the heart is filled with a deformable extracellular matrix. This "cardiac jelly" forms before cardiac tube fusion and is closely associated with the primordial myocytes.[111] At the pretubular heart stages, the extracellular matrix contains collagen types I and IV, fibronectin, and laminin. The primordial endothelial cells destined to form the endocardium interact and migrate through this matrix during the establishment of the primitive, bilateral heart tubes. Radioactive labeling has demonstrated that proteins produced in the myocardium flow toward the endocardium and are incorporated into the basal lamina.[112] The cardiac jelly has a variety of functions related to hemodynamic performance, cardiac looping and cell migration in cardiac septation, and the formation of the endocardial cushion valves at the atrioventricular (AV) junction and outflow tract of the heart.

The protein composition of the cardiac jelly modulates differentiation of the endothelium. Recent information explains the role of genes from the TGF-beta family of peptide growth factors as regulators of morphogenesis.[113] TGF-beta2 proteins are in the extracellular matrix and are an integral component of the morphogenetic changes at the AV cushion level, acting through second messengers such as protein kinase C.[114] In addition, fibronectin probably serves to set up migratory pathways in the cardiac jelly. These protein strands are arranged radially in the cushion, presumably along the lines of stress. The fibronectin strands also may serve as a template for the fibrous skeleton of the AV valve leaflets.[115-117] The extracellular matrix proteins stimulate transdifferentiation of the endocardium in these regions, prompting endothelial cells to transform to mesenchymal cells which migrate into the cushion matrix. Laminin and type IV collagen are stabilizing signals or markers, since these compounds are absent in the cushion regions but are present adjacent to the endocardial cells that maintain a typical epithelial integrity.

Endocardial Maturation

The endothelial cells that make up the lining of the embryonic heart initially are arranged as a single sheet. This squamous-like sheet has the morphologic features of an active tissue, including microvilli, ruffles, and intercellular openings.[118] The endocardium participates in the formation of endocardial cushions at the AV junction and in the outflow tract.[119] Transdifferentiation of the endocardium occurs in the endocardial cushions, where cells round up, produce pseudopodia, and migrate into the cardiac jelly.[120] These cells eventually make up a portion of the fibrous skeleton of the cardiac valves. Inductive chemical signals from the myocardium contribute to the endocardial transdifferentiation and regulate the migration of the mesenchymal cells.[120] In addition, hemodynamic alterations can influence the orientation of endocardial cells on the endocardial cushions[121] and the loci of dead and dying cells in the chick embryo heart.[122] This interaction likely is similar to the relation between the endothelium and smooth muscle of the mature vascular bed.[123] Finally, expansion of the endocardium is critical to the process of ventricular trabeculation, as is discussed below.

Looping

Following the formation of the straight heart tube, the human embryo is about 2 mm long and 23 days old. At the cephalic (or cranial) end of the myocardial heart tube, the nonmyocardial aortic sac can be recognized. The aortic sac is connected to the first pair of aortic arches and later also to the second, third, fourth, and sixth arches (the fifth pair of aortic arches does not normally develop in mammals or is very rudimentary). The extreme caudal part of the myocardial tube receives the paired confluence of veins that lie extrapericardially and are embedded in mesenchyme. In the early tubular stage, the heart hangs suspended from the ventral foregut by the so-called dorsal mesocardium. This structure disintegrates in the midportion of the tube, leaving the heart connected at the anterior pole at the level of the aortic sac and at the posteriorly located venous pole (atria and sinus venosus). At least three different biomechanical mechanisms may act in combination to generate the characteristic bend to the right of the cardiac tube: locally constrained growth, active cell deformation, and prestressed dorsal mesocardium.[124]

As the tubular heart continues to grow, it bends to the right and anteriorly (Fig. 9-4). This results in a compound sigmoid structure with a so-called d-loop (rightward) configuration. At this stage, it is easy to distinguish the sinus venosus, the common atrium, the atrioventricular canal, the future left and right ventricles, and the outflow segment. Internally, the developing muscular interventricular septum is recognizable, its crest characteristically expressing the molecular marker GLN2/HNK-1.[125,126] It is important to note that at this stage, all the future segments of the heart are still basically connected in series and that the common atrium connects, via the atrioventricular canal, completely to the left ventricle [i.e., double-inlet left ventricle (DILV)], while the outflow tract is connected exclusively to the right ventricle [i.e., double-outlet right ventricle (DORV)]. This is schematically depicted in Fig. 9-5.

The transition from a tubular heart in which the future segments are arranged in series (atrium to LV to RV to outflow tract) into a four-chambered heart in which the definitive chambers are arranged in parallel, separated by septa and valves, raises two important questions. The first is how the right atrium becomes connected to the right ventricle, and the second is how the left ventricle gains access to the aortic portion of the outflow tract. The remodeling of the so-called inner curvature of the looping heart tube plays an important role in this process and involves a rightward expansion of the AV canal and a concomitant leftward shift of the aorta. Immunohistochemical studies have demonstrated that this remodeling is intimately related to the development of the so-called primary ring (Fig. 9-6).[125,126] In the postnatal human heart, derivatives of the primary ring are found in the AV conduction system, in the right AV junction

(the right AV ring), and behind the aorta (the retroaortic root branch) (Fig. 9-7).[126]

ANOMALIES

Ventricular Inversion with Transposition of the Great Arteries

If the cardiac tube loops to the left and anterior (L-loop) rather than to the right and anterior, most of the structures adjacent to and including ventricular segments of the heart tube (the AV valves, the ventricles, and the arterial roots) will develop in an inverted position. Subsequently, the right atrium is connected via a morphologic mitral valve to a morphologic left ventricle and the left atrium is connected via a morphologic tricuspid valve to a morphologic right ventricle. Within the aortic sac, the aorticopulmonary septum develops in a normal fashion. However, as partitioning of the inverted conotruncus (outflow track) takes place in mirror image, the end result is L-transposition of the great arteries, with the aorta arising anteriorly from a left-sided, morphologically right (systemic) ventricle and the pulmonary trunk arising posteriorly from a right-sided, morphologically left (venous) ventricle. Because systemic and pulmonary venous return are still routed to the pulmonary and systemic arterial circulations, respectively, this anomaly commonly is referred to as "corrected" transposition.

Double-Outlet Right Ventricle

DORV is due to a failure in the leftward repositioning of the aortic portion of the outflow tract, resulting in the persistence of the more "primitive" embryonic morphology in which the entire outflow tract originates from the right ventricle. One morphologic hallmark of the failure of completion of the leftward shift of the aorta is the presence of myocardial tissue between the left AV valve and the aorta (mitral-aortic separation). This anomaly is found after a wide range of hemodynamic, metabolic, and genetic insults to the embryo, suggesting that the phenotype of the DORV may be a final common expression of a range of primary abnormalities that result in the persistence of the embryonic configuration.[127]

Myocardial Trabeculation

The processes of primary myocardial trabeculation, expansion of secondary and tertiary myocardial trabeculae, and myocardial compaction are critical to the structural maturation of the ventricular chambers. This process results in the transformation of the smooth-walled endocardial lining into complex three-dimensional structure of the right and left ventricular myocardium. Rapid cell division and interposition of endothelial cells along the right and left ventrolateral borders of the endocardial tube is associated with a rapid resorption of cardiac jelly, resulting in myocardial ridges and trabeculae lined with single layers of endocardial cells.[128] The initial number and orientation of the myocardial ridges differ between species.[129] In general, myocardial trabeculation begins at the ventricular outer curvature (future apex) and then extends proximally and distally. The intersection between the outer, compact myocardium and the base of the trabeculae probably is a site of peak wall stress, and myocyte division is most active at this site.[130,131] Retroviral marker studies also have shown that ventricular myocardial growth is associated with a transmural distribution of clonally related myocardial cells extending from the epi- to the endocardium.[79,80] Of note, these cells reside in muscle bundles that are oriented at an angle to the longitudinal axis of the heart, consistent with the adult myocardial architecture that results in efficient twist and contraction.[79,80] However, the mechanisms that regulate clonal myocardial expansion and compaction have not been defined.

With the onset of myocardial trabeculation, diverticula first appear as two sharply defined areas along the right and left ventrolateral borders of the endocardial tube (Fig. 9-8).[132] These diverticula develop initially at the expense of the cardiac jelly and later penetrate the myocardium

as it increases in thickness, producing a spongy mass of trabeculae.[128] The filling capacity of the heart is increased by the added intertrabecular spaces. The trabeculating embryonic heart now can be divided into primitive right and left ventricles as there are distinct morphologic differences between the trabecular architectures of the developing ventricular chambers. The developing LV is trabeculated along the majority of its greater curvature, while the developing RV has a significant portion of the greater curvature that is smooth-walled.[133] At this stage of development, the embryo is approximately 3 mm long and has an ovulation age of about 25 days.[107] The common outflow tract of the developing heart can be classified as having a proximal (conus) segment and a distal (truncus) segment. The conus eventually septates into the outflow portions of each ventricle with the incorporation of migrating neural crest cells, while the truncus contributes to the formation of the semilunar valves and the development of the aortic and pulmonary roots.

ANOMALIES

Noncompaction of the Ventricular Myocardium

Noncompaction of the ventricular myocardium is a rare, familial congenital cardiomyopathy that results from incomplete compaction of the trabecular embryonic myocardium.[134,135] The characteristic echocardiographic findings consist of multiple, prominent myocardial trabeculations and deep intertrabecular recesses communicating with the left ventricular cavity. The disease uniformly affects the left ventricle with or without concomitant RV involvement and results in systolic and diastolic ventricular dysfunction and clinical heart failure. Recent studies have characterized this disease in both children and adults. A higher incidence of Wolff-Parkinson-White syndrome was found in children, whereas left bundle branch block was more rare than reported in adults. Familial recurrence is high.[136] Recently, a case of ventricular noncompaction was identified in a patient who also had a haplotype deletion on the long arm of chromosome 5.[137] The affected region included the locus for the cardiac-specific homeobox gene *Nkx2.5*, suggesting an association between ventricular myocardial noncompaction and haploinsufficiency of *Nkx2.5*.

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

MECHANISMS OF CARDIAC SEPTATION

Cardiac and Extracardiac Orientation

Because of rapid growth and the progressive curvature of the longitudinal axis of the embryo during organogenesis, it is critical to define cardiac morphogenesis, including septation, with reference to extracardiac morphologic landmarks that relate to the longitudinal axis of the embryo.[138] In the following discussion of cardiac septation, therefore, the diaphragm (septum transversum) is assumed to maintain an approximately horizontal position, as it does in the mature heart. The terms *anterior*, *posterior*, *superior*, and *inferior* are employed accordingly. Although the formation of the various cardiac septa occurs almost simultaneously, for clarity it is necessary to consider their development separately.

Cardiac Septation

Cardiac septation involves the formation of several septal (myocardial and mesenchymal/fibrous) and valvar structures. All the original tissues of the tubular heart (myocardium, endocardium, endocardial cushion tissues) as well as the so-called extracardiac cell populations, which arrive in the heart at relatively late stages of development (neural crest, epicardium, ventral neural tube cells), appear to play a role during valvuloseptal morphogenesis.

The Sinus Venosus

In the 3-mm human embryo, the sinus venosus consists of a central, transverse portion of the sinus venosus and the right and left sinus horns (Fig. 9-9). The sinus venosus receives three pairs of veins: the omphalomesenteric (vitelline) veins, the umbilical (allantoic) veins, and the common cardinal veins. The proximal portions of the umbilical veins soon disappear. As a result of the increased blood flow associated with the right and left systemic veins, the right sinus horn and the proximal cardinal and vitelline veins attain a vertical position, increase in size, and form the smooth-walled, intercaval part of the atrium. The transverse portion and the proximal left sinus horn become the coronary sinus. Infolding of the sinoatrial junctional tissue at the right border of the sinoatrial foramen results in the formation of the right venous valve.[139,140] The left valve develops as a result of active growth, similar to that of the primary atrial septum (i.e., the left valve does not develop as a fold) (Fig. 9-10). Thus, the vertical sinoatrial orifice is flanked on each side by a valvelike structure in the 4- to 6-mm human embryo. Superiorly, the venous valves join to form the septum spurium. The venous valves, particularly the right venous valve, are relatively large in the 16-mm embryo. The superior aspect of the right venous valve eventually develops into the crista terminalis, or terminal crest. The left sinus valve fuses partly with the atrial septum. Inferiorly, the left venous valve intersects with the inferior part of the right venous valve. As a result, the right venous valve becomes divided into the relatively large inferior vena caval (or eustachian) valve and a smaller coronary sinus (or thebesian) valve.

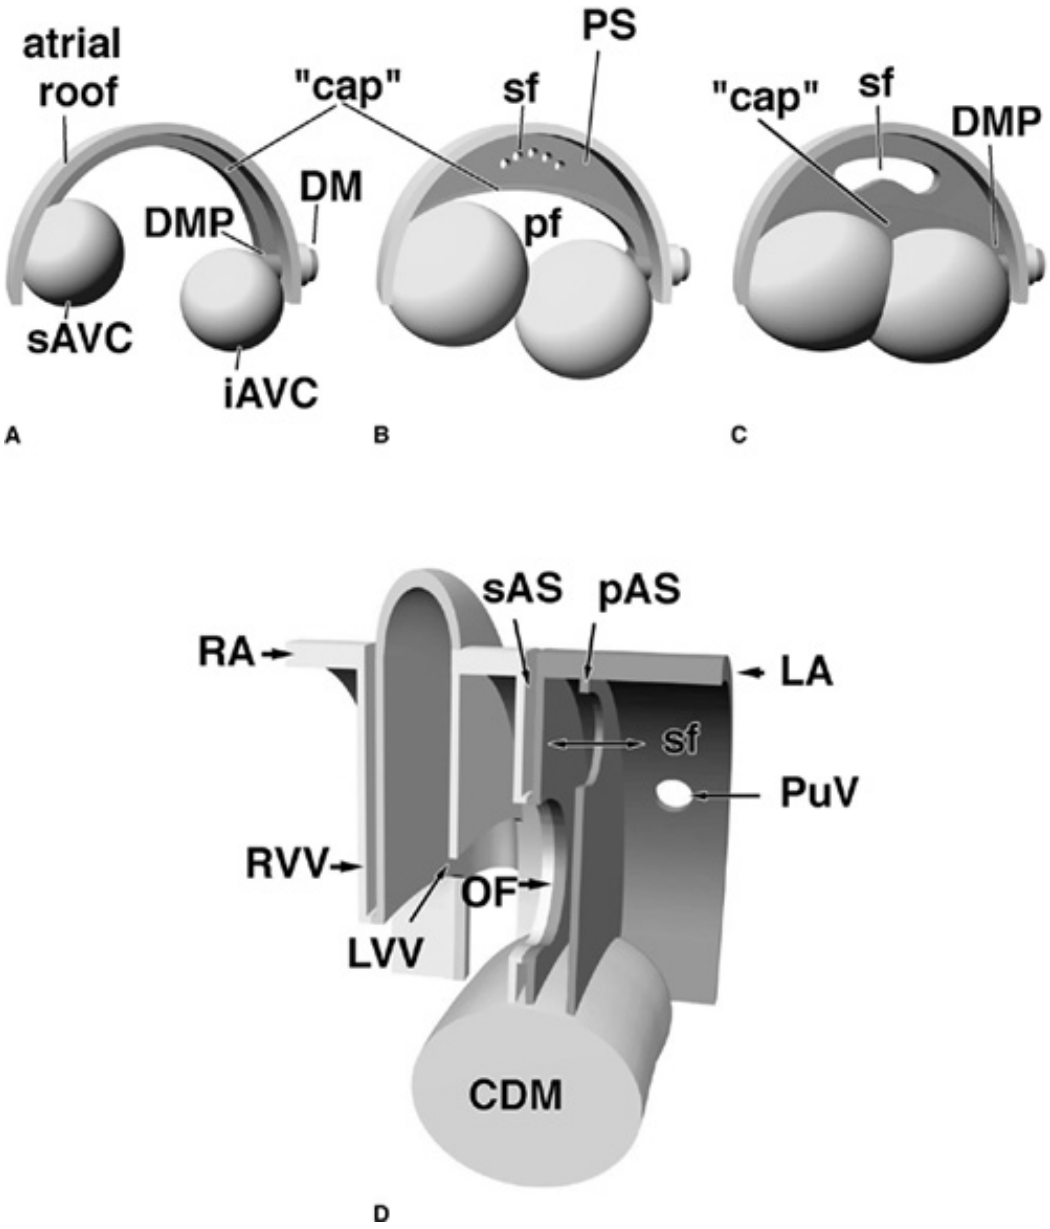

Figure 9-10: A model for the development of the atrial septal complex in the human heart. Panels *A-C* of this cartoon illustrate the key events in the formation of the primary atrial septum (*A-C*). Panel *D* schematically depicts the formation of the atrial septum and venous valves. Panel *A* represents a heart at approximately 4½ weeks of development. The AV cushions can be distinguished but have not yet fused. The leading edge of the primary septum is covered by a mesenchymal cap which is in continuity with the dorsal mesenchymal protrusion of the dorsal mesocardium. Panel *B* represents the situation at approximately 6 weeks of development. The leading edge of the primary atrial septum, covered with a mesenchymal cap, is now approaching the AV cushions, which are in the process of fusing. Within the myocardial portion of the primary septum, multiple fenestrations represent the developing secondary foramen. Completion of fusion of the mesenchymal tissues at 6 to 7 weeks of development (panel *C*) results in the closure of the primary interatrial foramen. At this time, a prominent secondary foramen can be found within the superior portion of the primary septum. The cartoon in panel *D* shows how the secondary atrial septum is formed as a result of infolding of the atrial roof. This occurs at the margin between the myocardium and the left and right atrial expression domain. The myocardium of the primary atrial septum is part of the left atrial expression domain; the orifice of the pulmonary vein also is surrounded by myocardium with a left atrial molecular phenotype. This panel also illustrates that based on the gene expression patterns, the left venous valve develops as a myocardial structure with a right atrial molecular phenotype, whereas the right venous valve (just like the secondary atrial septum) develops by infolding, in this case of the junctional tissue between the right atrium

and the sinus venosus. iAVC = inferior atrioventricular cushion; sAVC = superior atrioventricular cushion; DM = dorsal mesocardium; DMP = dorsal mesenchymal protrusion; pf = primary foramen; PS = primary atrial septum; sf = secondary foramen; LA = left atrium; RA = right atrium; OF = oval fossa; pAS = primary atrial septum; sAS = secondary atrial septum; PuV = pulmonary vein; LVV = left venous valve; RVV = right venous valve (From Wessels et al.[139])

ANOMALIES

Cor Triatriatum Dexter

Complete persistence of the right venous valve of the embryonic heart produces a septum in the right atrium, separating the intercaval part of the right atrium from the atrial body. The remaining opening may be quite small and restrictive.

Persistent Left Superior Vena Cava

Persistence of the left common cardinal vein and left sinus horn results in a left superior vena cava draining into the coronary sinus.

Atrial Septation

Septation of the embryonic common atrium involves two distinct mechanisms.[139] The primary atrial septum (septum primum) forms by active growth of a myocardial septum. Initially, the primordium of this septum can be seen as a ridge in the medical roof of the common atrium. The leading edge of the ridge is covered with a mesenchymal cap which is superiorly continuous with the superior AV cushion and inferiorly with the inferior AV cushion. As the primary septum descends from the roof of the atrium toward the atrioventricular canal, thus decreasing the size of the primary interatrial foramen, the mesenchymal leading edge continues to fuse with the AV cushions, which are also in the process of fusing. These events result in closure of the primary interatrial foramen (or ostium primum) and the formation of the central fibrous body (see Figure 9-12). Concomitantly, perforations appear in the superior aspect of the primary. The perforations coalesce, resulting in the secondary atrial foramen (ostium secundum). Next, the secondary atrial septum develops as an infolding of the atrial roof located between the primary septum and the left venous valve. The foramen ovale is the opening bordered by the free edge of the septum secundum. After fusion of the septum primum with the septum secundum, the foramen ovale becomes the fossa ovalis.

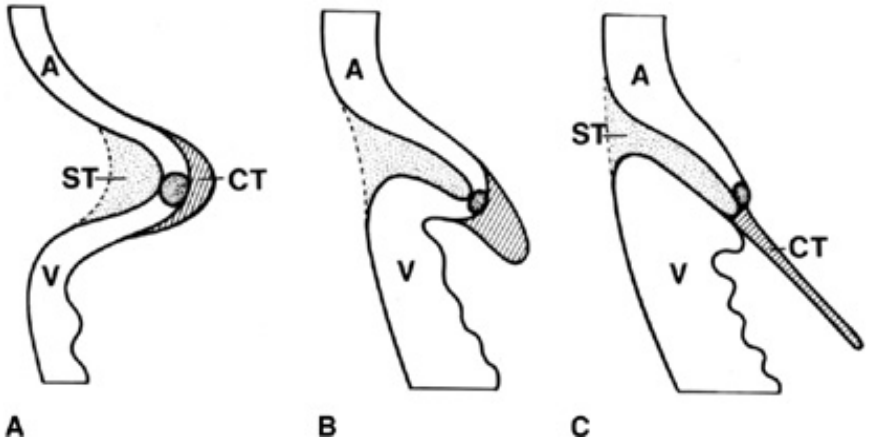

Figure 9-12: Schematic drawings of the formation of the atrioventricular junction in the human

heart. *A*. The situation at the atrioventricular junction at 4 to 5 weeks of development. Myocardial continuity between atrium and ventricle occurs through the myocardium of the atrioventricular canal. The AV junction is sandwiched between the tissues of the AV sulcus at the epicardial side and the AV cushion at the endocardial side. *B*. With progressive remodeling of the AV junction, the sulcus tissues expand toward the midline of the AV canal as the cushion tissue remodels. *C*. With completion of this process, continuity is lost between atrial and ventricular myocardium. A = atrium; V = ventricle; ST = sulcus tissue; AV = myocardium of the atrioventricular canal; CT = cushion tissue. (Adapted from Wessels et al.[148])

Development of the Pulmonary Veins

The so-called pulmonary pit, the future portal of entry for the main pulmonary vein, is recognizable at around 28 days of gestation and is situated in the midline of the inferior portion of the common atrium before atrial septation is initiated. The pulmonary pit is flanked by two myocardial reflections that are referred to as the left and right pulmonary ridges, respectively.[141] This pulmonary pit, actually an invagination of the endocardium into the dorsal mesocardium, can be traced toward the pulmonary mesenchyme as an endothelial strand. Remodeling of the tissues surrounding the pulmonary pit results in incorporation of the ostium of the pulmonary vein in the wall of the left ventricle.

ANOMALIES

Atrial Septal Defect at the Fossa Ovalis

This defect, which often is referred to as a secundum-type atrial septal defect, is due to malformation of the primary atrial septum, resulting in an oversized ostium secundum. Frequently, the atrial defect is further enlarged by a hypoplastic septum secundum. Total absence of both the septum primum and the septum secundum (common atrium) is rare and almost always is associated with a form of persistent AV canal.

Anomalous Pulmonary Venous Connection

The total form of anomalous pulmonary venous connection presumably is due either to lack of development or to a premature involution of the common pulmonary vein. A number of types of pulmonary venous to systemic venous connections occur, depending on which of the early embryonic channels connecting the pulmonary venous bed to the systemic venous circulation remains patent.

Cor Triatriatum Sinister

If incorporation of the common pulmonary vein into the left atrium does not take place and the common pulmonary venous ostium remains narrow, the result is a septum-like structure that may derive from the left pulmonary ridge and divides the left atrium into two components: One receives the pulmonary veins, and the other gives access to the mitral valve and the left atrial appendage.

The Atrioventricular Canal

Division of the AV canal into left-sided and right-sided orifices occurs as a result of fusion of the superior and inferior AV cushions, which are first evident in the 6-mm crown-rump (CR)-length human embryo. At this stage, the common AV canal is located exclusively over the left ventricle. The superior aspect of the developing interventricular septum is continous with the right aspect of the AV junctional myocardium. The communication between the developing right atrium and the

right ventricle is established by the rightward expansion of the AV canal. This expansion, combined with tissue remodeling, brings the right margin of the original AV junction, which still is in continuity with the posterior part of the interventricular septum, toward the posteromedial aspect of the AV junction, where it will form the AV node.[16,125]

Myocardialization

The term *myocardialization* refers to the process of active ingrowth of existing myocardium into mesenchymalized tissues of the heart. In the human heart, it takes place primarily in the conal septum, where it transforms the mesenchymal outlet septum, which is formed as a result of fusion of the conal ridges of the outflow tract, into the muscular outlet septum (Fig. 9-11).[142] It is believed that myocardialization is the driving force for the incorporation of the aortic portion of the outflow tract into the left ventricle and the rightward expansion of the AV junction. Absence or inhibition of myocardialization is associated with structural congenital heart disease in a number of experimental animal models.[143] Most of these malformations involve malalignment of the outlet septum with the muscular interventricular septum, resulting in ventricular septal defects with varying great vessel size disparity.[110]

Meanwhile, the AV canal has enlarged to the right, while the growing endocardial cushions project into the lumen. Smaller cushions appear on the lateral borders of the AV canal. In the 10-mm CR-length embryo, the major cushions reach each other and fuse, resulting in a complete division of the canal into right and left AV orifices. At the same time the cushions also bend, and after fusion they form an arch that is concavely directed anteriorly and toward the left ventricle[143] with its convexity directed anteriorly and toward the atria. The mesenchymal cap on the free margin of the atrial septum primum fuses with the convex atrial side of the fused endocardial cushions. The left limb of the fused AV cushion eventually becomes incorporated into the anterior cusp (aortic leaflet) of the mitral valve. The right half of the fused endocardial cushions comes to lie within the ventricles in a sagittal orientation somewhat to the right of the muscular interventricular septum. Thus, the communication that remains between right and left ventricles, the secondary interventricular foramen, is bordered by the muscular ventricular septum inferiorly and anteriorly, the right extremity of the fused endocardial cushions posteriorly, and the conal septum superiorly. The plane of the secondary interventricular foramen therefore inclines somewhat to the right; that of the primary interventricular foramen, as we have seen, has come to deviate to the left. Both interventricular foramens share the top of the muscular septum as part of their inferior borders.

ANOMALIES

Partial and Complete AV Canal Defect

The several forms of persistent AV canal are due to various degrees of failure of fusion of the superior and inferior AV canal cushions. Total lack of fusion results in a single AV ostium, i.e., the complete form of the anomaly. Since the arch or bay normally formed after the fusion of the endocardial cushions fails to develop, the lower mesenchymal border of the atrial septum cannot fuse with the endocardial cushions. The result is a low-lying large interatrial communication, and the AV part of the cardiac septum is absent. The upper part of the ventricular septum remains deficient to a greater or lesser degree, and there is an interventricular communication. In the partial forms, the endocardial cushions fuse only centrally. The result is an interatrial communication or so-called ostium primum-type atrial septal defect. The upper part of the muscular ventricular septum remains deficient, but this area of the ventricular septum is closed by fibrous tissue. Because the left side of the endocardial cushions does not fuse, the anterior or aortic cusp of the mitral valve is cleft. AV septal defects frequently are associated with trisomy 21 in humans and trisomy 16 in mice.[127] Genetic markers in patients without trisomy 21 also are

under investigation.

Ventricular Septal Defect

Some forms of perimembranous ventricular septal defect may be due to failure of fusion of the right extremity of the fused endocardial cushions, the upper border of the muscular ventricular septum, and the conal septum. Since the endocardial cushions fuse normally, there is no cleft in the anterior mitral valve cusp, and there also is no interatrial communication.

Single Ventricle, Left Ventricular Type with Rudimentary Outflow Chamber, or Double-Inlet Left Ventricle.

If the AV canal becomes divided into two separate ostia (by the fusing AV cushions) but fails to expand to the right, thus retaining its far leftward position, both ostia connect only to the primitive left ventricle. As a result, a communication between the right atrium and the right ventricle does not develop. The communication between the large ventricular chamber (i.e., left ventricle) and the rudimentary outflow chamber (i.e., right ventricle) represents the persistence of the primary interventricular foramen.

The Ventricles

As was mentioned above, the AV canal communicates exclusively with the primitive (or embryonic) left ventricle in the 5-mm CR-length human embryo and blood from the left ventricle reaches the primitive (or embryonic) right ventricle only by way of the primary interventricular foramen. In the developing human heart, the myocardium surrounding the interventricular foramen is characterized by the expression of the GFlN2/HNK antigen and is termed the "primary interventricular ring."[125]

The ventricles enlarge through centrifugal growth of the myocardium. The trabecular myocardium progresses from primary to secondary to tertiary trabeculations, while the compact outer myocardial layer remains relatively thin.[144] Coalescence of the secondary trabeculations into larger tertiary trabeculations occurs after septation, coincident with the formation of the AV valve leaflets.[145] The trabeculae positioned at the border between the developing left and right ventricle coalesce to form the major portion of the muscular ventricular septum.[145] On the right side, a large trabecula, the trabecula septomarginalis,[146] appears early (in embryos about 9 mm in CR length) and runs from the anteroinferior border of the primary interventricular foramen toward the apex.

ANOMALIES

Muscular Ventricular Septal Defect

Failure of compaction and fusion of the trabecular portion of the ventricular septum results in the most common congenital cardiovascular anomaly, the isolated muscular ventricular septal defect.

The Truncus Arteriosus

The embryonic "outflow tract" consists of the conus, truncus, and aortic sac and functions as the conduit between the primitive right ventricle and the aortic arches. Septation of the conotruncal area of the outflow tract begins in embryos about 6 mm in CR length with the appearance of two opposing truncal cushions. One of these cushions is located along the dextrosuperior truncal endocardium (dextrosuperior truncal cushion), and the other on the sinistroinferior wall (sinistroinferior truncal cushion). Coincident with the expansion of the conotruncus, the cushions

rapidly enlarge and fuse to form the truncal septum, thus dividing the truncus into aortic and pulmonary channels. The truncus is the first part of the heart to septate (at the 7-mm CR-length stage). Proximally, the truncal cushions merge with the superior aspects of the conal cushions, which are the comparable mesenchymal masses within the conus. Distally, the undivided portion of the truncus and the aortic sac enlarge to form the truncoaortic sac. Simultaneously, the origin and course of the sixth arches shift leftward, aligning with right ventricular outflow, and the origin and course of the fourth aortic arches shift rightward, aligning with left ventricular outflow. At the same time, a population of cells derived from the cardiac neural crest contributes to the formation of a vertical septum, the aorticopulmonary septum (APS), in the aortic sac.[89] The APS fuses with the truncal septum to complete septation of the aorta and the pulmonary trunk.[127,133,143,146,147]

ANOMALIES

Persistent Truncus Arteriosus

If the truncal cushions remain hypoplastic and fail to fuse, partitioning of the truncus arteriosus does not take place. If, in addition to the hypoplastic truncal cushions, both intercalated valve cushions persist, the result is a quadricuspid truncal valve. Usually, fusion occurs between adjacent valve anlagen, resulting in an apparently tricuspid truncal valve with one larger cusp containing a fused raphe. In the great majority of cases, the aorticopulmonary septum does develop, and a short common pulmonary trunk arises from the persistent trunk. The ductus arteriosus is almost always absent, except when it is associated with interruption of the aortic arch. In experimental models, persistent truncus arteriosus can be produced after selected ablation of neural crest tissue, as was mentioned above.[85]

Aorticopulmonary Septal Defect

This anomaly may be due to malalignment and/or failure of fusion between the distal truncal septum and the aorticopulmonary septum. Both arterial valves are present, but there is a communication of varying size (aorticopulmonary window) between the ascending aorta and the pulmonary trunk.

The Conus

The conal cushions make their appearance at about the same time as the truncal cushions. One is located on the dextrodorsal wall, and the other on the sinistroventral wall of the conus. On the right side, the dorsal conal cushion becomes contiguous with the superior truncal cushion, and on the left, the ventral conal cushion becomes contiguous with the inferior truncal cushion. Fusion of the conal cushion begins proximally and then progresses rapidly, completing the partition of the conal septum by the 14- to 15-mm CR-length stage in the human embryo. Conal septation reduces and then closes the small secondary interventricular foramen, which was bordered by the conal septum, the top of the muscular ventricular septum, and the right extremities of the fused endocardial cushions. The mesenchymal conal septum eventually becomes muscularized by myocardialization, resulting in the muscular outlet septum.[142]

ANOMALIES

Ventricular Septal Defect, Eisenmenger Type

A large basilar septal defect, dextroposition of the aortic valve, and a hypoplastic or absent infundibular septum probably are due to hypoplasia or absence of the conal cushions.

Ventricular Septal Defect, Supracristal Type

The supracristal type of ventricular septal defect probably is due to either simple failure of truncal and conal septal fusion or septal malalignment, which prevents fusion.

Tetralogy of Fallot

The primary anomaly in tetralogy of Fallot probably is an anterior displacement to a varying degree of the conal septum, leading to unequal partitioning of the conus and reduction of the right ventricular infundibulum. A large basilar ventricular septal defect and dextroposition of the aortic valve result from failure of the displaced conal septum to participate in closure of the interventricular foramen. Pulmonary vascular hypoplasia probably is a secondary result of diminished forward blood flow. As was mentioned above, tetralogy of Fallot frequently is associated with 22q11 deletion, particularly in the setting of severe pulmonary atresia or when associated with extracardiac anomalies.

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

DEVELOPMENT OF THE HEART VALVES

The Atrioventricular Valves

Initially, the tubular embryonic heart functions as a peristaltoid pump, relying on endocardial cushions to function as valves and regional variations in conduction velocity to facilitate forward flow. The endocardial cushions develop in the areas characterized by slow contraction and relaxation and, in combination with the specialized myocardium with which they are associated, serve to promote antegrade blood flow. Initially, it is possible to distinguish only two AV cushions: the inferior (iAVC) and the superior (sAVC) cushions. Fusion of these two cushions results in the formation of the two AV orifices. At later stages, the so-called lateral AV cushions appear. Over time, the cushion-derived tissues develop into the thin mature AV valve cusps.[148] The sAVC contributes to the aortic leaflet of the mitral valve, and the iAVC to the septal and posteroinferior leaflet of the tricuspid valve. The right lateral AVC contributes to the formation of the anterosuperior leaflet of the tricuspid valves, and the left lateral AVC is involved in the formation of the parietal leaflet of the mitral valve. Although the cushion-derived tissues form the main component of the leaflets (Fig. 9-12), it is important to note that an essential step in the morphogenesis of the valves is the delamination of the developing leaflets from the underlying ventricular myocardium.[149,150]

ANOMALIES

Tricuspid Valve Atresia and Mitral Valve Atresia

Tricuspid and mitral valve atresias are anomalies that probably are due to abnormal formation and/or premature fusion of the endocardial cushion tissue that borders the AV canal during or shortly after partitioning of the AV canal.

Ebstein's Anomaly of the Tricuspid Valve

Ebstein's anomaly of the tricuspid valve probably is due to an abnormality in the process of myocardial delamination required for AV valve and chordal formation.

The Arterial Valves

The primordia of the semilunar valves become visible as small tubercles on the distal extensions of each truncal cushion after truncal partitioning in the 9-mm embryo. One of each pair is assigned to the pulmonary and aortic channels, respectively. On the walls of both aortic and pulmonary channels, opposite the fused truncus cushions, a third small cushion appears.[146] These two intercalated valve cushions form the third member of each arterial valve primordium. Both the aortic and pulmonary roots, consisting of the sinuses of Valsalva and the semilunar valves, probably are derived from the truncus arteriosus and the truncal and intercalated valve cushions.

ANOMALIES

Bicuspid Arterial Valves

A bicuspid aortic or pulmonary valve is due to a failure of development of an intercalated valve cushion, resulting in a valve with two equal-size cusps, neither containing a raphe, or to fusion of adjacent valve anlagen, in which case the cusps are generally unequal in size, with the larger containing a raphe of varying length.

Arterial Valve Stenosis or Atresia

Fusion of two or all three of the arterial valve anlagen probably results in stenosis or atresia of the valve.

Absent Arterial Valves

Failure of the arterial valve anlagen to develop may explain the rare occurrence of absence of the pulmonary or aortic valve.

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

AORTIC ARCH DEVELOPMENT

Aortic arch development involves the sequential development and then the involution of six arch pairs. The first pair of arches in the 3-mm CR-length embryo is large when the second pair is just forming (Fig. 9-13*A*). Caudally, the dorsal aortas fuse to 0form a single vessel, and then vessel fusion progresses cranially. In a 4-mm embryo, the first and second arches have largely disappeared (Fig. 9-13*B*). The third aortic arch is well developed, and the fourth and sixth arches are being formed as ventral and dorsal sprouts of the aortic sac and dorsal aorta, respectively. The ventral portion of the sixth arch already has as its major branch the primitive pulmonary artery even though the arch itself has not yet been completed. Of note, in mammals the fifth aortic arch is rudimentary. By the 10-mm embryo stage, the first two aortic arches have regressed; the third, fourth, and sixth are present; and the truncoaortic sac has been divided by the formation of the aorticopulmonary septum so that the six arches are now continuous with the pulmonary trunk (Fig. 9-13*C*). Of note, the seventh cervical intersegmental arteries arise from the dorsal aorta near the midline and form the subclavian arteries. In a 14-mm embryo, the dorsal aortas between the third and fourth arches have disappeared and the third arches begin to elongate (Fig. 9-13*D*). At this point, the dorsal portion of the right sixth arch has disappeared, though the left sixth arch persists as the ductus arteriosus. The aortic sac has been broadened to contribute to the brachiocephalic trunk on the right and part of the definitive aortic arch up to the origin of the left third arch (common carotid artery). Finally, by the 17-mm embryo stage, the right dorsal aorta has become atrophic between its junction with the left dorsal aorta and the origin of the right seventh intersegmental artery has become attenuated and later disappears (Fig. 9-13*E*). The remaining components of the right dorsal aorta and right fourth aortic arch form the proximal subclavian artery. After birth, the distal part of the left sixth aortic arch, the ductus arteriosus, normally also involutes to form the ligamentum arteriosum. Thus, most aortic arch anomalies are secondary to abnormal retention or disappearance of various embryonic segments.

Anomalies

PATENT DUCTUS ARTERIOSUS

Persistence of the ductus arteriosus postnatally frequently occurs in permature infants as a result of delayed ductal involution. However, persistence of a large ductus arteriosus also occurs in isolation and in association with a variety of congenital cardiovascular malformations.

DOUBLE AORTIC ARCH

Double aortic arch is a result of persistence and continued patency of the segment of the right dorsal aorta between the origin of the right seventh intersegmental artery and its junction with the left dorsal aorta.

RIGHT AORTIC ARCH

In the right aortic arch anomaly, the right rather than the left dorsal aorta is maintained in its entirety. The branching pattern of the aortic arch therefore will be the mirror image of normal, with the brachiocephalic (innominate) artery arising as the first vessel on the left side rather than

the right side.

ANOMALOUS SUBCLAVIAN ARTERY

The subclavian artery can arise from the aortic arch distal to the left subclavian artery if the right dorsal aorta between the origin of the right seventh intersegmental artery and the junction with the left dorsal aorta is maintained to form the proximal portion of the right subclavian artery.[150]

INTERRUPTED AORTIC ARCH

Interrupted aortic arch anomaly type B results from the disappearance of the left fourth aortic arch (type A is a form of coarctation of the aorta) and has been shown in the mouse embryo to represent a unique population of neural crest cells.[150] The ascending aorta terminates as the brachiocephalic and left common carotid arteries and is isolated from the descending aorta, which is perfused by the pulmonary trunk by way of a patent ductus arteriosus. In the setting of an interrupted aortic arch, an anomalous right subclavian artery is frequently present because of comparable unique neural crest patterning of this vessel.[150]

ABSENT LEFT PULMONARY ARTERY

The left pulmonary artery is almost always absent in that it arises from a left-sided ductus arteriosus (or ligamentum arteriosum). This anomaly results from disappearance of the proximal left sixth arch. If in this anomaly the aortic arch is on the left side, the ductus arteriosus that feeds the intrapulmonary part of the left pulmonary artery arises from the usual position on the underside of the arch. If the aortic arch is on the right, the ductus arteriosus usually arises from the brachiocephalic trunk with the left common carotid and left subclavian arteries as a trifurcation or, rarely, from a diverticulum of the descending aorta. Usually the left subclavian artery in such cases also arises from the diverticulum.

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

CORONARY ARTERY DEVELOPMENT

Endothelial Cell Origin

Coronary vascular endothelial maturation closely parallels the development of the embryonic epicardium.[151] A series of cell-fate studies has revealed that the coronary endothelial cells as well as coronary smooth muscle cells derive from the so-called proepicardium, a cluster of cells attached to the ventral wall of the sinus venosus. As cells from the proepicardium spread out and cover the surface of the heart, a subpopulation of epicardially derived cells (EPDCs) transdifferentiate and migrate into the myocardial cell layers,[152-155] where they contribute to the formation of the coronary network. A part of this network reaches the mesenchymal border of the aortic annulus.[151] Initially, multiple connections between the coronary vascular plexus and the aortic root are present; however, only two connections persist. It is interesting to note that the heart begins to pump blood before perfusion by the coronary vasculature occurs, indicating that in these early stages, local diffusion of nutrients is sufficient for the early trabecular myocardium.

Vascular Smooth Muscle Cell Origin

Antibodies to smooth muscle alpha-actin document that the maturation of coronary smooth muscle precedes the maturation of the outflow vessels.[156] Several studies have demonstrated that coronary smooth muscle is derived from the epicardially derived cells. Interestingly, the orderly development of the coronary arterial branching pattern and elastic lamina is dependent on the presence of the neural crest (NC), demonstrating that the pertubation in the development of one subpopulation of extracardiac cells (neural crest-derived cells) can lead to the abnormal development of another subpopulation (epicardially derived cells). After experimental neural crest ablation in the chick embryo, persistent truncus arteriosus associated with a single origin of the coronary arterial three occurs.[156] The distribution and symmetry of the coronary vascular are distinctly abnormal after injury to the neural crest. In addition, the elastic lamina and collagen organization of the great vessels are markedly abnormal after NC ablation, as has been noted in some congenital cardiovascular anomalies.[157]

Vasculogenesis and Adaptation

It is important to note that the maturation of the coronary vasculature, as is the case with the systemic vasculature, represents both angiogenesis (sprouting of existing vessels) and vasculogenesis (fusion of precursor cells).[158] After increased ventricular pressure loading in the chick embryo, myocardial vasculogenesis increases to match increased ventricular mass.[159] This finding is consistent with the investigation of children with pressure-overload LV hypertrophy, in whom capillary density remains unchanged.[160]

ANOMALIES

Anomalous Origin of the Left Coronary Artery

Occasionally, the left coronary artery is found to arise from the pulmonary artery, and rarely from other aortic arch vessels. The developing coronary vessels perforate the aortic annulus in

association with specific immunohistochemical markers, and so it is likely that when this patterning event is altered, anomalies occur.

Abnormal Origin and Course of Coronary Arteries

Numerous variations in the architecture and course of the coronary arteries occur in association with structural cardiovascular malformations. For example, an anomalous origin of the left anterior descending coronary artery from the right coronary artery occurs in association with tetralogy of Fallot. Unfortunately, the mechanisms for these associations have not been defined.

Coronary Arterial Fistulas

Coronary arterial fistulas occasionally occur in isolation and also occur in association with pulmonary valve atresia with an intact ventricular septum. The mechanics responsible for these anomalies are unknown.

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

CONDUCTION SYSTEM DEVELOPMENT

The development of the conduction system has fascinated cardiovascular embryologists from the moment it became clear that a subpopulation of specialized myocytes is responsible for the regulation of the cardiac impulse in the heart.[161] During the last decade, several studies have revealed new aspects regarding the development of the conduction system. Immunohistochemical studies have shown that the developing conduction system in humans and other vertebrates is characterized by the expression of a unique set of antigens and genes, some of which also are expressed in the nervous system, sometimes referred to as neuromuscular markers (Fig. 9-14).[125,162,163] Retroviral cell-targeting and -tracing methods have defined subpopulations of cardiomyocytes that differentiate into Purkinje's cells within the trabecular myocardium.[125,164,165] Altered patterns of ventricular depolarization have been recognized in association with structural heart defects, such as the pattern of depolarization noted with endocardial cushion defects, and conduction abnormalities associated with atrial septum defects, as has been observed in patients with mutations in the *Nkx2.5* and *TBX5* (Holt Oram syndrome) genes.[166]

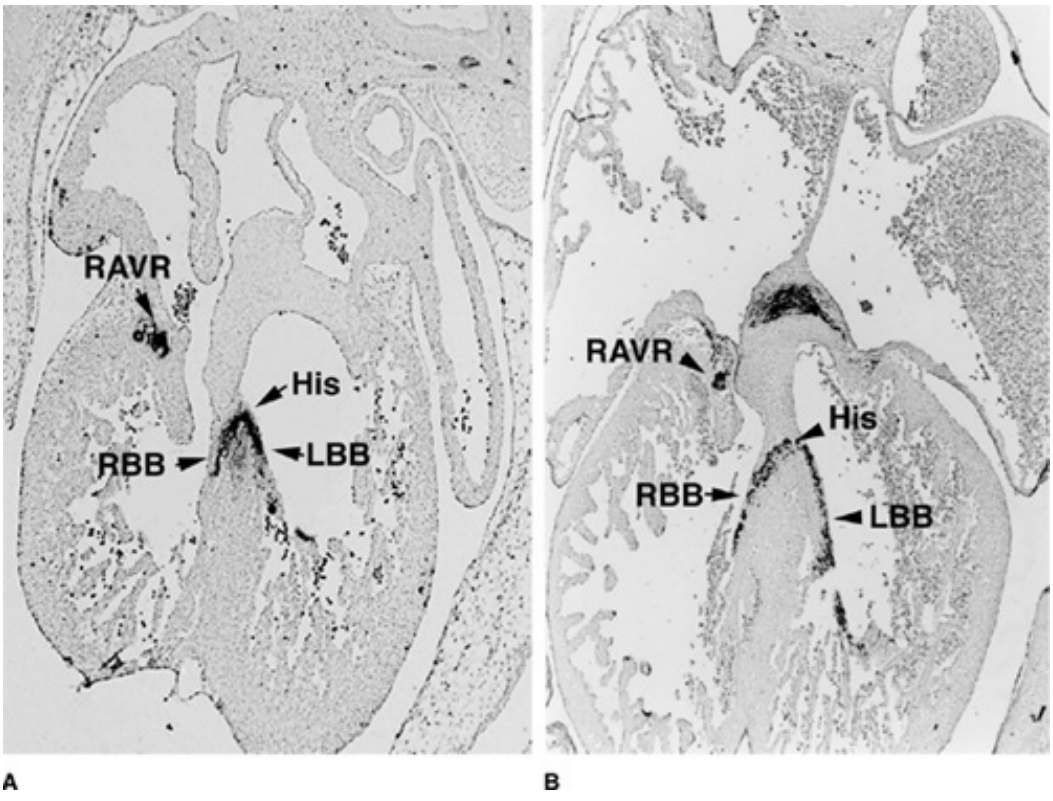

Figure 9-14: Expression of neuromuscular markers in the developing vertebrate heart. Panel *A* shows a transverse section of a human heart at 6 weeks of development immunohistochemically stained for the presence of a carbohydrate moiety recognized by the monoclonal antibody GlN2 (see also Wessels et al.[125]). The section shown in panel *B* is from a rabbit embryo at 15 days of development and is immunohistochemically stained for the presence of neurofilaments (Wessels et al.[139]). RAVR = right atrioventricular ring bundle; His = bundle of His; LBB = left bundle

branch; RBB = right bundle branch.

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

CARDIOVASCULAR INNERVATION

Despite numerous descriptive studies regarding the location of cardiac ganglia, little is known regarding the immunohistochemical cues required for the patterning of myocardial innervation. NC cell migration is critical for this process, as NC cells serve as precursors for the cardiac nerves and ganglia.[85] Cardiac ganglia and nerves are present in the 7-week gestation human embryo.[167] The density of cardiac innervation exhibits a gradient of decreasing density from the atrium to the ventricle. It is interesting to note that functional adrenergic receptors are present on the embryonic heart before histologic evidence of autonomic nerves.[168] The differential appearance and distribution of peptide-containing nerves indicate that there is a maturational order to the autonomic and sensory components of the developing human heart.[167]

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

FUNCTIONAL MATURATION OF THE EMBRYONIC HEART

Obviously, cardiovascular morphogenesis is influenced directly by the dynamic mechanical environment of the pulsatile embryonic heart. An overview of functional maturation, while critical, is beyond the scope of this chapter. The reader is referred to reviews of embryonic functional maturation in vertebrate and invertebrate species.[167,170]

Chapter 9: MOLECULAR DEVELOPMENT OF THE HEART

List of Figures

Figure 9-6: Schematic representation of the location of the so-called primary ring (characterized by the expression of the antigen GlN2) in different stages of human development. The drawings illustrate the development of the conduction system as a derivative of the primary ring but also show that the changes in the topography of the ring tissue reflects (1) the rightward expansion of the atrioventricular canal and (2) the leftward shift ("wedging") of the developing aorta. 1 = "primary ring"; 2 = right atrioventricular ring; 3 = atrioventricular nodal area; 4 = penetrating His bundle; 5 = crest of interventricular septum; 6 = septal branch; 7 = retroaortic branch. Areas indicated with an asterisk have lost their expression. The Carnegie stages of development presented in the drawings a to d are a = stage 14; b = stage 15; c = stage 17; d = stage 18-19. (Adapted from Wessels et al.[125])

Figure 9-7: Schematic representation of the localization of remnants of the primary ring in the neonatal human heart. The ring is projected on a superior view of the aortic mitral fibrous unit of the adult heart. The black dots indicate the areas in which remnants of the ring are detected in a series of neonatal hearts. 1 = anterolateral part of the right atrioventricular ring; 2 = posteromedial part of the right atrioventricular ring; 3 = "dead-end" tract of the conduction axis; 4 = lateral part of the retroaortic rootbranch; 5 = posterior part of the retroaortic rootbranch. AVN = atrioventricular node; AoV = semilunar valve of the aorta; LBB = left bundle branch; mi = mitral valve; PuV = semilunar valve of the pulmonary trunk; Rbb = right bundle branch; SB = septal branch; tri = tricuspid valve. (Adapted from Wessels et al.[126])

Figure 9-8: Schematic representation of myocardial trabecular development in the chick embryo. *A*. At the onset of ventricular trabeculation [around Hamburger-Hamilton (HH) stage 17], the process is limited to the primitive ventricle (V), while the inner curvature of the cardiac loop remains smooth. *B*. Transverse and frontal sections that show the distribution of secondary trabeculae (around HH stage 28). *C*. Mature tertiary trabecular pattern (HH stage 45). Only two of the principal bundles are shown in the left ventricle for clarity. In both ventricles, the trabeculae are arranged in a counterclockwise apicobasal spiral (viewed from base to apex). Differences between the right and left ventricles relate primarily to geometric differences (cone/crescent versus cylinder/prolate ellipsoid). Ct = conotruncus; At = primitive atrium. (Adapted from Sedmera et al.[144])

Figure 9-9: Posterior view of the atria and sinus venosus in embryos. *A*. 3-mm CR length; *B*. 5-mm CR length; *C*. 12-mm CR length. *D*. Newborn. Diagrammatic. A(C)CV = anterior (common) cardinal vein; AV = azygos vein; CS = coronary sinus; IVC = inferior vena cava; PCV = posterior cardinal vein; PV = pulmonary vein; SH = sinus horn; UV = umbilical vein; VM = vein of Marshall; VV = vitelline vein. (From Van Mierop LHS, Wiglesworth FW. Isomerism of the cardiac atria in the asplenia syndrome. *Lab Invest* 1962; 11:1303. Copyright by U.S. and Canadian Academy of Pathology.)

Figure 9-10: A model for the development of the atrial septal complex in the human heart. Panels *A*-*C* of this cartoon illustrate the key events in the formation of the primary atrial septum (*A*-*C*). Panel *D* schematically depicts the formation of the atrial septum and venous valves. Panel *A* represents a heart at approximately 4½ weeks of development. The AV cushions can be distinguished but have not yet fused. The leading edge of the primary septum is covered by a mesenchymal cap which is in continuity with the dorsal mesenchymal protrusion of the dorsal mesocardium. Panel *B* represents the situation at approximately 6 weeks of development. The leading edge of the primary atrial septum, covered with a mesenchymal cap, is now approaching the AV cushions, which are in the process of fusing. Within the myocardial portion of the primary septum, multiple fenestrations represent the developing secondary foramen. Completion of fusion of the mesenchymal tissues at 6 to 7 weeks of development (panel *C*) results in the closure of the primary interatrial foramen. At this time, a prominent secondary foramen can be found within the superior portion of the primary septum. The cartoon in panel *D* shows how the secondary atrial septum is formed as a result of infolding of the atrial roof. This occurs at the margin between the myocardium and the left and right atrial expression domain. The myocardium of the primary atrial septum is part of the left atrial expression domain; the

orifice of the pulmonary vein also is surrounded by myocardium with a left atrial molecular phenotype. This panel also illustrates that based on the gene expression patterns, the left venous valve develops as a myocardial structure with a right atrial molecular phenotype, whereas the right venous valve (just like the secondary atrial septum) develops by infolding, in this case of the junctional tissue between the right atrium and the sinus venosus. iAVC = inferior atrioventricular cushion; sAVC = superior atrioventricular cushion; DM = dorsal mesocardium; DMP = dorsal mesenchymal protrusion; pf = primary foramen; PS = primary atrial septum; sf = secondary foramen; LA = left atrium; RA = right atrium; OF = oval fossa; pAS = primary atrial septum; sAS = secondary atrial septum; PuV = pulmonary vein; LVV = left venous valve; RVV = right venous valve (From Wessels et al.[139])

Figure 9-11: Schematic drawing of some of the developmental events involved in the septation of the outflow tract. Panel *A* depicts the stage in which the endocardial cushion tissues in the outflow tract (conal cushions and truncal swellings) and the aorticopulmonary septum have not yet fused. Panel *B* illustrates that the truncal swellings contribute to the formation of the semilunar valves of the aorta and the pulmonary trunk, whereas the fusing conal cushions are forming the mesenchymal outlet septum. At this stage, the conal myocardium starts to myocardialize the outlet septum. Panel *C* shows one of the final stages. The aorticopulmonary septum has now completely separated the aorta and pulmonary trunk above the level of the semilunar valves, while below the valves the outlet septum divides the outlet segment of the heart in a subaortic and subpulmonary outlet.

Figure 9-12: Schematic drawings of the formation of the atrioventricular junction in the human heart. *A*. The situation at the atrioventricular junction at 4 to 5 weeks of development. Myocardial continuity between atrium and ventricle occurs through the myocardium of the atrioventricular canal. The AV junction is sandwiched between the tissues of the AV sulcus at the epicardial side and the AV cushion at the endocardial side. *B*. With progressive remodeling of the AV junction, the sulcus tissues expand toward the midline of the AV canal as the cushion tissue remodels. *C*. With completion of this process, continuity is lost between atrial and ventricular myocardium. A = atrium; V = ventricle; ST = sulcus tissue; AV = myocardium of the atrioventricular canal; CT = cushion tissue. (Adapted from Wessels et al.[148])

Figure 9-13: Development of the aortic arch system. Embryos of (*A*) 3 mm, (*B*) 4 mm, (*C*) 10 mm, (*D*) 14 mm, (*E*) 17 mm, (*F*) neonate. (Adapted from Congdon ED. Transformation of the aortic arch system during the development of the human embryo. *Contrib Embryol* 1922; 14:47.)

Figure 9-14: Expression of neuromuscular markers in the developing vertebrate heart. Panel *A* shows a transverse section of a human heart at 6 weeks of development immunohistochemically stained for the presence of a carbohydrate moiety recognized by the monoclonal antibody GlN2 (see also Wessels et al.[125]). The section shown in panel *B* is from a rabbit embryo at 15 days of development and is immunohistochemically stained for the presence of neurofilaments (Wessels et al.[139]). RAVR = right atrioventricular ring bundle; His = bundle of His; LBB = left bundle branch; RBB = right bundle branch.

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 10:

THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

Authors: Robert A. O'Rourke, James A. Shaver, Mark E. Silverman

In the assessment of patients with definite or suspected heart disease, relevant information can be acquired from the history, physical examination, chest roentgenogram, electrocardiogram, and other routine laboratory tests. These data, when integrated properly, result in an accurate diagnosis and appropriate decisions regarding therapy in many patients. In other patients, more information is necessary, and additional, more technical, and usually more expensive noninvasive cardiac tests such as echocardiography or radionuclide studies are needed. In some patients, the general assessment indicates the need for cardiac catheterization and contrast angiography, with or without additional noninvasive cardiac testing. For example, the proper approach to certain patients with symptomatic coronary artery disease may include both coronary arteriography and cardiac catheterization (anatomy and hemodynamics), as well as myocardial perfusion imaging with thallium or technetium sestamibi (extent of inducible ischemia).

Not all patients need every test, and the skillful use of low-technology approaches, including the history and general examination, may preclude the need for additional studies or may determine which of a wide variety of available sophisticated tests should be chosen for a particular patient. This chapter is divided into three sections. The first section concerns the proper application of the history and its use to delineate the differential diagnosis in patients who present with certain common cardiovascular symptoms. The second section details the essential components of the *physical examination* and their usefulness in establishing a likely diagnosis when specific abnormal findings are detected. Finally, the third section focuses on cardiac auscultation.

THE HISTORY

Elements of Accurate History Taking

A carefully obtained history is the cornerstone in the evaluation of a patient with known or suspected cardiac disease.[1,2] A deliberate, compassionate interview forms the basis for a patient-physician relationship that may continue for days, months, or years. Unfortunately, the interview may result in adversary roles for physician and patient if the interviewer appears hurried, demands exact answers, shows impatience, insists on exploring areas that are uncomfortable to the patient, fails to establish eye contact, accepts multiple interruptions during the discussion, seems to treat dreaded diseases casually, gives nonverbal signs of personal unhappiness, or appears to be unsympathetic.[2] When the medical interview is unsatisfactory due to poor communication and lack of rapport, inaccurate information often will be obtained.[2] Also, important facts not revealed during a meticulous initial history usually are not detected later as workup progresses and the patient and physician become focused on high-technology studies and more aggressive therapeutic interventions.[1]

The patient's chief complaint, which requires further elaboration and investigation, may not identify the patient's most serious problem. Symptoms other than the patient's chief complaint must be defined.[2] Rather than focusing entirely on the patient's present illness, the interviewer should note all existing symptoms and establish a present illness for each of these.[2]

A medical questionnaire given to the patient well in advance of the interview is useful. The patient can then record important data more accurately because of the time available for reflection and the checking of details.[2] Any abnormalities indicated on the questionnaire must be defined more completely during the interview, and related areas should be discussed.[2]

A proper interpretation of the past history is important, and the physician should not accept a past event as a fact when the evidence is not well established. Knowledge obtained from family members about the patient's symptoms and his or her response to the illness is extremely important.[2]

Importantly, serious heart disease can occur in patients with mild or no symptoms. Also, knowing the sensitivity, specificity, and predictive value of an answer to a question and of the presence or absence of a physical sign provides the physician with a better perspective. The physician must determine whether or not the history obtained is sufficient to support a decision-making process about the patient.[2] While many patients with severe heart disease have no symptoms, others have many symptoms associated with minor or no disease.

Some patients deny the presence of symptoms because they cannot accept the reality of the situation, whereas others may purposefully withhold information because they may lose their jobs if the truth were revealed.[2] Still other patients may overstate their symptoms for personal gain. Elderly patients, sedentary patients, and patients whose physical activity is limited by another illness may have no symptoms because they do not perform adequate physical effort to produce them.[2]

Past and Family History

The past history may provide important clues to the presence of cardiovascular disease. A definite history of rheumatic fever may be useful in defining the cause of a heart murmur, whereas a negative history of rheumatic fever does not exclude it.[2] A history of hypertension in a family member increases the likelihood that the patient has essential hypertension.[2] Previous trauma may be the cause of constrictive pericarditis, a thoracic aortic aneurysm, an arteriovenous fistula, and other types of cardiac lesions. A detailed history of the use of medications, addicting drugs, and alcohol, each of which may cause heart disease, is essential. A past history of pulmonary embolism, thrombophlebitis, or systemic embolism should be ascertained.

A history of dental work, some other diagnostic or therapeutic procedure, or recent infection suggests the possibility of infective endocarditis in a patient with valvular heart disease. Patients often give a history of having had a "heart attack," which, in fact, may have been an episode of unstable angina, heart failure, or arrhythmia. The "heart attack" history often becomes "myocardial infarction" in the patient's medical record unless more information about the episode is obtained or documentation of the event is reviewed.[1]

Many patients are referred who have had several catheterizations, percutaneous coronary interventions, angioplasties, and one or more coronary bypass operations in addition to multiple noninvasive tests. A thorough and often time-consuming review of records from other institutions, operative notes, cineangiographic films, and noninvasive studies often will provide an accurate assessment of the patient's current status without the unnecessary repetition of expensive and potentially risky procedures.[1]

Past and present therapeutic regimens must be reviewed carefully. Various treatment programs may have been inappropriate or suboptimal. The drugs currently used for the treatment of cardiovascular diseases have a larger number of potential side effects that can result in both cardiovascular and noncardiovascular symptoms (see Chap. 81).

Multiple risk factors for developing coronary artery disease (CAD) have been identified, including age, male sex, hypertension, hypercholesterolemia, low high-density lipoprotein (HDL) cholesterol, cigarette smoking, diabetes, and a family history of premature atherosclerosis (see Chap. 38). The presence or absence of risk factors can increase or decrease the statistical likelihood that an individual patient has CHD.

Patients should be questioned about previous health evaluations. In addition to being examined at the time of routine physicals or in association with other medical treatment, patients often have been examined for the military service, for athletics, or for insurance, and they may have been told of a heart murmur or hypertension on those occasions.[2] Rejection by the military or an insurance company is often due to a cardiovascular abnormality. Many patients have not seen a physician in the recent past or ever had a careful examination of the cardiovascular system.

The increasing hemodynamic burden of pregnancy may cause an otherwise marginally compensated

cardiac patient to become symptomatic. Specific inquiry should be made about heart failure, edema, dyspnea, or prescribed prolonged periods of bed rest during pregnancy.[1] Many normal women have had a murmur detected during pregnancy (see Chap. 82). A history of illicit parenteral drug use should raise the suspicion of infective endocarditis, especially in a febrile patient (see Chap. 73). Cocaine can cause coronary artery vasospasm and also raise myocardial oxygen demand by increasing heart rate and blood pressure. Angina, myocardial infarction, and sudden cardiac death have been well documented after cocaine use (see Chap. 71).

A history of moderate to excessive alcohol consumption, an enlarged heart on prior chest roentgenogram, periods of rapid weight gain or loss, and other illnesses may provide important information, as may questions concerning prior diagnoses made by the patient or by medical personnel.[1]

A family history of congenital heart disease indicates a higher risk of a congenital heart lesion (see Chap. 63). The patient's mother may give a history of rubella during the first few months of pregnancy; this increases the likelihood that the patient has patent ductus arteriosus, pulmonic valve stenosis, coarctation of the pulmonary arteries, or atrial septal defect.

Although most of the common cardiovascular diseases are sporadic, there are several examples in which genetic transmission can occur (see Chap. 62). These include mitral valve prolapse and the hypertrophic or dilated cardiomyopathies. Other genetically determined disorders include some of the inborn errors of metabolism, muscular dystrophies, Ehlers-Danlos syndrome, Marfan's syndrome, and the long Q-T syndromes with or without deafness (see Chaps. 62 and 63).

Symptoms Associated with Cardiovascular Disease

CHEST PAIN

Chest pain or chest discomfort is the foremost manifestation of myocardial ischemia and results from a disparity between myocardial oxygen demand and coronary blood flow in patients with CAD.[3] The most common causes of myocardial ischemia are coronary atherosclerosis, coronary vasoconstriction, and coronary artery thrombosis, the latter occurring particularly in patients with acute coronary syndromes such as acute myocardial infarction and unstable angina (see Chaps. 41 and 42). An increase in myocardial oxygen demand ($MV(r)O_2$) or demand ischemia, a decrease in or inadequate blood flow (supply ischemia), or their combination may be responsible for anginal chest pain (see Chap. 40).

The mechanism responsible for cardiac pain is not clearly understood. Nonmedullated small sympathetic nerve fibers that parallel the coronary arteries are thought to provide the afferent sensory pathway for angina; these enter the spinal cord in the C8-T4 segments.[4] Impulses are transmitted to corresponding spinal ganglia and then through the spinal cord to the thalamus and cerebral cortex. Angina pectoris, like other pain of visceral origin, is often poorly localized and is commonly referred to the corresponding segmental dermatomes.

The differential diagnosis of chest pain is extensive.[5] In addition to angina pectoris and myocardial infarction, other cardiovascular diseases, gastrointestinal diseases, psychogenic diseases, neuromuscular diseases, and diseases of the pulmonary system must be considered (Table 10-1; see also Table 40-6). An accurate interpretation of the etiology and significance of chest discomfort is critically dependent on a carefully taken history. Important clinically relevant information may be missed if the *overenthusiastic use of noninvasive or invasive diagnostic methods* replaces rather than augments direct physician-patient communication (see Chap. 40).

Table 10-1: Differential Diagnosis of Chest Pain

1. Angina pectoris/myocardial infarction
2. Other cardiovascular causes
    a. Likely ischemic in origin
        (1) Aortic stenosis
        (2) Hypertrophic cardiomyopathy
        (3) Severe systemic hypertension
        (4) Severe right ventricular hypertension
        (5) Aortic regurgitation
        (6) Severe anemia/hypoxia
    b. Nonischemic in origin
        (1) Aortic dissection
        (2) Pericarditis
        (3) Mitral valve prolapse

    d. Herpes zoster
    e. Chest wall pain and tenderness
6. Pulmonary
    a. Pulmonary embolus with or without pulmonary infarction
    b. Pneumothorax

c. Pneumonia with pleural involvement
7. Pleurisy

The original subjective description of angina pectoris by William Heberden[6] in the late eighteenth century has not been surpassed. It is quoted in Chap. 40.

Angina pectoris is defined as chest pain or discomfort of cardiac origin that usually results from a temporary imbalance between myocardial oxygen supply and demand. It may occur only with exertion or spontaneously at rest; various subtypes are defined in Chap. 40. The quality of the chest discomfort is usually described as "tightness," "pressure," "burning," "heaviness," "aching," "strangling," or "compression." Usually the patient is able to describe a deep rather than a superficial origin of the pain. Since the qualitative description of the pain is greatly influenced by the patient's intelligence, education, and social/cultural background, a definition of other characteristics of the chest discomfort is often extremely important in evaluating the symptoms appropriately. The most important of these characteristics are the *precipitating factors* for the onset of pain, its *mode of onset and duration*, its *pattern of disappearance*, and its *location*. Classically, the discomfort is induced by exercise, emotion, eating, or cold weather.

A recognizable pattern of reproducibility of chest pain by certain activities is an important characteristic of angina. Often, patients develop pain with exertion after meals, and there is a greater tendency for arm work, which involves a greater element of isometric exercise than isotonic leg exercise, to produce distress.[7-9] Occasionally, angina will dissipate despite continued exercise (the walk-through phenomenon) or will not occur when a second exercise effort is undertaken that previously produced chest discomfort (warm-up phenomenon).

Both circumstances may be attributed to the opening of functioning coronary arterial collaterals during the initial myocardial ischemia. Angina commonly occurs after the patient has eaten a heavy meal or when the patient is excited, angry, or tense. Cold showers increase blood pressure and heart rate, whereas hot showers cause an augmented cardiac output in response to vasodilation. Either may precipitate angina after exercise. The chest pain during any type of activity is often made worse by the use of tobacco. All the hemodynamic changes resulting from the use of nicotine increase the myocardial oxygen demand.

Angina pectoris characteristically has a crescendo pattern at onset and "builds up." Pains, often described as "shooting" or "stabbing," that reach their maximum intensity virtually instantaneously are often not angina but are of musculoskeletal or neural origin. Angina is usually relieved within 5 to 20 min by rest, with or without the use of vasodilator drugs such as nitroglycerin, although nitroglycerin characteristically hastens relief. Failure to obtain relief with rest or nitroglycerin suggests another cause of pain or actual impending myocardial infarction. The reproducible relief of chest pain in an appropriate time frame (within 10 min) can be strong evidence favoring ischemia. A trial of nitroglycerin can be a useful diagnostic strategy. Patients with angina pectoris usually are classified functionally from class I to class IV (Table 10-2), depending on the amount of activity necessary to induce chest pain.[10]

Table 10-2: Canadian Cardiovascular Society Functional Classification of Angina Pectoris

I.	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina results from strenuous or rapid or prolonged exertion at work or recreation.
II.	Slight limitation of ordinary activity. Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and under normal conditions.
III.	Marked limitations of ordinary physical activity. Walking one to two blocks on the level and climbing more than one flight under normal conditions.
IV.	Inability to carry on any physical activity without discomfort-anginal syndrome may be present at rest.

Localizing the site of chest discomfort provides additional information in determining its cause. Anginal pain is ordinarily retrosternal or felt slightly to left of the midline, beside or partly under the sternum. It is rarely isolated to the cardiac apex in the inframammary region. The chest pain of myocardial ischemia tends to radiate bilaterally across the chest into the arms (left more than right) and into the neck and lower jaw. Occasionally, radiation to the back or occiput is noted. In the arms, the pain passes down the ulnar and volar surface to the wrist and then only into the ulnar fingers, rarely into the thumb or down the outer (extensor) surface of the arm, which has a different dermatome pattern. Pain occasionally may be felt only in the arm or may start in the arm and radiate to the chest. Attention to the gestures that the patient uses in characterizing and localizing the site of pain may be useful in determining its etiology. One or two clenched fists held by the patient over the sternal area (Levine's sign) is much more indicative of ischemic pain than is a finger pointed to a small, circumscribed area in the left inframammary region. The latter more likely represents chest pain of psychogenic origin.

As indicated earlier, the *duration* of chest pain also may be a useful differentiating feature. Angina pectoris rarely lasts less than 1 min or more than 20 min in the absence of myocardial infarction or persistent arrhythmias. Most patients with angina report prompt relief in less than 5 min after cessation of activity or with the use of sublingual nitroglycerin. Delayed relief of chest pain by sublingual nitroglycerin may be ascribed to a placebo effect. Since nitrates are generalized smooth muscle relaxants, pain due to diffuse esophageal spasm or biliary colic also may be relieved by these same agents. Carotid sinus massage by the physician frequently will relieve anginal chest pain because of the resulting reflex bradycardia and the decrease in systolic blood pressure, thus reducing myocardial oxygen demand.[11] Carotid sinus massage should be performed only in the absence of extracranial occlusive cerebrovascular disease as manifest by carotid bruits or decreased carotid arterial pulsations and with careful auscultatory monitoring of the heart rate. The Valsalva maneuver also may relieve anginal pain by decreasing myocardial wall tension as a result of the reduced venous return and left ventricular volume accompanying the increase in intrathoracic pressure. *Associated symptoms*-such as nausea, vomiting, faintness, fatigue, or diaphoresis-often accompany severe episodes of myocardial ischemia in both men and women.[12] Severe myocardial ischemia often produces marked dyspnea due to a large increase in left ventricular (LV) diastolic filling pressure, sometimes producing an "angina equivalent" in the absence of chest discomfort.

Linked angina is a term applied to definite episodes of angina in patients with established CAD caused by gastrointestinal factors not related to an increase in cardiac work.[13] Episodes typically are induced by stooping or occur after eating; they can be mimicked by esophageal acid stimulation, which can reduce coronary blood flow (CBF).[13]

No consideration of myocardial ischemia as a likely cause of chest discomfort is complete without carefully considering the chest pain in the context of known risk factors for CAD (see above).

Angina pectoris should be considered a symptom and not a specific disease. Coronary arteriographic

studies have demonstrated that more than 90 percent of patients with chest pain precipitated by exercise and relieved by rest have angiographic evidence of significant CAD. However, other diseases may be associated with classic angina pectoris (see below).

Several reports have described certain patients with typical exertional chest discomfort and arteriographically normal coronary arteries.[14,15] These patients are more likely to be females, have fewer coronary risk factors, have variable responses to various antianginal agents, and less commonly, have more relief of pain by sublingual nitroglycerin than patients with occlusive CAD. Although the underlying cause of this condition remains unsettled, the life expectancy of these patients appears no different from that of an age- and sex-matched population without chest discomfort (see Chap. 40).

There is some evidence that abnormal function of small coronary arteries may cause limited CBF responses to stress or pharmacologic vasodilators in a subset of patients with anginal chest pain despite angiographically normal coronary arteries (*microvascular angina*).[16-22] In the past, investigators arguing for or against the existence of this syndrome often have used the term *syndrome X* to describe their patient cohort.[23] Syndrome X appears to include a heterogeneous group of patients with a wide spectrum of chest pain and a variety of vascular and smooth muscle hypersensitive constrictor responses. Multiple research studies continue in an effort to explain syndrome X.[24-30] It should be distinguished from the *metabolic syndrome X* of insulin resistance (glucose intolerance), hypertension, hyperlipidemia, and upper body obesity (see Chaps. 40 and 78).

Some patients with CAD experience angina at rest as a complication or an isolated clinical manifestation of ischemic heart disease.[11] Myocardial ischemic pain at rest more likely results from an acute reduction in CBF than from an increase in $MV(r)O_2$. Possible causative factors include isolated coronary artery spasm or embolism, coronary artery spasm superimposed on coronary atherosclerosis, and coronary thrombosis with spontaneous thrombolysis.[31-34] In patients with progressive coronary atherosclerosis, however, ischemic rest pain also may result from intermittent arrhythmias that increase $MV(r)O_2$ or decrease CBF or from labile hypertension with its increased wall stress. Chest pain at rest may occur only as nocturnal angina. In addition to the preceding mechanisms, nocturnal angina, also known as *angina decubitus*, may be produced by the increase in wall stress and thus $MV(r)O_2$ secondary to redistribution of the intravascular blood volume in the recumbent position.

The relative hypercapnia and acidosis that occur during sleep also may contribute to nocturnal angina. This condition also has been accompanied by concomitant rapid eye movement sleep patterns on the electroencephalogram, which may be associated with augmented sympathetic discharge increasing $MV(r)O_2$ or causing coronary constriction[8-11] (see Chap. 40).

Despite the more malignant natural history observed in many patients with rest angina, particularly associated with ST-T-wave changes, the predictive value of the history alone is not as accurate as with exertional angina. The quality of pain is usually similar to that of exertional angina, but the discomfort may be more severe and its duration longer. In addition, angina at rest is commonly associated with nausea, vomiting, and diaphoresis. The onset of shortness of breath during or after the beginning of chest discomfort suggests that the pain is due to extensive myocardial ischemia and usually results from an acute elevation of LV filling pressure secondary to the development of a large, transiently ischemic myocardial segment. Such patients are commonly found to have multivessel occlusive CAD on arteriography.

Chest pain or discomfort resulting from *myocardial infarction* (MI) is qualitatively similar to angina at rest. Differentiation between the pain resulting from ischemia and that due to MI is usually impossible based on the history alone.[7-9] Pain associated with transmural Q-wave MI is usually more severe and longer lasting than anginal pain and is often associated with nausea, vomiting, and diaphoresis. In addition, MI is frequently accompanied by symptoms of sustained LV dysfunction (dyspnea, orthopnea) and evidence of autonomic nervous system hyperactivity (tachycardia, diaphoresis, bradycardia).[7-9] Painless or atypical presentations of MI, however, occur in up to 30 percent of patients, particularly in diabetic patients and the elderly. Thus determination of serial serum enzymes, isoenzymes, and other serum markers (e.g., troponin I), providing evidence of myocardial necrosis, and serial electrocardiograms (ECGs), indicating myocardial

injury, are necessary to establish the diagnosis in most patients (see Chaps. 42 and 43).

There are two groups of *cardiovascular diseases causing chest pain that is not due to coronary atherosclerosis* (see Table 10-1). The first group consists of cardiac diseases causing myocardial ischemia-related angina in the absence of CAD; ischemia is due to hemodynamic changes associated with an inadequate CBF in relation to a normal or increased myocardial oxygen demand. Among these are *aortic valve stenosis* (see Chap. 56), *hypertrophic cardiomyopathy* (see Chap. 67), and *systemic arterial hypertension* (see Chap. 51), in which LV systolic pressure and LV wall tension are greatly increased or LV hypertrophy is present.[7-9] Chest pain due to myocardial ischemia also can occur with severe aortic regurgitation (see Chap. 56). The large ventricular volume load and increased ventricular dimensions result in increased $MV(r)O_2$, and the reduced diastolic perfusion pressure of the coronary arteries results in a relatively inadequate CBF. Occasionally, very severe anemia or hypoxia also may produce myocardial ischemia by an inadequate oxygen blood supply even in the absence of associated CAD as well as increases in angina in the presence of obstructive coronary artery disease.[7-9] In addition, severe right ventricular (RV) systolic hypertension, as often occurs with pulmonic stenosis or pulmonary hypertension, may cause exertional angina, presumably on the basis of RV subendocardial ischemia.[35]

A second group of cardiac diseases causing chest pain that is not usually due to myocardial ischemia includes *pericarditis* (see Chap. 72), aortic dissection (see Chap. 88), and mitral valve prolapse (see Chap. 58). Pericarditis is a relatively common cause of chest pain.[36] The chest pain of pericarditis is most often sharp and penetrating in quality, and patients often obtain relief by sitting up and bending forward (see Chap. 72). The cardinal diagnostic feature of pericardial pain is its frequent worsening by changes in body position, during deep inspiration, and occasionally, on swallowing. The chest discomfort may radiate to the shoulders, upper back, and neck because of irritation of the diaphragmatic pleura, which is innervated through the phrenic nerve by fibers originating in cervical sympathetic ganglia C3-C5. Therefore, the chest discomfort associated with pericarditis is due predominantly to parietal pleural irritation. Occasionally, the pain of acute benign, presumptive viral pericarditis may mimic that observed in acute MI. Importantly, the most common cause of pericarditis in middle-aged or older people is acute MI. The pericarditis usually occurs several days after the myocardial necrosis and must be distinguished from recurrent infarction or ischemia. Pericarditis also may be a cause of chest pain after cardiac surgery and may be a complication of aortic dissection, with leakage into the pericardium.

Aortic dissection (see Chap. 88) may be misdiagnosed on initial presentation as an acute MI; indeed, MI is a recognized complication of aortic dissection. The pain with dissection, however, is usually of sudden onset as compared with the pain of myocardial ischemia, which builds in intensity with time.[37] Patients frequently characterize the pain as excruciating, the most severe discomfort that they have ever experienced, and as having a tearing quality, commonly localized to the interscapular area. The discomfort may radiate widely into the neck, back, abdomen, flanks, and legs and may migrate, depending on the location and progression of the aortic dissection and the amount of arterial luminal compression. Neurologic symptoms and signs may occur when dissection involves the cerebral arteries. With the exception of patients with Marfan's syndrome (see Chaps. 66 and 76) or idiopathic cystic medial necrosis, most patients with aortic dissection have a history of long-standing systemic arterial hypertension or evidence of it on physical examination.

Psychogenic chest discomfort is a common type of recurrent chest pain that may be difficult to separate from angina pectoris, particularly when it occurs in patients with multiple risk factors for CAD or in otherwise asymptomatic patients with well-documented CAD. The most common psychogenic cause of chest discomfort is anxiety[38] (see Chap. 80). Psychogenic chest pain is often described as sharp or stabbing, is commonly localized to the left inframammary area, and is usually sharply circumscribed. Descriptors such as "stabbing" or "lightning-like" may be used to describe extremely short (<1 min) episodes of pain. At times, the pain may persist for many hours or several days. Patients often note psychogenic pain at rest. Also, nonvocal communication, such as a flat or worried facial expression, retarded motor activity, and hand wringing, may indicate underlying depression. Observation of the patient during pain that occurs spontaneously or during exercise testing often provides insight into a potential psychogenic etiology. Patients with anxiety often have multiple complaints such as breathlessness, giddiness, and palpitations. Associated symptoms, such as air hunger, circumoral paresthesias, globus hystericus, and multiple somatic

complaints, may suggest a neurasthenic personality or hyperventilation syndrome.

Pain originating in the gastrointestinal tract, particularly that of esophageal origin, is commonly confused with ischemic chest pain.[39] Diffuse esophageal spasm, a neuromuscular motor disorder of the esophagus characterized by chest pain, is the extracardiac condition most frequently confused with angina pectoris. Esophageal spasm may occur at any age but is more common in individuals in the fifth decade. The pain is usually retrosternal; may be burning, squeezing, or aching in quality; and often radiates to the back, arms, and jaw. It usually begins during or after a meal and can last minutes or hours. In some patients, the pain may be precipitated or exacerbated by exercise, and relief may be obtained with nitroglycerin, which also relaxes esophageal smooth muscle. A useful feature in the differentiation of diffuse esophageal spasm from ischemic chest discomfort is its frequent association with pain as a result of swallowing, dysphagia, and the regurgitation of gastric contents. Episodes of pain frequently are precipitated either by extremely hot or cold drinks or by an emotional upset. The diagnosis of diffuse esophageal spasm is based on the history, the exclusion of cardiac and musculoskeletal causes of chest pain, and the demonstration of abnormal esophageal motility on cineesophagograms or by esophageal manometry.

Reflux esophagitis results from mucosal irritation produced by failure of the lower esophageal sphincter to prevent regurgitation of highly acidic gastric contents into the distal esophagus.[40-42] The pain is usually epigastric or retrosternal, burning in quality, and frequently precipitated by the recumbent position or by bending over. "Heartburn" and regurgitation often occur after meals or ingestion of coffee or after postural changes. Patients are often awakened by chest discomfort due to acid reflux occurring in the recumbent position. Many of these patients are obese and report relief of discomfort from food, antacids, or elevation of the head of the bed. Dysphagia may result from stricture formation secondary to long-standing esophageal reflux. An upper gastrointestinal series may demonstrate hiatal hernia, but this does not establish the diagnosis of esophagitis or esophageal reflux. Esophagoscopy and esophageal biopsy may demonstrate mucosal lesions and are useful for assessing the severity of inflammation and for excluding malignancy. Sphincter incompetence may be documented by the use of esophageal manometry. Esophageal acid perfusion testing (Bernstein test) often will provoke the patient's characteristic symptoms, and distal esophageal pH monitoring will detect gastroesophageal reflux.[41]

Acute esophageal rupture, a serious and often rapidly lethal event, causes severe retrosternal pain secondary to the chemical mediastinitis produced by acidic gastric contents.[7-9] Spontaneous rupture usually results from a prolonged bout of vomiting or retching after a heavy meal. Rupture is a recognized iatrogenic complication of esophageal instrumentation. The pain varies in location depending on the rupture's site and position. The diagnosis is based on symptoms and signs of mediastinal air following vomiting or esophageal instrumentation.

Although peptic ulcer disease and biliary colic are less commonly confused with chest pain of cardiac origin, myocardial ischemic pain occasionally may be described as burning in character and located near the epigastrium.

Diseases involving the neuromuscular-skeletal systems may cause pain affecting dermatome patterns similar to those occurring with angina pectoris.[7-9] The thoracic outlet syndromes, in which various neural and vascular structures are compressed, may produce symptoms that are sometimes confused with cardiac chest pain. Although compression of the neurovascular bundle by a cervical rib or the scalenus anterior muscle may cause discomfort radiating to the head and neck, the shoulder region, or the axilla, most patients experience pain in the upper extremity resulting from somatic nerve compression, usually in the distribution of the ulnar nerve.[8-11] The presence of associated paresthesias, the presence of pain unrelated to physical exercise, the worsening of discomfort, and its aggravation by certain body positions are useful differentiating characteristics. The diagnosis of thoracic outlet syndrome can be confirmed in many patients by careful physical and neurologic examination.

Tietze's syndrome, or idiopathic costochondritis, is an occasional cause of anterior chest wall pain that is aggravated by movement and deep breathing. The reproduction of the chest pain syndrome by direct pressure over the involved costochondral junction or the relief of pain after local infiltration with lidocaine is a helpful diagnostic maneuver.[43] Degenerative arthritis of the cervical and thoracic vertebrae may cause bandlike pain confined to the chest, neck, or back that often radiates to the arms.[7-9] Radiologic evidence of degenerative changes involving the cervical and thoracic vertebrae is often found in asymptomatic elderly

patients. The production or exacerbation of pain by various postures, movement, sneezing, or coughing is more useful in the diagnosis of chest discomfort due to vertebral disease.[7-9]

The *preeruptive stage of herpes zoster* may be characterized by bandlike chest pain over one or more dermatomes. The advanced age of the patient, additional symptoms of malaise, headache and fever, the presence of hyperesthesia of the involved area on physical examination, and the eventual eruption of typical lesions 4 or 5 days after the onset of symptoms will result in the correct diagnosis. Chest wall pain and tenderness may occur for unknown reasons.[44] The discomfort may be reproduced by pressure over the painful area and by movements of the thorax such as bending, twisting, or turning. The variable duration of the pain and the absence of relief by nitroglycerin distinguish it from angina.

The syndrome of acute massive *pulmonary embolism* with its associated acute pulmonary hypertension and low cardiac output occasionally may simulate acute MI, since myocardial ischemia may be present in both conditions. The quality of chest pain may be identical to that observed in patients with nonradiating ischemic chest pain or may be pleuritic, as described below. The associated signs of severe dyspnea, tachypnea, and intense cyanosis, accompanied by profound anxiety and agitation, however, favor the diagnosis of pulmonary embolism[8-11] (see Chap. 54). The clinical setting may suggest the diagnosis because of the known increased likelihood of pulmonary embolism in the postpartum or postoperative state, during long trips, in patients with congestive heart failure and peripheral edema, and in those with deep-vein thrombophlebitis. Measurements of arterial blood gases, abnormal pulmonary perfusion-ventilation scans, and if needed, pulmonary arteriography will establish the correct diagnosis.[7-9]

Other pulmonary conditions associated with chest discomfort, such as pneumothorax, are rarely confused with ischemic chest pain because of additional characteristic clinical features. Spontaneous pneumothorax usually occurs in otherwise healthy males in the third and fourth decades. The clinical presentation is usually characterized by the abrupt onset of agonizing unilateral pleuritic chest pain associated with severe shortness of breath. The plain or expiratory chest film provides the definitive diagnosis. Chest pain associated with pneumonias of various etiologies, as well as pulmonary infarctions as a consequence of pulmonary embolus, may result from pleural irritation. The discomfort is sharp, varies acutely with breathing, and frequently is accompanied by a reduced inspiratory effort. Associated signs of pulmonary parenchymal infection or infarction usually indicate the underlying diagnosis.

EXTRATHORACIC PAIN

Intermittent claudication of the lower extremities due to peripheral atherosclerosis (see Chap. 90) may present as discomfort during exercise in the arch of the foot, calf of the leg, thighs, hips, or gluteal region.[7-9] Acute arterial occlusion in the lower extremities due to systemic embolism may cause the sensation of hypesthesia.[2] Intermittent claudication of the upper extremities or masseter muscles is usually due to nonatherosclerotic causes of arterial disease, such as arteritis.[2] The pain of Raynaud's disease may be noted in the fingers after exposure to cold, with pallor of the fingers prior to the sensation of pain. Pain and swelling of lower extremities may be caused by thrombophlebitis (see Chap. 90).

Head pain secondary to myocardial ischemia may be felt in the jaw, hard palate, cheek, and sometimes deep in the ear canals. The pain of temporal arteritis, commonly localized to the temporal area, often is associated with abnormal vision and polymyalgia rheumatica.[76] Migraine headache, frequently accompanied by nausea, scotoma, and intolerance to light, is vascular in origin and may be incapacitating.[2] A severe headache may be present in patients with uncontrolled hypertension (see Chap. 51).

Pain in the abdomen, often localized to the midabdomen and lower portion of the back, may be produced by an expanding or rupturing atherosclerotic abdominal aneurysm. Abdominal angina due to vascular disease of the mesenteric arteries is discussed in Chap. 88. The liver is often painful and tender in severe right-sided heart failure, with worsening of the pain during activity.[2]

Various types of *joint pain* may be associated with heart disease. Rheumatic fever, rheumatoid arthritis, lupus erythematosus, psoriatic arthritis, ankylosing spondylitis, gonococcal arthritis, Reiter's syndrome, and Lyme disease may be associated with valvular, myocardial, or pericardial disease.[2]

RESPIRATORY SYMPTOMS

Dyspnea is defined as difficult or labored respiration or the unpleasant awareness of one's respiration. It has many causes. A clue to the etiology is obtained from the factors that precipitate or relieve it.[1] Chronic dyspnea can be caused by heart failure, pulmonary disease, anxiety, obesity, poor physical fitness, pleural effusions, and asthma.[2] Acute dyspnea may occur with acute pulmonary edema, hyperventilation, pneumothorax, pulmonary embolism, pneumonia, and airway obstruction.[2]

Dyspnea on effort, a frequent symptom, is usually due to congestive heart failure, chronic pulmonary disease, or physical deconditioning (see Chap. 20). The amount of activity necessary to produce dyspnea needs definition. A recent or dramatic increase in the dyspnea is more likely to be due to the development of heart failure than to lung disease. When heart and lung disease coexist, however, the determination of the relative contribution of pulmonary and cardiac dysfunction to dyspnea can be very difficult.

Cheyne-Stokes respiration is a form of periodic breathing characterized by cycles beginning with shallow respirations that increase in rate and depth to significant hyperpnea, followed by decreasing rate and depth of respiration, and then a period of apnea that may last 15 s or longer.[1] This form of respiration occurs in advanced congestive heart failure and in some forms of central nervous system disease. Cheyne-Stokes respiration often occurs during sleep without the patient's awareness and is often reported by others.

Orthopnea results from an increase in hydrostatic pressure in the lungs that occurs with assumption of the supine position. It consists of cough and dyspnea in some patients with LV failure or mitral valve disease and necessitates the use of two or more pillows on lying down. The patient with severe obstructive lung disease, especially acute asthma, also cannot lie flat comfortably.

Paroxysmal nocturnal dyspnea (PND) is the occurrence of dyspnea during sleep, commonly 2 to 3 h after going to bed, that is relieved by assuming the upright position. Dyspnea usually does not recur after the patient goes back to sleep. Episodes can be mild, or they can be severe with wheezing, coughing, gasping, and apprehension.[1] Some episodes will progress to pulmonary edema. The probable mechanism for this *relatively specific symptom* of left-sided heart failure is the increase in central blood volume in the supine position.

A dry, nonproductive cough, occurring with effort or at rest, may be related to the pulmonary congestion associated with heart failure (see Chap. 20). Although dyspnea is usually present, cough may dominate the clinical picture. The cough that accompanies acute pulmonary edema is often associated with frothy, pink-tinged sputum, whereas the sputum associated with chronic bronchitis is usually white and mucoid.[2] The sputum associated with pneumonia is often thick and yellow, and that due to pulmonary infarction may be bloody, as may the sputum associated with cancer of the lung or bronchiolectasis. Cough also may be caused by angiotensin-converting enzyme inhibitors, which are often prescribed for heart failure or hypertension.

Recurrent coughing due to heart failure is often thought to be due to bronchitis, and patients with chronic bronchitis may cough more when heart failure ensues.[2] Patients with a high pulmonary blood flow due to congenital left-to-right shunts are subject to pulmonary infection. Patients with a high pulmonary venous pressure are more vulnerable to the development of pulmonary edema when they have viral pneumonitis than are patients with normal pulmonary venous pressure. This particularly applies to patients with mitral stenosis.

Hemoptysis occurs in many cardiac disorders. Posterior epistaxis due to systemic hypertension may cause blood-streaked sputum; patients on anticoagulants may have epistaxis that mimics hemoptysis. Epistaxis, however, is usually easily differentiated from bloody sputum. Bright red pulmonary venous blood from rupture of submucosal pulmonary venules may be expectorated by patients with pulmonary venous hypertension due to mitral stenosis or severe LV failure.[2] Darker blood or clots often occur with pulmonary emboli.

Pink, frothy sputum may be produced during acute pulmonary edema. Blood-streaked sputum is a feature of the "winter bronchitis" of mitral stenosis.[2] Massive hemoptysis with exsanguination or death from

asphyxiation can follow rupture of an aortic aneurysm or one of the cardiac chambers into the bronchial tree.[2] Rupture of a pulmonary artery by the balloon of an indwelling pulmonary artery catheter can cause abrupt, severe hemoptysis in hospitalized patients.

Wheezing associated with dyspnea may be due to lung or heart disease. If the symptoms have developed recently in an adult over age 40, other clues indicating heart disease should be sought. Wheezing due to heart disease is termed *cardiac asthma*.

EDEMA AND ASCITES

Edema is a common symptom or finding in patients with right- or left-sided heart failure. Fluid retention in heart failure results from increased venous pressure and abnormal activity of salt-retaining hormones (see Chap. 20). In an average-sized person, 5 to 10 lb of excess fluid is required for edema to become apparent; a history of recent weight gain often will correlate with a deterioration in clinical status. The amount of weight loss in response to treatment for heart failure in the past will relate to the severity of the problem. Minor degrees of edema are evident only after a period of dependency of the legs and will decrease after rest. Presacral edema may be most obvious when the patient has been at bed rest. Although edema of cardiac origin may progress to anasarca, cardiac edema rarely involves the face or upper extremities. Edema mainly affecting the face and arms is more likely to be due to venous or lymphatic obstruction by clot or neoplasm. Facial edema is a feature of the nephrotic syndrome, angioneurotic edema, and glomerulonephritis. Swelling or "puffiness" of the hands and fingers is not usually a symptom of cardiac disease. Persistent edema in the legs from which veins were harvested at the time of bypass surgery is common. Other causes of edema-such as varicosities, obesity, tight girdle, renal insufficiency, or cirrhosis with hypoproteinemia-must be considered.[1] A patient with chronic congestive heart failure may detect edema of the ankles and lower legs during the day and note that it diminishes during the night. It is important to ascertain whether edema of the extremities preceded or followed dyspnea on effort. The calcium antagonists may produce bilateral edema of the lower legs. Edema may occur in one or both legs following the harvesting of veins for conduits in patients undergoing coronary artery bypass graft (CABG) surgery.

Patients will be aware of ascites because of increased abdominal girth. Previously comfortable trousers or skirts may no longer fit. Bending at the waist is uncomfortable, with ill-defined abdominal fullness. Patients with severe edema due to congestive heart failure may develop ascites; however, ascites is particularly common in patients with constrictive pericardial disease, sometimes occurring before peripheral edema becomes obvious (see Chap. 72). Ascitic fluid is formed when elevated venous pressure leads to transudation of fluids from the serosal surfaces. Other causes of ascites-such as cirrhosis, nephrosis, and tumor-must be excluded.

FATIGUE AND WEAKNESS

Fatigue and *weakness* may be due to many causes and therefore are not specific symptoms for heart disease. The most common cause of these symptoms is anxiety and depression. Anemia, thyrotoxicosis, and other chronic disease states may be associated with fatigue and weakness.

When a patient with heart disease is volume overloaded, or when there is pulmonary congestion due to heart disease, the patient is likely to complain of dyspnea. With vigorous diuretic therapy, this complaint may be replaced by symptoms of fatigue and weakness,[2] probably related to inadequate cardiac output (see Chap. 21). The heart fails in its prime objective of nourishing all the tissues and organs of the body, including the skeletal muscles. As congestive heart failure worsens, fatigue may replace dyspnea as the major symptom. Beta blockers used to treat angina or hypertension often cause fatigue and lethargy. Hypotension or hypokalemia caused by diuretics can result in fatigue and weakness, as can relative hypovolemia due to the use of angiotensin-converting enzyme inhibitors.

Severe fatigue related to effort may result from transient global myocardial ischemia in patients with extensive CAD. Dyspnea and hypotension also may occur at the same time as the severe fatigue as *angina equivalents*.[2]

PALPITATION

Most normal individuals are intermittently aware of their heart action, particularly at the time of physical and emotional stress. When the heart action is more vigorous than usual or its perception is unpleasant, the term *palpitation* is appropriate.[1] The patient may complain of a "pounding," "stopping," "jumping," or "racing" in the chest. Palpitation is frequently a benign symptom without any serious cardiac disease present; at other times it may indicate a potentially life-threatening condition. Simple premature beats may be perceived as a "floating" or "flopping" sensation in the chest due to the more forceful beat that occurs after the pause following the premature beat. Sometimes a transient feeling of fullness in the neck (due to cannon a waves) is perceived with premature beats. Certain patients perceive almost every premature beat, whereas others are totally unaware of frequent or advanced arrhythmias. A report of skips or irregularity during uninterrupted sinus rhythm is not uncommon. Generally, thin, tense individuals are likely to be more aware of their cardiac activity than others. Individuals with and without arrhythmias often are aware of their cardiac activity when they first lie down on their side to sleep, especially if they lie on their left side.[1]

Rapid heart action of a paroxysmal tachycardia usually begins and terminates abruptly and causes a pounding sensation in the chest.[1] Patients often will indicate whether the tachycardia is regular or irregular and may be able to tap out the rate and rhythm of the episode (see Chap. 24). Chest pressure suggesting angina may occur with an episode of tachycardia even in young, healthy patients without CAD. Patients with CAD, however, often develop severe angina with a sustained arrhythmia because of increased $MV(r)O_2$. Depending on the rate and mechanism of the arrhythmia, faintness and syncope may be described during questioning. Nevertheless, sustained ventricular tachycardia can occur in the setting of serious underlying cardiac disease without a significant compromise in hemodynamics (see Chap. 24). Syncope due to tachyarrhythmias may occur without the patient being aware of palpitations.

SYNCOPE

Cardiac *syncope* (fainting) is defined as the transient loss of consciousness due to inadequate cerebral blood flow secondary to an abrupt decrease in cardiac output (see Chap. 32). *Near syncope* refers to the clinical situation in which the patient feels dizzy and weak and tends to lose postural tone but does not lose consciousness. In assessing the patient with syncope, one determines if there were precipitating factors, premonitory symptoms, injury with the episode, seizure activity or incontinence, or a postictal state.[1] Injury during an episode suggests a sudden profound loss of body tone and increases the likelihood of more serious causes. Brief, unsustained seizure activity can occur with syncope due to a cardiac arrhythmia.

The patient may be incontinent during cardiogenic syncope, but an aura, sustained tonic-chronic movements, tongue biting, and confusion or drowsiness after the event are more characteristic of syncope due to central nervous system disease. In contrast, return of consciousness to the alert state is prompt after reversal of the arrhythmia causing cardiac syncope.[1] The common faint (*vasovagal syncope*) results from bradycardia and hypotension caused by excessive vagal discharge. It is often associated with some precipitating event such as a "heavy" meal in a warm room and has brief premonitory signs and symptoms such as nausea, yawning, diaphoresis, and sometimes the feeling of decreased hearing or vision.[1] There is frequently sufficient warning that the patient does not fall abruptly. The results of head-up tilt-table testing indicate a vasovagal mechanism in some patients with syncope who do not have premonitory symptoms (see Chap. 32). Following a fainting episode, the patient may be pale and diaphoretic and have a slow heart rate. Syncope occurring in the setting of any gastrointestinal symptoms is likely to be vagal in origin. A history of similar episodes during the preceding several years is common in patients with vagal syncope.

A hypersensitive carotid sinus can cause syncope. A history of episodes during an activity such as shaving, wearing of a tight collar, or extreme turning of the head may occur but is unusual even when a sensitive carotid sinus is shown to be the cause of syncope. Syncope following urination (micturition syncope) may occur at the time of rapid decompression of a distended bladder, which typically occurs after a period of sleep. Paroxysms of coughing, usually in patients with underlying pulmonary disease, can result in syncope. Very fast or slow arrhythmias may decrease the cardiac output enough to cause alterations in consciousness, ranging from abrupt profound syncope to mild light-headedness. Stokes-Adams syncope is caused by intermittent complete heart block, sinus arrest, or ventricular tachyarrhythmias[77] (see Chap. 32). It is characterized by abrupt loss of consciousness without warning, a variable period of unconsciousness

(seconds to minutes), and then a rapid return of normal mental status without amnesia or a postictal state.

In the presence of several LV outflow obstruction (aortic stenosis or hypertrophic cardiomyopathy), loss of consciousness with effort may occur. Syncope can be due either to the heart's inability to increase its output in response to the peripheral vasodilatation that occurs during exercise or to a tachyarrhythmia. Intermittent obstruction of a cardiac valve by an intracavitary tumor or thrombus is a rare cause of syncope that occasionally may be precipitated when the patient changes position (see Chap. 77).

Many normal subjects experience transient light-headedness with rapid changes in position. This is more common in older patients, since the ability of the peripheral vasculature to respond is attenuated with aging (see Chap. 86). Postural hypotension is a well-defined cause of fainting or dizziness that usually occurs when the individual is upright and often just after rising from a supine or sitting position. Possible causes include peripheral neuropathy, autonomic dysfunction, volume depletion, or drug side effects.

OTHER CEREBRAL SYMPTOMS

Patients with decreased cardiac output secondary to heart failure may become mentally confused and disoriented. Such symptoms also may be due to hypoxia, to drugs that are invariably prescribed for such patients, and to renal or hepatic failure.[2] A completed stroke may be caused by a lacunar infarct, cerebral hemorrhage, cerebral arterial thrombosis, or a cerebral embolus (see Chap. 89). A transient cerebral ischemic attack is commonly due to an embolus. The embolus may originate in an atheromatous ulcer in the carotid artery system or the aortic arch; be related to infective endocarditis, a recent MI, atrial fibrillation, or clots on a prosthetic valve; or originate in the leg veins and pass through a patent foramen ovale to the brain (see Chap. 89).

The patient with cardiogenic shock or with a severe tachyarrhythmia who also has considerable intracranial or extracranial vascular disease may develop such severe cerebral hypoxia that coma occurs. Hypoxic encephalopathy may follow cardiac resuscitation and occasionally occurs after cardiopulmonary bypass for cardiac surgery. A cerebral abscess may occur in patients with congenital heart disease and a right-to-left shunt.[2]

FEVER, CHILLS, AND SWEATS

Patients with rheumatic fever usually do not have chills. Chills are common in patients with bacterial endocarditis. Symptoms of fever, chills, or sweats in any patient with a heart murmur should lead one to suspect infective endocarditis (see Chap. 73). A history of valvular heart disease is not a prerequisite for a diagnosis of endocarditis, since previously normal valves become infected. A history of recent dental work, genitourinary surgery, or illicit drug use increases the suspicion of infective endocarditis. Fever may accompany pericarditis. Myalgia, chills, and fever on rare occasions may be related to MI, presumably because of some form of immunologic response to the necrotic myocardial tissue. An intracardiac tumor (myxoma) may produce systemic symptoms in the absence of infection. Low-grade fever in a patient with heart failure may be a sign of pulmonary emboli.[2] A profuse "cold sweat" mediated by sympathetic discharge often accompanies early stages of acute MI. Excessive sweating may occur in patients with severe aortic regurgitation. Diaphoresis is often a sign of congestive heart failure in infants.

HOARSENESS

Although usually unrelated to cardiovascular disease, *hoarseness* can occur in patients with an aortic aneurysm that involves the left recurrent laryngeal nerve. Mitral stenosis occasionally may produce hoarseness due to the pressure of a large pulmonary artery on the recurrent laryngeal nerve. Pericardial effusion may be related to myxedema, which may be associated with a coarse, low-pitched voice. Hoarseness and loss of voice may occur following the use of an endotracheal tube during cardiac surgery.

INDIGESTION, HICCUPS, AND DYSPHAGIA

Many patients with angina pectoris due to CAD erroneously attribute their symptoms to *indigestion* or heartburn. Also, patients with heartburn, esophageal reflux, and esophageal spasm may believe they have

angina pectoris. *Hiccups* occasionally may occur in patients with MI and are common during the postoperative period after cardiac surgery. *Dysphagia* may occur in patients with progressive systemic sclerosis, an aortic arch anomaly, or an extremely large left atrium.

GASTROINTESTINAL SYMPTOMS

Anorexia, nausea, and vomiting may occur as a result of digitalis excess. Hepatomegaly associated with tricuspid valve disease or severe right-sided heart failure may cause right-upper-quadrant epigastric pain and fullness as well as anorexia. Abdominal pain due to visceral ischemia or infarction may occur in a patient who has had a period of very low cardiac output. The pain of some gastrointestinal diseases may be referred or extend to the chest or back and lead to confusion with myocardial ischemia.

ABNORMAL SKIN COLOR

Although *cyanosis* is a sign rather than a symptom, patients or family members may describe cyanosis during the history. *Cyanosis* is a bluish color of the skin or mucous membranes caused by excess amounts of reduced hemoglobin. About 4 g of reduced hemoglobin is required for cyanosis to be apparent (see Chap. 63). Severely anemic patients will not exhibit cyanosis. A distribution of cyanosis involving the mucous membranes as well as the periphery (central cyanosis) is caused by the admixture of venous blood at the level of the heart or great vessels. A patient or a family member may detect that the cyanosis is more intense in the feet than in the hands. This differential cyanosis suggests a right-to-left shunt through a patent ductus arteriosus in a patient with Eisenmenger physiology (see Chap. 63). Peripheral cyanosis does not involve the mucous membranes but is the result of slow peripheral flow with accumulation of excess reduced hemoglobin in the setting of circulatory failure, shock, or peripheral vasospasm.

Jaundice may be detected by a patient or by a member of the family. As a rule, hepatic congestion due to heart failure will not produce jaundice. When jaundice does occur in a patient with heart failure, it is appropriate to consider pulmonary infarction in addition to hepatic congestion or cirrhosis of the liver. Hemolysis of red blood cells may occur in patients with prosthetic valves and can produce jaundice.[2]

A history of flush of face and trunk, sometimes accentuated by alcohol, should lead one to search for the other signs and symptoms of carcinoid heart disease[2] (see Chap. 77). Cardiomyopathies due to hemochromatosis should be considered in the patient with diabetes whose skin color has changed from normal to bronze.[2] A slatelike color of the skin, hands, and nose may develop in patients who take amiodarone.

EMBOLIZATION

The entry of a blood clot, vegetation, or tumor fragment from the heart into the systemic circulation results in arterial embolus. Clots may occur in the left atrium behind a stenotic mitral valve, within a ventricular aneurysm, or in the left ventricle of a patient with cardiomyopathy. While many emboli originate in the heart, arteriosclerotic material in the ascending and descending aorta often embolizes to the periphery.[1] Many emboli are asymptomatic. Symptoms of a stroke occur with emboli to the cerebral vessels. MI can result from an embolus to a coronary artery. Hematuria, flank pain, and hypertension can result from embolization to a renal artery. The abrupt development of a cold, painful extremity follows embolic obstruction of an arm or leg artery.[1] Emboli from the vegetations of acute endocarditis may produce characteristic areas of vascular necrosis in the fingers or toes (see Chap. 77). Severe atherosclerosis in the abdominal aorta and iliac vessels can be responsible for showers of peripheral emboli with multiple small, reddish blue lesions on the lower extremities sometimes causing small areas of gangrene. An embolic event may be the presenting manifestation of previously unrecognized cardiac disease.

INSOMNIA

The most common causes of insomnia are mental conflict, emotional disturbances, and depression. Heart failure, however, also may cause insomnia. The patient with Cheyne-Stokes respirations (see above) may sleep during the apneic phase and wake during the hyperpneic phase of the condition. Occasionally, patients with pulmonary congestion due to heart failure have insomnia before they develop nocturnal

dyspnea.

Classification of Cardiac Disability

Several classifications have been proposed and used for many years for the systematic and reproducible grading of disability due to cardiac disease. Although the complete New York Heart Association method of classifying cardiac diagnoses, originally proposed many years ago, is not widely used now, the portion of the classification that concerns functional capacities[45] is still commonly used (Table 10-3). Although the Canadian Cardiovascular Society's grading system for angina (see Table 10-2) is more widely used for patients with chest pain, both classifications continue to be used in the medical literature and in clinical practice, particularly as criteria for the inclusion of heart patients in multicenter clinical trials.

Table 10-3: The Old New York Heart Association Functional Classification

Class 1	No symptoms with ordinary physical ac-tivity.
Class 2	Symptoms with ordinary activity. Slight limitation of activity.
Class 3	Symptoms with less than ordinary activity. Marked limitation of activity.
Class 4	Symptoms with any physical activity or even at rest.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

THE PHYSICAL EXAMINATION

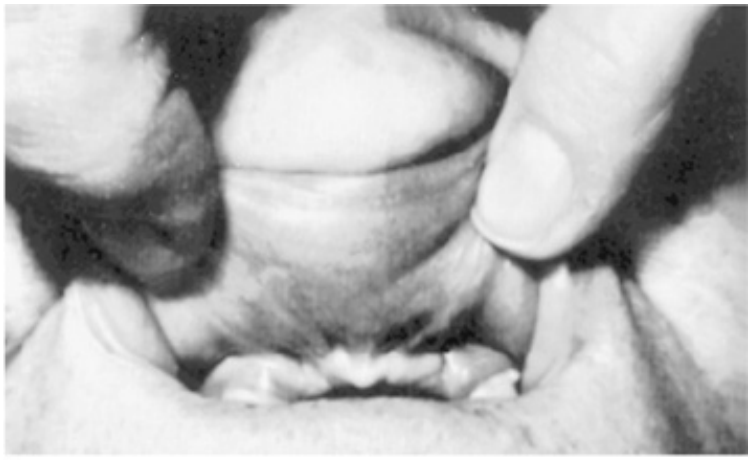
Important information concerning the patient with definite or suspected heart disease is often obtained by a careful and deliberate physical examination, which includes a general inspection of the patient, an indirect measurement of the arterial blood pressure in both arms and one or both lower extremities, an examination of central and peripheral arterial pulses, an evaluation of the jugular venous pressure and pulsations, palpation of the precordium, and cardiac auscultation. Based on the results of this rather inexpensive evaluation, a definite diagnosis often is made, and selected noninvasive and invasive testing is ordered only when appropriate.

General Inspection of the Patient

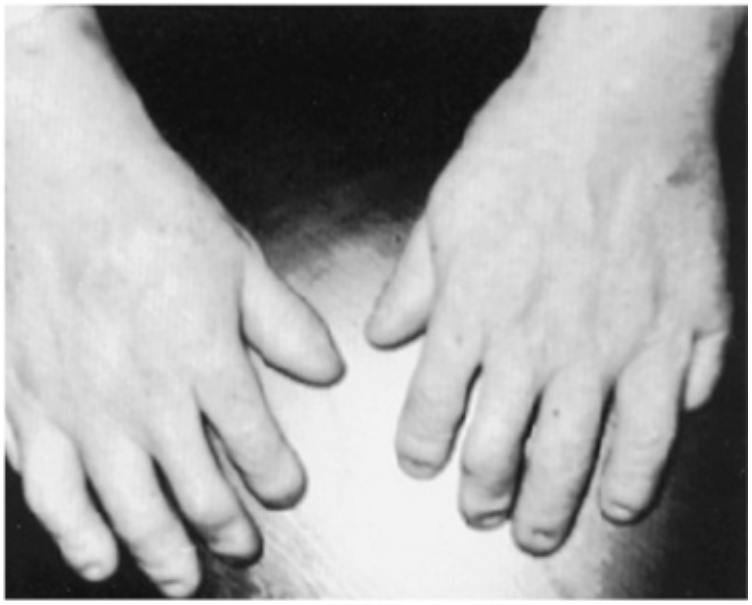
The art of bedside medicine begins with a careful overall appraisal of the patient. This visual approach is of great advantage in seeking clues to the etiology of cardiovascular disease. Since this discussion is organized according to the specific type of heart involvement, diseases that cause several problems are mentioned more than once. Each disorder is italicized, and its major manifestations are described the first time it is named.

Syndromes Associated with Congenital Heart Disease

Congenital heart disease syndromes may be classified into heritable disorders, connective tissue disorders, inborn areas of metabolism, chromosomal abnormalities, sporadic disorders, and teratogenic disorders (see also Chaps. 62, 63, 64 and 76). Occasionally, a particular syndrome falls into more than one category. In the first category, the *Ellis-van Creveld syndrome,* a common disorder in the Amish population, is a heritable form of dwarfism characterized by short extremities, polydactyly, dysplastic teeth and nails, and multiple frenula binding the upper eyelid to the alveolar ridge (Fig. 10-1). Over half the patients have heart disease, usually a large atrial septal defect or a single atrium.[46]



A



B

Figure 10-1: *Ellis-van Creveld syndrome. A.* Typical "lip tie" due to multiple frenulum. *B.* Polydactyly. This patient has a large septal defect.

The *thrombocytopenia-absent radius* (TAR) *syndrome* includes bilateral radial aplasia with a persistent thumb and thrombocytopenia and may be associated with an ostium secundum atrial septal defect (ASD) and/or tetralogy of Fallot. The Holt-Oram syndrome, an autosomal dominant trait, combines an ASD or other congenital heart disease with a thumb[47] (Fig. 10-2) that may be absent, hypoplastic, bifid, triphalangeal, or unusually long. *Tabatznik's syndrome* (heart-hand syndrome type II) is characterized by hypoplastic deltoids, skeletal anomalies of the forearm, bradydactyly, and atrial fibrillation. In the *Laurence-Moon-Bardet-Biedl syndrome*, mental retardation, polydactyly, obesity, retinitis pigmentosa, and hypogonadism occur with a variety of congenital heart diseases.[48]

Figure 10-2: *Holt-Oram syndrome:* fingerized thumb (arrow) associated with an atrial septal defect.

Arteriovenous fistulas involving the lung, liver, and mucous membranes are associated with multiple telangiectasias in patients with the hereditary hemorrhagic telangiectasis (*Osler-Weber-Rendu syndrome*).[49] *Cornelia de Lange's syndrome* is characterized by bushy, confluent eyebrows, downward-slanting eyes, a small mandible, low-set ears, hirsutism, long eyelashes, a broad, flat, upturned nose, severe growth and mental retardation, and a peculiar "chicken wing" extremity with a single thumblike digit (Fig. 10-3). A ventricular septal defect (VSD), patent ductus arteriosus, pulmonic stenosis, anomalous venous return, or ASD may be present.

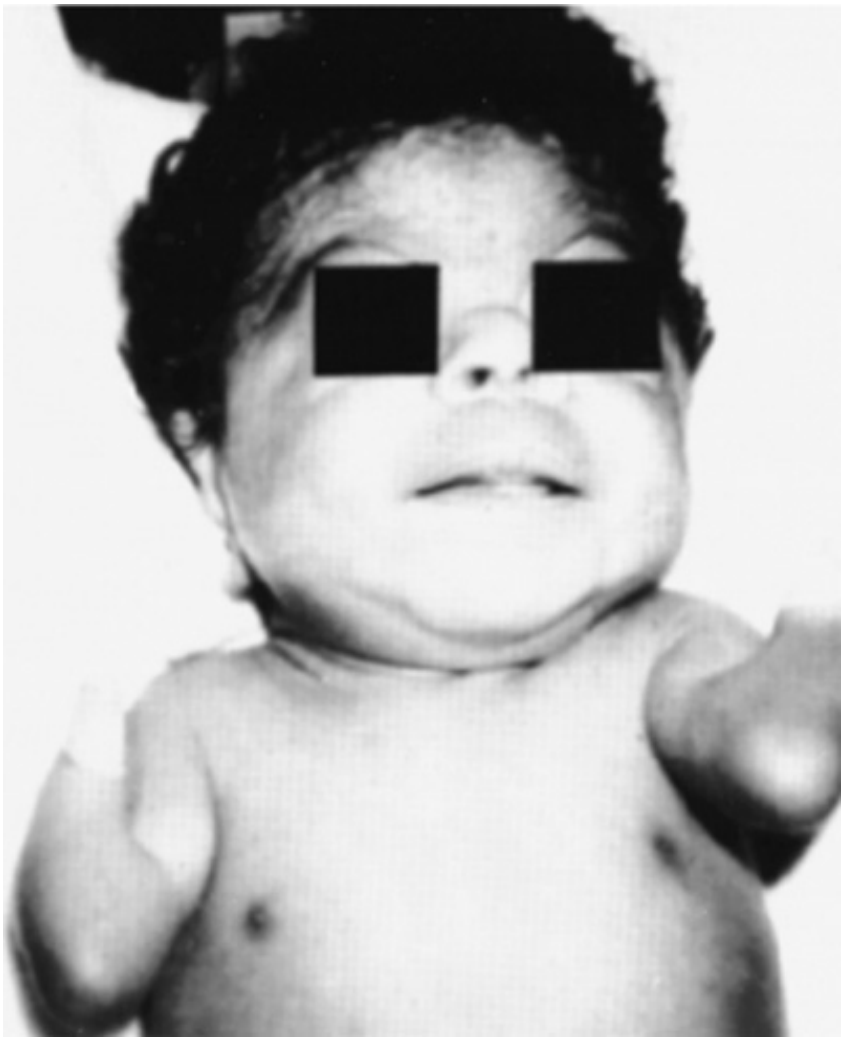


Figure 10-3: *Cornelia de Lange's syndrome:* low hairline, hirsutism, bushy brows, phocomelia, and a single thumblike digit. May be associated with ventricular septal defect.

There appears to be an increased incidence of congenital heart disease in children with a cleft palate or lip.[50] In the *Pierre Robin syndrome,* the cleft palate is associated with a hypoplastic mandible causing a "shrewlike" face (Fig. 10-4). A cleft palate, micrognathia, low-set ears, and truncus arteriosus may be present in the familial *third and fourth pharyngeal pouch syndromes*.

Figure 10-4: *Pierre Robin syndrome*: hypoplastic mandible associated with a ventricular septal defect.

Cutis laxis is a generalized disruption of elastic fibers with diminished skin resilience, frequent hernias, and pulmonary artery branch stenosis.[51] Patients with the *Ehlers-Danlos syndrome* (Fig. 10-5*A, B*) have hyperextensible joints and hyperelastic and friable skin that is often associated with arterial dilatation and rupture, aortic regurgitation, or mitral valve prolapse.[52] Patients with osteogenesis imperfecta have brittle bones, blue sclera, and short legs and have an increased incidence of aortic and mitral regurgitation.[53] Patients with pseudoxanthoma elasticum (see Chap. 76), who have degeneration of dermal elastic fibers and retinal angioid streaks, can develop aortic regurgitation and CAD (Fig. 10-6).

A

B

Figure 10-5: *Ehlers-Danlos syndrome. A.* Hyperextensible skin. *B.* Lax joints. Redundant chordae tendineae and arterial rupture may occur.

Figure 10-6: *Pseudoxanthoma elasticum*: grooved skin in a typical location. Arterial calcification may occur.

Marfan's syndrome, an autosomal dominant trait, is suggested by skeletal features such as increased height, long fingers, narrow palms, lax joints, kyphoscoliosis, pectus excavatum or carinatum, an elongated face, high-arched palate, and flat feet[54] (Fig. 10-7*A-C*). The legs are disproportionately long, resulting in an abnormal ratio of the upper-to-lower segments of at most 0.85. The arm span many exceed the height. When a patient with Marfan's syndrome clenches the hand around a flexed thumb, the thumb protrudes past the ulnar side of the hand. Such a patient also can easily encircle the wrist by grasping it with the fifth finger and thumb of the other hand (see Fig. 10-7*B*). Other signs include bilateral subluxation of the lens, severe myopia, and blue sclera (see Fig. 10-7*D*). Subcutaneous tissue is sparse. Valvular disease is common; patients with Marfan's syndrome usually have mitral valve prolapse (see Chap. 58), minimal to severe mitral regurgitation, a dilated and often calcified mitral annulus, and eventual chordal rupture. Aortic regurgitation is a consequence of a dilated aortic root, prolapse of the aortic cusps, or aortic dissection (see Chap. 76).

Aortic regurgitation also has been described in patients with inborn errors of metabolism including *Morquio's syndrome* (mucopolysaccharidosis IV) and *Scheie's syndrome* (mucopolysaccharidosis V).[55] Patients with Morquio's syndrome are identified by their short stature, short neck, barrel chest, broad mouth, short nose, widely spaced teeth, and cloudy cornea. In Scheie's syndrome, growth retardation, sternal protrusion, facial abnormalities, and cloudy cornea are present. In *Fabry's disease*, angiokeratomas identified as purplish pinpoint skin lesions occur on the lips, underarm, buttocks, scrotum, and penis (Fig. 10-8). Cardiomyopathy, ischemic heart disease, and conduction defects beginning in the third decade are associated with this sex-linked recessive disorder, in which there is a genetic deficiency of the enzyme α-galactosidase A.[56]

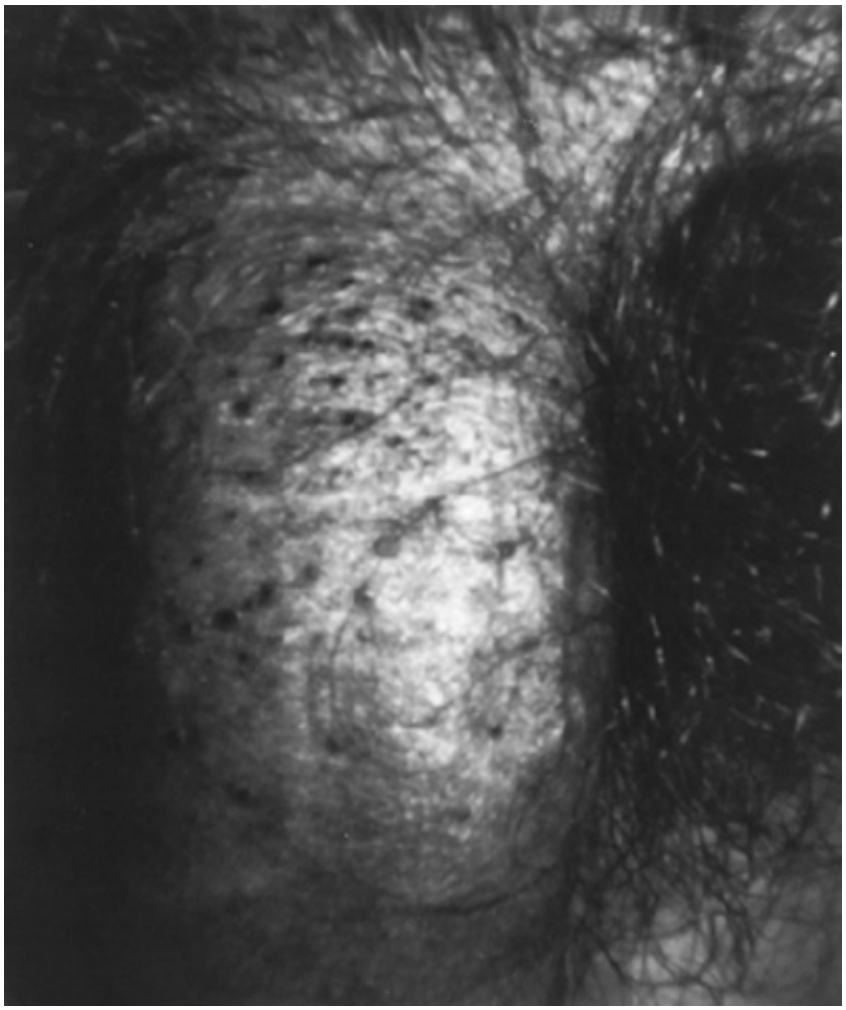

Figure 10-8: *Fabry's disease*: dark-red angiokeratomas on the penis may be linked with coronary artery disease.

Many chromosomal abnormalities have been associated with congenital heart disease. The well-recognized characteristics of *Down's syndrome* (trisomy 21) include a small head, shallow orbits, epicanthal folds, low-set ears, widely spaced eyes (hypertelorism), Brushfield's white spots of the iris, protruding tongue, transverse palmar creases, and mental retardation (see Chap. 64). Congenital heart disease occurs in 40 to 60 percent of patients; a VSD or endocardial cushion defect is the most frequent.[57] Less commonly, tetralogy of Fallot, secundum ASD, patent ductus arteriosus, and other abnormalities are present.[58,59]

Klinefelter's syndrome is characterized by gynecomastia, small testicles, a eunuchoid appearance, tall stature, and long extremities. Associated ASD's have been described.[58]

Patients with abnormalities involving chromosomes 1, 9, 11, and 22 often have congenital heart disease.[59] The findings with *chromosome 1 abnormalities* include a peaked nose, micrognathia, and long, tapering fingers. Children with *chromosome 9 abnormalities* have a prominent forehead, hypertension, anteverted nostrils, a long upper lip, a short neck, mental retardation, and external ear malformations. A child with a *chromosome 11 abnormality* shares similar features plus retraction of the lower lip. Psychomotor retardation, coloboma, hypertelorism (widely spread eyes), downward slanting of the eyes, and preauricular tags or fistulas are clues to a *chromosome 22 defect*.

Congenital heart disease, primarily patent ductus arteriosus, has been associated with the *49*

XXXXY syndrome. This unusual disorder should be suspected when a child has psychomotor retardation, hypoplastic genitals, prognathism, clinodactyly (inward curving of the fifth finger), and radioulnar synostoses.

Congenital heart disease of varied types is common in *trisomy 13* and *trisomy 18 syndromes*.[60] In *trisomy 13 syndrome*, the child has a cleft palate and lip; the ocular tissue and the nose may be missing. Polydactyly in combination with retroflexible thumbs, transverse creases, hyperconvex narrow nails, and flexion of the fingers and hands are characteristic of this syndrome. The features of the trisomy 18 syndrome are a small, triangular mouth with receding chin, small mandible, webbed neck, and tightly clenched fists with the index finger overlapping the third finger and the fifth finger over the fourth (Fig. 10-9).

Figure 10-9: *Trisomy 18 syndrome*: tightly clenched fist with overlapping index and fifth fingers. A ventricular septal defect was present.

Low hairline, low-set ears, deafness, small jaw, and short, webbed neck are physical findings common to both *Turner's syndrome* and the *Klippel-Feil syndrome*. Turner's syndrome also includes short stature, broad chest with widely spaced nipples, epicanthal folds, widely spaced eyes, pigmented moles, ptosis, clinodactyly, and a shortened fifth finger[61] (Fig. 10-10). Coarctation of the aorta, aortic stenosis, and hypertrophic cardiomyopathy are the usual cardiovascular considerations. The Klippel-Feil syndrome may cause facial asymmetry, cleft palate, torticollis, scoliosis, deafness, strabismus, and hydrocephaly. VSD is the most common associated cardiac disorder.[62]

Figure 10-10: *Turner's syndrome:* epicanthal folds, pigmented moles, hypertelorism, and scars on the neck where webs have been removed. May be associated with coarctation of the aorta.

There are many sporadic disorders associated with congenital heart disease. An imperforate anus may be associated with a cardiovascular malformation.[63] This may occur as an isolated finding or as a component of the *VATER association*,[64] the *asplenia syndrome*,[65] the *CHARGE syndrome*[66] (*coloboma, heart disease, atresia choanae, retarded growth, genital hypoplasia, ear anomalies*), or *cat's-eye pupil*[67] (a fissure of the iris and choroid associated with a cardiac defect). The VATER association includes vertebral defect, tracheoesophageal fistula, and radial and renal dysplasia. A ventricular defect occurs in 80 percent of these patients. The asplenia syndrome is associated with a high incidence of complex congenital heart disease. Cardiovascular malformations are found in 15 to 25 percent of newborns with omphalocele.[68]

Teratogenic effects resulting in congenital heart disease may be alcohol-induced, the result of rubella during pregnancy, or induced by phenytoin, thalidomide, or lithium.[69] From 30 to 40 percent of children born to alcoholic mothers are affected with the *fetal alcohol syndrome*.[70] These children have an undeveloped-appearing central face because of maxillary hypoplasia, a small and upturned nose, an indistinct or smooth philtrum, micrognathia, and a thin upper lip and vermilion (Fig. 10-11). ASDs and VSDs are most common, but many other cardiac defects also can be found. The teratogenic effects of the rubella syndrome include cataracts, deafness, and microcephaly. The most frequent congenital cardiac disorders are patent ductus arteriosus, pulmonic valvular and/or arterial stenosis, and ASD.[71]

Figure 10-11: *Fetal alcohol syndrome:* midface hypoplasia, absent philtrum, and microcephaly associated with a ventricular septal defect.

Important clues to the diagnosis of underlying congenital heart disease may be obtained from careful observation of the thorax and extremities. Bilateral prominence of the anterior chest with bulging of the upper two-thirds of the sternum is commonly present in children with a large VSD. A unilateral bulge at the fourth and fifth intercostal spaces at the lower left sternal border often is found in adults with VSDs. A bulge in the area of the second and third intercostal spaces at the left sternal border may result from an underlying ASD. Scoliosis is commonly present in cyanotic congenital heart disease. Underdeveloped musculature of the lower extremities compared with the upper extremities occurs with coarctation of the aorta. Clubbing of the digits and cyanosis of the skin or nails suggest congenital heart disease with right-to-left shunting of blood (Fig. 10-12, Plate 29).

Figure 10-12: (Plate 29) *Symmetric cyanosis*. Equal cyanosis and clubbing of hands and feet due to transposition of great vessels and a ventricular septal defect without patent ductus arteriosus.

Differential cyanosis often provides a clue to exact pathologic anatomy.[72] Cyanosis and clubbing of the toes associated with pink fingernails of the right hand and minimal cyanosis and clubbing of the left hand are due to pulmonary hypertension with normally related great vessels and a reversed shunt, with the patent ductus arteriosus bringing unoxygenated blood to the left arm and lower extremities (Fig. 10-13, Plate 30). The same pattern results from interruption of the aortic arch and a patent ductus arteriosus delivering desaturated blood to the legs. If the right subclavian artery arises proximal to the aortic obstruction, the right hand may be pink and the left hand cyanotic. When an anomalous right subclavian artery originates from the descending aorta, however, both hands are cyanotic. Cyanosis of the fingers greater than that in the toes suggests complete transposition of the great vessels with preductal coarctation or complete interruption of the aortic arch, pulmonary hypertension, and a reverse shunt through a patent ductus arteriosus delivering oxygenated blood to the lower extremities (Fig. 10-14, Plate 31). In this anomaly, the presence of aortic coarctation can be distinguished from complete interruption of the aortic arch. Slightly less cyanosis of the left arm when compared with the right arm favors aortic coarctation, whereas intense symmetric cyanosis of both arms is seen with complete aortic interruption. Red fingertips ("tuft erythema") may signify a small, intermittent right-to-left shunt with only slight reduction in arterial oxygen saturation (Fig. 10-15, Plate 32).

Figure 10-14: (Plate 31) *Differential cyanosis*. Clubbing of left hand (compare thumbs) and cyanosis of left hand and all toes due to patent ductus arteriosus with pulmonary hypertension and normally related great vessels. (Courtesy of Dr. Joseph K. Perloff, University of California, Los Angeles.)

Figure 10-15: (Plate 32) *Tuft erythema*. Erythema of fingertips due to small right-to-left shunt from AV canal defect.

Anotia (congenital absence of the pinna) and facial paralysis may be signs of an underlying VSD and pulmonic stenosis.[73] The presence of any congenital somatic abnormality always should prompt a search for congenital heart disease. Extracardiac anomalies were found in 25 percent of infants seen during the first year for significant cardiac disease in one study.[74] The defects were commonly found in the musculoskeletal system and were associated with specific syndromes.

Disorders Affecting the Valves

The cutaneous lesions of *infective endocarditis* (see Chap. 73) include Osler's nodes, Janeway lesions, clubbing of the fingers (Fig. 10-16, Plate 33), splinter hemorrhages of the nails, and petechiae.[75,76] *Osler's nodes* are reddish purple, tender nodules typically found in the distal pad of the finger or toe (Fig. 10-17, Plate 34). By contrast, *Janeway lesions* are hemorrhagic but nontender and involve the palms or soles. Splinter hemorrhages are linear and black and affect the distal third of the fingernail. They are also present in many unrelated diseases and may result from trauma in otherwise healthy people.

Certain features suggest primary valvular heart disease (see Chaps. 56, 57, and 59). Pulmonic stenosis may be part of Noonan's syndrome, Turner's syndrome (previously discussed), Rubinstein-Taybi syndrome, rubella syndrome (see above), the multiple-lentigines syndrome, pulmonary valve dysplasia, or Watson's syndrome. In *Noonan's syndrome*,[77] the characteristic findings include ptosis, low-set ears, downward-slanting eyes, webbed neck, hypertelorism, low posterior hairline, short stature, mental retardation, and normal chromosomes (Fig. 10-18). Broad toes and thumbs, a slanting forehead, a thin, beaked nose, and large, low-set ears are seen in *Rubinstein-Taybi syndrome*[78] (Fig. 10-19). Café-au-lait spots and mental retardation are linked to pulmonic valve stenosis in *Watson's syndrome*.

Figure 10-18: *Noonan's syndrome:* ptosis, hypertelorism, and low-set ears associated with valvular pulmonic stenosis.

Figure 10-19: *Rubinstein-Taybi syndrome* may be associated with a variety of congenital heart defects. (From Silverman ME, Hurst JW. The hand and heart. *Am J Cardiol* 1968; 22:718. Reproduced with permission from the publisher and authors.)

The *multiple-lentigines syndrome* is identified by the presence of multiple tan to brown macules varying in size from pinpoint to 5 cm in diameter (Fig. 10-20). These cutaneous lesions may affect the entire body but are most heavily concentrated on the neck and upper thorax. Other findings in this syndrome include hearing loss, short stature, hypertelorism, ptosis, prognathism, pectus excavatum or carinatum, kyphoscoliosis, café-au-lait spots, and other skeletal defects.[79]

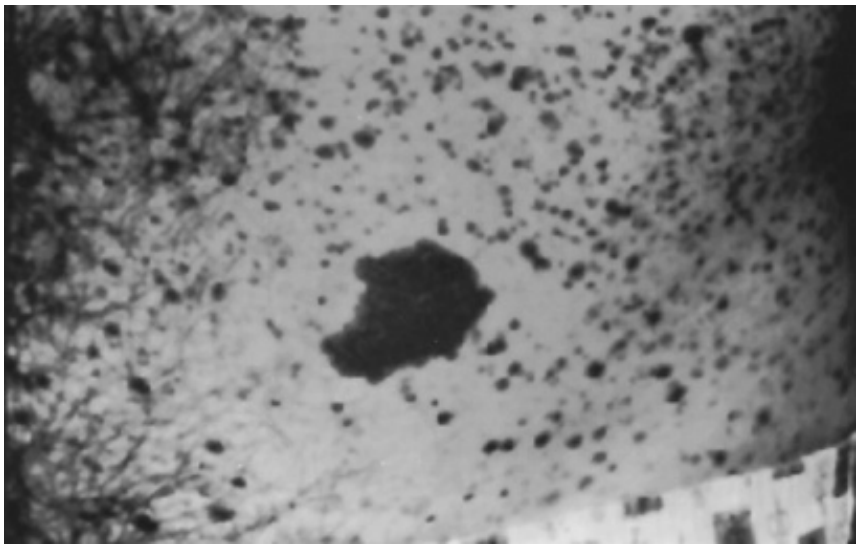

Figure 10-20: *Multiple lentigines syndrome:* dark-brown macular lesions of the abdomen associated with hypertrophic subaortic stenosis. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, October 1986. Reproduced with permission from the publisher and author.)

The *carcinoid syndrome* (see Chap. 77) may present as intense flushing of the face; a chronic cyanotic hue and telangiectasia may be present. Stenosis and/or regurgitation of the tricuspid and/or pulmonic valves often results when hepatic metastases are present.[80] When a patent ductus arteriosus, lung metastases, or a patent foramen ovale is present, the left-sided heart valves can be affected.

In *progressive systemic sclerosis* (scleroderma), tightening of the skin on the fingers and then the hands, forearms, upper chest, and face is associated with hair loss and disappearance of subcutaneous tissue and skin creases (Fig. 10-21). Flexion contractures on the fingers may cause a clawlike hand deformity. Raynaud's phenomenon is an early manifestation. The *CREST syndrome (calcinosis, Raynaud's esophageal involvement, sclerodactyly,* and *telangiectasia*) is a variant of scleroderma (Fig. 10-22). Although valvular changes include thickening of the edges of the mitral, aortic, and tricuspid valves, as well as thickening and shortening of the mitral chordae, the resulting valve disease is rarely significant.[81]

Figure 10-21: *Scleroderma:* clawlike hand deformity and shiny, tight skin. May be linked with myocardial fibrosis.

Figure 10-22: *CREST syndrome*. Telangiectasia of the face in a patient with Raynaud's phenomenon and sclerodactyly.

Joint disease associated with cardiac valvular disease is frequent with systemic lupus erythematosus, rheumatoid arthritis, rheumatic fever, polychondritis, ankylosing spondylitis, alkaptonuria, and Whipple's disease. In systemic lupus erythematosus, the joint inflammation is usually symmetric and nondeforming. Typical skin lesions include an erythematous, scaling eruption over the cheeks and bridge of the nose, circumscribed reddish purple plaques, telangiectasia, and patchy hair loss (Fig. 10-23). Verrucous endocarditis may involve any of the four cardiac valves; however, severe valvular dysfunction is unusual.[82,83] Sessile, small, nonbacterial vegetations and valvular thickening causing regurgitation rather than stenosis may be more common in patients with antiphospholipid antibodies[84] (see Chap. 76).

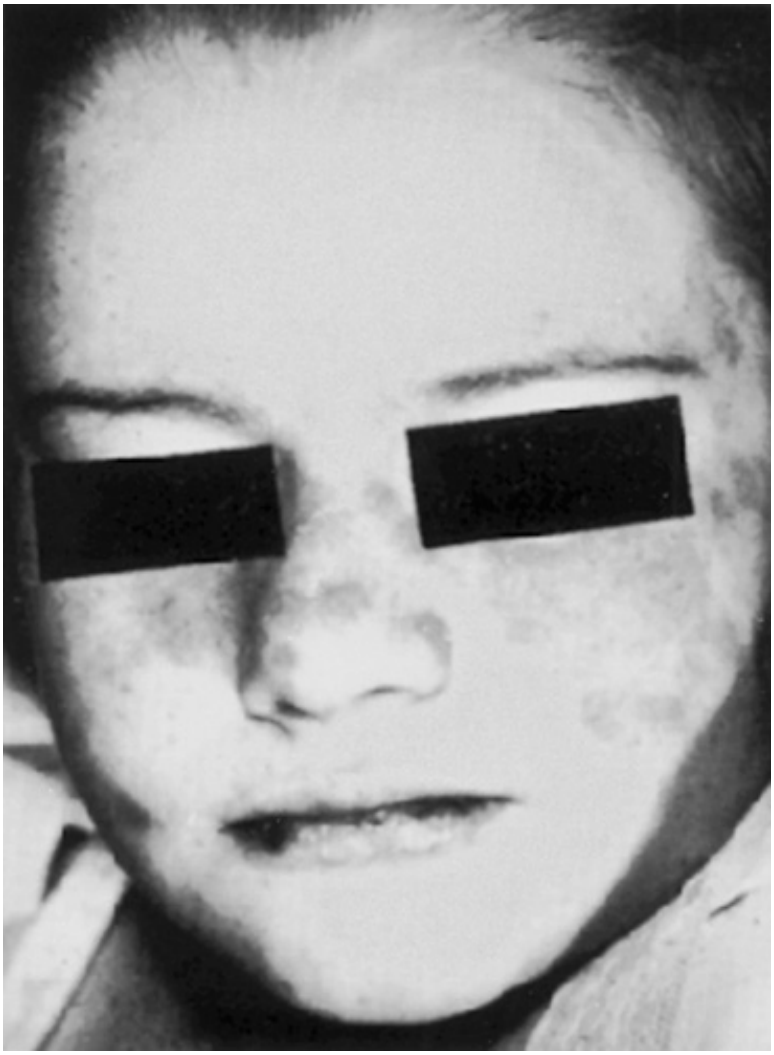

Figure 10-23: *Systemic lupus erythematosus:* butterfly rash associated with pericardial, myocardial, and endocardial disease.

In patients with *rheumatoid arthritis,* the metacarpophalangeal joints, proximal interphalangeal joints, wrists, metatarsophalangeal joints, shoulders, knees, ankles, and elbows are involved with inflammation and subsequent destruction. Advanced disease results in ulnar deviation of the fingers and flexion of the distal interphalangeal joints with hyperextension of the proximal interphalangeal joints, producing a "swan neck" deformity and a Z-shaped configuration of the

thumb (Fig. 10-24, Plate 35). Subluxation of the metacarpophalangeal joints with interosseal muscle wasting and thickening of the wrists are common. Granulomatous aortic or mitral valve disease with regurgitation is most common in patients who are seropositive and have subcutaneous nodules or classic rheumatoid deformities.[85] Rheumatic fever, often with cardiac involvement, should be suspected in patients with erythema marginatum, urticaria, and migratory polyarthritis involving the large joints (see Chap. 55). Subcutaneous nodules are found less frequently. Marked ulnar deviation at the metacarpophalangeal joints, suggesting rheumatoid arthritis, can be due to repeated attacks of rheumatic fever and is known as *Jaccoud's* or *post-rheumatic fever arthritis*. In contrast to rheumatoid arthritis, the fingers can be moved freely into a correct alignment, and x-rays of the hands are normal. It also occurs in systemic lupus erythematosus (SLE).

Figure 10-24: (Plate 35) *Rheumatoid arthritis:* with ulnar deviation of the fingers, flexion of the distal interphalangeal joints with hyperextension of the proximal interphalangeal joints.

Polychondritis causes an inflammatory destruction of the cartilage of the face, resulting in a saddle-shaped collapse of the nose or a cauliflower ear. Aortic regurgitation, aortic aneurysm, and rarely aortic root dissection are associated[86] (Fig. 10-25).

Figure 10-25: *Polychondritis. A,B.* Destruction of cartilage of the nose, producing a "saddle nose" in association with aortic regurgitation. (Courtesy of Dr. Warren Sarrell, Anniston, AL.)

Chronic synovitis involving the fibrocartilaginous joints of the spine occurs in patients with ankylosing spondylitis. The disease may be confined to a sacroiliac area or spread slowly upward. The patient with advanced disease is bent forward, is unable to stand upright, and must walk with a stiff and halting gait (Fig. 10-26). Aortic regurgitation due to thickening and shortening of the aortic cusps from perivascular inflammation and fibrosis occurs in up to 10 percent of patients.[87] Mitral regurgitation and complete heart block also may occur. Cogan's syndrome, consisting of ophthalmic inflammation and audiovestibular symptoms, is another cause of vasculitis involving the aortic root and leading to aortic regurgitation and coronary disease.[88]

Figure 10-26: *Ankylosing spondylitis:* immobile, curved spine with forward jutting of head. May be seen with AV block or aortic regurgitation. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, June 1987. Reproduced with permission from the publisher, author, and patient.)

Whipple's disease is suggested by the combination of polyarthritis, abdominal pain, and diarrhea. Aortic and mitral regurgitation and endocarditis are known complications.[89] Aortic or mitral valvular disease also may be due to an accumulation of homogentisic acid in *alkaptonuria*. Blue-black, stiff pinnae and joints are important clues to this inherited disorder of tyrosine metabolism.

External signs of mitral valve prolapse (see Chap. 58) include a straight thoracic spine, pectus excavatum, scoliosis, hypomastia, joint laxity, and various neuromuscular disorders. Systolic and rarely diastolic murmurs have been described with chest wall deformities due to *straight-back syndrome* and *pectus excavatum* (Fig. 10-27, Plate 36) that may impinge on or displace the heart.

Figure 10-27: (Plate 36) Marked pectus excavatum.

Disorders Associated with Cardiomyopathy

Hypertrophic cardiomyopathy (see Chap. 67) has been associated with *Friedreich's ataxia*, Turner's syndrome, Noonan's syndrome, Fabry's disease, neurofibromatosis, and the multiple-lentigines syndrome. Friedreich's ataxia is a spinocerebellar degenerative disorder that results in a broad-based, lurching gait, impaired vibration, position, and joint sense, and incoordination. Kyphoscoliosis and pes cavus (high instep, retraction of the toes at the metatarsophalangeal joints, and hammer toes) are two important physical signs (Fig. 10-28). Concentric and asymmetric LV hypertrophy that may evolve into a dilated cardiomyopathy have each been described.[90]

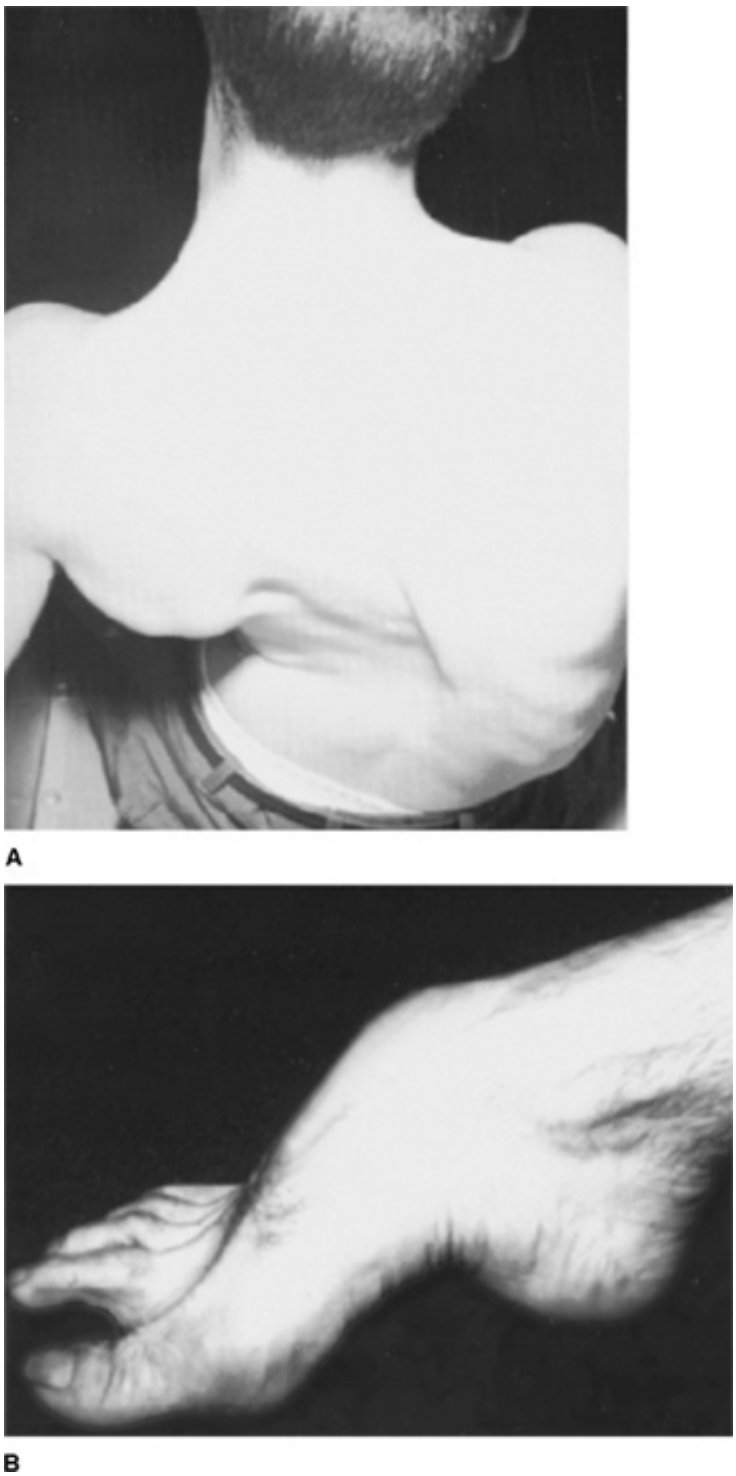

Figure 10-28: *Friedreich's ataxia* (photographs from different patients). *A.* Kyphoscoliosis. *B.* Pes cavus. Myocardial fibrosis and hypertrophy are often present. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, June 1987. Reproduced with permission from the publisher and authors.)

Myocardial hypertrophy may be secondary to extreme obesity or acromegaly. With acromegaly, the broad forehead, thickened skin, and enlarged nose, lip, and tongue produce coarsened facial features (Fig. 10-29), whereas elongation of the mandible leads to prognathism and overbite. The large, sausage-shaped fingers and spadelike configuration of the hands are typical.[91]

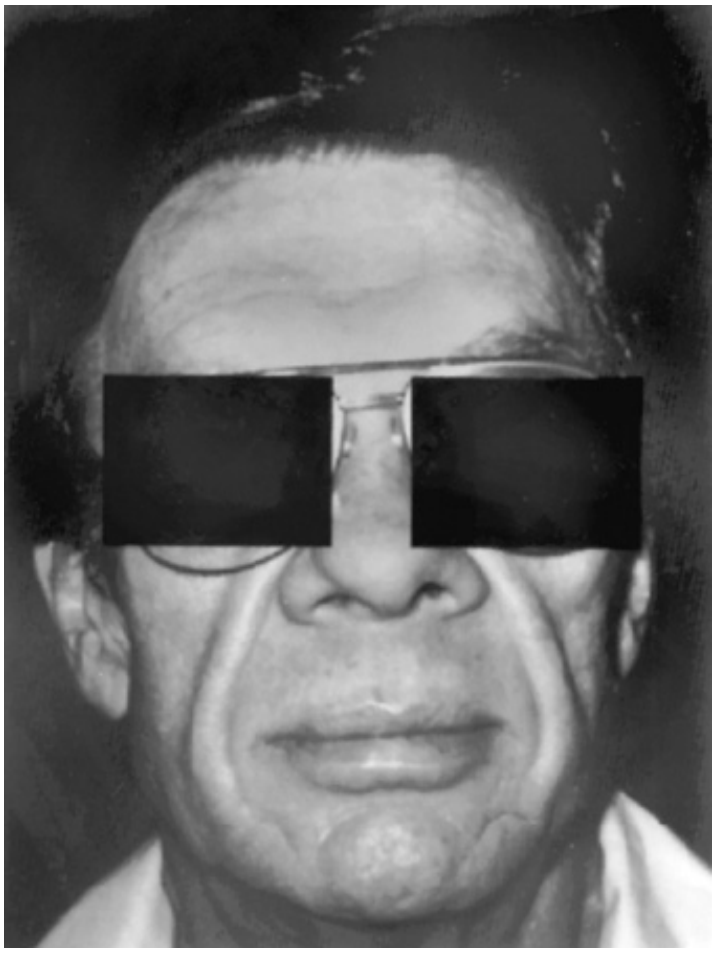

Figure 10-29: *Acromegaly*. Coarse facial features, folds of skin, and prognathism are associated with myocardial hypertrophy and fibrosis. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, February1987. Reproduced with permission from the publisher, author, and patient.)

Cor pulmonale and RV hypertrophy may be secondary to pulmonary hypertension caused by *kyphoscoliosis, restrictive lung disease, progressive systemic sclerosis, upper airway blockade* by enlarged tonsils[126] and adenoids, or the *sleep apnea syndrome* associated with extreme obesity.[92,93]

Myocarditis (see Chap. 69) occurs with SLE, rheumatic fever, Reiter's syndrome,[94] Kawasaki's disease,[95] Lyme arthritis,[96] and occasionally, Whipple's disease. Reiter's syndrome is characterized by conjunctivitis and hyperkeratotic coalescing lesions encrusted on the soles and palms, associated with arthritis and urethritis (Fig. 10-30, Plate 37). Kawasaki's disease begins with fever, nonexudative conjunctivitis, dry, fissured lips, cervical adenopathy, and a strawberry tongue. Later, the palms and soles become indurated and purplish red and then peel. A widespread erythematous rash may appear and then desquamate. *Lyme arthritis*, caused by the spirochete *Borrelia burgdorferi*, begins with a red macule or papule and then develops into an expanding erythematous rash with a bright red border known as *erythema migrans* (Fig. 10-31). The center of the rash may clear, indurate, blister, or become necrotic. Multiple annular lesions may develop.

Figure 10-30: (Plate 37) *Hyperkeratotic lesions* encrusted on the soles of the feet in Reiter's syndrome.

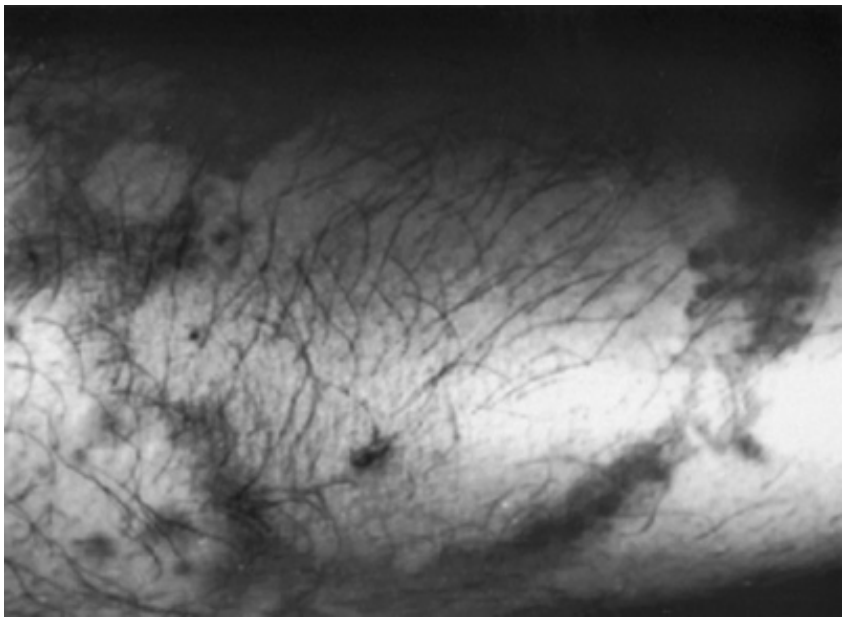

Figure 10-31: *Lyme arthritis:* annular expanding rash with a clear central area. May be associated with pericarditis and AV block. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, December 1986. Reproduced with permission from the publisher and author.)

Diseases that cause myocardial fibrosis include dermatomyositis, Duchenne's and Becker's muscular dystrophy, myotonic muscular dystrophy, Kearns-Sayres syndrome, Friedreich's ataxia, sarcoidosis, and progressive systemic sclerosis (see Chaps. 62 and 76). With dermatomyositis, an erythematous eruption and periorbital heliotropic discoloration affects the face (Fig. 10-32, Plate

38), and a scaly, erythematous rash may cover the knuckles, sparing the interphalangeal region.[97] A waddling gait and pseudohypertrophic calves are characteristic of Duchenne's muscular dystrophy. The ECG is commonly consistent with fibrosis of the posterior left ventricle.[98] In *myotonic dystrophy*, drooping eyelids, cataracts, a receding hairline, and a masklike expression are present.[99] The *Kearns-Sayre syndrome* is a form of ocular muscular dystrophy in which external ophthalmoplegia, ptosis, and retinitis pigmentosa occur.[100] The skin manifestations of sarcoidosis include erythema nodosum, lupus pernio (a red or violet plaque with a predilection for the nose, cheeks, eyelids, and ears), and waxy translucent papules found on the cheeks, periorbital area, ears, nasolabial folds, and elsewhere.[101] Uveitis, bilateral parotid and lacrymal gland enlargement, and arthritis are other signs (see Chap. 68).

Figure 10-32: (Plate 38) *Dermatomyositis*. A violaceous hue and edema of upper eyelid may be associated with myocardial disease.

Isolated noncompaction of the LV myocardium is characterized by numerous, prominent ventricular trabeculations, deep intertrabecular recesses, arrhythmias, and a distinctive facial dysmorphism.

Infiltrative diseases of the myocardium include Wilson's disease, Cori's disease, Fabry's disease, hemochromatosis, amyloidosis, glycogen storage disease, and sarcoidosis (see Chap. 68). *Wilson's disease* is an autosomal recessive disorder in which copper accumulates in tissues, including the myocardium.[102] Arrhythmias, autonomic dysfunction, and cardiomyopathy have been reported. Kayser-Fleischer rings, usually golden-brown in color and circling the edge of the cornea, provide a major clue to the correct diagnosis.

Cori's disease (type III glycogenosis) is suspected when a patient has xanthomas and a yellowish skin. In *hemochromatosis*, the skin has a bronze or slate-gray coloration; myocardial infiltration with iron deposits often causes a dilated or rarely a restrictive cardiomyopathy associated with arrhythmias and heart failure.[103] Macroglossia and waxy nodules of the skin and eyelids, which may hemorrhage when pinched, are clues to the diagnosis of *amyloidosis*[104] (Fig. 10-33) (see Chap. 68). Glycogen storage disease and myxedema also can enlarge the tongue.

Figure 10-33: *Amyloidosis*. Enlarged tongue may be a sign of an infiltrative cardiomyopathy. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, November1987. Reproduced with permission from the publisher, author, and patient.)

Disorders Associated with Pericardial Disease

Pericarditis may be a result of Reiter's syndrome, Whipple's disease, Kawasaki's disease, SLE, rheumatoid arthritis,[105] rheumatic fever, sarcoidosis, scleroderma, dermatomyositis, hemochromatosis, Behçet's disease, Degos' disease, uremia, mulibrey nanism, polychondritis, hypothyroidism, or metastatic disease among others (see Chap. 72). The components of *Behçet's disease* include erythema nodosum, superficial phlebitis, oral and genital ulcers, and iritis.[106] Patients with *Degos' disease* (malignant atrophic papulosis) present with painless, oval cutaneous lesions that have a white center and surrounding erythema. In this rapidly fatal disease, occlusive fibrosis of small and medium-sized arteries produces pleuritis and pericarditis. In far-advanced renal disease, urochrome pigmentation of the skin and uremic frost are cutaneous manifestations. The term *mulibrey nanism* describes a syndrome involving muscle, liver, brain, and eyes.[107] These patients have a triangular face, bulging forehead, low nasal bridge, growth retardation, pigmentary changes in the fundus, hemangiomas, and constrictive pericarditis. Hypothyroidism, a cause of often massive pericardial effusions, thickens the face and causes dry hair, puffy eyelids, and an enlarged tongue.

Disorders Causing Conduction System Disease

Acquired causes of atrioventricular (AV) block or bundle-branch block include sarcoidosis,[101] rheumatic fever, gout, Reiter's syndrome,[108] dermatomyositis, amyloidosis, Kawasaki's disease,[95] ankylosing spondylitis,[109] SLE,[83] and Lyme arthritis.[96] In gout, uric acid crystals may form nodules affecting the conduction system. AV block may be an early cardiac manifestation of ankylosing spondylitis.

Inherited or congenital disorders associated with conduction defects include SLE, Fabry's disease,

Friedreich's ataxia, Kearns-Sayre syndrome, multiple-lentigines syndrome, muscular dystrophy, myotonic dystrophy, tuberous sclerosis, and Refsum's disease. Maternal lupus is an important cause of congenital complete AV block in the newborn.[82] In *Refsum's disease,* a lipidosis and genetically determined neuropathy characterized by high levels of phytanic acid, cerebellar ataxia, night blindness, deafness, ichthyosis, cataracts, and polyneuropathy have been associated with myocardial disease and conduction abnormalities.

Syndactyly (webbing of the hands or feet) has been found with a long QT interval-a syndrome with a high risk of sudden death.[110]

Disorders Affecting the Vascular System

Aortic aneurysms and dissection (see Chap. 88) are frequent cardiovascular complications of Marfan's and Ehlers-Danlos syndromes. Aneurysms of other vessels and arterial rupture also may occur. A progressive looseness of skin producing pendulous folds and droopy eyelids can be due to cutis laxa, a generalized destruction of elastic tissue that can cause dilatation of the aorta or pulmonary artery and aortic rupture.[51]

Coronary artery stenosis from atherosclerosis can be associated with hyperlipidemia,[111] cerebrotendinous xanthomatoses, Werner's syndrome, uremia, progeria, acromegaly, and diabetes mellitus. *Hyperlipidemia* may be suspected when xanthomas or arcus senilis are present. Xanthelasma usually involve the upper eyelid. When they occur before age 50, there is a strong association with familial hypercholesterolemia and premature CAD. Eruptive xanthomata are recognized as papules with yellow centers surrounded by an erythematous halo. They often appear with a sudden outbreak of discrete 1- to 4-cm lesions on the buttocks, back, thighs, and exterior surfaces of the knees and elbows. They indicate a very high level of triglycerides and are associated with hyperlipidemia, diabetes mellitus, pancreatitis, myxedema, and the nephrotic syndrome. Tendon xanthomata are firm, painless nodules that thicken the exterior tendons of the hand, the Achilles tendons, and sometimes the tendons of the knees and elbows (Fig. 10-34). *Cerebrotendinous xanthomatosis* is a rare disorder in which tendon xanthomata, cataracts, dementia, ataxia, neuropathy, and accelerated atherosclerosis are present. Tuberous xanthomata are yellow to deep-orange papules erupting over the elbows, knees, buttocks, and heels. They may coalesce or be pedunculated and are a manifestation of hyperlipidemia, myxedema, and liver disease. Large, orange, lobulated tonsils are a finding in *Tangier disease,* in which there is deficiency of high-density lipoprotein.

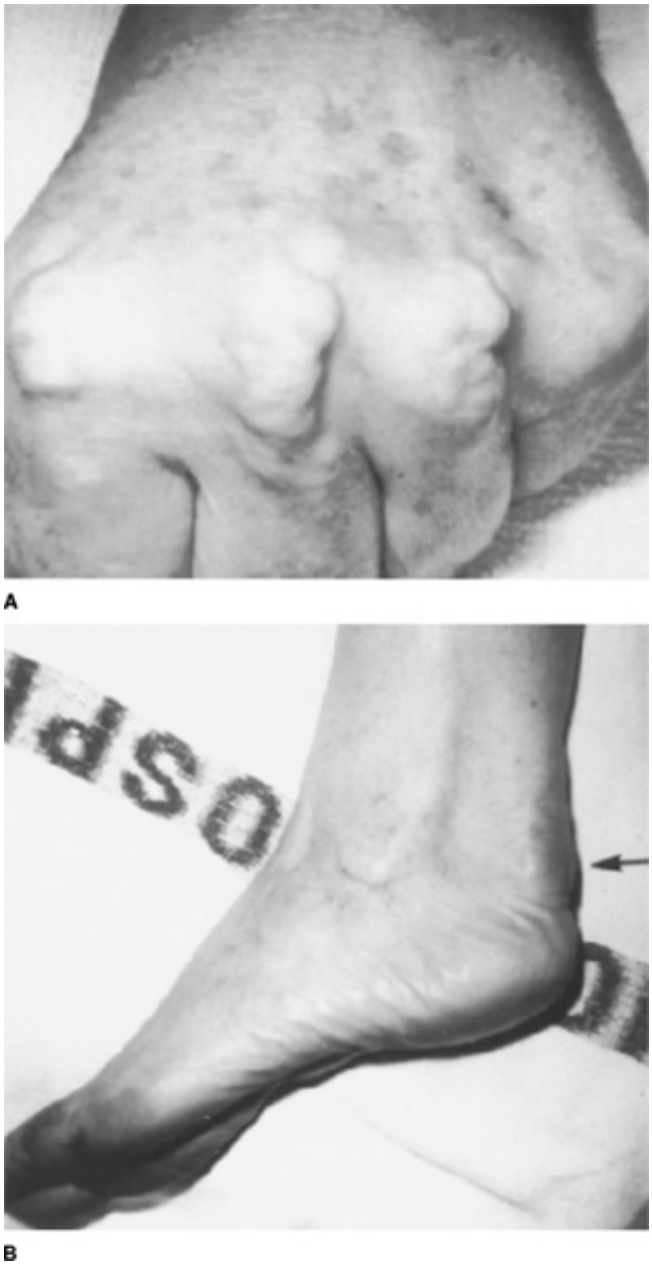

Figure 10-34: *Hyperlipidemia:* xanthomata associated with coronary artery disease. *A*. On the extensor tendons of the hand. *B*. On the Achilles tendon (arrow).

In *Werner's syndrome*, the skin is tightly stretched over the underlying bones.[112] There is marked loss of subcutaneous tissue, and ulcerations occur over the legs. Severe coronary atherosclerosis often results in MI at an early age. Physical findings in diabetes mellitus may include tight skin and necrobiosis diabeticorum, an atrophy of the skin of the lower extremities characterized by ovoid plaques with central telangectasia and a violet, undurated perimeter. *Progeria* is a rare disorder in which the face is small and prematurely aged, the eyes bulge, and the nose is beaked. Severe atherosclerosis with early MI is a common cause of death in early life.[113] A diagonal earlobe crease and short tufts of ear-canal hair curiously have been associated with coronary artherosclerosis.[114] There is a modest correlation between male-pattern baldness involving the vertex of the scalp in men under 55 years of age and an increased risk of MI.[115] Patients resemble those with Marfan's syndrome because they have long extremities, pectus carinatum, and kyphoscoliosis. Pseudoxanthoma elasticum has been associated with fibrosis of the coronary artery and calcification of peripheral arteries[116] (see Chap. 76). A glycosphingolipid is deposited in the arterial endothelium of patients with Fabry's disease and may result in angina pectoris or MI. Patients with Hurler's syndrome have mental retardation, a large, boat-shaped head, a broad

nose, large lips, small, widely spaced teeth, and a large, protuberant tongue. Glycosaminoglycan deposition in the coronary arteries is present.[117] Myocardial fibrosis due to repeated coronary small-vessel spasm has been postulated to be a result of progressive systemic sclerosis.[81]

Vasculitis may be due to SLE, rheumatoid arthritis, Behçet's disease,[108] Kawasaki's disease, and polyarteritis. Cutaneous infarction, nodules, petechiae, livedo reticularis, gangrenous digits, MI, heart failure, and hypertension may be due to polyarteritis[118] (see Chap. 76).

Arteriovenous shunts may be found in extensive skin disease, hereditary *hemorrhagic telangiectasia,* and the Klippel-Trenaunay-Weber syndrome. *Kaposi's sarcoma* or exfoliative dermatitis due to psoriasis may divert the blood supply through shunts in the skin to produce high-output cardiac failure. Clues to underlying arteriovenous fistula as a cause of high-output failure include a barely discernible scar from a knife wound or a surgical incision. Telangiectasias of the fingertips, face, palate, lips, and tongue, as well as pulmonary and hepatic arteriovenous fistulas, are components of *hereditary hemorrhagic telangiectasia*.[44] The triad of anomalies that Klippel-Trenaunay-Weber syndrome comprises are vascular nevus, large varices, and bony or soft tissue hypertrophy.[119] Marked enlargement of a limb(s) and facial hemihypertrophy are features of this disorder, in which part or all of the deep venous system is absent and arteriovenous malformation is often present. Hemangiomas of the skin also may indicate multinodular hemangiomatosis of the liver, a cause of high-output heart failure in infancy (Fig. 10-35).

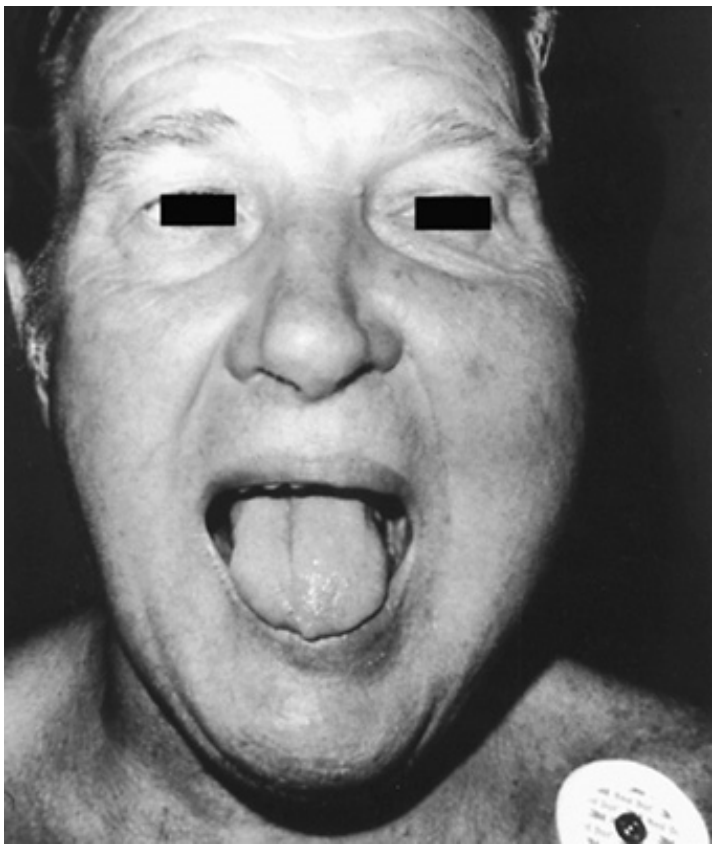

Figure 10-35: *Klippel-Trenaunay syndrome:* hypertrophy of left side of face and tongue in a patient with port-wine stains, gigantism of digits, and varicose veins.

Stenosis of large arteries may occur with supravalvular aortic stenosis, rubella syndrome, Turner's syndrome, and neurofibromatosis. The face of a child with supravalvular aortic stenosis (Williams syndrome) is almost diagnostic (Fig. 10-36). The head is small, with an elflike appearance; the

cheeks are full and baggy; and the mouth is large.[120] Thick lips and peg-shaped, widely spaced teeth are typical findings. The forehead is prominent and broad. Mental retardation is often present. The supravalvular aortic stenosis may be a localized ridge or a diffuse narrowing of the aorta beginning just above the sinuses of Valsalva. Pulmonic artery branch stenosis is frequently present. Coarctation of the aorta is a common cardiac lesion in Turner's syndrome,[61] and neurofibromatosis has been associated with renal artery stenosis.

Figure 10-36: *Supravalvular aortic stenosis:* turned-up nose, broad cheeks, large mouth with peg-shaped teeth, and large ears.

Facial swelling and jugular venous distention may be early signs of *superior vena caval obstruction* from clot or tumor.

Miscellaneous Disorders

Multiple lentigines, cutaneous myxomas, myxoid fibroadenomas of the breast, and various endocrine abnormalities are features of a recently described inherited disorder in which single or multiple cardiac myxomas occur.[121] Telangiectasia of the tongue and lips or under the fingernails may be associated with a pulmonary arteriovenous fistula (Figs. 10-37 and 10-38, Plates 39 and 40). A susceptibility to atrial fibrillation and atrial flutter has been documented in patients who have facioscapulohumeral muscular dystrophy.[122] Sinus node dysfunction, elbow contractures, and humeroperoneal weakness are manifestations of Emery-Dreifuss muscular dystrophy.[123]

Figure 10-37: (Plate 39) Hereditary hemorrhagic telangiectasia. Telangiectasia under nails. (From Silverman ME, Hurst JW. The hand and the heart. *Am J Cardiol* 1968; 22:609. Used with permission from the publisher.)

Figure 10-38: (Plate 40) Hereditary hemorrhagic telangiectasia. Telangiectasia of tongue and lips may be associated with a pulmonary arteriovenous fistula.

Single or multiple rhabdomyomas may develop within the myocardium and cause heart failure,

valvular obstruction, or arrhythmias in patients with tuberous sclerosis[124] (Fig. 10-39, Plate 41). The diagnosis is suggested by the presence of yellow-brown angiofibromas (adenoma sebaceum) on the face, subungual fibromas around the fingernail, café-au-lait spots, and subcutaneous nodules. Finally, horizontal ear creases often are associated with the presence of extensive CAD (Fig. 10-40, Plate 42).

Figure 10-39: (Plate 41) Tuberous sclerosis. Adenoma sebaceum may be associated with rhabdomyomas of the myocardium.

Figure 10-40: (Plate 42) Horizontal ear creases often are associated with the presence of extensive CAD.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

MEASUREMENT OF ARTERIAL BLOOD PRESSURE

A pneumatic cuff with a mercury or aneroid manometer for the noninvasive assessment of arterial blood pressure is the most commonly used method for determining the status of the circulation and the interaction between the heart and arterial system. Blood pressure deviations from normal often provide important diagnostic information in patients with a variety of cardiac and noncardiac diseases. Accordingly, the blood pressure is best recorded by the physician during his or her *initial* physical examination.

Physical Determinants of the Arterial Pressure

The arterial blood pressure, a measure of lateral force per unit area of vascular wall, is quantitated as millimeters of mercury or dynes per square centimeter. The factors responsible for the peak systolic blood pressure include the volume and velocity of LV ejection, the peripheral arteriolar resistance, the distensibility of the arterial wall, the viscosity of the blood, and the end-diastolic volume in the arterial system.[125] The subsequent diminution in pressure during diastole is, in turn, determined by blood viscosity, arterial distensibility, peripheral resistance to flow, and length of the cardiac cycle.[125] Important physical factors affecting arterial distensibility include (1) the elastic modulus of the arterial wall, the ratio of stress (force acting to deform the wall) to strain (the proportional deformation produced), and (2) the geometry of the arterial wall, i.e., the internal radius (r) and wall thickness (h), which govern wall tension (T) according to the modified Laplace equation $T = Pr/h$, where P is intravascular pressure. A decrease in elasticity or an increase in radius results in diminished distensibility and a greater rise in pressure per unit volume of blood.[126]

The mean arterial pressure is the product of the cardiac output and the total peripheral resistance, the latter often being increased by many mechanisms, including α-adrenergic stimulation, the renin-angiotensin system, or other circulating hormonal or humoral factors.[127]

Methods for Measuring the Arterial Pressure

DIRECT METHODS

In 1733, Stephen Hales recorded the arterial pressures in animals by cannulation and use of a blood-filled glass column.[128] Current techniques for the direct and continuous measurement of arterial pressure use the electromanometer, a transducer that converts mechanical energy into an electric signal suitable for amplification, display, and recording. The artery is cannulated with a saline-filled catheter or needle that mechanically couples the circulation to the arterial manometer. Pressures are recorded using atmospheric pressure as the "zero" reference level, and intravascular pressures are further referenced to the level of the heart by addition or subtraction of a gravitation factor. The gravitation factor is expressed by the formula pgh, where p is the density of blood (in grams per milliliter), g is the acceleration due to gravity (980 cm/s), and h is the transducer height (centimeters) above or below the horizontal plane of the heart.

The strain-gauge manometer is commonly used for the precise and accurate measurement of the arterial pressure. However, error may originate in the catheter or coupling system, in which the

properties of inertia, friction, and elasticity interact to produce damping of the frequency response. Systems may be overdamped or underdamped, both of which can result in signal distortion. Nevertheless, the appropriate combination of an inelastic cardiac catheter and connecting tube filled with bubble-free fluid produces "critical" damping in which the system response is constant to some desirable frequency level and adequate for the clinical recording of intravascular pressures.[125]

Measurement errors also occur when an end-hole catheter is positioned axial to flow in a vessel and may become especially important during high arterial flow, when kinetic energy may exceed 10 percent of the total fluid energy. Also, pressure transients due to catheter whip can falsely elevate the measured arterial pressure.[125]

Miniature, self-flushing strain-gauge manometers attached directly to an intravascular catheter or needle eliminate many of the problems related to transducer mounting and flushing and overdamping by connective tubing. The most satisfactory method for reducing measurement errors, however, is the use of intravascular electromanometers mounted on cardiac catheters or surgically implanted in the vascular wall.

INDIRECT METHODS

The invention of the pneumatic cuff manometer (Riva-Rocci, 1896) and the subsequent discovery and use of the arterial sounds (Korotkoff, 1905) permitted indirect measurement of the arterial pressure. The mercury manometer is the "gold standard," and the more fragile aneroid manometer should be calibrated against the mercury manometer at least every 6 months. Semiautomatic electronic devices, if used, should be validated according to Association for the Advancement of Medical Instrumentation (AAMI) guidelines.[129] The most commonly used noninvasive method is based on the auscultatory detection of low-pitched Korotkoff sounds over a peripheral artery at a point distal to cuff compression of the artery. McCutcheon and Rushmer[130] described two major components of these sounds: the initial transient (k_{-i}) and the compression murmur (k_c), which coincide with the opening tap and rumble sounds of Rodbard.[131] The initial sound k_{-i} occurs when cuff pressure reaches arterial pressure and likely results from abrupt arterial opening and vascular distention. The intensity of this initial sound depends on the slope of the pressure pulse and the level of the distal arterial pressure at the time of arterial opening, the sound being louder with vasodilatation and high-velocity flow and softer with arterial constriction or circulatory collapse. The initial transient is probably caused by oscillation of the arterial walls as the occluded segment is suddenly opened by systolic pressure, and the compression murmur is caused by a turbulent jet of flow distal to the partially compressed segment.

The Korotkoff sounds have been divided into five phases occurring in sequence as the occluding pressure declines (Table 10-4). To avoid error, the observer must be prepared to recognize two normal Korotkoff sound variations associated with blood pressure (BP) reading. (1) The *ausculatory gap* is a period of silence occurring during Korotkoff phases I and II. This disappearance of sound is temporary and is usually short, but the gap can occur over a period of 40 mmHg. It seems to be associated with higher BP readings. (2) An absent Korotkoff phase V occurs when sounds are heard to "0." When this is the case, phase IV should be recorded along with phase V. In this case, phase IV is the best reference for diastolic pressure.

Table 10-4: Phases of the Korotkoff Sounds

Phase I
The pressure level at which the first faint, consistent tapping sounds are heard. The sounds gradually increase in intensity as the cuff is deflated. The first of at least two of these sounds is defined as the systolic pressure.
Phase II
The time during cuff deflation when a murmur of swishing sounds are heard.
Phase III
The period during which sounds are crisper and increase in intensity.
Phase IV
The time when a distinct, abrupt, muffling of sound (usually of a soft blowing quality) is heard. This is defined as the diastolic pressure in anyone in whom sounds continue to zero.
Phase V
The pressure level when the last regular blood pressure sound is heard and after which all sound disappears. This is defined as the diastolic pressure unless sounds are heard to zero.

Proper technique is important for obtaining accurate measurements. The inflatable rubber bag within the compression cuff should have a width that is 20 percent greater than the limb diameter and a length adequate to encompass two-thirds the limb. The cuff should be applied snugly, with the inflatable bag positioned over the artery, at the level of the heart. Before auscultation, the cuff is quickly inflated to a pressure 20 mmHg above the systolic, as indicated by obliteration of the radial pulse. The stethoscope is then applied lightly but firmly over the artery, and auscultatory pressure is determined by noting the onset (peak systole) and behavior of the Korotkoff sounds as the cuff is deflated at a rate of about 3 mmHg per second. When the sounds disappear, the bag should be rapidly decompressed and 1 or 2 min allowed to pass before repeat determinations are made. When possible, the blood pressure should be taken with the subject upright as well as supine. Determination of the blood pressure in both arms is recommended, especially in the elderly. An American Heart Association hypertension primer recommends that the systolic pressure be recorded as the point at which the first tapping sounds occur for two consecutive beats (phase I) and that the diastolic pressure in adults be recorded as the point at which sounds become inaudible. In children and in adults with a hyperkinetic circulation, the diastolic pressure should be recorded as the point at which muffling of the sounds occurs (onset of phase IV). The arterial pressures at both the onset of muffling (phase IV) and the disappearance of sound (phase V) should be recorded. The mean blood pressure can be estimated by the addition of one-third the pulse pressure (systolic pressure minus diastolic pressure) to the diastolic pressure.

Patients with atrial fibrillation may have a significant beat-to-beat variation in their arterial pressure. Accordingly, the indirect blood pressure should be measured several times and the average noted.

This indirect method provides several potential sources of error due to improper equipment, inaccurate detection of the Korotkoff sounds, and observer techniques.[125] The standard pneumatic cuff often may be unsatisfactory for pressure measurement in the arms or in the legs of very obese subjects.[132] The arterial pressure may be underestimated if the cuff is deflated too rapidly, particularly when bradycardia or an irregular rhythm is present or if inadequate inflation does not result in complete arterial occlusion. When the cuff is deflated too slowly or is immediately

reinflated for multiple pressure determinations, the resulting venous congestion may elevate the diastolic pressure artificially and falsely decrease the systolic pressure by decreasing the intensity of phase I or phase II sounds to an inaudible level.

Studies correlating direct and indirect blood pressure measurements have been characterized by considerable variability between individual subjects but in general have shown a good correlation between indirect and direct measurements of blood pressure in the arm. The observed trend has been for the indirect method to underestimate systolic pressure by several millimeters of mercury, to overestimate diastolic pressure by several millimeters of mercury when phase IV is used as an end point, and to slightly underestimate diastolic pressure in normal individuals when phase V is taken as the end point.

Home blood pressure recordings using manual or automatic inflation and deflation of the cuff and detection of Korotkoff sounds by a microphone, stethoscope, or ultrasonic transducer are being used with increasing frequency for the ambulatory assessment of patients with hypertension. In general, ambulatory blood pressure devices do not meet the standards for automated devices of the Association for the Advancement of Medical Instrumentation.[129,133-135]

More recently, arterial tonometry has been used as a completely noninvasive method for monitoring the arterial pressure. This probe, with a micromanometer in its tip, operates on the principle of a piezo-resistive transducer of cantilever construction.[136-141]

Normal Arterial Pressure

Normal pressures have been defined on the basis of values included within two standard deviations of the mean of pressures obtained in a large population of apparently healthy individuals. The normal blood pressure range varies with age, sex, and socioracial grouping.[142] In the United States, the pressure increases rapidly during the first few days of life and then increases gradually, with a slightly greater increment in systolic than in diastolic values, throughout life. The pressure tends to be higher in Western, industrialized societies than in Asian, African, and technically undeveloped societies.

With increasing age and into senescence, the aorta undergoes progressive dilatation and elongation, with increasing stiffness of its walls.[143] As a result of this diminished vascular distensibility, there is an increase in systolic arterial pressure with less change in diastolic pressure.[144]

The normal blood pressure limits for adults (below 40 years of age and of mixed sex and race) living in the United States are approximately 100 to 140 mmHg systolic and 60 to 90 mmHg diastolic. In an individual subject, however, baseline pressures above or below these levels do not define a pathologic state, since the physiologic range of normal for an individual may overlap with the statistical range of abnormality.[125] The systolic arterial pressure rises slowly and progressively in most Americans between the ages of 20 and 60 and more rapidly later, increasing by about 20 mmHg between the ages of 60 and 80.[145] Diastolic pressure usually rises very little after age 45.[153] Data from the Framingham Study and then from more recent studies (e.g., MRFIT, SHEP, Syst-Eur) have shown a clear correlation between systolic pressure and cardiovascular events, a reduction in events with reduction of systolic blood pressure,[146-151] or even a negative association between diastolic blood pressure and events.[152]

In mildly to moderately hypertensive persons, the blood pressure "casually" recorded by a physician is significantly higher than the average value of a series of intermittent, indirect determinations or continuous direct recordings made during normal activity.[153] To estimate basal blood pressure, measurements have been obtained during sleep, when the subject first awakens in

the morning while still recumbent, or after several hours of reclining.

Factors contributing to variations in an individual's blood pressure during daily activities include (1) body posture, (2) state of muscular, cerebral, or gastrointestinal activity, (3) emotional or painful stimuli, (4) environmental factors such as temperature and noise level, and (5) the use of tobacco, coffee, alcohol, and other drugs with direct or neurally mediated vasomotor properties.[125,154] Twenty-four-hour pressures, obtained from normal and hypertensive subjects with an automatic recorder, have shown considerable variability with activity and emotional stimuli.[155,156] The average diurnal pattern of blood pressure consists of an increase throughout the day and early evening and a significant, rapid decline to a low point during the early, deep stage of sleep.

With normal respiration, the peak systolic blood pressure is greater during expiration than during inspiration by as much as 10 mmHg. An augmentation of this difference occurs in patients with pericardial tamponade (pulsus paradoxus; see Chap. 72) and during hyperventilation.

Isotonic exercise in both the supine and upright positions produces a moderate increase in blood pressure (systolic pressure greater than mean greater than diastolic pressure). Sustained isometric muscular contractions produce an abrupt increase in systolic, mean, and diastolic blood pressure that depends on the strength of the contraction.[157]

Abnormal Arterial Pressure

INCREASED PULSE PRESSURE

An increase in arterial pulse pressure is commonly observed during routine blood pressure recordings. This usually is due to an increase in stroke volume and ejection velocity, often with a decrease in peripheral resistance. Fever, anemia, hot weather, exercise, pregnancy, hyperthyroidism, or arteriovenous fistulas may produce this change. Several cardiac diseases, such as aortic regurgitation, patent ductus arteriosus, and truncus arteriosus, also can result in a widened pulse pressure. An increased pulse pressure due to a large stroke volume may occur with complete heart block or marked sinus bradycardia.[125]

Atherosclerosis of the large arteries often reduces arterial compliance and results in an elevated systolic pressure with a normal or even decreased stroke volume. The systolic hypertension of the elderly does not necessarily represent a change in arteriolar resistance. Efforts to lower this type of systolic pressure elevation are often appropriate but can result in diminished peripheral perfusion (see Chap. 51). The increased pulse pressure associated with systemic arteriovenous fistulas is less common; a relative tachycardia may be the only clinical clue. Compression of a systemic arteriovenous fistula can produce a prompt slowing of the heart rate (Branham's sign).

REDUCED PULSE PRESSURE

A narrow pulse pressure is uncommon in normal subjects but may result from an increased peripheral resistance (increased circulating catecholamines in heart failure), decreased stroke volume (severe aortic stenosis), and/or markedly decreased intravascular volume (diabetic ketoacidosis).[125]

UNEQUAL PULSE PRESSURES

The diagnostic importance of blood pressure differences between right and left arms has been enhanced in recent years by the recognition of supravalvular aortic stenosis and this "choana effect" in children and of the subclavian steal syndrome in adults.[158] Most patients with the

former have greater than 20 mmHg higher blood pressure in the right arm. The subclavian steal syndrome, often accompanied by symptoms of cerebrovascular insufficiency, usually results in a pronounced lowering or absence of brachial artery pressure in the ipsilateral extremity.[125]

A progressive increase in systolic pressure normally occurs as the point of measurement is moved peripherally from the central aorta (Fig. 10-41), and the increment in systolic pressure is equivalent in the large arteries of the upper arm and the thigh. Direct recordings of femoral and brachial arterial pressures (systolic, diastolic, and mean) in adults[159] and children[160] and indirect measurement of popliteal and brachial artery pressures using appropriate pressure cuffs[161] have demonstrated that mean pressures are equal at these sites. A difference in arm and leg pressures may occur because of coarctation of the aorta or acquired disease such as aortic dissection, aortic arch syndrome, or the subclavian steal syndrome.[125]

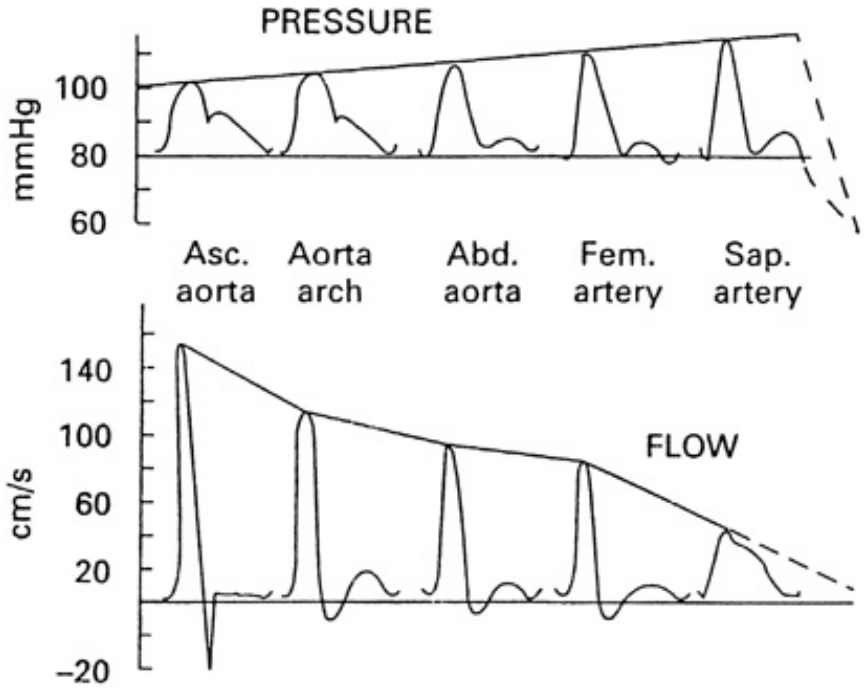

Figure 10-41: Micromanometer and catheter tip flow velocity as change in contour of pressure waves (above) and flow waves (below) between the ascending aorta and the saphenous artery. (From Vlachopoulos C, O'Rourke MF. The arterial pulse. *Curr Probl Cardiol* 2000; 25:296-346.)

Pulsus Alternans

Pulsus alternans may be detected by palpating a peripheral artery. The femoral artery is probably best for this purpose. One must, of course, be certain the heart rhythm is normal. The sphygmomanometer can be used to measure accurately the beat-to-beat variation in pressure that characterizes pulsus alternans.

Pulsus alternans, which is discussed at greater length later in this chapter, occurs in patients with severe heart disease who exhibit impaired LV contraction. It also can occur for a few beats following supraventricular tachycardia in normal persons or when the respiratory rate is half the pulse rate. This may be apparent when pulsus paradoxus is present in patients with cardiac tamponade.

Pulsus Paradoxus

A normal person may exhibit a 10- to 12-mmHg drop in systolic pressure during normal inspiration. A fall in pressure greater than this amount may be identified in patients with acute cardiac tamponade, constrictive pericarditis, severe obstructive lung disease, and restrictive cardiomyopathy.

Pulsus paradoxus is best detected by inflating the blood pressure cuff above systolic pressure and then slowly releasing it. As the cuff pressure is gradually reduced, the blood pressure sounds become audible during expiration. The difference in pressure between the first audible sound heard on expiration and the pressure level at which the sounds are heard during all phases of respiration gives a measurement of magnitude of pulsus paradoxus. The mechanism of pulsus paradoxus is discussed in Chap. 72.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

THE ARTERIAL PULSE

The arterial pulse is as any periodic fluctuation that is caused by the heart and occurs at the same frequency as the heartbeat. Ejection of blood with every cardiac contraction is converted to *flow* pulsations, *pressure* pulsations, and *dimension* pulsations in arteries throughout the body. While the term *pulse* refers to any such pulsation, the arterial pulse perceived by a clinician is the pressure pulse in a large, accessible artery. Palpation of the arterial pulse is a basic and important element of the physical examination.[162-166] Any discussion of the arterial pulse must include recent advances in measurement of arterial hemodynamics, assessment of the arterial wave contour, and frequency analysis of the pressure pulse.[162-170]

Physical Determinants of the Arterial Pulse

GENESIS OF THE ARTERIAL PULSE

Pressure and blood flow measurements in the ascending aorta result from the interaction between the heart and arterial system. When LV pressure exceeds the aortic pressure, it becomes the driving force for the movement of blood into the ascending aorta.[162] This driving force is dependent on the intrinsic contractility of ventricle muscle, the size and shape of the left ventricle, and the heart rate. It is opposed by several forces that impede the development of flow and are interrelated in a complex manner. Three major determinants of arterial impedance include (1) resistance, (2) inertia, and (3) compliance.

Resistance is related to blood viscosity and the geometry of the vasculature; it opposes flow and is unaffected by changes in heart rate. Inertia, which is related to the mass of the column of blood, opposes the rate of change of arterial blood flow (i.e., acceleration) and depends on the heart rate. Compliance is related to the distensibility of the vascular walls, opposes changes in arterial blood volume, and also depends on the heart rate. The heart rate dependency of inertia and compliance introduces phase shifts between instantaneous pressure and flow in a pulsatile system.[167] Inertia and compliance are important determinants of the character of ventricular ejection, especially in early systole, when flows and pressures are changing rapidly.

The arterial pulse wave begins with aortic valve opening and the onset of LV ejection. Aortic pressure rises rapidly in early systole because the LV stroke volume enters the aorta faster than it flows to distal sites. The rapid-rising portion of the arterial pressure curve is often termed the *anacrotic limb* (from the Greek, meaning "upbeat"). In experimental animals and in humans, peak proximal aortic flow velocity occurs slightly earlier than peak pressure.[167] After its peak, aortic pressure declines as ventricular ejection slows and peripheral blood flow continues. During isovolumic relaxation, a transient reversal of flow from the central arteries toward the ventricle just prior to aortic valve closure is associated with an incisura on the descending limb of the aortic pressure pulse. The subsequent smaller, secondary positive wave has been attributed to the elastic recoil of the aorta and aortic valve but is partially due to reflected waves from more distal arteries. Subsequently, aortic pressure decreases again as further "runoff" in the peripheral circulation occurs in diastole.

The proximal aortic pulse pressure is directly proportional to the ratio of stroke volume to arterial

distensibility, but multiple factors influence this complex relationship.[171] Arterial distensibility diminishes as the distending arterial pressure increases. Accordingly, the pulse pressure for a constant stroke volume will be larger if the mean blood pressure is elevated. In addition, arterial distensibility varies inversely with the rate of rise of intraluminal pressure. When the systolic ejection rate increases, the stiffer arterial wall results in a greater pulse pressure. Finally, the arterial pulse pressure is modified by reflected pressure waves and by the rate of blood flow from arterioles to veins.

CONTOUR OF THE ARTERIAL PULSE

Pulsatile changes in arterial diameter are virtually identical to the pressure pulse, with minor differences explained in terms of nonlinear elasticity and viscosity of the arterial wall. In 1939, Hamilton and Dow defined the pressure wave contour in different arteries in terms of wave reflection between the aortic valve and peripheral sites.[172] The pulse waveform recorded at any site of the arterial tree is the sum of a forward waveform and a backward-traveling one that is the "echo" of the incident wave reflected at peripheral sites. *Wave reflection is an important determinant of LV load and CBF*. A reflected wave occurring at systole increases systolic pressure and thereby increases ventricular afterload. In contrast, occurrence of the reflected wave at diastole is highly desirable because augmentation of pressure during diastole aids coronary perfusion.

Conventionally, the pulse is described in the *time domain,* where it is considered as a change in arterial pressure with time. An alternative approach that has the advantage of being quantitative is to analyze the pulse in the *frequency domain*. Pulse is conceived as a composite wave that can be resolved into component harmonics like a musical wave. Impedance is the measure of the opposition to flow presented by a system and can be approached quantitatively when harmonic analysis is used to relate frequency components of pressure and flow pulses.[173-178] Study of impedance provides valuable insights for several issues of vascular mechanics.

Usually, there is a linear relation between pressure and flow at the same point in an artery and between pressures at different points in the arterial system. From impedance curves, it is possible to identify the factors responsible for the relation between the pulsatile pressure and flow. Furthermore, the coefficient of reflection in peripheral vessels can be calculated from the relation of resistance to the minimal and subsequent values of impedance modulus. The peripheral arterial pressure wave recorded is the summation of the incident (initial) and reflected waves. The systemic circulation has been represented by a simple asymmetric T-tube model that emphasizes the importance of wave reflection at two arteriolar reflecting sites in the upper and lower parts of the body.[169] An important patient study indicates major reflection sites at the aortic level of the renal arteries and at a point distal to the terminal abdominal aorta bifurcation.[170]

PERIPHERAL TRANSMISSION OF THE ARTERIAL PULSE

As the normal aortic pulse wave is transmitted peripherally, significant changes in its contour occur due to (1) distortion and damping of pulse wave components, (2) different rates of transmission of various components, (3) distortion or exaggeration by reflected, resonant, or standing waves, (4) conversion of kinetic energy into hydrostatic or potential energy, (5) differences in distensibility and caliber of the arteries, and (6) changes in the vessel wall due to age and/or disease.[176]

The arterial pressure pulse enters the proximal aorta and travels distally at a velocity many times faster than maximum blood flow. The pressure wave is accompanied by a traveling wave distending the arterial wall, the pulse wave velocity increasing as arterial wall distensibility diminishes.[171] This normally occurs distally, as the arteries branch into smaller channels and their walls become stiffer. With increasing age or with systemic hypertension, however, arterial wall

distensibility diminishes, and pulse wave velocity is correspondingly greater.

The pulse wave arrives progressively later at more peripheral sites when timed from the QRS complex on the ECG. Representative time delays from the central aorta are as follows: carotid, 30 ms; brachial, 60 ms; radial, 80 ms; and femoral, 75 ms.

The arterial pulse wave undergoes a progressive change in shape during its transmission distally (Fig. 10-41). The pulse pressure and systolic amplitude increase, and the ascending limb of the pulse wave becomes steeper. The incisura of the central aorta pulse is gradually replaced by a smoother, somewhat later dicrotic notch that occurs at lower pressure levels. The dicrotic notch and the following positive secondary or dicrotic wave probably result from the summation of the forward pulse wave and reflected waves from the peripheral vessels.[162]

EXAMINATION OF THE ARTERIAL PULSE

All major arterial pulses should be examined bilaterally for both patency and waveform characteristics. The thickness and hardness of the arterial walls often can be assessed by "rolling" the vessel against underlying tissue. A pulse in the foot should not be considered absent unless examined with the foot in a dependent position. Otherwise, the arterial pulses usually are examined with the patient supine and with the trunk of the body slightly elevated.

The examiner uses tactile receptors in the tips of the fingers to sense movement of the arterial wall associated with the pressure pulse as it passes the site of palpation. Measurements in the proximal aorta show cyclic movement in both diameter and length proportional to the pulse pressure. In more peripheral arteries with connective tissue attachments, however, the detectable movement is small and variable, with radial expansion by only about 2 percent of the end-diastolic cross-sectional area.[162]

The usual technique for palpating the arterial pulse is to press with the examining fingers until the maximum pulse is sensed. The pulse is felt as changing displacement superimposed on the "baseline" displacement produced by compressing the artery. The examiner should apply varying degrees of pressure while concentrating on the separate phases of the pulse wave. This method, referred to as *trisection,* is useful for assessing the upstroke, systolic peak, and diastolic slope of the arterial pulse.[176] Controversy exists as to how many fingers should be used to palpate the pulse; the examiner should use whichever method he or she prefers.

Palpation of the carotid artery is preferred for assessing cardiac performance, since the carotid pulse corresponds more closely to the central aortic pressure. In certain cardiac diseases (e.g., aortic regurgitation), however, the abnormalities detected in the carotid pulse are accentuated in the more peripheral pulses. For determining the cardiac rate and rhythm, the radial pulse most often is used, but if it is irregular, cardiac auscultation often provides more reliable information. To evaluate the integrity of the peripheral arterial blood supply and to localize any lesions that exist, the arterial pulses in all four extremities should be examined and compared (see also Chap. 90).

Inspection of the carotid arterial and jugular venous pulsations should be performed at the same time. The carotid pulse is usually best examined with the sternocleidomastoid muscles relaxed and with the head rotated slightly toward the examiner. The carotid pulse may be timed from the first heart sound, which is heard slightly before the pulsation. The carotid pulse should be palpated in the lower half of the patient's neck in order to avoid carotid sinus compression. Occasionally, it is useful to palpate two arteries simultaneously (e.g., radial and femoral) to detect an apparent pulse wave delay, such as occurs in patients with coarctation of the aorta.

The examination of arterial pulses in the abdomen and upper and lower extremities should be

performed carefully in all patients and compared using a scale such as the following: 0 = complete absence of pulsation; 1+ = small or reduced pulsation; 2+ = normal or average pulsation; and 3+ = large or bounding pulsation. Furthermore, auscultation over the major arteries should be performed, since an audible bruit may be a clue to partial occlusion or may indicate transmission (e.g., carotid) of a cardiac murmur.

NORMAL ARTERIAL PULSE

The normal carotid pulse has a smooth, rapid upstroke or ascending limb to a smooth, dome-shaped summit (see Fig. 10-42). Then a downstroke occurs that is somewhat less rapid than the upstroke. The dicrotic notch and secondary diastolic wave usually are not felt but may be palpable in some normal individuals, particularly during fever, exercise, or excitement. The dicrotic notch usually occurs about 300 ms after the onset of the pulse wave when corrected for heart rate.

In arteries distal to the carotid, the pulse wave arrives later and has a steep initial wave that rises to a high peak pressure, whereas the diastolic pressure and the mean pressure are slightly lower. The systolic upstroke time (onset of pulse wave to its peak) tends to be shorter, but the apparent LV ejection time (onset of pulse wave to incisura) is longer in more peripheral arterial pulses. In the brachial artery, the heart rate-corrected systolic upstroke time averages 120 ms (range, 90-160 ms), and the systolic ejection time averages about 320 ms (range, 280-360 ms).

Graphic recordings of the arterial pulses frequently show two positive deflections during systole, the first shoulder being referred to as the *percussion wave* and the second as the *tidal wave*. In the normal proximal aortic pulse, the percussion wave is due to arrival of the impulse generated by LV ejection, the tidal wave may represent its echo from the upper part of the body, and the dicrotic or diastolic wave is a reflection from the lower part of the body.[166] The contour of the distal pulses can be explained in similar terms, with altered time relations between incident and reflected waves at different distances from peripheral reflecting sites.

With aging, there is a relative increase in the second (tidal) systolic wave and the height of the incisura relative to the first systolic wave.[162,177,179,180] The systolic upstroke time is longer, and the amplitude and duration of the diastolic wave tend to be less prominent.

ABNORMAL ARTERIAL PULSES

In hypertension and arteriosclerosis, the pressure pulse amplitude is increased, the tidal wave is prominent, and the diastolic wave is absent. All features of the pulse can be explained by increased wave velocity.[162,177] Reflected waves return to the proximal aorta during late systole, augmenting the tidal wave and increasing systolic pressure. With systemic hypotension, the pulse wave velocity is decreased, and the later tidal and diastolic waves are further displaced from the percussion wave.

Impairment of the pulse of one or both carotid arteries is usually produced by atherosclerosis, but multiple other causes include thrombosis, embolus, arteritis, and diseases of the aortic arch. Kinking of the carotid or brachiocephalic artery is relatively frequent, particularly in hypertensive patients, and may simulate aneurysmal dilatation. Femoral pulses may be diminished in the child or young adult as a result of coarctation of the aorta. In most adults, however, the diminution of the femoral pulsation is caused by atherosclerosis of the abdominal aorta, aortic bifurcation, or ileofemoral arteries (see also Chap. 90).

HYPERKINETIC ARTERIAL PULSE

Large, bounding arterial pulses usually indicate the rapid ejection of an increased volume of blood from the left ventricle (see Fig. 10-42*A*). Commonly, the arterial pulse pressure is increased, and the peripheral arterial resistance diminished. The hyperdynamic arterial pulse is sometimes referred to in terms that describe a particular component of the pulse wave. Thus the *water-hammer pulse,* named after a Victorian toy, refers to an extremely rapid, forceful ascending limb of the arterial pulse wave.[181] By contrast, *collapsing pulse* refers to a quick, marked decrease in the arterial pulse wave following its peak. Hyperkinetic pulses often are more prominent in the brachial, radial, and femoral arteries than in the carotid artery. The term *Quincke pulse* refers to visible small pulsations in the nail bed of patients with hyperdynamic arterial pulses from any cause, including aortic regurgitation.

Hyperkinetic arterial pulses occur in normal subjects with a hyperkinetic circulation (e.g., exercise, fever), patients with cardiovascular diseases associated with increased stroke volume, and subjects with marked bradycardia and an extremely large stroke volume (e.g., athletes). A hyperdynamic arterial pulse also occurs in patients with an abnormally rapid runoff of blood from the arterial system (e.g., patent ductus arteriosus, arteriovenous fistulas). Patients on chronic hemodialysis often have hyperdynamic pulses produced by the combination of a surgical arteriovenous fistula, anemia, and hypertension.

In aortic regurgitation, the rapid-rising, bounding arterial pulse results from increases in both stroke volume and the rate of LV ejection. The early systolic flow often produces palpable vibrations manifest as a thrill on the steep ascending limb. Later in systole, the rate of ventricular ejection and the arterial pulse wave decrease sharply, often resulting in systolic collapse.

BISFERIENS ARTERIAL PULSE

The bisferiens (from the Latin, meaning "twice beating") pulse has a waveform characterized by two positive waves during systole (see Fig. 10-42*B*). The pulse wave upstroke rises rapidly and forcefully, producing the first systolic peak (percussion wave). A brief decline in pressure is followed by a smaller and somewhat slower-rising positive pulse wave (tidal wave). Abnormalities of LV ejection and reflected waves from peripheral arteries contribute to the prominence of the second systolic wave in the bisferiens pulse. The bisferiens pulse, usually felt in the carotid artery, is sometimes more easily palpable in a brachial or radial artery. A bisferiens pulse often occurs in patients with pure aortic regurgitation and in patients with combined aortic stenosis and severe aortic regurgitation.[182] It also can occur in other conditions associated with the rapid ejection of an increased stroke volume from the left ventricle (e.g., exercise, fever, patent ductus arteriosus).

The bisferiens pulse often is present in patients with hypertrophic cardiomyopathy, many of whom have a pressure gradient in the LV outflow tract.[183] In this syndrome, the midsystolic negative wave usually coincides with a marked decrease in the rate of LV ejection. The second systolic wave, or tidal wave, most likely is produced by reflected waves from the periphery. The bisferiens pulse may be elicited by maneuvers that decrease the LV size or increase its contractility. The most characteristic aspect of the arterial pulse in hypertrophic cardiomyopathy is its rapid rate of rise. A physical finding nearly specific for hypertrophic cardiomyopathy is a much smaller arterial pressure pulse in the cardiac cycle following a premature ventricular beat (see Chap. 67).

HYPOKINETIC ARTERIAL PULSE

A small, weak arterial pulse is frequently present in patients with a diminished stroke volume (see Fig. 10-42*C*). Usually, the decreased stroke output is associated with decreased rate and duration of LV ejection, and there is a narrow arterial pulse pressure despite an increased arterial resistance. Common causes include hypovolemia, LV failure, and mitral or aortic valve stenosis.

PARVUS ET TARDUS PULSE

Patients with moderate or severe valvular aortic stenosis often have an arterial pulse that is small and has a delayed systolic peak.[184,186] Occasionally, there may be a detectable shoulder on the upstroke of the carotid pulse, referred to as *anacrotic*[184] (see Fig. 10-42*D*). Palpable coarse vibrations often are present as a systolic thrill over the slowly rising carotid pulse. The parvus et tardus pulse is much easier to detect in the carotid arteries than in more distal arteries.

Most middle-aged patients with uncomplicated severe aortic stenosis have a parvus et tardus pulse, but this pulse also may occur in relatively mild stenosis. Conversely, an apparently normal arterial pulse is not unusual in elderly patients with severe aortic stenosis who have decreased distensibility of the large arteries, which also alters the character of the arterial pulse.[162,164] Severe LV failure often results in a small, weak pulse that may be difficult to distinguish from that of aortic stenosis.

DICROTIC ARTERIAL PULSE

The dicrotic (from the Greek *dikrotos*, meaning "double beating") pulse is a twice-peaked pulse with one peak in systole and the second in diastole, the latter due to an accentuated and palpable dicrotic wave that follows the second heart sound[187] (see Fig. 10-42*E*). It is usually felt best in the carotids, although it also may be palpated over more peripheral arteries. Major abnormalities include a short systolic ejection phase, a low dicrotic notch, a large diastolic wave, a narrow pulse pressure, a diminished rate of rise of the pulse, and the lack of distinct percussion and tidal waves. The dicrotic pulse is most common in young or middle-aged patients with impaired LV performance. It is usually associated with a low cardiac output, markedly diminished stroke volume, elevated LV end-diastolic pressure, and high systemic arterial resistance. In general, the dicrotic wave becomes less prominent with age, hypertension, generalized atherosclerosis, and diabetes. Rarely, the dicrotic wave can be palpated in young, febrile patients in whom none of the other abnormal features of the dicrotic pulse are present.

PULSUS ALTERNANS

In pulsus alternans, beats occur at regular intervals with a regular alternation of the systolic height of the pressure pulses[188,189] (see Fig. 10-42*E*). Rarely, pulsus alternans is so marked that the weaker pulses are not felt at all. When pulsus alternans is noticed first after a premature beat, the extent of the difference in systolic pressure in alternating beats may decline for several cycles until the pulse amplitude is again constant. The initiation of post-premature ventricular beat pulsus alternans is probably related to the increased duration of LV filling after the premature beat, resulting in a greater end-diastolic volume and hence increased contractile force due to the Frank-Starling mechanism.

Sustained pulsus alternans (see Chap. 20) is seen in severe depression of LV performance with an alteration in aortic flow, systolic LV pressure, aortic systolic pressure, LV *dP/dt*, and LV end-diastolic pressure. Sustained pulsus alternans likely is due to alteration of the contractile state of at least part of the myocardium, which may be caused by the failure of electromechanical coupling in some cells during the weaker contraction.[189] A subsequent stronger contraction would then represent contraction of all cells, some of which were potentiated.[190]

Pulsus alternans may be better appreciated when palpating a distal artery, which normally has a slightly wider pulse pressure than the carotid artery. The patient's respiration should be held, since the small changes in arterial pressure caused by normal respiration may obscure the recognition of pulsus alternans. Pulsus alternans can be confirmed by using a sphygmomanometer and is usually

associated with a LV third heart sound.

PULSUS PARADOXUS

A *paradoxical pulse* is defined as a marked decrease in the pulse amplitude during normal quiet inspiration or a decrease in the systolic arterial pressure by more than 10 mmHg. The normal small decline in systolic blood pressure probably is produced predominantly by relative pooling of blood in the pulmonary vessels during inspiration and also may reflect the delayed transmission through the lungs of the preceding expiratory fall in venous pressure and RV cardiac output.[176]

In patients with cardiac tamponade, fluid accumulation in the pericardium increases intrapericardial pressure, and the heart's filling capacity is reduced. During inspiration, the expected augmentation of venous return to the right side of the heart occurs despite the elevated intrapericardial pressure.[191] The diminished thoracic pressure also causes a pooling of blood in the pulmonary veins and capillaries and diminishes pulmonary venous return to the left atrium. Since the high intrapericardial pressure limits flow to the heart and the total cardiac filling capacity is limited, the increase in right-sided heart volume with inspiration causes an obligatory decrease in left-sided heart filling. This, along with the pooling of blood in the pulmonary bed, produces a decline in LV stroke volume and systolic blood pressure during inspiration.[192]

Pulsus paradoxus is common with cardiac tamponade but infrequent with constrictive pericarditis (see Chap. 72). Different hemodynamic mechanisms contribute to the production of a paradoxical pulse in certain patients with superior vena cava obstruction, asthma, or obstructive airways disease; in some patients with pulmonary embolism or shock; and in some patients after thoracotomy.[176]

The extent of pulsus paradoxicus can be quantitated by cuff sphygmomanometry as the pressure difference between the first discernible Korotkoff sound on expiration and the pressure level at which Korotkoff sounds are audible during all phases of respiration.

EFFECTS OF ARRHYTHMIAS ON THE ARTERIAL PULSE

Premature Ventricular Depolarizations

A premature ventricular depolarization may be associated with no pulse, a small-amplitude pulse, or a normal arterial pulse depending on timing and whether or not the LV pressure generated is able to open the aortic valve.[193] The arterial pulse following a premature beat usually is greatly enhanced because of decreased aortic impedance, increased LV filling, and augmented LV contractility. At times, premature ventricular beats are so common as to produce an irregularly irregular pulse. Then the presence of cannon *a* waves in the jugular venous pulse should alert one to the correct diagnosis.

Tachyarrhythmias

The ECG is usually needed for the definitive diagnosis of any abnormality of heart rate or rhythm. On the other hand, careful observation of the arterial and jugular venous pulses frequently leads to the correct diagnosis. Simultaneous cardiac auscultation is also frequently helpful.

Most tachycardias associated with a regular pulse are of supraventricular origin. In sinus tachycardia, the arterial pulse will slow gradually with carotid sinus pressure and then again increase gradually. Paroxysmal atrial tachycardia has an "all or none" response. In patients with atrial flutter, carotid sinus pressure will increase the block at the AV junction, the pulse rate slowing and subsequently returning to its original rate in a "jerky" fashion.

In patients with ventricular tachycardia and AV dissociation, the variation in the atrial ventricular sequence of contraction and resulting variation in pulse amplitude often may be detected by palpation.[194]

An irregularly irregular pulse with a varying pulse pressure is usually the result of atrial fibrillation; however, multifocal atrial tachycardia is also a common cause of this finding in patients with severe chronic obstructive lung disease.

Bradyarrhythmias

An unusually slow heart rate frequently is associated with a decrease in the rate of rise and amplitude of the arterial pressure pulse. Complete heart block often is readily diagnosed by the variability in the arterial pulse amplitude, the changing intensity of the first heart sound, and intermittent cannon *a* waves in the jugular venous pulse, all due to the time-dependent variable contribution of atrial contraction to ventricular filling.

EFFECTS OF DRUG THERAPY ON THE ARTERIAL PULSE

Pulse wave analysis provides important information about the actions of drugs that, most importantly, may not be apparent with conventional methods.[162] *Nitrates* decrease central systolic pressure substantially while they have no or minimal effect on peripheral systolic pressure (Fig. 10-43).[162a] *Beta-blocking* agents have variable effect depending on their intrinsic properties. Nonselective agents tend to increase late systolic pressure augmentation; in contrast, those agents with vasodilating properties have the opposite effect. Both angiotensin-converting enzyme (ACE) inhibitors and calcium-channel blockers have significant effects on the arterial pulse by reducing late systolic pressure augmentation. These actions can be explained on the basis of wave reflection. Reduction of wave reflection is an important advantage in the logical treatment of hypertension and heart failure.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

THE VENOUS PULSE

An accurate assessment of the venous pulse is an integral part of the physical examination because it provides information concerning both the mean right atrial pressure and the hemodynamic events in the right atrium.[165] Factors influencing the right atrial and central venous pressure (CVP) include the total blood volume, thedistribution of blood volume, and the strength of right atrial contraction.

Venous blood returning from the systemic capillaries is nonpulsatile. Changes in volume flow created by skeletal muscles and the respiratory pump are nonsynchronous with the pulsatile activity of the heart. Changes in flow and pressure caused by right atrial and ventricular filling, however, produce pulsations in the central veins that are transmitted toward the peripheral veins, opposite to the direction of blood flow. With the possible exception of the *c* wave, which is the combined result of carotid arterial impact and an upward movement of the tricuspid valve, the pulsations observed in the neck are produced by right atrial and ventricular activity.[195]

Examination of the Jugular Venous Pulse

The two main objectives of the bedside examination of the neck veins are estimation of the CVP and inspection of the waveform.[197] Usually, the right internal jugular vein is superior for both purposes. In most normal subjects, the maximum pulsation of the internal jugular vein is observed when the trunk is inclined by less than 30°. In patients with an elevated venous pressure, it may be necessary to elevate the trunk further, sometimes to as much as 90°. When the neck muscles are relaxed, shining a beam of light tangentially across the skin overlying the internal jugular vein often exposes its pulsations. Simultaneous palpation of the left carotid artery aids the examiner in deciding which pulsations are venous.

Measurements of Venous Pressure

The difference between venous distention and venous pressure elevation must be considered. Veins may be markedly dilated with minimal increase in pressure or may not be visibly distended despite a very high venous pressure.[196] Venous pressure may be estimated by examining the veins on the dorsum of the hand. With the patient sitting or lying at a 30° elevation or greater, the arm is slowly and passively raised from a dependent position. When the venous pressure is normal, the veins collapse when the dorsum of the hand reaches the level of the sternal angle of Louis. Unfortunately, local venous obstruction or augmented peripheral venous constriction may diminish the accuracy of estimating CVP by this method.

The external or internal jugular veins also may be used to estimate venous pressure.[196] Because of its more direct route to the right atrium, the internal jugular vein is superior for the estimation of venous pressure and assessment of the venous waveform. The patient is examined at the optimal degree of trunk elevation for visualization of venous pulsations. The vertical distance from the top of the oscillating venous column to the level of the sternal angle is generally less than 3 cm. Greatly elevated venous pressure may be missed by failing to elevate the patient's head adequately. It may be necessary to actually have the patient sit upright. If the "pulsating meniscus" is very high, pulsations may not be apparent in the lower neck. When venous engorgement is

marked, the patient's earlobe may pulsate, and even the veins on the top of the head may be distended.

In patients suspected of RV failure but having a normal resting venous pressure, the abdominojugular test is useful.[196] With the patient breathing normally, firm pressure is applied with the palm of the hand to the upper right quadrant of the abdomen for 10 s or more. The patient should be instructed to continue to breathe normally during the test. In most subjects, the jugular venous pressure is not altered significantly. In some normal patients there is a transient increase in jugular venous pressure with a rapid return to or near baseline in less than 10 s. The dysfunctioning right ventricle, however, is unable to accept the increment in blood volume due to enhanced venous return without a marked increase in its filling pressure, which is transmitted to the neck veins. In patients with RV failure, which often results from left-sided heart failure, the venous pressure either rises rapidly and then partially declines slowly during continued abdominal compression or remains elevated by 4 cm of blood or more until the abdominal pressure is released (Fig. 10-44). Ducas et al.[198] also studied the abdominojugular test and confirmed its clinical value.

Analysis of Venous Waveforms

Again, the patient's trunk should be inclined to whatever elevation is necessary to reveal the top of the oscillating venous column.[199] Slow, deep inspiration will increase the amplitude of the presystolic *a* wave while decreasing the mean right atrial pressure. This is a useful technique for identifying the site at which the pulsations will be best visualized. Simultaneous palpation of the left carotid artery and cardiac auscultation aid the examiner in relating the venous pulsations to the timing of the cardiac cycle.

Normal Venous Pulse

The normal *jugular venous pulse* (JVP) reflects phasic pressure changes in the right atrium and consists of three positive waves and two negatives troughs (Fig. 10-45). It is useful to refer to the events of the cardiac cycle (Plate 2). The positive presystolic *a* wave is produced by right atrial (RA) contraction and is the dominant wave in the JVP, particularly during inspiration. During atrial relaxation, the venous pulse descends from the summit of the *a* wave. Depending on the PR interval, this descent may continue until a plateau (*z* point) is reached just prior to RV systole. More often, the descent is interrupted by a second positive venous wave, the *c* wave, that is produced by bulging of the tricuspid valve into the right atrium during RV isovolumic systole and by the impact of the carotid artery adjacent to the jugular vein.[200] Following the summit of the *c* wave, the JVP contour declines, forming the normal negative systolic wave, the *x* wave. The *x* descent is due to a combination of atrial relaxation, the downward displacement of the tricuspid valve during RV systole, and the ejection of blood from both ventricles (see Chap. 3).

The positive, later systolic *v* wave in the JVP results from the increase in blood volume in the venae cavae and right atrium during ventricular systole when the tricuspid valve is closed. After the peak of the *v* wave is reached, the RA pressure decreases because of the diminished bulging of the tricuspid valve into the right atrium and the decline in RV pressure that follows tricuspid valve opening. In the JVP, the latter occurs at the peak of the *v* wave. Following the summit of the *v* wave, there is a negative descending limb, referred to as the *y* descent or diastolic collapse, which is due to the tricuspid valve opening and the rapid inflow of blood into the right ventricle. The initial *y* descent corresponds to the RV rapid-filling phase. The trough of the *y* wave occurs in early diastole and is followed by the ascending limb of the *y* wave, which is produced by the continued diastolic inflow of blood into the right side of the heart. The velocity of this ascending pressure curve depends on the rate of venous return and the distensibility of the chambers of the right side of the heart. When diastole is long, the ascending limb of the *y* wave is often followed

by a small, brief, positive wave, the *h* wave, that occurs just prior to the next *a* wave. At times, there is a plateau phase rather than a distinct *h* wave. With increasing heart rate, the *y* trough and *y* ascent are followed immediately by the next *a* wave.

Usually, there are three visible major positive waves (*a*, *c*, and *v*) and two negative waves (*x* and *y*) when the pulse rate is below 90 beats per minute and the PR interval is normal. With faster heart rates, there is often fusion of some of the pulse waves, and an accurate analysis of the waveform is more difficult.

Abnormal Venous Pulse

ELEVATED VENOUS PRESSURE

The most common cause of an elevated jugular venous pressure is an increased RV pressure such as occurs in patients with pulmonic stenosis, pulmonary hypertension, or RV failure secondary to left-sided heart failure or RV infarction. The venous pressure also is elevated when obstruction to RV inflow occurs, as with tricuspid stenosis or RA myxoma, or when constrictive pericardial disease impedes RV inflow. It also may result from vena cava obstruction and, at times, an increased blood volume. Patients with obstructive pulmonary disease may have an elevated venous pressure only during expiration.

KUSSMAUL'S SIGN

Normally, during inspiration, there is an increase in the *a* wave of the JVP but a decrease in the mean jugular venous pressure as a result of the increased filling of the right-sided chambers associated with the decrease in intrathoracic pressure. *Kussmaul's sign* denotes an inspiratory increase in the venous pressure, which may occur in patients with severe constrictive pericarditis when the heart is unable to accept the increase in RV volume without a marked increase in the filling pressure. Although Kussmaul's sign was first described in patients with constrictive pericarditis, its most common cause is severe right-sided heart failure, regardless of etiology. The presence of Kussmaul's sign is also useful in the diagnosis of RV infarction[201] (see Chap. 72).

ABNORMALITIES OF THE *a* WAVE

The *a* wave in the JVP is absent when there is no effective atrial contraction, such as in atrial fibrillation (see Fig. 10-45*E*). In certain other conditions, the *a* wave may not be apparent. In sinus tachycardia, the *a* wave may fuse with the preceding *v* wave, particularly if the PR interval is prolonged. In some patients with sinus tachycardia, the jugular *a* wave may occur during the *v* or *y* descent and may be small or absent. In the presence of first-degree AV block, a discrete *a* wave with ascending and descending limbs is often completed prior to the first heart sound, and the *ac* interval is prolonged (see Fig. 10-45*F*).

Large *a* waves are of considerable diagnostic value (see Fig. 10-45*B*). When giant *a* waves are present with each beat, the right atrium is contracting against an increased resistance. This may result from obstruction at the tricuspid valve (tricuspid stenosis or atresia, right atrial myxoma) or conditions associated with increased resistance to RV filling.[200] A giant *a* wave is more likely to occur in patients with pulmonic stenosis or pulmonary hypertension in whom both the atrial and ventricular septa are intact.

Cannon *a* waves occur when the right atrium contracts while the tricuspid valve is closed during RV systole.[200] Cannon *a* waves may occur either regularly or irregularly and are most common in the presence of arrhythmias (see Fig. 10-45*G*).

ABNORMALITIES OF THE *x* WAVE

The most important alteration of the normally negative systolic collapse (*x* wave) of the JVP is its obliteration or even replacement by a positive wave. This is usually due to tricuspid regurgitation. Although atrial relaxation may contribute to the normal *x* descent, the development of atrial fibrillation does not obliterate the *x* wave except in the presence of tricuspid regurgitation. Accordingly, the occurrence of a positive wave in the JVP during ventricular systole is strong evidence of tricuspid regurgitation (Fig. 10-46*A*). Mild tricuspid regurgitation lessens and shortens the downward *x* wave as the regurgitation of blood into the right atrium produces a positive wave that diminishes the usual systolic fall in venous pressure. In some patients with moderate tricuspid regurgitation, there is a fairly distinct positive wave during ventricular systole between the *c* and *v* waves. This abnormal systolic waveform is usually referred to as a *v* or *cv* wave, although it has also been referred to as an *r* (regurgitant) or an *s* (systolic) wave. In patients with constrictive pericarditis, the *x* descent wave during systole is often more prominent than the early diastolic *y* wave (see Fig. 10-45*C* and Chap. 72).

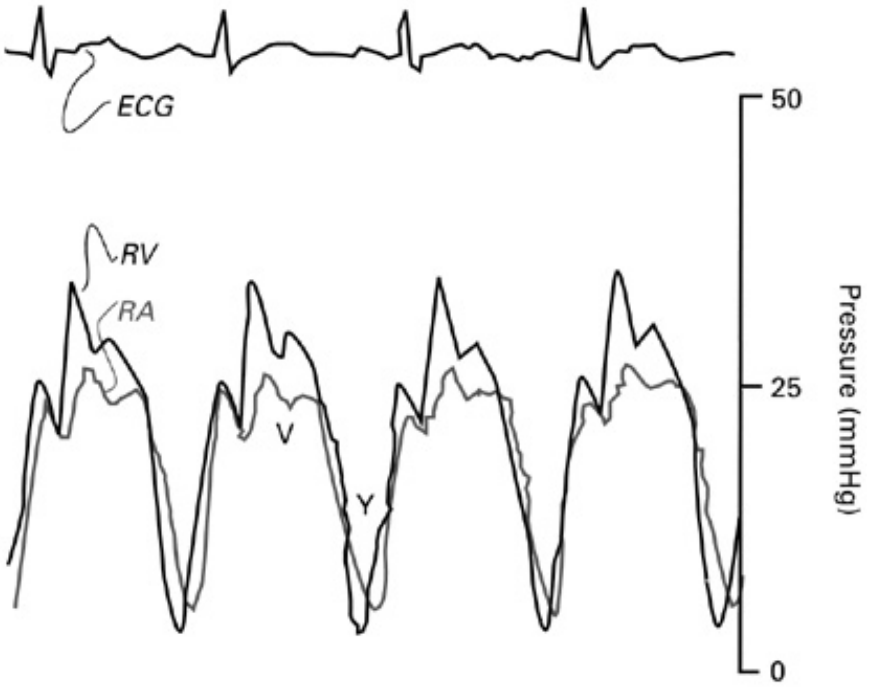

Figure 10-46: Right ventricular (RV) and right atrial (RA) pressure curves and simultaneous ECG from a patient with severe tricuspid regurgitation. Note ventricularization of the RA pressure curve.

ABNORMALITIES OF THE *v* WAVE

The positive, late systolic *v* wave results from the increasing RA blood volume during ventricular systole when the tricuspid valve normally is closed. With mild tricuspid regurgitation, the *v* wave and the obliteration of the *x* descent result in a single, large positive systolic wave (ventricularization) (see Figs. 10-45*A* and 10-46).

Normally in the JVP the *v* wave is lower in amplitude than the *a* wave. In patients with an ASD, however, the *a* and *v* waves are often equal in the right atrium and the JVP (see Fig. 10-46*D*). In patients with constrictive pericarditis and sinus rhythm, the RA *a* and *v* waves also may be equal,

but the venous pressure is increased, which is unusual with isolated ASD. In patients with constrictive pericarditis who are in atrial fibrillation, the *cv* wave is prominent and the *y* descent rapid.

ABNORMALITIES OF THE *y* TROUGH

The *y* descent, or diastolic collapse, is produced mainly by the tricuspid valve opening and the rapid inflow of blood into the right ventricle. A rapid, deep *y* descent in early diastole occurs with severe tricuspid regurgitation (see Fig. 10-45*A*). A venous pulse characterized by a sharp *y* descent, a deep *y* trough, and a rapid ascent to the baseline is seen in patients with constrictive pericarditis or with severe right-sided heart failure. A slow *y* descent in the JVP suggests an obstruction to RV filling and may be the only abnormal finding in patients with tricuspid stenosis or right atrial myxoma (see Fig. 10-45*B*). In both constrictive pericarditis and severe right-sided heart failure, the venous pressure is elevated with a sharp *y* dip in the JVP (see Chap. 72). The presence of a large positive systolic venous wave favors the diagnosis of severe heart failure.

Effects of Arrhythmias on the Venous Pulse

Large *a* waves in the JVP during arrhythmias are present when the *P* wave (atrial contraction) occurs between the onset of the QRS complex and the termination of the T wave (see Fig. 10-46*G*). Such cannon *a* waves may occur regularly in junctional rhythm. More commonly, they occur irregularly when AV dissociation accompanies premature ventricular beats, ventricular tachycardia, or complete heart block. The *a* wave is absent in patients with atrial fibrillation, and flutter *a* waves at a regular rate of 250 to 300 per minute occasionally are observed in patients with atrial flutter and varying degrees of AV block. Patients with multifocal atrial tachycardia often have prominent and somewhat variable *a* waves in the JVP. In these patients, many of whom have pulmonary hypertension secondary to lung disease, the *a* waves are often very large.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

EXAMINATION OF THE RETINA*

Inspection of the smaller vessels of the body is possible in only three areas: the retina, the conjunctiva, and the nail beds. The ophthalmoscope has made the retina by far the easiest and most rewarding site.[201] Viewing this two-dimensional vascular display is generally much easier if the pupils are dilated. Pulse and blood pressure determinations should be made prior to the instillation of rapidly acting mydriatics, since both may increase after absorption of the drops. The pupils are left undilated in patients in whom the iris seems closely apposed to the cornea and in those with a history of closed-angle glaucoma. Examination of the retina should proceed methodically. Best pupillary dilatation is maintained if the optic disk is observed first. Assess for evidence of edema and blurred margins and for cupping with sharp contours. Rule out neovascularization or the pallor of optic atrophy. Next, scan along the superior temporal arcade, inspecting the arteries carefully for embolic plaques at each bifurcation. Observe the arteriovenous crossing for obscuration of the vein and for pronounced nicking and banking of the vessels. The lower arcade and the nasal vessels may be inspected next. Avoid the macular area until all else has been viewed because the pupil constricts most intensely when this area is illuminated. To discover diabetic microaneurysms early, look just temporal to the fovea, along the horizontal raphe. To find cotton-wool infarcts, look circularly around the disk two disk diameters out. Using this method, the retina can be efficiently searched for evidence of cardiovascular disease[201] (Table 10-5).

Table 10-5: Retinal Topography

Finding	Most Common Location
Arteriovenous crossings	Upper temporal quadrant
Cotton-wool spots	Around optic disk
Hard exudates	Between disk and fovea
Microaneurysms	Temporal to fovea
Emboli	Arterial bifurcations
Diabetic new vessels	Nerve head and arcades

Alterations in retinal caliber along the course of a single artery or vein are more important than estimates of arteriovenous ratios or absolute vascular diameter. Determining the degree of tortuosity of straightening are of little value where the veins are large, dark, and tortuous.

Variations in the caliber of a single vessel are more important than determinations of arteriovenous ratios. These changes may take the form of focal narrowing, sometimes called *beading* or *spasm*.

Thickening of the Vascular Wall

Normally, only the blood column is visible when the retinal vessels are viewed. When changes in the walls do occur, they are most visible along the sides of the vessels, since the location of the tangential line of sight presents a greater thickness to the viewer. Fatty exudate (hard exudate) may collect along venous walls (never arteries), particularly in diabetic exudative retinopathy.

Arteriosclerosis

In arteriosclerosis, medial smooth muscle (which may hypertrophy in chronic hypertension) becomes hyalinized with the deposition of collagen. As the wall thickens, the vessel takes on a burnished coppery luster; with further thickening, this may transmute to silver.

Arteriovenous Compressions

Arteriovenous compressions or "nicking" results from the sharing by the artery and vein of a common adventitial sheath at their crossings. Arteriosclerotic thickening impedes venous outflow at these locations, with venous tortuosity, engorgement, and darkening of the flood column distal to the compression.[201]

Atherosclerosis

Retinal atheromata have a predilection for the bifurcation and bends within the first two branches of the central retinal artery, appearing as segments of irregular yellowish sheathing and having the crystalline knobbiness of a salted pretzel stick.[210]

Cotton-Wool Spots

Cotton-wool spots are generally a sign of serious systemic disease. They may be seen in patients with severe hypertension, blood dyscrasias, collagen diseases, or hemorrhagic shock. Cotton-wool spots also are seen frequently in patients with acquired immunodeficiency syndrome (AIDS) (Fig. 10-47, Plate 43). Cotton-wool "exudates" are not exudates but consist of a cluster of cell-like swollen ends of fragmented axons (cytoid bodies) in an area of edematous retina.[201]

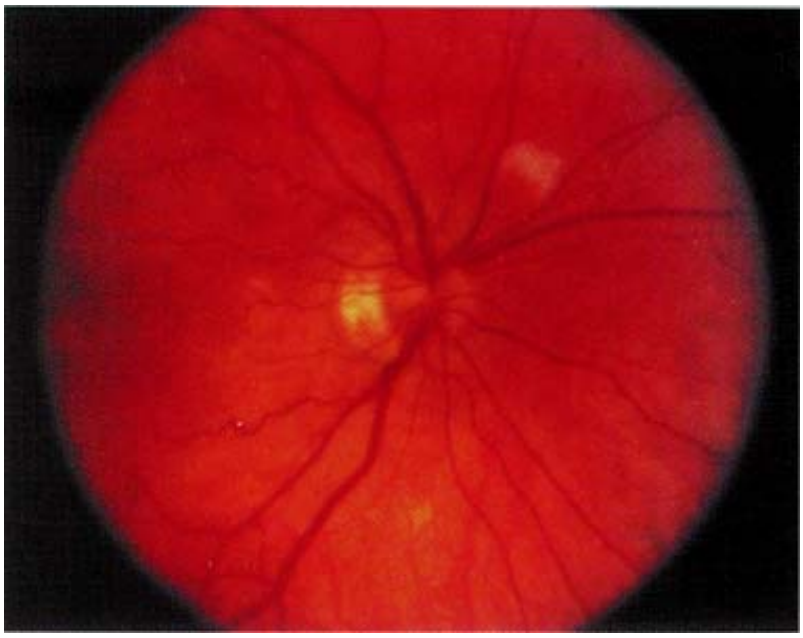

Figure 10-47: (Plate 43) Retinal cotton-wool spot. Cotton-wool spots are most frequently found close to the optic disk. Although they occur in acute uncontrolled systemic hypertension, the more common cause now, in younger patients, is infection with the human immunodeficiency virus (HIV). This normotensive 37-year-old man had no visual symptoms and no other retinopathy. There is a myopic crescent at the temporal disk edge, which is not abnormal. He died of complications related to the acquired immunodeficiency syndrome (AIDS) 2 years later.

Hard Exudates

Hard exudates are most likely residues of edema. They occur in situations where the vessels become leaky, and as the more watery component of the extravasation is resorbed, the lipid residue forms a hard, yellow, waxy deposit. These deposits may surround the leaking vessel in a circinate ring or may accumulate in the macula, radiating from the fovea in the spokes of a macular "star" (Fig. 10-48, Plate 44).

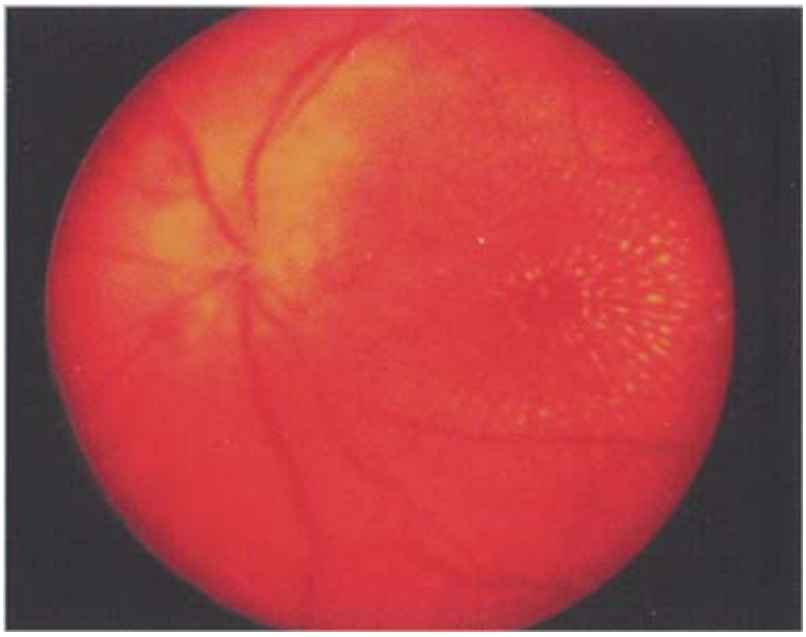

Figure 10-48: (Plate 44) Disk swelling and hard exudate in a macular "star" pattern. In this hypertensive patient with periarteritis nodosa, vascular leakage has led to the deposit of hard exudates around the fovea. Radial perifoveal connective tissue results in the star pattern of the exudate. Note also that the optic disk is edematous, with blurred margins, secondary to hypertension.

Microaneurysms

Microaneurysms are not unique to diabetes but occur in many disease states, including retinal venous obstructive disease, sickle cell disease, the dysproteinemias, Behçet's disease, sarcoidosis, and other forms of uveitis. They may represent abortive attempts at revascularization of compromised capillary bed (Fig. 10-49, Plate 45).

Figure 10-49: (Plate 45) Background diabetic retinopathy. Retinal microaneurysms, dot-and-blot hemorrhages, and a few fine upper temporal hard exudates are diagnostic of early diabetic retinopathy. The patient had no visual symptoms, but retinopathy of this magnitude can often be seen in patients with insulin-requiring diabetes of 15 or more years' duration.

Neovascularization

In neovascularization the new vessels generally originate from capillaries from the venous side of the circulation and are associated with greater or lesser degrees of fibrosis. In all cases, however, the new vessels are incorporated in an associated fibrous membrane (Fig. 10-50, Plate 46; Fig. 10-51).

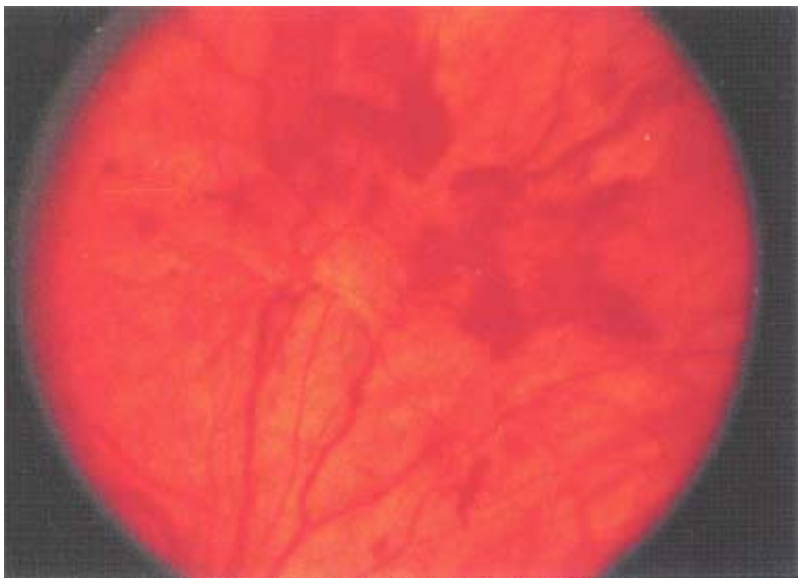

Figure 10-50: (Plate 46) Proliferative diabetic retinopathy with preretinal hemorrhage. When neovascularization develops, preretinal and vitreous hemorrhages are much more likely to occur.

Easily visible neovascularization either in the periphery of the retina, as in this diabetic patient, or at the disk is an indication for immediate panretinal laser photocoagulation.

Figure 10-51: Proliferative diabetic retinopathy, left eye. There is extensive neovascularization of the disk with an associated small intravitreal hemorrhage that obscures the upper temporal vessels. Along the inferior temporal arcade is another area of neovascularization. These new vessels are incorporated in fibrous membranes that may tent up the vessels and cause traction detachments of the retina, as at the lower right edge of the photograph.

Retinal Hemorrhage

Hemorrhage into the retina indicates further breakdown in the integrity of the vascular wall. When the hemorrhage occurs in the inner retina, as in hypertension, it assumes a feathery flame shape as it is molded and dispersed by the nerve fibers coursing toward the disk. In obstruction of the central retinal vein, the fundus may be splattered with blood (Fig. 10-52, Plate 47).

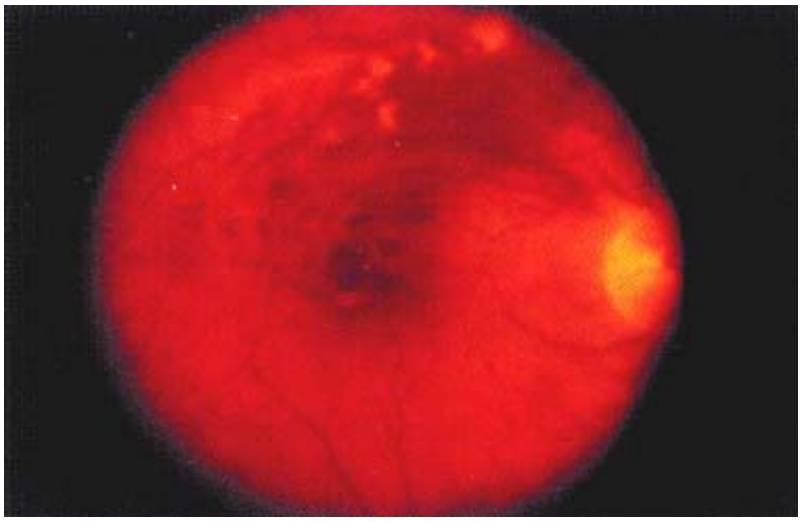

Figure 10-52: (Plate 47) Branch retinal vein obstruction. Thickening of the retinal arterial wall in diabetes and hypertension may compromise the lumen of the vein, where they share a common adventitial sheath at an arteriovenous crossing. The resulting obstruction produces hemorrhage retinopathy in the drainage area of the affected vein. Note here how the flame-shaped pattern of blood outlines the arcuate pattern of the nerve fibers as they run toward the optic disk.

Vascular Occlusion

When the central artery or one of its branches is occluded, the nonperfused retinal area becomes cloudy in a matter of minutes. At the fovea, where the retina is one cell layer thick and nourished by the choroid, the normal color and transparency persist. By contrast with the surrounding pallor, the fovea then has a cherry-red appearance (Fig. 10-53, Plate 48). Occlusions of branches of the central vein produce edema and hemorrhage in the drained area. As collateral drainage channels develop (see Fig 10-52 and Plate 47), the edema and hemorrhagic retinopathy subside, leaving white-walled veins, neovascularization, and microaneurysms in the affected area (Fig. 10-54, Plate 49).

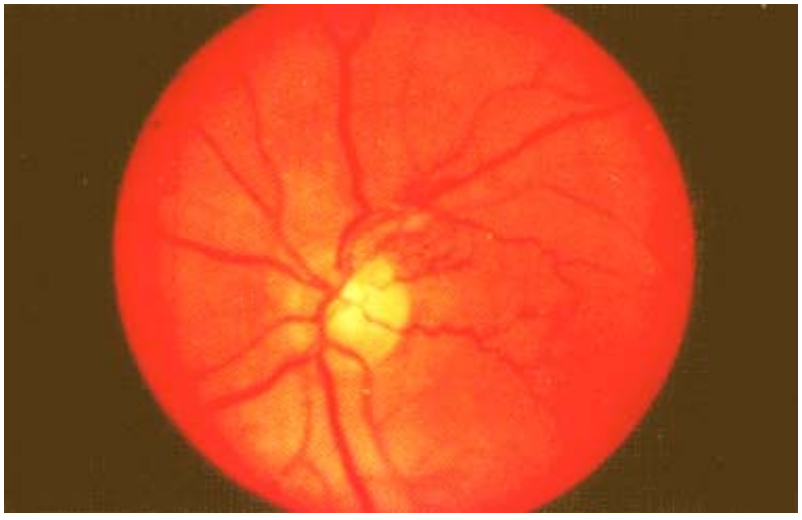

Figure 10-54: (Plate 49) Neovascularization after branch retinal vein obstruction. New vessels may develop late after obstruction of a branch of the central retinal vein. These most often serve to shunt flow around the obstructed vessel site and are thus not as exuberantly proliferative as those seen in diabetic retinopathy.

Optic Disk Edema

The term *papilledema* is reserved for the form of disk edema that is the result of increased intracranial pressure. It therefore has an etiologic connotation and is not used generally to mean optic disk edema. *Papillitis* is the term applied to inflammatory disk edema. Patients with anterior ischemic optic neuropathy commonly have a pale, edematous disk with an altitudinal field effect.

Embolism

Table 10-6 lists the characteristics of retinal emboli of cardiovascular significance. Of these, platelet emboli are at once the most common and the most evanescent. Hollenhorst cholesterol plaques may be identified at the same bifurcations for months to years after the embolic shower. Platelet emboli, Hollenhorst plaques (see Fig. 10-53, Plate 48; Fig. 10-55, Plate 49), and calcium emboli (Fig. 10-56, Plate 50) are usually seen along the course of a retinal artery. Roth spots (Fig. 10-57, Plate 51) and fat emboli may not appear to be intravascular and may not be associated with a vessel that is ophthalmoscopically visible (see Table 10-6).[201]

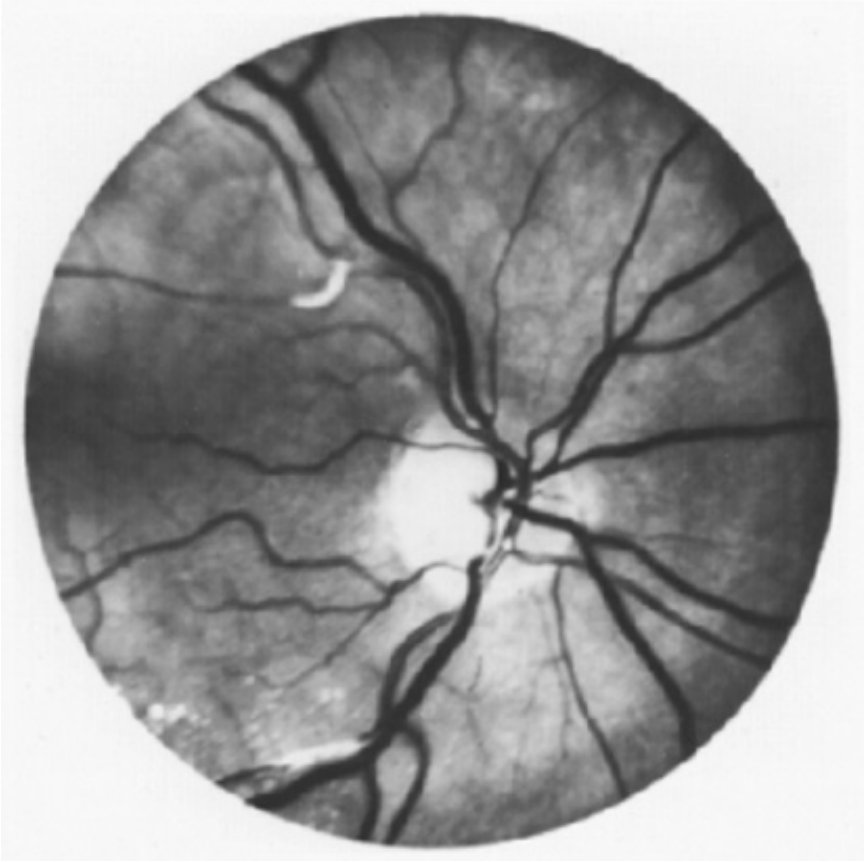

Figure 10-55: Retinal emboli often lodge at bifurcations, as in this patient with carotid atherosclerosis. Note that the embolic material often seems larger than the containing vessel, as in the embolus at the lower left edge of the photograph. Emboli may damage the vessel wall and cause leakage, as can be seen by the exudate deposited about the inferior embolus. Hollenhorst cholesterol plaques rarely obstruct arterial flow completely, and this patient maintained vision.

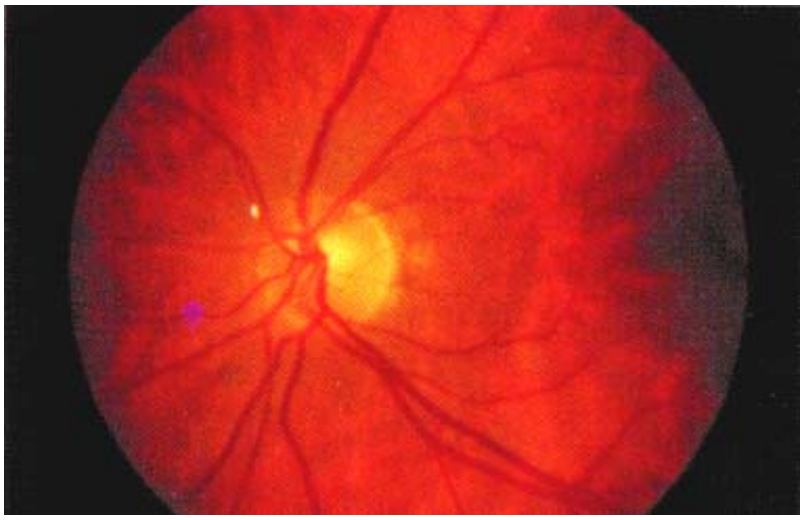

Figure 10-56: (Plate 50) Calcific retinal embolus associated with aortic valvular disease. Calcific aortic valvular disease and valve replacement surgery may result in retinal emboli. Like cholesterol emboli, these calcific flecks lodge at arterial bifurcations but seldom obstruct flow completely. They are white and glitter in the ophthalmoscope beam. Somewhat similar emboli may be seen after the intravenous injection of illicit drugs expanded with talc.

Figure 10-57: (Plate 51) Retinal hemorrhages after cardiac catheterization. Following cardiac catheterization, symptomatic and asymptomatic retinal hemorrhages may occur. The latter are more common. Presumably, these are the result of embolic events. Note, in this recently catheterized patient, the two oval hemorrhages and a small area of cloudy swelling just inferior and temporal to the fovea.

Table 10-6: Emboli of Cardiovascular Significance

Type	Appearance	Significance
Platelet	Dull pink to gray often with associated fibrin	Downstream vegetations, mural thrombi
Hollenhorst plaque	Glistening yellow-orange plaques at bifurcations	Downstream atheroma (containing cholesterol)
Calcium plaque	Glistening white plaques	Calcific aortic stenosis
Roth spot	Hemorrhage with gray-white center (see Plate 51, Fig. 10-57)	Blood dyscrasia or septic embolus as in subacute bacterial endocarditis
Fat embolus	Fuzzy-bordered gray-white spot without hemorrhage	Severe trauma with long bone fractures
Myxoma	Disk edema, retinal edema in arterial supply zone	Life-threatening atrial myxoma

Diabetes Mellitus

In diabetes mellitus, focal loss of a portion of the capillary bed is followed by microaneurysm formation and vascular dilatation around the borders of the area of capillary dropout (see Fig. 10-49 and Plate 45). Vascular leakage occurs with dot and blot hemorrhages and deposits of hard exudate (Fig 10-58). New blood vessels develop along the vascular arcades and at the optic nerve head (see Figs. 10-50 and 10-51 and Plate 50).

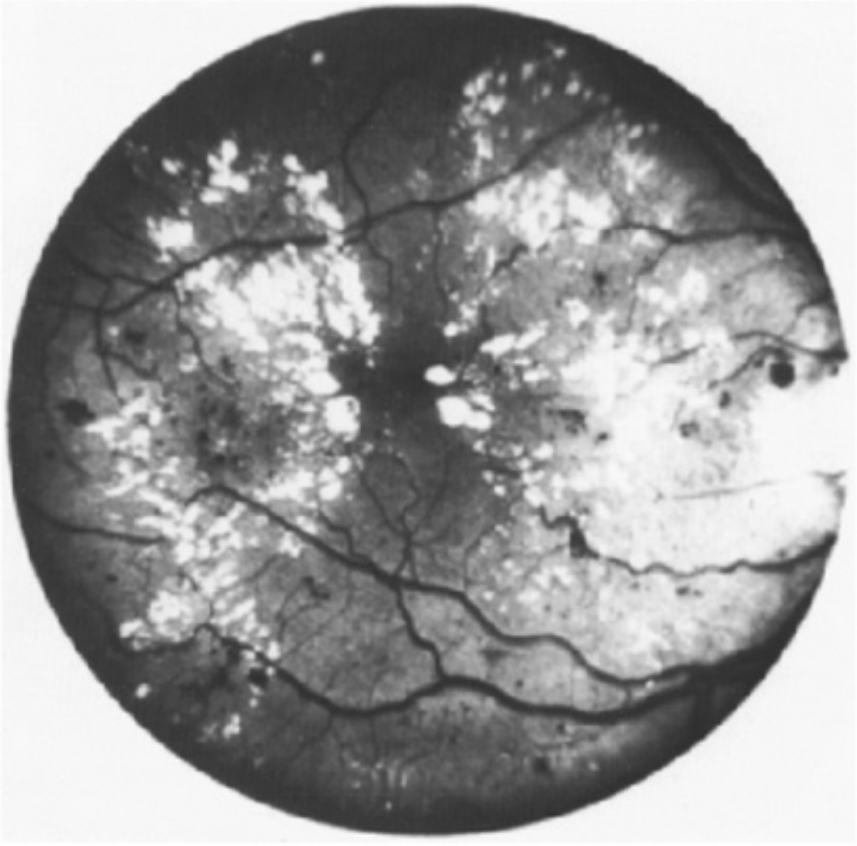

Figure 10-58: Exudative diabetic retinopathy, right eye, illustrating microaneurysms, dot-and-blot hemorrhages, and venous engorgement with extensive deposits of hard, yellow exudate.

Vasoconstriction of the arterial tree and thickening of the arterial vessel walls with consequent reduction in lumen diameter are homeostatic responses to hypertension. Arteriosclerotic narrowing of the vessels acts to insulate the capillary bed from the elevated pressure of the arterial supply. These arteriosclerotic changes are visible as narrowing, increases in central light reflexes, and copper and silver "wiring" of the arteries (Fig. 10-59, Plate 52). Radial arrangement of such exudate deposits in the macula produces a "star" (see Fig 10-48 and Plate 48). Hemorrhage may occur in the retinal layers in a characteristic flame pattern, and focal ischemia in the nerve fiber may result in cotton-wool microinfarcts. In severe hypertensive decompensation, the optic nerve head becomes swollen and edematous (see Fig. 10-48 and Plate 48).

Hypertensive patients should be classified as to whether or not their retinal circulation is compensated or has decompensated with observable edema, cotton-wool spots, flame hemorrhages, or swelling of the optic disk.[201]

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

PHYSICAL EXAMINATION OF THE CHEST, ABDOMEN, AND EXTREMITIES

Physical examination of the lungs is an important noninvasive technique requiring only a stethoscope.[202] Wheezing and a pleural friction rub are detected only by the clinical evaluation. The pleural friction rub may be a clue to the diagnosis of pulmonary infarction. Pleural fluid due to heart failure is usually located in the right pleural space. When pleural fluid is localized predominately to the left, a cause other than or in addition to heart failure, such as pulmonary infarction, should be considered.

A pneumothorax may develop as a consequence of spontaneous mediastinal emphysema or may be iatrogenic, due to procedures.[202] Hyperresonance and diminished breath sounds may be due to pulmonary emphysema. Signs of pulmonary consolidation may be due to pneumonia or pulmonary infarction. Wheezing and rales may be due to bronchial disease. Heart failure may be associated with rales in the lung bases, wheezing, and pleural fluid. Importantly, heart failure frequently is not associated with rales, since interstitial pulmonary edema usually does not produce rales.[202]

The diameter of the *abdominal* aorta should be determined in every patient[202] (see Chap. 88). An abdominal aortic aneurysm may be missed if the examiner fails to assess the area above the umbilicus.

Specific abnormalities of the abdomen may be secondary to heart disease. A large, tender liver is common in patients with heart failure or constrictive pericarditis. Systolic hepatic pulsations are frequent in patients with tricuspid regurgitation. A palpable spleen is a common but late sign in patients with severe heart failure and is also often present in patients with infective endocarditis.

Although hepatic cirrhosis is the most common cause of ascites, the latter may occur with heart failure alone, although it is less common with the use of diuretic therapy. Severe tricuspid regurgitation, as caused by infective endocarditis in drug addicts, may produce prominent systolic pulsation of the internal jugular veins in the neck, a large, moving, and pulsating liver, and ascites. Constrictive pericarditis should be considered when the ascites is out of proportion to peripheral edema. In many such patients, the heart is normal in size or only slightly enlarged, a pericardial "knock" is heard, and there is a rapid *x* and/or *y* descent in the internal jugular vein pulsation.[202] Restrictive cardiomyopathy can mimic constrictive pericarditis, but the heart is usually moderately large in patients with restrictive cardiomyopathy. When there is an arteriovenous fistula in the abdomen, a continuous murmur may be heard over the abdomen. Fistulas due to trauma and surgery may occur.

A systolic bruit may be heard over the kidney areas and may signify renal artery stenosis, particularly in patients with systemic hypertension. A systolic bruit often is auscultated over the abdominal aorta, but its presence does not indicate the severity of disease of the aorta.[202]

Examination of the upper and lower extremities may provide important diagnostic information (see Chap. 90). The clinical detection of arterial disease and thrombophlebitis is important. Atherosclerosis of the peripheral arteries may produce intermittent claudication of the buttock, calf, thigh, or foot, with severe disease resulting in tissue damage of the toes. Peripheral

atherosclerosis is an important risk factor for ischemic heart disease, and its presence increases the likelihood of coronary atherosclerosis. Thrombophlebitis often causes pain in the calf or thigh or edema, and its presence should raise the consideration of pulmonary emboli as well. Edema is a late sign of heart failure, and its predictive value as a diagnostic sign is poor. It frequently involves the right leg prior to the left. Considerable heart failure and a resulting weight gain may be present without edema being present. Edema of the lower extremities may be secondary to local factors such as varicose veins or thrombophlebitis or the removal of veins at CABG surgery. Under such circumstances, the edema often occurs in only one leg.

Edema may result from restrictive garments, and venous stasis often is secondary to a long trip in a car or airplane.[202] Edema may be due to salt and water retention in patients with primary renal disease. In the differential diagnosis of edema, local factors should be considered first. If local factors can be excluded, the cause of the salt and water retention should be determined with an assessment for evidence of primary renal disease. Rarely, peripheral edema can be an early sign of lymphatic obstruction produced by metastatic disease in the pelvis or abdomen.

Since the invention of the stethoscope by Laennec in 1826, cardiac auscultation has played a key role in the evaluation of patients with cardiovascular disease. New diagnostic techniques developed in recent years have led to a better understanding of the relationship between intracardiac pressure, flow, and valve motion and the resulting sound phenomena on the other. The analysis of heart sounds and murmurs by phonocardiography, together with information obtained by cardiac catheterization, angiography, echocardiography, and cardiac surgery, has made cardiac auscultation a precise discipline based on firm physiologic principles.[203]

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

INSPECTION AND PALPATION OF THE PRECORDIUM

Inspection and palpation of the cardiac pulsations of the anterior chest have been practiced by physicians since ancient times and have a solid scientific basis. The results of precordial inspection and palpation have been correlated with noninvasive studies, hemodynamic data, and surgical and autopsy studies[202,203] and remain an important part of the cardiovascular examination. Their usefulness depends on an understanding of cardiovascular physiology, the proficiency of the examiner, and his or her ability to integrate findings with history, the information obtained by other portions of the physical examination, the ECG, the chest roentgenogram, and other diagnostic tests.

Precordial Pulsations Due to the Heartbeat

Precordial pulsations, reflecting underlying movement of the heart and great vessels, occur principally in seven areas of the anterior chest[204,205] (Fig. 10-60):

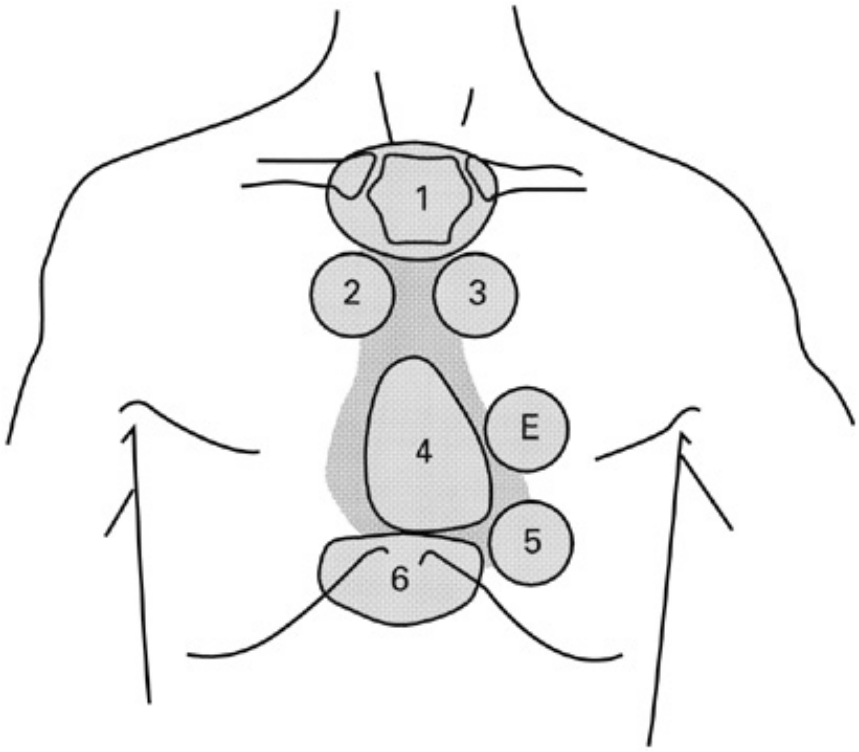

Figure 10-60: Seven areas to be examined for abnormal cardiovascular pulsations by inspection and palpation. (From Schlant RC, Hurst JW. *Examination of the Precordium: Inspection and Palpation.* New York: American Heart Association; 1990:1-28. Used with permission from the publisher and authors.)

1. The sternoclavicular area

2. The aortic area
3. The pulmonic area
4. The RV (left parasternal) area
5. The LV (apical) area
6. The epigastric area
7. Ectopic (variable-location) areas

While the cardiac apex is usually produced by the left ventricle, it is sometimes produced by an enlarged right ventricle that displaces the left ventricle laterally and posteriorly. Occasionally, the cardiac position is abnormal due to dextroposition, dextroversion, dextrocardia, or other changes in intrathoracic structures. Although the cardiac apex impulse is commonly referred to as the *point of maximal impulse* (PMI), the two terms are not necessarily synonymous, since the maximal precordial pulsation may be produced by an enlarged or hypertrophied right ventricle, a dilated aorta or pulmonary artery, or a LV wall-motion abnormality. Therefore, precordial pulsations should be described by their location, timing, contour, and duration.

Inspection of the Precordium

The examiner should first inspect the thorax from the foot of the bed with the subject supine, the legs horizontal, and the head and trunk elevated to approximately 30°.[205] The patient may have a barrel-shaped chest with an increased anteroposterior diameter, a straight-back syndrome, pectus excavatum, pectus carinatum, kyphoscoliosis, or ankylosing spondylitis. Each may produce or be associated with cardiac abnormalities. Asymmetry of the thorax due to convex bulging of the precordium suggests the presence of heart disease since childhood. Exaggerated movements of the cardiac apex often can be detected from this observation point.

Next, the examiner should move to the patient's right side and observe the patient's chest tangentially rather than from above. A light beam directed across the precordium may enhance subtle findings.[205,206] Precordial movements frequently can be recognized more easily if the tip of an applicator stick, tongue blade, or light pencil is held against the impulse as a fulcrum. Motion of the underlying chest wall is transmitted to the free end of the instrument and exaggerated, making the movements more obvious.

In patients with an abnormally prominent apical impulse and in some thin, normal individuals, the apical impulse or apex beat can be seen. The presystolic apical motion associated with the atrial contribution to ventricular filling (a fourth heart sound) sometimes may be visualized, as may the diastolic waveform due to rapid ventricular filling (a third heart sound). A late systolic bulge either at the apex or in an ectopic area, usually located either medial and superior or lateral to the apical impulse, may be observed in patients with a large dyskinetic ventricular aneurysm.[203] When precordial pulsations are exaggerated, they become visible as well as palpable. In general, however, outward movements are best discerned by palpation, whereas inward movements usually are seen more easily than felt.[202,203]

Palpation of the Precordium

With Tietze's syndrome, pain, sometimes with swelling and tenderness, may affect the costochondral, chondrosternal, or xiphosternal joints and may be reproduced by touching. Palpation also may reveal tender superficial veins on the anterior chest (Mondor's disease), a rare etiology of chest discomfort.[206] Collateral vessels in the posterior intercostal spaces may be palpable in patients with aortic coarctation.[206]

Palpation of the precordium is also best performed from the right side, with the patient supine and the upper trunk elevated 30°. Palpation with the right hand usually provides more information. Patients with suspected cardiovascular disease also should be examined in the left lateral

decubitus position, rotated 45 to 90°.[207] In this position, the normal LV impulse may be displaced several centimeters leftward and may appear more prominent and sustained. The size of the apex impulse rather than its distance from the midsternal or midclavicular line determines its normality.[207] Often, the apex impulse and other palpable events such as a LV rapid filling wave (S_3) or presystolic *a* wave (S_4) may be felt only in this position.

The location and size of the cardiac apex impulse should be defined, its contour characterized, and any abnormal precordial pulsations identified. The palm of the hand, ventral surface of the proximal metacarpals, and fingers should all be used for optimal appreciation of specific movements. The fingers appear to be particularly insensitive to movements of relatively large amplitude and very low frequency. This is consistent with the clinical observation that an examiner's hand occasionally can be seen to move up and down with precordial motion, although the same movements are imperceptible by palpation alone. By contrast, higher-frequency events, such as the vibrations associated with abnormally loud aortic or pulmonic components of the second heart sound, are easily palpable, even though the amplitude of their movement is not readily visible.[204]

The pads of the fingers are most useful for detecting LV and normal RV motion, whereas the palm and proximal metacarpals are usually best used for palpating larger, low-frequency movements such as the parasternal systolic lift of RV hypertrophy.[204] Varying pressure with the hand is often quite useful. High-frequency movements such as ejection sounds, valve closure sounds, and mitral opening snaps are detected more easily with the hand held firmly against the chest, whereas low-frequency movements such as ventricular diastolic filling events are best recognized with light pressure with the fingertips.

Thrills are palpable vibrations from murmurs or bruits ordinarily associated with grade 4/6 murmurs or louder. The location of a thrill often helps identify its origin. Thrills are palpated most easily with the fingertips or with firm pressure, using either the palm of the hand or the proximal metacarpals. Sometimes thrills are felt better during a held end-expiration with moderate pressure applied from the right hand on top of the left hand, which is placed on the chest. Occasionally, palpable murmurs are more readily detected with the right palm placed over the anterior chest and the left hand supporting the posterior thorax with equal force.[205]

To detect abnormal RV motion, the heel of the hand should be placed over the lower half of the sternum with the patient's breath held at end-expiration. The parasternal lift due to RV hypertrophy is often better visualized than actually felt. In patients with chronic obstructive pulmonary disease, subxiphoid and epigastric palpation with the patient's breath held at end-inspiration is useful for assessing RV motion.

Proper patient positioning is important. The location of the apex impulse is usually described in terms of its distance from the midsternal or midclavicular line and the intercostal space in which it is located. Although heart size is commonly estimated based on the size and location of the apex impulse with the patient supine, this is not always a reliable indicator of LV end-diastolic volume. The apex impulse is often faint or not palpable with the patient supine because of the distance of the ventricular apex from the chest wall. Palpation of the cardiac apex with the patient in the left lateral position, however, permits optimal assessment of the size (diameter) and contour of the systolic outward movement at the apex; diastolic movements are also best appreciated with the patient in this position. Since the apex impulse may shift several centimeters laterally when the patient rotates to the left lateral position, however, the location of the apex impulse may be incorrect in this position. Palpation with simultaneous cardiac auscultation often is useful for identifying the systolic or diastolic timing of precordial pulsations. Simultaneous palpation of the apical impulse and carotid pulse may be helpful in assessing the severity of aortic stenosis. An appreciable lag time between the onset of the apex impulse and carotid pulse usually indicates

severe aortic stenosis.

Physiology of Precordial Motion

Although only the apical impulse is palpable normally, a brief RV systolic motion can be felt at the left sternal edge in asthenic individuals. With the onset of isovolumic LV contraction, there is anterior movement of the left ventricle toward the chest walls (**see** Fig. 10-61). Counterclockwise rotation of the left ventricle along its longitudinal axis occurs as the cardiac apex moves anteriorly and makes contact with the chest wall in early systole.[208] The maximal outward movement occurs coincident with or just after aortic valve opening. After rapid early ejection, the left ventricle moves away from the chest wall, and the apex retracts during latter systole and returns to baseline well before the second heart sound.[204] The outward apex movement in early systole normally is palpable, but the later systolic inward movement is only visible (Fig. 10-61). Palpable movements of the apex in diastole result from LV filling. The early diastolic outward movement due to rapid ventricular filling (F wave), which corresponds to the normal S_3, is occasionally palpable in normal children and young adults (**see** Fig. 10-61). Later diastolic filling due to left atrial contraction (*a* wave) is not normally palpable. Precordial motion is modified by age, chest wall thickness, lung disease, and pleural or pericardial effusion.

Type of movement and associated clinical condition	Graphic Representation (palpable features in heavy line)	Location and accompanying features
NORMAL ADULT APEX IMPULSE		Cardiac apex; moderate systolic thrust; A and F waves usually imperceptible
HYPERKINETIC APEX IMPULSE "Normal Child "Hyperdynamic states "Ventricular septal defect "Patent ductus arteriosus "Mitral regurgitation "Aortic regurgitation		Exaggerated thrust at cardiac apex; F wave may be palpable, coincident with third heart sound
HYPERKINETIC RIGHT VENTRICULAR IMPULSE "Atrial septal defect "Pulmonary regurgitation	Same as above	Maximal at left sternal edge in third and fourth intercostal spaces
SUSTAINED APEX IMPULSE "Left ventricular hypertrophy, ""as in: "Aortic stenosis "Hypertension "Insert: a variation that ""may occur in hypertrophic ""cardiomyopathy		Maximal at cardiac apex; A wave may be visible and palpable coincident with fourth heart sound
SUSTAINED RIGHT VENTRICULAR IMPULSE "Right ventricular ""hypertrophy, as in: "Pulmonary hypertension "Pulmonary stenosis	Same impulse as in Sustained above	Maximal at left sternal edge in third and fourth intercostal spaces

AREA 1: STERNOCLAVICULAR AREA PULSATIONS

The sternoclavicular area (**see** Fig. 10-60) includes the right and left sternoclavicular joints, the manubrium, and the upper sternum. Usually, no pulsation is noted in this area. A slight, brief systolic pulsation of a sternoclavicular joint or the manubrium may be due to aortic regurgitation. Abnormal pulsations and movements in the sternoclavicular area are commonly produced by enlargement, dilatation, or diseases of the aorta, particularly aortic dissection, atherosclerotic aneurysm, or syphilitic aneurysm. An abnormal pulsation of a sternoclavicular joint in patients with chest pain may be an early clue to diagnosis of aortic dissection. A slight pulsation in the right sternoclavicular area may suggest a right-sided aortic arch in patients with cyanotic heart disease, particularly tetralogy of Fallot.[204] A kinked, tortuous right carotid artery or dilatation and tortuosity of other brachiocephalic vessels may produce visible and palpable pulsations in the suprasternal notch or the supraclavicular areas.

AREA 2: AORTIC AREA PULSATIONS

Vibrations of the aortic component (A_2) of the second heart sound may be palpated when they are accentuated, as in arterial hypertension. With valvular aortic stenosis, a systolic thrill is present frequently in the second and less commonly in the first and third right intercostal spaces near the sternum (see Fig. 10-60). It often radiates upward toward the right side of the neck and to the

suprasternal notch and right supraclavicular area. Less frequently, the thrill is palpable at the second or third left interspaces next to the sternum or at the apex. A systolic thrill in the aortic area and in the right carotid artery also can occur in patients with severe aortic regurgitation without stenosis. Abnormal systolic pulsations in the aortic area may be due to dilatation of the ascending aorta due to aneurysm and/or chronic aortic regurgitation.

AREA 3: PULMONIC AREA PULSATIONS

Vibrations associated with a loud pulmonic component of S_2 (see Fig. 10-60) often are palpable in patients with pulmonary hypertension from any cause. During simultaneous palpation of the carotid pulse, a palpable P_2 or A_2 coincides with the early downslope of the carotid pulse. A systolic thrill in the second and third left intercostal spaces near the sternum often occurs with pulmonic valve stenosis. The thrill often radiates toward the left side of the neck, in contrast to the thrill with aortic stenosis, which radiates upward and to the right.

Pulsations of a dilated pulmonary artery may be seen or felt in the second or third left intercostal space near the sternum. In normal infants and children or anxious adults with thin chest walls, a slight, brief, early systolic pulsation may be present in this area. This pulsation is accentuated by conditions that cause an increased cardiac output (e.g., fever, pregnancy). Idiopathic dilatation of the pulmonary artery also may cause a palpable systolic impulse in the same area.[205]

The common causes of an accentuated and sustained systolic pulsation in the pulmonary artery area are pulmonary hypertension, increased pulmonary blood flow, and their combination. In general, pulmonary hypertension causes a relatively slow, sustained, and forceful pulmonary artery pulsation, whereas a large pulmonary blood flow (e.g., ASD) produces an extremely active, more vigorous, but less sustained pulsation. Valvular pulmonary stenosis with poststenotic dilatation of the pulmonary artery may be associated with a palpable, sustained pulsation in this area, often with a slow rise of the initial phase.

AREA 4: LEFT PARASTERNAL-RIGHT VENTRICULAR OR TRICUSPID AREA PULSATIONS

A systolic thrill in the third, fourth, or fifth intercostal space in the parasternal area to the left of the sternum (see Fig. 10-60) is characteristic of VSD, although tricuspid regurgitation also can produce a thrill here.

Normally, the lower left parasternal region retracts very slightly during systole, and RV activity is not palpable. Slight, gentle outward pulsations of the lower sternum and left parasternal area may be recorded in normal children and young adults, in thin adults with a small anteroposterior thoracic diameter, or in patients with pectus excavatum. Sometimes, these pulsations can be palpated in the subxiphoid area and are increased by hyperdynamic cardiac function.

Abnormal pulsations of the sternal and left parasternal areas most commonly are due to RV hypertrophy or dilatation. The pulsation associated with RV hypertension is usually more sustained throughout systole and tends to rise more gradually than the pulsation produced by a RV volume load, which usually is more vigorous but often briefer.[203,208]

A predominant RV pressure load occurs with pulmonic stenosis and pulmonary hypertension due to LV failure, mitral valve disease, a left-to-right shunt, or pulmonary vascular disease. The sustained anterior precordial pulsation associated with isolated valvular pulmonic stenosis may not occur with tetralogy of Fallot because the thick right ventricle is not excessively dilated. ASD and VSD are two congenital lesions frequently associated with a RV volume load.

Moderate or severe mitral regurgitation may produce an abnormal late systolic anterior left parasternal pulsation even in the absence of pulmonary hypertension.[209] This precordial lift is brisk, and its greatest force coincides with the accentuated *v* wave in the left atrial pressure wave. It likely is due to the large volume of blood regurgitated into the expanding left atrium, which is located centrally behind the right ventricle and anterior to the spine. While expansion of the left atrium may contribute somewhat to the anterior motion of the heart, it is likely that most of the anterior motion and force is the result of a jet or squid effect.

Conditions associated with a decrease in RV compliance, such as RV hypertrophy secondary to pulmonary hypertension, may be associated with a palpable "right sided" S_4 in this area or, occasionally, in the epigastric area. Although a palpable S_3 in this area may reflect a large RV volume load, it usually indicates RV dysfunction or failure. RV S_3 and S_4 vibrations may be augmented during inspiration and may be attenuated or even disappear during expiration (see below).

AREA 5: APICAL AREA PULSATIONS

As mentioned earlier, the apex impulse (see Fig. 10-60) is not synonymous with maximum impulse or point of maximum impulse (PMI). The location, size, and character (duration, contour or shape, amplitude, and apparent force) of the apex impulse should be determined.[207] The examiner should focus on one phase of the cardiac cycle at a time and correlate the findings with other cardiovascular events.

The normal apex (apical) impulse usually is located within 10 cm of the sternal midline, at or within the left midclavicular line in the fifth intercostal space, when the patient is supine. It may be located lateral to the midclavicular line when associated with a high diaphragm, pregnancy, marked pectus excavatum, or other conditions that displace a normal heart to the left. The normal apex impulse is less than 3 cm in diameter and in most instances is considerably smaller. The early systolic outward movement of the apical area (Fig. 10-61) begins at about the same time as that of the S_1, just before the upstroke of the carotid pulse. Peak outward motion normally occurs with or just after blood is ejected into the aorta; then the apex normally moves inward. The outward movement of the apical impulse is normally not excessively forceful and is felt only during the first third of systole.

The apex impulse may be hyperkinetic or hyperdynamic with increased amplitude in normal individuals who have a thin chest wall, a flat chest, or a depressed sternum. Lying on the left side may cause a normal apical impulse to move laterally and to have increased amplitude and duration[207]; however, it still should not exceed a diameter of greater than 3 cm. A hyperdynamic apex impulse also may be found in anxious children, in patients with high cardiac output states, and in patients with a mild to moderate LV volume load from mitral or aortic regurgitation. The apex impulse is more sustained when mitral or aortic regurgitation is more severe or when LV systolic function is decreased.[204] In general, a greatly sustained apex impulse indicates either marked LV hypertrophy or depressed LV systolic function, whereas LV dilatation displaces the apex impulse laterally and inferiorly[207,210] (see Fig. 10-61).

Concentric LV hypertrophy without an increase in LV cavity size may occur in systemic hypertension, valvular aortic stenosis, and hypertrophic cardiomyopathy. Characteristically, the apex impulse is not displaced but is both abnormally forceful and sustained.[204,205] An S_4 vibration may be palpable or visible or both.

Severe LV dilatation-whether due to volume load or ventricular failure-may displace the apex impulse laterally and inferiorly and cause a marked increase in size. The duration of the apex

impulse is more sustained in patients with LV systolic dysfunction, particularly when associated with marked LV dilatation.

Important information about relative amounts of ventricular hypertrophy and dilatation often can be obtained from the apex impulse. Thus, in valvular aortic stenosis, with marked concentric LV hypertrophy but little or no dilatation, the apex impulse characteristically is small, forceful, and sustained but not displaced. A presystolic S_4 often is palpable at the apex. By contrast, in severe aortic regurgitation with marked dilatation of the left ventricle plus considerable eccentric hypertrophy, there is a diffuse apex impulse with increased force, duration, and amplitude, and it is displaced laterally and inferiorly.[205]

In some patients with acute MI, a sustained apex impulse may simulate that due to LV hypertrophy.[201] Those developing mitral regurgitation secondary to MI (papillary muscle dysfunction) may manifest LV dilatation and hypertrophy by a displaced and sustained, forceful, large apex impulse.[211] A late systolic bulge at the cardiac apex may be due to a functional LV aneurysm, occasionally resulting in a bifid apex impulse. In other patients, a late systolic bulge may be palpable in an ectopic area between the apex impulse and the left parasternal area.

A bifid apex impulse during systole also may be due to marked LV dilatation and hypertrophy in patients with both aortic stenosis and regurgitation or in patients with hypertrophic cardiomyopathy.[212] Infrequently, a faint systolic notch or vibration is palpable in the apex impulse of patients with mitral valve prolapse at the moment of a nonejection midsystolic click. Systolic retraction of the apical impulse usually indicates either constrictive pericarditis or severe tricuspid regurgitation with marked RV dilatation (see Fig. 10-61). An apical systolic thrill most commonly is produced by mitral regurgitation and often is diffuse, whereas a diastolic thrill is usually produced by mitral stenosis and is localized to a small, discrete periapical area.

Diastolic Events: Palpable Third and Fourth Heart Sounds

During early diastole, brief outward chest wall movement corresponding to a LV filling or a third heart sound (S_3) occasionally may be seen or felt, even if it is not audible with a stethoscope (see Fig. 10-61). In children and young adults, the presence of an early diastolic ventricular filling sound (S_3) and movement is usually normal. On the other hand, the presence of such a movement or sound in a sedentary adult or a patient with heart disease usually indicates an elevated LV diastolic pressure and volume and likely ventricular decompensation, often with a decreased ejection fraction. Patients with acute MI or transient myocardial ischemia during angina pectoris frequently develop a transient palpable and audible ventricular filling S_3, which reflects the acutely decreased ventricular compliance. A palpable ventricular rapid filling wave (S_3) may be present in patients with LV failure from any cause; however, hemodynamic systolic ventricular failure is often not always present when a ventricular filling wave or sound occurs in the presence of volume loading and dilatation of the left ventricle, as with mitral regurgitation or aortic regurgitation.

The presystolic left atrial contribution to the apical impulse (referred to as the *atrial impulse* or *a* wave) may be detected during late diastole, just prior to S_1 (see Fig. 10-61). Usually, a palpable atrial impulse coincides with an audible fourth heart sound and is associated with an increased LV end-diastolic pressure and decreased compliance. In general, an S_4 is not normally palpable but may be felt at the apex with its associated S_4 in some normal adults if the PR interval is long and circulation is hyperdynamic.[202] In some patients with ischemic heart disease, a palpable apical S_4 may develop or become more prominent during an episode of angina pectoris or even during exertion without chest pain. A palpable presystolic impulse, S_4, or both occur frequently in

patients with acute MI, and these are also frequently present in other conditions producing a decrease in LV compliance and increased end-diastolic pressure.

In a patient with mitral valve disease, the presence of a palpable left-sided atrial impulse or S_4, a palpable left-sided ventricular filling sound or S_3, or an abnormally sustained apical impulse is evidence against the diagnosis of isolated important mitral stenosis and suggests the presence of coincident LV disease.

A double, or bifid, apical impulse may be present in various circumstances, most commonly in the combination of an outward movement during ventricular systole and a second outward pulsation during diastole.[205] The diastolic impulse may occur either in early diastole (S_3) or in late diastole or presystole (S_4).

A bifid apical impulse with two systolic impulses may be present in patients with hypertrophic obstructive cardiomyopathy, complete left bundle branch block (LBBB), or MI. If these patients also develop a palpable impulse during either early (S_3) or late (S_4) diastole, a triple or trifid apical impulse may occur. When such patients develop both a palpable S_3 and a palpable S_4, it is occasionally possible to see and feel a quadruple apical impulse.

AREA 6: EPIGASTRIC AREA PULSATIONS

Some normal and many hyperkinetic individuals have visible or palpable pulsations of the aorta in the epigastric area (see Fig. 10-61). Abnormally large pulsations of the aorta may be due to an aortic aneurysm or aortic regurgitation. Hepatic movements may be identified in the epigastric area, particularly in patients with tricuspid regurgitation, tricuspid stenosis, or marked RV dilatation, hypertrophy, and hyperactivity.

In some patients with pulmonary hypertension due to chronic lung disease, the detection of RV hypertrophy by precordial palpation is difficult because the shape of the chest often conceals the enlarged right ventricle. To detect abnormal RV pulsations in patients with emphysema, the palm of the right hand should be placed on the epigastric area and moved cephalad while gently sliding the fingers under the rib cage. Aortic pulsations can be detected by the palmar surface of the fingers, and pulsations due to RV hypertrophy can be felt in the fingertips.

AREA 7: ECTOPIC AREA PULSATIONS

Occasionally, cardiac pulsations are encountered in areas other than those described previously, i.e., between the pulmonary and apical areas (see Fig. 10-61). Ischemic heart disease is the most common cause of an ectopic systolic pulsation, which may occur transiently during an episode of angina pectoris. A similar paradoxical systolic outward movement may be detected after acute MI and may persist; more commonly, it disappears within a few weeks. A persistent paradoxical ectopic pulsation also may be found in patients who develop a ventricular aneurysm after MI. Ectopic pulsations on the anterior chest wall also can be found in patients with cardiomyopathies of varying etiologies. In patients with severe mitral regurgitation and a giant left atrium that extends to the right, an ectopic systolic pulsation of the atrium occasionally may be felt in the right anterior or lateral chest or in the left axilla.[205]

Percussion versus Inspection and Palpation of the Precordium

When performed by a skilled examiner, percussion of the heart can provide an estimate of cardiac size and shape. Percussion of the heart only gives information about the location of the borders of cardiac dullness, whereas precordial inspection and palpation provide both information about the

location of the outer limits of cardiac pulsations and a determination of the size and character of the pulsations. Although percussion has been used in the diagnosis of pericardial effusion, it has limited value when the results are objectively correlated with the diagnosis as determined by more sensitive and specific noninvasive and invasive testing.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

CARDIAC AUSCULTATION

The Stethoscope

The physician must choose a stethoscope that fits the ears comfortably with the right angulation, has as short a segment of flexible tubing as possible, and is equipped with a diaphragm and a bell. Selection of the proper earpieces for comfort and the best transmission of sound is based on individual preference and is best evaluated by trial and error. A snug, comfortable fit depends on the size of the earpieces as well as the angle at which they enter the ear canal; the angulation of the rigid metal tubing therefore must be chosen to suit the comfort of the individual. The rubber tubing should be as short as feasible; experience indicates that tubing about 12 in (30 cm) long is the best compromise. Rapaport and Sprague[213] have shown that thick-walled tubing about 3 mm in diameter is best suited to transmit sounds and murmurs.

The human ear is most sensitive to auditory vibrations that occur in the frequency range between 1000 and 4000 to 5000 Hz; the sensitivity falls off sharply when the frequency of vibration is below 1000 Hz. This is particularly true of low-frequency sounds, which must be of considerably greater amplitude to reach the threshold of audibility than sounds of higher frequency. Most cardiovascular sounds and murmurs of diagnostic importance are between 30 and 1000 Hz, thereby placing the auscultator at considerable disadvantage.[214] Therefore, a stethoscope requires *both a diaphragm and a bell*, and each must be applied to the chest wall with optimal pressure. The diaphragm, which is fairly rigid, brings out the high frequencies and attenuates the lows. When the diaphragm is used to accentuate high-pitched sounds, it should be pressed very firmly against the skin. This technique will make a high-frequency murmur, such as the faint diastolic blowing murmur of aortic valve regurgitation, audible along the left sternal border when it would otherwise be missed. The bell tends to accentuate the low-frequency sounds and to filter out the high-pitched tones. Often, low-frequency sounds are more easily appreciated by palpation than by auscultation; in these situations, the stethoscope should be placed very lightly on the skin, with just enough pressure to seal the edge at the point of maximal impulse. With very light pressure of the bell, the low-pitched sounds are accentuated; however, with firm pressure of the bell against the skin, the skin itself becomes a relatively tight diaphragm, and the low-frequency sounds are suppressed. Although this technique can be very helpful, the stethoscope always should be equipped with a valve system that permits one to switch from the diaphragm to the bell with ease.

Examination of the Patient

The examination should take place in a quiet room that is well lighted and comfortably heated. The patient should be properly gowned, with adequate exposure to the waist. The examining table should be large enough that the patient can be instructed to lie flat, sit up, or roll to one side with complete ease. Usually, the physician will examine from the right side, and it is equally important that the physician be comfortable.

Prior to auscultation, the clinician should take advantage of the information obtained from the history as well as from the examination of the arterial, venous, and cardiac pulsations. When abnormalities are found, their auscultatory counterparts should be pursued diligently. For example, prominent *a* waves in the jugular venous pulse should alert the clinician to search

carefully for a low-pitched, right-sided fourth heart sound (S_4) or the subtle presystolic murmur of tricuspid stenosis, whereas large *v* waves that augment with inspiration should suggest tricuspid regurgitation. The presence of pulsus alternans always should demand a careful search for third and fourth heart sounds (S_3, S_4), as well as for the presence of functional mitral or tricuspid regurgitation, often present in severe cardiac decompensation. A rapid, jerky rise of the carotid pulse may be the clue to the diagnosis of hypertrophic cardiomyopathy, which can be confirmed by manipulating the systolic murmur with maneuvers that change the pre- and afterloading conditions of the heart.

There are four primary areas of cardiac auscultation: (1) the primary and secondary aortic areas in the second right interspace and the third left interspace adjacent to the sternum, respectively, (2) the pulmonary area in the second left interspace, (3) the tricuspid area in the fourth and fifth interspaces adjacent to the left sternal border, and (4) the mitral area at the cardiac apex. This does not mean to imply that auscultatory events arising from each valve are heard only in their respective areas. The murmur of aortic stenosis in the elderly is often heard best (and at times only) at the apex, whereas the murmur of a flail posterior mitral leaflet may radiate to the base and simulate the murmur of aortic stenosis. Ejection sounds arising from the stenotic aortic valve are usually most prominent at the apex, whereas the opening snap of mitral stenosis is heard best midway between the tricuspid and mitral areas. The murmur of tricuspid regurgitation may be appreciated best at the classic mitral area if the right ventricle occupies the apex. Furthermore, cardiac auscultation should not be restricted to just these four areas. For example, the murmur of aortic regurgitation secondary to abnormalities of the aortic root may be heard best to the right of the sternum, whereas the murmur of tricuspid regurgitation in the emphysematous patient with pulmonary hypertension may be heard best in the epigastrium. The continuous murmur of a patent ductus arteriosus is heard just below the left clavicle, whereas the murmur of large bronchial collaterals may be most prominent in the posterior thorax. Again, the overall clinical presentation will guide one to the appropriate area to auscultate.

During auscultation, one listens both specifically and selectively for heart sounds and then for murmurs, first during systole and then during diastole. As described by Levine and Harvey,[215] the physician should adopt a systematic approach to listening. The patient should be lying on his or her back, and each area should be surveyed with both chest pieces. In each area examined, the physician listens specifically for the first heart sound (S_1), noting its intensity, constancy, presence of splitting, and variation with respiration. This is followed by selective listening for the second heart sound (S_2), noting the same characteristics. Then extra sounds are searched for and carefully listened to, first in systole and then in diastole, with mental notations as to their time of appearance, pitch, and other characteristics that may identify them as gallop sounds, ejection sounds, or valve-opening sounds. Whether the examination is initiated at the base by listening to S_2 or at the apex by listening to S_1 depends on the physician's preference. Of greater importance is that the examination be performed in a methodical, systematic way, with the physician listening intently for one event at a time. Attention is then first turned to systole and then to diastole for the presence of murmurs. After this general survey, the physician listens selectively for certain sounds and murmurs. With the bell applied lightly to the skin at the apex, the patient is instructed to roll onto the left side, and the clinician selectively "tunes in" to diastole and the low-frequency range. This allows the physician to determine the presence or absence of diastolic filling sounds or diastolic rumbles arising from the AV valves. The examination is continued with the patient in the sitting position. While the patient leans slightly forward during quiet respiration, the clinician can optimally appreciate splitting of S_2. With the patient's breath held in deep expiration, the physician examines the aortic and pulmonic areas with the diaphragm firmly pressed against the chest wall, selectively "tuning in" to the high-frequency range in an effort to hear the faint blowing diastolic murmur of aortic regurgitation or, if the clinical situation warrants, the presence of a pericardial friction rub. Sounds and murmurs such as these are discovered only when they are searched out carefully with intent listening and concentration.

Auscultation of the heart should be considered a dynamic exercise. In addition to being auscultated in the left lateral ducubitus position, the patient should, when possible, also be examined while standing, squatting, and during the Valsalva maneuver and following its release. This type of dynamic examination changes the pre- and afterloading conditions of the heart and may yield diagnostic information because of the typical response of heart sounds and murmurs to these maneuvers.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

HEART SOUNDS

Heart sounds are of two types: high-frequency transients associated with the abrupt terminal checking of valves that are closing or opening and low-frequency sounds related to early and late diastolic filling events of the ventricles. Sounds related to closing and opening of the AV valves include mitral and tricuspid closing sounds (M_1, T_1), nonejection sounds, and the opening snaps; sounds related to closing and opening of the semilunar valves include aortic and pulmonic closure sounds (A_2, P_2) and early valvular ejection sounds or clicks. Low-frequency sounds include the physiologic heart sound (S_3) and the pathologic S_3 gallop associated with early ventricular filling events and the presystolic atrial S_4 gallop associated with late diastolic events resulting from the atrial contribution to ventricular filling. With tachycardia, these sounds may fuse, producing a summation gallop.[216,217]

The First Heart Sound

The first heart sound (S_1) as recorded by high-resolution phonocardiography consists of four sequential components: (1) small, low-frequency vibrations, usually inaudible, that coincide with the beginning of LV contraction and felt to be muscular in origin, (2) a large, high-frequency vibration, easily audible, related to mitral valve closure (M_1), (3) a second high-frequency component, following closely, related to tricuspid valve closure (T_1), and (4) small, low-frequency vibrations that coincide with accelerated flow of blood into the great vessel. The two major components normally audible at the left lower sternal border are the louder M_1 followed by T_1. They are separated by only 20 to 30 ms, and at the apex in the normal subject, and only a single sound (M_1) is usually appreciated. Splitting of the first heart sound is less evident with the tachycardia following coughing or with sustained handgrip exercises

ECHOCARDIOGRAPHIC CORRELATES AND SPLITTING OF S_1

The first high-frequency component of S_1 coincides with the complete coaptation of the anterior and posterior leaflets of the mitral valve. This sound is due to the sudden deceleration of blood setting the entire cardiohemic system into vibration when the elastic limits of the closed, tensed valves are met. It is unlikely that complete coaptation of the complex valve leaflets and final tensing are simultaneous; presumably it is the latter event that is associated with vibrations perceived as M_1. When T_1 is more widely separated from M_1, however, identical echocardiographic correlates have been demonstrated in patients with wide splitting of S_1 due to Ebstein's anomaly of the tricuspid valve.[216] This exaggerated T_1, or "sail sound," and its wide separation from M_1 have been a helpful sign in the diagnosis of this entity.[217] Wide splitting of S_1 with normal sequencing (M_1, T_1) is also present in right bundle branch block of the proximal type as well as in LV pacing, ectopic beats, and idioventricular rhythms originating from the left ventricle due to a delayed contraction of the right ventricle. In a similar manner, pacing from the right ventricle and ectopic beats and idioventricular rhythms originating from the right ventricle will produce reversed splitting of S_1 (T_1, M_1) due to delay in LV contraction. Reversed splitting of S_1 also may be present in patients with hemodynamically significant obstruction of the mitral valve, since mitral valve closure is delayed due to the increased left atrial pressure, which must be overcome by the rising LV pressure before closure can occur. Similar delay in M_1 also may be found in mitral obstruction secondary to left atrial myxoma.

HEMODYNAMIC CORRELATES OF S_1

Figure 10-62 illustrates the sound and pressure correlates of M_1. The first high-frequency component of M_1 coincides with the downstroke of the left atrial *c* wave and is delayed from the left ventricular-left atrial

pressure crossover by 30 ms. In the past, these findings have caused considerable confusion regarding the origin of both M_1 and T_1, since it was assumed that these sounds occurred at AV pressure crossover. However, the elegant studies of Laniado et al.[218] established that forward flow continued for a short period following left ventricular-left atrial pressure crossover due to the inertia of mitral flow, with M_1 occurring 20 to 40 ms later, coincidentally with cessation of mitral flow and closure of the valve. An even greater delay between the occurrence of T_1 and right ventricular-right atrial pressure crossover has been shown,[219] and O'Toole et al.[220] have shown that T_1 also coincides with the downstroke of the right atrial *c* wave. These hemodynamic data, together with the echocardiographic correlates of M_1 and T_1, confirm the prime role played by the AV valves in the genesis of S_1.

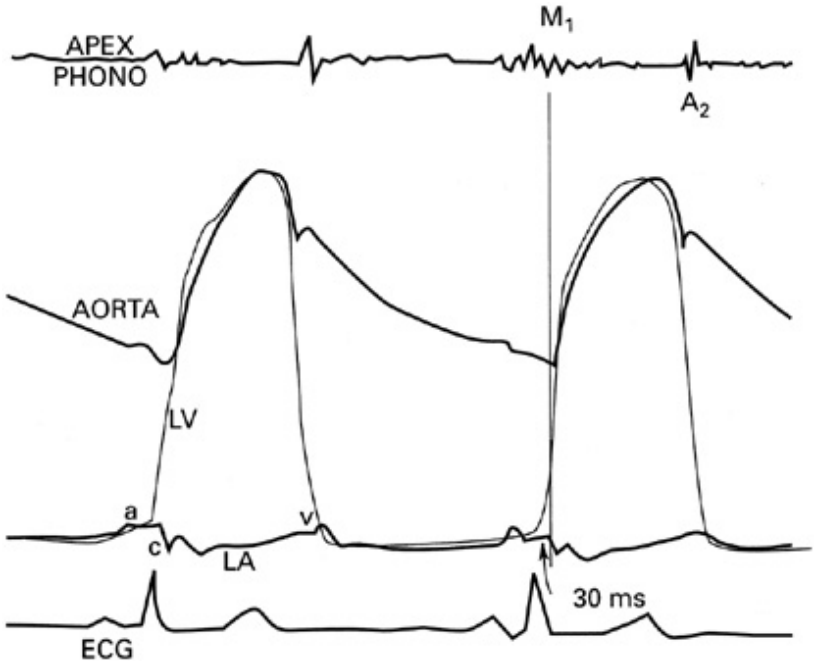

Figure 10-62: The apex phonocardiogram is displayed simultaneously with the cardiac cycle, as recorded by high-fidelity catheter-tipped micromanometers in the central aorta, left ventricle (LV), and left atrium (LA). The first high-frequency component of M_1 is coincident with the downstroke of the left atrial *c* wave and is separated from left ventricular-left atrial pressure crossover by an interval of 30 ms. (From Shaver JA, Saderni R, Reddy PS, et al. Normal and abnormal heart sounds in cardiac diagnosis: I. Systolic sounds. *Curr Probl Cardiol* 1985; 10:10-53. Reproduced with permission from the publisher and authors.)

INTENSITY OF S_1

The primary factors determining intensity of S_1 are (1) integrity of valve closure, (2) mobility of the valve, (3) velocity of valve closure, (4) status of ventricular contraction, (5) transmission characteristics of the thoracic cavity and thorax, and (6) physical characteristics of the vibrating structures.

Integrity of Valve Closure

In rare situations, usually in the setting of severe mitral regurgitation, there is inadequate coaptation of the mitral leaflets to a degree that valve closure is not effective. As a result, abrupt halting of the retrograde blood column during early ventricular contraction does not occur, and S_1 may be markedly attenuated or absent. Such may be the case in severe mitral regurgitation due to a flail mitral leaflet, as shown in Fig. 10-63.

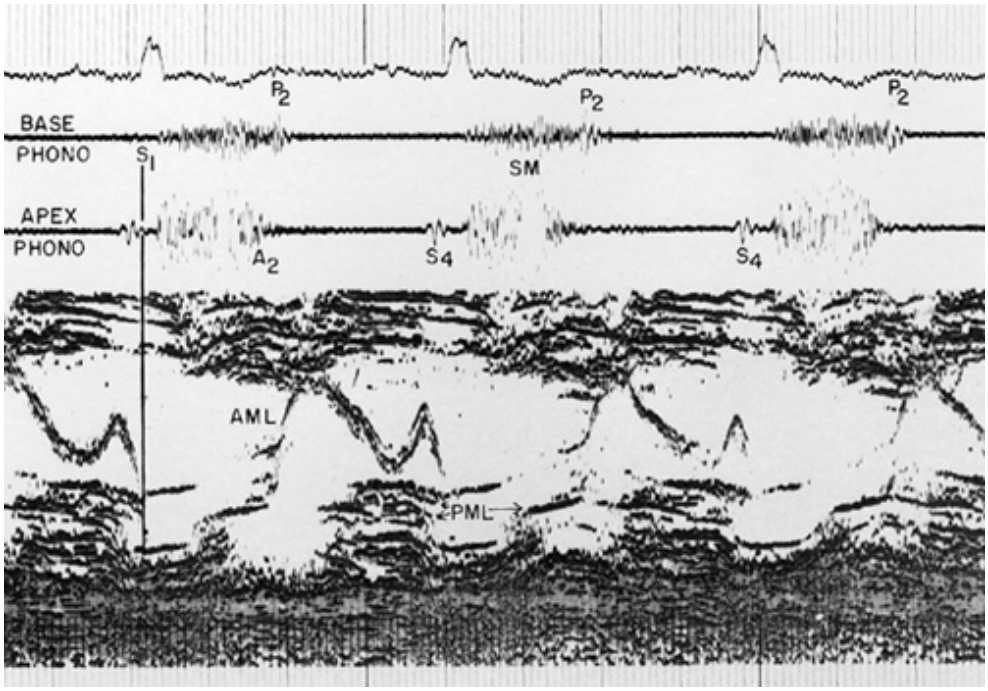

Figure 10-63: Base and apex phonocardiograms are recorded simultaneously with the mitral valve echocardiogram in a 62-year-old man who developed acute mitral regurgitation secondary to rupture of the chordae tendinae of a myxomatous valve. During diastole, multiple echoes arise from the flail posterior mitral leaflet (PML), and during early ventricular systole, effective mitral valve closure does not occur, resulting in an inaudible low-frequency vibration on the apex phonocardiogram. During systole, there is separation of the anterior (AML) and posterior mitral leaflets, resulting in severe mitral regurgitation. The murmur has a crescendo-decrescendo contour simulating the murmur of aortic stenosis ending prior to A_1. Wide physiologic splitting of S_1 is present. The prominent S_4 present on the apex phonocardiogram was associated with an apical presystolic impulse. (From Shaver JA. The physical examination in cardiac diagnosis. *Cardiol Consult* 1985; 6:3. Reproduced with permission from the publisher and author.)

Mobility of the Valve

Severe calcific fixation of the mitral valve with complete immobilization will cause a markedly attenuated M_1. This is seen most commonly in the setting of long-standing mitral stenosis.

Velocity of Valve Closure

The velocity of valve closure is the most important factor affecting the intensity of S_1 and is determined by the timing of mitral valve closure in relation to the LV pressure rise in early systole.[221] The relative timing of left atrial and LV systole may vary this relationship. As the PR interval progressively decreases from 130 to 30 ms, there is a progressive increase in the intensity of M_1 and progressive delay in M_1 relative to the onset of LV contraction. When left atrial and LV systole occur almost simultaneously at a PR interval of 10 ms, however, S_1 again becomes soft. At short PR intervals (30-70 ms), the mitral valve leaflets are maximally separated by atrial contraction at the onset of LV systole. With LV contraction, the mitral valve closes at a high velocity with a large excursion. This results in a loud, late M_1 occurring on a steeper part of the LV pressure curve when the retrograde blood column is suddenly decelerated at the moment the elastic limits of the mitral valve are met. At longer PR intervals, there is less separation of the mitral valve leaflets, which have already begun to close with atrial relaxation. When LV systole begins, there is less excursion of the mitral valve until tensing occurs, and S_1 occurs earlier relative to the onset of LV contraction at a lower LV pressure. Thus less force is applied to the mitral valve, its closing velocity is decreased, and less energy is generated when a column of retrograde blood is abruptly halted, resulting in a softer M_1.

The clinical finding of marked variation in the intensity of S_1 in a patient with a slow heart rate often will

alert the clinician at the bedside to the diagnosis of complete heart block with AV dissociation. Other conditions in which there are beat-to-beat variations in the intensity of S_1 include Mobitz type I heart block and ventricular tachycardia with AV dissociation. Variations in the intensity of S_1 also occur with atrial fibrillation with both normal and stenotic AV valves. The loud S_1 occurs at short RR intervals, whereas a softer S_1 occurs at longer RR intervals when the valve leaflets have closed partially.[222]

The position of the mitral valve at the onset of ventricular systole may be altered not only by the relative timing of atrial and ventricular systole but also by altering the rate of LV filling during atrial systole. Leonard et al.[221] have shown that the timing and intensity of both S_1 and S_4 in hypertensive patients can be influenced by variations in venous return. It is suggested that the mitral leaflets have a greater separation when venous return is decreased to the noncompliant hypertensive left ventricle because there is more effective atrial volume transport into a relatively underfilled ventricle. This results in a softer S_4 that migrates toward an increased S_1. When venous return is increased, the atrial contribution of ventricular filling is now operating on the steeper portion of the LV pressure volume curve. The S_4 becomes louder and earlier, and S_1 is decreased in amplitude due to partial atriogenic closure of the mitral valve. This is the most likely explanation of a soft S_1 frequently noted in hypertensive patients with normal PR intervals.

Status of Ventricular Contraction

The status of ventricular contractility is also an independent factor determining the amplitude of S_1.[221,222] In normal subjects, both exercise and catecholamine infusion have been shown to increase the amplitude of S_1, whereas administration of β-blocking agents decreases it.[221] In both situations, the prime factor in altering the intensity of S_1 is the rate of pressure development in the ventricle. This increased rate of pressure development partially explains why S_1 is increased in patients with anemia, arteriovenous fistulas, pregnancy, anxiety, and fever. It is also likely that these high-output states, often associated with tachycardia, result in wider separation of the AV valves at the onset of ventricular systole due to high flow through a shortened diastolic period. Similarly, the loud T_1 in an ASD is due to high flow through the tricuspid valve, secondary to the left-to-right shunt at the atrial level. A decrease in the intensity of S_1 associated with a decrease in the rate of LV pressure development may be found in myxedema, cardiomyopathy, and acute MI.[223,224] Beat-to-beat variation in the intensity of S_1 (auscultatory alternans) also has been found in patients with pulsus alternans, in whom beat-to-beat alteration in the rate of LV pressure development occurs.

Transmission Characteristics of the Thoracic Cavity and Chest Wall

The degree of attenuation of heart sounds generated by the vibrating cardiohemic system is a function of both sound frequency and the distance of the heart from the chest wall. The higher-frequency heart sounds are attenuated to a greater extent than are lower-frequency sounds. Conditions such as obesity, emphysema, and large pleural or pericardial effusions will decrease the intensity of all auscultatory events, whereas a thin body habitus would tend to increase the intensity.

Physical Characteristics of the Vibrating Structures

Alterations in the physical characteristics of the vibrating structures also may vary the intensity of S_1. Both MI and ischemia induced by pacing have been shown to decrease the intensity of S_1 secondary to these alterations.[224]

S_1 IN PATHOLOGIC CONDITIONS

Careful attention to the intensity of S_1 is an extremely important aspect of cardiac auscultation, often giving clues to the proper diagnosis and degree of abnormality of the involved structures. The following conditions are examples where alterations in the intensity of S_1 play a key role in the correct diagnosis.

S_1 in Mitral Stenosis

A loud, late M_1 is the hallmark of hemodynamically significant mitral stenosis.[225] When M_1 is loud, it is associated with a loud opening snap, and the intensity of both M_1 and the opening snap correlates with valve motility (Fig. 10-64, *left*). When calcific fixation of the stenotic mitral valve occurs, M_1 is soft, and the opening snap is absent. The relationship between sound and pressure and echocardiographic mitral valve motion is shown in Fig. 10-65. Significant scarring of the mitral valve is evident as a result of the rheumatic process. The increased left atrial pressure delays the time of pressure crossover between the left atrium and the left ventricle. As a result, M_1 occurs later and at a much higher than normal LV pressure, at a time when there is a more rapid rate of development of LV pressure. The presystolic gradient between the left atrium and the left ventricle prevents preclosure of the mitral valve leaflets. As a result, the closure of the leaflet begins from a domed position within the LV cavity and takes place over a much greater distance than normal following the onset of LV contraction. Both these factors increase the velocity of mitral valve closure and the momentum of blood directed toward the mitral valve leaflets, resulting in a loud M_1 when the elastic limits of the stenotic mitral valve are met. A similar mechanism is responsible for the booming S_1 with after vibrations in left atrial myxoma (see Fig. 10-65, *center*).

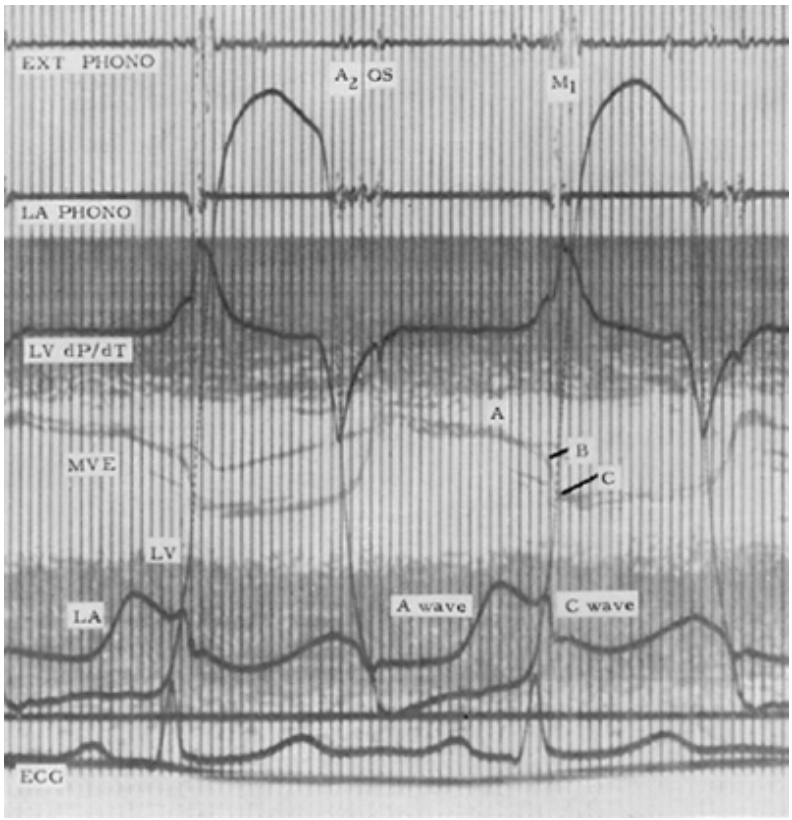

Figure 10-65: External sound, equisensitive LV and left atrial pressures (catheter-tipped micromanometer), LV *dP/dt*, and left atrial sound are recorded simultaneously with the mitral valve echocardiogram in a patient with hemodynamically significant mitral stenosis. A significant presystolic gradient is present due to atrial contraction, and the onset of the rapid closure of the mitral valve (*B*) is delayed until the LV pressure exceeds left atrial pressure. This occurs 40 ms after the beginning of the LV pressure rise at a time when LV *dP/dt* is much higher than normal. Following left atrial-left ventricular pressure crossover, there is rapid ventriculogenic closure of the mitral valve (*BC*), resulting in a very loud M_1 coincident with the *C* point of the mitral valve echocardiogram. Its separation from A_2 is determined by both the level of the left atrial pressure and the rate of LV pressure decline. (From Shaver JA, et al. Normal and abnormal heart sounds in cardiac diagnosis: I. Systolic sounds. *Curr Probl Cardiol* 1985; 10:10-53. Reproduced with permission from the publisher and the authors.)

S_1 in Mitral Valve Prolapse

Tei et al.[226] have reported a loud M_1 heard over the apex in patients with nonrheumatic mitral regurgitation; this is indicative of holosystolic mitral valve prolapse (see Fig. 10-64, *right*). Patients with the more common middle to late systolic prolapse have a normal S_1, whereas a soft or absent S_1 may indicate a flail mitral leaflet (see Fig. 10-65). The increased amplitude of leaflet excursion with prolapse beyond the line of closure explains the loud M_1 associated with holosystolic prolapse. An alternate explanation may be a summation of a normal M_1 and an early nonejection click of valvular prolapse.

S_1 and LBBB

In LBBB, M_1 is decreased in intensity and is frequently delayed, at times resulting in reversal of sequence of S_1.[227] The reason for the delay and the decreased intensity of M_1 in this condition is multifactional, with different mechanisms operative in different patients, depending on the degree of completeness of the LBBB, the site of block (proximal versus peripheral), and especially the status of LV function.[228] The primary factors involved are (1) delay in onset of LV contraction, (2) degree of LV dysfunction, (3) presence of concomitant first-degree heart block, and (4) presence of a noncompliant left ventricle facilitating atriogenic preclosure of the mitral valve. It is likely that more than one factor is operative in most patients with LBBB, with one or two factors predominating.

S_1 in Acute Aortic Regurgitation

One of the important auscultatory findings in acute aortic regurgitation is attenuation or absence of M_1.[222] Severe regurgitation into a left ventricle that has not had time to adapt to the acute volume overload causes a marked increase in the LV end-diastolic pressure, resulting in premature closure of the normal mitral valve in middiastole. With the onset of LV systole, minimal mitral valve excursion occurs, causing a marked reduction in the intensity of M_1.

Systolic Ejection Sounds

Ejection sounds are early systolic ejection events that can originate from either the left or the right side of the heart. These sounds may be classified as valvular, arising from deformed aortic or pulmonic valves, or as vascular, or root events caused by the rapid, forceful ejection of blood into the great vessels. The presence or absence of valvular ejection sounds is of great benefit in defining the level of RV or LV outflow tract obstruction, whereas root ejection sounds give insight into abnormalities of the great vessels with or without systemic or pulmonary hypertension.

AORTIC VALVULAR EJECTION SOUNDS

Aortic valvular ejection sounds are found in nonstenotic congenital bicuspid valves and in the entire spectrum of mild to severe stenosis of the aortic valve. This sound introduces the typical ejection murmur of aortic stenosis, is widely transmitted, and is often heard best at the apex. The aortic valvular ejection sound is delayed 20 to 40 ms after the onset of pressure rise in the central aorta and is coincident with the sharp anacrotic notch on the upstroke of the aortic pressure curve. The sound is coincident with the maximal excursion of the domed valve when its elastic limits are met.[229] The abrupt deceleration of the oncoming column of blood sets the entire cardiohemic system into vibration, the lower-frequency components being recorded as the anacrotic notch and the high-frequency components representing the valvular ejection sound. Inherent in this mechanism of sound production is the ability of the deformed valve to move. With severe calcific fixation of the valve, no excursion or piston-like ascent of the deformed valve is possible; therefore, no sudden tensing of the valve leaflets or abrupt deceleration of the column of blood occurs. Sound and motion correlates identical to those demonstrated by cineangiography have been found with phonoechocardiography, clearly showing the onset of the ejection sound to be coincident with the maximal opening of the valve[230] (Fig. 10-66). The intensity of the ejection sound correlates directly with the mobility of the valve, but there is no correlation between intensity and the severity of the obstruction. In mobile, nonstenotic bicuspid valves, the ejection sound is not only loud but also widely separated from S_1

due to the prolonged excursion of the mobile valve. The presence of an aortic valvular ejection sound is a valuable physical finding at the bedside; it not only defines the LV outflow obstruction at the valvular level but also gives insight into the mobility of the valve (see Fig. 10-66).

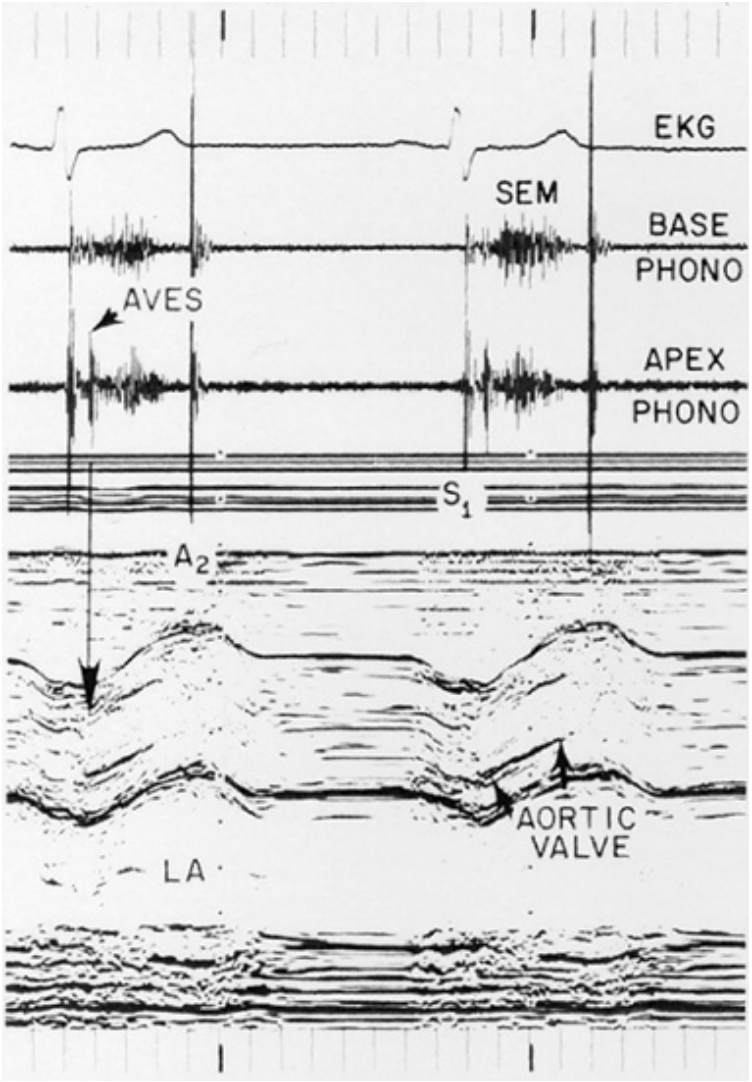

Figure 10-66: Base and apex phonocardiograms are recorded simultaneously with the aortic valve echocardiogram in a young man with valvular aortic stenosis. A prominent aortic valvular ejection sound (AVES) is recorded at the apex and is coincident with the maximal excursion of the aortic valve in early systole. It is followed by a crescendo-decrescendo systolic ejection murmur (SEM) that ends well before a loud A_2.

PULMONIC VALVULAR EJECTION SOUNDS

Pulmonic valvular ejection sounds have identical sound and pressure correlates as aortic valvular ejection sounds.[231] Echocardiographic correlations also have shown that the onset of the pulmonary ejection sound occurs at the maximal excursion of the stenotic pulmonary valve. In contrast to the aortic valvular ejection sounds and to most right-sided auscultatory events, the pulmonic sound or ejection click decreases in intensity or disappears with inspiration in mild to moderate pulmonic stenosis. In very mild valvular pulmonic stenosis, respiratory variation may be absent.[231] In very severe valvular obstruction, a vigorous atrial contraction can completely preopen the pulmonic valve in diastole, causing a crisp preejection sound. In this situation, RV pressure at the time of the atrial kick actually can exceed pulmonary artery end-diastolic pressure.[231] As the severity of the pulmonic stenosis increases, both the excursion of the deformed valve and the RV isovolumic contraction time decrease. The net effect of both these events is migration of

the pulmonary ejection sound toward S_1.

AORTIC VASCULAR EJECTION SOUNDS

Ejection sounds originating from the aortic root are common in systemic arterial hypertension in the setting of a tortuous sclerotic aortic root, a tight, noncompliant arterial tree, and forceful LV ejection. They are coincident with the upstroke of the high-fidelity central aortic pressure and have been interpreted as an exaggeration of the ejection component of the normal S_1. Echocardiographic correlations by Mills et al.,[230] however, have shown that this sound occurs at the moment of complete opening of the aortic valve and always on the pressure upstroke of the high-fidelity aortic pressure curve. These observations have led them to conclude that this sound probably originates from the valve leaflets.

In contrast to the ejection sound of the stenotic aortic valve, these aortic root sounds tend to be poorly transmitted from the aortic area and are not heard well at the apex. It may be difficult to differentiate this sound from the tricuspid component of a widely split S_1, which is best heard at the fourth left parasternal area and often increases with inspiration. In either condition, it should be emphasized that the benign S_1 ejection sound or M_1-T_1 complex is frequently misinterpreted as a pathologic S_4-S_1 sequence. Factors that favor the presence of an S_4-S_1 complex are an associated palpable presystolic apical impulse, optimal audibility of the S_4 with the stethoscope bell applied lightly at the apex, and a change in the intensity of the S_4 with maneuvers that vary venous return.

PULMONARY VASCULAR EJECTION SOUNDS

Vascular or root ejection sounds also may arise from the pulmonary artery, and the common denominator is dilatation of the pulmonary artery.[231] This dilatation can be idiopathic or secondary to severe pulmonary hypertension. Although it has been stated that this sound is louder during expiration, there is no consensus on this point. Unlike splitting of S_1, which is heard best at the mitral or tricuspid area, this sound is louder in the second and third left intercostal spaces.

Echocardiographic correlates of the pulmonary root ejection sound show it to be coincident with complete opening of the pulmonary valve, occurring during the upstroke of the high-fidelity pulmonary artery pressure recording. This has led to the conclusion that these vascular ejection sounds may originate from semilunar valve cusps that have undergone changes in structure in response to increased pressure. Other investigators have found that the pulmonary root ejection sounds in the setting of pulmonary hypertension coincide with the upstroke of the high-fidelity pulmonary artery pressure tracing, whereas in both idiopathic dilatation of the pulmonary artery and ASD, this sound occurs during the upstroke of the pulmonary pressure tracing.[231] In each of these conditions, it has been suggested that this sound is related to sudden checking of the rapidly accelerating blood column by the "tight" or "loose" pulmonary artery when its elastic limits are met.

Nonejection Sounds

The midsystolic click due to prolapse of the mitral or tricuspid valve is the most frequent cause of systolic nonejection sounds and is often associated with a systolic regurgitant murmur. Although originally thought to be extracardiac in origin, confirmation of their valvular origin has been shown by angiographic,[232,233] intracardiac phonocardiographic,[234,235] and echocardiographic studies.[236,237] As originally proposed by Reid,[238] the cause of this sound is due to tensing of the AV valves during systole. As with other high-frequency cardiac sounds, it is produced by vibrations of the entire cardiohemic system when the elastic limits of the prolapsed valve are suddenly reached.

The presence of a nonejection click on physical examination is sufficient to make the diagnosis of mitral valve prolapse (MVP). The sound has a sharp, high-frequency clicking quality and, although often confined to the apex, can be transmitted widely on the precordium. It may be an isolated finding, occurring most often in middle to late systole, or there may be multiple clicks, presumably as a result of different areas of the large, redundant, scalloped mitral leaflets prolapsing at different times. Numerous echocardiographic studies have shown the presence of the characteristic mid- to late-systolic prolapse as well as holosystolic

prolapse in patients with clicks. All these patterns may be seen in the presence of an isolated systolic click, click and late systolic murmur, or a late systolic murmur alone. The click usually occurs at the time of maximal prolapse.

A feature of MVP is the variability of the auscultatory findings from examination to examination and even from beat to beat (Fig. 10-67). The timing of the click or the click and late systolic murmur varies considerably with changes in posture[239] (Fig. 10-68). In the upright posture, the heart becomes smaller due to decreased venous return, and the click moves earlier in systole. Angiographic studies have confirmed an earlier and greater degree of prolapse in the upright posture compared with the supine position. Squatting, which causes an immediate increase in venous return and afterload, increases LV volume, resulting in later prolapse and movement of the click toward S_2. At the bedside, these simple maneuvers are helpful in differentiating the nonejection click from early ejection sounds, a split S_2, or an S_3 (see Chap. 58).

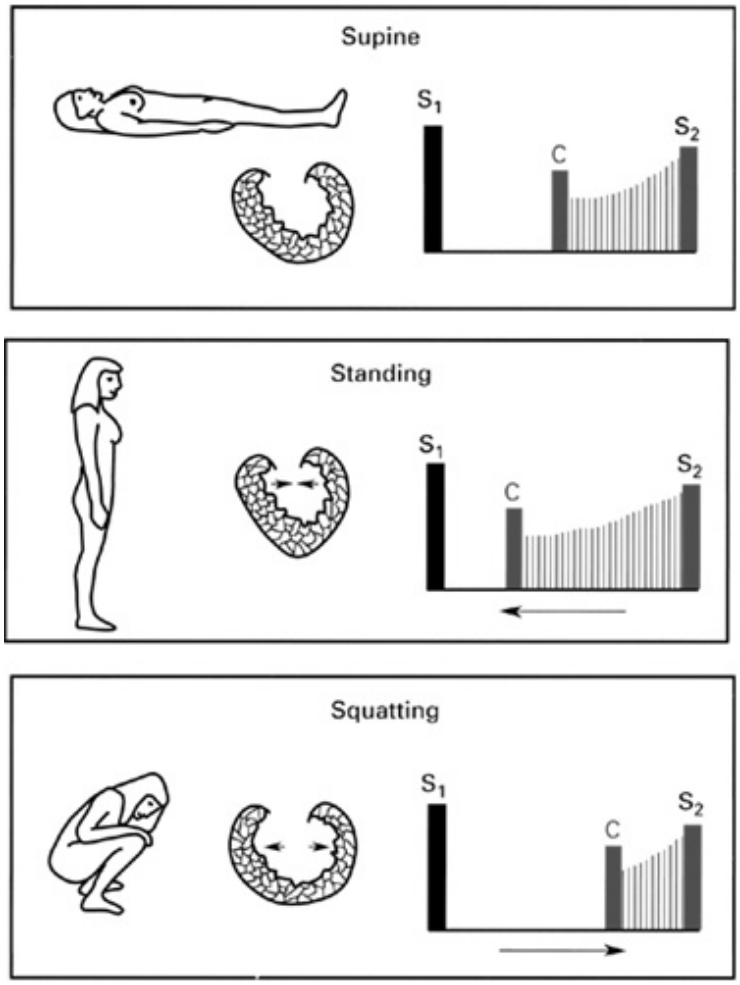

Figure 10-68: A midsystolic nonejection sound (*C*) occurs in mitral valve prolapse and is followed by a late systolic murmur that crescendos to S_1. With assumption of the upright posture, venous return decreases, the heart becomes smaller, the *C* moves closer to S_1, and the mitral regurgitant murmur has an earlier onset. With prompt squatting, both venous return and afterload increase, the heart becomes larger, the *C* moves toward S_2, and the duration of the murmur shortens. (From Shaver JA. *Examination of the Heart*, Part IV: Auscultation. Dallas: American Heart Association; 1990:13. Reproduced with permission from the publisher and the authors.)

In general, maneuvers that decrease LV volume-such as sitting, standing, or strain of the Valsalva maneuver-cause the click to move closer to S_1. Maneuvers that increase LV volume move the click toward S_2 (see Chap. 58).

Although the most common cause of nonejection clicks is prolapse of the AV valves, systolic sounds have been reported in patients with left-sided pneumothorax, adhesive pericarditis, atrial myxomas, LV aneurysm, aneurysm of the membranous ventricular septum associated with a VSD, and incompetent heterograft valves. The presence of these conditions usually can be recognized by the clinical setting and by the absence of the typical changes in the timing of the click associated with physiologic and pharmacologic maneuvers.

The Second Heart Sound

Leatham[240] has emphasized the importance of the S_2 in the cardiac examination by labeling it as the "key to auscultation of the heart." To appreciate the significance of the normal and abnormal S_2, knowledge of its relationship to the hemodynamic events of the cardiac cycle is essential.[241,242] Figure 10-69 records the two components of S_2 simultaneously with the cardiac cycle by high-fidelity catheter-tipped micromanometers. The A_2 and P_2 are coincident with the incisura of the aorta and pulmonary artery pressure trace, respectively, and terminate the LV and RV ejection periods. RV ejection begins prior to LV ejection, has a longer duration, and terminates after LV ejection, resulting in P_2 normally occurring after A_2. RV and LV systole are nearly equal in duration, and the pulmonary artery incisura is delayed relative to the aortic incisura, primarily due to a larger interval separating the pulmonary artery incisura from the RV pressure compared with the same left-sided event. This interval has been called the "hangout" interval, a purely descriptive term coined in our laboratory over 15 years ago. Its duration is felt to be a reflection of the impedance of the vascular bed into which the blood is being received.[243] Normally, it is less than 15 ms in the systemic circulation and only slightly prolongs the LV ejection time. In the low-resistance, high-capacitance pulmonary bed, however, this interval is normally much greater than on the left, varying between 43 and 86 ms, and therefore contributes significantly to the duration of RV ejection. Awareness of this interval is essential for proper understanding of normal physiologic splitting and for the abnormal splitting seen in conditions where significant alterations in pulmonary vascular impedance have occurred.

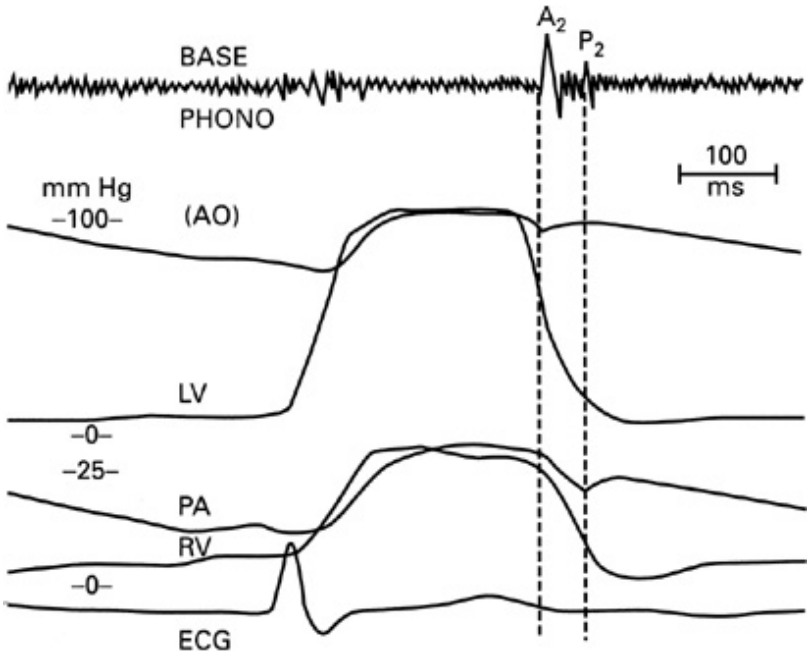

Figure 10-69: The cardiac cycle recorded by high-fidelity catheter-tipped micromanometers. The aortic (A_2) and pulmonic (P_2) closure sounds are coincident with the incisurae of their respective arterial traces. Although the LV and RV mechanical systoles are nearly equal in duration, the RV systolic ejection period terminates after LV ejection because of an increased right-sided "hangout" interval. (From Shaver JA. The second heart sound: Newer concepts: I. Normal and wide physiological splitting. *Mod Concepts Cardiovasc Dis* 1997; 46:7. Reproduced with permission from the American Heart Association and the authors.)

ECHOCARDIOGRAPHIC CORRELATIONS AND MECHANISMS OF SOUND PRODUCTION

Figure 10-70 illustrates the relationship between the aortic and pulmonary valve echocardiogram and A_2 and P_2. The first high-frequency component of both A_2 and P_2 is coincident with completion of closure of the aortic and pulmonic valve leaflets. A_2 and P_2 are not due to the clapping together of the valve leaflets but are produced by the sudden deceleration of retrograde flow of the blood column in the aorta and pulmonary artery when the elastic limits of the tensed leaflets are met. This abrupt deceleration of flow sets the cardiohemic system into vibration; the lower-frequency vibrations are recorded as in the incisura of the great vessels, whereas the higher-frequency components result in A_2 and P_2. This pressure gradient across the valves is the result of both the level of the diastolic pressure in the great vessel and the rate of pressure decline in the ventricle and is consistent with the well-known clinical observation of increased intensity of A_2 and P_2 in systemic and pulmonary hypertension.

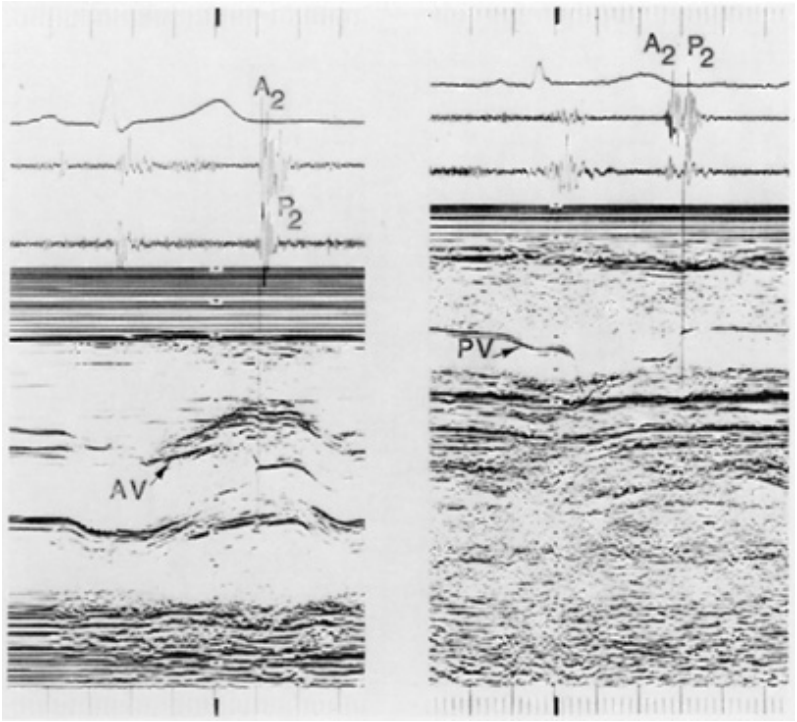

Figure 10-70: (*Left*) The base and apex phonocardiograms are recorded simultaneously with the aortic valve echocardiogram. The first high-frequency component of A_2 is coincident with the completion of closure of the aortic valve. (*Right*) Base and apex phonocardiograms are recorded with the pulmonary valve echocardiogram. The first high-frequency component of P_1 is coincident with the completion of closure of the pulmonic valve. (From Shaver JA, et al. Normal and abnormal heart sounds in cardiac diagnosis: I. Systolic sounds. *Curr Probl Cardiol* 1985: 10:43. Reproduced with permission from the publisher and the authors.)

NORMAL PHYSIOLOGIC SPLITTING

Normally during expiration, A_2 and P_2 are separated by an interval of less than 30 ms and are heard by the clinician as a single sound.[244] During inspiration, both components become distinctly audible as the splitting interval widens, primarily due to a delayed P_2, although an earlier A_2 contributes to a lesser degree[245] (Fig. 10-71). The traditional explanation of normal splitting was that the delayed P_2 during inspiration was secondary to increased venous return, prolonging the duration of RV systole, whereas a concomitant decrease in venous return to the left side of the heart shortened LV systole. More recent studies have shown that the delayed P_2 and early A_2 associated with inspiration are due to a complex interplay

between dynamic changes in pulmonary vascular impedance and changes in systemic and pulmonary venous return.[245]

On auscultation, splitting of S_2 is usually best heard at the second or third left intercostal space; the normal P_2 is softer than A_2 and is rarely audible at the apex. When P_2 is heard at the apex, either significant pulmonary hypertension is present or the apex is occupied by the right ventricle-a situation seen commonly in normotensive ASD. The absolute value of inspiratory splitting varies with age and depth of respiration. In younger subjects, maximal splitting during inspiration averages 40 to 50 ms; with age, this value decreases such that a single S_2 during both phases of respiration may be normal in subjects older than age 40.[246]

ABNORMAL SPLITTING

All conditions in which abnormal splitting of S_2 exists can be identified at the bedside by the presence of audible expiratory splitting (>30 ms)-i.e., the ability to hear two distinct sounds during expiration[246] (see Fig. 10-71). This finding must be present when the patient is auscultated in both the supine and upright positions. There are three causes of audible expiratory splitting: (1) wide physiologic splitting primarily due to delayed P_2, (2) reversed splitting primarily due to delayed A_2, and (3) narrow physiologic splitting as seen in pulmonary hypertension, where A_2 and P_2 are heard as two distinct sounds during expiration at a narrow splitting interval. Tables 10-7 and 10-8 classify the common causes of wide physiologic splitting and reversed splitting of S_2 according to the abnormality of the cardiac cycle responsible for the altered timing of A_2 and P_2. In each table, the cardiac cycle has been divided into three phases (see Fig. 10-69): (1) the electromechanical couple interval, the time from the onset of the Q wave to the rise of ventricular pressure, (2) ventricular mechanical systole, the sum of the isovolumic contraction time plus the ejection period minus the "hangout" interval (abnormalities of this interval exclude those conditions in which prolongation of the "hangout" interval is primarily responsible for the increased ejection time), and (3) "hangout" or impedance interval, the time between the incisura of the arterial trace and the ventricular pressure at the same level as the incisura (includes all conditions in which prolongation of this interval is primarily responsible for the increased ejection time).

Wide Physiologic Splitting of S_2

An example of wide physiologic splitting of S_2 due to delayed electrical activation of the right ventricle secondary to right bundle branch block is shown in Fig. 10-72. Prolongation of RV mechanical systole secondary to severe pulmonary hypertension and pulmonic stenosis are also responsible for a delayed P_2. Classic wide, fixed splitting of S_2 is found in patients with ASD. A composite in Fig. 10-73 documents the role played by decreased impedance of the pulmonary vascular bed in the audible expiratory splitting found in ASD, idiopathic dilatation of the pulmonary artery, and mild pulmonic stenosis with aneurysmal dilatation of the pulmonary artery. In each case, there is a marked increase in the "hangout" interval, as measured by high-fidelity pressure tracings. Wide physiologic splitting secondary to a decreased LV ejection time occurs in patients with acute mitral regurgitation.

Reversed Splitting of S_2

Almost all cases of reversed splitting of S_2 are due to a delay in A_2. As a result, the sequence of closure sounds is reversed, with P_2 preceding A_2. At the bedside, this abnormality is recognized by paradoxical movement of A_2 and P_2 with respiration.[247] During inspiration, P_2 moves toward A_2, and the splitting interval narrows, whereas during expiration, the two components separate, and audible expiratory splitting is present (see Fig. 10-71). The presence of reversed splitting of S_2 almost always indicates significant underlying cardiovascular disease.

Both RV ectopic and paced beats produce a delay in the onset of LV contraction, resulting in reversed splitting of S_2. The mechanism responsible is a delayed activation of the left ventricle, prolonging the Q to LV pressure rise interval. The most common cause of reversed splitting is complete LBBB, which can be

due either to delayed activation of the left ventricle, as seen in isolated proximal block, or to prolonged mechanical systole (primarily isovolumic contraction time), as seen in proximal or peripheral block invariably associated with significant LV dysfunction. Delay often exists in the onset of LV pressure rise when isovolumic contraction time is markedly prolonged, since in most cases of LBBB varying degrees of both mechanisms are present, with one predominating.

Reversed splitting of S_2 may occur in a patient with hypertrophic cardiomyopathy and is due to the large systolic pressure gradient and prolonged LV relaxation.[248] Although both these mechanisms may contribute to the reversed splitting observed in patients with valvular aortic stenosis, an additional mechanism is an exaggerated "hangout" interval.[249]

In hypertensive cardiovascular disease, splitting is usually physiologic, with the intensity of A_2 being increased; however, rare instances of reversed splitting do occur. Reversed splitting of S_2 also has been reported in ischemic heart disease and during episodes of angina pectoris. The latter is extremely uncommon and rarely has been documented by phonocardiography. It is most likely due to a prolonged isovolumic contraction time of the ischemic left ventricle, although during angina it also may be due to an increase in systemic arterial pressure or transient LBBB.[250]

Decreased impedance in the systemic vascular bed also can contribute to the delayed A_2 seen in poststenotic dilatation of the aorta. It also plays a role in the reversed splitting occasionally seen in both chronic aortic regurgitation and patent ductus arteriosus. Reversed splitting of S_2 also has been reported in some cases of type B Wolff-Parkinson-White syndrome, where early activation of the right ventricle through an accessory pathway has caused P_2 to occur prematurely.

Narrow Physiologic Splitting

Narrow physiologic splitting of S_2 is a common finding in severe pulmonary hypertension, as shown in Fig. 10-71.[251] In contrast to the normal situation, where only a single sound is heard during expiration, both A_2 and P_2 are easily heard, even though the splitting interval is less than 30 ms because of the increased intensity and high-frequency composition of P_2. Narrow splitting, although common in severe pulmonary hypertension, is not always the case, and wide splitting with an increased amplitude of P_2 is often present. Wide, persistent splitting becomes a useful sign of abnormal RV performance in patients with primary pulmonary hypertension. In order to reconcile these different responses in S_2 when pulmonary hypertension develops, it is essential to appreciate that normally the duration of RV and LV systole is nearly equal and that a potential interval (the normally wide right-sided "hangout" interval) can be encroached on as the pulmonary hypertension progressively decreases the capacitance and increases the resistance of the pulmonary vascular bed[252] (see Fig. 10-69). Thus a spectrum of the width of splitting may be seen in pulmonary hypertension, depending on the degree of selective prolongation of RV systole, always in the setting of a narrow "hangout" interval. Furthermore, it is clear that varying degrees of splitting may be seen in the same patient during different stages of the disease process producing the pulmonary hypertension. Similar hemodynamic correlates have been found in patients having hyperkinetic pulmonary hypertension secondary to large ASDs. Fixed splitting of S_2 occasionally has been documented in severe RV failure secondary to pulmonary hypertension. This usually has been attributed to the inability of the compromised right ventricle to accept the augmented venous return associated with inspiration.

SINGLE S_2

All conditions listed in Table 10-8 that delay A_2 may produce a single S_2 when the splitting interval becomes less than 30 ms. Also, conditions in which one component of S_2 is either absent or inaudible will produce a single S_2 (e.g., truncus arteriosus, severe tetralogy of Fallot, severe semilunar valve stenosis, pulmonary atresia, and most cases of tricuspid atresia). In Eisenmenger's VSD, the duration of RV and LV systole is necessarily equal, and a loud, single S_2 is appreciated because A_2 and P_2 occur simultaneously. The most common cause of an apparently single S_2 is the inability to hear the fainter of the two components

of the sound (usually P_2) because of emphysema, obesity, or respiratory noise. Another common cause of single S_2 is seen in individuals over age 50. Although this has been attributed to a delayed A_2, a decreased inspiratory delay in P_2 also has been reported. This latter finding has been shown to be due to a decreased right-sided "hangout" interval, most likely related to aging changes in the pulmonary vascular bed.

Opening Snaps

Opening of the normal AV valve is almost always a silent event. With thickening and deformity of the leaflets, usually rheumatic in origin, however, a sound is generated in early diastole in a manner analogous to ejection sounds arising from deformed semilunar valves. The term *opening snap* was first used by Thayer[253] in 1908 to describe the high-frequency early diastolic sound in mitral stenosis. Thayer also recognized that the sound had been absent in those patients who, on autopsy, had markedly thickened and essentially immobile valves. This mechanism was confirmed by hemodynamic and angiographic studies that showed sudden checking of the early diastolic descent of the funnel-shaped stenotic valve when its elastic limits were met.[254] Phonoechocardiography has given an even more precise correlation of the opening snap with the maximum opening motion of the anterior mitral leaflet (see Fig. 10-64, *left*).

The opening snap is a crisp, sharp sound that can be heard in the midprecordial location, usually best in the area from the left sternal border to just inside the apex. Often it is heard well at the base of the heart and frequently is not well heard at the maximal intensity of the diastolic murmur. The diastolic rumble generally follows the opening snap by a short interval. There is no variation in the intensity or timing of the mitral opening snap with respiration.

As with ejection sounds of valvular origin, the intensity of the mitral opening snap correlates well with the mobility of the valve. A loud opening snap is found in mobile stenotic valves with good excursions (see Fig. 10-64, *left*), whereas the opening snap is absent with severe calcific fixation of the valve. The intensity of M_1 parallels the intensity of the opening snap; mobile valves having a loud opening snap have an accentuated M_1, and immobile valves having a decreased or absent opening snap have marked attenuation of M_1. Although the presence of valvular calcification decreases valve mobility and the audibility of the opening snap, the sound is actually found in 50 to 60 percent of patients with calcific valves.

The opening snap follows A_2 by an interval of 0.03 to 0.15 s. In patients with mild mitral stenosis, the interval is usually long, whereas in patients with more severe stenosis, the A_2-opening snap interval is shorter. The A_2-opening snap interval in atrial fibrillation can vary with cycle length. With a short preceding RR interval, the left atrium has not had time to empty, the left atrial pressure remains high, and the A_2-opening snap interval is short. With a longer preceding RR interval, the left atrial pressure falls, and the A_2-opening snap interval widens.

There have been a number of attempts to use the A_2-opening snap interval to predict the level of left atrial pressure and the severity of mitral stenosis.[255] The opening snap occurs at the maximal mitral valve opening shortly after left ventricular-left atrial pressure crossovers. Factors that influence the timing of the opening snap relative to A_2 are (1) the rate of LV pressure decline, (2) the level of the LV pressure at the time of A_2, and (3) the level of the left atrial pressure. Increasing severity of mitral stenosis is usually accompanied by an increasing left atrial pressure and therefore a shortening of the A_2-opening snap interval. Because this interval is multifactorially determined, there is an imperfect correlation between the A_2-opening snap interval and the mitral valve area.[256] Tricuspid valve stenosis also can produce an opening snap.[258] This sound is frequently not detected because the findings of coexisting mitral stenosis, which is almost invariably present, overshadow those of tricuspid stenosis. The maximum intensity of the tricuspid opening snap tends to be found closer to the left sternal border, and unlike the mitral snap, the intensity of the tricuspid snap increases with inspiration. When present, it generally follows the mitral opening snap.[257] An early diastolic sound also can be caused by a right or left atrial myxoma. Although the clinical findings of a left atrial myxoma may be similar to those of mitral stenosis, the echocardiographic picture is classic (see Fig. 10-64, *center*). The tumor "plop" occurs at the maximal diastolic descent of the myxoma.

Although an opening snap is rarely heard with normal valves, it may be heard in situations where high flow exists across the AV valves.[258] An early diastolic sound is frequently present in large ASDs coincident with maximal opening of the tricuspid valve. Other conditions in which functional opening snaps have been found include large VSDs, thyrotoxicosis, and tricuspid atresia with a large ASD. The opening snap must be differentiated from other early diastolic sounds such as the S_3, the pulmonary component of a widely split S_2, and a pericardial knock. At the bedside, differentiation of an opening snap from P_2 is made by noting that the maximal intensity is near the apex rather than at the pulmonary area and that there is lack of movement with respiration. During continuous respiration, it is often possible to appreciate three sounds on inspiration, occurring in rapid sequence in the pulmonary area, and only two components on expiration.

The Third and Fourth Heart Sounds

The third and fourth heart sounds (S_3, S_4) are low-frequency events related to early and late diastolic filling of the ventricles (Fig. 10-74). When they are heard in disease states, they are called *gallop sounds*, and their presence gives valuable information to the clinician regarding the status of ventricular function and compliance.

THE THIRD HEART SOUND

Physiologic S_3

The physiologic S_3 is a benign finding commonly heard in children, adolescents, and young adults, but it is rarely present in adults after age 40 and, when present, is often associated with a thin, asthenic body habitus. This is a low-frequency sound that follows A_2 by 120 to 200 ms and occurs during rapid filling of the ventricle.[259,260] It is best heard at the apex in the left lateral position with the stethoscope bell pressed lightly against the skin and is differentiated from the pathologic S_3 primarily by the "company it keeps."[261]

Pathologic S_3

Most agree that the pathologic S_3 is an exaggeration of the physiologic S_3, with a common mechanism of production.[262] The exact genesis of the S_3 remains controversial. Three major mechanisms of production have been proposed: the valvular theory, the ventricular theory, and the impact theory. The most popular theory has indicated that these sounds have their origins within the left or right ventricle or their walls.[263] The dynamic interplay between the force of delivery of blood into the ventricle and the ability of the ventricle to accept this flow is an important factor in the genesis of this sound. When there is appropriate interaction between these factors, the S_3 occurs when the ventricle suddenly reaches its elastic limits and abruptly decelerates the onrushing column of blood, thereby setting the entire cardiohemic system into vibration. Thus an S_3 may be produced by excessive rapid filling into a ventricle with normal or increased compliance, as with high-output states and mitral regurgitation, or by a normal or less than normal rate of filling into a ventricle with decreased compliance, as in patients with hypertrophic cardiomyopathy. Likewise, decreased rates of filling into overfilled ventricles with large end-systolic volumes, as seen in patients with poor LV function and congestive heart failure, will produce this sound.[264]

Although this mechanism is likely responsible for the sound recorded within the ventricular cavity and on its epicardial surface, Reddy et al.[217,265] have reported convincing data that the sound heard with the stethoscope can be due to the dynamic impact of the heart with the chest wall. The force of the impact and resulting intensity of S_3 depend primarily on the size of the heart, the motion of the heart within the thorax, and the chest wall configuration. This theory explains the S_3 present in hyperdynamic states as well as those with an increased end-systolic volume secondary to LV dysfunction. In the latter, the space between the enlarged heart and the lateral chest wall is diminished, thereby facilitating a more forceful impact in early diastole. This results in an exaggerated rapid filling wave on the apex cardiogram and the prominent S_3 pathognomonic of congestive failure (Fig. 10-75, *lower panel*). Table 10-9 tabulates the major factors responsible for the production of the S_3 as recorded within the left ventricle and on the chest wall.

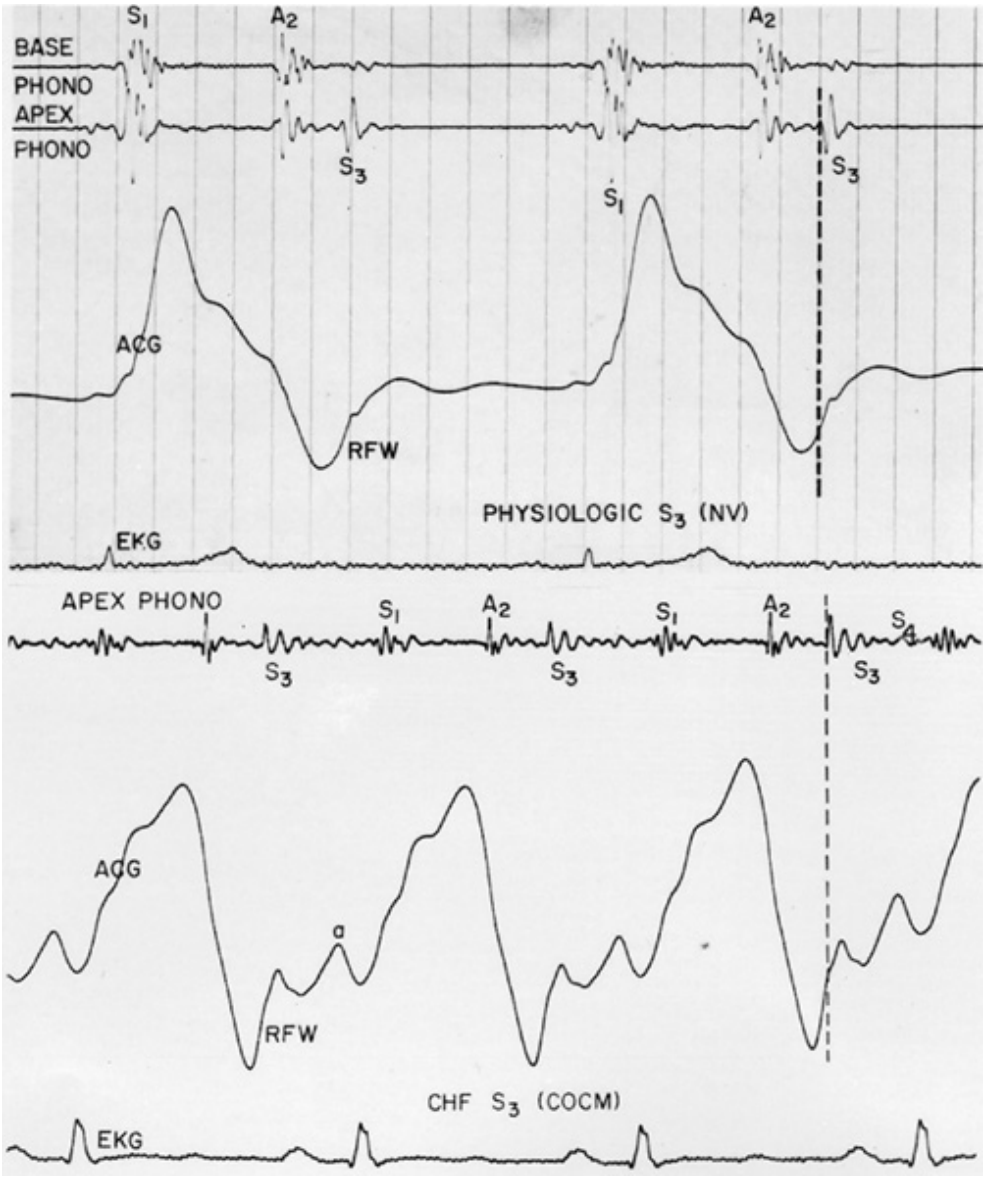

Figure 10-75: (*Top*) A physiologic S_3 (normal variant) recorded in a 24-year-old woman without evidence of cardiovascular disease. The onset of the S_3 occurs during the rapid filling wave (RFW) of the ACG between the *O* and *F* points. The remainder of the cardiovascular examination was entirely within normal limits. (*Bottom*) A very prominent S_3 gallop is recorded in a patient with severe congestive cardiomyopathy (COCM). On physical examination, there was a small-volume carotid pulse and marked engorgement of the neck veins with elevated venous pressure. The ACG shows a very prominent presystolic pulsation (a), and an extremely rapid filling wave is present. The onset of the S_3 occurs during the RFW of the ACG. The first heart sound is soft. A convenient classification of physiologic and pathologic states with an S_3 is presented in Table 10-10. Both the intensity and timing of the pathologic S_3 associated with LV dysfunction are related to the patient's volume status. With diuresis, the S_3 may decrease in intensity or disappear, and it tends to move away from A_2. A loud, persistent S_3 with cardiomyopathy or acute MI is an ominous sign associated with high mortality, whereas prompt subsidence with therapy suggests a more favorable outlook. LV third heart sounds are heard best at the apex, whereas RV third heart sounds are heard at the lower left sternal edge and may increase in intensity with inspiration.

Table 10-10: Third Heart Sound (S_3), Ventricular Diastolic Gallop, Protodiastolic Gallop, and Pericardial Knock

Physiologic S_3-children and young adults
Decreased prevalence with increasing age
Pathologic S_3
Ventricular dysfunction-poor systolic function, in-creased end-diastolic and end-systolic volume, decreased ejection fraction, and high filling pressures
Idiopathic dilated cardiomyopathy
Ischemic heart disease
Valvular heart disease

Congenital heart disease
Systemic and pulmonary hypertension
Excessively rapid early diastolic ventricular filling
Hyperkinetic states
Anemia
Thyrotoxicosis
Arteriovenous fistula
Atrioventricular valve incompetence
Left-to-right shunts
Restrictive myocardial or pericardial disease
Constrictive pericarditis (pericardial knock)
Restrictive cardiomyopathy
Hypertrophic cardiomyopathy?

In chronic aortic regurgitation, even though end-diastolic volume is increased, end-systolic volume may not be increased until LV dysfunction develops. As LV dysfunction develops, the ejection fraction decreases, resulting in an increased end-systolic volume, and a pathologic S_3 appears in these patients.[266] An S_3 is very common in acute aortic regurgitation and is usually followed by the middiastolic component of the Austin Flint rumble.

A pathologic S_3 resulting from excessive early diastolic filling is common in hyperkinetic states and AV valve regurgitation and often initiates a short flow rumble. It is often present in large left-to-right shunts due to high flow across the mitral valve with VSD or patent ductus arteriosus and with high flow across the tricuspid valve with ASD. The presence of this sound in these conditions does not imply congestive heart failure, and such patients may maintain normal myocardial contractility for years after the S_3 is detected.[267] Pathologic third heart sounds are heard in both restrictive and hypertrophic cardiomyopathy. In constrictive pericarditis, an early prominent sound of a somewhat higher frequency is heard-the *pericardial knock*. The evidence to date points to the simultaneous occurrence of the pericardial knock and the termination of rapid filling of the ventricles. Whether this relationship is causal or coincidental is unclear. The apex cardiac pulsation may show systolic retraction followed by an exaggerated diastolic impulse. The pericardial knock usually increases in intensity with inspiration and occurs near the nadir of the *y* descent of the jugular venous pulse. Atrial fibrillation is commonly present in severe constrictive pericarditis, and at times the loud early knock may be confused with the opening snap of mitral stenosis.

THE FOURTH HEART SOUND

Precordial vibrations resulting from atrial contraction are normally neither palpable nor audible. Under pathologic conditions, forceful atrial contraction generates a low-frequency sound (S_4) just prior to S_1 (also termed the *atrial diastolic gallop* or the *presystolic gallop*). Atrial contraction must be present for production of an S_4. It is absent in atrial fibrillation and in other rhythms in which atrial contraction does not precede ventricular contraction. The S_4 follows the onset of the P wave of the ECG by approximately 70 ms. Audibility of the S_4 depends not only on its intensity and frequency but also on its separation from S_1. The degree of this separation is determined primarily by the PR interval, but it is also somewhat influenced by the PS_4 and the QS_1 intervals. A loud S_1 also may mask the audibility of a preceding softer

S_4. The S_4 is best heard at the apex impulse with the patient turned in the left lateral position. It varies considerably with respiration, usually being heard best during expiration. A left-sided S_4 may radiate to the brachiocephalic and carotid vessel and be best heard in the areas in patients with severe lung disease or who are very obese. A left-sided S_3 may do likewise. A left-sided S_4 and S_3 may also be augmented post-tussively and with sustained handgrip exercise. Both the intensity and timing of the S_4 are closely related to the end-diastolic volume of the ventricle. Maneuvers that increase venous return increase the audibility by increasing the intensity of the sound and by causing it to occur earlier, thereby separating it further from S_1. Decreased venous return does the opposite. Audible fourth heart sounds are usually accompanied by a palpable presystolic apical impulse in the absence of obesity, emphysema, etc., but occasionally, palpable presystolic impulses are not audible. The S_4 generated by a forceful right atrial contraction is usually heard best at the lower left sternal border. Unlike the left-sided S_4, it tends to be accentuated with inspiration. It is also accompanied by prominent *a* waves in the JVP and is occasionally audible over the right jugular vein.[268]

As with the S_3, both the ventricular origin of the S_4 sound due to the abrupt deceleration of the atrial contribution to late diastolic filling and the impact theory have been proposed.[270] It is likely that the former is responsible for the sounds recorded within the ventricular cavities or on their epicardial surfaces, whereas the latter mechanism is responsible for the S_4 auscultated at the chest wall.

The presence of an S_4, particularly when associated with a palpable presystolic apical impulse, is an abnormal finding. Although it is considered to be a normal finding in older subjects by some investigators,[269] others feel strongly that a definite S_4 in a middle-aged or older person is unlikely to be a normal event.[268] Conditions such as obesity, emphysema, or barrel-chest deformity may hinder the clinical detection of both an S_4 and an apical presystolic impulse.

The common pathologic conditions in which S_4 is heard are listed in Table 10-11. A forceful atrial contraction into a hypertrophied, noncompliant ventricle almost always produces an early and easily audible and recordable S_4. The severe LV hypertrophy present in systemic hypertension, severe valvular aortic stenosis, and hypertrophic cardiomyopathy often is responsible for a loud S_4 (Fig. 10-76). In each case, the S_4 is associated with a prominent apical presystolic impulse and is widely separated from S_1.

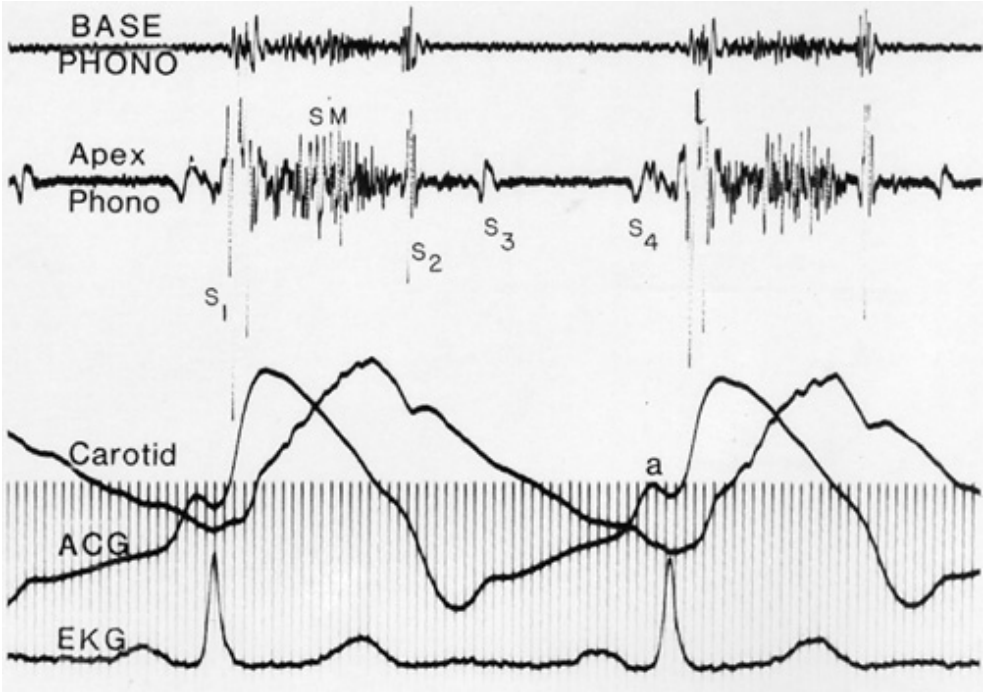

Figure 10-76: Atrial diastolic (ADG) and ventricular diastolic gallops (VDG) are recorded in an adult with severe calcific aortic stenosis. The ADG is associated with a prominent presystolic apical impulse (a), and the VDG occurs during the rapid filling wave of the ACG. The carotid pulse has a very slow rate of rise and a markedly prolonged LV ejection time. The classic diamond-shaped systolic ejection murmur (SM) is present at the base and apex. Note the higher-frequency composition of the SM at the apex but preservation of the crescendo-decrescendo pattern. (From Shaver JA. Current uses of phonocardiography in clinical practice. Idiopathic dilated cardiomyopathy
Excessively rapid late diastolic filling secondary to
Vigorous atrial systole
Hyperkinetic states
Anemia
Thyrotoxicosis
Arteriovenous fistula
Acute atrioventricular valve incompetence
Arrhythmias
Heart block

An audible S_4 with a palpable presystolic impulse is common in patients with ischemic heart disease during an acute episode of angina and in the early phases of transmural MI. Its prevalence is also increased with prior MI; however, audible fourth heart sounds in patients with ischemic heart disease without prior

infarction or hypertension are uncommon.[217] In patients with LV aneurysm or idiopathic or ischemic cardiomyopathy, abnormal fourth heart sounds are commonly present and often associated with an S_3, producing a quadruple rhythm. If tachycardia is present, or if the PR interval is prolonged, S_3 and S_4 may fuse, giving rise to a loud summation gallop (see Fig. 10-74).

Quadruple rhythms are common in hyperkinetic states where the S_3 is due to excessively rapid early diastolic filling and the S_4 results from a forceful atrial contraction into a volume-loaded ventricle. With varying degrees of tachycardia, incomplete summation may occur, simulating a diastolic rumble, or complete fusion may occur, generating a loud summation gallop (see Fig. 10-74). In acute AV valve regurgitation, vigorous atrial contraction into an acutely volume-loaded ventricle can produce an S_4 associated with a presystolic apical impulse. At times it may be difficult to appreciate because of the masking effect of the loud systolic murmur. This contrasts with most patients with chronic mitral regurgitation, who do not have an S_4 but frequently have an S_3.

Presystolic and isolated diastolic fourth heart sounds as well as summation gallops may be heard with varying degrees of heart block. First-degree heart block facilitates audibility of the S_4 because it further separates S_4 from S_1. In 2:1 heart block, an isolated S_4 may be heard in diastole, and a presystolic S_4 may be audible because of the increase in diastolic volume. In complete heart block, S_4 may be heard randomly throughout diastole, and when it occurs simultaneously with rapid early ventricular filling, a loud summation gallop may occur. Fourth heart sounds also have been reported in ventricular systole when atrial contraction occurred during systole in a patient with heart block. The occurrence of an S_4 when the mitral valve is closed excludes its ventricular origin due to either a pressure or volume change and is in keeping with the impact theory of S_4 sound production.[217]

Prosthetic Valve Sounds

The sounds produced by prosthetic valves are varied, depending on the type of valve, its position, and whether or not it is functioning normally. Mechanical valves produce opening and closing clicks that are easily audible and in many patients can be heard even without a stethoscope. Ball-in-cage valves such as the Starr-Edwards produce the loudest and most distinctive opening and closing clicks in any position as long as there is normal valve and ventricular function. In the aortic position, a crisp opening click occurs 0.06 to 0.07 s after S_1 and is coincident with maximal ball excursion, as demonstrated by echocardiography. The metallic ball of the Starr-Edwards valve also produces multiple early systolic clicks when the freely moving ball bounces against the cage during early systolic ejection. These clicks occur during the harsh systolic ejection murmur. Absence or decrease in intensity of these clicks can occur with valve obstruction or LV dysfunction. A decrease in the intensity of the opening and closing clicks, which normally have an intensity ratio of more than 0.5, and the absence of the opening click are also indications of valve malfunction.

In the mitral position, a prominent opening click occurs 0.05 to 0.15 s after A_2. Narrowing of this interval indicates an elevation of left atrial pressure, which may be due to either valvular obstruction or regurgitation. Interference with ball motion also can produce prolongation or significant beat-to-beat variation of this interval. A closing click is also prominent. Just as is seen with the normal S_1, there is variability in the intensity of the closing click, with the changing RR intervals of atrial fibrillation being louder with short RR intervals and softer with long intervals. A decreased intensity with first-degree AV block also occurs due to partial atriogenic closure of the valve, thus reducing the ball excursion and therefore the click intensity. Although a decreased intensity of the valve clicks occurs with valve malfunction, the presence of normal ball motion on an echocardiogram suggests that a nonvalvular cause such as severe LV dysfunction is responsible for the decreased intensity.

The auscultatory findings of disk valve prostheses vary, depending on the type of disk valve. Central occluder valves such as the Beall valve, which was used predominantly in the mitral and tricuspid positions, produce distinct, audible opening and closing sounds. The more commonly used tilting-disk valves do not ordinarily produce audible opening sounds in either the aortic or mitral position.[205] The closing sounds of disk valves are distinct and easily heard in both aortic and mitral positions. LV dysfunction, first-degree AV

block, or another arrhythmia that causes the disk to move to a partially closed position prior to the onset of ventricular contraction will result in a softer sound. This finding must be distinguished from malfunction caused by either fibrosis or thrombus disturbing the disk motion. Auscultation of the bileaflet St. Jude valve is similar to that of the tilting-disk valve.

The sounds produced by tissue prosthetic valves are more like normal heart sounds than the sounds from a mechanical valve.[205] In the aortic position, an opening sound is usually not audible. In the mitral position, an opening sound is audible in about 50 percent of patients at an interval of 0.07 to 0.11 s after A_2.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

EXTRACARDIAC SOUNDS

Pacemaker Sounds

High-frequency sounds of brief duration are occasionally present in patients with transvenous pacemakers located in the RV apex. They are extracardiac in origin, occurring nearly synchronously (within 6-10 ms) with the pacemaker spike, and are due to stimulation of intercostal nerves adjacent to endocardial electrodes.[270] This stimulus results in contraction of the intercostal muscles, and frequently twitching of the muscle can be observed. The presence of these sounds always should suggest possible myocardial perforation by the endocardial lead, although this is not always present. Stimulation of the pectoral muscles, as well as diaphragmatic stimulation, also has been reported to produce these extracardiac sounds. They also have been observed in patients having transthoracically placed epicardial leads.

Pericardial Friction Rub

Inflammation of the pericardial sac with or without fluid may cause a pericardial friction rub. These friction sounds are very high-pitched, leathery, and scratchy in nature. They seem close to the ear and are auscultated best with the patient leaning forward or in the knee-chest position, holding his or her breath after forced expiration. The pericardial rub may have three components during the intervals of the cardiac cycle when the heart has the greatest excursions within the pericardial sac-at the time of atrial systole, at the time of ventricular contraction, and during rapid early diastolic filling. The usual friction rub occurs during the first two intervals, although three-component rubs may be heard. Triple-component friction rubs are common in uremic pericarditis, particularly when the underlying cardiac disease is hypertension. In this situation, the heart is hyperkinetic due to both pressure and volume overload as well as to the anemia associated with renal failure. Pericardial friction rubs are very common in the acute phase of transmural MI, although they often last for only a few hours. There is a common misconception that friction rubs are not heard when there is a large amount of fluid in the pericardial sac; this is not the case, because usually some portions of the visceral and parietal pericardial surfaces are in contact despite the large amount of fluid (see Chap. 72).

Occasionally, certain midsystolic (ejection) murmurs have a scratchy character and may be misinterpreted as friction rubs. This is particularly true of the short, scratchy pulmonic ejection murmur heard in hyperthyroidism (Means-Lerman sign).[271] Such scratchy sounds should not be considered to be a friction rub unless both systolic and diastolic components are heard.

Mediastinal Crunch: Hamman's Sign

When air is present in the mediastinum, a series of scratchy sounds (Hamman's sign[272]) may occur, related indirectly to both heartbeat and respiratory excursion. These sounds occur most frequently during ventricular systole and in a random fashion. The diagnosis of mediastinal emphysema may be confirmed by crepitation in the neck secondary to subcutaneous air. These crunching sounds due to air in the mediastinum are common following cardiac surgery.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

HEART MURMURS

A *cardiac murmur* is defined as a relatively prolonged series of auditory vibrations of varying intensity (loudness), frequency (pitch), quality, configuration, and duration.[273] Although the exact physical principles that govern the production of murmurs have been debated for years, most authorities now agree that turbulence is the prime factor responsible for most murmurs. Turbulence arises when blood velocity becomes critically high due to high flow, flow through an irregular or narrow area, or a combination of both. Leatham has attributed the production of murmurs to three main factors: (1) high flow rate through normal or abnormal orifices, (2) forward flow through a constricted or irregular orifice or into a dilated vessel or chamber, and (3) backward or regurgitant flow through an incompetent valve, septal defect, or patent ductus arteriosus. Frequently, a combination of these factors is operative.

While the intensity of a systolic murmur is not always proportional to the hemodynamic disturbance, grading the loudness of a murmur from 1 to 6 as described by Freeman and Levine[274] is generally used. A *grade 1 murmur* is so faint that it can be heard only with special effort. A *grade 2 murmur* is faint but can be heard easily. A *grade 3 murmur* is moderately loud, a *grade 4 murmur* is very loud, and a *grade 5 murmur* is extremely loud and can be heard if only the edge of the stethoscope is in contact with the skin but cannot be heard if the stethoscope is removed from the skin. A *grade 6 murmur* is exceptionally loud and can be heard with the stethoscope just removed from contact with the chest. Experience has shown that systolic murmurs of grade 3 or more in intensity are usually hemodynamically significant.[275] Systolic thrills usually are associated with murmurs of grade 4 or louder. The intensity of the murmur varies directly with the velocity of blood flow across the area of murmur production. The velocity, in turn, is directly related to the pressure head that drives the blood across the murmur-producing area. For example, high velocity of flow through a small VSD produces a loud murmur, whereas a large flow at low velocity through an ASD produces no murmur. The *intensity* of a murmur as auscultated at the chest wall is also determined by the transmission characteristics of the tissues intervening between the source of the murmur and the stethoscope. Obesity, emphysema, and the presence of significant pericardial or pleural effusion will decrease the intensity of a murmur, whereas a thin, asthenic body habitus often will accentuate it.

The frequency of a murmur bears a direct relationship to the velocity of blood flow, as does the intensity of the murmur. The low-velocity flow resulting from a small pressure head across a stenotic mitral valve produces a low-pitched rumbling murmur, whereas the large diastolic pressure gradient across a regurgitant aortic valve causes a high-pitched murmur. A recent study has further demonstrated that the dominant frequencies contained in heart murmurs due to stenotic lesions are directly related to the instantaneous jet velocities distal to the associated obstruction. Occasionally, the frequency composition of the same systolic murmur may vary, depending on the area auscultated. For example, the systolic murmur of aortic stenosis frequently sounds higher-pitched at the apex than at the base.[276] Some murmurs such as the "cooing dove" regurgitant murmur of a ruptured or retroverted aortic cusp, the systolic "whoop" or "honk" of mitral valve prolapse, or the high-pitched systolic murmur of a degenerated bioprosthetic valve-have a very distinctive musical quality.

In addition to the intensity and frequency of murmurs, their *timing* also should be described. There is seldom any difficulty distinguishing between systole and diastole, since systole is considerably shorter at normal heart rates. At rapid heart rates, however, the durations of these two intervals approach each other. Under such circumstances, the examiner usually can time the murmur by simultaneous palpation of the lower right carotid artery or can rely on the fact that the second heart sound (S_2) is usually the louder sound at the base. Once S_2 is identified, murmurs can be located properly in the cardiac cycle as systolic or diastolic. If the murmur in question is at the apex, the proper timing can be ensured by the "inching" technique popularized by Harvey and Levine.[215] This consists of slowly moving the stethoscope down from the base to the apex while repeatedly fixing the cardiac cycle in mind, using S_2 as a reference point. With sinus tachycardia, carotid sinus pressure may temporarily slow the rate and make it possible to differentiate

systole from diastole. Continuous murmurs are heard throughout the cardiac cycle in systole and diastole and usually have their peak intensity around S_2.

The *location* and *radiation* of a murmur are determined multifactorially by the site of origin, intensity, and direction of blood flow, as well as by the physical characteristics of the chest. The duration and time intensity contour (murmur *envelope*) of a specific murmur are intimately related to the instantaneous pattern of blood flow velocity causing the murmur.

Systolic Murmurs

Systolic murmurs may be classified into two basic categories-ejection (midsystolic) murmurs and regurgitant murmurs. This simple classification is attractive because it has a physiologic as well as a descriptive basis. Systolic *ejection* murmurs are due to forward flow across the LV or RV outflow tract, whereas systolic *regurgitant* murmurs are due to retrograde flow from a high-pressure cardiac chamber to a low-pressure chamber.[277]

SYSTOLIC EJECTION (MIDSYSTOLIC) MURMURS

The systolic *ejection* murmur begins shortly after the pressure in the left or right ventricle exceeds the aortic or pulmonic diastolic pressure sufficiently to open the aortic or pulmonic valve. As a result, there is a delay between the S_1, which occurs shortly after AV pressure crossover, and the beginning of the murmur (Fig. 10-77). The murmur then waxes and wanes in a crescendo-decrescendo fashion often described as "diamond shaped" or "spindle shaped" in configuration. The murmur ends before the semilunar valve closure on the side from which it originates. The contour of the time-intensity pattern or *envelope* of the murmur corresponds to the contour of the flow velocity, and the murmur is heard when the sound produced during the peak turbulence exceeds the audible threshold. Thus not only is the overall intensity of the murmur proportional to the rate of ventricular ejection, but also its shape depends on the instantaneous flow velocity during the period of ejection. As can be seen in Fig. 10-78, during normal LV ejection, a disproportionately large volume flow occurs in early systole. If velocity of flow exceeds the murmur threshold, a short midsystolic or ejection murmur results, and its envelope corresponds to the flow velocity pattern. If the stroke volume of the ventricle is increased, this pattern of ejection persists in an exaggerated fashion; the resulting murmur has a tendency to peak early in systole and fade out about halfway through the ejection phase. Such murmurs have been referred to as "kite shaped" and are common in high-output states or conditions such as aortic regurgitation or heart block, where stroke volume is high.

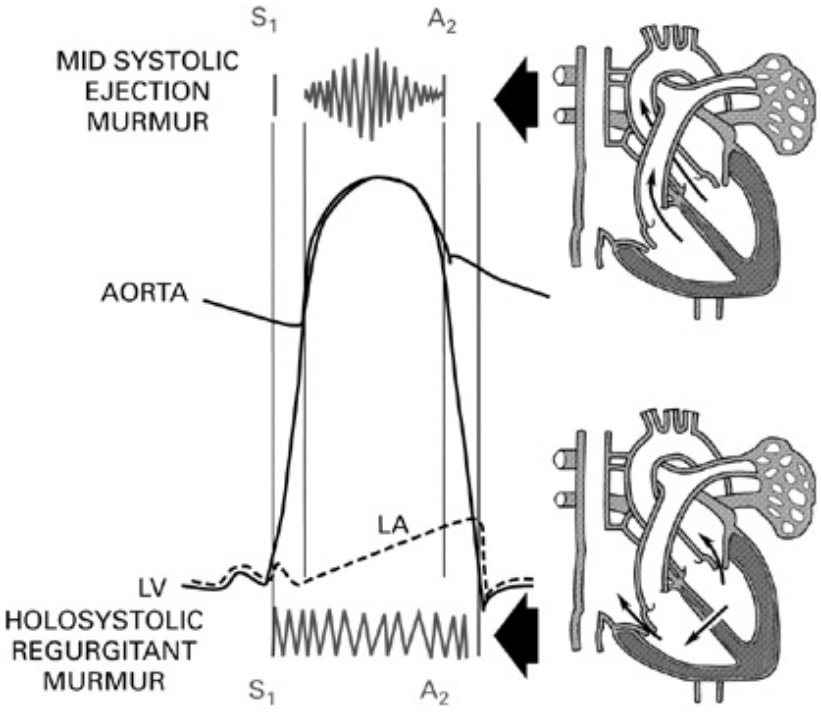

Figure 10-77: Midsystolic ejection murmurs are caused by forward flow across the LV or RV outflow tract, whereas pansystolic regurgitant murmurs are caused by retrograde flow from a high-pressure cardiac chamber to a low-pressure one. (*Left*) Diagrammatic representation of the midsystolic ejection murmur and the pansystolic regurgitant murmur, as related to LV, aortic, and left atrial (LA) pressures. The systolic ejection murmur occurs during the period of LV ejection; the onset of the murmur is separated from S_1 by the period of isovolumic contraction and the crescendo-decrescendo murmur terminates before A_2. The pansystolic regurgitant murmur begins with, or may replace, S_1, and the murmur continues up to and through A_2 as LV pressure exceeds left atrial pressure during the period of isovolumic relaxation. The murmur has a plateau configuration and varies little with respiration. (*Right*) Flow diagram. (Left panel reproduced from Reddy PS, Shaver JA, Leonard JJ. Cardiac systolic murmurs: Pathophysiology and differential diagnosis. *Prog Cardiovasc Dis* 1971; 14:19. Entire figure reproduced with permission from Shaver JA. Systolic murmurs. *Heart Dis Stroke* 1993; 2:10.)

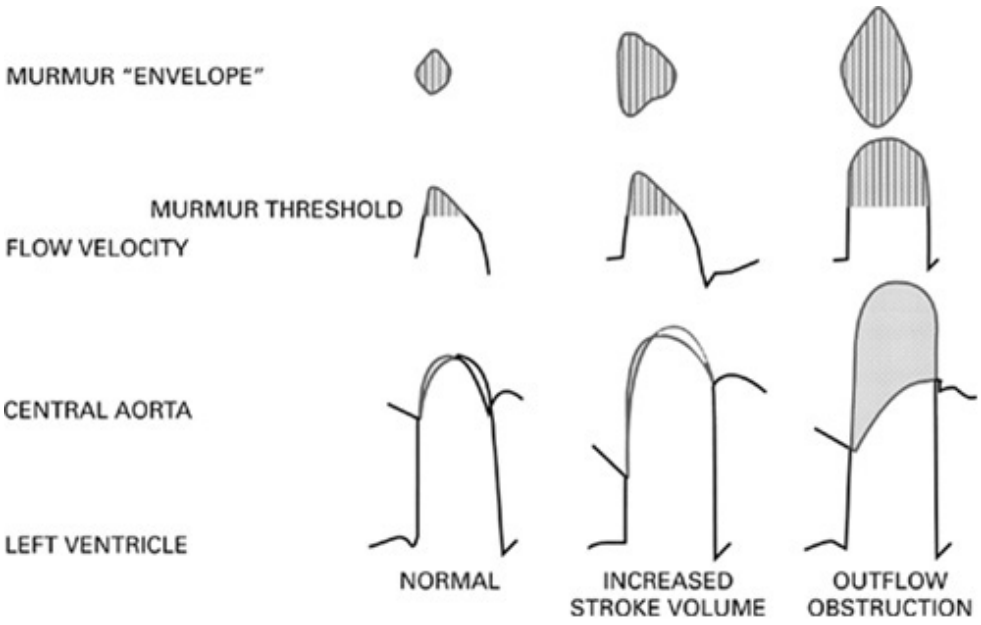

Figure 10-78: The simultaneous time-intensity course of the murmur "envelope," aortic flow velocity, and

LV and central aortic pressure. During normal LV ejection (*left*), peak flow velocity is early, with two-thirds of the ventricular volume ejected during the first half of systole. The murmur threshold may be exceeded during the early peak flow and the corresponding murmur envelope inscribed. (*Center*) Exaggeration of the normal pattern of LV ejection with a high stroke volume, as in high-output states. With critical aortic stenosis (*right*), rapid early ejection is no longer possible; the flow velocity is increased, and the contour becomes rounded and prolonged, producing the typical diamond-shaped murmur of aortic stenosis. (Modified from Reddy PS, et al. Cardiac systolic murmurs: Pathophysiology and differential diagnosis. *Prog Cardiovasc Dis* 1971; 14:4. Reproduced with permission from the publisher and the authors.)

The flow characteristics of normal RV ejection are somewhat different. Early ejection rates are not nearly as high, and the flow curve peaks somewhat later, having a more rounded contour. This flow pattern may well explain some of the long systolic ejection murmurs heard in ASDs and the straight-back syndrome, where only minimal gradients are found across the RV outflow tract.[278] With true valvular obstruction, rapid early ejection is no longer possible; the aortic flow velocity patterns become rounded, resulting in the more symmetric murmur of aortic stenosis. In such cases, the instantaneous flow pattern is determined by the instantaneous pressure head with the resulting high correlation between the contour of the pressure gradient and the murmur envelope. If LV or RV obstruction is severe, systole is prolonged, and closure sound of the semilunar valve is delayed. The murmur, however, always stops before the closure sound on the side from which it originates, although it may envelop the closure sound of the opposite side of the circulation. Because of the high correlation between the shape of the murmur and its underlying flow velocity characteristics, careful attention must be given during auscultation to the shape and duration of the murmur as well as to its intensity.

The intensity of ejection murmurs closely parallels changes in cardiac output. Any condition that increases forward flow-such as exercise, anxiety, fever, or increased stroke volume associated with the long diastolic filling period after a premature beat-increases the intensity of the murmur. Likewise, conditions that decrease cardiac output-congestive heart failure, beta blockade, or other negative inotropic agents-will decrease the intensity of the ejection murmur. This intimate relationship to flow, particularly with beat-to-beat variations, usually will allow the clinician to differentiate a systolic ejection murmur from a systolic regurgitant murmur. Furthermore, definitive diagnosis of the systolic murmur often can be made during auscultation by careful attention to the response of the murmur to various bedside maneuvers that alter the flow and loading conditions of the heart.[279] These maneuvers include respiration, the strain and release phases of the Valsalva maneuver, standing, squatting, passive leg elevation, isometric hand-grip exercise, inhalation of amyl nitrite, and transient arterial occlusion.

Innocent Murmurs

Innocent murmurs are always systolic ejection in nature and occur without evidence of physiologic or structural abnormalities in the cardiovascular system when peak flow velocity in early systole exceeds the murmur threshold.[275] These murmurs are almost always less than grade 3 in intensity and vary considerably from examination to examination and with body position and level of physical activity. They are not associated with a thrill or with radiation to the carotid arteries or axillae. They may arise from flow across either the normal LV or RV outflow tract and always end well before semilunar valve closure.

Innocent murmurs are found in approximately 30 to 50 percent of all children. In young children, especially children aged 3 to 8 years, the vibratory systolic (Still's) murmur is common. It has a very distinctive quality described as "groaning," "croaking," "buzzing," or "twanging." It is heard best along the left sternal border at the third or fourth interspace and disappears by puberty. Considerable controversy exists as to the origin of the vibratory systolic murmur. Regardless of the exact cause, most authorities agree that this murmur originates from flow in the LV outflow tract.

Innocent systolic ejection murmurs also have been attributed to flow in the normal RV outflow tract and have been termed *innocent pulmonic systolic murmurs* because the site of their maximal intensity is auscultated best in the pulmonic area at the second left interspace with radiation along the left sternal border. These are low to medium in pitch, with a blowing quality, and are common in children, adolescents, and young adults. Stein et al.,[280] who used high-fidelity catheter-tipped micromanometers to record

intracardiac sound and pressure in the aorta and pulmonary artery in adults with normal valves, invariably recorded the ejection murmur in the region of the aortic valve. They concluded that these murmurs, despite their precordial location, were aortic in origin.

In adults over age 50, innocent murmurs due to flow in the LV outflow tract are often heard and may be of a higher frequency, with a musical quality, and frequently loudest at the apex. They may be associated with a tortuous, dilated sclerotic aortic root, often in the setting of systolic hypertension. Mild sclerosis of the aortic valve also may be present.

The preceding descriptive breakdown of innocent murmurs is based primarily on age, precordial location, and distinctive acoustic qualities. Since all these murmurs are equally innocent, and because there is considerable overlap among them with respect to origin, transmission, and frequency composition, they are best characterized as systolic ejection murmurs without associated abnormalities of the cardiovascular system. Since both innocent and pathologic ejection murmurs have the same mechanism of production, it is "the company the murmur keeps" that affords the differential diagnosis of the pathologic systolic ejection murmur from the innocent murmur[281] (Fig. 10-79).

For a murmur to be considered innocent, the examination of the cardiovascular system must disclose no abnormalities. Blood pressure and contour of the carotid, femoral, and brachial arteries always should be evaluated carefully. For example, a seemingly innocent murmur in the setting of hypertension, particularly in a younger patient, always should suggest the diagnosis of coarctation of the aorta, which can be diagnosed readily by palpation of weak or nearly absent femoral pulses and confirmed by taking the blood pressure in the lower extremities. There should be no elevation of the jugular venous pulse, and the contour of the jugular pulse should be normal, without exaggeration of either the *a* or *v* wave. Evidence of cardiac enlargement on physical examination should be absent, and palpation of the apex in the left lateral position should show no evidence of a presystolic impulse, sustained systolic motion, or hyperdynamic circulation. On auscultation, normal physiologic splitting should be present. A physiologic S_3 is often present in association with an innocent murmur in children and young adults but should not be heard after age 30. An S_4 is rarely heard in normal children and adults (younger than 50 years) and always should be considered to be abnormal when associated with a presystolic impulse. Systolic ejection sounds of valvular origin as well as midsystolic nonejection sounds should be absent because their presence points to minor abnormalities of the semilunar and AV valves, respectively (see Fig. 10-79). The remainder of the physical examination should show no evidence of a cardiac cause of pulmonary or systemic congestion. In almost all patients with innocent murmurs, the ECG and the cardiac silhouette on chest x-ray should be normal.

The supraclavicular arterial murmur or bruit is a common finding in normal individuals, particularly children and adolescents. These murmurs are maximal in intensity above the clavicles and tend to be louder on the right, although they are often heard bilaterally. The bruit begins shortly after S_1, is diamond-shaped, and is of brief duration, usually occupying less than half of systole. Although the exact mechanism is unknown, it is related to peak flow velocity near the origin of the normal subclavian, innominate, or carotid artery. When particularly prominent, this murmur may transmit to the basal region of the heart and simulate a systolic ejection murmur. However, unlike the cardiac ejection murmur, the supraclavicular murmur is always louder above the clavicles than below them. Complete compression of the subclavian artery may cause the murmur to disappear completely, whereas partial compression occasionally may intensify it. Hyperextension of the shoulders is a simple bedside maneuver that may decrease the intensity of the murmur and cause it to disappear completely. In the adult, the supraclavicular murmur must be distinguished from the murmur of true organic carotid obstruction, this latter murmur being longer, often extending through S_2, and frequently associated with a history suggestive of transient ischemic attacks.

Functional Systolic Ejection Murmurs

Systolic ejection murmurs produced by high cardiac output states are functional and flow-related but are excluded from the category of innocent murmurs because of their associated altered physiologic state. These include the cardiac murmurs of thyrotoxicosis, pregnancy, anemia, fever, exercise, and peripheral arteriovenous fistula, which are best interpreted in light of the total presentation of the patient (see Fig. 10-77). Although these murmurs are often grade 3 and occasionally grade 4 in intensity, they always end well before S_2 and are only rarely confused with obstruction of the LV or RV outflow tract. The large stroke

volume associated with high-degree heart block often produces a functional systolic murmur; when found in the setting of complete heart block, beat-to-beat variations in the intensity of the murmur are present due to the random contribution of atrial systole to LV filling.

The functional systolic murmur in patients with a hemodynamically significant ASD is due to the increased flow in the RV outflow tract secondary to the left-to-right shunt at the atrial level. It is easily diagnosed at the bedside "by the company it keeps." The hallmark of this condition is wide, fixed splitting of S_2. When the shunt is large (more than 2.5:1), a hyperdynamic parasternal impulse is usually present, and a diastolic flow rumble is often heard in the tricuspid area. In addition, the tricuspid closure is loud, and prominent *a* and *v* waves are seen in the JVP. An important condition to be differentiated from an ASD is narrowing of the anteroposterior diameter of the bony thorax. Prominent systolic murmurs-often grade 3 or 4-are heard in patients having the straight-back syndrome and/or pectus excavatum.[282] Audible expiratory splitting is frequently present and, coupled with a prominent pulmonary artery on the chest x-ray (secondary to the narrow anteroposterior diameter), can lead to additional unnecessary procedures to rule out an ASD. Careful attention at the bedside to the physical examination of the spine, thoracic cage, and sternum should be part of the routine evaluation of any patient with a murmur. Often, confirmation of the thoracic abnormality with a lateral chest film is all that is necessary for definitive evaluation. Similar systolic murmurs from the RV outflow tract are also present in patients having significant left-to-right shunting at the ventricular level.

Prominent systolic ejection murmurs are the rule in patients with significant aortic regurgitation secondary to the large forward stroke volume. Although no significant LV outflow gradient is found in these patients, the intensity of such murmurs may be grade 4 or 5, and occasionally they are associated with a thrill. They always end well before aortic closure and are clearly separated from the early regurgitant murmur. Such a murmur is rarely confused with significant valvular obstruction because of the peripheral findings of wide-open aortic regurgitation. When true valvular obstruction is present (mixed stenosis and regurgitation of the aortic valve), the longer systolic ejection murmur is often associated with a prominent thrill. Systolic ejection murmurs due to large RV stroke volume are also seen in severe organic pulmonic valvular regurgitation.

Ventricular ejection into a dilated great vessel is commonly associated with a systolic ejection murmur. In the elderly, such murmurs are due to ejection into a dilated, sclerotic aorta and often are best appreciated at the apex. Frequently, degenerative changes of the aortic valve are also present, and the clinician is faced with a difficult decision as to whether or not true obstruction exists. The presence of significant calcification on fluoroscopic examination favors true obstruction and can be confirmed when a significant gradient is demonstrated by Doppler studies. A systolic ejection murmur due to RV ejection into a massively dilated pulmonary artery is frequently present in idiopathic dilatation of the pulmonary artery (see Fig. 10-73), which is often confused with an ASD due to the wide auditory expiratory splitting present in this condition. The prominent pulmonary ejection sound also may be confused with a loud tricuspid closure sound of a patient with an ASD. Short systolic ejection murmurs, frequently associated with a prominent late pulmonary ejection sound, are also seen in dilated pulmonic arteries secondary to severe pulmonary hypertension of any cause. Physical findings of severe pulmonary hypertension are always present, including a prominent parasternal impulse and increased intensity of the pulmonic component of S_2, which is well heard at the apex. Prominent *a* waves in the neck and a right-sided S_4 that increases with inspiration are present if the ventricular septum is intact. If the pulmonary hypertension is associated with intracardiac shunting, cyanosis frequently is present. A high-pitched, early diastolic murmur of pulmonic regurgitation secondary to severe pulmonary hypertension often is present.

LV Outflow Tract Murmurs

Obstruction to LV outflow may be congenital or acquired and may be located at the valvular, supravalvular, or subvalvular level. Stenosis is occasionally present at more than one level. In the clinical evaluation, one should attempt to define the severity and the level of obstruction. A summary of this differential diagnosis can be found in Table 10-12 (see Chap. 56).

The murmur of fixed stenosis of the LV outflow tract, regardless of the site, is crescendo-decrescendo, and

its contour closely parallels the instantaneous pressure gradient. As long as cardiac output is maintained, there is an excellent correlation between the intensity and length of the murmur with severity of obstruction. Although there is a tendency toward late peaking of the murmur with increasing severity of the obstruction, this delayed peaking has not been found to correlate as well with the severity of valvular obstruction in aortic stenosis as it has in pulmonic stenosis.[283] The murmur of significant fixed LV outflow tract obstruction usually is best heard in the second right and second and third left interspaces near the sternum. It radiates widely into the neck and along the great vessels. With radiation to the apex, particularly in the elderly patient, the high-frequency components of the murmur predominate, and the apical murmur has a high pitch and often a musical quality. This characteristic change in the pitch between the proximal and distal radiation of the murmur is a repeated source of confusion on auscultation. There is an almost overpowering urge to call it a separate murmur of mitral regurgitation; however, observations repeatedly demonstrate that this murmur, regardless of its timbre or harmonics, retains a spindle-shaped configuration whenever it is heard or recorded. The murmur of aortic stenosis varies directly with the length of the preceding diastole; the longer the preceding ventricular filling period, the louder is the systolic murmur (Fig. 10-80). In contrast, the apical murmur of mitral regurgitation is associated with little or no variation in intensity with varying cycle lengths. This observation is useful in patients with atrial fibrillation or frequent premature contractions and helps to identify whether an apical murmur is due to radiation of an ejection murmur or is an additional regurgitant murmur of mitral regurgitation. Beat-to-beat variations in the intensity of the murmur of aortic stenosis have been noted in both pulsus alternans and AV dissociation.

A loud early systolic valvular ejection sound or click is the hallmark of congenital valvular aortic stenosis, and its presence defines the obstruction at the valvular level (**see** Fig. 10-66). As discussed earlier in this chapter, its intensity correlates well with the motility of the valve, and there is little correlation with the severity of the obstruction. It disappears when the valve becomes immobile due to calcific fixation and is absent in fixed subaortic stenosis. With progressive increase in the severity of the outflow obstruction, the duration of LV ejection is prolonged, resulting in narrow, single, or reversed splitting of S_2. Reversed splitting of S_2 in aortic stenosis in the absence of LBBB is always associated with severe obstruction (see Chap. 56).

Regardless of the site of obstruction, significant stenosis always results in LV hypertrophy, with a decreased diastolic compliance. Clinically, this is manifest as a presystolic apical pulsation on palpation and as an S_4 on auscultation (see Fig. 10-76). In patients older than age 12, the S_4 is generally associated with a LV diastolic pressure above 11 mmHg and a left atrial *a*-wave peak of about 13 mmHg. The relationship between the severity of obstruction and the presence of S_4 gallops is indirect, reflecting hypertrophy and decreased compliance of the left ventricle rather than obstruction per se.

Because of the frequent coexistence of hypertensive or arteriosclerotic heart disease in elderly patients with calcific aortic stenosis, the presence of an S_4 is nonspecific and correlates poorly with the severity of obstruction. The S_3 gallops also may be heard in LV outflow tract obstruction, particularly when decompensation occurs (see Fig. 10-76).

The diagnosis of hemodynamically significant aortic stenosis in the elderly presents a particularly difficult problem. The murmur is often of low intensity due to the decreased cardiac output and poor LV function. An ejection sound or click is rarely present, due to calcific fixation of the valve leaflets, and S_2 is of low amplitude. The murmur is often loudest at the apex, has a high-frequency content, and may be difficult to define as ejection in nature because S_1 and A_2 may be poorly heard and therefore lost as landmarks defining the onset and end of mechanical systole.[283] In most patients with severe aortic stenosis, no A_2 is heard, and the systolic murmur obliterates P_2. In the elderly, the rate of rise of the carotid pulse may be nearly normal due to the hard, sclerotic vessels even with severe obstruction. As shown in Fig. 10-80, the response of the murmur following a premature ventricular contraction (PVC) may be very helpful in confirming the ejection nature of the murmur. Differentiation from the benign murmur of mild aortic sclerosis may be difficult and often necessitates confirmation of obstruction and its quantitation by echo-Doppler examination[284] (see also Chaps. 15 and 56).

RV Outflow Tract Obstruction

Obstructions to RV outflow are congenital anomalies and may be at the level of the valve, infundibulum, and proximal or distal branches of the pulmonary artery. Isolated infundibular pulmonic stenosis with an intact septum is rare and is usually associated with a large VSD (tetralogy of Fallot). When the ventricular septum is intact, there is an excellent correlation between both the intensity and duration of the murmur and the severity of obstruction.[285] Figure 10-81 contrasts the auscultatory findings of progressively more severe valvular pulmonic stenosis with an intact ventricular septum with those in tetralogy of Fallot with progressively more severe RV outflow obstruction.[286] As with valvular aortic stenosis, an early systolic ejection sound defines the level of obstruction at the valve. In mild to moderate valvular obstruction, the intensity of this sound is markedly attenuated or may disappear with inspiration. In more severe valvular obstruction, this sound may fuse with S_1 or actually may present as a presystolic click when the pressure generated by a forceful right atrial contraction exceeds RV end-diastolic pressure, causing doming of the stenotic valve in late diastole. Although obstruction to RV outflow in tetralogy of Fallot is usually at the infundibular level, valvular stenosis also may be present. In this setting, a pulmonary valvular ejection sound introduces a systolic murmur, and little variation in the intensity of the ejection sound is found with respiration.

The classic late peaking of the systolic ejection murmur of severe pulmonic stenosis with an intact ventricular septum is demonstrated in Fig. 10-82. Note that the late vibrations of the murmur completely envelop A_2, whereas P_2 is markedly delayed and decreases in intensity secondary to the low pulmonary artery closing pressure. In moderate to severe valvular pulmonic stenosis, an excellent correlation has been found between the A_2-P_2 interval and the RV peak pressure. When the ventricular septum is intact in severe RV outflow obstruction, prominent *a* waves are present in the JVP in association with a right-sided S_4 that may increase with inspiration. Neither of these is present in uncomplicated tetralogy of Fallot. Occasionally, in very severe pulmonic stenosis, a low-pitched presystolic murmur may be present due to forward flow across the stenotic valve that has been opened prematurely by forceful right atrial contraction in late diastole. Such patients are often cyanotic due to right-to-left shunting through a patent foramen ovale.

In isolated infundibular obstruction, a pulmonic ejection sound is usually not encountered, and the pulmonic closure (P_2) is usually not audible except in the mildest cases. Both valvular pulmonic stenosis and isolated infundibular pulmonic stenosis with an intact septum can be differentiated from tetralogy of Fallot by noting the marked intensification of the ejection murmur after the inhalation of amyl nitrite. In contrast, the murmur of tetralogy of Fallot shortens and decreases in intensity.

In branch stenosis of the pulmonary artery, there is a systolic murmur of varying intensity at the upper left sternal border that is widely transmitted to the right side of the chest, back, and both axillae. The murmur is usually less harsh and of higher pitch than the murmur of valvular stenosis. With more peripheral branch stenosis, systolic ejection murmurs or even continuous murmurs may be heard over the lung fields. The wide radiation of this murmur is particularly helpful in alerting the clinician to this type of right-sided obstruction.

Systolic Regurgitant Murmurs

Systolic regurgitant murmurs are produced by retrograde flow from a chamber of high pressure to a chamber of lower pressure. The classic examples of such murmurs are the holosystolic (pansystolic) murmur of mitral regurgitation, tricuspid regurgitation, and VSD. Since there is usually a high-pressure differential between the two chambers throughout systole, the murmurs are holosystolic in duration, high-pitched and blowing in quality, and plateaulike in configuration.

HOLOSYSTOLIC REGURGITANT MURMURS

The murmur of chronic mitral regurgitation is the prototype of the holosystolic regurgitant murmur, as shown in Fig. 10-77. It begins with or replaces S_1 and continues throughout systole in a plateaulike fashion beyond A_2, finally terminating when the LV pressure drops to the level of the left atrial pressure during isovolumic relaxation.[287] In contrast to the systolic ejection murmur, there is little variation in its intensity

with varying cycle lengths.[288] It is heard best at the apex and radiates well into the axilla; only the loudest murmurs are associated with a thrill at the apex. There is little variation in its intensity with respiration, and it is frequently accompanied by a loud diastolic filling sound followed by a short rumble. In this situation, the loud S_3 is not a manifestation of congestive failure but a reflection of hemodynamically significant mitral regurgitation. Likewise, the short rumble does not mean concomitant obstruction at the mitral valve but rather is secondary to extremely rapid early diastolic filling. The intensity of the murmur is directly related to the pressure gradient between the left ventricle and the left atrium.

The diagnosis of hemodynamically significant mitral regurgitation is established by the presence of the holosystolic regurgitant murmur and loud S_3 associated with a short flow rumble. The etiology, however, is determined by the clinical presentation and associated physical findings and is best confirmed by echocardiography (see Chap. 13).

The classic holosystolic (pansystolic) murmur of tricuspid regurgitation in the setting of RV pressure overload is best heard at the lower left sternal border. At times it may be heard laterally to the midclavicular line, indicating that the right ventricle occupies the region of the cardiac apex. Furthermore, it generally can be differentiated from mitral regurgitation because its intensity is usually strongly influenced by respiration.[289] During continuous and accentuated respiration, the murmur increases in intensity with inspiration due to the increased venous return and RV filling associated with inspiration. The inspiratory increase in loudness of right-sided auscultatory events is known as *Carvallo's sign*. Careful inspection of the JVP while auscultating the murmur will be of further help in defining its tricuspid origin, showing a prominent *v* wave with a rapid *y* descent that augments during inspiration. In severe RV failure, this respiratory variation may be absent, but it may reappear as the state of compensation improves. With severe tricuspid regurgitation, a short flow rumble introduced by an S_3 can be present, just as with mitral regurgitation, and both will increase with inspiration.[290]

The holosystolic murmur of VSD is heard best just off the sternal border in the fourth, fifth, and sixth intercostal spaces and is usually accompanied by a forceful thrill.[291] The murmur does not radiate to the axilla as with mitral regurgitation and does not have the respiratory variation characteristic of tricuspid regurgitation. Wide physiologic splitting with an easily heard P_2 is usually present when the left-to-right shunt is hemodynamically significant. When the shunt is large, there is a left ventricular S_4 followed by a short flow rumble. The regurgitant murmur is due to high-velocity flow from the high-pressure left ventricle to the lower-pressure right ventricle, and its intensity correlates poorly with the degree of left-to-right shunting. For example, a grade 5 murmur may be associated with a very high velocity flow through a small hemodynamically insignificant muscular VSD (Roger). On the other hand, an equally loud murmur associated with a thrill may be present with a larger defect having massive left-to-right shunting. When the defect is very large and the RV and LV pressures are equal, however, no murmur may be produced across the defect; instead, the short pulmonary ejection murmur of severe pulmonary hypertension is present (Eisenmenger's VSD). The murmur of VSD is very sensitive to vasoactive agents that alter vascular impedance, and a marked decrease in both the LV-RV pressure gradient and the intensity of the murmur is seen following the administration of amyl nitrite.

EARLY SYSTOLIC REGURGITANT MURMURS

Rarely, a regurgitant murmur confined to early systole is seen in the presence of a small VSD. This murmur begins in the usual manner at the onset of ventricular systole and stops suddenly in early or middle systole.[292] The sudden cessation of the murmur is due to the fact that as ejection continues and ventricular size decreases, the small defect is sealed shut as the ventricular septum thickens during systole and the flow ceases. This murmur is important because it is characteristic of the type of VSD that may disappear with age.

In contrast to the holosystolic murmur of chronic mitral regurgitation, acute severe mitral regurgitation may present as an early systolic spindle-shaped murmur.[293] Common conditions producing acute mitral regurgitation include spontaneous rupture of the chordae tendineae of a myxomatous valve, acute or subacute bacterial endocarditis of the mitral valve, papillary muscle rupture or dysfunction secondary to acute MI, and disruption of the mitral apparatus due to chest trauma.[294] In each of these conditions, large-

volume flow regurgitates into a relatively normal left atrium that has not had the time to make the adaptive changes in compliance seen in chronic long-standing mitral regurgitation. As a result, an extremely high *v* wave is generated in the left atrium.

This high *v* wave abolishes the left ventricular-left atrial gradient during the latter part of systole, resulting in termination of retrograde flow and abbreviation of the systolic murmur. As shown in a patient with acute mitral regurgitation secondary to spontaneous rupture of the chordae tendineae of a myxomatous valve, the murmur ends before A_2. Audible expiratory splitting with an accentuated P_2 is present at the base, and a loud S_4 is recorded at the apex. The presence of the S_4 associated with a prominent presystolic impulse on palpation is an important clue that indicates the acute nature of the mitral regurgitation and is rarely present in mitral regurgitation of a chronic nature. The systolic murmur of acute mitral regurgitation, which can mimic ejection murmurs, may have classic radiation to the axilla and back, especially if it is due to prolapse of the anterior leaflet of the valve with flow directed over the posterior leaflet. When the murmur is loud, it may be conducted to the top of the head and to the sacrum along the spinal column. Occasionally, the murmur is conducted to the base of the heart and great vessels, simulating aortic stenosis. The quick-rising carotid pulse with rapid falloff, as well as the wide physiologic splitting of the second heart sound, helps differentiation from aortic stenosis.[295]

The systolic murmur of organic tricuspid regurgitation is often unimpressive and presents as an early systolic murmur ending well before A_2, even in the presence of severe regurgitation.[296] In this condition, the RV pressure is nearly normal, and massive regurgitation may be present with only a small pressure differential between the right ventricle and the right atrium. The small pressure head results in a low-velocity flow, minimal turbulence, and a soft, abbreviated murmur. Occasionally, only minimal early systolic vibrations are heard. In most patients, large *v* waves are readily apparent in the JVP. The murmur retains the characteristic inspiratory augmentation seen in right-sided regurgitant murmurs and is frequently associated with an S_4 that increases in intensity with inspiration. A right-sided S_4 and a prominent diastolic tricuspid flow rumble are the rule when the tricuspid regurgitation is acute, as in endocarditis of the tricuspid valve. After total excision of the tricuspid valve for infective endocarditis related to intravenous drug abuse, the systolic murmur is often very unimpressive or may be completely absent. Giant *v* waves in the neck are easily visible, however, and palpable venous thrills and a murmur at the base of the neck may be present secondary to rapid retrograde flow in the jugular system.[297] Other causes of organic tricuspid regurgitation include carcinoid heart disease, RV infarction, chest trauma, and damage of the tricuspid valve during open heart surgery.

MID- AND LATE-SYSTOLIC REGURGITANT MURMURS

Midsystolic murmurs can occur with mitral regurgitation due to papillary muscle dysfunction.[298] The timing of the murmur of papillary muscle dysfunction also may be late systolic, and the murmur may be either intermittent or constant. It occurs with ischemia or infarction of either the posteromedial or anterolateral papillary muscle. Often these murmurs are transient, being provoked by episodes of ischemia.

Varying degrees of mitral valve prolapse are the most frequent cause of a late-systolic murmur, and this entity is one of the most common causes of systolic murmurs seen in clinical practice[299] (see Chap. 58). The murmur is best heard at the apex and often has a tendency to a late systolic crescendo. It is frequently introduced or accompanied by nonejection clicks. These clicks may be single or multiple, and they can occur independently without an accompanying systolic murmur. As shown in Fig. 10-67, the click occurs near the time of maximal prolapse in midsystole, and the late-systolic murmur continues up to and through A_2 due to prolapse of the posterior leaflet during the remainder of systole.

The timing and intensity of these murmurs vary with physiologic and pharmacologic maneuvers that alter the end-diastolic volume of the heart (see Fig. 10-68). These murmurs are also sensitive to conditions that alter the peripheral vascular impedance as well as the inotropic state of the heart. These variations in the timing and duration of the murmur can be understood most easily by considering mitral valve prolapse as a condition in which the valve is too big for the ventricle (see Chap. 58). This valvuloventricular disproportion manifests itself at a given geometric size and configuration during LV contraction. These dynamic changes can best be appreciated at the bedside by examining the patient in the supine, left lateral,

sitting, and standing positions as well as during prompt squatting. Late-systolic murmurs also may originate from prolapse of the tricuspid valve (see Chap. 59).

Levine and Harvey[215] described a musical, apical systolic murmur that they called a "whoop" because it simulated the "whoop" of whooping cough. These murmurs are loud, high-pitched, musical, sonorous, and vibratory, are best heard at the apex in late systole, and are frequently intermittent. They may vary strikingly with respiration, from beat to beat, and from examination to examination. They are often preceded by clicks and originate in the mitral valve. They are associated with ballooning of the mitral valve or mitral regurgitation (or both), and their unusual quality is secondary to the high-frequency vibrations of the mitral apparatus. The systolic "whoop" or "honk," together with late systolic murmurs, with or without associated clicks, is part of a continuum representing abnormalities of the mitral valve apparatus of varying etiologies. Similar honking noises, with or without clicks, may arise from the tricuspid valve and also have been produced by transvenous pacemaker catheters situated across the valve. These murmurs are best auscultated at the fourth left intercostal space and have the typical inspiratory augmentation of tricuspid murmurs (see Chap. 59).

MURMUR OF HYPERTROPHIC "OBSTRUCTIVE" CARDIOMYOPATHY

The classic cardiac findings of hypertrophic cardiomyopathy (HCM) with a LV outflow gradient are demonstrated in Fig. 10-83, and the echocardiogram on the right gives insight into the mechanism of production of the systolic murmur. Systolic anterior motion of the mitral apparatus impinges on the massively thickened septum, producing high-velocity flow in middle and late systole, resulting in a midsystolic ejection murmur usually with its maximal intensity at the left sternal edge.[300] Varying degrees of mitral regurgitation also may be present during systole due to the distorted mitral apparatus. Frequently, on auscultation, the skilled clinician has difficulty deciding whether the systolic murmur found in HCM is ejection or regurgitant in nature.[301] Usually, the murmur recorded by the precordial phonocardiogram is actually the summation of the murmurs of LV outflow obstruction and mitral regurgitation as transmitted to the chest wall.[302]

In patients with dynamic LV outflow gradients, the intensity of both the systolic ejection murmur and the mitral regurgitant murmur varies directly with the magnitude of the pressure gradient. Thus physiologic maneuvers and pharmacologic interventions that increase the pressure gradient will increase the intensity of the precordial murmur, and vice versa. Decreases in LV preload and afterload or increases in LV contractility are associated with increases in the pressure gradient and the intensity of the murmur, whereas increases in LV preload and afterload or decreases in LV contractility will decrease the pressure gradient and the intensity of the murmur.[303,304] For example, the upright posture and the strain phase of the Valsalva maneuver decrease venous return and LV preload, and the murmur increases in intensity. On reclining or with prompt squatting, augmented venous return increases LV preload, and the murmur decreases in intensity. Vasoactive drugs such as amyl nitrite decrease blood pressure, and a marked increase in the intensity of the murmur occurs, whereas vasoconstrictive drugs such as phenylephrine increase the afterload, and the murmur is decreased or abolished (see Chap. 67).

These responses to vasoactive drugs should be compared with the diametrically opposite responses shown in a patient with a holosystolic murmur of chronic mitral regurgitation.

In the absence of a LV outflow gradient at rest or with provocation, the murmur of HCM is less impressive. Although a short ejection murmur is usually recorded due to rapid early LV ejection, it is often softer and extends through less of systole than when a gradient is present. There is also little variation in the intensity with changes in preload, afterload, or contractility.

In HCM with and without a gradient across the LV outflow tract, massive LV hypertrophy is present, and a prominent presystolic impulse associated with a LV S_4 is the rule when normal sinus rhythm is present. An S_3 is also a common finding in patients with HCM, and occasionally there is an early diastolic rumble that may mimic the diastolic murmur of mitral stenosis. Such rumbles are felt to be due to the increased impedance to LV filling secondary to the decreased diastolic compliance of the left ventricle.

Diastolic Murmurs

Diastolic murmurs have two basic mechanisms of production. Diastolic filling murmurs or rumbles are due to forward flow across an AV valve, whereas diastolic regurgitant murmurs are due to retrograde flow across an incompetent semilunar valve[305] (Fig. 10-84).

DIASTOLIC FILLING MURMURS (RUMBLES)

Diastolic rumbles are caused by forward flow across the AV valves and are delayed from their respective semilunar closure sound by the isovolumic relaxation period. Only following this period, when the atrial pressure exceeds the declining ventricular pressure, do the AV valves open and filling begins. Since there are two phases of rapid ventricular filling-early diastole and presystole-these murmurs have a tendency to be most prominent during these two filling periods. Because the velocity of flow is relatively low, these murmurs have a low-frequency content and are rumbling in character.

Diastolic Rumbles due to Obstruction of the AV Valve

The murmur of mitral stenosis is heard best at the apex in the left lateral position, and its duration correlates well with the duration of the mitral diastolic gradient. Its intensity is related to the severity of the obstruction and to the flow across the valve.[306] As a result, there is poor correlation between the intensity of the murmur and the severity of the obstruction; e.g., high flow across a mild obstruction may produce a loud rumble, whereas low flow across a severely stenotic valve may produce a very soft murmur or may be silent. When the stenotic mitral valve is mobile, the murmur is introduced by a prominent opening snap (see Fig. 10-64, *left*). The duration of the interval between A_2 and the opening snap correlates well with the level of left atrial pressure; the shorter the A_2-opening snap interval, the higher is the left atrial pressure, and vice versa. The S_1 is also loud when the stenotic valve is mobile and is usually preceded by a crescendo murmur. Although originally attributed to increased flow secondary to left atrial systole, phonoechocardiographic studies have suggested that this short "presystolic" murmur is actually due to high-velocity antegrade flow through a progressively narrowing mitral orifice during very early (isovolumic) ventricular systole (see Fig. 10-64, *left*). This mechanism also may be responsible for the brief crescendo presystolic murmur observed in patients with mitral stenosis in atrial fibrillation following a short cycle length. The exact physical principles causing the production of this crescendo murmur are still in question.

Although the intensity of the diastolic rumble in mitral stenosis correlates poorly with the severity of obstruction, there is an excellent correlation of severity with the duration of the murmur. When sinus tachycardia or rapid atrial fibrillation is present, a rumble starting with an opening snap and continuing to S_1 may not be meaningful because of the short diastolic time. Carotid sinus pressure may be very helpful in temporarily slowing the heart rate, thereby allowing the clinician to uncover the potential length of the rumble.

Obstruction of the mitral orifice also can be produced by a left atrial tumor. The diastolic murmur may be very similar to that produced by mitral stenosis (as shown in Fig. 10-64, *center*). A loud tumor "plop" is present instead of the opening snap, and the presystolic crescendo murmur occurs as the protruding tumor mass returns rapidly through the mitral orifice into the left atrium during early ventricular systole. A systolic murmur of mitral regurgitation also may be present, and both murmurs may vary from examination to examination and with changes in body position.

The murmur of tricuspid stenosis is usually heard in the xiphoid area just off the sternal border. Since right atrial systole occurs earlier than left, the diastolic murmur of tricuspid stenosis may have a crescendo-decrescendo configuration. Even when the PR interval is normal, the presystolic accentuation of the diastolic rumble may terminate before S_1. Since tricuspid stenosis almost always occurs in the presence of mitral stenosis, this diastolic diamond-shaped murmur, which augments during inspiration, and the presence of large *a* waves in the JVP are clues to this additional diagnosis. When atrial fibrillation is present, the murmur is in middiastole and has the typical inspiratory augmentation. A tricuspid opening snap, which usually follows the mitral opening snap, also may be present and may initiate the murmur.

Diastolic Rumbles due to High Flow Across the AV Valves

High-velocity flow across the normal or insufficient AV valve may result in short middiastolic rumbles often accompanied by an S_3 and should not be confused with murmurs produced by true obstruction of the AV valves. Such rumbles are common in both VSD and patent ductus arteriosus due to the large flow across the mitral valve secondary to the left-to-right shunt.[307] Likewise, the left-to-right shunt in a large ASD often produces a tricuspid rumble. Similar low-pitched rumbling murmurs also may be present in hyperkinetic states and occasionally are heard in patients with complete heart block and increased diastolic blood flow in each cardiac cycle. Common to all these conditions is high-volume flow during the latter phase of the rapid filling period. Phonoechocardiography has shown that these murmurs occur during the rapid closing motion of the mitral valve, suggesting a functional "obstruction" during the period of rapid early diastolic filling.[308] Identical phonoechocardiographic correlates also have been shown with mitral and tricuspid regurgitation, where early diastolic filling is also extremely rapid. With tricuspid regurgitation, the early rumble will increase with inspiration, typical of right-sided murmurs across the tricuspid valve. During rapid atrial fibrillation, ventriculogenic closure of the normal mitral valve during the rapid filling phase of a short cardiac cycle may cause a "presystolic" murmur by a similar mechanism.

Mitral valvulitis during an episode of acute rheumatic fever may cause a short diastolic rumble, the *Carey Coombs murmur*.[309] This rumble, especially in children or in the presence of fever and anemia, may be introduced by an S_3 rather than by an opening snap. This combination of an S_3 with a short rumble indicates that there is not enough obstruction to the valve to alter the characteristics of rapid early ventricular filling.

The Austin Flint murmur, as originally described in 1862,[310] consisted of an apical presystolic murmur observed in two patients with considerable aortic regurgitation and no evidence of mitral stenosis at autopsy. Since its original description, the timing of this murmur has been extended to include a middiastolic component. It is heard best at the apex and has many of the qualities of the murmur of mitral stenosis. It is introduced by an S_3 rather than by an opening snap, however, and S_1 is of normal or decreased amplitude. Maneuvers or pharmacologic agents that increase the degree of aortic regurgitation, such as hand grip or vasoconstricting drugs, will increase the intensity of the rumble, whereas vasodilating agents such as amyl nitrite will decrease its intensity. In most cases of severe aortic regurgitation, particularly when the regurgitation is acute, the presystolic component of the Austin Flint murmur is lost. In this situation, there is marked elevation of the LV end-diastolic pressure, and the reverse pressure gradient between the left ventricle and the left atrium causes premature closure of the mitral valve.

Elegant phonoechocardiographic studies have shown that the murmur is associated with the rapid closing motion of the mitral valve leaflets during middiastole and presystole, presumably due to antegrade flow across a closing orifice in a manner similar to the flow rumble of AV valvular regurgitation and high-output states.[311] Austin Flint murmurs have been observed in the absence of rapid closing of the mitral valve, however, and Reddy et al.[312] have suggested that incomplete valve opening rather than excessively rapid closure rates may be the essential requirement for producing the increased mitral flow velocity. One echo-Doppler study has suggested that patients with an Austin Flint murmur usually have an aortic regurgitant jet aimed directly at the mitral valve, causing deformity and shuddering of the valve, in contrast to patients with equally severe regurgitation, in whom the murmur is absent.[313] Right-sided Austin Flint murmurs of similar quality have been reported in association with severe pulmonic regurgitation associated with pulmonary hypertension.[314]

DIASTOLIC REGURGITANT MURMURS

Holodiastolic Aortic Regurgitant Murmurs

The early diastolic murmur of aortic regurgitation is blowing and high-pitched in character and is often more difficult to record than to hear because of its high-frequency content. Since isovolumic relaxation of the left ventricle is very rapid, a large gradient quickly develops between the aortic and LV diastolic pressures, and the murmur builds up to maximum intensity almost immediately after A_2. As diastole progresses, the gradient between the two chambers falls slowly, and the murmur envelope closely parallels

the pressure drop in a decrescendo fashion up to S_1. When the aortic regurgitation is valvular in origin, the murmur is usually best heard at the third and fourth left parasternal areas. The finding that the murmur is heard best to the right of the sternum should alert the clinician to an aortic root etiology of the regurgitation.[315] It should be pointed out that this finding is helpful only if present, since most patients with aortic regurgitation secondary to dilatation of the aortic root have the usual radiation with peak intensity to the left of the sternum. Although the frequency content of the murmur is in a range advantageous to the human ear, the amplitude of the vibrations may be quite small and the murmur quite faint. Therefore, the murmur may be overlooked if the examiner does not listen with the patient sitting up and leaning forward and does not listen with the diaphragm of the stethoscope pressed firmly against the chest wall. In addition, one should listen while the patient holds his or her breath after deep expiration.

The degree of aortic regurgitation is directly proportional to the pressure head driving the flow in a retrograde fashion. Maneuvers or pharmacologic agents that increase or decrease the diastolic aortic-left ventricular pressure gradient will increase or decrease the intensity of the regurgitant murmur. Prompt squatting often will bring out a very faint aortic regurgitant blowing murmur at the bedside, and inhalation of amyl nitrite will markedly decrease its intensity. It should be remembered that the murmur of mild aortic regurgitation often disappears during the latter stages of pregnancy due to the low peripheral vascular resistance. Pure aortic regurgitation without associated valvular stenosis may present with a prominent systolic ejection murmur as well as an Austin Flint rumble at the apex. The carotid pulse is rapid-rising and has a large volume. The A_2 is often diminished or even absent when the regurgitation is valvular in origin due to inadequate coaptation and checking of the retrograde blood column by the deformed leaflets.

The etiology of the aortic regurgitation usually cannot be determined by the quality of the murmur. An exception to this rule is the presence of a "cooing dove" or musical diastolic murmur, which usually denotes a rupture or retroversion of an aortic cusp. Such ruptures occur secondary to trauma, bacterial endocarditis, and occasionally in the presence of arteriosclerotic involvement of the aortic valve. Retroversion and subsequent rupture of the aortic valve with a musical murmur are also a complication of syphilitic aortic regurgitation (see Chap. 56).

Abbreviated Aortic Diastolic Regurgitant Murmur

The murmur of very mild aortic regurgitation may be abbreviated and may end by middiastole. This is particularly true of the functional aortic regurgitant murmur of systemic arterial hypertension. As the volume of blood in the aorta decreases during diastole, the aortic annulus becomes smaller, and coupled with the decreasing aortic-left ventricular diastolic gradient, retrograde flow ceases, and the murmur disappears.

The murmur of aortic regurgitation also may be abbreviated if the aortic regurgitation is acute. Acute regurgitation of blood into a ventricle that has not had time to adapt to a large-volume load results in marked elevation of the LV end-diastolic pressure and equilibration of the aortic and LV diastolic pressures. With this, retrograde flow ceases, and the murmur disappears in the latter part of diastole. In the syndrome of acute aortic regurgitation, there may be preclosure of the mitral valve, resulting in a soft or absent S_1 as well as absence of the presystolic component of the Austin Flint murmur. The auscultatory findings of acute versus chronic aortic regurgitation are contrasted in Fig. 10-85. Common causes of acute aortic regurgitation include aortic valve endocarditis, trauma, acute aortic dissection, and dehiscence of an aortic valve prosthesis (see Chap. 56).

Holodiastolic Pulmonic Regurgitant Murmur

Pulmonic regurgitation is found most commonly in the setting of severe pulmonary hypertension and dilatation of the pulmonary artery with inadequate coaptation of the leaflets of the pulmonic valve. The functional murmur of pulmonic regurgitation (Graham Steell murmur)[316] is similar in both frequency and contour to that of aortic regurgitation because the hemodynamics responsible for their production are identical. The differential diagnosis is made by the "company the murmur keeps," and when it is associated with the peripheral signs of hemodynamically significant aortic regurgitation or with the findings of severe pulmonary hypertension, there is rarely a problem. However, when rheumatic mitral stenosis is the primary lesion, the semilunar regurgitant murmur may be secondary either to associated rheumatic aortic

regurgitation or to the Graham Steell murmur if the pulmonary hypertension is severe. Careful investigation of the semilunar blowing murmur in the setting of mitral stenosis has shown that it is almost always due to aortic regurgitation, even when significant pulmonary hypertension is present.[317] More common causes of the Graham Steell murmur of functional pulmonary regurgitation are primary pulmonary hypertension and Eisenmenger's syndrome.

Early diastolic murmurs occasionally are heard in end-stage renal failure, particularly when there is concurrent anemia, hypertension, and fluid overload. Doppler echocardiography demonstrated that these murmurs are usually pulmonic in origin.[318] They are often transient in nature and are related to fluid overload. Such murmurs are diminished by extracellular fluid removal and reflect correctable pulmonary hypertension.[318]

Delayed Pulmonic Regurgitant Murmur

The murmur of organic (non-pulmonary hypertensive) pulmonary regurgitation is quite different in quality and duration as compared with either aortic regurgitation or the Graham Steell murmur of pulmonary hypertension.[319] The murmur is delayed from P_2 by a short interval and then builds up quickly to a crescendo followed by a decrescendo that ends well before S_1. In organic pulmonic regurgitation, the pulmonary artery pressure may be normal, and the diastolic gradient between the pulmonary artery and right ventricle may be very small, resulting in low-velocity retrograde flow and a lower-pitched murmur. The murmur is heard only during the period of maximal gradient in early and middle diastole, as the pulmonary artery pressure begins to equilibrate with the RV end-diastolic pressure in the latter part of diastole. This type of murmur may be congenital or acquired, as with pulmonary valve endocarditis, carcinoid syndrome, or surgical procedures on the pulmonic valve. It is often associated with a prominent systolic ejection murmur secondary to the large RV stroke volume.

CONTINUOUS MURMURS

A *continuous murmur* is defined as one that begins in systole and extends through S_2 into part or all of diastole. It need not occupy the entire cardiac cycle; therefore, a systolic murmur that extends into diastole without stopping at S_2 is considered to be continuous even if it fades completely before the subsequent S_1. A physiologic classification of continuous murmurs as described by Myers[320] is detailed in Table 10-13.

Table 10-13: Physiologic Classification of Continuous Murmurs

Continuous murmurs due to rapid blood flow
Venous hum
Mammary souffle
Hemangioma
Hyperthyroidism
Acute alcoholic hepatitis
Hyperemia of neoplasm (hepatoma rental cell carcinoma, Paget's disease)
Continuous murmurs due to high-to-low pressure shunts
Systemic artery to pulmonary artery (parent ductus arteriosus, aortopulmonary window, truncus arteriosus, pulmonary atresia, anomalous left coronary, bronchiectasis, sequestration of the lung)
Systemic artery to right heart (ruptured sinus of Val-salva, coronary artery fistula)
Left-to-right atrial shunting (Lutembacher's syndrome, mitral atresia plus atrial septal defect)

Venovenous shunts (anomalous pulmonary veins, portosystemic shunts)
Arteriovenous fistula (systemic or pulmonic)
Continuous murmurs secondary to localized arterial ob- struction
Coarctation of the aorta
Branch pulmonary stenosis
Carotid occlusion
Celiac mesenteric occlusion
Renal occlusion
Femoral occlusion
Coronary occlusion

Continuous Murmurs due to Rapid Blood Flow

High-velocity blood flow through veins and arteries may cause a continuous murmur. The cervical venous hum is a continuous murmur with diastolic accentuation and is easily heard in almost all children. This murmur also can be heard in healthy adults and is present in nearly all women in the later stages of pregnancy. High cardiac output states such as thyrotoxicosis and anemia are also associated with easily heard venous hums. This murmur is usually poorly heard in the supine position, and its presence in this position in an adult strongly suggests a hyperdynamic circulatory state. Peak intensity is in the supraclavicular fossa just lateral to the sternocleidomastoid muscle, and it is usually more prominent on the right side. When the murmur is loud, it may radiate below the clavicles and occasionally can be confused with the continuous murmur of patent ductus arteriosus. This error should never be made, however, because the cervical venous hum can be terminated easily by digital compression of the JVP.

The mammary souffle is another example of a continuous murmur occurring in 10 to 15 percent of pregnant women during the second and third trimesters and in the early postpartum period, particularly in lactating women, and is heard between the second and sixth anterior intercostal spaces. This murmur may be obliterated by firm pressure on the stethoscope or by digital pressure applied just lateral to the site of auscultation and therefore should not be confused with the continuous murmur of patent ductus arteriosus or with arteriovenous fistula. The mammary souffle disappears after termination of lactation. Other causes of continuous murmurs due to rapid blood flow through arterial or venous channels are outlined in Table 10-13.

Continuous Murmurs due to High-to-Low-Pressure Shunts

A group of congenital cardiovascular anomalies has shunting from the high-pressure systemic (aortic) circulation to the low-pressure pulmonary arterial circulation, resulting in a large gradient between the two systems throughout the cardiac cycle. The murmur of patent ductus arteriosus is the classic example of this type of anomaly. It is heard best in the left infraclavicular area and the second left intercostal space. The peak intensity of the murmur is at the time of S_2, after which it gradually wanes until it terminates before S_1.[221] The length of the murmur is determined by the difference in the vascular resistance between the greater and lesser circulation. As the pulmonary vascular resistance increases, the diastolic pressure in the

pulmonary artery approaches and finally reaches systemic levels, diminishing and finally abolishing diastolic flow and the diastolic portion of the murmur. With equilibration of aortic and pulmonary artery pressure, systolic flow across the shunt diminishes and finally disappears, leaving the ductus silent (Eisenmenger's patent ductus arteriosus). Surgically produced aortopulmonary connections (Blalock, Waterston, and Pott's shunts), as well as the murmur of aortic pulmonary window, have identical qualities, and the effect of pulmonary hypertension on their length is analogous. It is important to distinguish these types of continuous murmurs from to-and-fro murmurs. The latter is a combination of the systolic ejection murmur and a semilunar diastolic murmur. The classic example of a to-and-fro murmur is the murmur of aortic stenosis and regurgitation. The continuous murmur builds to a crescendo around S_2, whereas the to-and-fro murmur has two components. The midsystolic ejection component decrescendos and may disappear as it approaches S_2, leaving a silent period before the onset of the regurgitant murmur. Truncus arteriosus is a rare congenital anomaly and probably produces a continuous murmur only if there is coexisting pulmonary artery stenosis (see Chap. 63). In the presence of severe RV outflow obstruction, bronchial collateral arteries can enlarge their normal precapillary anastomoses with pulmonary arteries, and the resulting aortic pulmonary fistula can produce a continuous murmur. This murmur can be heard in the same location as the patent ductus but radiates widely, especially over the posterior thorax. Large bronchial collateral arteries producing such continuous murmurs are more common with pulmonary atresia but also occur with tetralogy of Fallot. Bronchial artery-pulmonary artery collaterals sufficient to produce continuous murmurs are also found in far-advanced bronchiectasis and sequestration of the lung (see Chap. 63).

An anomalous left coronary artery arising from the pulmonary artery may cause a continuous murmur when the left-to-right shunt flow is large; it is usually best heard at the left sternal border. In this condition, the origin of the right coronary artery is from the aorta, and the left-to-right shunt is from the high-pressure right coronary arterial bed through large arterial collaterals to the left coronary system, which empties into the low-pressure pulmonary artery.

Sinus of Valsalva aneurysms may cause continuous murmurs when they rupture into the right side of the heart. In almost all cases, rupture occurs from the right and noncoronary sinuses into the right atrium or the right ventricle.[321] The murmur is heard maximally at the lower sternal border or xiphoid over the area corresponding to the fistulous tract. Diastolic accentuation of this murmur is an important sign to differentiate ruptured sinus from patent ductus arteriosus or arteriovenous fistula. Systolic suppression of the murmur is due to both mechanical narrowing of the fistulous tract during systole as well as the probable Venturi effect created by the rapid ejection of blood past the aortic origin of the fistula.

Coronary artery fistulas usually empty into the right atrium or ventricle and cause a continuous murmur that is best heard to either the left or the right of the lower sternal area. Since the majority of coronary flow occurs during diastole, the diastolic component of the murmur is louder. When the coronary artery fistula empties into a high-pressure right ventricle, only a diastolic murmur may be heard because the pressure gradient across the shunt is reduced during systole. Left-to-right shunting through an uncomplicated ASD produces no murmur audible on the chest wall because of the minimal pressure gradient and absence of turbulence. When mitral valve obstruction is present, as with Lutembacher's syndrome or mitral atresia, however, there can be a high-pressure gradient between the left and right atria across a small defect, and a continuous murmur may be present.[322] This murmur increases in intensity with inspiration and decreases with the Valsalva maneuver. Occasionally, a small ASD is produced following transseptal catheterization or balloon valvuloplasty for mitral stenosis, and a continuous murmur is produced due to high-velocity flow resulting from the large pressure gradient from the left to the right atrium.

Total anomalous pulmonary venous drainage into a systemic vein may produce a continuous venous hum usually heard in the pulmonary area or the left infraclavicular area. Frequently, a constriction at the junction of the anomalous venous conduit and the innominate vein or superior vena cava may cause augmentation of the murmur (see Chap. 63).

Arteriovenous fistulas between peripheral vessels produce a classic continuous murmur with systolic accentuation caused by shunting of a large volume of blood at rapid flow rates from a high-pressure artery into a low-pressure vein. These murmurs are best heard at the site of the fistula. Local compression of the veins may decrease the intensity of the murmur by raising venous pressure and reducing the arteriovenous

pressure gradient. Complete obliteration of the fistula will terminate the murmur, and if the shunt is of considerable magnitude, a baroreceptor-mediated reflex bradycardia may occur (Branham's sign). Likewise, a reflex tachycardia will occur on release of the obstruction. Pulmonary arteriovenous fistulas usually produce only a systolic murmur because the peripheral vascular resistance of the normal lung is very low, and the normally small diastolic pressure gradient from pulmonary artery to pulmonary vein is not significantly increased by the presence of the fistula.

Continuous Murmur Secondary to Localized Arterial Obstruction

Localized stenosis of systemic or pulmonary arteries may produce a continuous murmur or bruit if the obstruction is critical and adequate collateral flow is not available.[323] Most partially obstructed arteries have only systolic murmurs that are delayed relative to cardiac systole, depending on the transit time of pulsatile flow from the heart to the site of obstruction. This lack of diastolic gradient is explained by the fact that the collateral arteries around the obstruction deliver adequate flow such that the diastolic pressure on either side of the localized obstruction is essentially equal. Thus a localized, partial arterial obstruction characteristically produces only a systolic murmur or bruit. If adequate collateral flow is not present, however, a diastolic and a systolic pressure gradient can be produced, together with a continuous murmur with systolic accentuation. Depending on the degree of inadequacy of collaterals, the murmur is truly continuous when collateral circulation is essentially nonexistent, or it extends only partially through diastole when collateral flow is somewhat compromised. Such is the case in severe coarctation of the aorta, where, in addition to the systolic and/or continuous murmurs heard over the thorax and produced by rapid blood flow through the tortuous intercostal collaterals, a continuous murmur may be produced at the site of the coarctation. This latter murmur is best heard over the back midline between the scapulae.

Continuous murmurs also may arise from branch pulmonary stenosis or partial obstruction of a major pulmonary artery occluded by a massive pulmonary embolus. Other common locations of continuous murmurs secondary to localized arterial obstructions are listed in Table 10-13. Common to all these murmurs is critical narrowing of the vessel with inadequate collateral flow such that a continuous pressure gradient is produced throughout the cardiac cycle. Murmurs produced by obstruction of major coronary arteries are rarely loud enough to be transmitted to the chest wall. When audible, they produce only diastolic murmurs, even with inadequate collateral circulation.

Chapter 10: THE HISTORY, PHYSICAL EXAMINATION, AND CARDIAC AUSCULTATION

List of Figures

Figure 10-20: *Multiple lentigines syndrome:* dark-brown macular lesions of the abdomen associated with hypertrophic subaortic stenosis. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, October 1986. Reproduced with permission from the publisher and author.)

Figure 10-21: *Scleroderma:* clawlike hand deformity and shiny, tight skin. May be linked with myocardial fibrosis.

Figure 10-22: *CREST syndrome*. Telangiectasia of the face in a patient with Raynaud's phenomenon and sclerodactyly.

Figure 10-23: *Systemic lupus erythematosus:* butterfly rash associated with pericardial, myocardial, and endocardial disease.

Figure 10-24: (Plate 35) *Rheumatoid arthritis:* with ulnar deviation of the fingers, flexion of the distal interphalangeal joints with hyperextension of the proximal interphalangeal joints.

Figure 10-25: *Polychondritis. A,B.* Destruction of cartilage of the nose, producing a "saddle nose" in association with aortic regurgitation. (Courtesy of Dr. Warren Sarrell, Anniston, AL.)

Figure 10-26: *Ankylosing spondylitis:* immobile, curved spine with forward jutting of head. May be seen with AV block or aortic regurgitation. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, June 1987. Reproduced with permission from the publisher, author, and patient.)

Figure 10-27: (Plate 36) Marked pectus excavatum.

Figure 10-28: *Friedreich's ataxia* (photographs from different patients). *A*. Kyphoscoliosis. *B*. Pes cavus. Myocardial fibrosis and hypertrophy are often present. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, June 1987. Reproduced with permission from the publisher and authors.)

Figure 10-29: *Acromegaly*. Coarse facial features, folds of skin, and prognathism are associated with myocardial hypertrophy and fibrosis. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, February1987. Reproduced with permission from the publisher, author, and patient.)

Figure 10-30: (Plate 37) *Hyperkeratotic lesions* encrusted on the soles of the feet in Reiter's syndrome.

Figure 10-31: *Lyme arthritis:* annular expanding rash with a clear central area. May be associated with pericarditis and AV block. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, December 1986. Reproduced with permission from the publisher and author.)

Figure 10-32: (Plate 38) *Dermatomyositis*. A violaceous hue and edema of upper eyelid may be associated with myocardial disease.

Figure 10-33: *Amyloidosis*. Enlarged tongue may be a sign of an infiltrative cardiomyopathy. (From Silverman ME. Visual clues to diagnosis. *Primary Cardiology*, November1987. Reproduced with permission from the publisher, author, and patient.)

Figure 10-34: *Hyperlipidemia:* xanthomata associated with coronary artery disease. *A*. On the extensor tendons of the hand. *B*. On the Achilles tendon (arrow).

Figure 10-35: *Klippel-Trenaunay syndrome:* hypertrophy of left side of face and tongue in a patient with port-wine stains, gigantism of digits, and varicose veins.

Figure 10-36: *Supravalvular aortic stenosis:* turned-up nose, broad cheeks, large mouth with peg-shaped teeth, and large ears.

Figure 10-37: (Plate 39) Hereditary hemorrhagic telangiectasia. Telangiectasia under nails. (From Silverman ME, Hurst JW. The hand and the heart. *Am J Cardiol* 1968; 22:609. Used with permission from the publisher.)

Figure 10-38: (Plate 40) Hereditary hemorrhagic telangiectasia. Telangiectasia of tongue and lips may be associated with a pulmonary arteriovenous fistula.

Figure 10-39: (Plate 41) Tuberous sclerosis. Adenoma sebaceum may be associated with rhabdomyomas of the myocardium.

Figure 10-52: (Plate 47) Branch retinal vein obstruction. Thickening of the retinal arterial wall in diabetes and hypertension may compromise the lumen of the vein, where they share a common adventitial sheath at an arteriovenous crossing. The resulting obstruction produces hemorrhage retinopathy in the drainage area of the affected vein. Note here how the flame-shaped pattern of blood outlines the arcuate pattern of the nerve fibers as they run toward the optic disk.

Figure 10-53: (Plate 48) Embolic retinal arterial obstruction (*A* and *B*). Cholesterol crystals may dislodge from the walls of the heart, aortic arch, or carotids. Carried into the retinal circulation as Hollenhorst plaques, they seldom obstruct the arterioles completely. Although amaurosis fugax is more common, the embolic burden may occasionally be so large as to produce retinal infarction. Note in the photograph of the macular area (*A*) that this patient's fovea remains red, while there is a pale, cloudy swelling nasal to it. This has produced a half "cherry-red" spot. With complete central retinal artery occlusion, the red foveal area is completely surrounded by pale swollen retina. Hollenhorst cholesterol plaques can be seen in both the upper and lower temporal retinal arteries. In *A*, the inferior temporal arteriole demonstrates "boxcar" segmentation of the blood column, indicative of very slow flow.

Figure 10-54: (Plate 49) Neovascularization after branch retinal vein obstruction. New vessels may develop late after obstruction of a branch of the central retinal vein. These most often serve to shunt flow around the obstructed vessel site and are thus not as exuberantly proliferative as those seen in diabetic retinopathy.

Figure 10-55: Retinal emboli often lodge at bifurcations, as in this patient with carotid atherosclerosis. Note that the embolic material often seems larger than the containing vessel, as in the embolus at the lower left edge of the photograph. Emboli may damage the vessel wall and cause leakage, as can be seen by the exudate deposited about the inferior embolus. Hollenhorst cholesterol plaques rarely obstruct arterial flow completely, and this patient maintained vision.

Figure 10-56: (Plate 50) Calcific retinal embolus associated with aortic valvular disease. Calcific aortic valvular disease and valve replacement surgery may result in retinal emboli. Like cholesterol emboli, these calcific flecks lodge at arterial bifurcations but seldom obstruct flow completely. They are white and glitter in the ophthalmoscope beam. Somewhat similar emboli may be seen after the intravenous injection of illicit drugs expanded with talc.

Figure 10-57: (Plate 51) Retinal hemorrhages after cardiac catheterization. Following cardiac catheterization, symptomatic and asymptomatic retinal hemorrhages may occur. The latter are more common. Presumably, these are the result of embolic events. Note, in this recently catheterized patient, the two oval hemorrhages and a small area of cloudy swelling just inferior and temporal to the fovea.

Figure 10-58: Exudative diabetic retinopathy, right eye, illustrating microaneurysms, dot-and-blot hemorrhages, and venous engorgement with extensive deposits of hard, yellow exudate.

Figure 10-59: (Plate 52) *A.* Retinal arteriosclerosis. This 75-year-old hypertensive woman has marked arteriosclerosis of the upper temporal retinal arteriole and its branches. When the narrowed blood column can no longer be seen, the thickened wall produces the "silver-wire" appearance seen here. Where the arteriole crosses its associated vein, the course of the vein is altered, and its blood column cannot be seen. This venous "nicking" and "banking" is associated with impairment of outflow, and the affected veins become darker, larger, and more tortuous. *B.* Low-power view showing the silver-wire arteriole.

Figure 10-60: Seven areas to be examined for abnormal cardiovascular pulsations by inspection and palpation. (From Schlant RC, Hurst JW. *Examination of the Precordium: Inspection and Palpation*. New York: American Heart Association; 1990:1-28. Used with permission from the publisher and authors.)

Figure 10-61: Graphic representation of apical movements in health and disease. Heavy line indicates palpable features. P_2, pulmonary component of second heart sound; A, atrial wave, corresponding to a fourth heart sound (S_4) or atrial gallop; F, filling wave, corresponding to third heart sound (S_3) or ventricular gallop. (From Willis P IV. Inspection and palpation of the precordium. In: Hurst JW, ed. *The Heart*, 7th ed. New York: McGraw-Hill; 1990:164. Reproduced with permission from the publisher and author.)

Figure 10-62: The apex phonocardiogram is displayed simultaneously with the cardiac cycle, as recorded by high-fidelity catheter-tipped micromanometers in the central aorta, left ventricle (LV), and left atrium (LA). The first high-frequency component of M_1 is coincident with the downstroke of the left atrial *c* wave and is separated from left ventricular-left atrial pressure crossover by an interval of 30 ms. (From Shaver JA, Saderni R, Reddy PS, et al. Normal and abnormal heart sounds in cardiac diagnosis: I. Systolic sounds. *Curr Probl Cardiol* 1985; 10:10-53. Reproduced with permission from the publisher and authors.)

Figure 10-63: Base and apex phonocardiograms are recorded simultaneously with the mitral valve echocardiogram in a 62-year-old man who developed acute mitral regurgitation secondary to rupture of the chordae tendinae of a myxomatous valve. During diastole, multiple echoes arise from the flail posterior mitral leaflet (PML), and during early ventricular systole, effective mitral valve closure does not occur, resulting in an inaudible low-frequency vibration on the apex phonocardiogram. During systole, there is separation of the anterior (AML) and posterior mitral leaflets, resulting in severe mitral regurgitation. The murmur has a crescendo-decrescendo contour simulating the murmur of aortic stenosis ending prior to A_1. Wide physiologic splitting of S_1 is present. The prominent S_4 present on the apex phonocardiogram was associated with an apical presystolic impulse. (From Shaver JA. The physical examination in cardiac diagnosis. *Cardiol Consult* 1985; 6:3. Reproduced with permission from the publisher and author.)

Figure 10-64: Simultaneous phonocardiograms are recorded with the mitral valve echocardiograms in three patients: mitral stenosis (*left*), left atrial myxoma (*center*), and prolapse of the mitral valve (*right*). In each condition, a loud M_1 is present and coincident with the closing point of the mitral valve echocardiogram. Common to each condition is wide separation of the mitral leaflets at the onset of LV systole, with high-velocity closure occurring over a large excursion. In the left panel, a mobile stenotic valve is demonstrated, and a loud opening snap is coincident with the E point. In the center panel, an early diastolic tumor plop (TP) is coincident with the maximal excursion of the tumor during its rapid descent into the ventricle. Note the presystolic crescendo murmur (PSM) occurring during the rapid closure of the mitral valve in both mitral stenosis and left atrial myxoma. In the right panel, a pansystolic murmur (PSM) with late systolic accentuation is secondary to the prolapse of the mitral valve with late systolic hammocking. (From Shaver JA. Current uses of phonocardiography in clinical practice. In: Rapaport E, ed. *Cardiology Update: Reviews for Physicians. New York*: Elsevier; 1981:370. Reproduced in part (center panel) with permission from the publisher and author. Copyright 1981 by Elsevier Science Publishing Co, Inc.)

Figure 10-65: External sound, equisensitive LV and left atrial pressures (catheter-tipped micromanometer), LV *dP/dt*, and left atrial sound are recorded simultaneously with the mitral valve echocardiogram in a patient with hemodynamically significant mitral stenosis. A significant presystolic gradient is present due to atrial contraction, and the onset of the rapid closure of the mitral valve (*B*) is delayed until the LV pressure exceeds left atrial pressure. This occurs 40 ms after the beginning of the LV pressure rise at a time when LV *dP/dt* is much higher than normal. Following left atrial-left ventricular pressure crossover, there is rapid ventriculogenic closure of the mitral valve (*BC*), resulting in a very loud M_1 coincident with the *C* point of the mitral valve echocardiogram. Its separation from A_2 is determined by both the level of the left atrial pressure and the rate of LV pressure decline. (From Shaver JA, et al. Normal and abnormal heart sounds in cardiac diagnosis: I. Systolic sounds. *Curr Probl Cardiol* 1985; 10:10-53. Reproduced with permission from the publisher and the authors.)

Figure 10-66: Base and apex phonocardiograms are recorded simultaneously with the aortic valve echocardiogram in a young man with valvular aortic stenosis. A prominent aortic valvular ejection sound (AVES) is recorded at the apex and is coincident with the maximal excursion of the aortic valve in early systole. It is followed by a crescendo-decrescendo systolic ejection murmur (SEM) that ends well before a loud A_2.

Figure 10-67: Simultaneously recorded base and apex phonocardiograms and mitral valve echocardiogram (MVE) demonstrating the frequent association of a late systolic murmur with a prominent late systolic click. Although the murmur is well transmitted to the base, the click transmits poorly. In the first two complexes, an additional softer click precedes the click murmur complex. The last complex shows only a single click, demonstrating the variability of the auscultatory findings even at rest. The large click occurs at maximal prolapse, and the smaller click occurs near the onset of echocardiographic prolapse.

Figure 10-68: A midsystolic nonejection sound (*C*) occurs in mitral valve prolapse and is followed by a late systolic murmur that crescendos to S_1. With assumption of the upright posture, venous return decreases, the heart becomes smaller, the *C* moves closer to S_1, and the mitral regurgitant murmur has an earlier onset. With prompt squatting, both venous return and afterload increase, the heart becomes larger, the *C* moves toward S_2, and the duration of the murmur shortens. (From Shaver JA. *Examination of the Heart*, Part IV: Auscultation. Dallas: American Heart Association; 1990:13. Reproduced with permission from the publisher and the authors.)

Figure 10-69: The cardiac cycle recorded by high-fidelity catheter-tipped micromanometers. The aortic (A_2) and pulmonic (P_2) closure sounds are coincident with the incisurae of their respective arterial traces. Although the LV and RV mechanical systoles are nearly equal in duration, the RV systolic ejection period terminates after LV ejection because of an increased right-sided "hangout" interval. (From Shaver JA. The second heart sound: Newer concepts: I. Normal and wide physiological splitting. *Mod Concepts Cardiovasc Dis* 1997; 46:7. Reproduced with permission from the American Heart Association and the authors.)

Figure 10-70: (*Left*) The base and apex phonocardiograms are recorded simultaneously with the aortic valve echocardiogram. The first high-frequency component of A_2 is coincident with the completion of closure of the aortic valve. (*Right*) Base and apex phonocardiograms are recorded with the pulmonary valve echocardiogram. The first high-frequency component of P_1 is coincident with the completion of closure of the pulmonic valve. (From Shaver JA, et al. Normal and abnormal heart sounds in cardiac diagnosis: I. Systolic sounds. *Curr Probl Cardiol* 1985: 10:43. Reproduced with permission from the publisher and the authors.)

Figure 10-71: (*Top*) Normal physiologic splitting. During expiration, A_2 and P_2 are separated by less than 30 ms and are appreciated as a single sound. During inspiration, the splitting interval widens, and A_2 and P_2 are clearly separated into two distinctly audible sounds. (*Bottom*) Audible expiratory splitting. In contrast to normal physiologic splitting, two distinct sounds are easily heard during expiration. Wide physiologic splitting is due to delay in P_2. Reversed splitting is due to delay in A_2, resulting in paradoxical movement; i.e., with inspiration, P_2 moves toward A_2, and the splitting interval narrows. Narrow physiologic splitting is seen in pulmonary hypertension, and both A_2 and P_2 are heard during expiration at a narrow splitting interval due to an increased intensity and high-frequency composition of P_2. (From Shaver JA. *Examination of the Heart*, Part IV: Auscultation. Dallas: American Heart Association; 1990:17. Reproduced with permission from the publisher and the authors.)

Figure 10-72: (*Left*) Wide physiologic splitting of S_2 is seen in a patient with complete right bundle branch block. Audible expiratory splitting that widens normally with inspiration is present. Note also the wide splitting of the first heart sound into its mitral (M_1) and tricuspid (T_1) components, as recorded at the apex. (*Right*) The base phonocardiogram is recorded simultaneously with high-fidelity catheters in the right ventricle and pulmonary artery during cardiac catheterization. There is marked prolongation of the Q to the onset of the RV pressure rise of 96 ms, resulting in wide physiologic splitting of S_2. The delayed P_2 is secondary to delayed activation of the right ventricle. (From Shaver JA. Current uses of phonocardiography in clinical practice. In: Rapaport E, ed. *Cardiology Update: Reviews for Physicians*. New York: Elsevier; 1981:337. Reproduced originally in part (left panel) with permission from the publisher and author, and from Shaver JA, et al. Normal and abnormal heart sounds in cardiac diagnosis: I. Systolic sounds. *Curr Probl Cardiol* 1985; 10:48. Reproduced in total with permission from the publisher and authors.)

Figure 10-73: (*Upper left*) Sound and pressure correlates of S_2 in a 45-year-old woman with a normotensive atrial septal defect (shunt 2:1). Wide, fixed splitting of S_2 is demonstrated; P_2 and A_2 are coincident with their respective incisurae, and the duration of the "hangout" interval is nearly equal to the A_2-P_2 interval. (*Upper right*) Simultaneous RV and LV pressures clearly show that the duration of RV and LV systole is equal. (*Lower left*) Sound and pressure correlates of a patient with idiopathic dilatation of the pulmonary artery. P_2 is coincident with the incisura of the pulmonary artery and separated from the RV pressure tracing by a "hangout" interval of 90 ms (almost identical to the splitting interval). (*Lower right*) Similar sound and pressure correlates in a patient with mild valvular pulmonic stenosis and aneurysmal dilatation of the pulmonary artery. Most of the delay in P_2 is due to a wide "hangout" interval of 56 ms. In each patient all pressures are recorded by catheter-tipped micromanometers. (From Shaver JA, et al. Second heart sound: The role of altered greater and lesser circulation. In: Leon DF, Shaver JA, eds. *Physiologic Principles of Heart Sounds and Murmurs*. Monograph 46. New York: American Heart Association;1975:63. Reproduced originally in part (top panel) with permission from the publisher and the authors, and from Shaver JA. The second heart sound: Hemodynamic determinants. *Acta Cardiol* 1985; 40:12. Reproduced in total with permission from the publisher and authors.)

Figure 10-74: *A.* The S_4 occurs in presystole and is frequently called an atrial, or presystolic, gallop. *B.* The S_3 occurs during the rapid phase of ventricular filling. It is a normal finding and is commonly heard in children and young adults, disappearing with increasing age. When it is heard in a patient with cardiac disease, it is called a pathologic S_3, or ventricular gallop, and usually indicates ventricular dysfunction or AV valvular incompetence. *C.* In constrictive pericarditis, a sound in early diastole, the pericardial knock (K), is heard earlier and is louder and higher-pitched than the usual pathologic S_3. *D.* A quadruple rhythm results if both S_4 and S_3 are present. *E.* At faster heart rates, the S_3 and S_4 occur in rapid succession and may give the illusion of a middiastolic rumble. *F.* When the heart rate is sufficiently fast, the two rapid phases of ventricular filling reinforce each other, and a loud summation gallop (SG) may appear; this sound may be louder than either the S_3 or S_4 alone. (From Shaver JA. *Examination of the Heart*, Part IV: Auscultation. Dallas: American Heart Association; 1990:27. Reproduced with permission from the publisher and the authors.)

Figure 10-75: (*Top*) A physiologic S_3 (normal variant) recorded in a 24-year-old woman without evidence of cardiovascular disease. The onset of the S_3 occurs during the rapid filling wave (RFW) of the ACG between the *O* and *F* points. The remainder of the cardiovascular examination was entirely within normal limits. (*Bottom*) A very prominent S_3 gallop is recorded in a patient with severe congestive cardiomyopathy (COCM). On physical examination, there was a small-volume carotid pulse and marked engorgement of the neck veins with elevated venous pressure. The ACG shows a very prominent presystolic pulsation (a), and an extremely rapid filling wave is present. The onset of the S_3 occurs during the RFW of the ACG. The first heart sound is soft. (From Shaver JA. Early diastolic events associated with the physiologic and pathologic S_3. *J Cardiogr*. 1984; 14(suppl 5):30. Reproduced with permission from the publisher and the authors.)

Figure 10-76: Atrial diastolic (ADG) and ventricular diastolic gallops (VDG) are recorded in an adult with severe calcific aortic stenosis. The ADG is associated with a prominent presystolic apical impulse (a), and the VDG occurs during the rapid filling wave of the ACG. The carotid pulse has a very slow rate of rise and a markedly prolonged LV ejection time. The classic diamond-shaped systolic ejection murmur (SM) is present at the base and apex. Note the higher-frequency composition of the SM at the apex but preservation of the crescendo-decrescendo pattern. (From Shaver JA. Current uses of phonocardiography in clinical practice. In: Rapaport E, ed. *Cardiology Update: Reviews for Physicians*. New York: Elsevier; 1981:356. Reproduced with permission from the publisher and author. Copyright 1981 by Elsevier Publishing Co., Inc.)

Figure 10-77: Midsystolic ejection murmurs are caused by forward flow across the LV or RV outflow tract, whereas pansystolic regurgitant murmurs are caused by retrograde flow from a high-pressure cardiac chamber to a low-pressure one. (*Left*) Diagrammatic representation of the midsystolic ejection murmur and the pansystolic regurgitant murmur, as related to LV, aortic, and left atrial (LA) pressures. The systolic ejection murmur occurs during the period of LV ejection; the onset of the murmur is separated from S_1 by the period of isovolumic contraction and the crescendo-decrescendo murmur terminates before A_2. The pansystolic regurgitant murmur begins with, or may replace, S_1, and the murmur continues up to and through A_2 as LV pressure exceeds left atrial pressure during the period of isovolumic relaxation. The murmur has a plateau configuration and varies little with respiration. (*Right*) Flow diagram. (Left panel reproduced from Reddy PS, Shaver JA, Leonard JJ. Cardiac systolic murmurs: Pathophysiology and differential diagnosis. *Prog Cardiovasc Dis* 1971; 14:19. Entire figure reproduced with permission from Shaver JA. Systolic murmurs. *Heart Dis Stroke* 1993; 2:10.)

Figure 10-78: The simultaneous time-intensity course of the murmur "envelope," aortic flow velocity, and LV and central aortic pressure. During normal LV ejection (*left*), peak flow velocity is early, with two-thirds of the ventricular volume ejected during the first half of systole. The murmur threshold may be exceeded during the early peak flow and the corresponding murmur envelope inscribed. (*Center*) Exaggeration of the normal pattern of LV ejection with a high stroke volume, as in high-output states. With critical aortic stenosis (*right*), rapid early ejection is no longer possible; the flow velocity is increased, and the contour becomes rounded and prolonged, producing the typical diamond-shaped murmur of aortic stenosis. (Modified from Reddy PS, et al. Cardiac systolic murmurs: Pathophysiology and differential diagnosis. *Prog Cardiovasc Dis* 1971; 14:4. Reproduced with permission from the publisher and the authors.)

Figure 10-79: The differential diagnosis of the innocent murmur versus the pathologic systolic murmur is made by the "company the murmur keeps." The innocent murmur must be found in the setting of an otherwise normal cardiovascular examination. C, midsystolic nonejection sound; AVES, aortic valvular ejection sound; PVES, pulmonic valvular ejection sound; AR, aortic regurgitation. (From Shaver JA, et al. *Examination of the Heart*, Part IV. Auscultation. Dallas: American Heart Association; 1990:40. Reproduced with permission from the publisher and the authors.)

Figure 10-80: Effect of the long diastolic filling period following a premature ventricular contraction (PVC) on the intensity of a systolic ejection murmur (SEM). There is a marked increase in the intensity of the aortic stenosis murmur recorded at the base and at the apex. Despite the higher-frequency content of the apical murmur, this response clearly identifies this murmur as ejection in nature. (From Paley H. Left ventricular outflow tract obstruction: Heart sounds and murmurs. In: Leon DF, Shaver JA, eds. *Physiologic Principles of Heart Sounds and Murmurs*. Monograph 46. Dallas: American Heart Association; 1975:112. Reproduced with permission from the publisher and the author.)

Figure 10-81: In valvular pulmonic stenosis with intact ventricular septum, RV systolic ejection becomes progressively longer with increasing obstruction to flow. As a result, the murmur becomes louder and longer, enveloping the aortic closure sound. At the same time, pulmonic closure occurs later; splitting becomes wider but is more difficult to appreciate because the aortic closure sound is lost in the murmur; and the pulmonic closure sound becomes progressively softer due to the low pulmonary artery pressure. With increasing severity of pulmonic stenosis, the pulmonary ejection sound may fuse with S_1. In severe obstruction with concentric hypertrophy and decreased RV compliance, an S_4 appears. In tetralogy of Fallot, with increasing obstruction at the infundibular area, more and more RV blood is shunted across a silent VSD with less flow across the obstructed RV outflow tract. With increasing obstruction, the murmur becomes shorter, earlier, and fainter. The pulmonic closure sound is absent in severe tetralogy of Fallot. The dilated aorta receives almost all the cardiac output from both ventricular chambers, and there is an aortic ejection sound (Aej). (From Leonard J, et al: *Examination of the Heart*, Part 4: Auscultation. Dallas: American Heart Association; 1974:45. Reproduced with permission from the publisher and authors.)

Figure 10-82: (*Left*) The phonocardiogram of a patient with severe valvular pulmonic stenosis as recorded at the second left intercostal space (2LICS) and the apex. The long ejection murmur (ESM) has late systolic peaking and spills through A_2. There is a marked delay in P_2, which is very small in amplitude. (*Right*) At cardiac catheterization, the markedly delayed P_2 is shown to be secondary to a very large systolic pressure gradient, and its decreased intensity is due to the low pulmonary artery pressure at the time of valve closure. The late peaking of the ejection murmur correlates with the maximal pressure gradient between the right ventricle and the pulmonary artery. (From Curtiss EI, et al. First and second heart sound. In: Horwitz LD, ed. *Signs and Symptoms in Cardiology*. Philadelphia: Lippincott; 1985:200. Reproduced with permission from the publisher and authors.)

Figure 10-83: Simultaneous base and apex phonocardiograms are recorded with the carotid pulse and ACG in the left and center panels, respectively, in a 54-year-old man with hypertrophic cardiomyopathy. The carotid pulse rises rapidly and has a late systolic plateau and a prolonged ejection period. Prominent S_4 and S_1 are demonstrated and are associated with the *a* wave and the rapid filling wave (RFW), respectively, of the ACG. Note the late systolic bulge (LSB) on the ACG. S_2 is single. A loud, grade 5 systolic ejection murmur is present and is of greatest intensity at the apex. In the right panel, the apical systolic murmur is recorded together with the M-mode echocardiogram. Simultaneous high-fidelity LV and central aortic pressures are recorded by catheter-tipped micromanometers. Marked thickening of the interventricular septum and SAM of the mitral valve are present on the echocardiogram. A large systolic pressure gradient is demonstrated beginning shortly after the onset of the SAM. (From Shaver JA, et al. Phonoechocardiography and intracardiac phonocardiography in hypertrophic cardiomyopathy. *Postgrad Med J*. 1986; 62:538. Reproduced with permission from the publisher and the authors.)

Figure 10-84: Diastolic filling murmurs or rumbles are caused by forward flow across the AV valves, whereas diastolic regurgitant murmurs are caused by retrograde flow across incompetent semilunar valves. (*Left*) Diagrammatic representation of the diastolic filling murmur and the diastolic regurgitant murmur as related to LV, aortic, and left atrial (LA) pressures. The diastolic filling murmur occurs during the diastolic filling period and is separated from S_2 by the isovolumic relaxation period. The rumbling murmur is most prominent during rapid, early ventricular filling and presystole, terminating with S_1. The diastolic regurgitant murmur begins immediately after S_2 and continues in a decrescendo fashion up to S_1, closely paralleling the aortic LV diastolic pressure gradient. (*Right*) Flow diagram. (From Shaver JA. Diastolic murmurs. *Heart Dis Stroke* 1993; 1:98-103. Reproduced with permission from the American Heart Association.)

Figure 10-85: Diagram contrasting the auscultatory findings in chronic and acute aortic regurgitation. In chronic aortic regurgitation, a prominent systolic ejection murmur (SEM), resulting from the large forward stroke volume, is heard at the base and apex and ends well before S_2. The aortic diastolic regurgitant murmur begins with S_2 and continues in a decrescendo fashion, terminating before S_1. At the apex, the early diastolic component of the Austin Flint (AF) murmur is introduced by a prominent S_3. A presystolic component of the AF is also heard. In acute aortic regurgitation, there is a significant decrease in the intensity of the SEM compared with chronic aortic regurgitation because of the decreased forward stroke volume. S_1 is markedly decreased in intensity because of preclosure of the mitral valve, and at the apex the presystolic component of the AF murmur is absent. The early diastolic murmur at the base ends well before S_1 because of the equilibration of the LV and aortic end-diastolic pressure. Significant tachycardia is usually present. (From Shaver JA. Diastolic murmurs. *Heart Dis Stroke* 1993; 1:98-103. Reproduced with permission from the American Heart Association.)

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 11:

THE RESTING ELECTROCARDIOGRAM

Authors: Agustin Castellanos, Alberto Interian, Jr., Robert J. Myerburg

What is commonly called an *electrocardiogram* (ECG) is the graph obtained when the electrical potentials of an electrical field originating in the heart are recorded at the body surface.[1-4] Although the ECG gives very useful clinical information, it only provides an approximation of the voltage produced by the source. The ECG has not been able to achieve interesting new insights into its own *basic* theoretic limitations, which some have considered as the solutions of the "forward" problem and the "inverse" problem of electrocardiography.[1,2] Whereas the former seeks the description of a specific electrocardiographic pattern in response to a specific local or regional intracardiac change in electrical activity, the latter seeks to predict the behavior of the cardiac generator from potentials recorded at the body surface.[1,2] Nevertheless, recent experimental studies have provided new information capable of expanding the clinical usefulness of the ECG, as will be discussed throughout this chapter. The ECG has many uses: It may serve as an independent marker of myocardial disease; it may reflect anatomic, hemodynamic, molecular, ionic, and drug-induced abnormalities of the heart; and it may provide information that is essential for the proper diagnosis and therapy of many cardiac[1] problems[4] (see also Chap. 24). In fact, it is the most commonly used laboratory procedure for the diagnosis of heart disease. Underreading or misreading due to insufficient knowledge of pathologic conditions, overreading due to an inability to recognize technical errors, and most important, failure to correlate ECG findings with the clinical findings may result in iatrogenic heart disease. Every physician interpreting ECGs as well as those learning electrocardiographic interpretation should read the *Guidelines for Electrocardiography of the American College of Cardiology, American Heart Association Task Force*.[4]

VENTRICULAR DEPOLARIZATION AND REPOLARIZATION

Fluxes of ions across the cell membranes cause the differences in voltage between resting and activated myocardial cells. To understand the electrical forces produced by the heart as a whole at the body surface, it has been conventional to first discuss the electrical properties of a hypothetical muscle strip from the free wall of the left ventricle extending from endocardium to epicardium.[5-7] In the resting or polarized state, the charges are at rest. A unipolar electrode facing the epicardial side of the strip, such as V_6, registers an isoelectric line.[5-13] If activation of this relatively large muscle strip starts in the endocardial side, it initiates the process called *depolarization*.[5-13] The *sequence* of this process is thus from endocardium to epicardium. Depolarization has been described as a moving wave *with the positive charges in front of the negative charges*. The previously mentioned lead V_6 overlying the epicardium of the left ventricle will record a positivity because it consistently faces positive charges throughout the entire depolarization sequence.[5-13] On the other hand, the *sequence* of ventricular repolarization is from epicardium to endocardium.[5-13] The *negative charges*, however, travel *in front* because repolarization tends to reestablish the resting, polarized state of the previously depolarized cells. As a consequence of the latter, V_6 will record a positive deflection (T wave) because it constantly faces positive charges throughout the entire repolarization sequence. The earlier epicardial end of repolarization has been attributed to the shorter duration of repolarization that epicardial cells have in comparison with

endocardial cells. Thus repolarization finishes at the epicardium while it still has not been completed at the endocardium. Hence the *sequence* of repolarization is, as noted previously, from epicardium to endocardium. This simplistic view is of didactic value only because it fails to take into consideration the role played by the M cells described by Antzelevitch et al.[14] since the beginning of this decade. According to these authors, M cells play a determining role in the inscription of the T wave **because** currents flowing down voltage gradients on either side of the usual (but not necessarily) mid-myocardial cells determine both the height and width of the T wave, as well as the degree to which the ascending or descending limbs of the T wave are interrupted.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

ELECTROCARDIOGRAPHIC LEADS

To record an ECG, an electric circuit between the heart and the electrocardiograph must be completed.[11] For this purpose, electrodes are placed on different parts of the body surface and are connected to the instrument by means of cables.[11] Thus the whole system consists of an instrument, electrodes, cables, and leads.

Bipolar Standard Leads

An ECG lead can be defined as a pair of terminals with designated polarity, each of which is connected either directly or via a passive-active network to recording electrodes. In 1913, Einthoven et al.[3] developed a method of studying the electrical activity of the heart by representing it graphically in a *two-dimensional* geometric figure, namely, an equilateral triangle. There are several simplifying assumptions on which Einthoven's hypothesis is founded[3-13]: (1) The body is a homogeneous volume conductor. Although the conductivity of the various tissues is not the same, the differences are not great enough to invalidate that the body can be considered as a homogeneous volume conductor. (2) The sum of all the electric forces, or the mean of all the forces generated during the cardiac cycle, can be considered as originating in a dipole located in the electrical center of the heart. (3) Electrodes placed on the right arm (RA), left arm (LA), and left leg (LL) are used to pick up the potential variations on these extremities. Standard (bipolar) leads (I, II, and III) are obtained by recording, respectively, the potential differences between LA and RA, LL and RA, and LL and LA. These leads record potential variations in a single frontal plane only. (4) Attachment between these limb electrodes, on the forearms and limbs, corresponds to a position in the root of the corresponding limb. For example, an electrode in the right forearm records the electrical activity that reaches the right shoulder. It should be pointed out that when the electrodes are placed proximally to the roots of the extremities, they lose their relatively "far" distance from the heart. Hence Einthoven's equilateral theory does not hold. The latter is of importance to understand why leads placed proximally to the roots of the extremities, such as those used for exercise testing and coronary care unit and Holter monitoring, by being only "equivalent" to the corresponding bipolar leads, are in some cases markedly different from the "true" standard bipolar leads.

Wilson Central Terminal

The sum of the potentials from the right arm (RA), left arm (LA), and left leg (LL) is equal to zero throughout the cardiac cycle with respect to any point at the body surface.[3,5,6,13] Lead wires attached to electrodes on each limb are connected together, through 5000-Ω resistors, at a point. When this common point-*Wilson's central terminal*-is attached to the negative pole of the ECG machine and an "exploring" electrode is connected to the positive pole, the potential variations recorded will be those of the latter only. A lead taken by this method is called a *unipolar lead.* Actually, the central terminal is not zero because the RA, LA, and LL are not equidistant from each other and from the heart, the body tissues vary in resistance, and the heart and extremities do not lie in exactly the same plane in the body. The potential of the central terminal has been said to average around 0.3 mV.[9]

Unipolar Extremity Leads

At present, unipolar extremity leads are obtained by disconnecting the input to the central terminal of Wilson from the extremity being explored. This results in a one-and-a-half increase in their voltage. These *augmented* (a) extremity leads are the ones usually used for clinical electrocardiography and are labeled aV_R, aV_L, and aV_F.[5,9,13]

Unipolar Precordial Leads

The unipolar precordial ECG is obtained by placing the exploring electrode (connected to the positive pole of the ECG machine) on the classic six locations of the anterior and left portions of the chest.[5,6,13] The central terminal is used as the indifferent electrode. Precordial (V) leads yield a positive deflection when facing positive charges and negative deflections when facing negative charges.[5,6,12,13,15-17] They do this according to what Wilson called the *solid-angle concept*.[5,13] A solid angle is merely an imaginary cone extending from the site in the chest throughout the heart. The precordial electrode is at its apex, and its base is at the opposite epicardial surface.[13] This concept is most important to understand precordial lead morphologies. According to Wilson's scalar concept of electrocardiography, this occurs because the solid angle subtended by the corresponding lead records the electrical activity from the regions of the heart over which the lead is placed as well as from distant regions.[5,13] Thus, if V_2 is placed over (thereby facing) the right ventricle, part of the initial positive ventricular deflection reflects right ventricular activation, with the corresponding electrical forces moving toward the electrode.[13] Most portions of the terminal S wave represent activation of muscle other than the right ventricle (septum and free left ventricular wall), reflecting electrical forces moving away from the electrode.[13] Acceptance that the amount of muscle activity recorded by various unipolar leads is not the same implies different "real" duration of depolarization and repolarization, irrespective of that supposedly resulting from the projections of a vector on an idealized horizontal lead axis (see sections on QT dispersion and vectorcardiography). For practical purposes, the peak of the r (or R) wave in precordial leads gives a rough estimate of the moment of arrival of excitation (*intrinsicoid* deflection) at the muscle underneath the electrode.[13] This encompasses a considerable number of muscle fibers (given by the solid-angle concept), however-in fact, a greater number than if the electrode is placed directly on the epicardial surface.[13] In the latter case, the moment of arrival of excitation at the electrode affects a lesser number of fibers and is thus given by the *intrinsic* deflection.[13]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

NORMAL ACTIVATION OF THE HEART: VENTRICULAR DEPOLARIZATION

After emerging from the sinus node, the cardiac impulse propagates throughout the atria in its journey toward the atrioventricular (AV) node. The *normal* P wave (resulting from activation of the myocardium of both atria) is a consequence of, but does not directly represent, sinus node activity. During sinus rhythm, the right atrium is activated before the left atrium.[6] This explains why high-fidelity recordings of the P waves of some normal persons show a small notch at the top. The latter simply reflects the normal asynchrony existing between the atria.[6] Because of the anatomic position of the sinus node, the sequence of atrial depolarization occurs in an inferior, leftward, and somewhat posterior direction. The normal P waves are always positive in leads I, II, aV_F, and V_3 to V_6 and negative in lead aV_R. According to the anatomic position of the heart, the P wave may be diphasic in V_1 and aV_L or negative in the latter lead. Atrial repolarization, also called T_a, is directly opposite in polarity to the P wave.[6,11] It is usually not seen because it coincides with the PR segment (not to be confused with the PR interval) and QRS complex. The PR interval (used to estimate AV conduction time) includes conduction through the "true" AV structures (AV node, His bundle, bundle branches, and main divisions of the left bundle branch), as well as through those parts of the atria located between sinus and AV nodes.[8] The onset of ventricular depolarization (given by the beginning of the normal q wave) reflects activation of the left side of the interventricular septum. This has been attributed to the fact that the left bundle system is shorter than the right bundle branch.[8,15] In addition, the large fanlike distribution of the ramifications of the fascicles of the left bundle branch on the left septal surface produces activation of a greater number of ordinary muscle cells per unit of time.[6,8,15] For this reason, the normal initial depolarization is oriented from left to right, therefore explaining the small q wave in lead V_6 and the small r wave in lead V_1. After the cardiac impulse descending through the right bundle branch reaches the right septal surface, the interventricular septum is activated in both directions. Septal activation is thereafter encompassed within or neutralized by free-wall activation. The most distal ramifications of both bundle branches (Purkinje fibers) form networks within the subendocardial regions of both ventricular walls. The latter are activated as soon as the multiple ramifications emerge from the Purkinje fibers.[6,15] The greater mass of the left ventricular (LV) free wall explains why LV free-wall events overpower those of the interventricular septum and right ventricular free wall.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

ELECTRICAL AXIS

The *electrical axis* (EA) may be defined as a vector originating in the center of Einthoven's equilateral triangle.[3,13] A *vector* is a mathematical value expressed as an arrow that has magnitude, sense, and direction. On the other hand, *scalar* values only have magnitude. When applied to the EA of the QRS complexes, the vector that represents it also gives the direction of the activation process as projected in the plane of the limb leads. Its length represents the manifest potential of the dipole in the center of the triangle. These general considerations apply either to the instantaneous EA (the vector indicating the direction of the impulse at the instant at which it is determined) or to the mean EA (which is the resultant of all instantaneous electrical axes). Although the term *EA* can be used in reference to any of the major components of the ECG (P, T, or QRS), it is generally applied to the QRS. There are many methods for determining the mean EA. The one recommended by electrocardiographers of the classical school consists of calculating the net areas enclosed by the QRS complex in leads I, II, and III.[3,6,7,12,13] The net area is the absolute sum of the positive and negative areas of the QRS complex in the corresponding lead. One of the drawbacks of this method is that the absolute values of the net area cannot be determined *accurately* by inspection. Since the absolute magnitude of the EA is not of fundamental clinical importance, it has been recommended that arbitrary units be used. When this is done, the results can be counterchecked by using Einthoven's law. For example, if in a given case lead I is +4 units, lead II is +2 units, and lead III is -2 units, the calculation is accurate because the sum of leads I and III (+4 plus -2) must always equal lead II (+2). After having determined the net area, the results are plotted on the sides of the triangle, and perpendiculars are dropped from two or all three leads. The perpendiculars will meet at a point away from the center of the triangle. A line drawn from the latter to the former defines the mean EA. A simpler, though less precise, method of calculating the quadrant (or parts of a quadrant) in which the EA is located consists of using the maximal QRS deflection in leads I and aV_F and, when necessary, lead II. This method is inexact from the mathematical viewpoint but has the value of simplicity.[15,16]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

VENTRICULAR GRADIENT

The relationship between the EA of the QRS complex and the T wave was referred to by Wilson as the *ventricular gradient*.[17] In contrast to what occurs in an epicardial-to-endocardial muscle strip (as mentioned previously), in the isolated muscle strip, the *sequence* of ventricular depolarization occurs in the same direction as that of repolarization.[12] Although the QRS and T deflections have opposite polarity, the algebraic sum of QRS and T *areas* is zero. In the human heart, however, not only is the sequence different, but the pathways of ventricular depolarization and repolarization are not exactly the same.[12] Thus the algebraic sum of QRS and T *areas* is no longer zero. Therefore, a *gradient* is said to exist. The ventricular gradient can be calculated by determining the electrical axis of the QRS and T (using *areas*) and then obtaining the resultant by the parallelogram method. Wilson considered that the ventricular gradient could be of help in differentiating between T-wave inversion of various causes (primary changes) and the obligatory secondary T-wave changes resulting from abnormalities in depolarization, such as bundle branch block, ventricular hypertrophy, ventricular pacing, and preexcitation syndromes.[12,13,17] In practice, calculation of the ventricular gradient is difficult and time consuming because it has to be determined by areas and not maximal amplitude.

Apparent Challenges to the Concept of the Ventricular Gradient

Rosenbaum et al.[18] studied the prolonged depolarization occurring during long periods of ventricular stimulation and found two types of altered ventricular repolarization. One, corresponding to Wilson's classic theory, was transient and proportional in magnitude to the QRS complex but of opposite polarity. The other, concealed by (and during) the former, required a longer time (even days) to reach maximal effect as well as to disappear, becoming apparent *only when* normal activation recurred (Fig. 11-1). The latter type was attributed to modulated electrotonic interactions occurring during cardiac activation in such a way that repolarization was accelerated at ventricular sites where depolarization begins and delayed in areas where depolarization terminates. T-wave changes appearing after prolonged depolarization was no longer present showed accumulation and (fading) *long-term* memory for variable time (see "Secondary ST-T-Wave Changes," below).[18] Recently, Goyal et al.[19] reported the occurrence of *short-term* memory after periods of altered ventricular repolarization as short as 1 min in duration. In addition, according to Surawicz,[20] the term *memory* also has been applied to gradual adjustments of action potential duration (corresponding to QT intervals) after abrupt changes in cycle lengths (events influenced by past history) without necessarily requiring abnormal ventricular repolarization (Fig. 11-2). The cellular mechanism responsible for any form of cardiac memory is beyond the scope of this chapter.

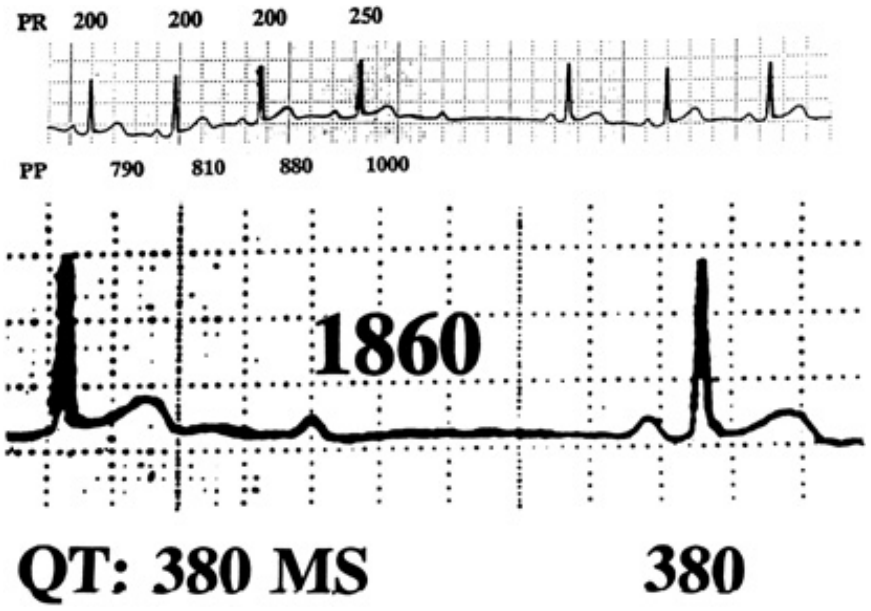

Figure 11-2: Vagal-induced AV nodal block in a young person without structural heart disease. All values are expressed in milliseconds. The uncorrected QT interval does not increase at the end of an 1860-ms (RR) pause. This can be due to the form of short-term cardiac memory whereby the QT interval "remembers" its prepause values because of the slow adjustment to abrupt changes in cycle length in otherwise *normal* subjects.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

ABNORMAL ST-SEGMENT CHANGES

In orthodox ECG language, *injury* implies *abnormal* ST-segment changes, *necrosis* implies *abnormal* Q waves, and *ischemia* implies *symmetric* T-wave inversion (or elevation).[5-7,9-13,16] Following conventional ECG theory, several authors consider that ECG "injury" occurs because the affected cells are unable to maintain their normal polarization during diastole.[5-7,12,16,21] Various hypotheses have been postulated to explain how this diastolic hypopolarization or generalized diastolic depolarization is manifested as abnormal ST-segment shifts in the surface ECG[21-24] (Fig. 11-3). One hypothesis is based on the existence of a diastolic current of "injury." During the control (diastolic) period, both membrane resting potential and surface ECG baseline are at their normal level. At the onset of injury, the resting intracellular potential decreases (e.g., from 90 to 70 mV), and the ECG baseline shifts below its preinjury level. Because the injured cells leak negative ions, their *exterior* becomes relatively negative (or less positive) than that of the normal cells. Thus a "current of injury" flows between the negative ("injured") zone and the positive ("normal") region.[10] This produces a negative displacement of the surface ECG *baseline* in the leads facing the injured region. In the surface ECG, depolarization (by virtue of the electrical negativization of the nonaffected area) practically reduces the potential difference between noninjured and injured regions. Therefore, the ST segment remains at the preinjury level, which is relatively *elevated* in reference to the injury baseline.[21-24] Consequently, the ST segment appears to be abnormally displaced above the latter. Note that the apparent presence of a systolic current of injury actually reflects disappearance of the diastolic current of injury. Finally, after the end of repolarization, the current of injury between injured and noninjured regions is reestablished, and the ECG baseline is again depressed (as it was immediately before depolarization). Since the precise moment at which injury starts is not recorded in the usual alternating-current (ac) electrocardiographic recordings, the baseline that is almost invariably recorded is the postinjury baseline.[10] It also has been shown that the abnormal ST-segment elevation in leads facing the affected zone does not merely represent the (passive) return of the baseline to its preinjury level but reflects a true, active, positive displacement.[10,21-24] Thus, when depolarization of both normal and injured regions has occurred, the surface of the normal cells will (on account of their greater initial polarization) be able to accumulate more negative ions. Hence the normal regions become more negative than the injured regions, which are relatively more positive. In consequence, the ST segment becomes actively elevated above and beyond the preinjury baseline because of the relative potential difference existing at the end of depolarization. Most likely, injury reflects both disappearance of diastolic baseline shifts and active ST-segment elevation.[10,24]

According to the current-of-injury theory, this process results in ST-segment elevation when the injured muscle is located between normal muscle and the corresponding unipolar electrode. On the other hand, ST-segment depression occurs when normal muscle is located between the injured tissue and the corresponding electrode[10,12] (see Fig. 11-3). The mechanism of abnormal ST-segment elevation in anatomically defined ventricular aneurysms has not been fully established. Some authors consider that it results from the earlier repolarization of a ring of persistently viable (but nevertheless affected) tissue surrounding the aneurysm.[8,10] For other investigators, chronic ST-segment elevation reflects functional (echocardiographic) dyskinesia, thus not necessarily being due to a pathologic ventricular aneurysm.[8,25-27] Coronary artery disease is the most frequent cause of abnormal ST-segment elevation. The latter, when generalized, also can be due to

epicardial injury due to pericarditis. Both should be differentiated from the benign "early repolarization" pattern, a normal variant.[28,29] In its classic form, there is J-point elevation (of no more than 3 mm) with an upwardly concave ST segment. R waves may be tall and at times have a distinct notch and slur on the downstroke (Fig. 11-4). ST-segment elevation is more frequent in chest leads but can occur in leads I and II. These dynamic ECG changes may be affected by exercise and hyperventilation. Isoproterenol reduces and propranolol increases ST-segment elevation.[30,31] Although the mechanism of early repolarization has not been fully elucidated, it has been related to enhanced activity of the right sympathetic nerves.[30]

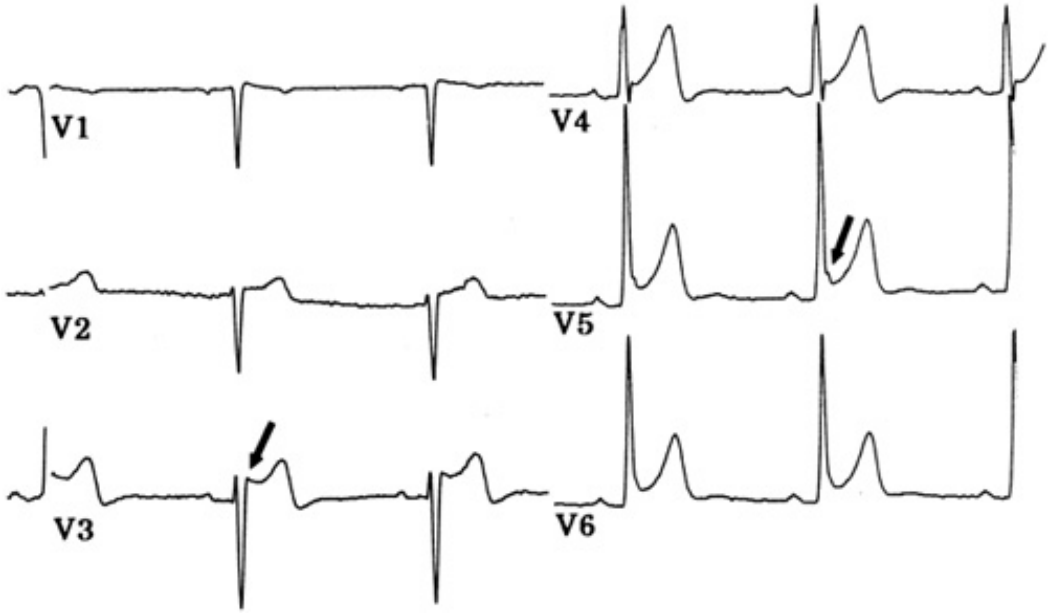

Figure 11-4: Early repolarization. This normal variant is characterized by narrow QRS complexes with J-point and ST-segment elevation in the chest leads. Left chest leads often show tall R waves with a distinct notch or slur in their downstroke (*arrow* in V_5), while the right chest leads may display ST segments having a "saddleback" or "humpback" shape (*arrow* in V_3).

Chapter 11: THE RESTING ELECTROCARDIOGRAM

SELECTIVE NONISCHEMIC ST-SEGMENT ELEVATION IN THE RIGHT PRECORDIAL LEADS

High-takeoff ST segments of either the caved or saddleback type localized to the right chest leads associated with different degrees of right bundle block with or without T-wave inversion and sudden death due to ventricular fibrillation are seen in the *Brugada syndrome*[32] (Fig. 11-5, *left*). This is a familial entity ascribed to a "primary" electrophysiologic abnormality. Similar findings were reported in the familial cardiomyopathy and sudden cardiac death syndrome described by Corrado et al.[33] Strong Na channel blocking drugs can produce ST-segment elevations even in patients without any evidence of syncope or ventricular fibrillation.[34] The changes produced by potassium are discussed in the section of hyperkalemia (below). Slight ST-segment elevation with an incomplete right bundle branch block pattern showing an epsilon wave has been described in arrhythmogenic right ventricular dysplasia[35] (see Fig. 11-5, *right*).

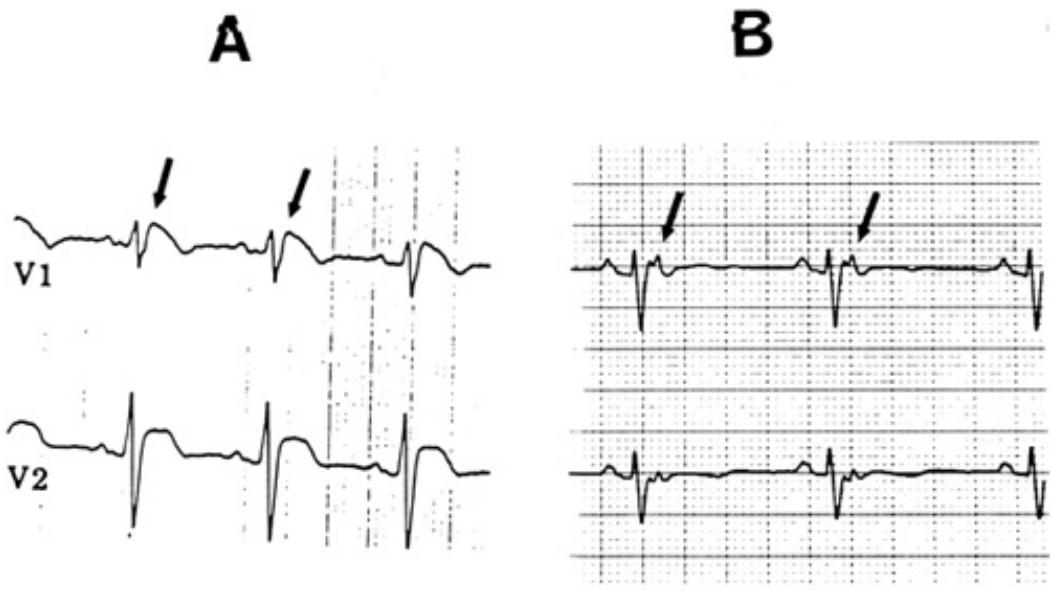

Figure 11-5: *A.* Nonischemic ST-segment elevation in the right precordial leads in a young patient with the Brugrada syndrome. *B.* Epsilon wave of a patient with arrhythmogenic right ventricular dysplasia.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

ABNORMAL Q WAVES

Abnormal Q waves appearing several hours after total occlusion of a coronary artery result from necrosis secondary to the decreased blood supply. The number of affected cells has to be large enough so as to produce changes reflected at the body surface. In general, the depth of the Q wave is proportional to wall-thickness involvement.[7] Thus, in lead aV_F a QS complex was said to reflect transmural necrosis. On the other hand, clinical myocardial infarction (MI) without abnormal Q waves was categorized as subendocardial infarction. Presently, MIs are no longer classified as transmural or subendocardial (but as Q or non-Q MIs).[36] The duration of the Q wave is proportioned to the extent of the area of necrosis parallel to the epicardial surface. If the latter is large enough, starts in the subendocardium, and extends toward (but not quitereaching) the epicardium, the corresponding unipolar leads will record QR or Qr complexes depending on the amount of living tissue located between dead tissue and the recording electrode. Therefore, abnormal Q waves may occur in MIs that are not completely transmural.[7,36] The following changes have been said to be equivalent to Q waves in non-Q-wave MI: R/S ratio changes, acute frontal plane right-axis deviation, new left-axis deviation or left bundle branch block, initial and terminal QRS notching, and some types of "poor r-wave progression."[36] Although the concept of non-Q-wave MI as a discrete clinicopathologic entity, different from Q-wave MI, has gained almost universal acceptance, it was challenged recently by a group of respectable electrocardiographers.[36]

In the course of the clinical entity known as *acute myocardial infarction* (MI), persisting Q waves are usually (but not invariably, as will be discussed subsequently) due to anatomic (lack of blood flow-related) necrosis. Abnormal Q waves also can occur transiently in unstable angina, Prinzmetal's angina, coronary artery spasm (without chest pain), and exercise-induced ischemia. This has been attributed to an intensity of cellular affectation ("injury") severe enough to produce a significant degree of hypopolarization (to, let us say, around 60 mV). Because the cells become electrically unexcitable (even though they are not anatomically, irreversibly necrotic),[7,8,15,16] abnormal Q waves occur. Spontaneous recanalization of an occluded vessel, spontaneous reversion of the ischemia, or spasm and interventions (pharmacologic or mechanical) that improve cellular metabolism and oxygenation can restore the normal polarization. If these cells become again excitable, the abnormal Q waves may disappear or vanish.[16,37] Ischemic necrosis usually takes longer to appear than the accelerated abnormal Q waves seen in the majority of patients with Q-wave MI after successful thrombolysis or effective coronary artery angioplasty performed early in the course of the process.[5] The genesis of these Q waves is not well understood.[37] Some authors consider them an expression of the acceleration of necrosis secondary to explosive cell swelling in already irreversibly injured tissue.[31] Because some of these Q waves also tend to disappear quickly, other authors consider that they reflect factors other than myocardial necrosis, such as reversal of regional dysmetabolism or the occurrence of transient interstitial ischemia or hemorrhage.[38] Profound and prolonged ischemia can cause myocardial stunning with reversible functional, metabolic, ultrastructural, and electrophysiologic abnormalities.[39] Thus transient Q waves may be the ECG counterpart (electrical stunning) of the corresponding mechanical stunning.[37-40] It is possible for myocardial stunning to lag behind electrical recovery.[37] *Myocardial stunning* should be differentiated from *myocardial hibernation*. The latter is a term used in reference to mechanical dysfunction of an ischemic area that is not transient but chronic.[41,42] Although the ECG counterpart of this type of mechanical dysfunction requires

further study, it is conceivable that (in some cases) the disappearance of chronic Q waves after coronary artery bypass surgery with improvement of wall motion abnormalities indicates that these Q waves were due not to cellular death but to cellular hibernation[41,42] (see also Chaps. 37 and 40). Finally, abnormal Q waves need not be the end result of coronary artery disease because they may be seen after primary (due to infections or drugs) cellular necrosis and in other pathologic processes such as myocardial infiltration and certain types of interventricular septal (and LV) hypertrophy, Wolff-Parkinson-White syndrome, and muscular dystrophies.[43]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

ISCHEMIC T-WAVE CHANGES

Symmetric T waves, inverted or upright (as in "hyperacute" T waves), characteristic of ECG "ischemia," have been considered to reflect a type, or degree, of cellular affection resulting only in action potentials of increased duration.[7,10,16] Because the QT interval recorded at the body surface can be considered as the sum of all action potentials (i.e., of the QT intervals of individual cells), any process (such as ECG ischemia) that increases action potential duration will cause prolongation of ventricular depolarization and QT interval. T-wave inversions[7,10] do not always reflect "physiologic" ischemia (due to decreased blood supply) because they also can be seen in evolving pericarditis, myocardial contusion, and increased intracranial pressure, as well as in the right chest leads of young patients (persistent juvenile pattern).[43]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

SECONDARY ST-T-WAVE CHANGES

Alterations in the sequence of (and sometimes delay in) ventricular depolarization (such as those produced by bundle branch blocks, ventricular pacing, ectopic ventricular impulse formation, preexcitation syndromes, and ventricular hypertrophy) result in a change in the sequence of ventricular repolarization. The latter causes nonischemic T-wave inversions (secondary T-wave changes) in leads showing a predominantly positive QRS deflection.[6,10,12,17] As mentioned earlier in the discussion of ventricular gradient and cardiac memory, disappearance of these alterations in ventricular depolarization may be followed by narrow QRS complexes with negative T waves[18] (see Fig. 11-1). After disappearance of "complete" left bundle branch block (LBBB) and in right ventricular pacing, inverted T waves appear in leads (such as V_1 and V_2) where the S wave predominates (see Fig. 11-1). Finally, marked ST-segment changes may occur *during* rapid supraventricular tachycardias, even in young patients without metabolic evidence of (physiologic) ischemia.[44]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

NONSPECIFIC ST-SEGMENT-T-WAVE CHANGES

While it seems more appropriate to discuss ST-segment and T-wave changes separately, they will be dealt with together because of their often coexistence. While nonspecific (or rather, nondiagnostic) ST-segment-T-wave changes are the most commonly diagnosed ECG abnormalities, they have not been categorized adequately and represent different findings for various interpreters.[45] In the classic paper, Friedberg and Zager[46] considered depth of ST-segment depression and T-wave inversion as well as their contour (Fig. 11-6).[46] When analyzed without clinical information, this diagnosis was made in 40 percent of 410 abnormal ECGs. The number was reduced to 10 percent, however, when clinical data became available. In the absence of structural heart disease, these changes can be due to a variety of physiologic (i.e., hyperventilation, anxiety, body position, food, neurogenic influences, and temperature), pharmacologic (i.e., antiarrhythmic and psychotropic drugs, digoxin), and extracardiac (i.e., electrolyte abnormalities, upper gastrointestinal processes, allergic reactions, etc.) factors.[45]

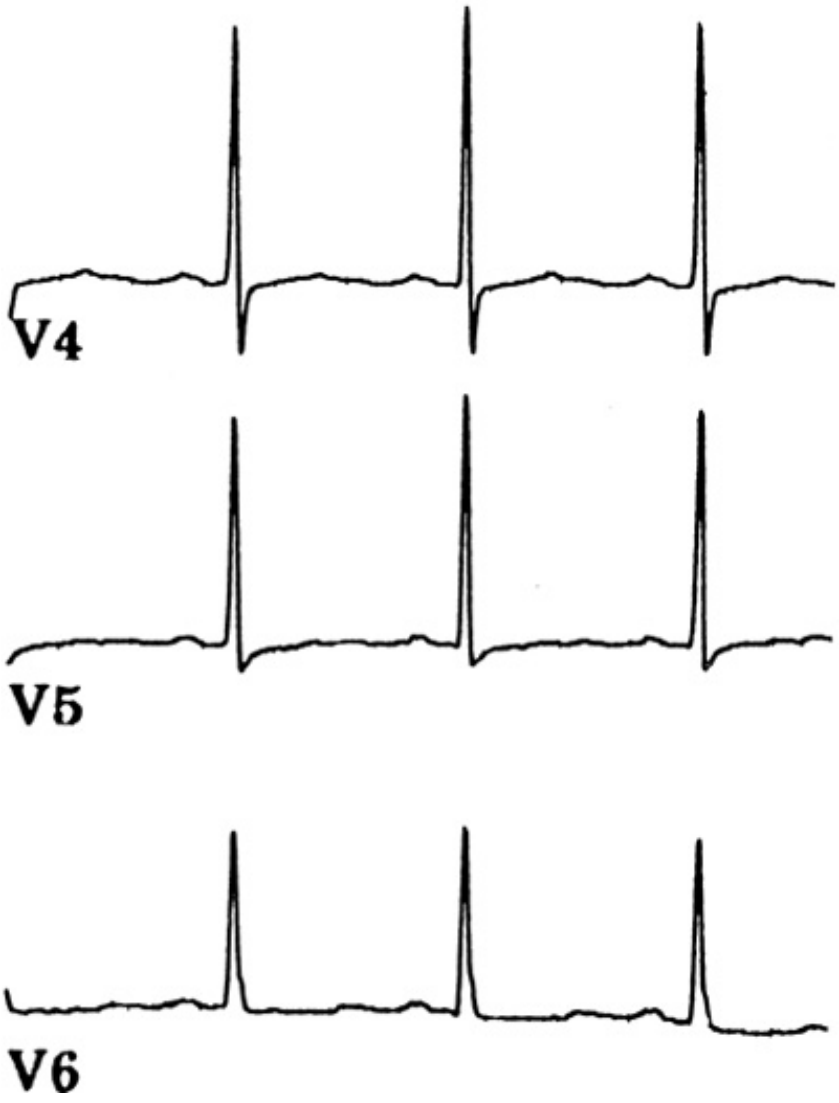

Figure 11-6: Nonspecific (nondiagnostic) ST-segment-T-wave changes, the most common abnormalities in ECG interpretation.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

U WAVE

A number of hypotheses have been advanced to explain the genesis of the U wave. Foremost among them is the relationship to late repolarization of the Purkinje system. A criticism of this hypothesis is that the conducting system does not have sufficient mass to generate a large deflection at the body surface. The recent identification of another population of (M) cells between epicardium and endocardium may provide the necessary mass to produce not only U waves but also the J (or Osborn) wave characteristic of hypothermia.[14] What sometimes appears to be a U wave merging with a T wave simple may be a notched T wave whose ascending or descending limbs are interrupted by differences in the end of the composite action potential of epicardial and M cells.[14] The normal U wave, most prominent in leads V_2 and V_3, has the same polarity as the T wave and is approximately 10 percent of its amplitude. A large positive U wave may be due to hypokalemia and multiple antiarrhythmic drugs. In orthodox ECG interpretation, merging of T and U is still considered a stage in hypokalemia but can result from such drugs as quinidine and sotalol.[14] According to Antzelevitch, repolarization of the His-Purkinje system was first suggested by Watanabe as the most likely cause of the "real" U wave.[14] Causes of negative U waves are ischemia, hypertension, and occasionally, right ventricular enlargement.[45]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

ACUTE MI

Although a recent article challenged this distinction,[36] MIs are no longer classified as transmural and subendocardial but as Q-wave and non-Q-wave.[36,47-50] In the thrombolytic era, the prevalence of the latter seems to be greater than that of the former (see Chap. 42), presumably due to a reduction in infarct size.[42-44] The prethrombolytic "classic" evolution of acute MI has been transformed by pharmacologic therapy and interventional techniques.[49,50] The succession of events in the course of a Q-wave MI is from hyperacute positive T waves (on occasion) to ST-segment elevation to abnormal Q waves to T-wave inversion[49,50] (Figs. 11-7 and 11-8). Commonly, two or more of these findings appear together, depending on the timing of the first recorded static ECG. Acceleration of these phases can occur with effective reperfusion. The time course of ST-segment elevation is a good predictor of reperfusion. Because prethrombolytic 12-lead ECG studies on ST-segment evolutions were based on static recordings obtained at fixed time intervals, it became clear that continuous monitoring in the coronary care unit (which falls outside the realm of this chapter) was essential to adequately record the dynamics of ST-segment trends (Figs. 11-9 and 11-10). Sensitivity increases as frequency of monitoring increases.[51-53] Continuous monitoring is thus essential to evaluate occurrence of reperfusion. Resolution of ST-segment elevation has been defined as a progressive decrease within 40 to 60 min to less than 50 percent of its maximally elevated value.[51,52] It has been suggested that in patients treated with thrombolytics, the dichotomization for Q-wave and non-Q-wave MI should be made by the predischarge, rather than the 24-h, ECG due to possible crossover from one group to another.[54]

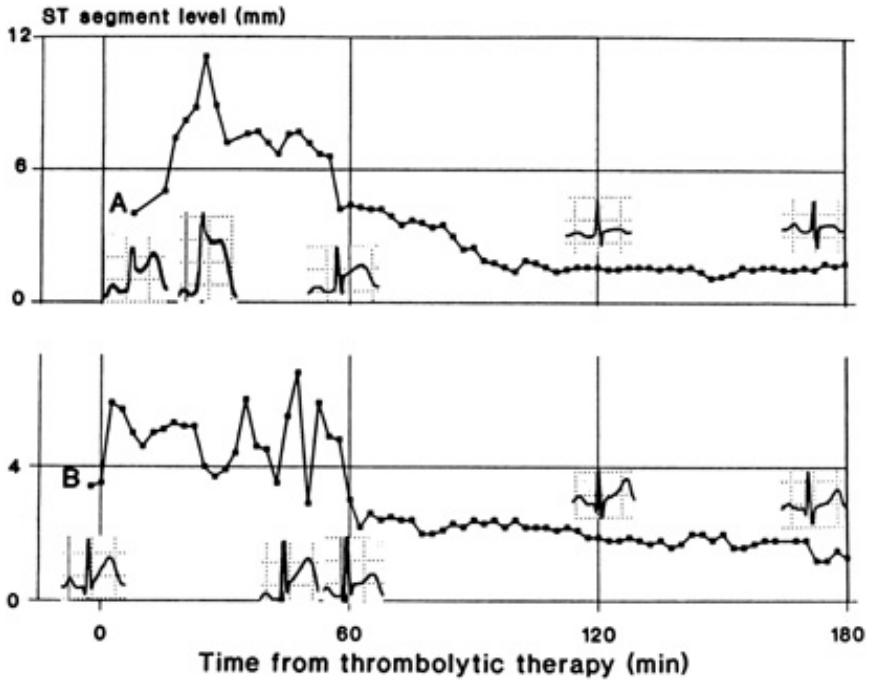

Figure 11-9: Plots of ST-segment levels versus time from therapy in two selected patients with patency of the infarct-related vessel at 60 min. Note that a 50 percent decrease in ST-segment

levels within 60 min occurred only when measurements were made from the peak ST-segment level (highest ST-segment level measurement within the first 60 min).

Aspects of the ECG other than ST-segment changes may be altered particularly during acute, anterior-wall MI. In fact, the same degree of ST-segment elevation in V_2 and V_3 with disappearance of the S waves indicates a greater degree of affectation than with preservation of this negative wave[55] (see Fig. 11-8, *top*).

Chapter 11: THE RESTING ELECTROCARDIOGRAM

LOCATION OF THE SITE OF Q-WAVE MI

Table 11-1 shows an acceptable classification for the ECG location of MI according to leads showing abnormal Q waves. In addition, it depicts other processes that may result in false patterns of Q-wave MI. During the acute phase, ST-segment changes give a clue to the area at risk, but because of the normal variability in coronary anatomy and the presence of previous occlusions, there is sometimes more than one possible explanation for a specific ECG pattern.[55]

Table 11-1: Electrocardiographic Location of Infarction Sites Based on the Presence of Abnormal Q Waves

Site	Leads	False Patterns
Inferior (diaphragmatic)	II, III, aV_F	WPW (PSAP), HCM
Inferolateral	II, III, aV_F, V_4-V_6	
'True' posterior (postero-basal)	V_1*	RVH, 'atypical' incomplete RBBB, Left AP
Inferoposterior	II, III, aV_F, V_1*	WPW (left PSAP), HCM
Inferior-right ventricular	II, III, aV_F plus V_{4R}-V_{6R} or V_1-V_3	ASMI as defined from axis
Anteroseptal	V_1, V_2, V_3	LVH, chronic lung disease, LBBB, chest electrode misplacement
Anterolateral	I, II, V_4-V_6	HCM, ventricular septal defect
Extensive anterior	I, aV_L, V_1-V_6	
High lateral	I, aV_L	
Anterior (apical)	V_3-V_4	
Posterolateral	V_4-V_6, V_1*	WPW (LFWAP)
Right ventricular	V_{4R} with V_{4R}-V_{6R} or V_1-V_3	ASMI

*Tall R wave, 'reciprocal' to changes in 'indicative' back lead.

NOTE: ASMI = anteroseptal myocardial infarction; HCM = hypertrophic cardiomyopathy; LBBB = left bundle branch block; LFWAP = left free-wall accessory pathway; PSAP = posteroseptal accessory pathway; WPW = Wolff-Parkinson-White syndrome; RVH = right ventricular hypertrophy.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

RECIPROCAL ST-SEGMENT CHANGES

In an inferior MI with abnormal ST-segment elevation limited to this wall, the reciprocal ST-segment changes will occur in diametrically opposed leads located in the *same* plane. For example, "indicative" ST-segment elevation in leads III and aV_F,which record the electrical activity of the inferior (posteroinferior or diaphragmatic) wall, yields "reciprocal" ST-segment depression in leads I and aV_L because they face the superior (anterolateral) wall[11,56,57] (see Fig. 11-3). ST-segment depression in lead V_2 may reflect injury in the anterior subendocardial wall as well as injury in the posterobasal (or true) posterior wall.[10] The ECG by itself cannot distinguish with absolute certainty between these two possibilities.[10] The differential diagnosis perhaps can best be made by performing cardiac catheterization or radionuclear studies in the acute phase of the MI, when the ST-segment changes are still present. Another way is by analyzing ST-segment changes occurring during percutaneous transluminal coronary angioplasty in patients with proven single-vessel disease.[58,59] This has shown that reciprocal ST-segment depression in leads V_2 and V_3 can occur during balloon occlusions of dominant right, as well as of dominant left, coronary arteries.[59]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

RIGHT VENTRICULAR MI

According to Braat et al.,[60] an ST-segment elevation of at least 1 mm in lead V_{4R} in patients with *acute inferior MI* had a sensitivity of 100 percent, a specificity of 87 percent, and a predictive accuracy of 92 percent for the diagnosis of right ventricular infarction in patients with ST-segment elevation in leads II, III, and aV_F (see Fig. 11-3). These changes disappeared within 10 to 18 h after the onset of chest pain in 50 percent of their patients and after 72 h in the remaining patients.[60] In addition to V_{4R}, ST-segment elevation can be seen in leads V_5 and V_{6R} and in some cases (with decreasing amplitude) in V_1, V_2, and even V_3. It is possible for ST-segment depression in V_5 and V_6 to be reciprocal to right ventricular involvement (see Fig. 11-3).

Chapter 11: THE RESTING ELECTROCARDIOGRAM

PERICARDITIS

The ECG pattern of acute (generalized) pericarditis not due to MI is produced by the associated epimyocarditis, which in turn results in diffuse epicardial "injury."[6] The ST segments can be elevated in all leads except aV_R and, rarely, in V_1 (Fig. 11-11). Symmetric T-wave inversion (due to epicardial "ischemia") usually develops after the ST segments have returned to the baseline (but can appear during the injury stage).[6] Neither reciprocal ST-segment changes nor abnormal Q waves are seen. In most cases of acute pericarditis, the PR segment is depressed (see Fig. 11-11). Average ECG resolution occurs in close to 2 weeks.[11] The ECG pattern of acute pericarditis has to be differentiated from the normal variant referred to as *early repolarization* (see Fig. 11-4).

Chapter 11: THE RESTING ELECTROCARDIOGRAM

FASCICULAR BLOCKS

Generalities

There are several ways of proving that a given QRS pattern is due to a specific type of conduction abnormality.[15,57,61] First is extrapolation from animal experiments.[15,61] Second is ECG-pathologic correlation.[15,61] Third is an analysis of **QRS** changes produced by the inadvertent section of the conduction fascicles during open heart surgery or catheter-induced trauma.[62] Fourth is a comparison of tracings obtained before, during, and after the appearance or disappearance of conduction disturbances that are either persistent or (spontaneously or iatrogenically) intermittent. Under such circumstances, the QRS changes produced by fascicular block occur side by side with the control morphologies.[8,15,6162-63] The various criteria proposed for diagnosis of fascicular blocks, though empirical, have been accepted for a very pragmatic reason: the need to interpret clinical ECGs. In reality, the sensitivity and specificity of these criteria require independent confirmation.[61,64] One can speculate that the latter may be provided by newer methods of intraoperative and body surface mapping and refinements in the technique of phase imaging or even perhaps Carto mapping, since few centers in the United States are currently performing histopathologic studies of the distal intraventricular conduction system.

Left Anterior Fascicular Block

In left anterior fascicular block (LAFB), the posteroinferior regions of the LV endocardium are activated abnormally before the anterosuperior LV area.[8,15] After emerging from the posteroinferior division of the left bundle branch, the impulse first propagates in an inferior, rightward, and usually anterior direction for a short period of time, producing q waves in leads I and aV_L and r waves in leads II, III, and aV_F (see Fig. 11-12). Thereafter, the general direction of the activation process (which determines the direction of the EA) occurs in a superior and leftward direction. Consequently, from the ECG viewpoint, the fascicles of the left branch behave more as if they were "superior" and "inferior" rather than "anterior" and "posterior" (Figs. 11-12 and 11-13). For this reason, the most significant abnormalities produced by LAFB, in the absence of complete right bundle branch block (RBBB), occur in the standard and unipolar extremity leads rather than in the precordial leads[8,15] (see Figs. 11-12 and 11-13). S waves frequently are recorded V_5 and V_6 because the depolarization wave first moves towards them and later, because of their relatively low position, away, in a more superior direction. The degree of left-axis deviation required for the diagnosis of complete LAFB has been a subject of debate and speculation.[8] It should be remembered that LAFB is but one of the causes of left-axis (superior and leftward) deviation (Table 11-2). Criteria for the diagnosis of pure LAFB are presented in Table 11-3,[864-68] and illustrative examples are shown in Figs. 11-12 and 11-13. When LAFB coexists with certain congenital types of right ventricular enlargement and extensive anterolateral MI, the EA can be shifted to the "undeterminate" (right superior) quadrant. Thus the constant feature of the axis deviation produced by LAFB is its *superior* orientation, not its superior and leftward orientation (abnormal left-axis deviation).[61] Because of the multiple interconnections between the fascicles of the left bundle branch system, the appearance of LAFB does not increase QRS duration by more than 0.025 s.[8] Therefore, a LAFB pattern with a wider QRS complex generally indicates the presence of additional conduction disturbances such as RBBB (Fig. 11-14, *top*), MI, or intraventricular conduction delays due to free wall fibrosis. Masquerading RBBB is said to be present when (with the classic findings in lead V_1) lead I shows what seems to be a left bundle branch block (LBBB) due to the absence of q and S waves (see Fig. 11-14, *bottom*). This pattern has been attributed to a terminal delay perpendicular to lead I associated with diffuse intramyocardial fibrosis.[15]

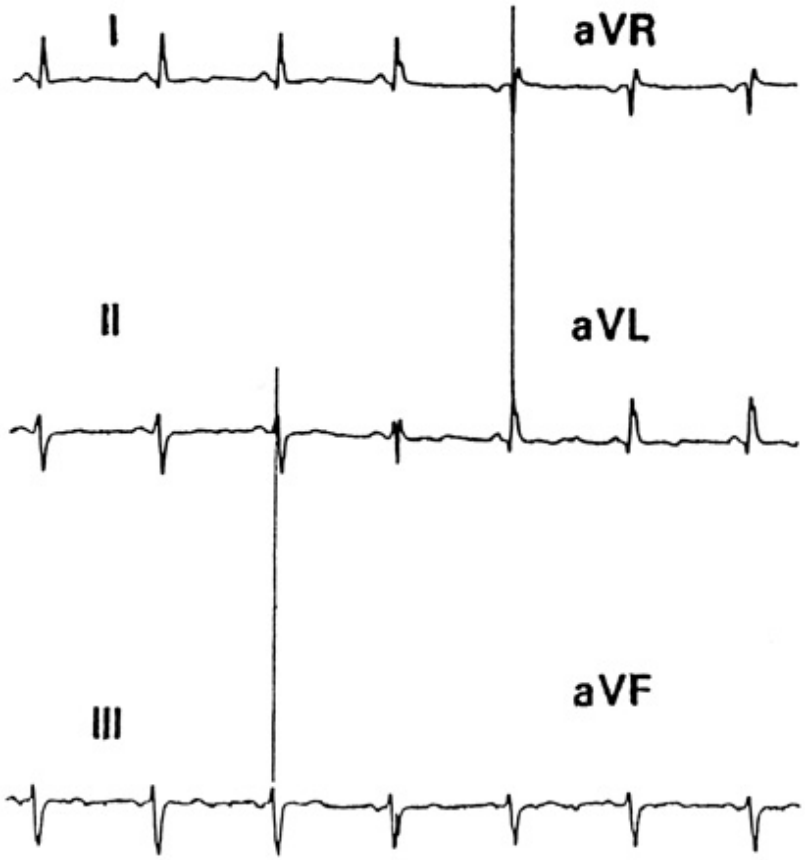

Figure 11-12: LAFB in a patient with primary conduction system disease. QRS duration: 0.10 s. At normal paper speeds (25 mm/s), the relationship between the peaks of the R waves (*vertical lines*) in simultaneously recorded leads II and III and aV_L and aV_R cannot be determined with the desired accuracy (see Fig. 11-13).

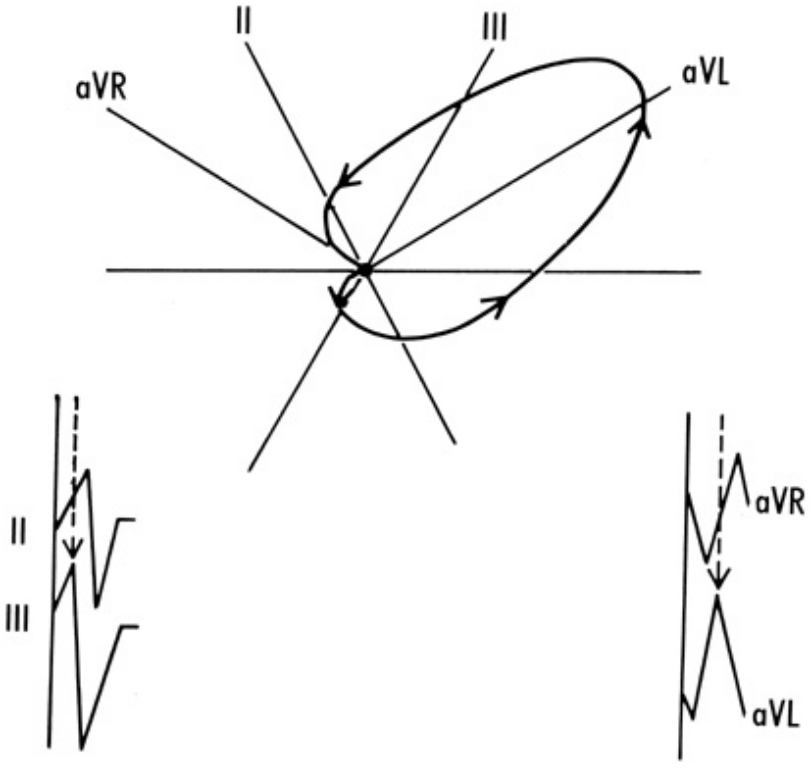

Figure 11-13: Derivation of electrocardiographic leads from a frontal plane QRS loop showing LAFB. Due to the counterclockwise rotation of the left superior loop, the peak of the R in aV_L preceded the peak of this deflection in aV_R (lower right). Furthermore, because the initial portion of the loop was inscribed on the positive half of the axis of lead III before it was inscribed on the positive half of the axis of lead II, the peak of the R in the former lead occurred before that in the latter lead. (From Castellanos A, Pina L, Zaman L, et al. Recent advances in the diagnosis of fascicular blocks. *Cardiol Clin* 1987; 5:469-488. Reproduced with permission from the publisher and authors.)

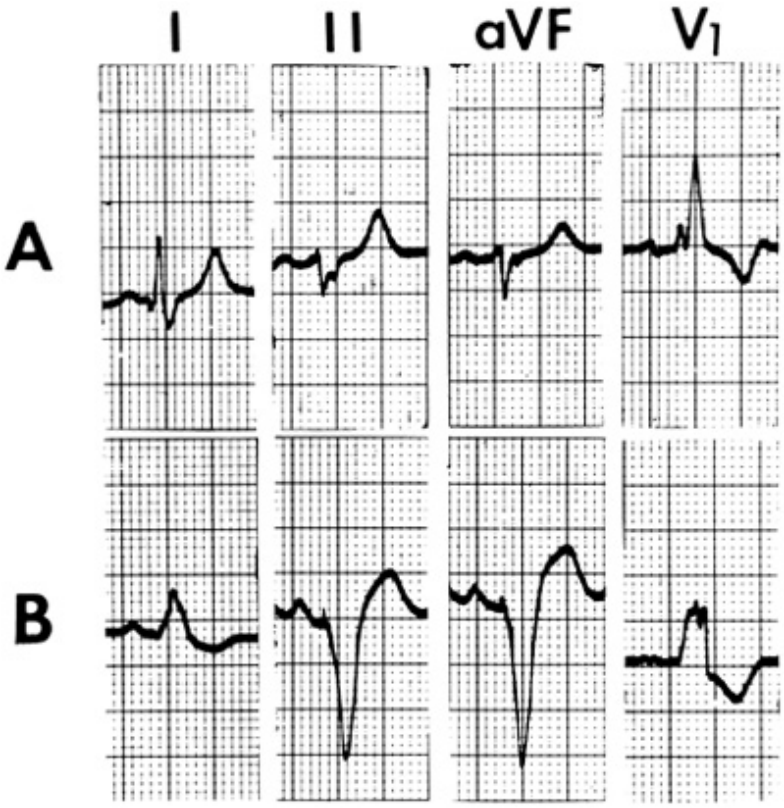

Figure 11-14: LAFB with wide QRS complexes. Whereas panel *A* shows LAFB with RBBB, these conduction disturbances coexist with diffuse septal and inferoposterior fibrosis in panel *B*. Consequently, the expected small q wave and the wide S wave in lead I are not present. This pattern has been called "masquerading" bundle branch block because the standard leads suggest LBBB, while the chest leads are diagnostic of RBBB.

Table 11-2: Causes of Abnormal (-30° to -90°) Left-Axis Deviation

Cause	Characteristic Features
1. Left anterior fascicular block	1. rS complexes in lead II with positive T waves
2. Extensive inferior wall (AC5)MI	2. Qr complexes in lead II with ST-segment elevation and/or T-wave inversion
3. Extensive inferior wall MI with possible (AC7)LAFB	3. QS pattern in leads II, III, and aV_F with ST-segment elevation and/or T-wave inversion
4. Wolff-Parkinson-White syndrome (posteroseptal accessory pathway)	4. Short PR interval; delta wave
5. Hyperkalemia	5. Wide QRS complexes; peaked T waves

6. Pulmonary emphysema	6. Low voltage; peaked P waves, S waves in standard and precordial leads
7. Right ventricular apical pacing	7. Pacemaker spikes; predominantly negative ventricular deflections in V_1
8. Middle cardiac vein pacing	8. Pacemaker spikes; predominantly positive QRS deflections in V_1
9. Left coronary arteriography	9. Knowledge that dye was injected in left coronary artery

Left Anterior Fascicular Block Coexisting with MI

The ECG changes imposed by MIs of different locations on the LAFB are shown in Fig. 11-15. An inferior wall MI can be masked by a LAFB if the infarction does not involve the areas first depolarized by the impulse emergency from the unaffected fascicle.[8] In these cases, an r (slurred or not) can be seen in leads III and aV_F. It also has been stated that the change in left septal activation produced by the fascicular block may produce small r waves in V_1, V_2, and V_3 capable of modifying the characteristics QS complexes produced by anteroseptal MI in these leads.[8]

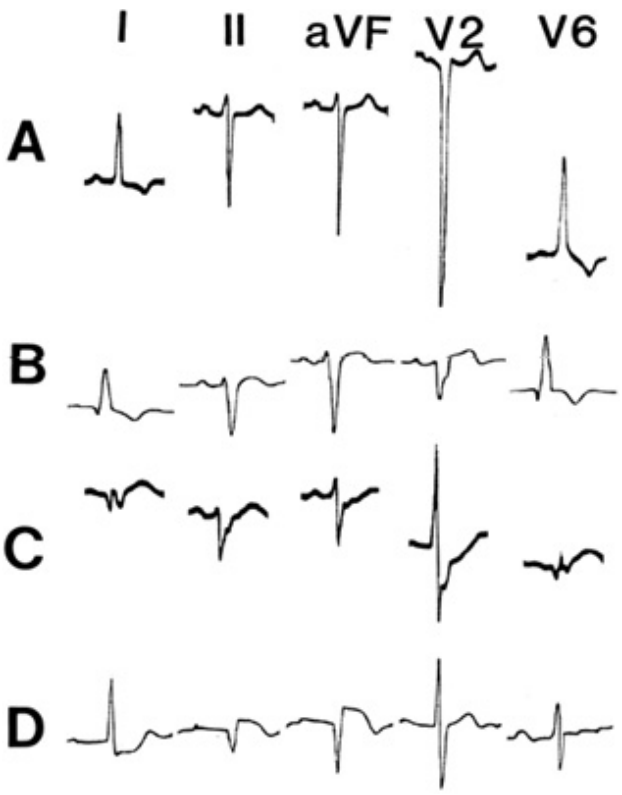

Figure 11-15: Diagnosis of LAFB associated with MI. Diagnostic feature given in parentheses. *A*. LAFB and anteroseptal MI (QR or QS complex in right chest leads). *B*. LAFB and anterolateral MI (abnormal Q wave in leads I and V_6). *C*. LAFB and anterolateral MI with electrical axis in the right superior quadrant (Q wave in leads I and V_6). *D*. LAFB and inferior wall MI (QR or QS complexes and elevation of J point and ST segments in leads II and III).

Nonspecific Intraventricular Conduction Delays

Several names have been applied to the conduction disturbances occurring in the left-sided Purkinje-myocardial junctions, left septal surface, or free wall of the left ventricle: *arborization block*, *diffuse (nonspecific) intraventricular block*, *peri-infarction block*, *parietal block*, *focal block*, etc.[8,66-75] These conduction disturbances have different electrogenetic mechanisms. Thus the cellular "affectation" due to acute injury resulting from coronary artery disease, hyperkalemia, drugs, and intracoronary injections of contrast material occurs within (inside) the affected regions.[5,15,75] Blocks occurring in subacute or chronic MI after the appearance of abnormal Q waves (peri-infarction block) (Fig. 11-16), as well as those occurring in the presence of diffuse myocardial fibrosis (Fig. 11-17), are due to the circuitous and irregular activation of living cells surrounding areas of fibrotic tissue.[68-75]

Left Posterior Fascicular Block

In pure left posterior fascicular block (LPFB), the impulse emerges from the unblocked anterosuperior division, thus producing small q waves in leads II, III, and aV_F.[8,15] Thereafter, the impulse moves through the electrically predominant left ventricle in an inferior and rightward direction, thus explaining the S waves in leads I and aV_L as well as the R waves in leads II, III, and aV_F.[8,15] Radiologic studies of the human heart in situ have shown that the paraseptal regions of the posteroinferior (diaphragmatic) surface of the anatomic *left* ventricle are spatially located more to the *right* than certain (anterior) portions of the anatomic right ventricle.[15] Since the portions of the left ventricle that are spatially located to the right are less than those located superiorly, the degree of right-axis deviation produced by pure LPFB is of lesser magnitude than that of left-axis deviation produced by LAFB.[15] The hallmark of LPFB, therefore, is an "inferior" axis shift as much as "right" axis deviation (Figs. 11-18 to 11-20). Because a similar sequence of ventricular activation also can occur in right ventricular hypertrophy, pleuropulmonary disease (acute or chronic), and extremely vertical anatomic heart positions due to a slender body build or chest wall

deformities, it is evident that the diagnosis of "pure" LPFB cannot be made from the ECG alone. Additional clinical, radiologic, or pathologic information is required for this purpose.[8,15,61,66] The changes imposed in LPFB by MIs of different locations are depicted in Figs. 11-18 to 11-20.

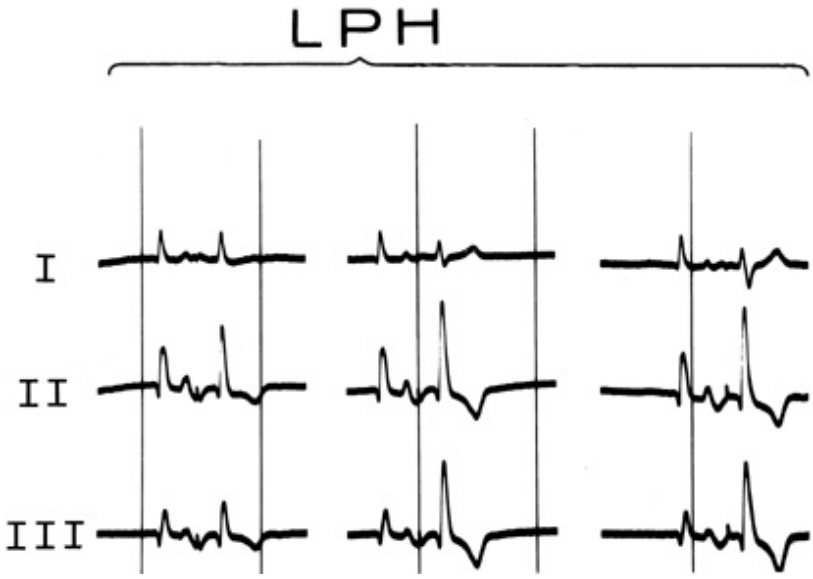

Figure 11-18: Premature atrial beats showing increasing degrees of (incomplete and complete) LPFB aberration. The first beats in all panels are escape beats with the same morphology as that of sinus beats. The second, aberrantly induced ventricular complexes show different degrees of right-axis shift with an increase in size of the R waves in leads II and III. Note that the fundamental characteristic of LPFB was not right-axis deviation (beyond +90°) but an inferior-axis shift. (From Castellanos A, Myerburg RJ. *The Hemiblocks in Myocardial Infarction*. New York: Appleton-Century-Crofts; 1976. Reproduced with permission from the publisher and authors.)

Left Fascicular Blocks Produced by Intra-His Bundle Lesions

Rosenbaum et al.[8] attributed surgically induced LAFB (coexisting with RBBB) to a lesion of the "pseudobifurcating" part of the His bundle. The production of LBBB and LPFB by catheters located in the right-sided cavities, however, cannot be explained by assuming direct affectation of these left-sided structures.[76,77] Nevertheless, they have been reported and attributed to the His bundle trauma produced by Swan-Ganz catheters.[76,77] In fact, certain clinical and experimental studies have shown that some bundle branch block patterns could be normalized by distal His bundle pacing.[78] Longitudinal dissociation of conduction within a usually diseased His bundle should be present for this to occur. There is, however, disagreement as to the mechanism involved, especially in regard to the predestination of fibers (within the His bundle) to specific right- or left-sided structures and to the role played by the transverse fibers connecting the various longitudinal strands.[77-80]

Left-Middle (Septal) Fascicular Blocks

This disorder has been demonstrated anatomically and is associated with ischemic heart disease and fibrosis of the middle (septal) fascicle of the left branch.[81,82] While some authors consider that the right precordial leads show prominent R waves (similar to those found in true posterior, basal, myocardial infarction), others have described Q waves in leads V_1, V_2, and V_3.[81,82] It also has been considered that left-middle (septal) fascicular blocks are manifested by the absence of the expected q waves in leads V_5 and V_6 in ECG intermediate or horizontal hearts. Such a diversity of diagnostic criteria shows that there are marked discrepancies regarding the ECG characteristics of this conduction disturbance. Recently, Dhala et al.[83] described what they considered as the unmasking of the trifascicular conduction system by catheter ablation of the right bundle branch with a diseased left intraventricular conduction system. In these cases, ablation-

induced damage to "predestined" fibers in a diseased His bundle cannot be totally excluded.

Complete RBBB

A "complete" RBBB pattern (with QRS duration of ≥0.12 s) does not necessarily reflect the existence of a total conduction block in the right branch. This pattern only indicates that the entire or major parts of both ventricles are activated by the impulse emerging from the left branch.[15,84,85] Thus a significant degree of conduction delay ("high grade" or "incomplete" RBBB) can produce a similar pattern. In pure complete RBBB, the EA should not be deviated *abnormally* either to the left or to the right. These axis deviations reflect coexisting fascicular block (see Figs. 11-14 and 11-19) or right ventricular hypertrophy.

Incomplete RBBB Pattern

For many years what has been proven with endocardial (catheter) and epicardial mapping has been recognized-namely, that incomplete RBBB "patterns" can be produced by various mechanisms[84-90]: (1) different degrees of conduction delays through the main trunk of the right bundle branch, (2) an increased conduction time through an elongated right bundle branch that is stretched because of a concomitant enlargement of the right septal surface, (3) a diffused Purkinje-myocardial delay due to right ventricular (RV) stretch or dilatation, (4) surgical trauma or disease-related interruption of the major ramifications of the right branch ("distal" RBBB), or (5) congenital variations of the distribution of the major distal ramifications resulting in a slight delay in activation of the crista supraventricularis.[6] In arrhythmogenic RV dysplasia, the S wave in V_1 is followed by a sharp, wide, positive deflection (epsilon wave; Fig. 11-5*B*) attributed to delayed ventricular activation (postexcitation) in some RV myocardial fibers.[39] Wide QRS complexes in this lead (wider than in other precordial leads) were attributed to a "parietal" block superimposed on a RBBB.[35]

Concealed RBBB

A minor conduction delay in the main trunk of the right bundle branch or in its major ramifications may be "concealed" (not manifested in the surface ECG) when there are coexisting (and of greater degree) conduction disturbances in the main left bundle branch, the anterosuperior division of the left bundle branch, and/or the free LV wall.[8,15] An RBBB also can be concealed in some patients with Wolff-Parkinson-White syndrome if the ventricular insertion of the accessory pathway causes preexcitation of the RV regions that would be activated late because of the RBBB.[91]

Complete LBBB

This conduction disturbance is characterized by wide (>0.11 s) QRS complexes. The diagnostic criteria consist of prolongation of the QRS complexes (>0.11 s) with neither a q nor an S wave in leads I, aV_L, and a *properly placed* V_6. A wide R wave with a notch on its top ("plateau") is seen in these leads. Apparently, the EAs of most *uncomplicated* complete LBBBs usually are not located beyond 30°.[8,15,16] Complete LBBB with abnormal left-axis deviation indicates a great degree of left Purkinje and myocardial disease.

Complete LBBB with Acute MI

The classic pattern of LBBB may not be modified by a small area of myocardial necrosis. This explains why thrombolytics may be given if clinical findings characteristic of MI occur in patients with a LBBB pattern. Recent studies, however, have shown that occlusions of a coronary artery by either an angioplasty balloon or (a presumably large) MI can produce ST-segment changes as in the absence of a conduction disturbance.[112] Recently, Sgarbossa[92] has suggested that ST-segment elevation of 1 mm or more concordant with QRS polarity has a high specificity and sensitivity. ST-segment elevation of 5 mm or more discordant with QRS polarity, ST-segment depression of 1 mm or more in V_1, V_2, and V_3, and (sudden) positive T waves in V_4 and V_5 have a high specificity but a low sensitivity. The latter can occur transiently during acute ischemia (pseudonormalization) without myocardial necrosis or be persistently present in

cases where its significance is unclear. Examples of LBBB complicated by acute anterior and inferior MI are shown in Figs. 11-21 and 11-22. The above-mentioned criteria also can be applied to diagnose acute MI in patients with pacemakers.[92,93]

Complete LBBB with Old MI

Normally, in complete LBBB, the impulse emerges from the right bundle branch and propagates inferiorly, to the left, and slightly anteriorly. This orientation of the initial forces tends to abolish previously present inferiorly and laterally located abnormal Q waves characteristic of inferior and lateral wall MIs.[15,93,94] If the infarction is anteroseptal, however, the impulse cannot propagate toward the left. Instead, the initial vectors point toward the free wall of the right ventricle because now the RV free-wall forces are not neutralized by the normally preponderant septal and/or initial LV free-wall forces.[15] Thus a small q wave will be recorded in leads I, V_5, and V_6, where it is not normally present in complete LBBB (Fig. 11-23*A*). For a recent review of this subject, see Ref. 92. Similar findings can be seen in paced beats when in lead I the spike is followed by a well-defined q wave (see Fig. 11-23*B*). Several studies reported that Q waves in lead I or in two or more lateral leads (I, aV_L or V_5 and V_6) have high specificity but moderate sensitivity.[92] The sign of Cabrera and Friedland (late notching of S waves in V_3 through V_5) has been found to have higher to moderate specificity and moderate to low sensitivity.[94] Notching of the upstroke of the R wave in leads I, aV_L, V_5, and V_6 (sign of Chapman) has a sensitivity of 21 percent and a specificity of 82 percent.[94]

Complete LBBB with LV Hypertrophy

This is discussed under "LV Hypertrophy," below.

Incomplete LBBB Pattern

An incomplete LBBB pattern can be diagnosed if leads I and an *appropriately placed* V_6 show an R wave not preceded by a q wave.[6] Lead V_1 shows rS or QS complexes, and lead V_2 shows rS complexes. Although QRS duration usualy ranges between 0.08 and 0.11 s, this *pattern* can be observed with QRS durations of 0.12 and 0.13 s.

Wide QRS Complexes in Patients with Manifest Preexcitation Syndromes

The characteristic pattern of manifest Wolff-Parkinson-White syndrome during sinus rhythm is well known.[95-103] The ventricular complex is a fusion beat resulting from ventricular activation by two wave fronts.[116-126] The degree of preexcitation (amount of muscle activated through the accessory pathway) is variable and depends on many factors. Foremost among these are the distance between the sinus node and atrial insertion of the accessory pathway and, more important, the differences in refractory period duration and in conduction time through the normal pathway and the accessory pathway. Other things being equal, a patient with rapid (enhanced) AV nodal conduction will have a smaller delta wave than a patient with slow conduction through the AV node. Moreover, if there is total block at the AV node or His-Purkinje system, the impulse will be conducted exclusively via the accessory pathway bundle.[96,99-101] Consequently, the QRS complexes are different from fusion beats, although the direction of the delta wave remains the same. Moreover, the QRS complexes are as wide as (and really simulating) those produced by artificial or spontaneous beats arising in the vicinity of the ventricular end of the accessory pathway.[96,99-101] The original ECG classification of manifest Wolff-Parkinson-White syndrome proposed by Rosenbaum et al.[97] is now of historical interest only. Nevertheless, initial noninvasive determination of the anatomic position of the accessory pathway is of great clinical importance because of the introduction of surgical and catheter ablative techniques for symptomatic cases of preexcitation.

Toward the end of the millennium, Basiouny et al.[104] reported that there were 41 publications dealing with methods for localizing the accessory pathways of patients with preexcitation syndrome. Of these, they analyzed what they considered the most important algorithms available for this purpose. The interested

reader can consult this article.[104] For the purposes of this chapter and due to space limitations, we will refer to the pioneer study of Milstein et al.,[102] who analyzed the direction of the delta wave and divided the mitral and tricuspid ring areas where the pathways are located into various segments. These investigators considered that only four segments were necessary. This appeared logical, for at the time that this method was proposed, most ablations were performed surgically.[102,103] Left free-wall accessory pathways are characterized by isoelectric and even positive delta waves in leads I, aV_L, V_5, or V_6. Lead V_1 shows R or Rs complexes (Fig. 11-24). During sinus rhythm, the electrical axis may be normal, but when atrial fibrillation develops and exclusive accessory pathway conduction occurs, the EA is deviated to the right and inferiorly (see Fig. 11-24). Posteroseptal accessory pathways show negative delta waves in leads III and aV_F and R waves in V_2. An Rs (or RS) wave in V_1 suggests a left posteroseptal pathway; a QS complex in the same lead may correspond to a right posteroseptal pathway (Fig. 11-25). Right free-wall accessory pathways display an LBBB pattern defined, for purposes of accessory pathway localization, by an R wave greater than 0.09 s in lead I and rS complexes in leads V_1 and V_2 with an electrical axis ranging between +30 and -60° (Fig. 11-26).

Right anteroseptal accessory pathways show an LBBB pattern (as defined) with an electrical axis ranging between +30 and +120° (Fig. 11-27). A q wave may be present in lead aV_L but *not* in leads I and V_6. Mixed patterns resulted from the existence of two separate accessory pathways.

Since accessory pathways can traverse almost any part of the atrioventricular annulus, this classification is obviously insufficient when catheter ablation is contemplated. As mentioned earlier, multiple algorithms have been proposed. Since the most useful are complex, electrocardiographers find them difficult to memorize. They are also not completely satisfactory, since smaller degrees of preexcitation seem to limit diagnostic accuracy, and the polarity of delta waves [positive, biphasic (+ or -), negative, and isoelectric] has to be properly categorized. Figure 11-28 illustrates a useful algorithm to predict accessory pathway location from the 12-lead ECG.[105]

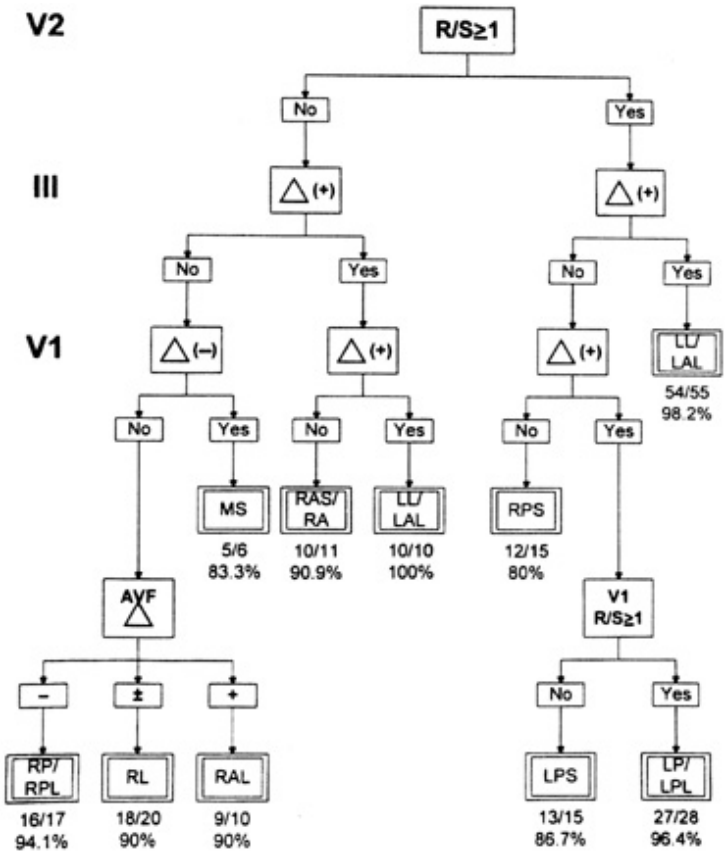

Figure 11-28: Useful algorithm to predict accessory pathway location from the 12-lead ECG. Step 1:

Analysis of R/S ratio in V_2. Step 2: Existence of positive (+) delta wave in lead III (initial 40 ms). Step 3: Existence of positive or negative (-) delta wave in V_1 (initial 60 ms). Step 4: Delta-wave polarity in aV_F (initial 40 ms) or analysis of R/S ratio in V_1 (± = biphasic or isoelectric). The accuracy of the algorithm for each location in 187 prospective patients is also shown at the bottom. LAL, left anterolateral; LL, left lateral; LP, left posterior; LPL, left posterolateral; LPS, left posteroseptal; MS, midseptal; RA, right anterior; RAL, right anterolateral; RAS, right anteroseptal; RL, right lateral; RP, right posterior; RPL, right posterolateral; RPS, right posteroseptal. (From Chiang et al.[105] Reproduced with permission from the publisher and authors.)

Wide QRS Complexes Produced by Ventricular Pacing from Different Sites

In determining the location of the stimulating electrodes, one should take special care not to consider that the distortion produced by large unipolar spikes constitutes parts of the pacing-induced QRS complexes. It is best *not* to describe the electrically produced ventricular beats as having an RBBB or LBBB morphology, since what is relevant is the polarity of the *properly positioned* V_1 and V_2 electrodes and the direction of the EA[106,107] (Fig. 11-29). For example, endocardial or epicardial stimulation of the *anteriorly* located right ventricle at any site [apical (inferior), or mid/outflow tract (superior)] yields predominantly negative deflections in the right chest leads due to the *posterior* spread of activation (first and second vertical rows in Fig. 11-29). The reverse (positive deflections in V_1 and V_2) occurs when the epicardial stimulation of the superior and lateral portions of the posterior left ventricle by catheter electrodes in the distal coronary sinus or great and middle cardiac veins (or by implanted electrodes in the nearby muscle) results in *anteriorly* oriented forces (third and fourth vertical rows in Fig. 11-29). Right ventricular apical pacing may produce positive deflections in V_1 if this lead is (mis)placed above its usual level. On the other hand, *superior* deviation of the electrical axis only indicates that a spatial *inferior* ventricular site has been stimulated, regardless of whether this site is the apical portion of the right ventricle or the inferior part of the left ventricle, the latter being paced through the middle cardiac vein (first and fourth vertical rows in Fig. 11-29). Conversely, an *inferior* vertical axis is simply a consequence of pacing from a *superior* site, which can be the endocardium of the RV outflow tract or the epicardium of the posterosuperior and lateral portions of the left ventricle (second and third vertical rows in Fig. 11-29). The changes produced on the basic ECG patterns of paced beats produced by MI were briefly discussed in the section of LBBB and MI. The method discussed above to locate the site of impulse initiation during pacing is simpler than the more complicated ones used to determine the ventricular sites of exit from accessory pathways (crossing the AV junction), which require the use of right anterior oblique and, specially, left anterior oblique projections. The currently used nomenclature for accessory pathway location was discussed recently and challenged by a group of notable experts in the field of preexcitation.[108]

Figure 11-29: QRS changes (location of the electrical axis and polarity of lead V_1) produced by pacing from right ventricular apex (RVA), right ventricular outflow tract (RVOT), great cardiac vein (GCV), and middle cardiac vein (MCV).

Left Atrial Hypertrophy

Munuswamy et al.,[109] using M-mode echocardiography as the "gold standard," evaluated the specificity and sensitivity of the most important clues for determining left atrial hypertrophy. These included (1) P wave duration greater than 0.11 s and notched P wave with an interpeak interval in excess of 0.04 s and (2) negative phase of P in V_1 longer than 0.04 s and greater than 1 mm in lead V_1. There are, however, problems when applying these criteria in a given ECG. For example, according to Josephson,[110] prolonged duration of the P wave and of (posteriorly directed) terminal forces reflected delayed left atrial activation, not left atrial enlargement. In fact, most criteria mentioned above also apply for intraatrial block. Moreover, a negative P wave in lead V_1[110] may reflect improper (high) placement of this lead, a common error made by ECG technicians. Generally, if the previously mentioned findings are found in patients with LV enlargement or mitral stenosis, left atrial hypertrophy is most likely present, but in their absence, such findings usually indicate an intraatrial conduction defect. In any case, the ECG pattern of left atrial hypertrophy results from a hypertrophy-induced (stretching) intraatrial conduction delay.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

LV HYPERTROPHY

As emphasized by Surawicz,[111] since the advent of other noninvasive techniques, there has been a changing role for the ECG in the diagnosis of ventricular hypertrophy. Necropsy studies have exposed the superiority of echocardiography (see Chap. 13) with respect to electrocardiography to detect LV hypertrophy.[111] Echocardiography is also a better method for the serial follow-up of changes during progression or regression of LV hypertrophy. Multiple criteria have been proposed to diagnose LV hypertrophy using necropsy or echocardiographic information[49,112-115] (Tables 11-4 and 11-5). Of these, the Sokolow-Lyon criterion (SV_1 + RV_{5-6} ≥35 mm) is the most specific (>95 percent) but is not very sensitive (≈45 percent) (see Table 11-4). The Romhilt-Estes score has a specificity of 90 percent and a sensitivity of 60 percent in studies correlated with echocardiography. The following are some of the other criteria[49]: The Casale (modified Cornell) criterion (Ra_{VL} + SV_3 >28 mm in men and >20 in women) is somewhat more sensitive but less specific than the Sokolow-Lyon criterion.[116] The Talbot criterion[117] (R ≥16 mm in a_{VL}) is very specific (>90 percent), even in the presence of MI and ventricular block, but not very sensitive. The Koito and Spodick criterion[118] (RV_6 > RV_5) claims a specificity of 100 percent and a sensitivity of more than 50 percent. According to Hernandez Padial,[119] a total 12-lead QRS voltage of greater than 120 mm is a good ECG criterion of LV hypertrophy in systemic hypertension and is better than those most frequently used. With echocardiography as the "gold standard," several authors postulated ECG criteria for diagnosis of LV hypertrophy in the presence of complete LBBB and LAFB[120,121] (Tables 11-6 and 11-7). The high sensitivity and specificity reported by Gertsch et al.[121] for diagnosis of LV hypertrophy with LAFB have not been corroborated in preliminary studies performed in our department (unpublished observations; nevertheless indicated in Table 11-7).

Table 11-4: Electrocardiographic Criteria for Left Ventricular Enlargement

	SENSITIVITY		
Specificity Accuracy Voltage Criteria	(%)	(%)	(%)
RI + S_{III} > 25 mm	10.6	100	55
RVL > 7.5 mm	22.5	96.5	59.5
RVL > 11 mm	10.6	100	55
RVF > 20 mm	1.3	99.5	50
SV_1 + RV_{5-6} > 35 mm (Sokolow-Lyon)	55.6	89.5	73
In V_1-V_6, the tallest S + the tallest R > 45 mm	45	93	69
RV_{5-6} > 26 mm	25	98	62

Chapter 11: THE RESTING ELECTROCARDIOGRAM

PROCESSES PRODUCING OR LEADING TO RV HYPERTROPHY AND ENLARGEMENT

RV hypertrophy is manifest in the ECG only when the RV forces predominate over those of the left ventricle. Since the latter has, roughly, three times more mass than the former, the right ventricle may double in size (when the left ventricle is normal) or triple its weight (when there is significant LV hypertrophy) and still not result in the necessary requirements to pull the electrical forces anteriorly and to the right. For these reasons, RV hypertrophy cannot be recognized easily in adult patients. Despite these limitations, the ECG manifestations of RV hypertrophy or enlargement can be subdivided into the following main types[1] (see Figs. 11-11, 11-12, and 11-16): (1) the posterior and rightward displacement of the QRS forces associated with low voltage, as seen in patients with pulmonary emphysema (Fig. 11-30), (2) the incomplete RBBB pattern *with right-axis deviation* occurring in patients with chronic lung disease and some congenital cardiac malformations resulting in volume overloading of the right ventricle (Fig. 11-31), (3) the true posterior wall MI pattern with normal to low voltage of the R wave in V_1 of mitral stenosis (Fig. 11-32), and (4) and the classic RV hypertrophy and strain pattern seen in young patients with congenital heart disease (producing pressure overload) or in adult patients with high-pressure ("primary" pulmonary) hypertension (Fig. 11-33). False patterns of RV hypertrophy may occur in patients with true posterior (basal) MI, complete RBBB with LPFB, and Wolff-Parkinson-White syndrome resulting from AV conduction through left free wall or posteroseptal accessory pathways.

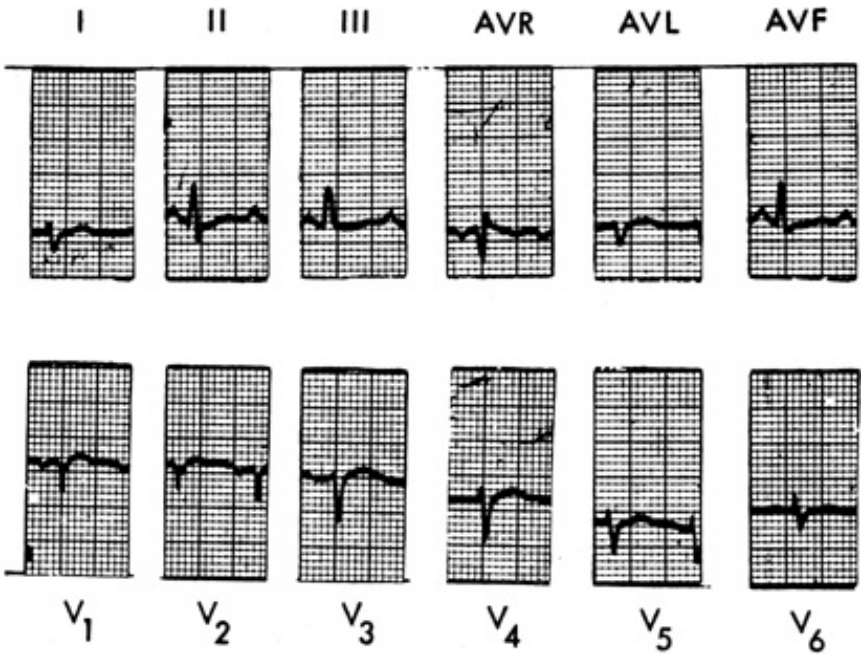

Figure 11-30: ECG taken on a patient with pulmonary emphysema showing slight right-axis deviation with small rS complexes in lead I, an electrically vertical heart position, overall tendency to low voltage, and rS complexes in all chest leads. Chapter 11: THE RESTING ELECTROCARDIOGRAM

ELECTROLYTE IMBALANCES

Because multiple factors can affect ventricular repolarization in diseased hearts, the finding characteristic of a specific electrolyte abnormality may be modified, and even mimicked, by various pathologic processes and the effects of certain drugs. In practice, the major problem with the ECG diagnosis of electrolyte imbalance is not the negative ECG with abnormal serum values but the production of similar changes by other conditions in patients with normal serum values.[122]

Hyperkalemia

The initial effect of acute hyperkalemia is the appearance of peaked T waves with a narrow base (Fig. 11-34, *left*). The diagnosis of hyperkalemia is almost certain when the duration of the base is 0.20 s or less (with rates between 60 and 110 beats per minute).[122] As the degree of hyperkalemia increases, the QRS complex widens (Fig. 11-35), with the electrical axis usually being deviated abnormally to the left and only rarely to the right. In addition, the PR interval prolongs, and the P wave flattens until it disappears.[45,122] If untreated, death ensues either due to ventricular standstill or coarse, slow ventricular fibrillation. Death also can result if wide QRS complexes occurring at fast rates are diagnosed as ventricular tachycardia and the patient is treated with antiarrhythmic drugs. On the other hand, class IA, IC, and III drugs as well as large doses of tricyclic antidepressants (especially when ingested for suicidal purposes) also can produce marked QRS widening. These processes, however, do not coexist with narrow-based, peaked T waves. Rarely, hyperkalemia produces (in the absence of coronary artery disease) a degree of ST-segment elevation in the right chest leads capable of suggesting anteroseptal myocardial injury (see Fig. 11-35). These constitute the "dialyzable currents of injury in potassium intoxication" reported by Levine et al.[123]

Hypokalemia

The abnormal and delayed repolarization that occurs in hypokalemia is best expressed as QU, rather than QT, prolongation, since at times it can be difficult to differentiate between notchingof the T wave and T- and U-wave fusion.[122] On the basis of the previously mentioned M cells, these U waves are part of notched T waves, suggesting that that term be used in place of U. As the serum potassium level falls, the ST segment becomes progressively more depressed, and there is a gradual blending of the T wave into what appears to be a tall U wave (Fig. 11-36, *top*). An ECG pattern similar to that of hypokalemia can be produced by some antiarrhythmic drugs, especially quinidine and, experimentally, DL-sotalol. In any case, when repolarization is greatly prolonged, ventricular arrhythmias, including the so-called torsades de pointes, can occur.

Hypomagnesemia

Hypomagnesemia does not produce QU prolongation unless the coexisting hypokalemia (with which it is almost invariably associated) is severe.[122] Long-standing and very marked magnesium deficiency lowers the amplitude of the T wave and depresses the ST segment.[122] It may be difficult to differentiate the changes produced by magnesium from those produced by potassium. For this reason, it has been stated that hypomagnesemia does not cause any changes in the ECG.[45]

Hypermagnesemia

Similarly, in clinical tracings, the effects of hypermagnesemia on the ECG are difficult to identify because the changes are dominated by calcium.[124] According to some authors, administration of intravenous magnesium to patients with normal ECGs may shorten the QT interval.[45] Other authors found no effects on ventricular refractoriness that are reflected by changes in the QT interval.[125] Intravenous magnesium given to patients with torsades de pointes controls the arrhythmia in a high percentage of patients without changing the prolonged QT interval significantly.[126] The calcium-blocking activity of magnesium was suggested to be one of the mechanisms responsible for this antiarrhythmic activity.[146]

Hypercalcemia

During sinus rhythm with normal rates, the QT interval is short (see Fig. 11-36, *bottom*). In some cases, the Q-to-apex of T intervals is also short. If factors known to modify the QT interval are not present, it has been said that a reasonably accepted correlation exists between the duration of the interval and serum calcium levels.[122] Occasionally, the ST segment disappears, and the T waves may become inverted in left and right chest leads. Digitalis also shortens the QT interval but produces its characteristic "effects" in leads where the R waves predominate. The classic upward concavity of the ST segment is seen in the left chest leads in patients with LV hypertrophy and in leads V_1 and V_2 when there is RV hypertrophy (with predominantly positive deflections in these leads).

Hypocalcemia

The typical ECG pattern of hypocalcemia consists of QT prolongation at the expense of the ST segment.[45,122] The T wave is usually of normal width but can be narrow if there is coexisting (moderate) hyperkalemia (see Fig. 11-34*B*). A very marked injury (with the so-called hyperacute ST-T changes) can produce a similar pattern, but in such cases the T wave, though peaked, is not as narrow based. It has been said that hypocalcemia per se does not produce T-wave inversion. When present, the latter is usually a reflection of coexisting processes such as LV hypertrophy and incomplete LBBB. An ECG pattern similar to that of hypocalcemia can be produced by some organic abnormalities of the central nervous system and by congenitally prolonged QT intervals (see below).

QT Interval: Normal and Prolonged

The QT interval is measured from the beginning of the q wave to the end of the T wave.[1,11] The latter may be difficult to define. The point at which the maximal downslope of the T wave crosses the baseline helps to identify the end of this wave.[45] The QT interval is affected by autonomic tone and cathecolamines and has day-night differences. It varies with heart rate and sex. Several formulas have been proposed to take these variables into account and provide a corrected measurement (QTc interval).[127]

In general, the unadjusted (noncorrected), usually resting QT interval decreases from ±0.42 s at rates of 50/min to ±0.32 s at 100/min to ±0.26 s at 150/min.[9,11] During exercise, the rate becomes faster; the QTc first increases until reaching, approximately, a rate of 120/min, thereafter again decreasing.[128] Although the value of the normal QTc is open to question, it is still used in routine computer interpretations. Because the 12-lead ECG shows a normal degree of QT and QTc dispersion, indexes have been used to quantify the extent of heterogeneity in ventricular repolarization. The difference between the longest and shortest QT interval is referred to as *QT dispersion*.[129-134] Since 1990 it has been used as a prognostic marker not only in patients with

prolonged QT intervals but also in those with acute MI.[130-132] The upper limits of normal vary with different investigators; a value of 65 may be an acceptable compromise according to Antzelevitch.[14] Others may disagree. Coumel et al.[133] emphasized that QT dispersion could be an illusion or a reality.[133] Inferred from the oncoming section on spatial vectorcardiography, the fact is that a truly *spatial* QRS-T loop cannot yield *abnormal* QT dispersion, for in planar projections of this spatial loop (as well as in the standard and unipolar extremity leads of the ECG) the shortest interval occurs because the terminal forces are perpendicular to the plane or derived lead. On the other hand, if precordial leads are considered scalar leads capable of recording (as stated in a previous section) local potentials with different durations, then QT dispersion is a reality.

The M-cell studies of Antzelevitch allow for the differentiation of this global "dispersion" (derived from *multiple* leads) from "local" transmural dispersion in *single* leads reflecting the time elapsing between the peak of the T wave (given by the end of the composite epicardial action potentials) and the end of the T wave (given by the end of the composite M-cell action potentials).[14]

The QT intervals are shortened with hypercalcemia, pure hyperkalemia, digoxin, and acidosis.[45] Prolongation of the QT interval may be congenital or acquired and is an important marker for malignant ventricular arrhythmias (see Chap. 24). A partial list of conditions causing a prolonged QT or, in some instances, prolonged QU intervals (delayed repolarization) is given in Table 11-8.[45]

Table 11-8: Acquired QT Prolongation Usually Bradycardia-and(or) Pause-Dependent

1. Electrolyte disturbances
a. Hypokalemia

c. Cryptococcal meningitis
4. Congenital syndromes
5. Electrocardiographic ischemia
6. Arrhythmias
a. Posttachycardia syndrome

b. Cardiac arrest of any etiology
c. Chronic idioventricular rhythms
7. Hypothermia

Hypothermia

Characteristic ECG changes develop when the body temperature drops to approximately 30°C.[11] The QT interval becomes prolonged. In addition, a deflection, called an *Osborn wave*, appears in a place said to be located between the end of the QRS complex and the beginning of the ST segment[135] (Fig. 11-37). This deflection has been attributed to delayed depolarization, to a current of injury, or to "early" repolarization.[153] In leads facing the left ventricle, the deflection is positive, and its size is inversely related to body temperature. The role played by the intramyocardial M cells in its genesis has been discussed previously.[14]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

ARTIFACTS

During the last few years, the number and types of instruments used for noninvasive and invasive (electrical and nonelectrical) study of cardiac functions have multiplied. Naturally, physicians and hospital administrators have concentrated their attention on them. Technicians have been more interested in working in these more lucrative services. Such factors, and others, have downgraded the importance of recording 12-lead ECGs, relegating them to less qualified personnel. Not surprisingly, the quality of technicians and of the ECG that they record has deteriorated in many centers. Optimal quality can only be achieved if the parties involved understand what is happening. The following are some of the artifacts commonly seen in current routine 12-lead ECGs. They are important because they can confound the interpreter and, worse, the computer program.

Muscle Tremor and Alternating-Current Interference

These are the most frequently encountered artifacts because some patients will continue to have disease processes producing tremor and because the amount of electronic equipment causing interference in a hospital environment has increased.

Improper Limb-Lead Positioning

This has become more frequent after relaxation of quality control, especially in hospitals with inadequate standards for hiring technicians and with poor on-site training. Mixing up the cables from the ECG machine has gone beyond switching the right arm and left arm cables.[11] Various types of misplacements of only one cable are illustrated in Fig. 11-38. The method depicted in this illustration, based on the use of unipolar extremity leads only, is simpler than those incorporating the analysis of bipolar standard leads.[11] Not frequently recognized in ECG textbooks is the incontrovertible fact that in some centers even the "sanctity" of the attachment of the right leg (ground) cable to the right leg has been violated[136] (Fig. 11-39). In our experience, this error is usually identified as improper lead placement, but determination of the cables involved is usually not made correctly.[136]

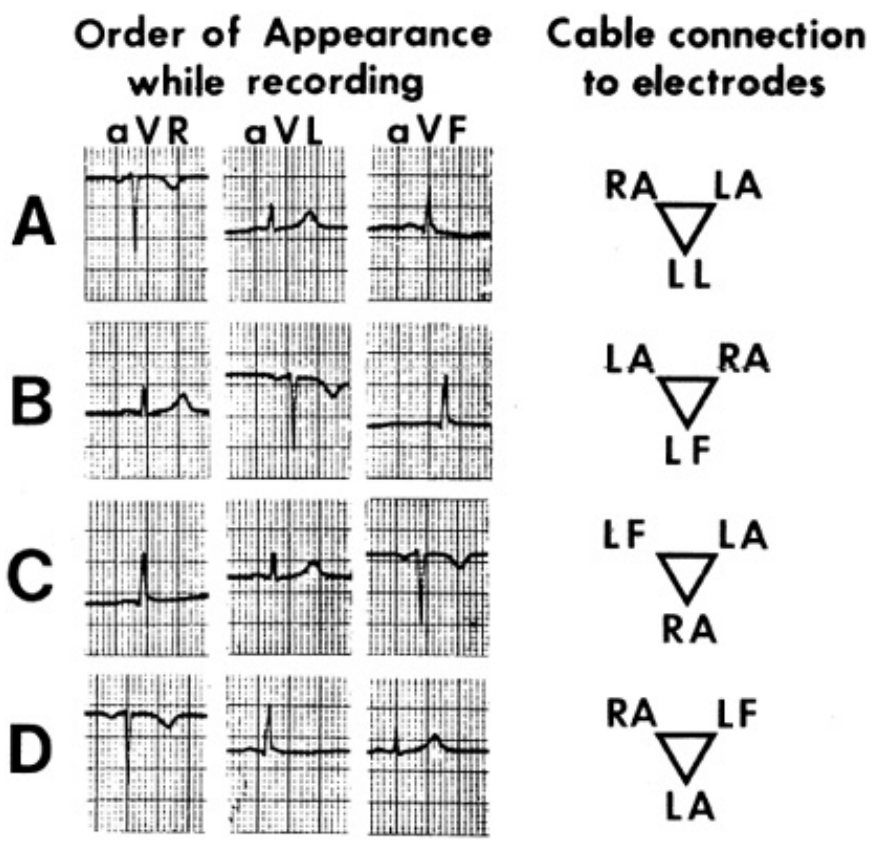

Figure 11-38: Identification of improper connections of a single cable from the electrocardiographic machine to the corresponding electrodes placed on the patient's limbs. Note that aV_R, aV_L, and aV_F invariably refer to whatever morphology is recorded when, while the ECG is being obtained, the corresponding knobs are turned in this order (regardless of whether the cables were attached properly or improperly). On the other hand, RA (right arm), LA (left arm), and LL (left leg) or LF (left foot) correspond to the normal morphology recorded by the cables so labeled. This method, based solely on the analysis of the unipolar extremity leads, is simpler than the method based on the study of the bipolar standard leads but is useful only when a single cable is misconnected. *A.* Normal. *B.* Since LA appears in aV_R and RA appears in aV_R (with LF being in its normal position), the right arm and left arm cables must have been switched. *C.* Since LF appears in aV_R and RA appears in aV_F (with LA in its normal position), the right arm and left leg cables must have been switched. *D.* Since LA appears in aV_F and LF appears in aV_L (with RA in its normal position), the left arm and left leg cables must have been switched.

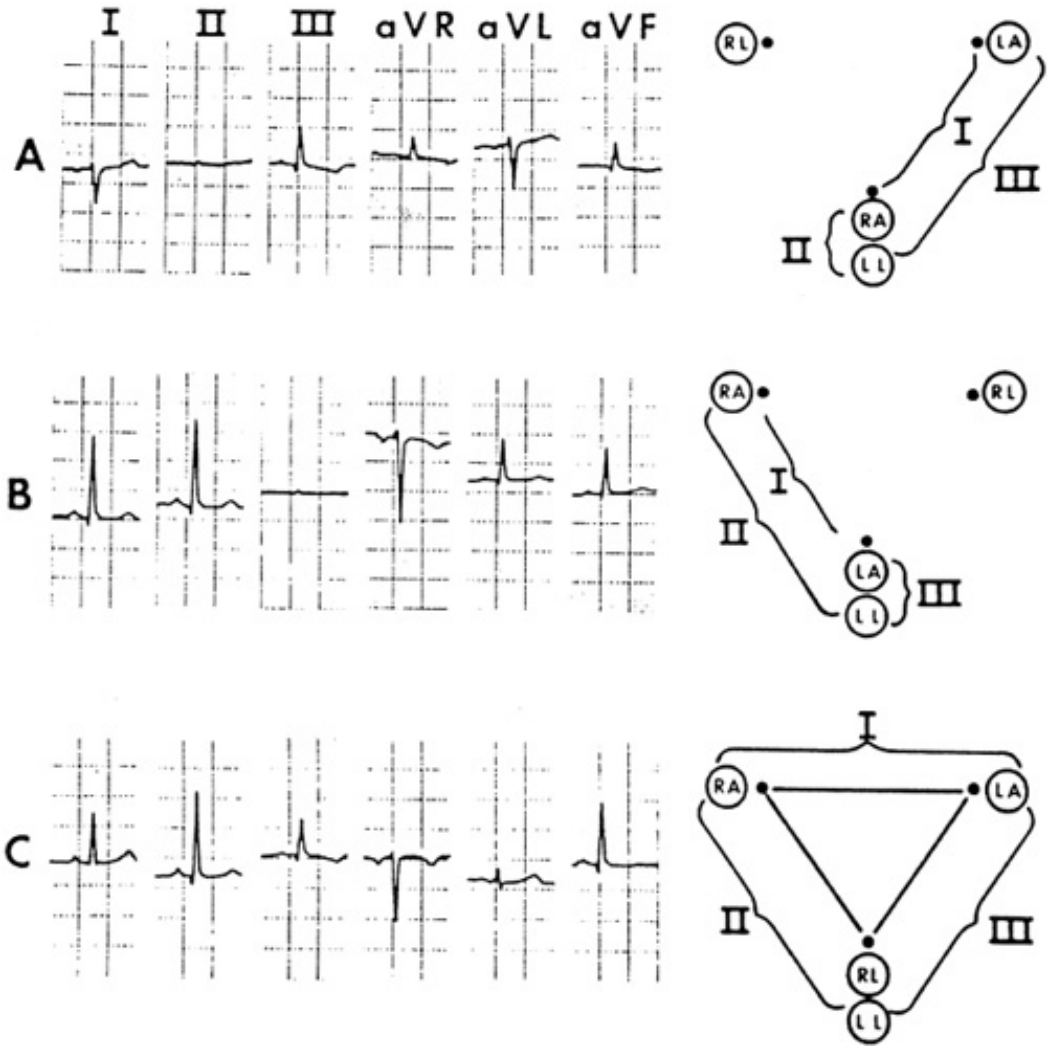

Figure 11-39: Identification of improper connections of the right leg (RL) (ground) cable. *C* can be regarded as almost equal to the control tracing because the RL (ground) and left leg (LL) cables were switched. The corresponding morphologies are not identical to the control morphologies because a very small difference in potential between both legs does exist. The latter is seen in *A*. Because the RL and RA cables were switched, lead II (RA-LL) records the difference in potential between both legs, which seems to be approximately 0.15 mV. The latter results in an almost straight line interrupted by a small blip. In addition, lead I represents the mirror image of normal lead III, and lead III is the normal lead III. In *B*, where the LA and RL cables have been switched, lead III (LA-LL) records almost a straight line. In addition, lead I is the normal lead II, and lead II is the normal lead II. [From Castellanos A, Saoudi NC, Schwartz A, et al. Electrocardiographic patterns resulting from improper connection of the right leg (ground) cable. *PACE* 1985; 8:364-368. Reproduced with permission from the publisher and authors.]

Variations in Precordial-Lead Placement

This is a problem more common now than when, in 1961, Simonson noted the considerable variation in chest lead placement in the same patient by different technicians and even by the same technician in several ECGs in the same patient.[137] Simonson also found that in a controlled study, placement of the V_2 electrode varied 10 cm vertically and 8 cm horizontally in 103 healthy subjects.[137] Moreover, Kerwin et al.[138] found a rather large error in placement of chest electrodes (2 to 3 cm in both the horizontal and vertical directions) in repeated trials in the same patients by the same technicians.[138] Perhaps the frequency of precordial-lead misplacement is greater than that of somatic tremor. In our institution, the most frequent cause of "poor" r-wave progression in the anteroseptal leads (often misinterpreted by the computer as indicative of anteroseptal MI) is

misplacements of leads V_2 and V_3.

False Variations in Voltage

Garson[139] noticed how, in several patients, ECGs taken weeks apart showed markedly different QRS voltages. The latter were sometimes of enough magnitude to cause a pseudonormalization of a ventricular hypertrophy pattern. There had been no changes in hemodynamics, but different types of ECGs were used. A study of this problem demonstrated that electrocardiographic data had a different voltage depending on whether they were recorded and displayed on an analog electrocardiograph or on a digital electrocardiograph. Thus, if there is a statistically significant difference among ECGs, the serial comparisons must be done with the same machine. Moreover, criteria for voltage are only applicable to the type of instrument with which the data were gathered.

In addition, overshooting, overdamping, and running down of the standardization battery can cause significant changes in QRS voltage and ST segments.

How Should an ECG Be Performed?

This question is appropriate in view of the many artifacts and technical (machine and human) problems occurring when ECGs are recorded. The Task Force of the American College of Cardiology (ACC)-American Heart Association (AHA) in their *Guidelines for Electrocardiography*[4] have stated that the ECG should be performed and interpreted in accordance with the guidelines for optimal electrocardiography described in the ACC *Tenth Bethesda Conference Report*,[140] the guidelines for training described in the ACC *Seventeenth Bethesda Conference Report on Cardiology Training*,[141] the recommendations for standardization of leads and specifications for instruments in electrocardiography and vectorcardiography of the AHA,[142] and the recommendations for standardization and specifications for automated electrocardiography of the AHA.[143]

Chapter 11: THE RESTING ELECTROCARDIOGRAM

COMPUTER APPLICATIONS

It has been almost 40 years since the first attempts were made to apply computer technology to the interpretation of ECGs.[144] Today its use is universal.[1,144-147] In general, computer systems for true analysis of ECGs have, as their main component, a program usually having the following four basic functions: (1) the measuring of ECG parameters, which includes an automatic wave-front-recognition section and a measurement section that extracts the wave fronts, a set of values, and control, (2) theinterpretation of previously acquired information, responsible for the final statements generated by the program, (3) the identification of various rhythms, both normal and abnormal, and (4) the comparison with previous ECGs to recognize significant changes. There is a lack of standardized, universally agreed-on diagnostic terms and criteria. This problem, however, is not solely that of computers but is related to all ECG interpretations, whether performed by individuals or by machines. It has to be remembered that the program used depends on criteria imposed on it by human programmers. Physicians should insist that the program selected has to be "tuned in" with the operational environment (e.g., community hospital or teaching institution, urban center or rural areas, etc.) in which it has to perform. Once a program has been selected and is in use, it requires initial and periodic evaluation. The most practical method consists of accepting as standard constrained human observers, the constrained observers being given a set of measurements or criteria agreed on before the evaluation. Proper computerization has the following definite advantages: (1) speed in providing reports with the resulting improved turnaround time, (2) optimal utilization of emergency ECG services, (3) reproducibility of measurements, (4) improvements in quality control, (5) possible decrease in physician's reading time and more consistency in interpretations, (6) enhancement of the capacity to handle large volumes of ECGs, and (7) substantial improvement in record storage and retrieval with better comparison with previous tracings.

Administrators are usually the ones selecting equipment, and frequently they know nothing about its medical performance. They usually use standard cost-effective, not medically-effective methods. That is, the economics involved-initial investment, operational costs, payroll, overhead, and professional fees-become priorities. This is important because it was estimated that even 10 years ago more than 40 percent of all ECGs recorded in the United States were obtained by some type of automatic system.[144] Presently, however, this figure is reaching 100 percent. Finally, emphasis should be placed on the obvious: All computer ECG interpretations, particularly those of rhythm disturbances, must be checked by a physician qualified to interpret ECGs and with an in-depth knowledge of the program used. Decisions based on a computerized interpretation may, on occasion, lead to improper patient care. This also can have medicological implications. Of clinical importance was the report finding that computer interpretations of ECGs obtained 1 min apart were grossly different in 36 of 92 (39 percent) unselected pairs of tracings.[148] The latter refers to only one program but nevertheless should be an impetus to designers and manufacturers to improve their product and a warning to those who rely, exclusively, on computer interpretations.[148] The ACC/AHA Task Force on Guidelines for Electrocardiography states: "There is no computer program that can replace the skilled physician."[4] Finally, cardiology fellows in training should interpret ECGs without a printed computer interpretation rather than by having to evaluate the latter.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

SPATIAL VECTORCARDIOGRAPHY

Generalities

The following statements, which need reemphasis, should not be considered redundant: (1) Since the ECG deals with electrical forces, it follows that very strictly speaking, electrocardiography can be considered vectorial.[149,150] (2) Orthodoxically, a scalar quantity only has magnitude, whereas a vector quantity has magnitude, direction, and sense. When analyzing the vectorcardiogram (VCG), one should consider the activation of each muscle cell as producing an electrical force that can be represented by a vector depicting the spatial orientation and magnitude of this force.[149]

During the spread of the activation process, innumerable electrical forces are generated. These multiple forces vary in magnitude and differ in direction. At any given moment, the resultant of these electrical forces can be represented by a spatial vector possessing magnitude, direction, and sense. This vector is referred to as an *instantaneous vector* and represents the resultant of *all* the forces of the heart acting at that particular moment. Immediately afterward, the wave of accession spreads to different areas of the myocardium, and the new instantaneous vector representing all the forces of the heart now occupies a different spatial position and has a different magnitude. This continues throughout the cardiac cycle, with the succeeding instantaneous vector occupying different spatial positions. If all manifest spatial vectors are diagrammatically represented as having a common point of origin, and if the distal points of the vectors are joined, a single spatial loop is formed for ventricular depolarization (QRS), ventricular repolarization (ST-T), and the atrial complex (P). The VCG consists of four different loops. The electrical activity of the atria is recorded as a small loop designated the *P loop*, the depolarization of the ventricles is recorded as a large loop designated the *QRS loop*, while the repolarization of the ventricles is recorded as a smaller loop designated the *ST-T loop*. Finally, at high magnifications, even a small *U loop* also can be recorded.[149-153]

Space: The Final Frontier

The theory of the truly spatial VCG is theoretically attractive. Because the heart is a tridimensional structure (located in space), its electrical activity should best be recorded by a spatial method. Indeed, space, as conceived by physicists through objects and their motion, has three dimensions, and positions are characterized by three numbers. The instant of an event is the fourth number. Four definite numbers correspond to every event; a definite event corresponds to any four numbers. Therefore, the world of events really forms a four-dimensional continuum. Unfortunately, judging by what is being published in the literature, the quest for finding an optimal method of visualizing the spatial loop apparently has been abandoned. Nevertheless, the spatial VCG is still of importance in children with congenital and acquired heart disease because in this population the criteria for pressure and volume overloading have proven value.[151] In our opinion, it is also of great value in categorizing the various types of intraventricular conduction defects.[151-153] While this may be attributed to the spatial technique per se, it also can be due to the use of instruments having a higher fidelity than routinely employed electrocardiographs. The VCG also has been found useful in detecting MI and certain types of RV enlargement.[151-153] In practice, it has not been proven that the VCG gives more information than the routine 12-lead ECG,[151] although some computer programs may still use the Frank orthogonal leads *X*, *Y*, and *Z*.

These programs thus constitute a 15-lead system. In addition, the time required to obtain a VCG is longer than the time required to record a 12-lead ECG. These are the main reasons for the decrease in the use of spatial vectorcardiography during recent decades. Other reasons are nonreimbursement and the continuously increasing interest in other noninvasive methods of recording electrical activity (such as signal averaging, body surface mapping, and heart rate variability) or nonelectrical activity (such as echocardiography or magnetic resonance imaging, which looks at planes from *different* views). To obtain the spatial VCG, electrodes are placed on the body surface in a way to record three leads whose planes are at right angles to each other. The true spatial VCG requires three corrected orthogonal leads with the following features[151-154]: (1) Mutual perpendicularity, with each lead being parallel to one of the rectilinear coordinate axes of the human body. Such axes are the horizontal, *X* (left-to-right and right-to-left) axis; the vertical, *Y* (inferosuperior or superoinferior) axis; and sagittal, *Z* (anteroposterior or posteroanterior) axis. (2) Equal amplitude from the vectorial viewpoint. (3) Retention of the same magnitude and direction for all points where cardiac electromotive forces are generated. For example, even if the leads forming Einthoven's frontal plane were to be spatially correct, Einthoven's theory itself would make any electrodes placed for the purpose of obtaining the horizontal and sagittal planes (such as the tetrahedral system) spatially incorrect. The most widely used, corrected spatial VCG method probably is the one introduced by Frank.[154] Since the spatial loop cannot be analyzed tridimensionally, it is customary to study its planar projections (Fig. 11-40). By proper attachment to the oscilloscope, the *X* and *Y* leads are used for the frontal plane, the *X* and *Z* leads for the horizontal plane, and the *Z* and *Y* leads for the sagittal plane (of which the right side has been the most popular).

Differences between Electrovectorcardiography and Spatial Vectorcardiography

Spatial vectorcardiography is distinctly different from the various vectorial methods of ECG interpretation, such as those of Sodi-Pallares et al.[7] and Grant.[56,57] In clinical practice and in teaching, both seem to be considered equal, but this is so only for pragmatic and didactic reasons. Although the spatial VCG and the ECG should each be studied as distinct methods, most electrocardiographers either memorize loop patterns or attempt to derive the leads with which they are familiar from the corresponding QRS loops. Thus bipolar standard and unipolar extremity leads are derived from the frontal plane more or less as when, in clinical ECG, they are derived from the electrical axis. To do this in spatial vector loops, the electrical axis is equated with the maximal QRS vector that extends from the point of origin of the loop to its farthest point. The unipolar precordial leads are derived from the horizontal plane loops. Leads thus derived are different from the usual precordial ECG leads. The latter, as mentioned previously, record electrical forces moving toward or away from them, including local potentials that can be of different duration in different precordial leads.[13,35,133] In the 12-lead ECG (especially when the precordial electrodes are misplaced), however, these forces can move spatially not only in a left-to-right and anteroposterior direction but also in an inferosuperior direction as in leads V_5 and V_6 in patients with a very superior and leftward deviation of the EA. On the other hand, the theory of spatial vectorcardiography states that the horizontal plane and unipolar leads derived from them just record left-to-right and anteroposterior forces and that they do not record local potentials so that any difference in the duration of intervals is merely an illusion[133,151] (Fig. 11-41). In spatial vectorcardiography, electrical forces oriented superiorly or inferiorly cannot be reflected in the horizontal plane but only in the frontal and sagittal planes. Most of the information contained in the sagittal plane is present in the frontal and horizontal planes. In practice, the sagittal plane is useful to act as a "judge" in cases of apparent discrepancy between the other two planes. For example, it serves to determine if a localized delay present in one of the two planes is "real" or is due to perpendicularity of vectors. It also serves for a better evaluation of the upward or downward direction of the initial 0.01- and 0.02-s vectors than the frontal plane. Projections of normal spatial QRS and ST-T loops in the corresponding planes are depicted in Fig. 11-42.

Chapter 11: THE RESTING ELECTROCARDIOGRAM

List of Figures

Figure 11-22: Morphologic features of complete LBBB complicated by acute inferior MI. There is abnormal ST-segment elevation in leads II, III, and aV_F (QRS duration: 0.14 s). AV block is also present.

Figure 11-23: *A.* Complete LBBB with old anterior MI. Abnormal Q waves are present in lead I (QRS duration: 0.18 s). *B.* Pacing-induced complete LBBB pattern in a patient with old anterior MI. There are abnormal Q waves in lead I after spikes (QRS duration: 0.20 s). Note resemblance between natural and artificial (electrically induced) QRS patterns.

Figure 11-24: Wolff-Parkinson-White syndrome in a patient with a left free-wall accessory pathway. *A.* Sinus rhythm with fusion beats showing different degrees of preexcitation. *B.* Maximal preexcitation during atrial fibrillation. Note marked change in QRS duration and electrical axis.

Figure 11-25: Wolff-Parkinson-White syndrome in a patient having a posteroseptal accessory pathway. Note short PR intervals with negative delta waves in leads III and aV_F (false pattern of inferior MI). Lead V_2 shows all-positive QRS complexes.

Figure 11-26: Wolff-Parkinson-White syndrome in a patient with a right free-wall accessory pathway. Note LBBB "pattern" characterized for diagnostic (of accessory pathway location) purposes by a QRS duration greater than 0.09 s in lead I with rS complexes in leads V_1 and V_2. The electrical axis is approximately +15°.

Figure 11-27: Wolff-Parkinson-White syndrome in a patient with a right anteroseptal accessory pathway. Note LBBB pattern (as defined in Fig. 11-26). The most important difference with the latter is that the electrical axis points more vertically, toward +60°, thereby being located within the range of the axis (+30 to +120°) reported for right anteroseptal accessory pathways.

Figure 11-28: Useful algorithm to predict accessory pathway location from the 12-lead ECG. Step 1: Analysis of R/S ratio in V_2. Step 2: Existence of positive (+) delta wave in lead III (initial 40 ms). Step 3: Existence of positive or negative (-) delta wave in V_1 (initial 60 ms). Step 4: Delta-wave polarity in aV_F (initial 40 ms) or analysis of R/S ratio in V_1 (± = biphasic or isoelectric). The accuracy of the algorithm for each location in 187 prospective patients is also shown at the bottom. LAL, left anterolateral; LL, left lateral; LP, left posterior; LPL, left posterolateral; LPS, left posteroseptal; MS, midseptal; RA, right anterior; RAL, right anterolateral; RAS, right anteroseptal; RL, right lateral; RP, right posterior; RPL, right posterolateral; RPS, right posteroseptal. (From Chiang et al.[105] Reproduced with permission from the publisher and authors.)

Figure 11-29: QRS changes (location of the electrical axis and polarity of lead V_1) produced by pacing from right ventricular apex (RVA), right ventricular outflow tract (RVOT), great cardiac vein (GCV), and middle cardiac vein (MCV).

Figure 11-30: ECG taken on a patient with pulmonary emphysema showing slight right-axis deviation with small rS complexes in lead I, an electrically vertical heart position, overall tendency to low voltage, and rS complexes in all chest leads. (From Lemberg and Castellanos.[151] Reproduced with permission from the publisher and authors.)

Figure 11-31: ECG from a patient with RV enlargement (volume overload in type) due to a small atrial septal defect (ostium secundum). Right-axis deviation was associated with an incomplete RBBB pattern (rsR' complexes in lead V_1). (From Lemberg and Castellanos.[151] Reproduced with permission from the publisher and authors.)

Figure 11-32: ECG from a patient with RV hypertrophy due to pure mitral stenosis showing P "mitrale," right-axis deviation, an all-positive deflection (R wave of only approximately 5 mm) in V_1, and rS complexes from V_2 to V_6. (From Lemberg and Castellanos.[151] Reproduced with permission from the publisher and authors.)

Figure 11-33: ECG from a 17-year-old patient who had RV enlargement (pressure overloading in type) due to severe pulmonic stenosis. Note extreme right-axis deviation, overall high voltage, and qR complexes in lead V_1 without an incomplete RBBB pattern. (From Lemberg and Castellanos.[151] Reproduced with permission from the publisher and authors.)

Figure 11-34: Electrocardiographic manifestations of early hyperkalemia. The nonprolonged QRS complex is followed by a peaked T wave having a very narrow base. Uncorrected and corrected QT intervals of 0.32 and 0.44 s, respectively (*A*). Hyperkalemia with hypocalcemia characterized by prolongation of the QT interval at the expense of the ST segment preceding the narrow-based T wave. Uncorrected and corrected QT intervals of 0.52 and 0.53 s, respectively (*B*).

Figure 11-35: Advanced hyperkalemia. The wide (0.14-s) QRS complexes are followed by peaked T waves (best seen in lead V_3). The hyperkalemia-induced ST-segment elevation in lead V_1 (*arrows*), known as the *dialyzable currents of injury*, disappeared after appropriate treatment.

Figure 11-36: Electrocardiographic manifestations of hypokalemia (*upper strip*) and hypercalcemia (*lower strip*).

Figure 11-37: ECG obtained from a patient with hypothermia. The characteristic Osborn wave (*arrows*) is the terminal deflection inscribed between the slender part of the QRS complexes and the beginning of the ST segment. Note that it is not easy to determine where the ST segment starts. In addition, there is marked prolongation of the QT interval.

Figure 11-38: Identification of improper connections of a single cable from the electrocardiographic machine to the corresponding electrodes placed on the patient's limbs. Note that aV_R, aV_L, and aV_F invariably refer to whatever morphology is recorded when, while the ECG is being obtained, the corresponding knobs are turned in this order (regardless of whether the cables were attached properly or improperly). On the other hand, RA (right arm), LA (left arm), and LL (left leg) or LF (left foot) correspond to the normal morphology recorded by the cables so labeled. This method, based solely on the analysis of the unipolar extremity leads, is simpler than the method based on the study of the bipolar standard leads but is useful only when a single cable is misconnected. *A*. Normal. *B*. Since LA appears in aV_R and RA appears in aV_R (with LF being in its normal position), the right arm and left arm cables must have been switched. *C*. Since LF appears in aV_R and RA appears in aV_F (with LA in its normal position), the right arm and left leg cables must have been switched. *D*. Since LA appears in aV_F and LF appears in aV_L (with RA in its normal position), the left arm and left leg cables must have been switched.

Figure 11-39: Identification of improper connections of the right leg (RL) (ground) cable. *C* can be regarded as almost equal to the control tracing because the RL (ground) and left leg (LL) cables were switched. The corresponding morphologies are not identical to the control morphologies because a very small difference in potential between both legs does exist. The latter is seen in *A*. Because the RL and RA cables were switched, lead II (RA-LL) records the difference in potential between both legs, which seems to be approximately 0.15 mV. The latter results in an almost straight line interrupted by a small blip. In addition, lead I represents the mirror image of normal lead III, and lead III is the normal lead III. In *B*, where the LA and RL cables have been switched, lead III (LA-LL) records almost a straight line. In addition, lead I is the normal lead II, and lead II is the normal lead II. [From Castellanos A, Saoudi NC, Schwartz A, et al. Electrocardiographic patterns resulting from improper connection of the right leg (ground) cable. *PACE* 1985; 8:364-368. Reproduced with permission from the publisher and authors.]

Figure 11-40: The spatial vectorcardiographic loops cannot be analyzed routinely in space with presently available techniques. Therefore, it is customary to study their projections in three planes seen as depicted in this figure. Note that (1) the frontal plane conforms to Einthoven's view of his equilateral triangle, (2) the horizontal plane is seen in such a way that the anterior surfaces of the heart and sternum are displayed in the inferior portions of the paper (in contrast to other noninvasive, nonelectrical methods), and (3) the sagittal plane is viewed from the right side of the patient. (From Lemberg and Castellanos.[151] Reproduced with permission from the publisher and authors.)

Figure 11-41: Method used to derive the morphology of a unipolar precordial lead (in this example lead V_6) from the planar projection of the spatial QRS and ST-T loops on the horizontal plane. First (*left panel*), a line is drawn from the estimated location of the corresponding electrode to the point of origin of the loops. Thereafter, a perpendicular to this line passing from the point of origin is drawn. This divides the thorax into a negative area (for V_6) that is located beyond the perpendicular line and a positive area that is located between the perpendicular line and the electrode. Thus, in the top right schematic, the small part of the loop located beyond the perpendicular line produces the small q wave in V_6. The other schematics show how progression of depolarization and repolarization produces parts of the QRS loop (and the entire ST-T loop), which are positive in lead V_6. The S wave occurs because the terminal part of the QRS loop is located beyond the perpendicular line. When using this type of lead derivation, any precordial lead will only record forces moving in an anteroposterior (or posteroanterior) and in a left-to-right or right-to-left direction. Forces moving up or down will not be recorded. This contrasts with scalar concept of precordial leads which can, especially when misplaced, record forces moving in any direction. (From Lemberg and Castellanos.[151] Reproduced with permission from the publisher and authors.)

Figure 11-42: Planar projections of normal spatial VCG obtained with the Frank method. The ST-T loops are enlarged in the bottom view. In the horizontal plane, the QRS loop shows the expected, normal, counterclockwise (CCW) rotation (indicated by arrows). Although the narrow frontal plane QRS loop has clockwise (CW) rotation, in this plane either CCW, CW, or figure-eight rotations can be normal. In the right sagittal plane, the QRS loop displays its normal (CW) rotation. Enlargement of the ST-T loop clearly shows that its first half is inscribed more slowly. Therefore, the dashes (each representing 0.0025 s, or 25 ms) are closer together. Note that the rotation of the ST-T loop is similar to the rotation of the QRS loop in all planes. (From Lemberg and Castellanos.[151] Reproduced with permission from the publisher and authors.)

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 12:

THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

Author: James T. T. Chen

On November 8, 1895, Wilhelm Conrad Roentgen discovered x-rays[1] and ushered in a new era of diagnostic roentgenology. With wavelengths only 1/10,000 those of visible light, x-rays can penetrate the human body to produce roentgenograms, which revolutionized the field of medical diagnosis. Chest roentgenography in particular has since become a routine part of medical workup because of the invaluable information it can provide.

Familiarity with the altered anatomy and understanding of the underlying pathophysiology of a diseased heart are the cornerstones to appropriate interpretation of its roentgen manifestations. The conventional four-view cardiac series is tabulated in Table 12-1 and the views are illustrated in Fig. 12-1*C* *D* *E* to *F*.

Table 12-1: Conventional Four-View Cardiac Series

Posteroanterior (PA) view	With barium
Left lateral (lateral) view	With barium
45° Right anterior oblique (RAO) view	With barium
60° Left anterior oblique (LAO) view	Without barium

The approach to the chest roentgenogram should be thorough and objective so that no clue is overlooked and no bias is incorporated in the process of radiographic analysis.[2-5] Rib notching (see Fig. 12-1*A*, *B*), for example, offers important clues to the diagnosis of coarctation of the aorta.[4,6] To prevent occasional erroneous clinical information from misleading the radiographic interpretation, films should at first be read without any knowledge about the patient. A patient may be referred, for instance, because of "bronchial asthma" refractory to therapy, only to be found later to suffer from cardiac asthma due to critical mitral stenosis. In this case, the classic radiographic manifestations of severe mitral stenosis should help clarify the confusion and prompt a change in patient management.

On other occasions, a secundum atrial septal defect may be misinterpreted as mitral stenosis because of similar physical signs. The split second sound may be misinterpreted as the opening snap. The diastolic rumble due to increased flow through a normal tricuspid valve may mimic the diastolic murmur of mitral stenosis. The x-ray signs of the two entities, however, are quite different (Fig. 12-2*B* versus Fig. 12-3*A*).

The final radiologic conclusion, however, should be drawn only after correlating the x-ray findings with clinical information and other laboratory parameters.

The radiologic examination for heart disease consists of six major steps. They are (1) roentgenographic examination for anatomy; (2) fluoroscopic examination for dynamics, (3) comparison, (4) statistical guidance, (5) clinical correlation, and (6) conclusion (Table 12-2).

Table 12-2: Major Steps of Roentgenologic Examination

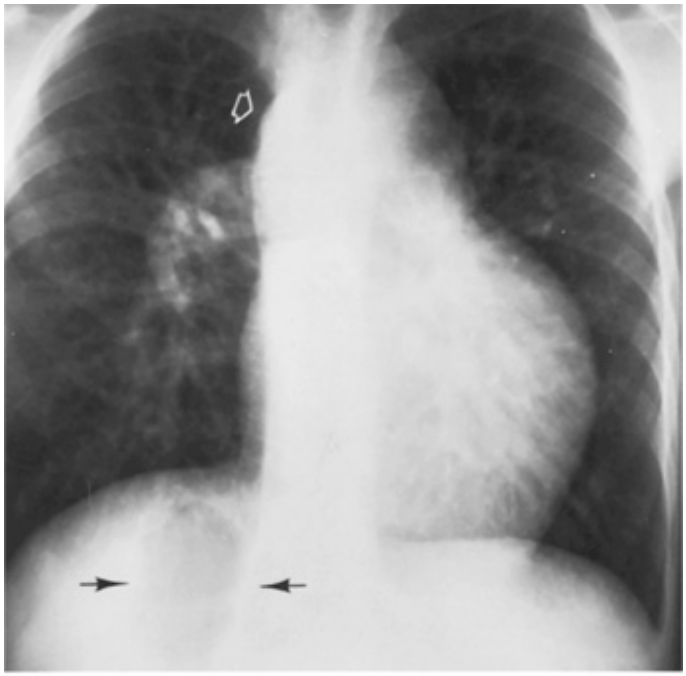
Roentgenographic examination for anatomy
Overview, e.g., rib notching
Pulmonary vascularity, e.g., shunt vascularity in ASD
Lung parenchyma, e.g., ossification in critical MS
Cardiac size, e.g., huge right heart in Ebstein's anomaly
Cardiac contour, e.g., boot-shaped heart in TOF
Abnormal densities, e.g., calcification of LV aneurysm
Abnormal lucency, e.g., conspicuous fat stripes in PE
Cardiac malpositions, e.g., dextrocardia with SS
Other abnormalities, e.g., Holt-Oram syndrome
Fluroscopic observation for dynamics
Comparison
Statistical guidance
Clincal correlation
Conclusion

ABBREVIATIONS: ASD = atrial septal defect; MS = mitral stenosis; TOF = tetralogy of Fallot; LV = left ventricle; PE = pericardial effusion; SS = situs solitus.

ROENTGENOGRAPHIC EXAMINATION FOR ANATOMY

An Overview

The first step is to survey the roentgenogram and assess the entire situation, searching particularly for noncardiac conditions that may reflect heart disease. For instance, a right-sided stomach with an absent image of the inferior vena cava may suggest the possibility of congenital interruption of the inferior vena cava with azygos continuation[7,8] (Fig. 12-4). A narrowed anteroposterior diameter of the thorax may be the cause of an innocent murmur[9] (Fig. 12-5).



A

B

Figure 12-4: Patient with situs ambiguous, interruption of the inferior vena cava, ventricular septal defect, and polysplenia. *A.* Posteroanterior view shows that the aortic arch and the heart are left-sided and the stomach (*lower arrows*) is right-sided. The azygos vein (*upper arrow*) is markedly enlarged. The heart is mildly enlarged, and there is a moderate increase in pulmonary vascularity. *B.* Lateral view shows an absent image of the inferior vena cava. The azygos arch (*arrow*) is markedly dilated.

Pulmonary Vasculature

The lung may often reflect the underlying pathophysiology of the heart. By careful evaluation of the pulmonary vasculature, one may narrow down the diagnostic possibilities to a manageable level. For

example, if uniform dilatation of all pulmonary vessels is present, the diagnosis of a left-to-right shunt (see Fig. 12-2*B*) is more likely than a left-sided obstructive lesion. The latter typically shows a cephalic pulmonary blood flow pattern (see Fig. 12-3*A*). More detailed analysis of the pulmonary vascularity will be discussed separately below.

Lung Parenchyma

With right-sided heart failure, the lungs become unusually radiolucent because of decreased pulmonary blood flow (PBF). On the other hand, significant failure on the left side of the heart is characterized by the presence of pulmonary edema and/or a cephalic blood flow pattern (Fig. 12-6). Long-standing, severe pulmonary venous hypertension may lead to hemosiderosis and/or ossification of the lung.[10,11] When right-sided heart failure results from severe left-sided heart failure, the preexisting pulmonary congestion may improve because of the decreased pulmonary blood flow (see Fig. 12-6*B*).

Cardiac Size

A significantly enlarged heart is always abnormal; however, mild cardiomegaly may reflect a higher than average cardiac output from a normal heart, as seen in athletes in active training. The cardiothoracic ratio remains the simplest and most practical yardstick for assessment of cardiac size.[2] The mean value for adults in an upright position in the posteroanterior (PA) view is 44 percent. More accurate roentgen measurements of cardiac size have been well documented[12,13] but are beyond the scope of the present discussion.

The nature of cardiomegaly usually can be determined by the specific roentgen appearance. As a rule, when the PBF pattern remains normal, cardiac lesions with volume overload tend to present a greater degree of cardiomegaly than lesions with pressure overload alone. For example, patients with aortic stenosis typically show features of left ventricular hypertrophy without dilatation. On the other hand, the left ventricle both dilates and hypertrophies in the case of aortic regurgitation, producing a much larger heart even before the development of congestive heart failure.

Both right- and left-sided heart failure can cause gross cardiac enlargement. The associated vascular abnormality in each case, however, is drastically different (see "Pulmonary Vascularity," below).

A smaller than average heart is encountered in patients with chronic obstructive pulmonary disease (Fig. 12-7*A*), Addison's disease, anorexia nervosa, and starvation. An abnormally small heart, however, is difficult to define except in a retrospective fashion, when the heart has returned to its normal capacity following successful therapy. For example, in patients with Addison's disease, the heart may become significantly larger following appropriate steroid therapy.

Cardiac Contour

Any significant deviation from the normal cardiovascular contour may serve as a clue to the correct diagnosis. For instance, *coeur en sabot*, a "boot-shaped heart" (see Fig. 12-2*C*), is characteristic of tetralogy of Fallot. A bulge along the left cardiac border with a retrosternal double density is virtually diagnostic of left ventricular aneurysm (Fig. 12-8). A markedly widened right cardiac contour in association with a straightened left cardiac border is seen frequently in patients with severe mitral stenosis leading to tricuspid regurgitation (see Fig. 12-7*D*).

Abnormal Densities

Besides the familiar double density cast by an enlarged left atrium, other increased densities may be found within the confines of the heart, indicating a variety of dilated vascular structures, e.g., tortuous descending aorta, aortic aneurysm, coronary artery aneurysm, pulmonary varix, etc.[3] Furthermore, large cardiac calcifications are seen easily, particularly in lateral and oblique views. If smaller calcific deposits are suspected, they should be verified promptly or ruled out by cardiac fluoroscopy or computed tomographic (CT) scanning (see Chap. 17). Any radiologically detectable calcification in the heart is of clinical importance. The heavier the calcification, the more significant it becomes (see Fig. 12-1*F*). The

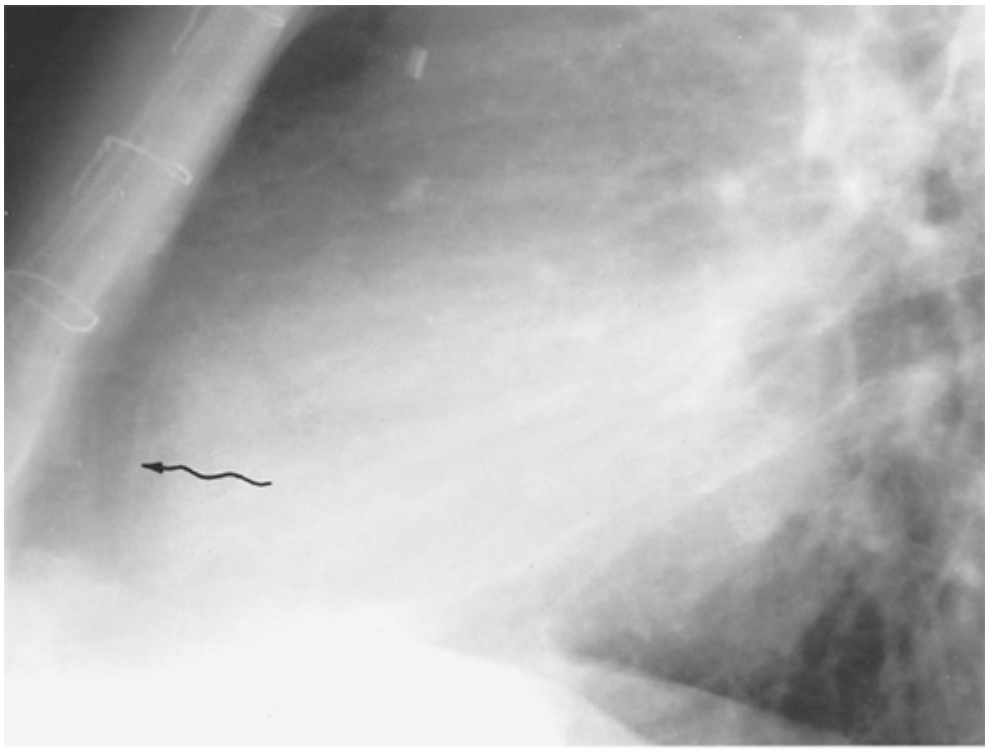
extent of valvular calcification tends to be proportionate to the severity of the valve stenosis regardless of the other roentgen signs of the disease.[2,3,14,15] Calcification of the coronary artery is almost always atherosclerotic in nature. Mönckeberg's medial calcification of the coronary system is extremely rare. A fluoroscopically detectable coronary calcification is correlated with major vessel occlusion in 94 percent of patients with chest pain;[16] however, the sensitivity of the test is only 40 percent (see "Cardiac Fluoroscopy," below).

Recently, electron-beam CT scanning has proved to be a sensitive tool for the detection and quantification of coronary calcifications (see Chap. 17). A negative result may indicate no need for further testing in asymptomatic individuals. A positive result, however, does not necessarily denote obstructive coronary artery disease. The sensitivity for detecting any coronary calcifications is greater than 95 percent with a *specificity of less than 65 percent* for significant coronary artery disease. Another use of this method is to identify high-risk patients with calcific nonobstructive atherosclerotic lesions. By vigorous therapeutic intervention, one may be able to halt progression or even cause regression of their disease. In fact, the results of such interventions can be correlated with the increase or decrease in coronary calcific plaques[15] (see Chap. 17).

A calcified ascending aortic aneurysm with aortic regurgitation is highly suggestive of syphilitic aortitis[14] (Fig. 12-9).

Abnormal Lucency

The abnormal lucent areas in and about the heart include (1) displaced subepicardial fat stripes caused by effusion or thickening of the pericardium (Fig. 12-10), (2) pneumopericardium (Fig. 12-11), and (3) pneumomediastinum. Pneumomediastinum is differentiated from pneumopericardium by the fact that the former shows a superior extension of the air strip beyond the confines of the pericardium.



A

B

Figure 12-10: Developing pericardial effusion in 2 weeks. *A.* A magnified view of the retrosternal area showing the hairlike normal pericardium (*arrow*) sandwiched between the subepicardial fat stripe interiorly and the mediastinal fat stripe exteriorly. The maximal width of normal pericardium is 2 mm. *B.* The same patient 2 weeks later, with moderate pericardial effusion. The pericardial cavity now measured more than 1 cm in width (*arrow*).

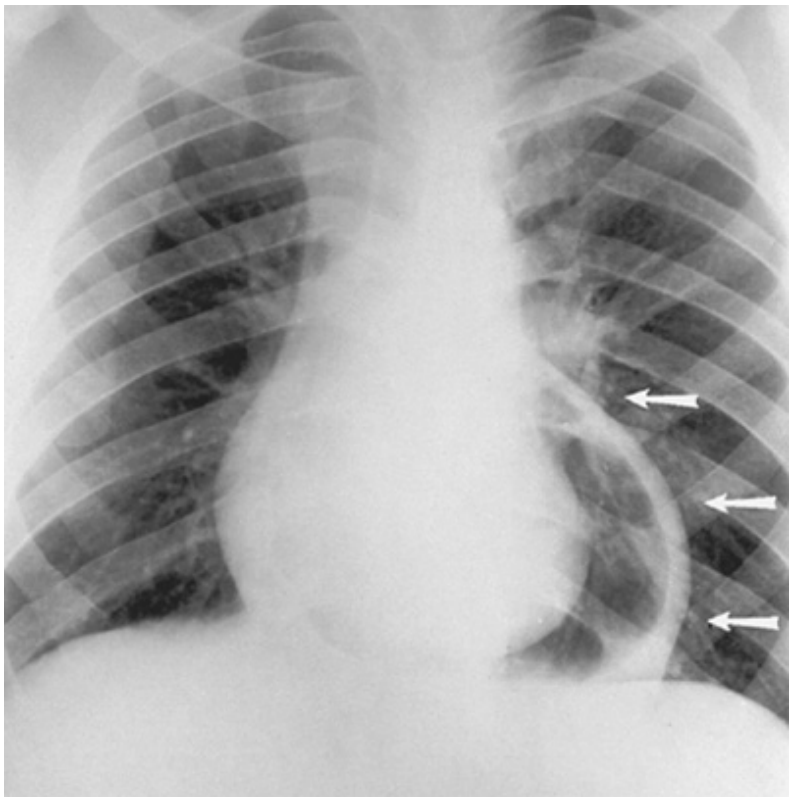


Figure 12-11: Traumatic constrictive-effusive pericarditis in a young man. Following emergent pericardiocentesis and injection of air, a radiograph was taken in the supine position. Air is confined to the left side of the pericardium. Note markedly thickened parietal layer (*arrows*).

Cardiac Malposition

According to Elliott and Schiebler, "cardiac malpositions" are diagnosed only when either the heart or the stomach is out of the normal left-sided position. This definition is crucial in distinguishing an isolated right-sided aortic arch from a cardiac malposition.[7,8]

DEXTROCARDIA WITH SITUS INVERSUS

Recently, the term *dextrocardia* has been used to indicate any congenital right-sided heart regardless of the position of abdominal viscera. To specify the kind of dextrocardia under test, one must affix the status of the abdominal viscera. *Dextrocardia with situs inversus* means the mirror image of normal. In this situation, the incidence of congenital heart disease is only 5 percent, which is a ninefold increase over the general population. The combination of dextrocardia, sinusitis, and bronchiectasis is known as *Kartagener's triad*.

DEXTROCARDIA WITH SITUS SOLITUS

This represents an anomaly with normal situs but a right-sided heart. Radiographically, normal situs (situs solitus) is a certainty when both the aortic knob and the gastric air bubble are on the left side. *Situs solitus* also means that both the abdominal viscera and the atria are in the normal position. Under these circumstances, if the ventricles fail to swing from the primitive right-sided position to the normal left-sided position, abnormal relationships between the ventricles and the rest of the cardiovascular structures are bound to develop. This entity was formerly termed *dextroversion*.

In patients with dextroversion, the incidence of congenital heart disease has been estimated at 98 percent. More than 80 percent have congenitally corrected (or L-loop) transposition of great arteries. The next most commonly associated lesions are a combination of ventricular septal defect and pulmonary stenosis, a tetralogy-like pathophysiology (Fig. 12-12). Therefore, from a statistical point of view, it is important to be able to differentiate this entity from dextrocardia with situs inversus, which is associated with a much lower incidence of congenital heart disease (see above and also Chap. 63).

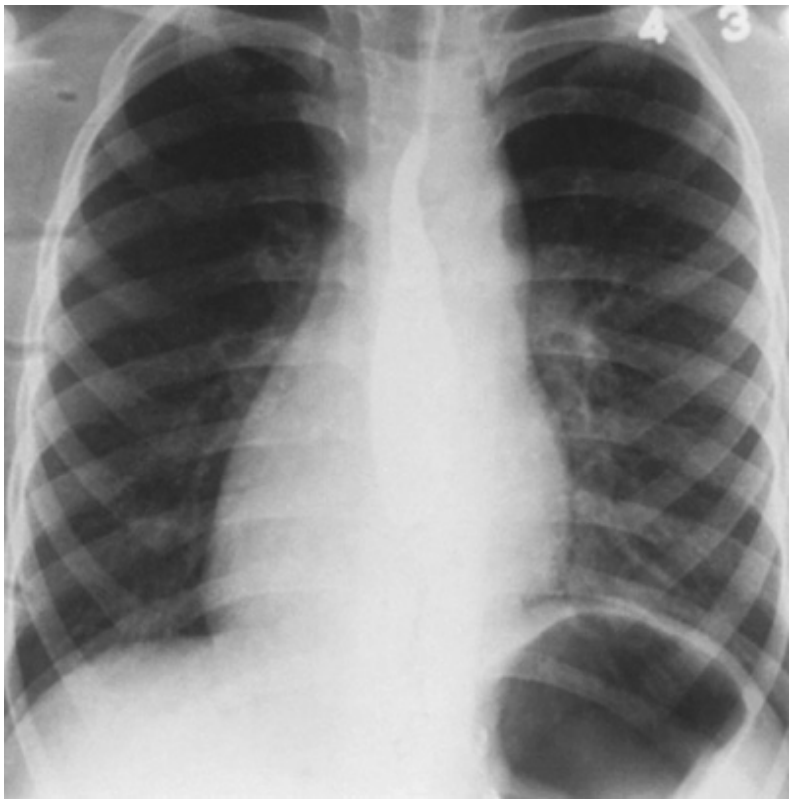

Figure 12-12: Posteroanterior view of a patient with dextrocardia and situs solitus. Note that the aortic arch and the stomach air bubble are both on the left (*situs solitus*) and the apex of the ventricles is pointing to the right inferiorly. According to statistics and proved by cardiac catheterization, this patient had the typical

combination of congenitally corrected transposition of the great arteries, ventricular septal defect, and pulmonary stenosis. He was cyanotic. The pulmonary vascularity appears decreased.

LEVOCARDIA WITH SITUS INVERSUS

This is a mirror image of dextroversion, and it is associated with an extremely high incidence (nearly 100 percent) of cyanotic congenital cardiac lesions similar to those seen in dextroversion. This entity was formerly termed *levoversion*.

LEVOCARDIA WITH SITUS SOLITUS

This is entirely normal.

CARDIAC MALPOSITIONS WITH SITUS AMBIGUUS

In this group, the patient's heart may be either left- or right-sided. The situs is ambiguous because the aortic arch and the stomach are not on the same side. Under these circumstances, we are dealing with either asplenia or polysplenia syndrome. Patients with polysplenia syndrome tend to be acyanotic, running a milder clinical course, and frequently survive into adulthood. The associated lesions are bilateral left-sidedness, interruption of the inferior vena cava with azygos continuation (see Fig. 12-4), polysplenia, and a left-to-right shunt, most frequently an atrioventricular septal defect.[17] Patients with asplenia syndrome, on the other hand, tend to be cyanotic and critically ill and die in infancy. The associated lesions are bilateral right-sidedness, asplenia, midline liver, and pulmonary stenosis or atresia with oligemic lungs. It is noteworthy that interruption of inferior vena cava has never been reported in patients with asplenia.

Other Abnormalities

GREAT VESSELS

The roentgen appearance of the great vessels often provides valuable information for the diagnosis of heart disease.[2,3,18,19] For example, selective dilatation of the ascending aorta is the hallmark of valvular aortic stenosis (Fig. 12-13); generalized dilatation of the entire thoracic aorta (Fig. 12-14), on the other hand, favors the diagnosis of aortic regurgitation, systemic hypertension, or both, depending on the size of the left ventricle. A larger left ventricle is associated with aortic regurgitation because of volume overload. In atrial septal defect and mitral stenosis, the pulmonary trunk is quite large, and the aortic knob is usually small (see Figs. 12-2*B* and 12-3*A*). This is explained on the basis of a leftward cardiac rotation that occurs when an enlarged right ventricle coexists with a normal-sized left ventricle. When the heart rotates to the left, the aorta folds on itself in the midline and becomes inconspicuous. Meanwhile, the pulmonary trunk is brought laterally and looks larger than it actually is. Aortic aneurysm (Fig. 12-15) and dissection frequently are associated with hypertensive and atherosclerotic disorders.

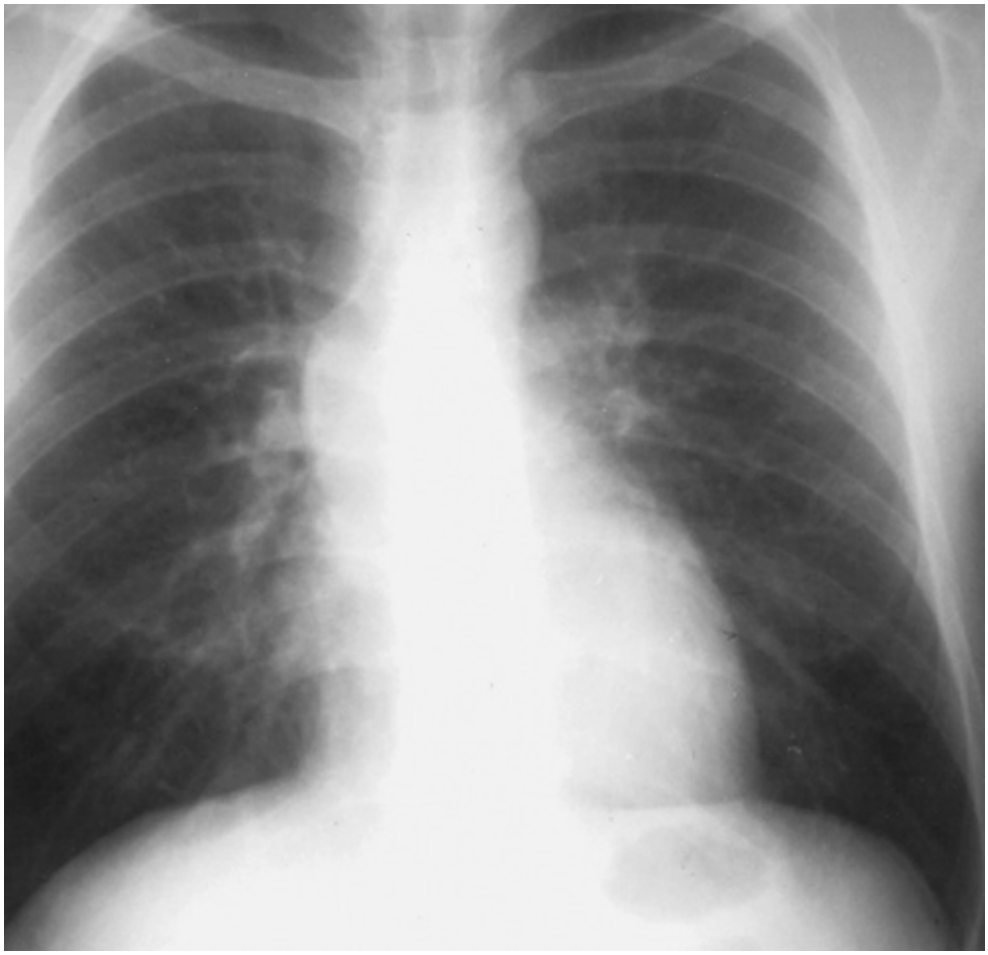

Figure 12-13: A 17-year-old boy with congenital aortic valve stenosis. Note dilatation of the ascending aorta, increased convexity of the left ventricle, and normal pulmonary vascularity. The systolic aortic pressure gradient was 100 mmHg.

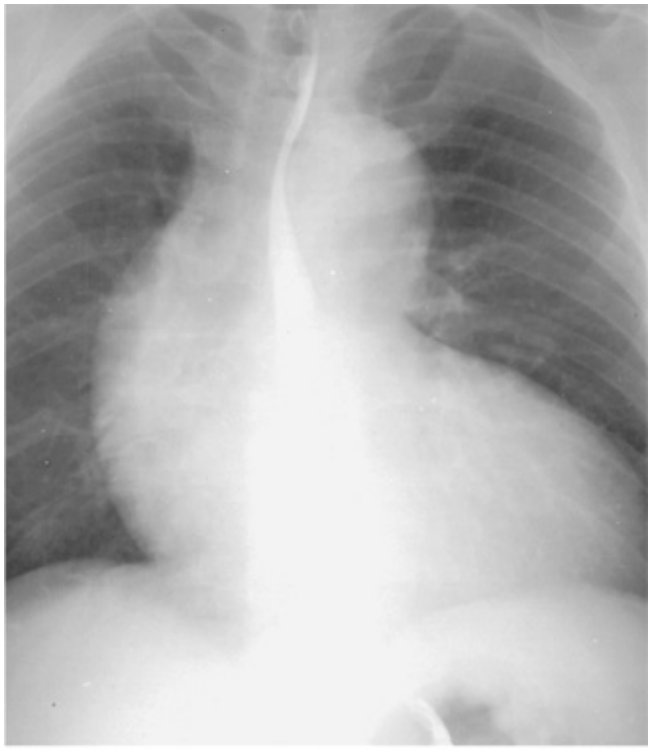
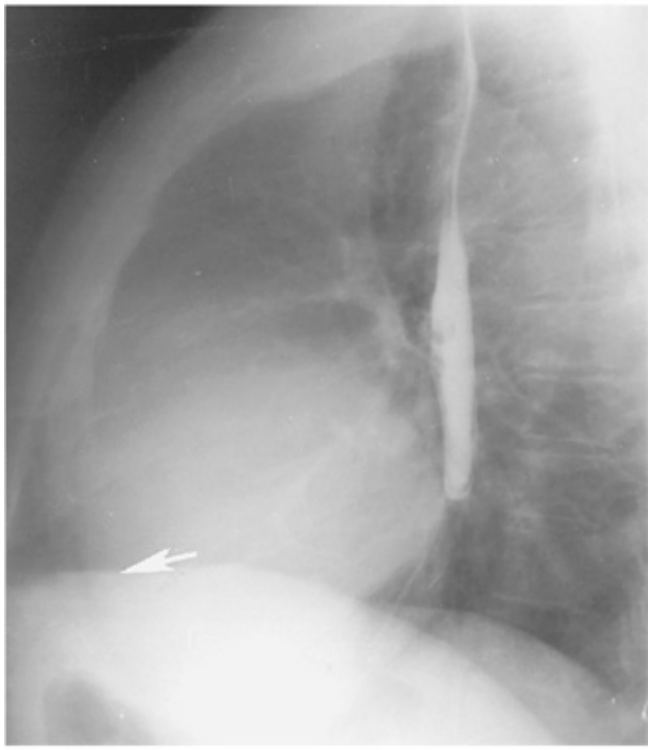


A



B

Figure 12-14: A 45-year-old man with Marfan's syndrome, severe aortic regurgitation, and proximal aortic dissection into the pericardial cavity. *A*. Posteroanterior view shows a huge left ventricular and aneurysmal dilatation of the ascending aorta. There is no sign of heart failure. *B*. Lateral view shows a small pericardial effusion (*arrow*).

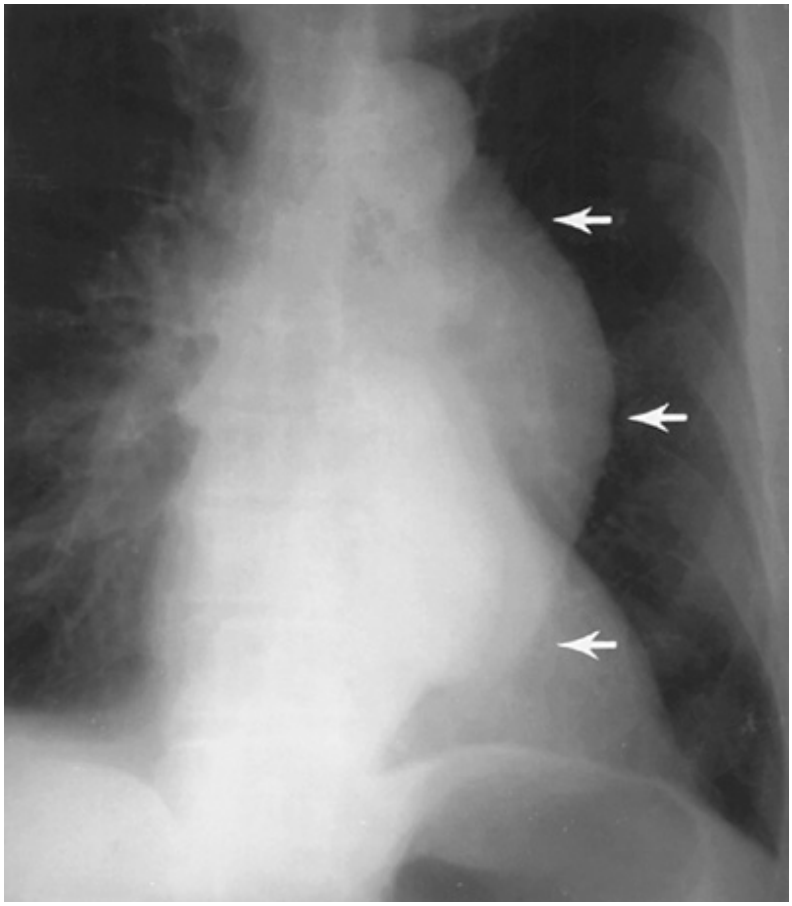


Figure 12-15: Posteroanterior view of a 77-year-old man shows a huge descending aortic aneurysm (*arrows*).

As already mentioned, prominence of the pulmonary trunk is a reliable secondary sign of right ventricular enlargement (Fig. 12-16; also see Fig. 12-2*B*), with the following exceptions: (1) tetralogy of Fallot with right ventricular hypertrophy but pulmonary trunk hypoplasia, (2) idiopathic dilatation of the pulmonary artery, (3) patent ductus arteriosus with dilated pulmonary trunk but normal right ventricle, and (4) straight-back syndrome, pectus excavatum, and scoliosis with narrowed anteroposterior diameter of the chest. Under the latter conditions, the heart is compressed, displaced, and rotated to the left, giving rise to a falsely enlarged pulmonary artery.

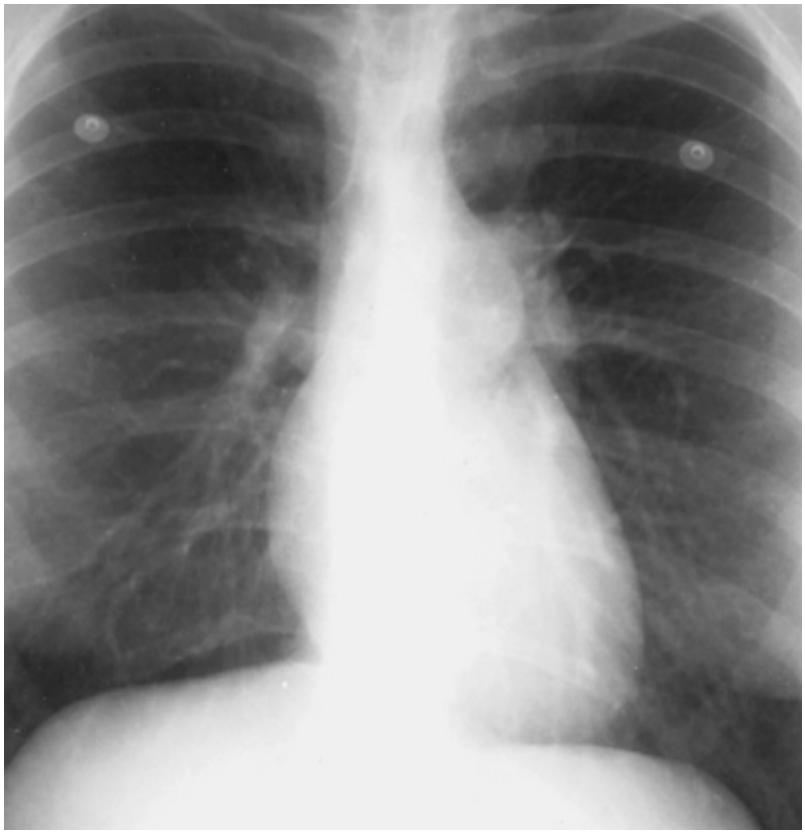

Figure 12-16: A 37-year-old woman with congenital valvular pulmonary stenosis. Note enlarged pulmonary trunk and left pulmonary artery versus diminished right pulmonary artery. Also note increased pulmonary blood flow on the left side and decreased pulmonary blood flow on the right side.

In coarctation of the aorta, the engorged aortic knob and the poststenotic dilatation of the descending aorta may cause a "3 sign" on the aorta and an "E sign" on the barium-filled esophagus, both depicting the site of coarctation[6] (see Fig. 12-1*C*).

The abnormal size and distribution of both the pulmonary and systemic veins are important clues to the presence of certain conditions, e.g., anomalous pulmonary venous connections, pulmonary arteriovenous fistulas, pulmonary varix, persistent left superior vena cava, and interruption of inferior vena cava with azygos continuation (see Fig. 12-4).

The significance of aortic arch anomalies is discussed under "Statistical Guidance," below.

MEDIASTINAL STRUCTURES

The mediastinal organs frequently are affected by the cardiovascular structures because of their close spatial interrelationships. An enlarged left atrium not only displaces the esophagus (see Fig. 12-1*C*, *D*, *E*) and the descending aorta but also elevates and compresses the left mainstem bronchus. A double aortic arch may compress both the trachea and the esophagus. On the other hand, malignant processes may invade the heart and great vessels, causing cardiac tamponade or the superior vena cava syndrome, for example. Usually, these mediastinal changes are evident on the chest roentgenogram and should be recognized promptly.[18-22]

PLEURA

A right-sided pleural effusion often is present with left-sided heart failure. A bilateral hydrothorax, on the other hand, suggests bilateral heart failure or a noncardiac etiology of the effusion. Congestive heart failure is also known to be associated with a pseudotumor or "vanishing" tumor, representing an interlobar collection of pleural fluid (Fig. 12-17). As congestive heart failure improves, the "tumor" disappears.

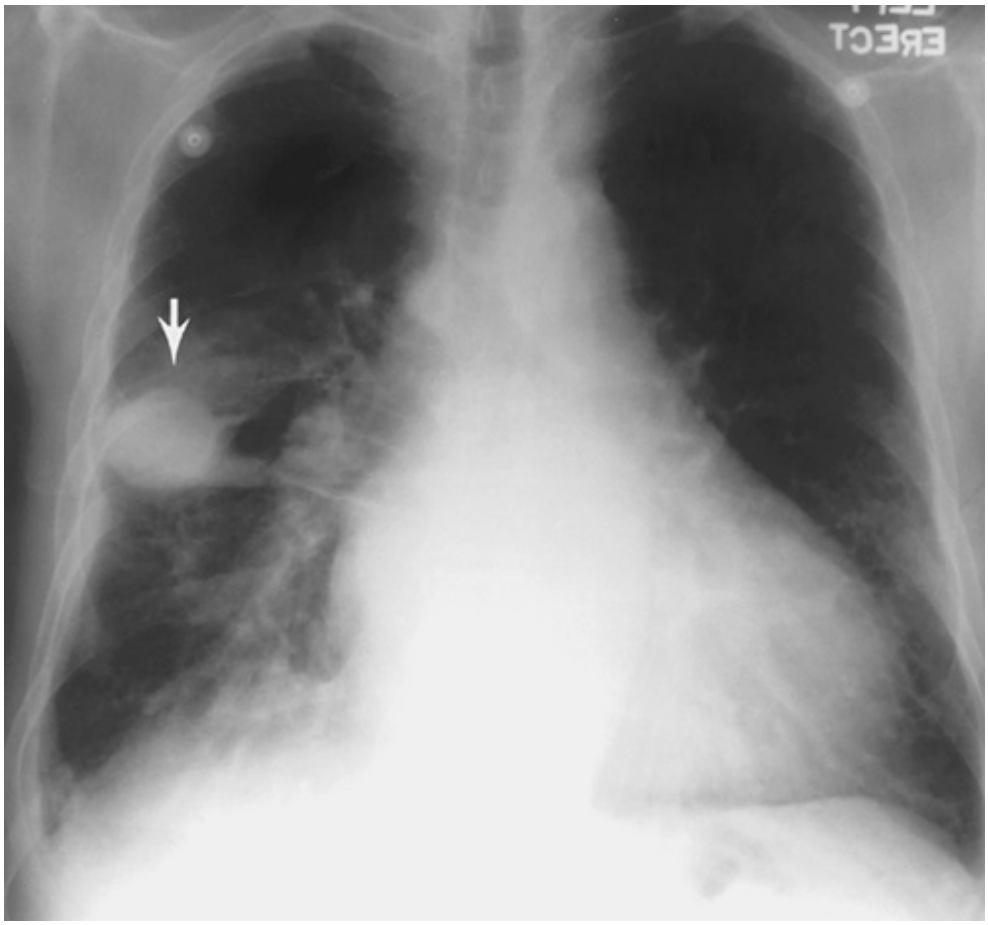

Figure 12-17: Patient with congestive heart failure. Note gross cardiomegaly, cephalization, interstitial pulmonary edema, and right-sided pleural effusion. Some of the fluid was loculated in the minor interlobar fissure (*arrow*), which disappeared with improved cardiac function.

BONES AND JOINTS

Notching of the ribs has many origins. Basically, any of the three major intercostal structures can enlarge, compress, and erode the lower borders of the ribs, producing areas of notching. They are intercostal arteries, veins, and nerves. Coarctation of the aorta[6] (see Fig. 12-1*A*) represents the most common cause of rib notching due to dynamic dilatation and tortuosity of the arteries. Superior vena cava syndrome may cause a similar phenomenon of venous origin. Neurofibromatosis also can produce rib notching by numerous intercostal neurofibromas.

SOFT TISSUES OVER THE CHEST

Patients with renal failure may show severe edema in the soft tissues over the chest as part of the picture of general anasarca (Fig. 12-18).

EXTRATHORACIC STRUCTURES

In Holt-Oram syndrome (Fig. 12-19), the upper extremity abnormalities may be evident in a chest roentgenogram or on other films in the patient's x-ray folder (see also Chap. 63). A large arteriovenous malformation with curvilinear calcifications may be seen in the neck, thereby providing a clue as to the etiology of the patient's congestive heart failure. Radiographic evaluation of the patient's abdominal viscera is an integral part of the workup for cardiac malpositions.[7,8]

Chapter 12: THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

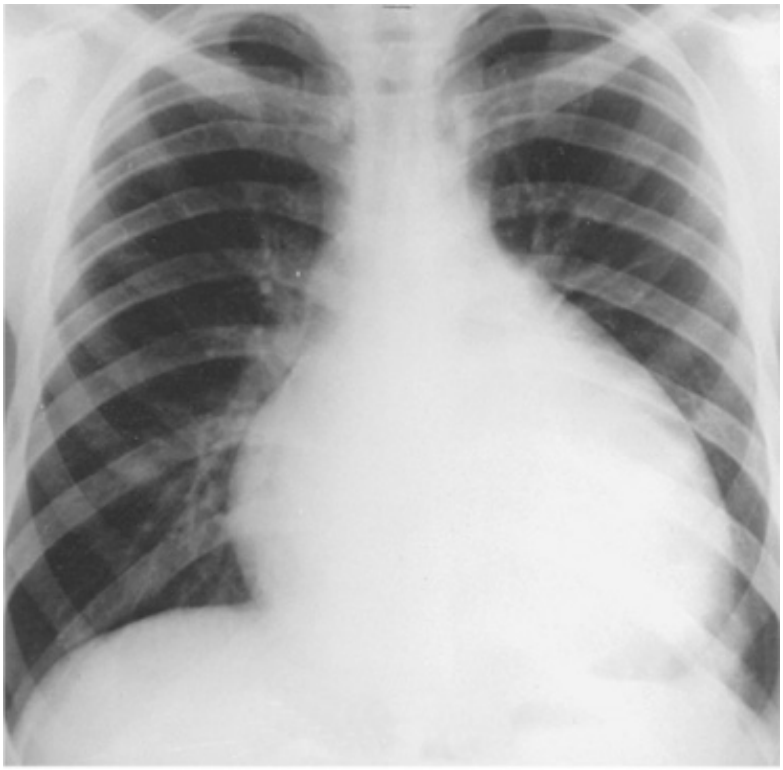
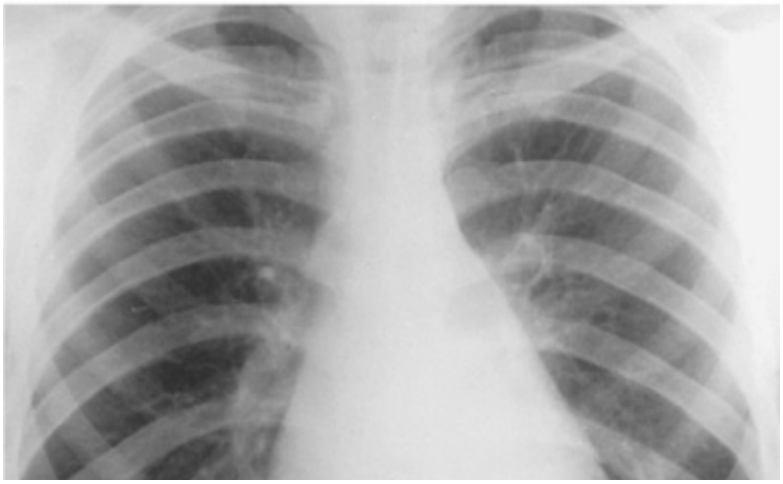
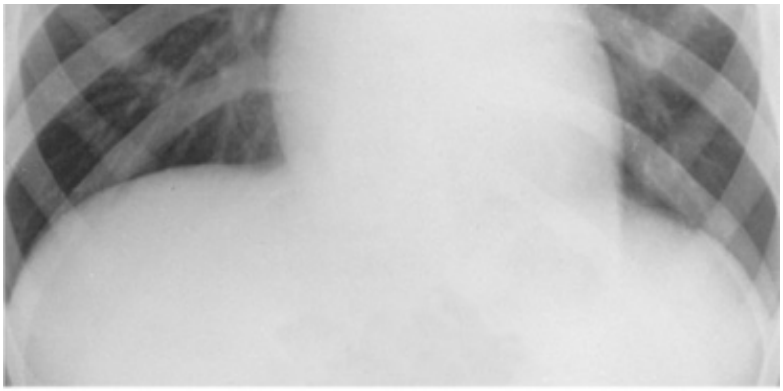
COMPARISON

To appreciate the acuteness or chronicity of the disease or its response to therapy, one must carefully compare serial roentgenograms. As demonstrated in Fig. 12-7*B*, the heart may be considered neither enlarged nor failing if the baseline study made 3 years earlier in Fig. 12-7*A* were not available for comparison (see "Heart Failure," below). Similarly, an enlarging heart with normal pulmonary vascularity is highly suggestive of pericardial effusion. Conversely, a shrinking heart in the presence of normal vascularity is compatible with resolution of a pericardial effusion (Fig. 12-20).



A





B

Figure 12-20: Young man with acute pericarditis with effusion. *A.* Posteroanterior view shows a water bottle-shaped cardiomegaly, clear lungs, and normal pulmonary vascularity. *B.* Repeat film taken 5 days later shows excellent response to therapy.

Chapter 12: THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

STATISTICAL GUIDANCE

Certain roentgenologic findings are by themselves diagnostic of a disease; other signs are suggestive of a diagnosis on the basis of statistics only. Nevertheless, the latter can be quite useful by virtue of their high predictive value of a particular disease or a group of similar diseases. Therefore, one should always keep the statistical information in mind.

The incidence of congenital heart disease in patients with right-sided aortic arch increases 10- to 100-fold depending on the anatomic details of the anomaly.[21,22] Of practical importance, there are only two types of right-sided aortic arch. The first has been called the *avian type*, implying a normal status for birds but a detrimental one for humans. The overwhelming majority of patients with this type are born with cyanotic congenital heart disease. The second may be called the *common type* because of its higher incidence in the general population. Most patients with the common type are physiologically normal and have their anomaly incidentally diagnosed on chest radiographs or a barium meal study. The x-ray findings of the two types are similar in the PA view but are quite different in the lateral view (Fig. 12-21). The incidence and list of congenital heart diseases with each type[20] are shown in Table 12-3. Only 2 percent of patients with the avian type are physiologically normal. Tetralogy of Fallot should be the diagnosis in these patients until proved otherwise.[21,22]

Table 12-3: Cardiac Defects Associated with Each Type of Right-Sided Aortic Arch

	Type of Anomaly	
	Avian	Common
Anatomic details	With mirror-image branching; the arch is anterior to the trachea	With aberrant left subclavian artery arising from a large aortic diverticulum that is posterior to the esophagus
Patients with cardiac defects, %	98	12
Type of defects, %		
Tetralogy of Fallot	90	71
Truncus arteiosus	2.5	
Transposition of great arteries	1.5	
Atrial septal defect and/or ventricular septal defect	0.5	21
Coarctation of aorta		7

Others	5.5	1

Patients with a double aortic arch, on the other hand, rarely have congenital heart disease, although they tend to be symptomatic in infancy because of a compressing vascular ring.[21]

Chapter 12: THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

CLINICAL CORRELATION

The next step in the examination is to correlate the roentgenologic findings with the clinical information and other laboratory parameters for a final conclusion. It may become necessary at this point to reexamine the radiograph or review the fluoroscopic observation or both. After detailed analysis of some finer points, a wrong impression may be corrected or a correct diagnosis reinforced[2] (see Table 12-2).

Chapter 12: THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

PULMONARY VASCULARITY

Normal

The normal roentgen appearance of the pulmonary vasculature of an upright human being is typified by a caudal flow pattern because of gravity. The pressure differential between the apex and the base of the lung is approximately 22 mmHg in adults in the upright position.[2,23] Therefore, more flow under higher distending pressure is expected in the lower-lobe vessels than in the upper. Normally, one sees very little vascularity above the hilum, whereas more and larger vessels are found below the hilum. Since the pulmonary resistance is normal, all vessels taper gradually in a treelike manner from the hilum toward the periphery of the lung. The right descending pulmonary artery measures 10 to 15 mm in diameter in males and 9 to 14 mm in females[2,24] (see Fig. 12-2).

Abnormal

Abnormal pulmonary vascularity can be classified into two categories, either in terms of volume or in terms of distribution[2,10,25] (Table 12-4).

Abnormalities in Volume

In the evaluation of pulmonary vasculature, the caliber of the vessels is more important than the length or the number. As long as the PBF pattern remains normal, with a greater amount of flow to the bases than to the apices, the volume of the flow is proportional to the caliber of the pulmonary arteries (see Fig. 12-2). In addition to measuring the right descending pulmonary artery, one also may assess the pulmonary blood volume by comparing the size of the pulmonary artery with that of the accompanying bronchus where they are viewed on end. Normally, the two structures have approximately equal diameters.[2,26] When the artery-bronchus ratio is greater than unity, increased blood flow is suggested. Conversely, when the ratio is smaller than unity (see Fig. 12-2), decreased flow is likely.

INCREASED PBF

In the case of mild to moderate left-to-right shunts, for example, the vessels dilate in proportion to the increased flow with no significant change in pressure, resistance, or flow pattern. This phenomenon is also called *shunt vascularity* or *equalization*. Equalization of PBF between the upper and lower lung zones is only apparent rather than real, however; the lower lobes still receive a great deal more blood than the upper lobes, although the ratio of PBF between the two zones has changed-e.g., from 5:1 to 4:1 or 3:1. A mild increase in pulmonary vascularity with slight cardiomegaly is commonly found in pregnant women and trained athletes with increased cardiac output and supernormal performance of the heart (see Chaps. 82 and 85).

DECREASED PBF

Patients with tetralogy of Fallot frequently show decreased pulmonary vascularity with smaller and shorter pulmonary arteries and veins and more radiolucent lungs (see Fig. 12-2*C*).

Marked reduction in PBF is also encountered in patients with isolated right-sided heart failure without a right-to-left shunt (see Fig. 12-7). This is attributed to the significant decrease in cardiac output from both ventricles.

Abnormalities in Distribution

An abnormal distribution of PBF (or an abnormal PBF pattern) always reflects a changed pulmonary vascular resistance, either locally or diffusely.

CEPHALIZATION

In the presence of postcapillary pulmonary hypertension, physiologic disturbances may begin when the total intravascular pressure exceeds the oncotic pressure of the blood. As a result, fluid leaks out of the vessels and collects in the interstitium before pouring into the alveoli.

Pulmonary edema interferes with gas exchange, resulting in a state of hypoxemia. Alveolar hypoxia has a profound influence on the pulmonary vessels, causing them to constrict. Since there is greater alveolar hypoxia in the lung bases than in the apices, the basilar vessels constrict significantly, forcing the blood to flow upward. This phenomenon actually represents a reversal of the normal PBF pattern: redistribution or cephalization of the pulmonary vascularity.

Cephalization occurs in any of three conditions: (1) left-sided obstructive lesions, e.g., mitral stenosis[24] (see Fig. 12-3*A*) or aortic stenosis, (2) left ventricular failure, e.g., coronary heart disease or cardiomyopathies, and (3) severe mitral regurgitation even before pump failure of the left ventricle occurs. It should be emphasized that unless there is obvious constriction of the lower-lobe vessels, the diagnosis of cephalization should not be made. Dilatation of the upper-lobe vessels is of secondary importance and can be found without narrowing of the basilar vessels in a number of entities, most noticeably left-to-right shunts.

CENTRALIZATION

In the presence of precapillary pulmonary hypertension, the pulmonary trunk and central pulmonary arteries dilate, whereas the distal pulmonary arteries constrict in a concentric fashion from the periphery of the lung toward the hilum. This phenomenon is called *centralization of the pulmonary vascularity*. It occurs in patients with primary pulmonary hypertension (see Fig. 12-3*B*), Eisenmenger's syndrome, recurrent pulmonary thromboembolic disease, or severe obstructive emphysema (see Fig. 12-7*A*, *B*).

LATERALIZATION

Massive unilateral pulmonary embolism may cause a lateralized PBF pattern. Since one major pulmonary artery is obstructed, the blood is forced to flow through the healthy lung only. The paucity of pulmonary vascularity in the diseased lung with the obstructed pulmonary artery is termed the *Westermark sign* (see Fig. 12-3*C*). In the case of congenital valvular pulmonary stenosis, a jet effect from the stenotic valve can cause a lateralized PBF pattern in favor of the left side (see Fig. 12-16).

LOCALIZATION

A localized abnormal flow pattern is exemplified by a congenital pulmonary arteriovenous fistula in a cyanotic child (see Fig. 12-3*D*).

COLLATERALIZATION

Patients with markedly decreased PBF (e.g., severe tetralogy of Fallot) tend to show numerous small and tortuous bronchial arterial collaterals in the upper medial lung zones near their origin from the descending aorta. The native pulmonary arteries are extremely small, although smooth and gracefully branching (see Fig. 12-3*E*).

Combined Abnormalities

In reality, an abnormal pulmonary vascularity is often a mixed type. There is a great variety of possible combinations-e.g., cephalization plus decreased flow in severe mitral stenosis (see Fig. 12-3*A*) or centralization with increased PBF in Eisenmenger's atrial septal defect (Fig. 12-22).

Summary

Roentgen analysis of the pulmonary vasculature is accomplished in two steps. First, the volume of the pulmonary flow can be estimated by the degree of pulmonary arterial enlargement as long as the PBF pattern remains normal. Second, the distribution of the pulmonary flow is assessed by the presence of an abnormal flow pattern. The volume and the distribution of pulmonary blood flow may change singly or in combination de pending on the nature and severity of the underlying heart disease.

Chapter 12: THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

HEART FAILURE

In addition to specific chamber enlargement, the pulmonary vasculature uniquely portrays the underlying pathophysiology of heart failure. In the chronic setting, decreased flow with increased pulmonary lucency is the hallmark of right-sided heart failure (see Fig. 12-7); striking cephalization of the pulmonary vasculature is typical for left-sided decompensation (see Figs. 12-3*A* and 12-6*B*).

Left-Sided

ACUTE LEFT-SIDED HEART FAILURE

The pulmonary vascular changes associated with acute left ventricular failure are usually not discernible for two reasons: (1) the resulting severe pulmonary edema obscures the pulmonary vasculature, and (2) the redistribution of PBF secondary to acute left-sided heart failure is usually relatively mild. The combination of alveolar pulmonary edema and a normal-sized heart is the hallmark of acute left-sided heart failure[10] (see Fig. 12-6*A*), most commonly seen in acute myocardial infarction. The edema fluid under this circumstance tends to distribute in a butterfly pattern.[27] The reason for this is poorly understood.

CHRONIC LEFT-SIDED HEART FAILURE

Chronic left-sided heart failure is characterized by gross cardiomegaly, striking cephalization of the pulmonary vasculature and interstitial pulmonary edema or fibrosis with multiple distinct Kerley B lines. Pulmonary hemosiderosis, ossification, or both may result from long-standing severe postcapillary pulmonary hypertension (see Figs. 12-6*B*, *C*, *D* to *E*).

Right-Sided

ACUTE RIGHT-SIDED HEART FAILURE

Acute right-sided heart failure most commonly results from massive pulmonary embolism. The typical radiographic signs are rapidly developing centralization of the pulmonary vasculature and dilatation of the right-sided cardiac chambers and venae cavae. In addition, the lungs may show localized or lateralized oligemia (see Fig. 12-3*C*). Eventually, opacities in either or both lungs may develop as a result of pulmonary infarction.

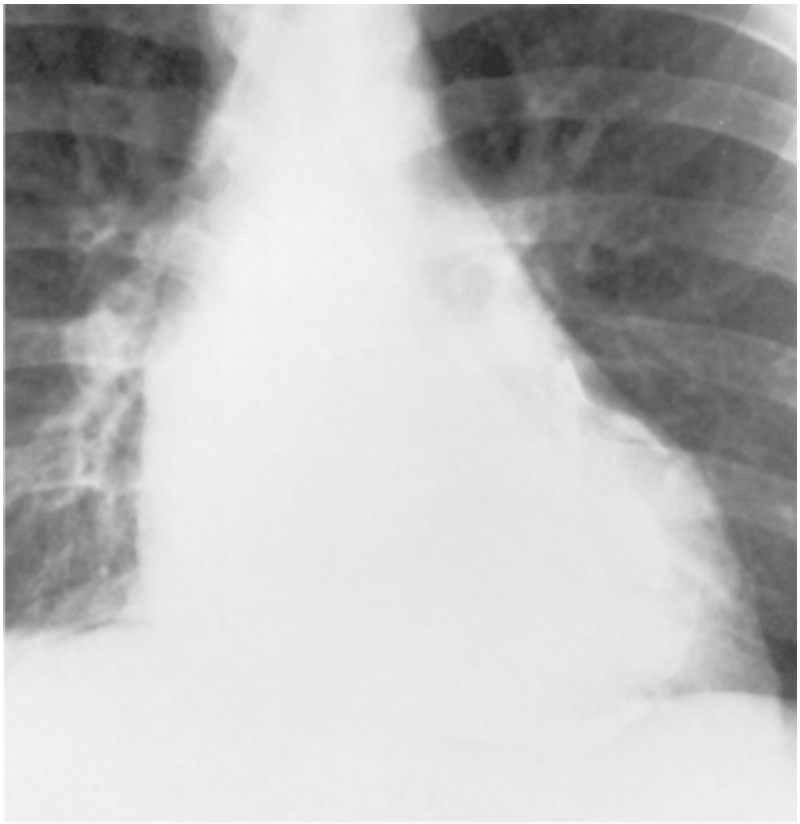
CHRONIC RIGHT-SIDED HEART FAILURE

Chronic right-sided heart failure has a number of causes. The common ones include congenital pulmonary stenosis, Ebstein's anomaly, severe chronic obstructive pulmonary disease, and recurrent pulmonary thromboembolic disease. Diffusely decreased pulmonary vascularity with unusually lucent lungs is seen in patients with right-sided heart failure without pulmonary hypertension (see Fig. 12-7*C*). Centralized PBF pattern is encountered when the right-sided heart failure is secondary to precapillary pulmonary hypertension (see Fig. 12-7*A*, *B*). A cephalized flow pattern with unusually lucent lungs is found in patients with right-sided

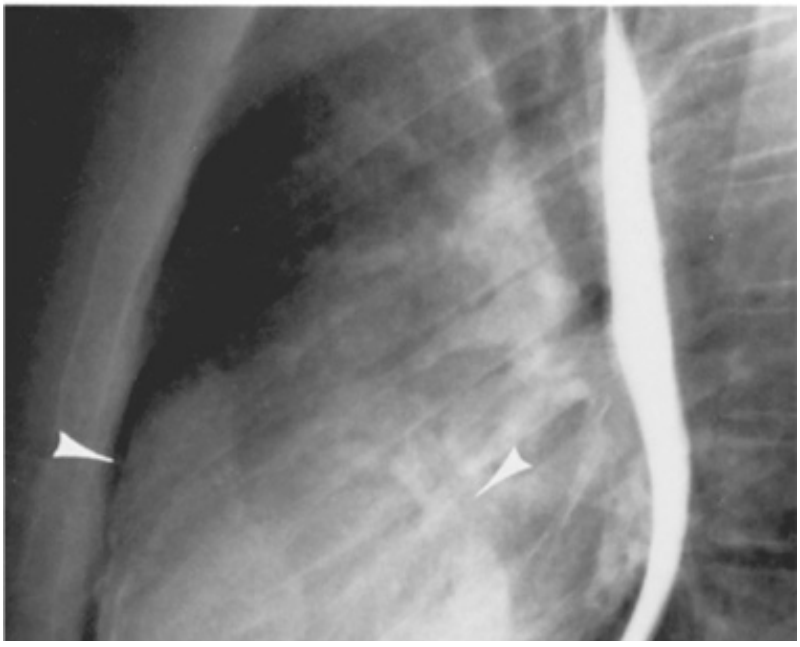
heart failure secondary to long-standing severe left-sided heart failure (see Fig. 12-7*D*). The degree of right-sided chamber enlargement is proportional to the severity of tricuspid regurgitation.

Combined

It is generally believed that right-sided heart failure is caused most often by severe left-sided heart failure. This is exemplified by patients with severe mitral stenosis leading to severe tricuspid regurgitation (see Fig. 12-7*D*). Other examples of bilateral heart failure are cardiac tamponade and constrictive pericarditis, when both sides of the heart are affected (Fig. 12-23).



A



B

Figure 12-23: Patient with calcific constrictive pericarditis. Typically there is only mild postcapillary pulmonary hypertension due to left-sided constriction. Severe pulmonary venous congestion is prevented by the concurrent right-sided constriction. *A*. Posteroanterior view shows moderate cardiomegaly and mildly cephalic pulmonary blood flow pattern. *B*. Lateral view shows heavy calcification of the pericardium (*arrows*) and left atrial enlargement deviating the barium-filled esophagus posteriorly.

Chapter 12: THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

CARDIAC FLUOROSCOPY

Cardiac radiography deals primarily with anatomic details by filming at short exposure times that stop the motion. Cardiac fluoroscopy, on the other hand, explores the dynamic features of the organ that are discernible only in motion.[28] The two techniques are mutually complementary.

Description

A good-quality image intensifier is a prerequisite for the proper performance of cardiac fluoroscopy.[2,19] The modern intensifier with cesium iodide phosphors has increased the brightness of the fluoroscopic image at least 10,000 times. Television viewing permits cone vision under dim light with better perception of detail. The attached videotape or videodisk recorder providesa means for instant playback as well as future analysis of the fluoroscopic observations.

The milliamperage and kilovoltage of the fluoroscope should be adjusted according to the patient's size in different projections. The milliamperage ranges from 1.5 to 3.5 mA, and the kilovoltage varies between 90 and 120 kV. Too high a kilovoltage tends to reduce the contrast, and excessive milliamperage blurs the margin of the image. The shortest fluoroscopic time and the smallest shutter opening are employed to keep the dose of radiation to the patient to the minimum. The average examining time for this author is 3 min.

The patient is routinely examined in the erect position with four views. The patient should be asked to stop breathing during the brief moment of fluoroscopy. A barium meal is given only after a thorough search for cardiac calcifications is completed. Occasionally, a recumbent position is used for better visualization of small calcifications, as well as for a critical evaluation of cardiac asynergy. The cardiac output increases and the heart rate decreases on assuming recumbency, thereby giving a truer and more representative picture of the left ventricular contractility. In obese patients, the thick layer of soft tissue over the thorax is compressed and pushed aside, thereby improving the fluoroscopic image significantly.

Results

When performed properly, cardiac fluoroscopy is useful in the following areas of investigation: (1) assessment of cardiovascular dynamics, (2) detection of small cardiovascular calcifications, (3) visualization of important anatomic landmarks, e.g., subepicardial fat stripes, (4) differentiation of cardiac from noncardiac disease, and (5) evaluation of cardiac valve prostheses, pacemakers, and radiopaque foreign bodies.

Precautions

Although no complication from modern fluoroscopy has been reported, both the patient and the examiner should be protected from excessive radiation. Even with an image intensifier, a routine cardiac fluoroscopy still involves more radiation than does two-view chest roentgenography. Therefore, the fluoroscopist should accomplish the task within the shortest possible period of time. Although all aspects of the heart are surveyed briefly, one should emphasize special areas of interest for each patient, as suggested by the baseline radiographs. If coarctation of the aorta is suspected in a patient older than 40 years of age, for instance, particular attention should be paid

to finding calcium in a stenotic bicuspid aortic valve.

Applications

ASSESSMENT OF CARDIOVASCULAR DYNAMICS

The chest roentgenogram that is taken at random largely records the diastolic image of the heart. Fluoroscopy, on the other hand, provides a continuous vision of the pulsating organ through the entire cardiac cycle. On becoming familiar with the normal cardiovascular movements, the fluoroscopist will find that any deviation from the norm will be obvious.[2,29-32]

The telltale x-ray signs of many cardiac lesions manifest themselves only in ventricular systole. Therefore, what may be missed on the film is often readily seen and diagnosed under the fluoroscope. For instance, left ventricular enlargement may be the only radiographic abnormality of severe aortic regurgitation in children or young adults. On fluoroscopy, however, the aorta is vigorously expanding in systole and rapidly collapsing in diastole. This dynamic alternation is characteristic of aortic regurgitation (Fig. 12-24). Other examples include mild mitral regurgitation, mitral valve prolapse, left ventricular dyskinesia, and broad-based left ventricular aneurysm.

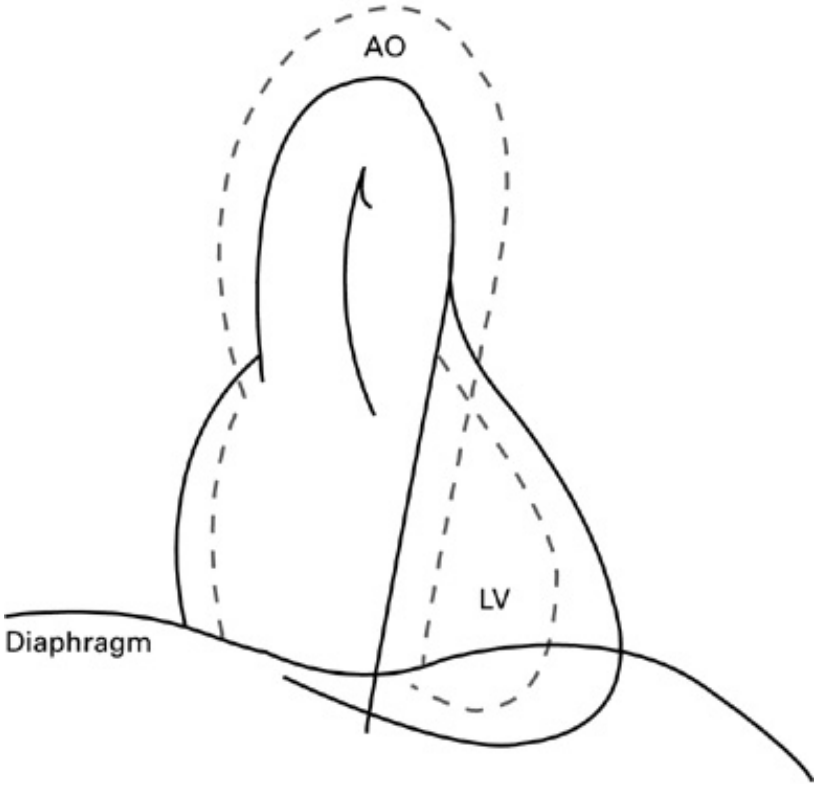

Figure 12-24: Schematic representation of dynamic changes of aortic regurgitation. Blue interrupted lines represent images in systole; solid lines, those in diastole.

In valvular pulmonary stenosis, vigorous pulsation of the pulmonary trunk and its left branch is in bold contrast to the diminished pulsation of the right pulmonary artery.[31] Increased pulsation of diffusely enlarged pulmonary arteries is characteristic of left-to-right shunts. When marked discrepancy in size and pulsation is noted between the central and peripheral vessels, Eisenmenger's syndrome should be considered. Exaggerated left atrial expansion in ventricular systole is a reliable sign of mitral regurgitation.[32]

DETECTION OF CARDIOVASCULAR CALCIFICATIONS

Heavy calcifications of the heart and vessels are easily detected by chest roentgenography, particularly in the lateral and oblique views (Fig. 12-25). Small calcifications, on the other hand, can be registered only by fluoroscopy by virtue of their rhythmic movements from the pulsating heart.[3,8] Detection of even tiny coronary artery calcifications is of vital practical importance. The combination of chest pain and coronary calcification results from major vascular obstruction 94 percent of the time.[16] Since the major coronary arteries are embedded in the subepicardial fat stripes in the grooves between cardiac chambers (Fig. 12-26), such fat stripes can be used effectively to locate the calcified arteries. Under the fluoroscope, the fat stripes present as pulsating radiolucent (bright) lines, in contrast to the accompanying pulsating radiopaque (dark) lines of calcified coronary arteries. If the artery coincides with the fat line within the left atrioventricular groove (aL), it portrays the circumflex coronary artery. The right coronary artery is moving synchronously with the right atrioventricular groove (aR). The anterior descending artery coincides with the anterior interventricular groove (vA), as does the posterior descending artery with the posterior interventricular groove (vP).

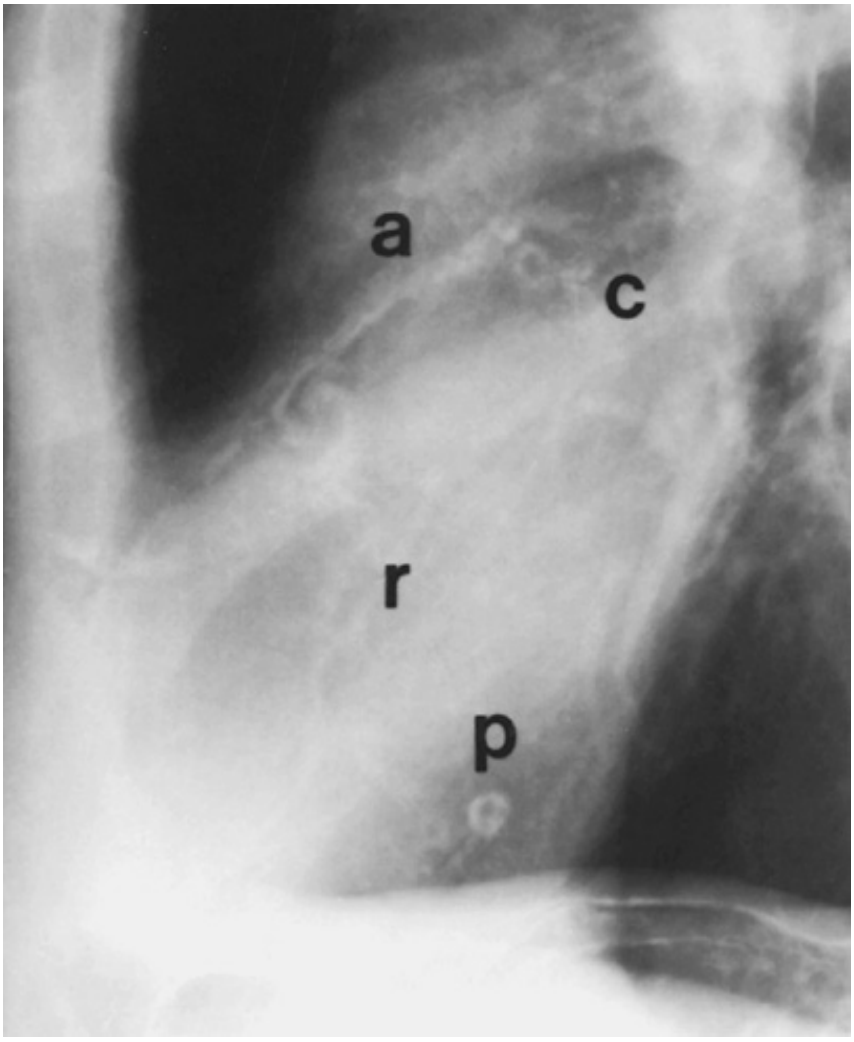

Figure 12-25: Lateral view shows heavy railroad track-like calcification of all three major coronary arteries. r, right coronary artery; a, anterior descending; c, circumflex; p, posterior descending. Note the ringlike densities representing vessels viewed on end.

The lateral view is the best or the only view for detection of a calcified right coronary artery. The left anterior oblique view at 20 to 30° is the most suitable for localizing the bifurcation of the left coronary artery. In this view, the left coronary artery is brought into relief between the hilar shadow anteriorly and the spinal column posteriorly. A ringlike density is seen frequently in this view, representing the end-on image of the calcified anterior descending artery. The right anterior oblique angle is used to view a calcified left main coronary artery. If both the anterior descending and the circumflex branches are also calcified, a Y-shaped density may be seen. The calcified cardiac valves, the myocardium, and the pericardium are easily confirmed by fluoroscopy.[2,29]

VISUALIZATION OF SUBEPICARDIAL FAT STRIPES

The subepicardial fat lines are important landmarks in the diagnosis of heart disease. The fat stripe is a cushion-like structure separating the myocardium from the pericardium. Normally, it is difficult to see the fat line because of the adjacent similar radiolucency of the air-filled lung. The in-between hairline density of the normal pericardium is delicate and also difficult to see except in the left lateral view (Fig. 12-10*A*). In the presence of pericardial effusion or thickening, the subepicardial fat line is displaced interiorly and becomes more visible because of the added background of water density (**see** Fig. 12-10*B*). The subepicardial fat pulsates with the contracting myocardium within the immobile band of pericardial fluid. This is diagnostic of pericardial effusion.[33] In contrast, when pericardial thickening alone is present, the exterior border of the heart pulsates with the fat line. This, in turn, suggests the diagnosis of pericardial constriction.

Although the displaced subepicardial fat stripe is visualized only in the lateral radiograph (**see** Fig. 12-10*B*), fluoroscopically, the pulsating fat line is clearly visible in all four views throughout the entire cardiac cycle (Fig. 12-27).

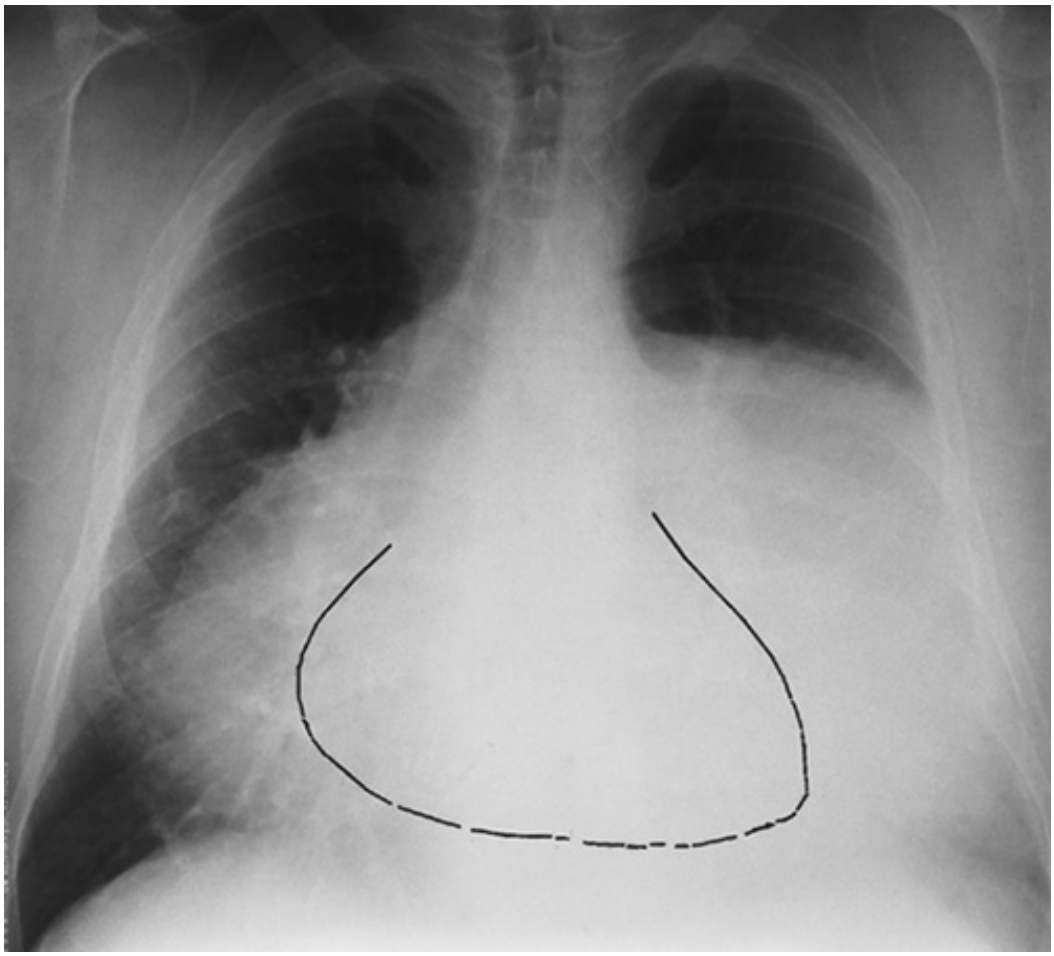

Figure 12-27: A young man with a slowly developed pericardial effusion without cardiac tamponade. His posteroanterior view shows a huge water bottle-like cardiac silhouette. Note the lungs are clear and the PBF pattern is normal. The subepicardial fat stripe (black curvilinear line) within the immobile pericardial effusion was clearly visible and bouncing vigorously under the fluoroscope. The amplitude of excursion of the fat stripe reflected the normally functioning myocardium.

DIFFERENTIATION OF CARDIAC FROM NONCARDIAC DISEASE

When respiration is suspended, any structures that are moving are likely to be cardiovascular in nature. Conversely, noncardiac structures are immobile. This is exemplified by a bullet in the heart versus another in the chest wall. A pulmonary varix or an azygos vein collapses on Valsalva maneuver, with exaggerated pulsation following release of the breath. Enlarged lymph nodes in these areas, on the other hand, will not change with such a maneuver.

EVALUATION OF VALVE PROSTHESES AND PACEMAKERS

The normal movements of cardiac valve prostheses are parallel between the two phases of the cardiac cycle. If a significant angle of tilt (more than 12°) is formed between the two phases, instability of the valve with associated regurgitation is nearly always present.[2,29,32,34]

The bileaflet St. Jude valve[35] is used in both mitral and aortic positions. The valve is difficult to see radiographically (Fig. 12-28) but is readily detected under the fluoroscope.[1,2,35] When the leaflets move sluggishly, thrombotic stenosis of the valve should be suspected. Rarely, one leaflet may dislodge and embolize distally, causing acute valvular regurgitation.[35]

Figure 12-28: Patient with congenitally corrected transposition of the great arteries. The left-sided atrioventricular valve was replaced with a St. Jude prosthesis. The valve was caught in the opened position (in diastole), when both leaflets were seen as a pair of parallel lines (*arrows*). The same valve was invisible in the closed position (*not shown*).

The position of the pacemaker can be determined promptly under the fluoroscope and recorded on film.[2,36] The subepicardial fat line overlies the myocardium and underlies the pericardium. If the pacing catheter is found within the fat stripe, it may have passed through the coronary sinus and entered one of the major cardiac veins. If the tip of the catheter is seen outside the fat stripe, however, it may have perforated the myocardium and thus be lying in the pericardium or beyond.[2] Although the wires and electrodes of a transmediastinal pacemaker may look normal on the films, minor breakage can be appreciated only in ventricular systole with the aid of fluoroscopy.[36]

Chapter 12: THE CHEST ROENTGENOGRAM AND CARDIAC FLUOROSCOPY

List of Figures

Figure 12-4: Patient with situs ambiguous, interruption of the inferior vena cava, ventricular septal defect, and polysplenia. *A.* Posteroanterior view shows that the aortic arch and the heart are left-sided and the stomach (*lower arrows*) is right-sided. The azygos vein (*upper arrow*) is markedly enlarged. The heart is mildly enlarged, and there is a moderate increase in pulmonary vascularity. *B.* Lateral view shows an absent image of the inferior vena cava. The azygos arch (*arrow*) is markedly dilated.

Figure 12-5: A 16-year-old girl with straight-back syndrome. *A.* Posteroanterior radiograph shows normal pulmonary vascularity and normal heart size. Note leftward displacement and rotation of the heart, making its left border unusually prominent. *B.* Lateral view shows that the anteroposterior diameter of the chest is extremely narrow. The heart is squeezed, creating an innocent murmur.

Figure 12-6: Roentgen appearance of left-sided heart failure. *A.* Acute. Patient with acute mitral regurgitation due to rupture of chordae tendineae showing "bat wings" appearance of severe alveolar type of pulmonary edema and a normal-sized heart. *B.* Chronic. Patient with severe mitral and tricuspid regurgitation and mild aortic regurgitation. This is a predominantly left-sided failure pattern. Note gross cardiomegaly with striking cephalization and interstitial pulmonary edema. The giant left atrium forms the right cardiac border (*open arrow*), makes its appendage bulge outward on the left side (*upper large arrow*), and splays the mainstem bronchi wide apart (*solid lines*). The huge right atrium forms a double density within the right cardiac border (*three small arrows*). The upper small arrow marks the peribronchial cuffing of edema fluid. The lower large arrow points to multiple Kerley B lines. *C.* Magnified view of right costophrenic sulcus showing multiple Kerley B lines (*arrow*). *D.* A 44-year-old woman with severe mitral stenosis. Her radiograph shows a diffuse stippling with fine nodules representing hemosiderosis. Hemosiderin-laden macrophages were found in her sputa. *E.* Posteroanterior radiograph of a 63-year-old man with severe mitral stenosis, status post mitral valve replacement, shows multiple scattered bony nodules (*arrows*) 2 to 10 mm in diameter throughout the lower two-thirds of both lungs, compatible with pulmonary ossification.

Figure 12-7: Roentgen appearance of right-sided heart failure. *A.* Patient with severe obstructive emphysema showing overaeration of the lungs, centralized flow pattern, and a small heart size. *B.* Three years later, the patient was in frank right-sided heart failure. Note that the heart got bigger as his emphysema got worse. The centralized flow pattern became more severe. *C.* Patient with Ebstein's anomaly showing gross cardiomegaly with severe decrease in pulmonary vascularity. The right cardiac border represents the huge right atrium, and the left cardiac border represents the giant right ventricle. *D.* Patient with mitral stenosis showing a giant right atrium (*arrow*) representing severe functional tricuspid regurgitation due to unrelenting left-sided failure. The pulmonary venous congestion had improved following the onset of right-sided heart failure.

Figure 12-8: Left ventricular aneurysms. *A.* Posteroanterior view of patient 1 shows a localized bulge (*arrows*) along the left cardiac border representing a left ventricular aneurysm from the anterolateral wall. *B.* Lateral view shows a double density with sharp borders anteriorly and superiorly (*arrows*). This is the left ventricular aneurysm that casts a shadow on the normal right ventricle. Fluoroscopically, it is easy to confirm its origin and to separate it from the right ventricle by rotating the patient under direct vision. *C.* Posteroanterior view of patient 2, a 69-year-old man, shows total calcification of an anterolateral apical left ventricular aneurysm (*arrows*). *D.* Lateral view shows the same (*arrows*).

Figure 12-9: A 71-year-old woman with syphilitic aortitis. Her posteroanterior radiograph (*A*) shows a huge, calcified ascending aortic aneurysm (*arrows*). In addition, the entire aorta and the left ventricle are markedly dilated, compatible with severe aortic regurgitation (From Chen,[14] with permission.) A magnified view of the ascending aorta (*B*) shows the calcified aneurysm to better advantage.

Figure 12-10: Developing pericardial effusion in 2 weeks. *A.* A magnified view of the retrosternal area showing the hairlike normal pericardium (*arrow*) sandwiched between the subepicardial fat stripe interiorly and the mediastinal fat stripe exteriorly. The maximal width of normal pericardium is 2 mm. *B.* The same patient 2 weeks later, with moderate pericardial effusion. The pericardial cavity now measured more than 1 cm in width (*arrow*).

Figure 12-11: Traumatic constrictive-effusive pericarditis in a young man. Following emergent pericardiocentesis and injection of air, a radiograph was taken in the supine position. Air is confined to the left side of the pericardium. Note markedly thickened parietal layer (*arrows*).

Figure 12-12: Posteroanterior view of a patient with dextrocardia and situs solitus. Note that the aortic arch and the stomach air bubble are both on the left (*situs solitus*) and the apex of the ventricles is pointing to the right inferiorly. According to statistics and proved by cardiac catheterization, this patient had the typical combination of congenitally corrected transposition of the great arteries, ventricular septal defect, and pulmonary stenosis. He was cyanotic. The pulmonary vascularity appears decreased.

Figure 12-13: A 17-year-old boy with congenital aortic valve stenosis. Note dilatation of the ascending aorta, increased convexity of the left ventricle, and normal pulmonary vascularity. The systolic aortic pressure gradient was 100 mmHg.

Figure 12-14: A 45-year-old man with Marfan's syndrome, severe aortic regurgitation, and proximal aortic dissection into the pericardial cavity. *A.* Posteroanterior view shows a huge left ventricular and aneurysmal dilatation of the ascending aorta. There is no sign of heart failure. *B.* Lateral view shows a small pericardial effusion (*arrow*).

Figure 12-15: Posteroanterior view of a 77-year-old man shows a huge descending aortic aneurysm (*arrows*).

Figure 12-16: A 37-year-old woman with congenital valvular pulmonary stenosis. Note enlarged pulmonary trunk and left pulmonary artery versus diminished right pulmonary artery. Also note increased pulmonary blood flow on the left side and decreased pulmonary blood flow on the right side.

Figure 12-17: Patient with congestive heart failure. Note gross cardiomegaly, cephalization, interstitial pulmonary edema, and right-sided pleural effusion. Some of the fluid was loculated in the minor interlobar fissure (*arrow*), which disappeared with improved cardiac function.

Figure 12-18: A child suffering from nephrotic syndrome, which was treated successfully. *A.* Posteroanterior view during the worst period of his disease shows general anasarca, pulmonary edema, and pleural effusion. Note considerable soft tissue edema in the chest wall. *B.* With proper treatment, everything returned to normal in 2 weeks.

Figure 12-19: Patients with Holt-Oram syndrome. *A.* Posteroanterior view of patient 1, a 7-year-old girl, shows a globular cardiac contour with increased pulmonary blood flow. The aortic arch is on the right side. Catheterization diagnosis: secundum atrial septal defect. *B.* Her left arm shows absent radius and thumb with radial clubhand. Her right arm is a mirror image of the left (not shown). *C.* Forearms of patient 2, a 33-year-old woman with secundum atrial septal defect, show bilateral absence of thumb.

Figure 12-20: Young man with acute pericarditis with effusion. *A.* Posteroanterior view shows a water bottle-shaped cardiomegaly, clear lungs, and normal pulmonary vascularity. *B.* Repeat film taken 5 days later shows excellent response to therapy.

Figure 12-21: Statistical guidance focusing on the best diagnostic possibilities. *A.* Posteroanterior view of a patient with tetralogy of Fallot showing a right aortic arch, avian type. Note that the esophagus and trachea are deviated to the left. The cardiovascular structures are otherwise within normal limits. *B.* Lateral view of the same patient showing the aortic arch normally situated, in front of the trachea and esophagus. *C.* Posteroanterior radiograph of a healthy woman shows a right aortic arch (*large arrow*) with a large aortic diverticulum (*small arrow*) that protrudes to the left of the midline. The distal segment of the trachea is deviated to the left side by the right arch. Unlike double aortic arch, the left lateral margin of the trachea is not indented because the diverticulum is posterior and not lateral in position. *D.* Lateral view of similar patient, a healthy man. Note that both the esophagus and the trachea are markedly displaced anteriorly by a huge diverticulum, which invariably gives rise to the aberrant left subclavian artery.

Figure 12-22: A 42-year-old man with Eisenmenger's atrial septal defect. Note increased pulmonary blood flow with a centralized pattern.

Figure 12-23: Patient with calcific constrictive pericarditis. Typically there is only mild postcapillary pulmonary hypertension due to left-sided constriction. Severe pulmonary venous congestion is prevented by the concurrent right-sided constriction. *A.* Posteroanterior view shows moderate cardiomegaly and mildly cephalic pulmonary blood flow pattern. *B.* Lateral view shows heavy calcification of the pericardium (*arrows*) and left atrial enlargement deviating the barium-filled esophagus posteriorly.

Figure 12-24: Schematic representation of dynamic changes of aortic regurgitation. Blue interrupted lines represent images in systole; solid lines, those in diastole.

Figure 12-25: Lateral view shows heavy railroad track-like calcification of all three major coronary arteries. r, right coronary artery; a, anterior descending; c, circumflex; p, posterior descending. Note the ringlike densities representing vessels viewed on end.

Figure 12-26: Schematic representation of the subepicardial fat stripes in relation to major coronary arteries. *A.* Posteroanterior view. *B.* Lateral view. *C.* Right anterior oblique view. *D.* Left anterior oblique view. AL, left atrioventricular groove (circumflex); aR, right atrioventricular groove (right); vA, anterior interventricular groove (anterior descending); vP, posterior interventricular groove (posterior descending); F, apical fat pad; AO, aorta; LV, left ventricle.

Figure 12-27: A young man with a slowly developed pericardial effusion without cardiac tamponade. His posteroanterior view shows a huge water bottle-like cardiac silhouette. Note the lungs are clear and the PBF pattern is normal. The subepicardial fat stripe (black curvilinear line) within the immobile pericardial effusion was clearly visible and bouncing vigorously under the fluoroscope. The amplitude of excursion of the fat stripe reflected the normally functioning myocardium.

Figure 12-28: Patient with congenitally corrected transposition of the great arteries. The left-sided atrioventricular valve was replaced with a St. Jude prosthesis. The valve was caught in the opened position (in diastole), when both leaflets were seen as a pair of parallel lines (*arrows*). The same valve was invisible in the closed position (*not shown*).

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 13:

THE ECHOCARDIOGRAM

Authors: Anthony N. DeMaria, Daniel G. Blanchard

INTRODUCTION

The term *echocardiography* refers to the evaluation of cardiac structure and function with images and recordings produced by ultrasound. In the past three decades it has rapidly become a fundamental component of the cardiac evaluation. Currently, echocardiography provides essential (and sometimes unexpected) clinical information and has become the second most frequently performed diagnostic procedure after electrocardiography.[1] What began as a one-dimensional method performed from the precordial area to assess cardiac anatomy has evolved into a two-dimensional (2D) modality performed from either the thorax or from within the esophagus, capable of also delineating flow and deriving hemodynamic data.[2] Newly evolving technical developments likely will extend the capacity of ultrasound to routine 3D visualization[3] as well as to the assessment, in conjunction with contrast agents,[4] of myocardial perfusion.

The development of echocardiography is usually credited to Elder and Hertz in 1954.[5] Primitive cross-sectional images of the excised human heart were produced in 1957[6]; however, for nearly two additional decades, clinical echocardiography consisted primarily of 1D time-motion (M-mode) recordings, as popularized by Feigenbaum.[7] In the mid-1970s, Bom and associates developed a multielement linear-array scanner that could produce spatially correct images of the beating heart.[8] 2D images of superior quality were soon achieved by mechanical sector scanners[9,10] and ultimately by phased-array instruments as developed by Thurston and Von Ramm, which are the present-day standard.[11] In the past several years, 3D instruments capable of real-time volumetric imaging have been developed.

Although efforts to use the Doppler principle to measure flow velocity by ultrasound were begun in the early 1970s by Baker et al.,[12] clinical application of this technique did not thrive until the work of Hatle in the early 1980s.[13,14] Pulsed and continuous-wave Doppler recordings soon were expanded to full 2D color-flow imaging.[15] Most recently, miniaturization of ultrasound transducers has led to their incorporation into gastroscopes and cardiac catheters to achieve transesophageal and intravascular images.[16,17]

Chapter 13: THE ECHOCARDIOGRAM

PRINCIPLES OF ECHOCARDIOGRAPHY

Physics and Instrumentation

Sound is an energy form that travels through a medium as a series of alternating compressions and rarefactions of the molecules (Fig. 13-1). Sound is typically characterized by its wavelength, which is the distance between any two consecutive phases of the cycle (e.g., peak compression to peak compression), and by its frequency, which is the number of wavelengths per unit time [customarily expressed as cycles per second, or hertz (Hz)]. The velocity of sound is the product of wavelength and frequency; thus there is an inverse relationship between these two characteristics: the greater the frequency, the shorter the wavelength. Ultrasound is sonic energy with a frequency above the audible range of the human ear (greater than 20,000 Hz) and is useful for diagnostic imaging, since, like light, it can be directed as a beam that will obey the laws of reflection and refraction.[14-18] Thus, an ultrasound beam will travel in a straight line through a homogeneous medium. If the beam meets an interface of different acoustic impedance, however, part of the energy will be reflected, and the remaining attenuated signal will be transmitted. The reflected energy, or echo, is used to construct an image-in the case of echocardiography, an image of the heart (Fig. 13-2).

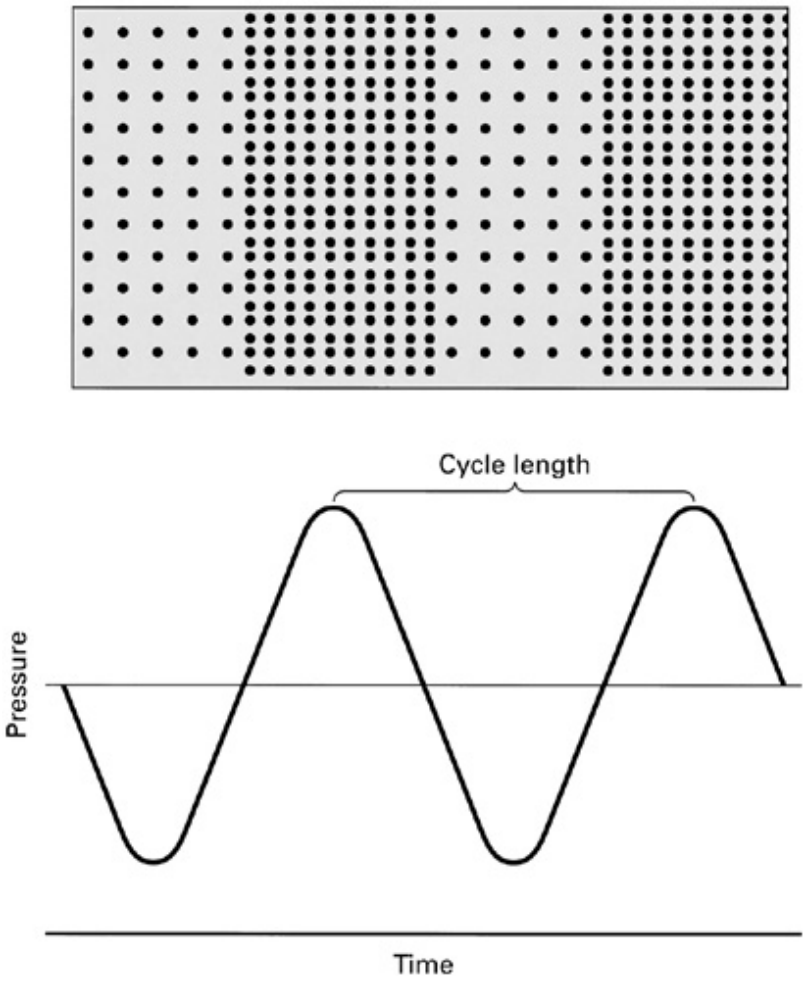

Figure 13-1: Sound energy results in alternating compression and rarefaction of particles in a conducting

medium. This alternation, which can be plotted against time (or distance), conforms to a sine-wave pattern (*bottom panel*). (Modified from Hagan AD, DeMaria AN. *Clinical Applications of Two-Dimensional Echocardiography and Cardiac Doppler.* Boston: Little, Brown; 1989, with permission.)

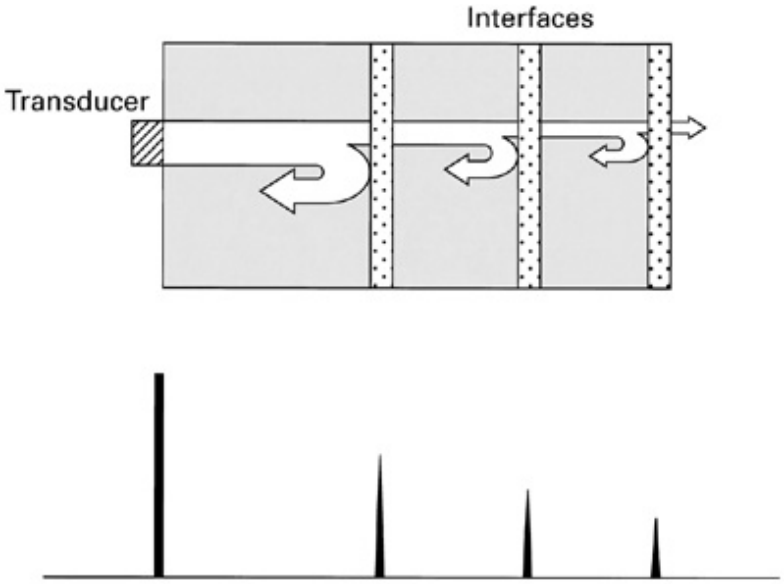

Figure 13-2: *Upper panel:* Attenuation of an ultrasound beam emitted from a transducer. There is reflection and progressive loss of energy at each interface encountered. *Lower panel:* the reflected wavefronts are recorded as signals of varying amplitudes (A mode) via the piezoelectric crystal. (Upper panel modified from Hagan AD, DeMaria AN. *Clinical Applications of Two-Dimensional Echocardiography and Cardiac Doppler.* Boston: Little, Brown; 1989, with permission.)

The most fundamental component of any echocardiographic instrument is the transducer, which is responsible for both transmitting and receiving the ultrasound signal. The transducer consists of electrodes and a piezoelectric crystal whose ionic structure results in deformation of shape when exposed to an electric current.[18] Thus, piezoelectric crystals are composed of synthetic materials, such as barium titanate, that, when exposed to electric current from the electrodes, alternately expand and contract to create sound waves. When subjected to the mechanical energy of sound returning from a reflecting surface, the same piezoelectric element changes shape, thereby generating an electrical signal detected by the electrodes (Fig. 13-3). Thus the transducer both produces and receives ultrasonic signals.

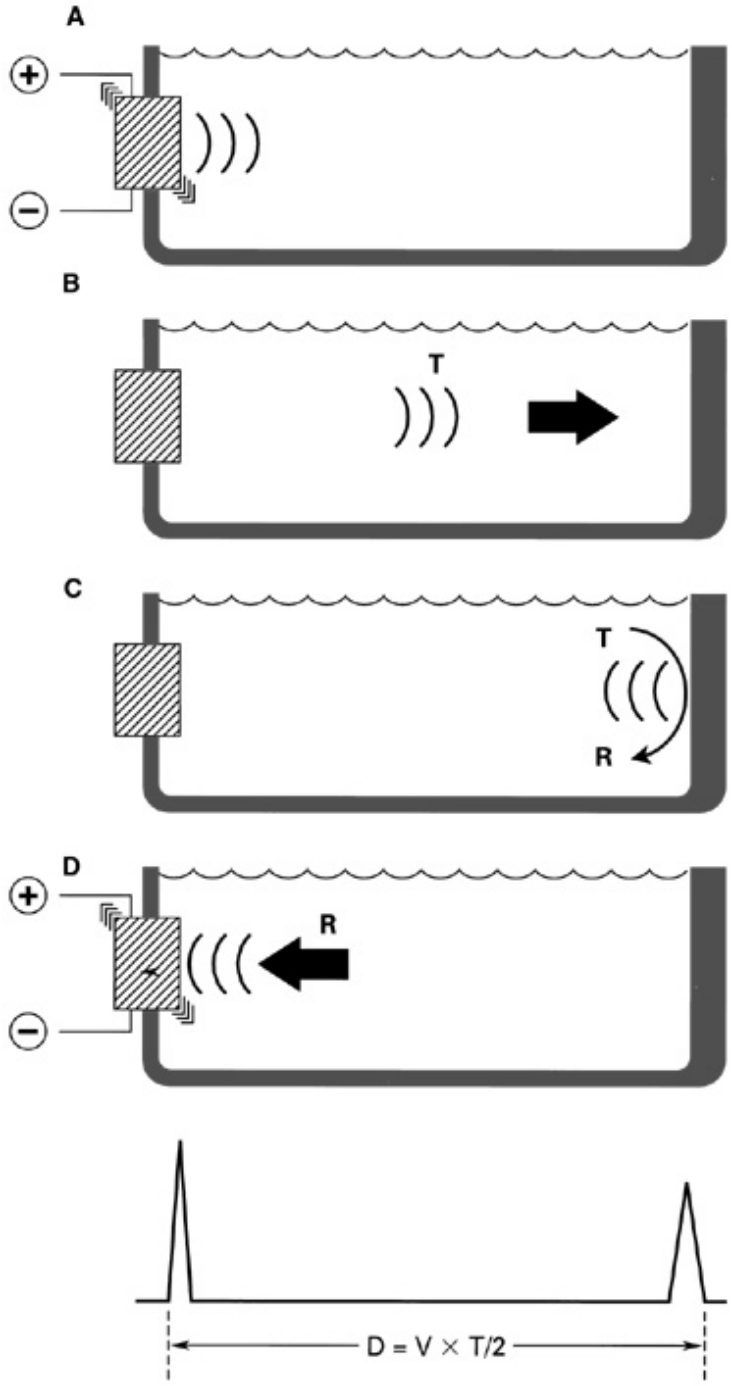

Figure 13-3: *A* through *D:* the basic principle of ultrasonic imaging. The piezoelectric crystal is activated, producing a transmitted pulse (T), which reflects off the interface. The reflected pulse (R) excites the crystal, producing an electric current. As the velocity of the pulse is constant, distance can be calculated based on the transit time. (Because the pulse must travel back and forth from the interface, the time is divided by 2.) (Modified from Weyman AE. *Principles and Practice of Echocardiography,* 2d ed. Philadelphia: Lea & Febiger; 1994, with permission.)

In the past, echographs have both transmitted and received signals of the same frequency. Recently, *harmonic imaging* has been implemented, in which ultrasound energy is transmitted at one frequency (fundamental) and received at a higher harmonic of that frequency (usually the first). Tissue harmonic signals are created by alteration of the frequency of the wave as it propagates through the structure.[18a] Contrast microbubbles produce harmonics by virtue of resonating (expanding/constricting) in the ultrasound field.[18b] The net effect of harmonic imaging is to reduce the signal intensity of background noise and enhance that from true tissue (or microbubble) structure, although some blooming of the signals from valves may be observed.[18a]

As an imaging modality, ultrasound carries with it several unique technical difficulties. Sound energy is poorly transmitted through air and bone, and the ability to record adequate images is dependent upon a thoracic window that gives the interrogating beam adequate access to cardiac structures. The degree to which ultrasonic energy will be reflected when striking an interface of differential impedance is dependent upon how perpendicular the interrogating beam is to the interface. When the ultrasound beam is directed parallel or near parallel to the interface, little or no sound energy will be reflected to the transducer. Therefore poor signal transmission, a nonorthogonal orientation of the ultrasound beam to the surface, and energy attenuation can result in failure to record signals from cardiac structures-a phenomenon referred to as *echo dropout*.[19] Conversely, some structures may be such strong ultrasonic reflectors-being perpendicular to the beam or extremely dense-that sufficient energy returns to the transducer to be reflected and again transmitted into the field. This phenomenon can lead to reverberations, or the reproduction of the echoes of anatomic structures at multiple locations within the image.[20] In addition, background noise artifacts, or signals generated from the system rather than tissue, can also be encountered. Finally, since the ultrasound beam diverges with distance from the transducer and always has a finite width, targets lying on the periphery of the beam may be recorded and displayed as if they were located along the central scan line (Fig. 13-4). This problem may be accentuated in the setting of very strong reflectors that result in the formation of *side lobes*.[21] In either case, beam-width problems associated with ultrasound may result in the depiction of targets in erroneous locations and create problems in interpreting the images.[22]

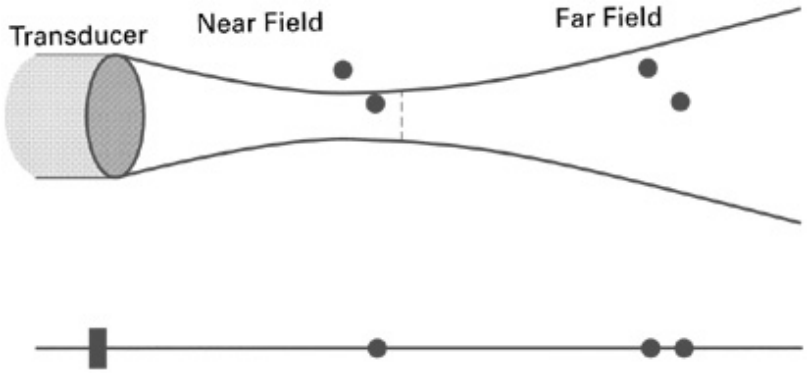

Figure 13-4: *Upper panel:* The transducer emits an ultrasonic beam that has a near field (where the beam is relatively focused) and a far field (where the beam width increases). *Lower panel:* B-mode diagram showing the effect of beam width. In the near field, the beam reflects off only one of two objects in close proximity to each other. In the far field, however, two similarly positioned objects are both within the beam width. Therefore, lateral resolution is compromised and the objects' positions are misrepresented.

The construction of a cardiac image from ultrasound signals is based upon computation of the distance between an anatomic structure and the transducer (Fig. 13-3). Thus, an ultrasound beam is produced by a hand-held transducer positioned on the thorax and directed into the heart. This beam will travel in a straight line until it reaches an interface between structures of different acoustic impedance, such as blood and myocardium. At this point, some ultrasonic energy will be reflected (depending on the density of interface), some will be scattered, and some will continue forward. The amplitude of the propagating signal will be attenuated because of the reduction in energy at the interface (Fig. 13-2). The reflected sound waves return to the transducer and form the basis of the echogram. Electronic circuitry within the echograph measures the time interval required for the transit of the ultrasound beam from the transducer to the interface and back again. Since the velocity of sound in soft tissue is constant (approximately 1540 m/s), the instrument can calculate the total distance traveled to and from the reflecting surface as the product of transit time and velocity of sound. Interface location is derived as one-half of the total transit distance, and a signal is depicted on an oscilloscope or video monitor at that point (Fig. 13-3). The amplitude of ultrasonic energy reflected from each target interface is represented by the brightness of the signal that is displayed.

The one-dimensional ultrasonic B- (or brightness) mode scan line resulting from a single transmitted beam is the cornerstone of echocardiographic imaging. In the most basic form of echocardiography, a single scan line produced by a piezoelectric crystal is passed through the heart (Fig. 13-5). At each structural

interface, ultrasonic energy is reflected back and displayed at the appropriate distance as a signal, whose amplitude represents the acoustic impedance or density of the material encountered. These signals are subsequently displayed as dots, whose brightness is proportional to the amplitude of reflected ultrasonic energy. The distance from the transducer of these B-mode dots changes as the cardiac structures move during the cardiac cycle. Accordingly, if repetitive B-mode scan lines are produced and swept across the screen over time, the movement of the heart can be obtained as a time-motion (or M-mode) recording,[23] providing dynamic rather than merely static cardiac images (Fig. 13-5). In clinical use, the piezoelectric crystal within the transducer is activated by alternating electric current to transient at a rate of approximately 1000 pulses per second. This same crystal also receives the returning echo reflections and actually spends the great majority of the time (>90 percent) in the "receive" rather than "transmit" mode. Because the beam is confined to a single location and transmits ultrasound signals at the pulse rate of the transducer, M-mode echocardiography provides very high temporal resolution. Importantly, M mode is an excellent modality for timing cardiac events or recording high-velocity motion.

As ultrasound technology advanced and it became possible to determine accurately the spatial orientation of the interrogating beam, multiple B-mode scan lines from different imaging angles were collected and displayed in proper alignment to create a 2D image. As opposed to B- or M-mode recordings, which are unidimensional (on an anterior-posterior axis), 2D echocardiography provides additional information in either superior-inferior or medial-lateral directions. At the current time, M-mode recordings are derived from the 2D images rather than as a stand-alone signal.

Several characteristics of sound energy are of fundamental importance in determining the quality of the images obtained. High-quality images require optimal resolution-that is, the ability to distinguish two individual objects separated in space. Short wavelengths yield excellent resolution in echo imaging, since the shorter the cycle length, the smaller the object that will reflect the signal and be detected by the echo scanner. Since wavelength is inversely related to frequency, transducers that emit a high-frequency signal (3.5 to 7.0 MHz or greater) yield high-resolution images. High-frequency signals also overcome an important limitation of ultrasonic imaging associated with lateral resolution. Since ultrasonic beams diverge as they propagate away from the transducer, the width of the beam can become sufficiently great to encompass multiple targets and diminish resolution (Fig. 13-4). The degree of beam divergence is less with high-frequency sonic energy than with low-frequency signals. The smaller wavelengths associated with high-frequency signals, however, are subject to greater reflection and scattering (therefore substantially higher attenuation) as the beam propagates through tissue. The resultant attenuation is greater than that with low-frequency signals and leads to decreased sensitivity. Therefore, in clinical practice, echocardiographic examinations are performed utilizing the highest-frequency transducer capable of obtaining signals from all potential targets within the ultrasound field.[23]

M-Mode Echocardiography

THE STANDARD M-MODE EXAMINATION

Although largely supplanted by 2D imaging, M-mode echocardiography remains a useful part of a complete ultrasound examination. Figure 13-6*A* through *D* shows the typical views obtained when the transducer is placed at the left parasternal area and rocked through the heart from apex to base. Tissue typically reflects ultrasound at its surface (specular reflectors) and from internal inhomogenicity (backscatter), while blood is homogenous and does not produce reflections. Thus, blood is free of ultrasonic signals on the echocardiogram. At the mitral valve level (Fig. 13-6*C*), the cardiac structure seen closest to the transducer is the right ventricular (RV) free wall; it is followed by the RV cavity, the interventricular septum, the mitral valve apparatus, and the left ventricular (LV) posterior wall as the beam travels backward. At this level, mitral valve excursion is well seen and is more easily recorded for the longer anterior leaflet. For the anterior leaflet, diastolic mitral opening is bipeaked (M-shaped), with maximal opening during early diastolic filling at the E point, a subsequent reclosure downslope to the F point, and a reopening with atrial contraction at the A point prior to valve closure at the C point[24] (Fig. 13-7). The posterior leaflet manifests a mirror-image W-shaped pattern. When LV end-diastolic pressure is elevated, a shoulder (B notch) is often present between the A and C points[25] (Fig. 13-8). If the transducer beam is directed inferolaterally from the mitral valve level, the papillary muscles and LV apex will be imaged (Fig. 13-6*A*). With superior and medial angulation, the left atrium, aortic valve, and aortic root are seen. The tricuspid valve can be imaged by angulating the transducer inferomedially and

the pulmonic valve by angulating slightly superiorly and laterally.

ASSESSMENT OF SYSTOLIC FUNCTION BY M-MODE ECHOCARDIOGRAPHY

Measurements of the LV cavity dimension and wall thickness can be readily derived from M-mode recordings (Fig. 13-9) and are usually made according to the recommendations of the American Society of Echocardiography at end diastole (the onset of the QRS complex) and end systole (the point of maximum upward motion of the LV posterior wall endocardium).[26] These measurements should be made from leading edge to leading edge to avoid incorporating artifacts and reverberations; they are accurate if the beam is orthogonal to the long axis of the ventricle. By convention, left atrial (LA) dimension is measured at end systole and aortic root diameter is recorded at end diastole at the level of the base of the heart (Fig. 13-9). During systole, opening of the aortic leaflets appears as a parallelogram produced by motion of the right coronary and (usually) the noncoronary aortic valve cusps.[27]

The M-mode LV cavity dimensions can be used to estimate ventricular volumes and ejection fraction (EF) if desired, most simply by merely cubing the value (D^3); but these calculations involve several assumptions regarding LV geometry that are not uniformly valid.[28,29] In addition, the M-mode dimension may not be representative of the entire ventricle. The fractional shortening can also be determined.[30] This value is often helpful in assessing systolic function, but it reflects the function of the LV in one chord and in one plane and can be misleading with asynchronous contraction [for example, left bundle branch block (LBBB)] or segmental dyssynergy.[31] An additional M-mode marker of systolic function is *E point-septal separation* (EPSS), or the distance between the anterior mitral valve leaflet at its most anterior opening excursion (the E point) and the interventricular septum. A value of 8 mm or greater is abnormal.[32] The normal M-mode measurements are seen in Table 13-1.

Table 13-1: Normal Values

	Mean ± Standard Deviation	Range	Mean ± Standard Deviation	Range
No. of patients	25	-	50	-
Age, years	10 ± 3	4-18	24 ± 6	1.10-2.53
BSA, m^2	1.33 ± 0.38	0.72-2.04	1.81 ± .34	1.10-2.53
$LVID_d$, mm	44 ± 6	32-50	50 ± 3	42-60

Two-Dimensional Echocardiography

A number of technical approaches exist by which multiple individual B-mode scan lines can be rapidly transmitted, received, and displayed in appropriate spatial orientation to construct a 2D image of the heart. The initial approach simply utilized a linear array of 20 piezoelectric crystals placed side by side, each of which transmitted and received signals independently[8] (Fig. 13-10*A*). The resulting scan lines were displayed simultaneously to yield rectangular images. Unfortunately, transducer size and interaction between the elements resulted in images of unsatisfactory quality.

Current 2D scanners utilize B-mode scan lines that are independently transmitted and received and are directed through a wedge-shaped sector of cardiac anatomy by means of mechanical or electrical beam steering (Fig. 13-10*B* to *D*). A variety of motorized devices are available that, by rapidly oscillating or rotating one or more ultrasonic crystals through space, can mechanically direct multiple scan lines through a sector arc of the cardiovascular system.[9,10] The position of the beam in space is derived by determining the orientation of the piezoelectric crystal. A majority of current 2D scanners utilize a phased-array approach, where multiple ultrasonic crystals are employed in concert to create individual B-mode scan lines.[11] The piezoelectric crystals are activated in a closely coordinated temporal sequence such that the individual wavelets produced by each element merge to form a single beam whose direction is determined by the sequence of crystal firing (Fig. 13-11). Since the direction of the resultant beam is determined by the sequence of activation of the individual elements, the beam can be electrically swept throughout a 90-degree sector arc. In addition to electronic beam steering, a firing sequence can be employed that results in dynamic focusing of the beam along its length to achieve minimal beam width and increased resolution. Phased-array 2D scanners employ small transducers without moving parts that could require repair. The increased complexity of these scanners, however, makes the systems more costly.

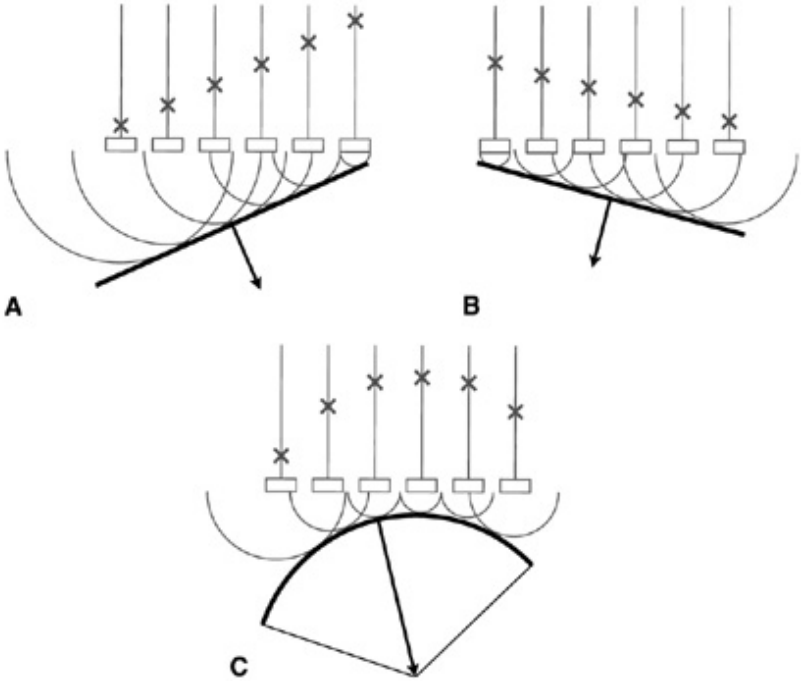

Figure 13-11: Electronic "steering" of a phased-array ultrasound beam. *A.* Elements are fired in sequence from left to right, resulting in a beam directed to the left. *B.* Elements are fired in sequence opposite to those in (*A*), producing a beam directed to the right. *C.* Elements are fired from the periphery toward the center, producing a beam that converges on a given focal point. (From Hagan AD, DeMaria AN. *Clinical Applications of Two-Dimensional Echocardiography and Cardiac Doppler.* Boston: Little Brown; 1989, with permission.)

Originally, echocardiographic data were displayed in analog form on a standard oscilloscope, transferred to a video monitor by a television camera, and hard-copied onto videotape or paper. Currently, computerized analog-to-digital scan conversion is standard, so that the polar signals of individual scan lines are converted to a series of numerical gray-level values for individual box-like picture elements (pixels) aligned along *X-Y* coordinates.[33] The ability of a digital step-gradation technique to reproduce the continuous gradation of analog methods is a function of the density of pixels in the matrix and the shades of gray levels available. No loss of data can be detected in current digitally converted images, and the digital format provides the opportunity for image processing, enhancement, and quantitation. More importantly, storage in digital format can avoid the image degradation inherent in videotape, provide random access and easy comparison of studies, enable rapid image transmission, and prevent deterioration with image copying and prolonged storage. Technology for fully digital echocardiography is now becoming available, and fully digital acquisition and storage of echocardiograms will be commonplace in the near future, replacing analog videotape recordings.

THE STANDARD TWO-DIMENSIONAL EXAMINATION

The heart can be imaged through a multitude of planes with 2D echocardiography. To help standardize the 2D examination, the American Society of Echocardiography has recommended that cardiac imaging be performed in three orthogonal planes: long-axis (from aortic root to the apex), short-axis (perpendicular to long axis), and four-chamber (traversing both ventricles and atria through the mitral and tricuspid valves)[34] (Fig. 13-12). It is important to recognize that the long and short axes are those of the heart, not the body. These three planes can be visualized using four basic transducer positions: parasternal, apical, subcostal, and suprasternal[35,36] (Figs. 13-13*A*, *B*, and *C*). In general, the long-axis plane is best imaged from parasternal, apical, and occasionally the suprasternal positions, while the short-axis plane is best imaged in the parasternal and subcostal positions. The four-chamber views are obtained from the apical and subcostal positions. The American Society of Echocardiography recognizes that these basic positions and planes may be modified somewhat and recommends that an image obtained within 45 degrees of a basic orthogonal plane be identified with that orthogonal plane. Table 13-2 lists the standard transducer positions and transthoracic echocardiographic views. Anatomic drawings of the various imaging planes are

seen in Figs. 13-13, 13-14, 13-15, 13-16, 13-17, 13-18, 13-19 and 13-20.

Short axis

As opposed to other types of cardiac imaging, such as chest radiography, which are well standardized, the echocardiographic examination is iterative and largely determined by the anatomic characteristics of the patient and manual manipulation of the transducer by the operator. Of paramount importance is the identification of a thoracic site (window) that enables transmission of the ultrasound signal to the heart. In actual practice, the echocardiographic examination is performed with the operator either to the patient's left or right. The patient is in the left lateral decubitus position for most of the examination, with the head of the bed elevated 20 to 30 degrees. Alternate positioning may be employed for individual patients and views. Use of a thick foam rubber mattress (made expressly for echocardiography) that has a removable section under the area of the cardiac apex may facilitate the examination.

The examination customarily begins with the transducer in the left parasternal position in the long-axis view (Fig. 13-14). This provides excellent images of the left ventricle, aorta, left atrium, and the mitral and aortic valves. By angling the beam slightly rightward and inferiorly (right ventricular inflow view), the right atrium, right ventricle, and tricuspid valve are visualized (Fig. 13-15). If the beam is turned slightly leftward and rotated clockwise from the standard parasternal long-axis view, the right ventricular outflow tract, pulmonic valve, and main pulmonary artery appear (right ventricular outflow view).

A 90-degree clockwise turn of the transducer produces the parasternal short-axis view. Slight axial angulation of the transducer enables visualization of the LV at various levels of the short axis, including the papillary muscle, mitral leaflets, and aortic valve (Fig. 13-16). With angulation toward the base, the LA right heart structures, main pulmonary artery, and occasionally the left atrial appendage are also

recorded.

The apical views are best acquired with the patient in a steep left lateral decubitus position and the transducer at the point of the apical impulse. The four-chamber view is obtained by turning the transducer so that both ventricles, atrioventricular valves, and atria are visualized (Fig. 13-17). In this view, the septal, apical, and lateral walls of the LV are visualized. Slight superior angulation of the transducer will add the aortic valve and proximal ascending aorta to the echocardiographic image (apical five-chamber view). From the four-chamber view, 90 degrees of counterclockwise transducer rotation will produce the apical two-chamber view (Fig. 13-18). This imaging plane demonstrates the LA and the inferior, apical, and anterior wall segments of the LV (the right heart structures are absent). If the transducer is rotated slightly back toward the four-chamber plane, a three-chamber view similar to the parasternal long-axis view is produced (Fig. 13-18) and provides images of the posterior, apical, and anteroseptal LV wall segments as well as the LA, aorta, and mitral and aortic valves.

To facilitate subcostal imaging, the patient is moved into a supine position. The subcostal four-chamber view is much like the apical four-chamber view (Fig. 13-19), but because the ultrasound beam is now more perpendicular to the interventricular and interatrial septa, subcostal imaging is often helpful in the examination of these structures. A 90-degree rotation of the transducer will record a subcostal short-axis view. The transducer can also be angled to image the RV outflow and pulmonary artery as well as the inferior vena cava (Fig. 13-19).

The long-axis suprasternal imaging plane is shown in Fig. 13-20. In adult echocardiography, the LV is usually not visualized satisfactorily from the suprasternal position, but these imaging planes are well suited for examination of the thoracic aorta, pulmonary artery, and great vessels. Normal values for 2D echocardiographic measurements are shown in Table 13-3.

Three-Dimensional Echocardiography

Several approaches exist to obtaining 3D echocardiographic images. The simplest approach is to merely move the transducer through a defined space and align the tomographic slices appropriately. A variety of spatial locator devices can be attached to the transducer to provide spatial orientation. This enables the acquisition of data from many transducer positions. Recently, two orthogonally positioned crystal arrays have been applied in conjunction with rapid parallel signal processing to achieve real-time 3D volumetric imaging. A pyramid-shaped ultrasound beam is produced that can often encompass the entire heart from one transducer location and acquire an entire data set in a single cardiac cycle (Fig. 13-20*C*). The resultant 3D data sets from any approach can be displayed as 2D tomographic cuts with 3D spatial orientation, as wire runs, or with surface rendering. 3D images have been particularly of value in providing accurate quantitation, in assessing congenital heart disease, and in evaluating structures of complex geometry such as the right ventricle.[36a,36b]

ASSESSMENT OF SYSTOLIC FUNCTION BY TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Because 2D echocardiography enables visualization of the entire LV perimeter in multiple planes, it is significantly superior to M-mode approaches for the measurement of cardiac chamber volumes and EF.[37-40] Numerous algorithms have been applied to calculate LV volumes by echocardiography (Fig. 13-21). Most such algorithms have assumed that the LV conforms to the shape of a prolate ellipsoid and calculated volume by diameter-length or area-length formulas.[38,41] Multiple studies comparing LV volume calculated by area-length methods to those obtained by other techniques have yielded good correlations, with the best results obtained utilizing biplane apical views.[41,42] Other algorithms have assumed an LV cavity configuration that is a combination of geometric shapes, such as a cylinder-cone or a cylinder-hemiellipse.[41,43] Currently, the most commonly used algorithm to calculate LV volumes is based upon the Simpson rule, which derives measurements by dividing the LV by parallel planes into a number of small segments and then summating the area of the individual disks. This approach has the advantage of making no assumptions about the geometry of the ventricle. A number of modifications of the basic Simpson rule method have been applied to calculate LV volumes. Although all have yielded good results, the optimal correlations have been achieved with a modification that separately quantifies the volume of the apex as an ellipsoid.[40-45]

Regardless of the methodologic approach used, accurate calculations of LV volumes by echocardiography require attention to detail and are critically dependent upon high-quality images to delineate the endocardium and image the entire LV perimeter. As a rule, echocardiographic estimates of LV volumes underestimate those calculated by other techniques and are most accurate in the absence of significant alterations of LV size and contraction. End-systolic measurements are more accurate than those made at end-diastole, probably owing to superior endocardial definition. Nevertheless, echocardiographic calculations of LV volumes have generally yielded correlation coefficients in excess of 0.75 as compared with radionuclide angiography, cineangiography, and autopsy studies regardless of the algorithm employed.[37-45] Of importance, calculation of LV volumes generally yields values with a standard error of estimate that renders these measurements suitable for clinical decision making in the care of most patients.

In an attempt to refine and facilitate the derivation of LV volume measurements from echocardiography, a number of technical developments have been evaluated. Images of the power spectrum of the Doppler signal produced by contraction/relaxation and colorization of the B-mode tissue image have been utilized to visualize the endocardial surface.[46] These techniques have been reported to be useful in identifying endocardial signals, particularly in patients with suboptimal tissue images. Greater enhancement of endocardial border delineation and improvement of the reliability of measures of LV size and contraction has been achieved through utilization of tissue harmonic imaging and by the injection of ultrasonic contrast agents to produce LV cavity opacification.[18a,46a] A software package that provides instantaneous and automated endocardial border delineation throughout the cardiac cycle has been developed based upon the display of tissue signals as backscatter rather than specular reflection.[47] This technique of automated quantitation can yield continuous measurements of LV volume throughout the cardiac cycle and can derive values for ejection fraction, ejection rate, and rate of filling during diastole (Fig. 13-22). This same technology has been utilized to display endocardial excursion throughout systolic contraction or diastolic expansion in a color format superimposed upon the tissue image (Fig. 13-23, Plate 53). This technique has proved to be of value in the recognition of abnormalities of LV contraction and regional disturbances of LV diastolic function.[4849-49a] Finally, studies employing 3D echocardiography have reported improved reproducibility of measures over 2D methods. Although these technical developments are relatively untested, they promise to facilitate the quantitative assessment of LV size and function from routine echocardiograms.

Chapter 13: THE ECHOCARDIOGRAM

DOPPLER ECHOCARDIOGRAPHY: PRINCIPLES AND APPLICATIONS

The Doppler Principle

Although 2D and M-mode echocardiography provide abundant information about cardiac structure and movement, they supply no direct data concerning blood flow. This is a significant limitation, as the presence and severity of conditions such as valvular regurgitation and intracardiac shunting can be suspected or inferred only indirectly by 2D imaging. Using the principle first delineated by the physicist Johann Christian Doppler,[50] one can use ultrasound to determine the velocity and direction of blood flow by measuring the change in frequency produced when sound waves are reflected from red blood cells.[51-53] In this way, information regarding the presence, direction, velocity, and turbulence of blood flow can be acquired by cardiac ultrasound.[54]

The Doppler principle states that when a sound (or light) signal strikes a moving object, the frequency of that signal will be altered, and the increase or decrease in frequency will be proportional to the velocity and direction at which the object is moving. This is illustrated in Fig. 13-24. If a stationary transducer at the apex emits a sound wave with a transmitted frequency of *fo* and the wave is reflected by nonmoving red blood cells (RBCs) in an isovolumic phase of the cardiac cycle, then the received frequency *fr* will be identical to *fo*. If the signal is reflected by RBCs that are moving toward the transducer, as through the mitral valve in diastole, the returning waves will be compressed so that *fr* will be greater than *fo*. Conversely, if the target RBCs are moving away from the transducer, as in the outflow tract in systole, the returning sound waves will be elongated and the received frequency will be decreased. Of importance, the magnitude of change in the received frequency is directly related to the velocity at which blood is flowing toward or away from the transducer.[53] If the velocity of sound and the angle θ between the direction of RBC flow and the beam path are known, then the velocity of the RBCs is described by the Doppler equation:

$$V = fd(c)/2fo(\cos\theta)$$

where *fd* is the frequency shift recorded, *fo* the transmitted frequency, and *c* the velocity of sound. Note that the denominator is doubled because the sound wave does not originate with the RBC but must travel back and forth from the transducer. By measuring Doppler shift frequencies, the velocity and direction of blood flow can be calculated, displayed, and recorded.

The angle between the direction of blood flow and the course of the sound beam is a most important factor in Doppler ultrasound (Fig. 13-25). Velocity is a vectorial entity, having magnitude and direction, and Doppler will detect only those velocities parallel or near parallel to the interrogating signal. Since the relationship between velocity and the angle is a cosine function and the cosine of angles up to 20 degrees is 0.9, little error is introduced within this range.[53] Because the processor that calculates blood velocity assumes that the angle is 0 degrees, however, considerable errors occur when it is greater than 20 degrees. Moreover, the angle of incidence in 3D space usually cannot be determined with certainty from 2D echocardiographic images. Therefore, in order to obtain accurate velocity determination by Doppler, it is crucial to position and direct the transducer so that the beam is as parallel to flow as possible.

In clinical use, the frequency of transmitted ultrasound is in the range of 2 to 7 MHz, the velocity of sound in tissue is approximately 1540 m/s, and the Doppler shift frequency is relatively small (approximately 1 to 4 kHz) as compared with the transmitted frequency. As the Doppler shift frequencies are in the audible range, a speaker integrated into the Doppler echocardiography system can present them as an audible signal. Normal signals are tonal or musical. The Doppler shift also can be presented graphically to provide a hard copy printout and enable measurement.

Figure 13-26 shows the typical graphic pulsed Doppler pattern of normal systolic blood flow through the RV outflow tract into the pulmonary artery, with flow velocity on the *y* axis and time on the *x* axis. The location and size of the area from which Doppler recordings are derived is determined by the operator by positioning a sample volume on the echo image. The absence of flow is represented by the zero or no-flow line, termed the *baseline.* By convention, flow toward the transducer is displayed above the baseline and flow away from the transducer is displayed below the baseline. The velocities above and below baseline represent flow toward or away from the transducer and not forward or backward in the circulation. Because of the effects of viscous friction, the sample volume almost invariably includes RBCs flowing at slightly different velocities. Even normal laminar blood flow in the great vessels varies in velocity across the lumen, as RBCs in the center of the vessel move at higher velocity than those exposed to viscous friction at the wall, and this creates a parabolic rather than a flat flow profile. Therefore, any returning Doppler shifted signal contains a spectrum of velocities, each of which can be displayed by means of fast Fourier transform analysis. The graphic output of the Doppler signal displays the range of velocities within the sample volume site at any time in gray scale and the number of RBCs moving at any velocity as relative intensity. Normal laminar flow is characterized by a uniformity of velocity and direction of individual RBCs, and therefore a narrowly dispersed signal, while disturbed or turbulent flow is manifest by marked variability in velocity and direction and therefore a broad signal, which is multitoned, dissonant, and harsh.

Recently, echographs have been modified to enable recording of the low-velocity, high-amplitude Doppler signals produced by moving tissue as well as those of RBCs. The ability to asses tissue velocity provides an evaluation of transmural rate of contraction and relaxation.[53a] Also, Doppler tissue recordings permit assessment of regional function, and appear to be less susceptible to the influence of LV loading conditions than are Doppler blood flow recordings.[53b,53c]

Continuous- and Pulsed-Wave Doppler

Time-velocity spectral recordings of blood flow are generally obtained with two types of Doppler interrogation: continuous wave and pulsed wave (Fig. 13-27).[54,55] In the *continuous-wave* (CW) mode, sound waves are both transmitted and received continuously. This requires two piezoelectric crystals in each transducer, one for transmitting and one for receiving. Because all flow velocities along the beam are recorded, CW Doppler cannot define individual signals at specific distances from the transducer-a problem referred to as *range ambiguity.* Continuous-wave Doppler, however, has no upper limit of velocity that can be accurately recorded. Thus, a CW Doppler beam can accurately measure the direction and velocity of overall flow but cannot discern the precise site of origin of individual components within the signal (Fig. 13-28*B*).

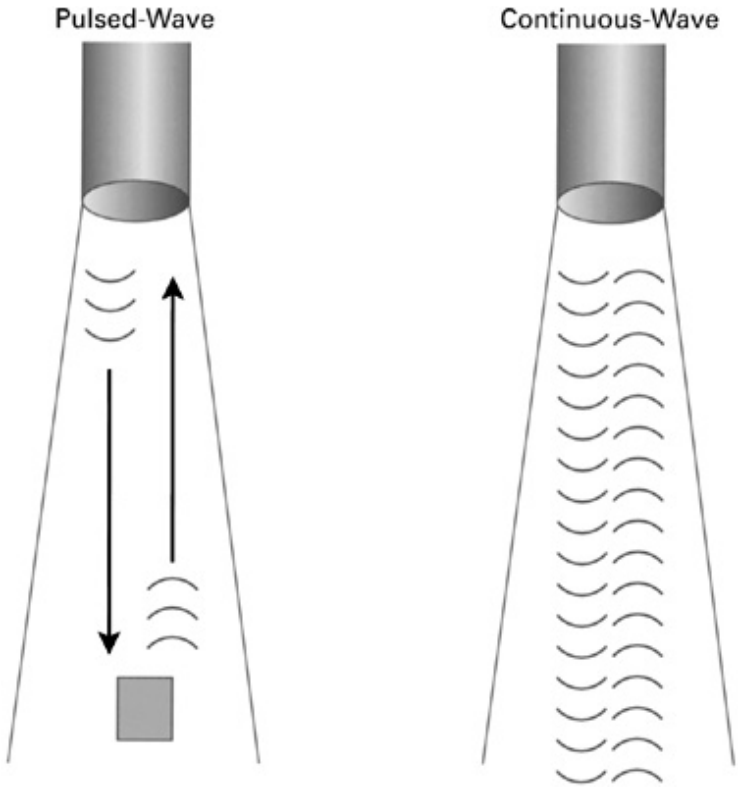

Figure 13-27: Pulsed-wave (PW) and continuous-wave (CW) Doppler. With PW, a single pulse of ultrasound energy is emitted and its reflection from a sample volume is received before the following pulse is transmitted. With CW, there is continuous transmission and reception of ultrasound energy.

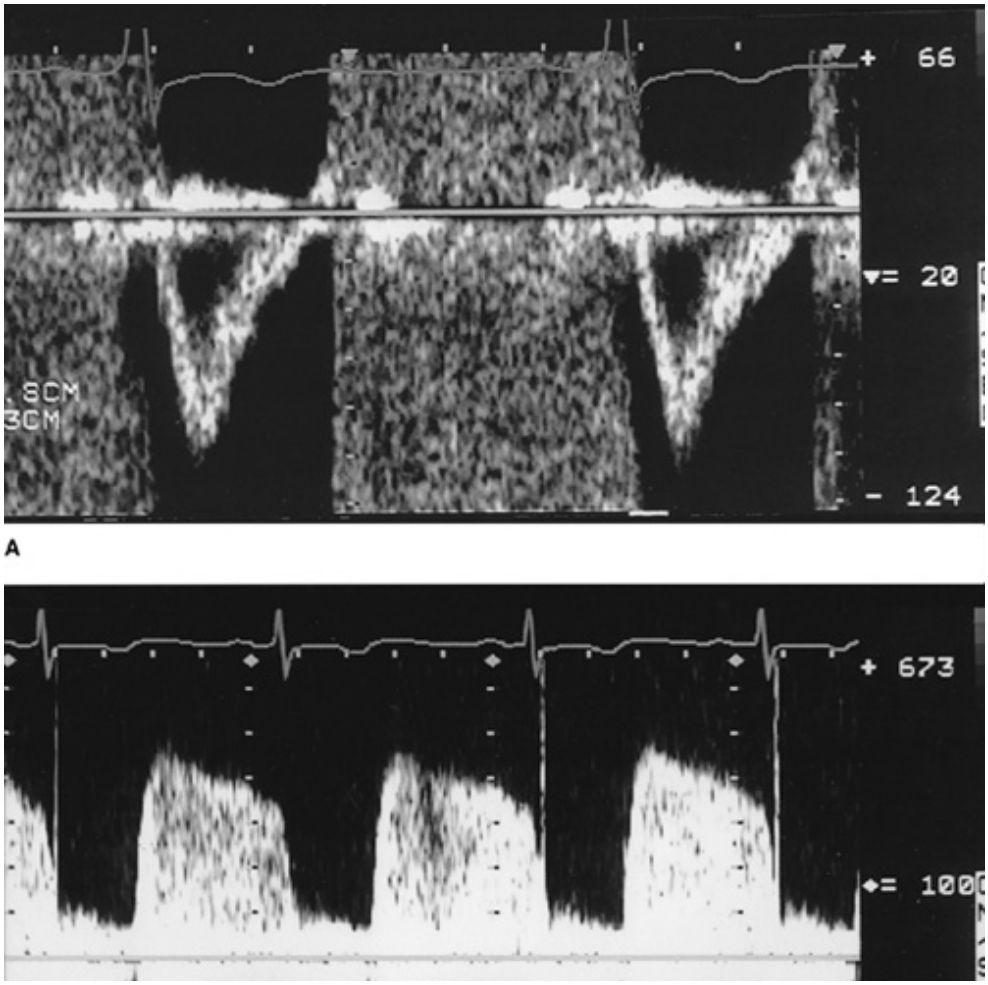

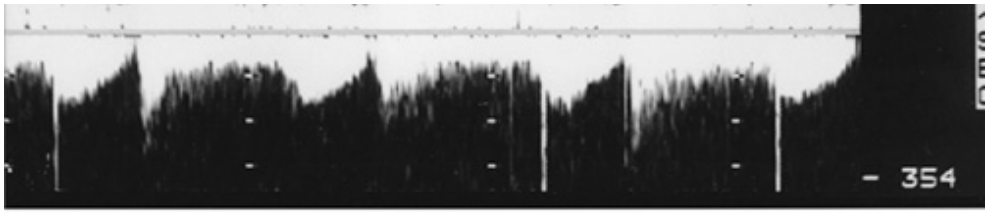

B

Figure 13-28: *A.* Pulsed-wave Doppler tracing from a patient with aortic regurgitation. The transducer is in the apical position and the sample volume is in the left ventricular outflow tract. A laminar envelope is seen during systole, while aliased flow is present during diastole because of high-velocity flow. *B.* Continuous-wave Doppler tracing through the left ventricular outflow tract (with transducer in the apical position). The maximal velocity of the aortic regurgitation is now measurable, but all other velocities along the Doppler beam are recorded as well.

The problem of range ambiguity can be overcome by *pulsed-wave* Doppler. In this mode, short bursts of signal are transmitted from the transducer at a given *pulse-repetition frequency* (PRF). The instrument then receives the signal for only a brief period-an interval that corresponds to the time required for sound energy to travel and return from a specific site along the beam path. In practice, the operator selects the location at which flow is to be examined by positioning a sample volume, and the instrument determines the period during which to receive the incoming reflected frequencies. With pulsed-wave Doppler, only a single piezoelectric crystal is needed and flow can be recorded in one small area within the heart or vasculature.[54,55] Unfortunately, pulsed Doppler techniques employ intermittent sampling and are therefore susceptible to a problem of range ambiguity referred to as *aliasing*.[56] By definition, aliasing is the erroneous representation of flow in the direction opposite to that in which it is actually occurring. To correctly record the velocity of blood flow by pulsed Doppler, the PRF must be at least double the Doppler shift frequency, a value known as the *Nyquist limit.* If the blood flow examined is of very high velocity or far from the transducer (requiring a long transit time), it may necessitate an unobtainably high PRF. In such cases, aliasing will occur as Doppler signals that depict flow at high velocity in ambiguous or opposite directions compared to actual flow (Fig. 13-28). An intermediate mode between pulsed and CW methods, high-PRF Doppler, is also available.[57,58] This mode enables higher-velocity recordings to be obtained at a compromise of depicting two to four sample sites simultaneously.

Color-Flow Doppler

The major limitation of pulsed and CW Doppler (sometimes referred to as *spectral Doppler*) is that no spatial information regarding the size, shape, and 2D direction of flow is provided. An extension of pulsed-wave Doppler techniques, *color-flowDoppler* (CFD), provides real-time M-mode or 2D imaging of blood flow by presenting the velocity and direction of RBC movement as shades of color superimposed upon gray-level 2D tissue structure. Standard pulsed Doppler yields flow signals from a single site along a single scan line. In CFD, rapid pulsed-wave interrogations are performed at multiple sites for multiple scan lines to create a spatially correct and dynamic display of moving blood within the heart and vasculature[59-61] (Fig. 13-29). Doppler signals are presented as colors assigned to individual sites (Fig. 13-30, Plate 54). Blood flow moving toward the transducer is displayed in red, flow away from the transducer is displayed in blue, and increasing velocity is depicted in brighter shades of each color. The variance within each signal is calculated as a statistical marker of turbulence and is presented by adding green to the image (Fig. 13-31, Plate 55). Therefore, turbulent flow jets appear as a mosaic mix of colors. CFD also can be superimposed onto M-mode tracings (Fig. 13-32, Plate 56), often termed *M/Q imaging,* and is helpful in clarifying the timing of flow phenomena. Given the time constraints imposed by collecting the large volume of data required by CFD, velocity estimates are performed by autocorrelation techniques that are less accurate than fast Fourier transform analysis.[62] Nevertheless, CFD technology is a major advance that has improved the rapid detection of cardiac pathology, especially valvular regurgitation and intracardiac shunts.

Normal and Abnormal Flow Dynamics

The clinical application of Doppler recordings is based on the fundamental differences between normal and disturbed blood flow. Normal flow is laminar, with all RBCs exhibiting the same velocity and direction of

flow. Although some abnormalities, such as atrial septal defects, involve laminar flow, most pathologic conditions involve disturbed or turbulent flow and share a common hydrodynamic basis for the resultant flow dynamics. Specifically, nearly all circulatory disturbances (stenosis, regurgitation, shunt) involve blood flow from a high-pressure chamber to a lower-pressure chamber through a restricted orifice.[53] Aortic valve disease is a perfect example. Aortic stenosis is a forward flow disturbance in which turbulent blood travels from a high-pressure LV to a lower-pressure aorta through a restricted aortic orifice in systole. Aortic regurgitation is a retrograde flow disturbance in which turbulent blood regurgitates from a high-pressure aorta to a lower-pressure left ventricle through a small regurgitant orifice in diastole. In each case, the pressure gradient results in a high-velocity jet coursing through a restricted orifice, reaching its maximal velocity at a site just distal to the orifice, designated the *vena contracta*, at which time shear forces produce vortices resulting in flow of varying direction and velocity (Fig. 13-33). In each case, the velocity of the jet is related to the pressure gradient across the orifice. Thus, the hallmark of disturbed flow is a very high velocity jet with adjacent vortices of varying direction and velocity of flow. On pulsed Doppler recordings, these hemodynamic abnormalities cause broadening of the spectral signal and aliasing. On CW recordings, high velocity represents the primary abnormality. By color-flow imaging, the disturbance is manifest by the increased variance and higher velocities in the signal. With any of these techniques, of course, inappropriate timing of flow serves to highlight the abnormality (e.g., high-velocity LA flow during systole in mitral regurgitation).

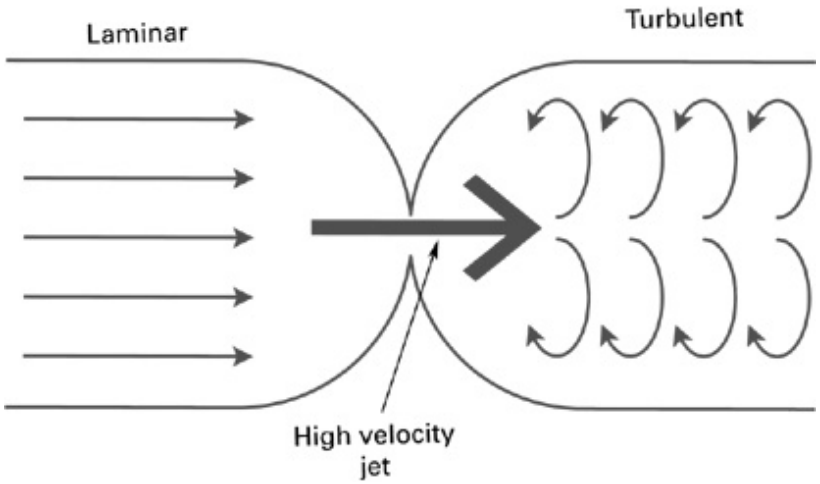

Figure 13-33: Flow characteristics through a stenotic orifice. Proximal to the stenosis, the flow is laminar. Near the point of maximal stenosis, the flow velocity is markedly increased. Turbulent flow is present distal to the stenosis.

The Standard Doppler Examination

A clinical Doppler examination must be performed with full consideration of the three different Doppler modalities available, the types of information each can provide, the multiple sites for flow interrogation, and the spectrum of pathologic lesions that produces flow disturbances. In light of these considerations, it is understandable that the Doppler examination may not be as standardized as the format for 2D cardiac imaging; however, a number of usual practices have emerged. A vast majority of echocardiographic examinations include screening for flow disturbances by CFD. Since Doppler signals are best recorded with the ultrasound beam parallel to flow, screening is typically performed in long-axis or apical views. Any flow disturbances visualized are subsequently examined by CW spectral recordings and, in most laboratories, by pulsed-wave Doppler. Although CW examination is typically reserved for flow disturbances, pulsed-wave Doppler also may be of value in quantifying flow dynamics in the setting of laminar flow. In this regard, pulsed Doppler recordings obtained at the mitral, tricuspid, and aortic valve orifices, pulmonary artery, and pulmonary veins constitute part of a standard echocardiogram in many laboratories (Figs. 13-26, 13-34, 13-35, 13-36 and 13-37).

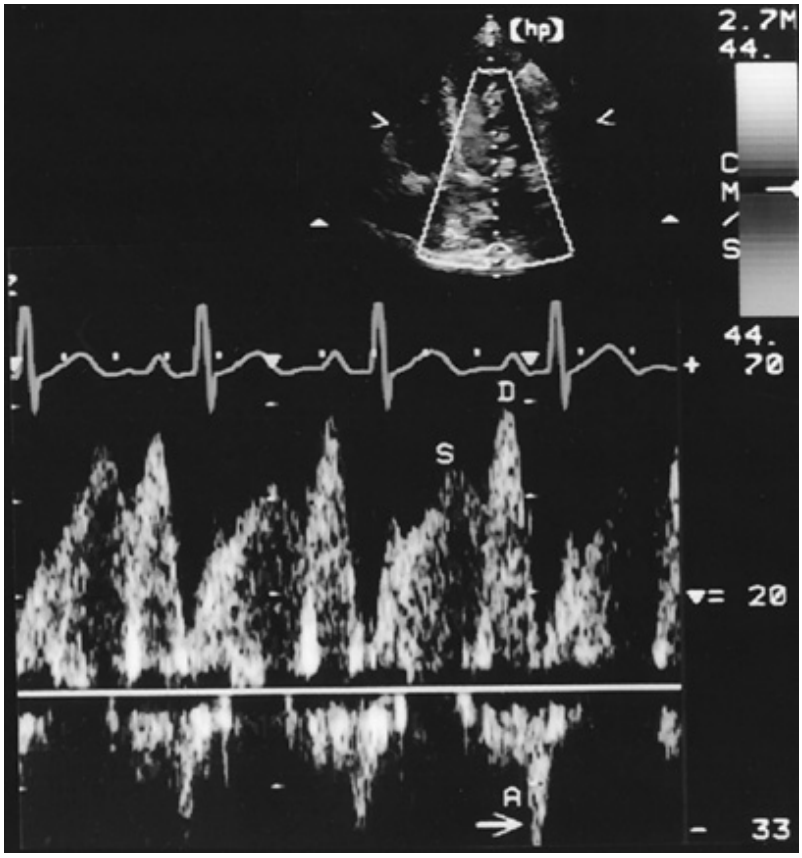

Figure 13-36: Pulsed-wave Doppler tracing from the right upper pulmonary vein (recorded from the apical transducer position). Flow toward the heart is biphasic, with peaks in systole (S) and diastole (D). A small amount of reversed flow is seen during atrial contraction (A).

The normal Doppler examination is characterized by uniformity of flow velocity and the absence of high-velocity turbulent flow. CFD recordings demonstrate laminar flow through the atrioventricular valves in diastole and the semilunar valves in systole. Since the Doppler examination is usually performed with a long-axis or apical transducer orientation, diastolic filling is characteristically encoded in red and ejection in blue (Fig. 13-30, Plate 54). Color aliasing is often observed at the levels of the mitral annulus and LV outflow tract as an abrupt change from bright red to bright blue or vice versa, usually in the center of the flow stream. Pulsed Doppler recordings of transmitral flow velocities are often recorded at the level of both the leaflet tips and annulus. Velocities are higher at the tips, while recordings at the annulus offer the ability to calculate flow through a cross-sectional area that is relatively uniform throughout the cardiac cycle. A sample volume positioned in the right upper pulmonary vein reveals systolic and diastolic emptying flow of nearly equal magnitude followed by a short, low-velocity reversal of flow into the pulmonary veins following atrial contraction (Fig. 13-36). Flow in the LV outflow tract and aortic annulus area is characterized by a progressive increase of velocity peaking in early systole, followed by a more gradual deceleration of flow (Fig. 13-35). Minimal if any flow velocities are detected in the mitral valve orifice and LV outflow tract in systole and diastole, respectively, in normal examinations. Examinations of the tricuspid and pulmonic valves give qualitatively similar results to those of the mitral and aortic valves (Figs. 13-26 and 13-37). Normal values for forward flow velocity are given in Table 13-4. As can be seen, velocity in normal individuals is highest in the aorta and is less than 2 m/s.[63] Other commonly made measurements include the acceleration time (from the beginning of flow to peak velocity of flow in the ascendingaorta or pulmonary artery); and the deceleration time, from LV inflow peak E-wave velocity extrapolated to baseline zero velocity.

Table 13-4: Normal Intracardiac Doppler Velocities

	Velocity, m/s
Right ventricle	
Tricuspid flow	0.3-0.7
Pulmonary artery	0.6-0.9
Left ventricle	
Mitral flow	0.6-1.3
Aorta	1.0-1.7

Doppler Assessment of Diastolic Function

In recent years, there has been a great deal of interest in using mitral inflow velocity patterns to evaluate LV diastolic properties.[6474-74a] Transmitral filling velocities reflect the pressure gradient between the LA and LV during diastole[65] (Fig. 13-34). In early diastole, pressure in the LV normally falls below that in the LA, producing an increase in velocity due to rapid transmitral inflow (E wave). Flow decelerates as the pressures equilibrate in middiastole. In late diastole, LA contraction restores a small gradient, causing transmitral flow to accelerate to a second peak (A wave) that is of less magnitude than the E wave. In individuals in whom early LV relaxation is impaired, the transmitral pressure gradient is blunted, resulting in a decrease in both the velocity of early filling and rate of E-wave deceleration[66,68,70] (Fig. 13-38). Conversely, in patients with marked increases of LA pressure and LV stiffness, early diastolic filling velocities are high, deceleration is rapid, and late filling following atrial contraction is markedly reduced. This is the so-called restrictive pattern of LV filling (Fig. 13-39). Accordingly, an E-wave velocity that is substantially less than the A-wave velocity and is accompanied by a prolonged deceleration time represents evidence of impaired early diastolic relaxation by Doppler, while an increased E-wave velocity and decreased A-wave velocity (E/A ratio greater than 2.5 or 3 to 1) accompanied by a diminished deceleration time (less than 100 ms) is indicative of a noncompliant LV with markedly elevated lef atrial pressures.[69,70,73,73a] Although a restrictive pattern can be seen with restrictive cardiomyopathy or advanced LV dysfunction of any cause, it also occurs in pericardial disease.[75] Of significance, a restrictive pattern of LV filling has been associated with an increased mortality rate in patients with advanced congestive heart failure,[76] and persistence of this pattern despite changes in loading condition is an additional poor prognostic sign.[76a,76b]

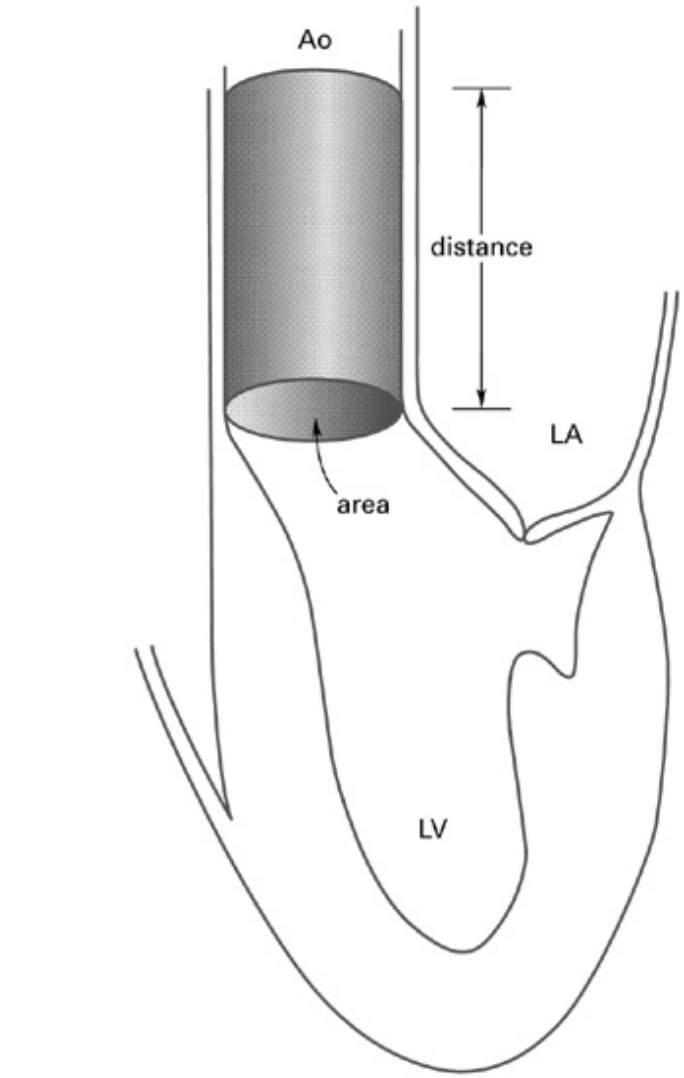
These abnormal mitral inflow patterns can be clinically useful and, when they are markedly distorted, are generally reliable in identifying and characterizing diastolic dysfunction. A number of variables other than diastolic function, however, are capable of influencing transmitral filling velocities. It has been shown that transmitral Doppler filling dynamics are affected by the age of the patient,[77,78] changes in heart rate,[79,80] respiration,[81] and even the position of the Doppler sample volume within the mitral valve orifice.[82-84] Of greatest significance, transmitral inflow is very sensitive to loading conditions, and reductions in LV preload induced by nitroglycerin and/or lower-body negative pressure can induce a striking decrease in early transmitral filling velocities independent of changes in diastolic properties.[85,86] The influence of LV loading upon transmitral filling is most striking when an increase in LA pressure due to cardiac dysfunction restores early diastolic filling velocities and obscures impaired relaxation, thus inducing "pseudonormalization."[68] Therefore, as Doppler transmitral filling dynamics have many limitations in assessing diastolic function, particular filling patterns should not be interpreted as "pathognomonic" findings of diastolic dysfunction but rather as a component of a complete clinical and echocardiographic evaluation.

Recently, attention has focused upon ancillary Doppler techniques to evaluate LV diastolic dysfunction and LA pressure. An impaired systolic filling wave and increased A-wave flow reversal in the velocity recordings from pulmonary veins in the setting of a relatively normal transmitral pattern of diastolic filling suggests elevated LV filling pressures and may be useful in distinguishing normal from pseudonormal mitral inflow pattern (Fig. 13-36). In addition, an increased amplitude of the pulmonary vein A-wave reversal in comparison with the forward transmitral A-wave velocity, especially in regard to duration, has been found to be of value in detecting elevated LV filling pressures by Doppler.[87,88] Tissue Doppler recordings also yield early diastolic and late atrial velocity signals which are altered in a similar fashion to transmitral filling in the setting of diastolic dysfunction.[53a] Tissue Doppler recordings are less influenced by LV loading, and may be of value in distinguishing pseudonormalization.[53c] The rate of propagation of the transmitral LV filling stream into the LV may also be utilized to detect impaired diastolic function as well as constrictive pericarditis.[53a]

Doppler Assessment of Systolic Function and Cardiac Output

Although measurements of LV volumes and ejection fraction can be obtained by 2D echocardiography, Doppler interrogation provides a unique and complementary noninvasive assessment of systolic function. Thus, LV systolic dysfunction often results in decreased aortic velocity and acceleration time.[89-91] As discussed below, in the presence of *mitral regurgitation* (MR), the acceleration of the MR jet can provide information regarding contractile function.[92]

One of the most important applications of Doppler is in the calculation of the stroke volume.[93] The theory involved is relatively simple. The volume of flow through any orifice or tube can be calculated as the product of the cross-sectional area through which flow occurs and the velocity of that flow (Fig. 13-40). Measures of anatomic cross-sectional area can be derived from echocardiographic images, while velocity can be determined by Doppler. As the annulus of the aortic valve is nearly circular, its cross-sectional area can be estimated from a measurement of diameter, as $\pi(\text{diameter}/2)^2$. The pulsed-wave Doppler envelope also can be recorded at the same level. The *mean* flow velocity through the orifice is calculated by integrating velocity over time. (that is, by measuring the area under the Doppler curve). This velocity-time integral, often called the *stroke distance*, is then multiplied by the cross-sectional area at the level of the Doppler interrogation to obtain the stroke volume.[93-96] The product of the stroke volume and heart rate then yields cardiac output.



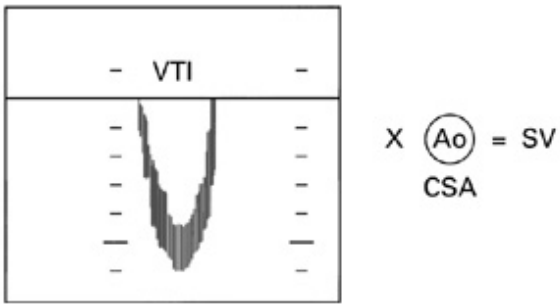


Figure 13-40: Calculation of stroke volume. Multiplying the cross-sectional area (CSA) of the blood column in the ascending aorta by the distance the column moves during a single cardiac contraction yields the stroke volume (SV). The velocity-time integral (VTI), expressed in units of length, represents the "stroke distance." (Modified from Pearlman AS. Technique of Doppler and color flow Doppler in the evaluation of cardiac disorders and function. In: Schlant RC, Alexander RW, eds. *The Heart, Arteries, and Veins*, 8th ed. New York: McGraw-Hill; 1994:2229, with permission.)

Calculation of stroke volume by the Doppler method involves a number of assumptions. The orifice must be circular and constant in size, and the flow velocity must be uniform throughout the cross-sectional area. In addition, the angle between flow and the interrogating beam must be less than 20 degrees. Despite the uncertainty of these assumptions, Doppler-derived measurements of cardiac output and stroke volume have been shown to correspond well with thermodilution, Fick, and the angiographic calculations, though the correlation is not perfect.[93-99]

Theoretically, stroke volume can be calculated at any valve annulus.[96,97,100-102] In clinical practice, however, this is not always possible (e.g., it is difficult to obtain an accurate diameter of the pulmonary artery in every patient). Because the measurement of annular radius is squared in the computation of area, it is the most important source of error of Doppler stroke-volume analyses. Stroke-volume analysis through the mitral annulus is cumbersome; it is uncertain whether the mitral annulus is best described as a circle or an ellipse, and the cross-sectional area of the annulus probably changes slightly during diastole. Calculations using the tricuspid annulus are hampered by similar problems. Despite these limitations, measurements of stroke volume through the various cardiac valves are clinically useful and can be used to calculate pulmonary-to-systemic shunt ratios, regurgitant volumes,[103-110] and orifice areas of stenotic valves by the continuity equation[111-115] (see below).

The Bernoulli Equation

An important application of Doppler echocardiography is the calculation of pressure gradients within the cardiovascular system using a modification of the Bernoulli equation.[116-118] This theorem states that the pressure drop across a discrete stenosis in the heart or vasculature occurs because of energy loss due to three processes: (1) acceleration of blood through the orifice (*convective acceleration*), (2) inertial forces (*flow acceleration*), and (3) resistance to flow at the interfaces between blood and the orifice (*viscous friction*).[119] Therefore, the pressure drop across any orifice can be calculated as the sum of these three variables (Fig. 13-41). In most clinical situations, the contribution of inertial forces and viscous friction are minimal and can be discounted. Since convective acceleration is determined by velocity, the pressure gradient can be calculated from the velocities of blood proximal to and at the level of an orifice as gradient = 4[(orifice velocity)^2 - (proximal velocity)^2]. If the blood velocity proximal to the stenosis is low (<1.0 m/s), this term can be ignored as well. The resulting modified equation states that the pressure gradient across a discrete orifice is equal to four times the square of the peak velocity (V) through the stenosis (PG = $4V^2$).[116-119]

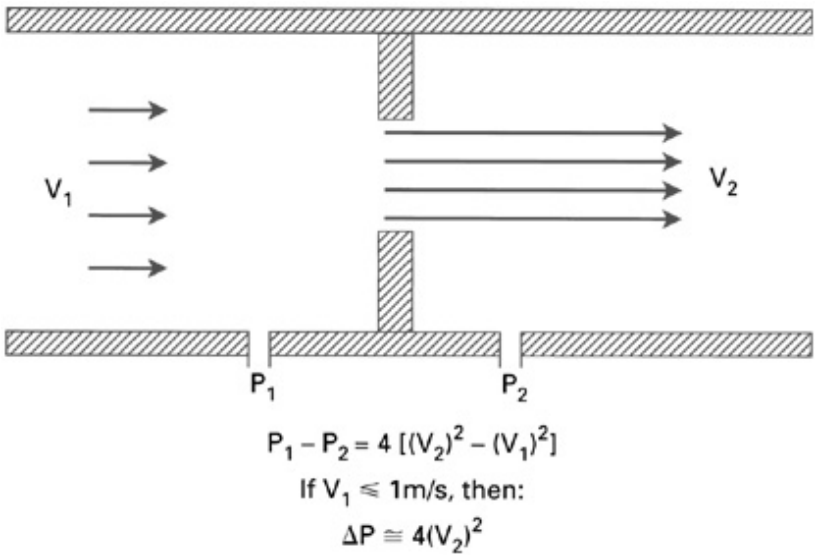

Figure 13-41: The modified Bernoulli equation. Pressure drop across a small orifice can be estimated as four times the square of the peak velocity (if the proximal velocity is less than 1 m/s). V_1 and P_1 = proximal velocity and pressure; V_2 and P_2 = distal velocity and pressure. (Modified from Pearlman AS. Technique of Doppler and color flow Doppler in the evaluation of cardiac disorders and function. In: Schlant RC, Alexander RW, eds. *The Heart, Arteries, and Veins*, 8th ed. New York: McGraw-Hill; 1994:2229, with permission.)

The modified Bernoulli equation can be used to calculate pressure gradients across any flow-limiting orifice and has been validated against invasive measurements.[116-122] The method was originally applied to aortic,

mitral, and pulmonic stenosis, but further uses have been identified. If at least trivial valvular regurgitation is present, systolic gradients across the tricuspid and end-diastolic gradients across the pulmonic valve can be calculated.[123,124] If the RV diastolic pressure is known (or estimated as the right atrial or central venous pressure), peak RV and pulmonary artery pressure (assuming pulmonic stenosis is absent) can be computed as follows[125,126]:

$$\text{Peak pulmonary artery pressure} = 4(\text{TR velocity})^2 + \text{RA pressure}$$

End-diastolic pulmonary artery pressure (PAD) also can be calculated:

$$\text{PAD} = 4(\text{end-diastolic pulmonary regurgitation velocity})^2 + \text{RA pressure}$$

In the presence of mitral regurgitation, a variety of calculations can be made. With measurement of peak systolic arterial pressure, systolic left atrial pressure can be estimated[127]:

$$\text{Left atrial systolic pressure} = \text{systolic blood pressure} - 4(\text{MR velocity})^2$$

Further, the acceleration of the MR jet can be used to estimate LV systolic *dP/dt*.[128] Thus, from the Bernoulli equation, the LA-to-LV pressure gradients at regurgitant velocities of 1 and 3 m/s are 4 and 36 mmHg, respectively. Therefore, *dP/dt* can be calculated as 32 mmHg divided by the time (in seconds) required for the mitral regurgitant jet to accelerate from 1 to 3 m/s. In the case of ventricular septal defects or aortopulmonary shunts, measurements of the peak systolic arterial pressure and the peak Doppler velocity across the defect allows calculation of the right ventricular (or pulmonary arterial) systolic pressure.

The Continuity Equation

Although transvalvular pressure gradients can be calculated from CW Doppler recordings using the modified Bernoulli equation, gradients sometimes can be misleading in the evaluation of valvular stenosis. The transvalvular gradient is determined by both the size of the stenotic orifice and the stroke volume traversing it. Severe aortic stenosis and accompanying LV systolic dysfunction may produce a low transvalvular gradient despite a small valve area, while coexistent aortic regurgitation may result in a large gradient with only mild aortic stenosis. The calculation of orifice area by Doppler echocardiography employs the *continuity equation*, which is derived from the law of the conservation of mass and states that the product of cross-sectional area and velocity is constant in a closed system of flow[129] (Fig. 13-42). Thus, in the case of aortic stenosis, the product of the area and velocity of the left LV outflow tract equals the product of the area and velocity of the aortic valve orifice. Annulus diameter and integrated velocity measurements are derived by the standard volumetric approach, while the velocity across the stenotic orifice is derived by CW Doppler. The equation is then solved for the valve area.[111-116]

$$(A_1) = \pi r^2 = \pi\left(\frac{D}{2}\right)^2 = 0.785\,(D^2)$$

$$(A_2)(V_2) = (A_1)(V_1) \text{ or } (A_2) = \frac{(A_1)(V_1)}{(V_2)}$$

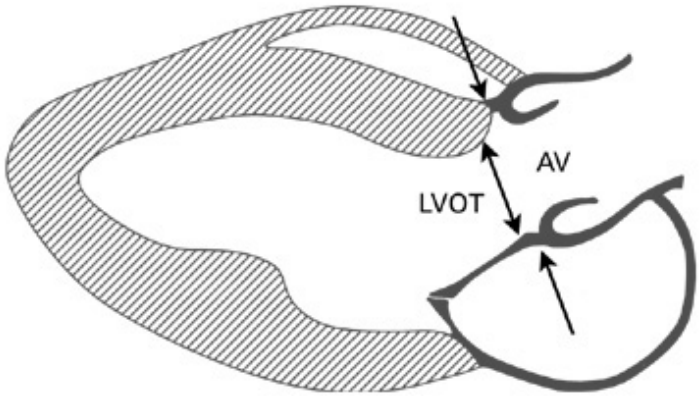

Figure 13-42: The continuity equation. In a closed system (*top*) with constant flow, $Q_1 = Q_2$. Therefore, $A_1 \times V_1$ must equal $A_2 \times V_2$. Determination of any three of the variables allows calculation of the fourth. Clinically (*bottom*), the area of the left ventricular outflow tract (LVOT) can be estimated and used to determine aortic valve area. (From Hagan AD, DeMaria AN. *Clinical Applications of Two-Dimensional Echocardiography and Cardiac Doppler.* Boston: Little, Brown; 1989, with permission.)

The continuity equation is simple and the constituent factors are readily measured, but a number of potential errors can occur. The most common pitfall is an inaccurate estimation of the cross-sectional area proximal to the stenosis. In addition, it is essential that blood velocity proximal to a stenosis be measured outside the area of flow acceleration. Finally, the continuity equation actually solves for the area of the vena contracta, which is usually just distal to the stenotic orifice. Although this area is very similar to the area of the stenotic orifice, occasional discrepancies occur.

Determinants of the Size of Flow Disturbances

Although CFD yields primarily qualitative information, it is unique in its ability to provide measurements of the size of flow disturbances. It is logical that the size of a turbulent jet should correlate with the volume of blood contained within the flow disturbance. Regardless of the lesion, however, the area of turbulence recorded by CFD has multiple determinants.[130-134] The volume of flow present in the disturbance is, of course, a major factor in its size. The pressure gradient operative in any flow disturbance is also an important determinant of the spatial distribution or "spray area" of turbulence.[134] In addition, the size of a flow disturbance is influenced by the orifice through which flow occurs as well as the size and compliance of the receiving chamber.[130-136] Finally, a number of technical factors can influence jet size as imaged by CFD, including instrument gain, the angle of incidence of the interrogating beam, the frequency and pulse repetition rate of the transducer, and the temporal sampling rate.[137] Therefore, measurements derived from the size of the turbulent jet recorded by color Doppler, are at best semiquantitative and should not be expected to correlate with the volume of blood contained in the flow disturbance.

Chapter 13: THE ECHOCARDIOGRAM

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transthoracic echocardiography (TTE) usually defines cardiac anatomy and function satisfactorily, often obviating the need for further cardiac imaging. Occasionally, however, TTE does not provide complete or adequately detailed information. This is especially true in the evaluation of posterior cardiac structures (e.g., the LA, the left atrial appendage, the interatrial septum, the aorta distal to the root), in the assessment of prosthetic cardiac valves, and in the delineation of cardiac structures less than 3 mm in size (e.g., small vegetations or thrombi). Ultrasonic imaging from the esophagus is uniquely suited to these situations, as the esophagus is adjacent to the LA and the thoracic aorta for much of its course[138,139] and affords excellent access of the interrogating beam to these structures.

Over the past decade, a number of technologic advances have occurred in the field of *transesophageal echocardiography* (TEE), and flexible transesophageal ultrasound probes capable of multiplanar imaging of the heart are now widely available.[140-142] The current generation of probes also provide full pulsed-wave, CW, and CFD capabilities.

Although images can be recorded from a variety of probe positions most authorities recommend three basic positions: (1) posterior to the base of the heart, (2) posterior to the left atrium, and (3) inferior to the heart (transgastric position; Fig. 13-43). Figures 13-44 through 13-47 show TEE images obtained in various planes through the heart. It must be emphasized that, with the transducer in the esophagus, posterior structures appear at the top of the image. With the transducer in the stomach, a short-axis view is standardly obtained, with long-axis and apical views available to a variable degree. Upon withdrawing the transducer to the esophagus, one usually obtains apical-equivalent four-chamber and long-axis views, with multiple intermediate projections. Further withdrawal of the probe to the base yields excellent views of the atria, great vessels and semilunar valves, and pulmonary veins. Of particular value are views that delineate the LA appendage, all three leaflets of the aortic valve in short axis, and the transverse and descending aorta.[143]

TEE has become an important imaging modality for the diagnosis and management of infective endocarditis and its complications, including valvular vegetations, chordal rupture, fistulas, perivalvular abscesses, and mycotic aneurysms.[143-148] TEE is more accurate in detecting vegetations and abscesses than TTE[143,149,150] and provides prognostic information as well[150] (Fig. 13-48). In addition, TEE imaging may aid in accurate quantification of valvular disease (particularly mitral regurgitation) if TTE is inconclusive[151] (Fig. 13-49, Plate 57). TEE is especially useful for Doppler interrogation of the pulmonary veins (Fig. 13-50, Plate 58). Flow patterns in these vessels reflect LA pressure, and systolic reversal of pulmonary venous flow has been identified as an accurate marker of mitral regurgitation.[152,153] Although mitral regurgitant color jets are easier to see with TEE than TTE, they are usually larger, and care must be exercised not to overestimate severity of the regurgitation.[154] Multiplane TEE can be used to planimeter the orifice area in AS.[155,155a] The technique is also quite helpful in detection of aortic disease, including dissection, aneurysm, congenital malformations, and atherosclerosis.[139,156,157] Because of its portability, accuracy, and short preparation and procedural times, TEE is now recommended as the preferred diagnostic study in many cases of suspected aortic dissection (Fig. 13-51, Plate 59).[139,158]

Thromboemboli may originate from posterior cardiac structures such as the left atrium (LA) and appendage, interatrial septum, and aorta[159-168]; therefore, TEE has received wide application in the evaluation of possible cardiogenic embolization. Since the most common site of LA thrombi is the appendage, the ability of TEE to visualize this structure is of particular value (Fig. 13-52). TEE can also detect spontaneous contrast signals (that appear to represent transient rouleaux formation and predispose to thromboemboli).[169] In addition, TEE has provided unique real-time images of mobile, pedunculated, atherosclerotic "debris" in the thoracic aorta (Fig. 13-53). Although the optimal therapy for this disorder is currently unknown, warfarin may be helpful and mobile or protruding aortic atheromas appear to be significant risk factors for embolic events.[167,168,170,171171a-171b] The optimal role for TEE in the detection of intracardiac sources of emboli is controversial, and clinical trials are ongoing to evaluate the effect of treatment after discovery of potential embolic sources.

One of the proven applications of TEE is the evaluation of prosthetic valve dysfunction, particularly mechanical valves in the mitral position.[172-174] Since the materials used in artificial valves are strong reflectors and often cause ultrasonic shadowing, the areas behind prosthetic valves are usually hidden from view when transthoracic imaging is used. Because of its unique window on the heart, TEE is clearly superior to TTE imaging for detection of prosthetic regurgitation, infection, tissue ingrowth, and thrombosis[172,174] (Fig. 13-54).

TEE has also become an important intraoperative tool for the detection of cardiac ischemia, the evaluation of valve function after repair or replacement, and the delineation of congenital heart disease.[175-183] Cardiac surgeons often request intraoperative TEE for evaluation of cardiac anatomy and confirmation of a success of surgical repair before closing the chest. In this regard, TEE has almost completely replaced epicardial echocardiography. When TEE images are inadequate, TEE is helpful in managing critically ill patients[184-187] and also can be used to monitor or guide interventional procedures, such as transseptal catheterization,[185-190] mitral valvuloplasty, pericardiocentesis, and endomyocardial biopsy.[191]

Chapter 13: THE ECHOCARDIOGRAM

CONTRAST ECHOCARDIOGRAPHY

Opacification of the right heart cavities with dense ultrasonic reflectances during intravenous contrast injection was first applied clinically in 1968.[192] Subsequently, it became clear that the origin of the dense intracavitary echoes were microbubbles within the injectate, and that any agitated liquid injected intravenously caused the effect.[193] Since room-air microbubbles with the diameter of pulmonary capillaries persist in blood for less than 1 s before dissolving, agitated agents injected intravenously cannot cross the lungs and enter the left-sided cardiac chambers. Thus, the presence of echocardiographic contrast entering left heart chambers after intravenous injection of an agitated liquid indicates the presence of a right-to-left shunt.[194,195]

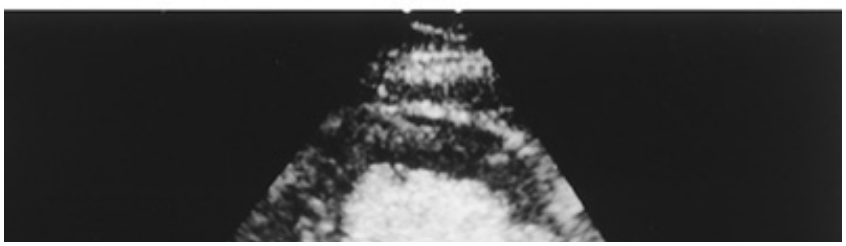
Identification of intracardiac shunts, particularly patent foramen ovale in patients with unexplained cerebral ischemia (Fig. 13-55), remains the most frequent indication for contrast echocardiography.[196] Simple agitated normal saline solution remains the most commonly used contrast agent for such studies.

In recent years, many attempts have been made to achieve echocardiographic opacification of the LV cavity and myocardium.[197-200] Initial attempts utilized direct left-sided administration. Injection of agitated saline or other fluids into the LV or aorta causes echocardiographic opacification of those chambers and has been used as an alternative to angiography to evaluate mitral and aortic regurgitation.[194] In addition, injection of sonicated radiographic contrast agents into the aortic root or coronary arteries can produce myocardial opacification[201] (Fig. 13-56). The presence of echocardiographic contrast within the myocardium after such injections reflects the spatial distribution of coronary blood flow (CBF)[198] and is valuable in identifying collateral CBF and the absence of reflow following reperfusion therapy of acute myocardial infarction (MI).[202-210] Of significance, the presence of microcirculatory flow and integrity in these studies was a reliable predictor of viable myocardium.[207-209]

Direct injection of coronary contrast into the left heart is limited by its invasive nature. Therefore, stabilized solutions of microbubbles have been developed which can traverse the pulmonary capillary bed in high concentration after intravenous injection. These new ultrasonic contrast agents have been designed to achieve prolonged bubble persistence or survival after injection into blood. The persistence time of a bubble prior to disolving in blood can be increased by utilizing a shell or surface modifying of gas across the bubble surface. Alternatively, prolonged bubble survival can be achieved by utilizing a dense, high-molecular-weight gas with a reduced capacity to diffuse across the bubble shell and a low saturation constant in blood, which favors return of gas back into the bubble. Therefore, the new ultrasonic contrast agents utilize shells made of human serum albumin, liposomes, or even biodegradable poliment materials, and the fluorocarbon gases, which are dense and poorly soluble. These new microbubble agents are all capable of producing dense, high-intensity signals not only within the LV but also within the myocardium following intravenous injection.[210a,210b]

Efforts to produce stabilized solutions of microbubbles have now resulted in a commercially available agent, Optison, which is composed of a perfluorocarbon gas in an albumin shell. Intravenous injection of Optison opacifies the left ventricle in nearly all patients, thereby facilitating identification of the endomyocardial border. This capacity has found its greatest application in stress echocardiography, where detection of the endocardium is of fundamental

importance in recognizing abnormal contraction produced by ischemia. By intensifying backscatter within the intracardiac cavities, new ultrasonic agents also enhance Doppler recording of flow abnormalities.[211] Marginal Doppler spectral tracings in cases of mitral regurgitation, tricuspid regurgitation, and aortic stenosis often improved dramatically after contrast injection, facilitating the quantitation of valvular lesions and pulmonary hypertension.[212-216] In addition to new contrast agents, novel imaging technology directed to the amplification of contrast signals are also available. Second harmonic imaging enhances the ultrasonic backscatter from contrast microbubbles (which resonate in an ultrasonic field) while decreasing the returning signal from myocardium (which does not resonate).[217-219] (Fig. 13-57). Power Doppler imaging is a method that correlates signals between successfully transmitted pulses to derive images of moving blood or cardiac structures. Power Doppler techniques are especially well delineated to detect the changing signals produced by movement and/or dissolution of contrast microbubbles.[46] Finally, since exposure to ultrasound energy can produce microbubble destruction, intermittent electrocardiography (ECG) gated rather than continuous ultrasound transmission can also prolong microbubble persistence and amplify contrast signals.[220,221] When combined with the new ultrasonic contrast agents, these refined imaging modalities can achieve visualization of myocardial opacification following intravenous drug administration, thereby delineating myocardial perfusion. Initial studies indicate that myocardial contrast echocardiography can yield information regarding myocardial perfusion comparable to that obtainable by radionuclide techniques and can be of value in delineating coronary artery stenoses.[221a,221b] Intravenous injection of new contrast agents may actually permit visualization of intramyocardial vessels (Fig. 13-58).[214-217,221c] The ability to delineate regional myocardial perfusion is a major step forward in noninvasive imaging and can be expected to provide important information regarding coronary artery disease (CAD) in the near future.



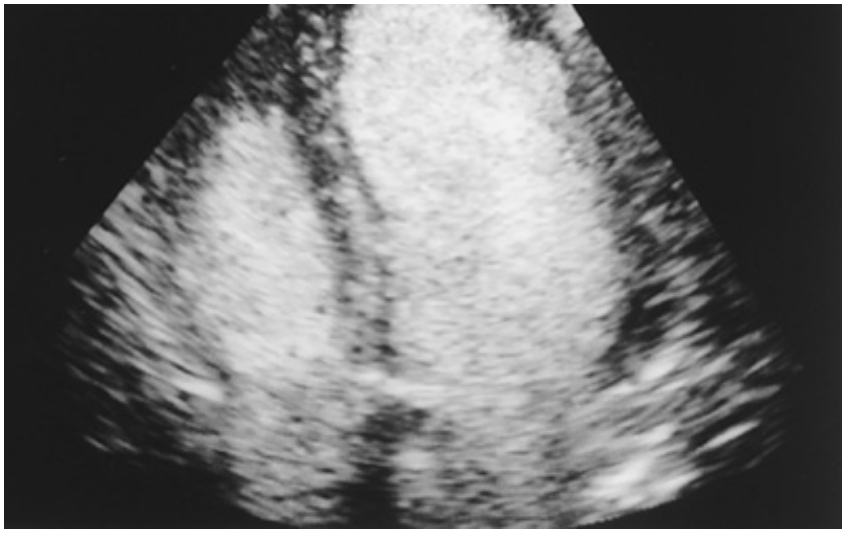


Figure 13-57: Harmonic imaging with second-generation echocardiographic contrast. Endocardial border definition before injection is fair (*upper panel*) but is markedly improved with harmonic imaging following contrast injection (*lower panel*).

In addition to new contrast agents, novel imaging technologies directed to the amplification of contrast signals are also available. For example, second-harmonic imaging enhances the ultrasonic backscatter from contrast microbubbles (which resonate in an ultrasonic field) while decreasing the returning signal from myocardium (which does not resonate)[217-219] (Fig. 13-57). Early after contrast injection, second-harmonic imaging increases the cavity-to-myocardium contrast intensity ratio, improving visualization of the left ventricular cavity. Second-harmonic imaging may also enhance the myocardial contrast phase, which follows LV cavity opacification with second-generation contrast agents.[217-219] As exposure to ultrasound energy can produce microbubble destruction, intermittent rather than continuous ultrasound transmission can also prolong microbubble persistence and amplify contrast signals.[220,221,210b] In recent years, harmonic imaging has been used to visualize cardiac structures in the absence of contrast injection. This tissue harmonic imaging decreases clutter and other artifacts, often improving endocardial definition (Fig. 13-58*A*).

Chapter 13: THE ECHOCARDIOGRAM

DISEASES OF THE AORTIC VALVE AND AORTA

Aortic Stenosis

The aortic valve is best imaged in the parasternal views.[222] The leaflets are thin, linear structures. All three can be visualized in the short-axis view and produce a triangular orifice during systolic opening. The long-axis view exhibits the right and usually the noncoronary leaflets, which normally open to the walls of the aorta. Mild thickening and reduction of mobility is often observed in the elderly (aortic sclerosis) and is associated with an increased risk of CAD. In older adults, acquired aortic stenosis (AS) is manifested by markedly thickened, often calcified, immobile aortic valve leaflets,[223] while doming of the leaflets suggests congenital aortic stenosis and is usually encountered in younger patients (Fig. 13-59).[224] Echocardiography can distinguish valvular from sub- and supravalvular AS, can accurately identify bicuspid valves, and can delineate the presence of LV hypertrophy.[225,226] Subaortic stenosis may be caused by asymmetrical septal hypertrophy with systolic anterior mitral motion, a subaortic membrane, or (less commonly) a subaortic tunnel. Bicuspid valves exhibit an oval rather than triangular orifice (Fig. 13-60). Although the severity of stenosis can be assessed semiquantitatively by 2D and M-mode image echocardiography, valvular calcification may shadow the leaflets or produce reverberations and obscure their motion.[223] Therefore, attempts to measure valve area by transthoracic planimetry have been unsuccessful, although multiplane TEE has been of greater value[155] (Fig. 13-61). Thus, 2D-echocardiographic imaging accurately detects the presence and etiology of AS but not the severity. Likewise, CFD demonstrates turbulent flow through the aortic valve and may guide continuous wave interrogation but provides little quantitative data.[227] The use of Doppler echocardiography and the modified Bernoulli and continuity equations have now made noninvasive calculation of aortic gradients and valve area routine and have affected utilization of cardiac catheterization in AS patients.[228] (See also Chap. 56).

The cornerstone of the ultrasound evaluation of AS is CW Doppler interrogation through the aortic valve. The calculated gradient using the peak Doppler velocity [4(AS velocity)^2] correlates closely with the peak instantaneous gradient measured at catheterization[117-119] (Fig. 13-62). In interpreting echocardiographic studies, it is important to distinguish between the peak instantaneous pressure gradient, the mean gradient, and the peak-to-peak gradient. The first two physiologic parameters represent simultaneous pressure differences between LV and aorta and can be measured accurately by Doppler echocardiography. The *peak-to-peak gradient,* commonly used in the catheterization laboratory, compares the highest pressures reached in the LV and aorta (even though not simultaneous) and is uniformly lower than the peak instantaneous gradient recorded by Doppler. Therefore, the maximal Doppler gradient does not correlate with the peak-to-peak catheterization gradient, and comparisons between the two should be avoided (Chap. 56).

A number of potential sources of error exist in the estimation of the transvalvular aortic gradient by CW Doppler recordings. It is imperative that Doppler signals from the stenotic jet be obtained with an angle of incidence of less than 20 degrees. Since the direction of the jet rarely can be known with precision from 2D techniques, each examination must employ all possible windows and angulations, including apical, parasternal, and suprasternal transducer positions. Also, one must be careful to account for the proximal flow velocity in the Bernoulli equation if it is 1.5 m/s or greater. Finally, since some degree of pressure recovery occurs distal to the aortic valve

leaflets, it is important to record continuous wave signals as close to these structures as possible.

Values for aortic valve area can be calculated using the continuity equation by measuring the velocity of the jet across the aortic valve with CW Doppler, the velocity in the LV outflow tract just proximal to the valve with PW Doppler, and by deriving the area of the outflow tract from the diameter of the aortic annulus. Results from the continuity equation have been found to correlate well with the area calculations based on catheterization data and the Gorlin formula.[111-115] As both AS jet velocity and aortic annulus radius are squared in the continuity equation, accurate determination of these parameters is essential for reliable measurements. When atrial fibrillation is present, the peak Doppler velocity still correlates with peak instantaneous gradient through the aortic valve, but *calculations of valve area may be problematic*, as the outflow tract and peak aortic velocities are not measured simultaneously.

In summary, a comprehensive echocardiographic examination in a patient with AS should establish both the presence and severity of disease. Echocardiographic imaging should identify the structural abnormality involving either the subvalvular, valvular, or supravalvular area; distinguish congenital from acquired etiologies; and evaluate the state of LV hypertrophy and function. CW Doppler recordings should provide accurate measurements of instantaneous and mean transaortic valvular gradients, and the continuity equation should provide reliable estimates of aortic valve area. In cases where the relative roles of orifice stenosis and LV dysfunction are uncertain, TEE imaging or Doppler recordings during inotropic stimulation with dobutamine may be of value.[155,229] Cardiac catheterization is still necessary for the delineation of coronary anatomy.

Aortic Regurgitation

In contrast to AS, the aortic valve leaflets are often anatomically normal by echocardiography in patients with aortic regurgitation (AR).[230,231] 2D and M-mode echocardiography often provide indirect evidence of the presence of AR, including signs of LV volume overload, diastolic fluttering of the anterior mitral valve leaflet, aortic root enlargement, and incomplete coaptation of the aortic valve leaflets.[232,233] The important M-mode finding of premature diastolic closure of the mitral valve prior to the onset of systole due to LV filling by the regurgitant jet signifies acute, severe AR[234] (Fig. 13-63) and the need for surgery (Chap. 56).

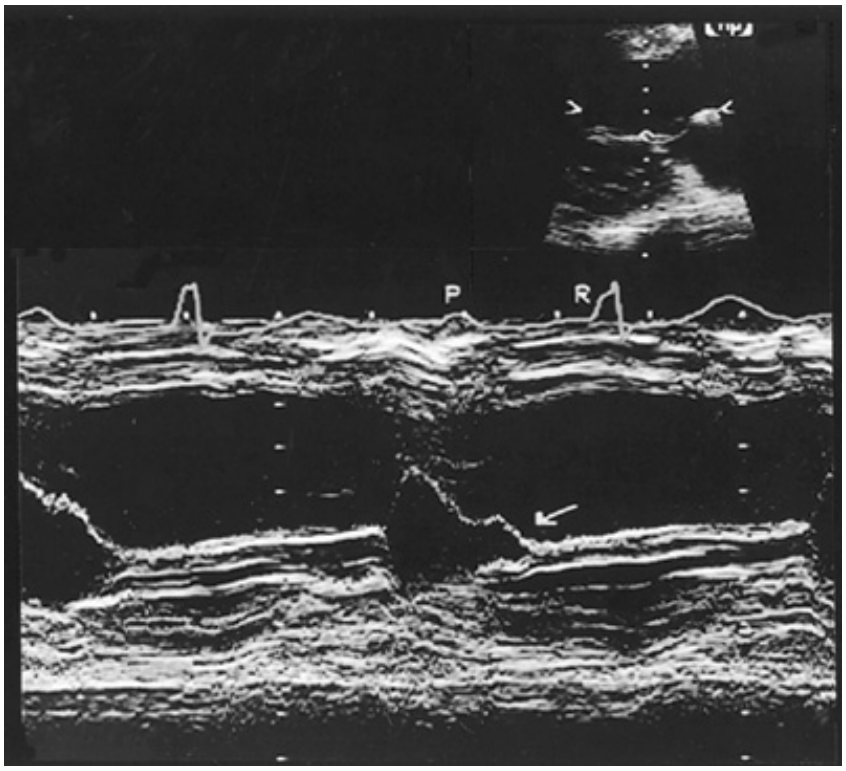

Figure 13-63: M-mode tracing (from the parasternal position) in a patient with acute severe aortic regurgitation. The mitral valve leaflets close (*arrow*) before ventricular contraction begins. P = p wave, R = QRS complex.

Perhaps the most important contribution of echocardiographic tissue imaging to the assessment of AR is in identifying the etiology.[235] Thus, thickened leaflets that are restricted in movement are observed in patients with acquired AS, while oval doming of two functional leaflets will be observed in the presence of a bicuspid aortic valve (Fig. 13-60). AR due to infectious endocarditis can be identified by the presence of valvular vegetations, while regurgitation due to diseases of the aorta are manifest by anatomic changes of the vessel. Less common etiologies of AR, such as those associated with subvalvular pathology or ventricular septal defect, may also be recognized by echocardiographic imaging.

Although the findings yielded by echocardiographic imaging are useful, Doppler interrogation is necessary to obtain direct evidence of the presence and severity of AR. Screening with CFD demonstrates turbulent flow in the LV outflow tract during diastole in virtually all views[236] (Fig. 13-64*A*, *B*, and *C*, Plate 60). The jet is typically elliptical and may be located anywhere in the LV outflow tract. CW Doppler spectral recordings from this jet yield a high-velocity diastolic signal directed toward the apex[237] (Fig. 13-62). Since AR jet velocity accurately reflects the diastolic pressure gradient between aorta and LV, it is maximum at the point of valve closure and decreases throughout diastole.[238] The flow pattern of AR may be readily distinguished from mitral inflow in that it is higher in velocity, begins immediately after aortic valve closure, generally has a much slower deceleration, and does not have an increased velocity following atrial contraction.

Several approaches exist for the quantitation of AR by echocardiography. Conventional echocardiographic imaging can provide evidence of the presence and extent of LV volume overload. More direct evidence of the severity of AR can be derived from the deceleration rate of the jet recorded by CW Doppler (Fig. 13-65).[237-240] In the presence of mild degrees of AR, the transvalvular pressure gradient will be maintained throughout diastole, creating a high-velocity jet with a minimal deceleration rate. Conversely, severe AR reduces aortic pressures and increases

LV pressures in diastole, eliminating the pressure gradient and creating a rapid jet deceleration to a low velocity (Fig. 13-65). Severe, acute AR can also cause diastolic MR (Fig. 13-64*C*, Plate 60). The most common approach to assessing the deceleration rate of the AR jet is by calculating the time required for the velocity to fall to one-half of the maximal pressure equivalent, a technique similar to the pressure half-time measurements performed in the quantitation of mitral stenosis (MS). Previous studies have demonstrated that a pressure half-time of less than 250 ms reliably identifies patients with severe degrees of aortic regurgitation as assessed by invasive methods.[240] Application of the pressure half-time approach to quantifying AR must take into account that, since the deceleration rate is a reflection of pressure gradient, it is determined by both the volume of AR and the compliance of the left ventricle. Accordingly, ventricles that vary greatly in stiffness or distensibility will yield different AR deceleration rates for the same regurgitant volume.

The estimate of severity most commonly derived from echocardiography is the size of the AR jet by CFD.[236] Conceptually, jets that are distributed over a small area of the LV outflow tract represent lesser degrees of AR than jets that penetrate widely and to the level of the papillary muscles. Some studies have demonstrated a general correlation between jet length and severity of AR.[241] The optimal results have been obtained when the width of the AR jet just proximal to the valve was expressed as a percentage of the width of the LV outflow tract; a jet occupying 50 percent or more of the outflow tract correlates with severe regurgitation by angiography.[236] Quantitation of AR based upon the size of the flow disturbance is subject to errors induced by the other factors that influence jet area: transvalvular pressure gradient, volume and compliance of the receiving chamber, regurgitant orifice, the Coanda effect (wall effect), and technical factors relating to the operator and instrument settings. In addition, entrainment and displacement of RBCs in the LV outflow tract also influence the size of the regurgitant jet. Finally, convergence of AR with normal transmitral filling may obscure the flow disturbance. Therefore, assessment of the severity of AR by analysis of the size and shape of the flow disturbance *is at best semiquantitative.*

The AR volume can be estimated by comparing volumetric measurements of LV inflow and LV outflow calculated from annular velocity and cross-sectional area (derived from pulsed Doppler and 2D images respectively).[110] This method is contingent upon the absence of valvular stenosis and of other regurgitant lesions. In the setting of AR, the volume ejected through the aortic annulus represents both systemic flow and regurgitant volume, while the volume coursing through the mitral annulus represents only systemic flow. Thereby, LV outflow will exceed LV inflow by the amount of the regurgitant volume.[110,242-244] This technique can provide useful estimates of regurgitant volume, but with any flow volume calculation by echocardiography, errors in technique and the assumptions involved in volume calculation can result in significant errors. An alternate *quantitative approach* derives estimates of regurgitant fraction from reverse diastolic flow in the aorta.[245] Assuming a constant cross-sectional aortic area, comparison of integrated flow velocities during forward systolic flow and retrograde diastolic flow should yield an estimate of regurgitant fraction. Although this is somewhat imprecise, the presence of a significant flow reversal in the aorta visualized by color or spectral Doppler is a reliable marker of severe AR (Fig. 13-66).

Determination of the optimal timing of surgical intervention in patients with AR remains a difficult problem in clinical medicine (see also Chap. 56). Several criteria derived from echocardiographic recordings have been proposed to guide this decision.[246-249] Most prominently, an LV end-systolic dimension of 55 mm or greater with a shortening fraction of 25 percent or less have been advocated as sufficient criteria for surgical intervention in the absence of symptoms.[250] Considerable debate continues regarding this issue, however, and no universally accepted echocardiographic criteria exist by which to determine the optimal role for surgical treatment.

Diseases of the Aorta

The thoracic aorta is best visualized from the left and right parasternal positions and from the suprasternal notch.[251] The descending aorta may also be imaged from subcostal and modified apical views. Normally, short-axis images of the aortic root yield a circular structure, while long-axis images exhibit two parallel linear walls with a maximal diameter of 35 mm.[252] Although 2D imaging is used most commonly, M-mode recordings of the aortic root facilitate precise measurement of its dimensions.

AORTIC DISSECTION

In recent years, 2D echocardiography has dramatically changed the diagnostic approach to aortic dissection. TTE is a convenient screening test (Fig. 13-67) and often enables accurate detection of ascending aortic dissection.[253] The diagnostic findings include a dilated aorta with a mobile intimal flap that presents as a thin, linear signal within the lumen. Transthoracic imaging is unreliable for detection of descending aortic dissection,[254] although it occasionally visualizes the complete length of the thoracic aorta (see also Chap. 88).

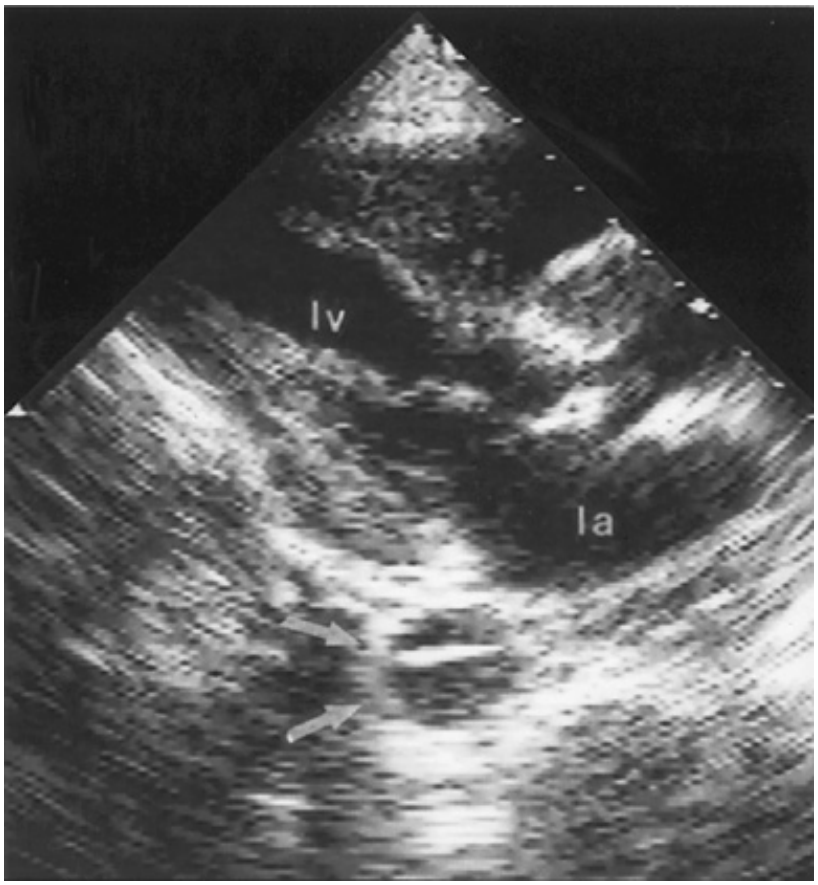

Figure 13-67: Transthoracic parasternal long-axis plane demonstrating a dissection of the descending thoracic aorta. The aortic root is dilated, the aortic valve is thickened, and an intimal flap is present in the descending aorta (*arrows*). LV = left ventricle; LA = left atrium.

Although several noninvasive methods exist to diagnose aortic dissection, TEE has become the procedure of choice in many hospitals because of its accuracy, portability, rapid procedural time, and ability to provide data regarding valvular regurgitation and LV function.[139,158,255-257] Except for *a short portion of the proximal aortic arch*, which is obscured by the bronchus, multiplane TEE provides excellent visualization of the entire thoracic aorta and high accuracy in detecting

aortic enlargement, intimal tears, and false lumen thrombus (Fig. 13-68). CFD may reveal communications between true and false channels (Fig. 13-51, Plate 59; Fig. 13-69, Plate 61). TEE also appears useful for the diagnosis of aortic intramural hematoma, an increasingly recognized disorder which has a clinical prognosis similar to that of classic dissection.[258,259]

AORTIC ANEURYSM

Aneurysms of the aorta may be saccular or fusiform and are recognized as localized or circumferential areas of aortic enlargement, often with thin walls. TTE is especially useful in detecting ascending aortic dilatation but can also visualize descending thoracic and abdominal aortic aneurysms.[252,260] Echocardiography has been used extensively to assess aortic pathology in patients with Marfan syndrome.[261] The nature of the lesion is relatively specific in that there is symmetrical dilatation of the annulus, sinuses of Valsalva, and aortic root (Fig. 13-70, Plate 62). Aortic leaflet coaptation may be compromised leading to AR. Echocardiography is helpful in determining prognosis and optimal timing of aortic root replacement.[262-264]

Sinus of Valsalva aneurysms are also well visualized by both TTE and TEE.[265,266] These lesions cause asymmetrical dilatation of the aortic root and seem to affect the right coronary sinus most frequently. They are prone to rupture, often into the right heart[267] (Fig. 13-70*A*). Doppler echocardiography in such settings demonstrates fluttering of the tricuspid valve, a color jet crossing from the aortic root into the right heart, and occasionally diastolic opening of the pulmonic valve.

Congenital aortic disease, such as supravalvular aortic stenosis (SAS), aortic coarctation, patent ductus arteriosus, and truncus arteriosus also can be detected with echocardiography (see Chaps. 63 and 64).[225,268] In these conditions, suprasternal and transesophageal imaging are often helpful. SAS is recognized as an "hourglass" narrowing just distal to the leaflets, while coarctation presents a more localized, abrupt luminal reduction in the descending aorta. Patent ductus arteriosus and truncus arteriosis are often best identified by virtue of the accompanying flow disturbance on CFD.[269,270]

AORTIC ATHEROSCLEROSIS

As mentioned in the section on TEE, recent studies suggest that aortic atherosclerosis is an important cause of stroke and embolic events.[167,168] Mobile and protruding intimal plaques have been detected by TEE (Fig. 13-53) in patients with stroke with a prevalence greater than in controls, a finding not previously appreciated by other imaging techniques.[271] Optimal treatment for extensive aortic atherosclerosis is currently unknown; although warfarin appears useful.[171b] It appears that detection of large aortic arch plaques prior to cardiopulmonary bypass should prompt adjustment of cannula placement to avoid dislodging the aortic debris.[272]

Penetrating aortic ulceration, which affects the descending aorta and mimics the clinical syndrome of acute aortic dissection, may also be diagnosed by TEE (Fig. 13-71, Plate 63).[273,273a] The diagnosis is based upon visualization of a localized defect with protrusion of the ulcer into the vessel wall (in the absence of dissection). This disease entity, which occurs in the setting of atherosclerosis, warrants urgent surgery to avoid aortic rupture. Aortic tears induced by trauma are also accurately detected by TEE[273b,273c] (Fig. 13-72).

Chapter 13: THE ECHOCARDIOGRAM

DISEASES OF THE MITRAL VALVE

Mitral Stenosis

Detection of *mitral stenosis* (MS) was one of the earliest clinical applications of echocardiography[274] (see Chap. 57). In most individuals, the mitral valve leaflets are easily visualized and yield thin linear echoes that exhibit wide bipeaked excursions as they open in early and late diastole.[24] The characteristic 2D ultrasound findings of MS are seen clearly in nearly all patients with this disorder.[275] The mitral valve leaflets are thickened and often present bright high-intensity reflections indicating calcification. The process may involve thickening and shortening of the chordal apparatus as well. There are varying degrees of commissural fusion restricting mitral leaflet separation, especially at the distal tips.[276,277] This leads to diastolic "doming" or a right-angle bend of the anterior mitral valve leaflet, as high LA pressure creates a bulge in the leaflet's midportion (which is generally more pliable than the distal portion) (Fig. 13-73). The posterior leaflet actually may be pulled anteriorly during diastole because of commissural fusion with the longer anterior leaflet.[278] Mitral doming may also occur in congenital valvular disease, but it is not seen when mitral leaflet opening is reduced due to low-flow states[32] or AR jets. The LA is nearly always enlarged with MS.

The effects of stenosis upon mitral valve motion are often best demonstrated by M-mode recordings (Fig. 13-74). In addition to leaflet thickening and reduced excursion, M-mode tracings also depict a characteristic decrease in the reclosure rate of the anterior mitral leaflet in early diastole (reduced E-F slope) due to a persistent LA-LV pressure gradient and a slow rate of LV filling.[276-279] The decrease of the E-F slope has been found to correlate grossly with the severity of mitral stenosis. This finding is not specific for MS, however, and may occur whenever early diastolic filling is reduced.[24,280] Attempts to calculate mitral valve orifice area using the E-F slope have proved unsatisfactory.[281]

The entire perimeter of the mitral valve orifice can be visualized in the 2D parasternal short-axis view, and mitral leaflet excursion normally approaches the endocardial borders of the LV at the mitral tip level. In the setting of MS, the thickened leaflets form a fish-mouth orifice, which occupies only a small portion of the cross-sectional area of the left ventricle (see also Chap. 57).[275,282] Measurements of mitral valve area may be obtained by planimetry of the orifice visualized in the parasternal short-axis view and correlate well with those obtained by cardiac catheterization (Fig. 13-73).[282-284] Since the shape of the mitral valve resembles a funnel, it is crucial to identify the smallest cross-sectional area and obtain recordings with orthogonal beam orientation at that point in order to avoid overestimation. Optimal gain settings must be employed to avoid encroachment of tissue signals upon the orifice.[285]

Doppler examination provides additional quantitation of MS.[286,287] Interrogation of mitral inflow with either PW or CW modes (depending on velocity and Nyquist limit) reveals elevated diastolic velocities, with a reduction in the rate of deceleration in early diastole yielding a pattern similar to decreased E-F slope seen with M-mode in MS (Fig. 13-75). In a fashion similar to that of AS, the maximal gradient across the mitral valve can be calculated from the peak diastolic velocity utilizing the Bernoulli equation.[286,288] But since the maximal transmitral gradient is very sensitive to changes in heart rate and loading, the mean transmitral gradient obtained as the

average of a number of individual gradients derived throughout diastole is customarily utilized to assess the severity of MS.[288] In addition, Doppler technique may provide estimates of mitral valve area (MVA) by means of the calculation of the pressure half-time.[284,287] The pressure half-time represents the interval required for transmitral velocity to decelerate from its highest point (E) to a velocity that yields one-half of the pressure equivalent (Fig. 13-75). As the severity of MS increases, the rate of deceleration decreases, prolonging the pressure half-time. Further, dividing an empiric constant of 220[289] by the pressure half-time yields an estimate of MVA, which correlates with values obtained during cardiac catheterization. Since Doppler estimates of mitral valve area are indirect and involve the use of empiric constants, they are considered less accurate than direct measurements of MVA derived by planimetry of the mitral valve orifice.[290] The pressure half-time method is inaccurate immediately following mitral commissurotomy.[291,292]

Echocardiography can help assess the feasibility and appropriateness of percutaneous catheter balloon mitral commissurotomy (CBMC) to treat individual patients with MS[293,294,294a] (Chap. 37). An echocardiographic scoring system based on evaluation of mitral valvular thickening, calcification, mobility, and subvalvular involvement has been devised. Each variable is assigned a grade of 1 (minimal involvement) to 4 (severe), with a maximal score of 16. Although the prognostic capability of this method is limited, the outcome of balloon valvuloplasty in patients with higher scores, particularly greater than 12, is less satisfactory and involves a higher risk of complications than in patients with lower scores.[293,294,294b] Therefore, echocardiographic analysis is an important part of the decision-making process prior to CBMC. Preprocedural TEE is also often performed to detect left atrial thrombi, which can embolize during transseptal catheterization.[295,296] Following CBMC, echocardiography can identify complications including mitral regurgitation[297] and atrial septal defect.[298]

Mitral Regurgitation

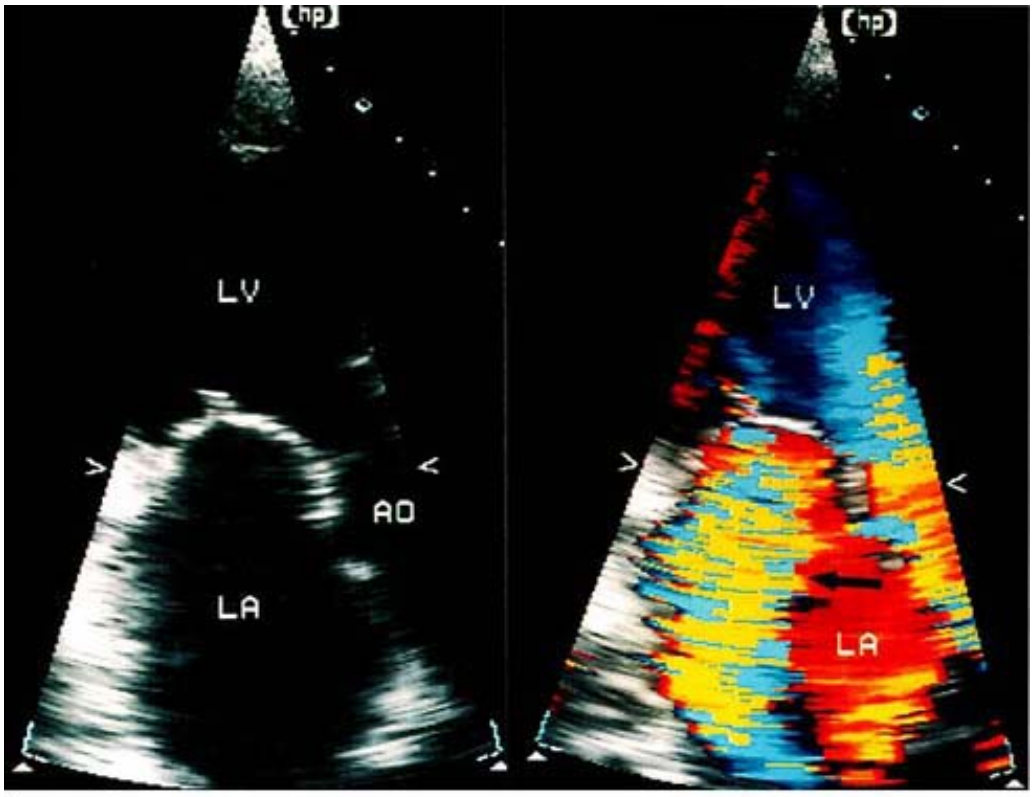
Although echocardiography is extremely accurate in the detection of mitral (and aortic) regurgitation, *quantitation* is more difficult. 2D imaging alone does not provide direct evidence of mitral regurgitation (MR) but usually reveals the etiology of the lesion.[299] Thus, 2D echocardiography reveals thickened, restricted leaflets in rheumatic disease, vegetations in infective endocarditis, flail mitral leaflets with torn chordae, and redundant leaflets with abnormal coaptation in mitral valve prolapse.[300] 2D echocardiography can also detect LA and LV abnormalities associated with MR, such as myxoma, papillary muscle dysfunction, and dilated cardiomyopathy. In addition, enlargement of these chambers offers indirect evidence of MR severity. In cases of chronic, severe MR, 2D echocardiography can also discern the presence of depressed LV function and decreased ejection fraction (see also Chap. 57).

Doppler echocardiography is the primary method for the detection and evaluation of MR[301-303] and reveals a disturbed flow jet in the LA during systole. Spectral Doppler recordings provide several indexes of severity which are of semiquantitative value. Since the intensity of the Doppler signal is a function of the number of RBCs in the sample volume, the videodensity of the jet correlates in a general way with regurgitant volume.[304] Similarly, an increase in transmitral filling velocities reflects increased forward flow and suggests a large regurgitant volume.[304a] Measurements obtainable from the envelope of the CW Doppler recording of the MR jet include a slow rate of acceleration, indicative of a diminished LV *dP/dt*[305] (Fig. 13-76). Early peaking followed by rapid deceleration of the MR jet suggests a large V wave, increased left atrial pressure, and usually acute severe MR.[306]

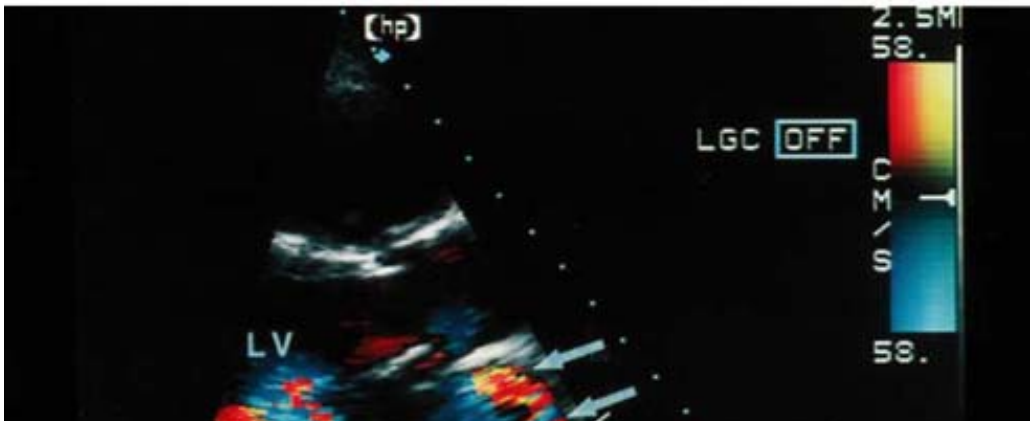
As in the case of AR, volumetric calculations of LV inflow and outflow by combined pulsed Doppler and 2D-echocardiographic imaging techniques can be used to derive measurements of regurgitant volume.[307,308] In the case of MR, transmitral filling represents both systemic and regurgitant volume, while aortic outflow represents only systemic flow. Therefore, mitral filling

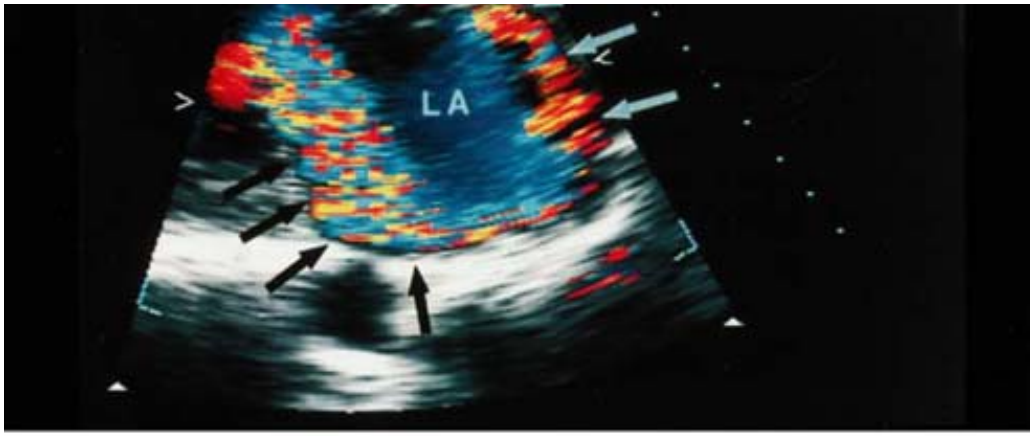
should exceed left ventricular ejection, and the difference will be regurgitant volume.

The most commonly applied method for evaluation of MR is assessment of jet size by CFD.[303,309,310] Imaging of the left atrium in systole reveals a turbulent, mosaic jet of varying direction, size, and configuration (Fig. 13-77*A* and *B*, Plate 64). Previous studies have demonstrated that a mitral regurgitant jet whose absolute area exceeds 8 cm^2 [303,310] or fills at least 40 percent of the area of the LA[309] is predictive of finding 3+ to 4+ MR by LV angiography. Unfortunately, neither jet size nor angiographic grade correlates closely with measurements of actual regurgitant volume.[310] The lack of correlation between CFD jet area and regurgitant volume is attributable to the additional variables that influence the distribution of the flow disturbance, such as pressure gradient and the volume and compliance of the LA, as well as technical limitations. The Coanda effect is of particular significance in regard to MR, since jets into the left atrium are often eccentric (for example, in cases of mitral valve prolapse and torn chordae tendineae). Due to differential frictional forces and resistance to flow, eccentric MR jets are drawn along the walls of the LA, resulting in cross-sectional jet areas that are smaller than centrally directed flow disturbances of comparable regurgitant volume (Figs. 13-77 and 13-78). This effect can lead to underestimation of severity of regurgitation.[311,312]



A





B

Figure 13-77: (Plate 64) *A.* Mitral regurgitation. *Left:* apical three-chamber plane. Right: same plane with color Doppler imaging. A large jet of mitral regurgitation (*arrow*) is present. AO = aorta; LA = left atrium; LV = left ventricle. *B.* Parasternal long-axis view from a patient with angiographically proved severe mitral regurgitation. The color Doppler jet in this case is directed posteriorly and eccentric (*black arrows*). The jet hugs the wall of the left atrium (LA) and wraps around all the way to the aortic root (*white arrows*). LV = left ventricle.

TEE is also useful for assessment of MR, as the close proximity of the probe and its higher-frequency interrogating beam permit imaging of regurgitant jets in greater detail than TTE.[313-315] Eccentric jets and mitral valvular anatomy are well visualized (Fig. 13-78*A* and *B*, Plate 65), and rightward bulging of the interatrial septum with severe MR is also sometimes apparent. As the regurgitant jets often appear larger with TEE than with TTE, one must avoid overestimation of MR severity.[154] TEE often yields Doppler interrogation of the pulmonary veins that is superior to TTE, and several recent studies have shown that systolic reversal of flow into the pulmonary veins is a reliable sign of severe MR[152,315a,315b] (Fig. 13-79).

Another color Doppler method of flow quantitation involves measurement of the zone of flow convergence proximal to the regurgitant orifice (or the *proximal isovelocity surface area, referred to as PISA*).[316-319] The mechanism for this phenomenon is derived from the hydrodynamic principle that blood flow accelerates before passing through a small orifice under high pressure. If this increase in flow velocity exceeds the Nyquist limit, color aliasing occurs and the velocity aliasing border is equal to the Nyquist limit (Fig. 13-31 and Fig. 13-80*A* and *B*; Plate 66). If one assumes that the aliasing border conforms to the geometry of a hemisphere around the mitral orifice, then the instantaneous flow rate of blood through the orifice can be calculated as:

$$\text{Flow} = 2\pi r^2 \cdot V_r$$

where r is the radius of the hemisphere shell (distance from alias border to orifice) and V_r is the velocity of blood at distance r (the Nyquist limit velocity).[316] If the maximal calculated flow rate is divided by the peak regurgitant flow velocity (measured with CW Doppler), the regurgitant orifice area is then obtained.[320] The product of regurgitant orifice area and integrated velocity of the MR jet by CW yields regurgitant volume.

The PISA method avoids the variables associated with jet size and the assumptions and technical limitations of volumetric calculations. Numerous studies have shown a correlation between both flow rate and regurgitant orifice area calculated by PISA and the severity of MR assessed by standard methods.[316,320] In addition, flow convergence calculations have been applied to other valvular lesions, including AR and MS[321,322] (Fig. 13-81, Plate 67), ventricular septal

defect,[323] and prosthetic heart valves.[324] The proximal flow convergence assumes a hemispheric geometry for the PISA signal and that the plane of the mitral leaflets is flat, two sources of potential error.[325] Despite these limitations, the method holds considerable promise for the clinical evaluation of valvular regurgitation.

Mitral Valve Prolapse

As is true of so many aspects of mitral valve prolapse (MVP),[326] the echocardiographic findings in this disorder have been controversial for many years.[327] Recent insights into the anatomy of the mitral annulus and the significance of abnormal leaflet structure have established a central role for echocardiography in the diagnosis and prognosis of MVP.[328] The classic echocardiographic findings in overt MVP syndrome consists of mid- to late-systolic bulging of one or both mitral leaflets across the plane of the mitral valve annulus into the LA (Fig. 13-82*A* to *C*).[329] The leaflets are often observed to be structurally abnormal, with thickening, elongation, and hooding.[330] Mid- to late-systolic MR is sometimes present, often eccentric, and generally directed away from the prolapsing leaflet.[326] The chordae tendineae may be thickened and elongated, the aortic root may be dilated, and the tricuspid valve leaflets may prolapse as well. LV function is usually normal, although the LA and LV may be enlarged if MR is significant. The greater temporal resolution of M-mode over 2D echocardiography often yields striking evidence of abrupt midsystolic posterior/superior motion of the mitral valve leaflets in prolapse patients[331] (Fig. 13-82*C*). Although such M-mode findings, which resemble a question mark on its side, are specific for mitral valve prolapse, patients with classic MVP occasionally may demonstrate diagnostic findings only with 2D imaging (Chap. 58).

Although the diagnosis of classic, fully expressed MVP is straightforward by echocardiography, identification of mild prolapse is more difficult, and no absolute diagnostic criteria currently exist.[329] This is largely related to the absence of any "gold standard" with which to validate findings, including auscultation, angiography, and even pathology.[326] For prolapse to be present, the mitral valve leaflets must cross the plane of the mitral valve annulus after initial systolic coaptation. Recent studies have established that the mitral valve annulus is not flat but rather saddle-shaped.[332] The annulus reaches its nadir in the apical four-chamber view, and even normally coapting mitral valve leaflets may appear to prolapse in this projection. Therefore, current criteria require that MVP be diagnosed only when one or both of the mitral leaflets clearly bulge past the plane of the mitral valve annulus in the parasternal long-axis view.[328] Unfortunately, the degree to which the mitral leaflets must break the plane of the annulus is unclear. The greater the portion of the mitral valve leaflets entering the LA, the more likely the existence of signs and symptoms related to this disorder; a peak distance behind the annulus of 2 mm almost invariably establishes the presence of MVP.[329] The diagnosis of mild MVP may be assisted by examination of the structure of the leaflets and chordae tendineae, since it has been demonstrated that patients with redundant or thickening valve leaflets (greater than 5 mm in midleaflet) are at increased risk of complications, including severe MR and infective endocarditis[333] (Chap. 73).

Torn Chordae Tendineae

Rupture of chordae tendineae may occur spontaneously or in conjunction with MVP or endocarditis. This can result in a flail mitral leaflet and severe MR. Although TTE often detects these lesions, TEE is especially sensitive and accurate and often demonstrates free motion of the leaflet and ruptured chord into the LA even when the TTE is equivocal (Fig. 13-83*A* and *B*).[334] As with MVP, the MR jet in this condition is usually eccentric and directed away from the affected leaflet, often "hugging" the adjacent left atrial wall (Coanda effect). Therefore, the jet's cross-sectional area may be misleadingly small. The findings of mitral valvular anatomy on TEE may also be helpful in predicting the feasibility and success of valve repair surgery.[335]

In the setting of ischemic heart disease, both LV enlargement and papillary muscle dysfunction (from infarction or transient ischemia) may cause MR.[336] Both the MR and the contractile abnormality responsible for it are usually well visualized by 2D echocardiography. In rare cases, papillary muscle rupture (partial or complete) occurs in the postinfarction period.[337] Rapid echocardiographic diagnosis often requires TEE and may be lifesaving in these cases.[334]

Mitral Annular Calcification

The finding of mitral annular calcification (MAC) is fairly common in adults and occurs more frequently with advancing age. Although ultrasound cannot discern histology, calcification typically appears as thickened, extremely high-intensity ("bright") signals (Fig. 13-84). The posterior portion of the mitral annulus is affected much more commonly than the anterior segment, and calcification often extends into the posterior mitral leaflet, sometimes restricting its motion.[338-340] The abnormality, best visualized in the parasternal long- and short-axis views, is seen as a bright calcific density at the junction of the posterior mitral leaflet and the annulus. In the short-axis view, the posterior band of calcification often appears crescentic. Rarely, the calcification is extensive enough to cause marked valvular thickening and clinically significant mitral stenosis.[339] MAC has also been implicated as a source of cardiogenic embolization.[341]

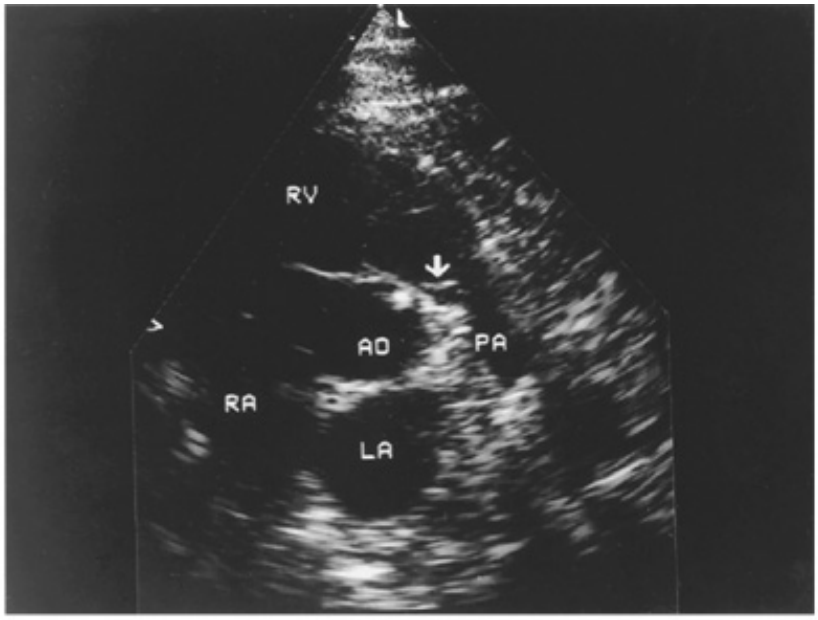
Chapter 13: THE ECHOCARDIOGRAM

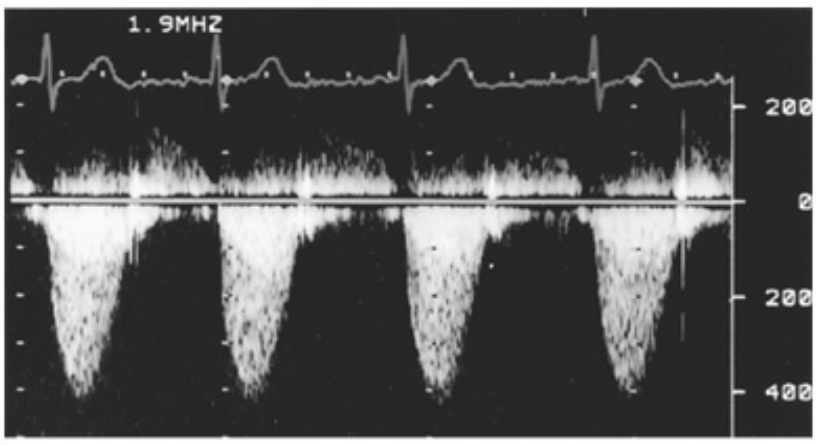
RIGHT-SIDED VALVULAR DISEASE ANDPULMONARY HYPERTENSION

Pulmonic Valve

Major structural abnormalities of the pulmonic valve are relatively rare. *Pulmonic stenosis* (PS) is usually congenital in origin and resembles congenital AS in many respects. The stenotic valve does not open fully and exhibits characteristic thickening and systolic doming on 2D imaging[342] (Fig. 13-85). M-mode recordings of the pulmonic valve often show a large a wave, since right ventricular diastolic pressure is often so high and pulmonary artery (PA) pressure so low that the atrial "kick" is sufficient to open the pulmonic valve.[343] Doppler interrogation reveals turbulent flow distal to the valve, and CW measurements can be used to calculate gradients and valve areas with the Bernoulli and continuity equations much as in aortic stenosis.[344]



A



B

B

Figure 13-85: *A.* Pulmonic stenosis. The pulmonic valve leaflet is thickened and echo-reflective (*arrow*). RA = right atrium; LA = left atrium; AO = aorta; PA = pulmonary artery; RV = right ventricle. *B.* Doppler interrogation reveals increased flow velocity (4 m/s) through the valve orifice.

Although severe *pulmonic regurgitation* (PR) is rare, mild PR is common and appears as a flame shaped flow disturbance in the *right ventricular outflow tract* (RVOT) in diastole.[345] Many individuals have trivial PR on color Doppler examination; this is a physiologic, normal variant (Fig. 13-86). Hemodynamically significant PR is uncommon; when present, it is usually due to congenital heart disease, valvular tumors, endocarditis, or carcinoid heart disease (Chap. 59). The echocardiographic grading of PR is semiquantitative, based on the density of the CW envelope, area of the color Doppler jet, and width of the jet at the valve.[346,347] The PR pressure half-time by CW Doppler may be shorter with more severe PR, but this is not as well investigated as in the case of aortic regurgitation. Measurements derived from the CW Doppler recording also provide estimates of end-diastolic pulmonary artery pressure using the Bernoulli equation as follows[348]: [4(PR end-diastolic velocity)^2 + central venous pressure (CVP).

Tricuspid Valve

Tricuspid stenosis (TS) is usually rheumatic in origin, and coexistent mitral and aortic valvular disease is the rule. Congenital or acquired (nonrheumatic) causes of TS are quite uncommon. On rare occasions, tricuspid stenosis may be caused by carcinoid heart disease or by leaflet adhesions to permanent pacemaker leads. Because of the large size of the tricuspid annulus, obstruction by masses, even multiple vegetations, is unlikely to cause stenosis (Chap. 59).

Regardless of the etiology, diastolic doming of the valve leaflets suggests stenosis.[349,350] CW Doppler interrogation is also helpful and mimics the findings of MS (high diastolic velocity with prolonged pressure half-time).[349] The pressure half-time equation of mitral valve area calculation cannot be applied directly to the tricuspid valve, and large studies comparing Doppler echocardiography with right heart catheterization in TS are not available.

Tricuspid regurgitation (TR) is much more common than TS, and like PR is present to a mild degree in many normal individuals (Chap. 59). Hemodynamically significant TR may be caused by endocarditis, rheumatic valvular disease, pulmonary hypertension, congenital heart disease (for example, Ebstein's anomaly), carcinoid heart disease, flail TR leaflet (which can occur as a complication of cardiac trauma or endomyocardial biopsy), and tricuspid valve prolapse. Echocardiographic findings in patients with TR generally mirror those found in MR.[351] Although 2D imaging can detect abnormalities associated with TR, such as incomplete leaflet coaptation, flail leaflet, and right-sided chamber enlargement, the technique cannot accurately quantify TR grade. Doppler echocardiography, especially color-flow mapping, has become the procedure of choice to detect TR, and has reasonable accuracy for semiquantitation of severity.[352,353] As with MR, severity of TR can be estimated by regurgitant jet area, ratio of jet area to right atrial area, and size of proximal flow convergence zones[354] (Fig. 13-31). Doppler interrogation of the hepatic vein is also useful, as systolic flow reversal within the vein suggests severe TR[355] (Fig. 13-87). Peak right ventricular (and pulmonary artery) pressure can be estimated using measurements of peak TR velocity by CW Doppler (see section on Bernoulli equation, above). If necessary, intravenous echocardiographic contrast agents can be injected to accentuate the TR Doppler jet and facilitate more accurate measurements of pulmonary artery pressure.[352-354]

Right Ventricular Function and Pulmonary Hypertension

Right ventricular (RV) enlargement and pulmonary hypertension can be diagnosed and assessed by echocardiography[355,356] (Fig. 13-88*A* and *B*). Because of the asymmetrical and crescentic shape of the RV, accurate volume calculations are difficult.[357,358] Nonetheless, 2D imaging provides useful general information regarding RV size and function. In the apical four-chamber view, the RV should appear somewhat smaller than the LV; therefore RV enlargement can be diagnosed qualitatively when the RV cross-sectional area exceeds that of the LV. RV chamber area measurements in the apical four-chamber imaging plane can also be compared to standardized normal values.[359] Although not well standardized, measurements of RV wall thickness can be performed from the parasternal view; a value of 5 mm is generally accepted as the upper limit of normal.[360,361] Systolic motion of the RV free wall and LV lateral wall toward the interventricular septum should be similar and roughly symmetrical in normal situations. Asymmetrical hypokinesis of the RV free wall indicates RV dysfunction.[362]

RV volume overload can lead to RV hypertrophy, chamber enlargement, and, in advanced stages, depressed RV systolic function. TR can result from or cause RV overload, and the TR Doppler velocity allows estimation of the peak RV systolic pressure. The interventricular septum also becomes abnormal in RV overload and tends to flatten or even bulge toward the LV (Fig. 13-89).[363] The pattern of septal movement can help distinguish between volume and pressure overload: in pure volume overload, the RV diastolic pressure may equal or exceed that of the LV, while the systolic pressure of the LV greatly exceeds that of the RV. Therefore, the interventricular septum flattens during diastole and returns to its normal curvature during systole.[363,364] With RV pressure overload, however, the abnormally high RV pressures persist through the entire cardiac cycle and the interventricular septum remains deformed during both systole and diastole.[364]

The hallmark of pulmonary hypertension by Doppler echocardiography is a high-velocity TR jet in the absence of PS. Peak TR jet velocity can be converted to peak systolic PA pressure as follows[365]:

$$4(\text{TR velocity})^2 + \text{CVP}$$

In the setting of severe pulmonary hypertension, the main PA and the inferior vena cava are often dilated. If RA pressure is elevated, the inferior vena cava (IVC) does not decrease in diameter with inspiration as normally expected.[366] M-mode examination of the pulmonic valve in pulmonary hypertension may show a characteristic W-shaped motion of the valve leaflet during systole[367-369] (Fig. 13-90) and loss of the normal a dip caused by partial opening of the valve during atrial contraction. The loss of the a wave is probably due to the large pressure difference between the RV and pulmonary artery during late diastole and the resulting inability of the atrial contraction to partially open the pulmonic valve. The midsystolic closure of the valve and partial reopening in late systole (sometimes called the *flying W*) may be caused by elevated pulmonary vascular resistance and oscillation of a pressure wavefront within the pulmonary artery.[370]

Characteristic pulsed-wave Doppler abnormalities in pulmonary hypertension include a decrease in the velocity-time integral of flow through the pulmonic valve (secondary to depressed RV stroke volume) and a shortening of the acceleration time (measured from beginning of flow through the pulmonic valve to peak velocity). The acceleration time (in milliseconds) can be used to estimate the mean pulmonary artery (PA) pressure[371] as:

$$\text{Mean PA pressure} = 80 = (\text{acceleration time}/2)$$

Pulmonic regurgitation is also common in the setting of pulmonary hypertension and is usually

well recorded by pulsed Doppler. As discussed above, the end-diastolic PR velocity can be used to estimate PA end-diastolic pressure by the Bernoulli equation.

Chapter 13: THE ECHOCARDIOGRAM

PROSTHETIC CARDIAC VALVES

Echocardiography is a critically important tool in the evaluation and serial follow-up of mechanical and bioprosthetic valves.[372] Unfortunately, the increased echo reflectivity of prosthetic valves (especially the mechanical models) causes extensive distal shadowing and reverberations that markedly limit the utility of transthoracic 2D echocardiography (Figs. 13-91 and 13-92). TTE imaging may detect partial ring dehiscence manifest as abnormal "rocking" motion of a prosthetic valve. TTE may also identify reduced movement of the valve disks or leaflets and may occasionally visualize adherent thrombi, tissue ingrowth, and vegetations.[373-375] Leaflet thickening, detachment, and flail motion also may be visualized for bioprosthetic valves.

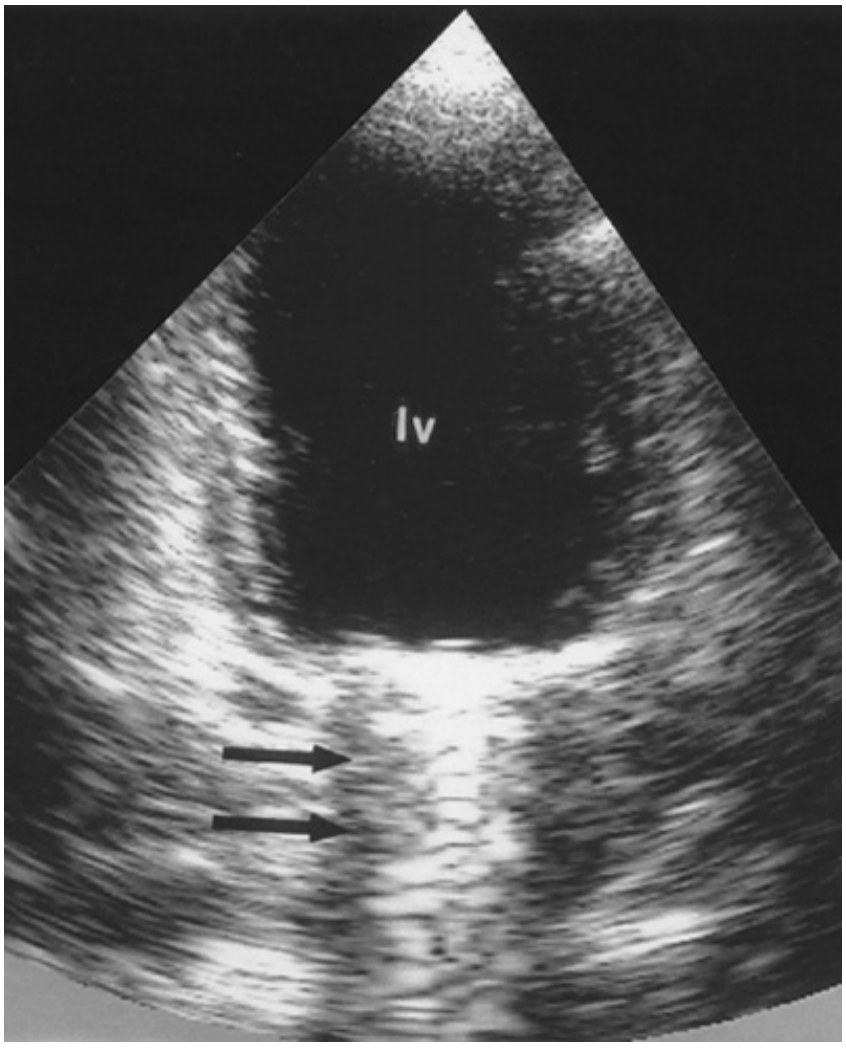

Figure 13-91: Apical two-chamber view of a mechanical prosthetic valve (mitral position) during systole. The left atrium is completely obscured by ultrasonic shadowing (*arrows*). LV = left ventricle.

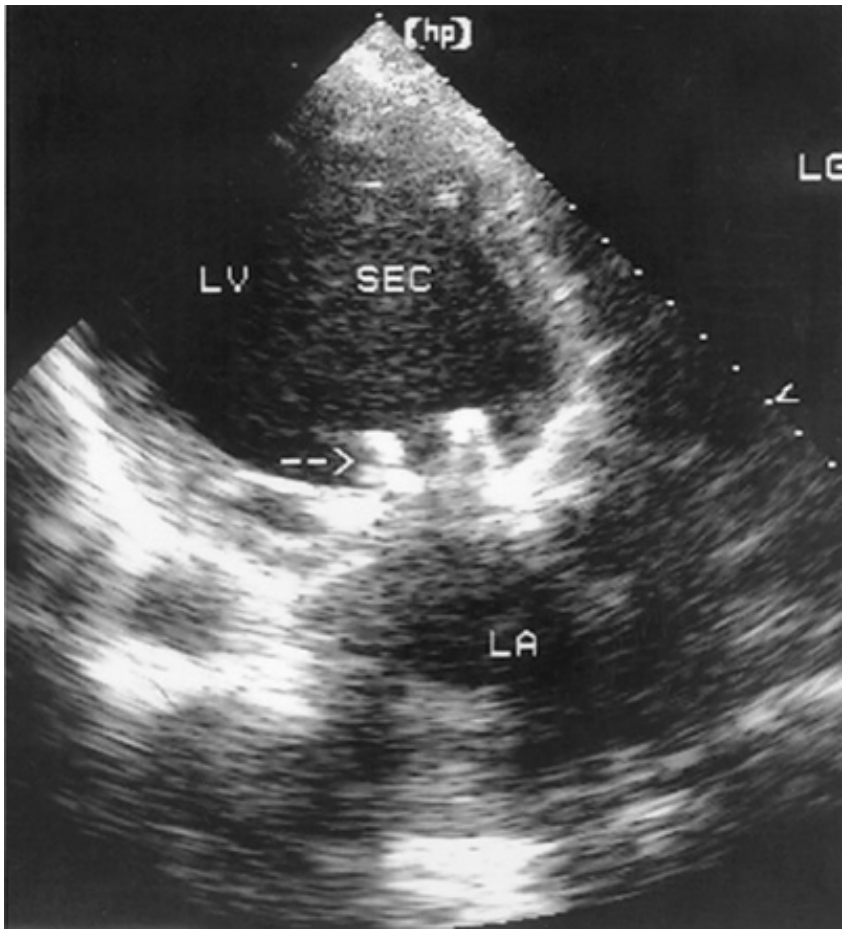

Figure 13-92: Apical view of a bioprosthetic valve (*arrow*) in the mitral position (two of the three prosthetic valve struts are apparent). Spontaneous echo contrast (SEC) is also present, secondary to systolic dysfunction and enlargement of the left ventricle (LV); LA = left atrium.

Doppler interrogation is the cornerstone of the echocardiographic assessment of prosthetic valvular stenosis and regurgitation.[376-379] Color-flow imaging can document the presence, direction, and size of the forward flow stream. Color-flow Doppler can also detect regurgitant flow jets, but like 2D imaging, is limited by acoustic shadowing distal to the prosthesis. Doppler color jets due to prosthetic AR can be readily visualized from the transthoracic apical view, but jets produced by prosthetic mitral and tricuspid regurgitation are often obscured.[380,381] Therefore, although detection of prosthetic regurgitation by transthoracic Doppler is usually feasible, quantitation is often difficult. A small flow signal shortly after valve closure may be observed frequently with prosthetic valves and is likely related to the blood caught behind the occluder as it closes.[382]

Doppler flow velocities and gradients (calculated by the Bernoulli equation) through normal prosthetic valves vary depending upon the type, position, and diameter of the prosthesis.[376-379] The velocities and gradients across prosthetic valves are flow-dependent as well[383] and therefore related to LV function. Given these variables, it is not surprising that a wide range of transvalvular gradients exists for normally functioning prosthetic valves. Nevertheless, "normal" ranges have been reported for various valve types and can be used as a guide to recognize malfunction. High prosthetic valvular gradients due to increased flow volume rather than stenosis can be recognized by high flow velocity across the remaining native valves, a short pressure half-time for mitral prostheses, and a short ejection time for aortic prostheses. With aortic valve prostheses, peak systolic Doppler velocities may indicate higher systolic pressure gradients than those actually

found during cardiac catheterization.[384,385] This problem may be more prevalent with StarrEdwards (ball-in-cage) and St. Jude (bileaflet tilting disks) valves than with Medtronic-Hall (single tilting disk) and bioprosthetic valves. The inaccuracies with Starr-Edwards and St. Jude valves are probably due to the presence of multiple flow channels (with various orifice areas) and the phenomenon of flow recovery.[385,386] Because of these variabilities, an echocardiographic examination is warranted following prosthetic valve implantation to establish its baseline Doppler characteristics.[387] As opposed to peak gradients, mean transvalvular gradients calculated by Doppler correlate reasonably well with direct catheter measurements.

TEE has dramatically changed the diagnostic approach to prosthetic valve dysfunction,[380,381] and is especially useful for assessing mitral prostheses, as it overcomes the problem of left atrial shadowing and reverberation (Fig. 13-93). TEE is extremely accurate in the detection of prosthetic regurgitation and impaired movement of the valve occluder, and it is the diagnostic procedure of choice in most cases of suspected prosthetic valve endocarditis.[388-390] Small thrombi, tissue ingrowth, infected or sterile vegetations, and even sutures in the sewing ring usually can be readily visualized. The enhanced sensitivity of TEE requires operator experience and judgment, as nearly all mechanical prostheses exhibit a normal small amount of regurgitation, which should not be misinterpreted as pathologic.[382] TEE may also visualize thin fibrinous strands sometimes attached to prosthetic valves; these structures appear to be a potential source of cardiogenic embolization.[391,392] The technique is quite accurate in the diagnosis of prosthetic valve thrombosis, a potentially fatal medical emergency, and can assist clinical decision making in this disorder.[393-395]

Chapter 13: THE ECHOCARDIOGRAM

INFECTIVE ENDOCARDITIS

Infective endocarditis remains an all too common illness, with a significant risk of morbidity and mortality (see also Chap. 78). Traditionally, the diagnosis has been based on either the cumulative results of blood cultures, physical examination, and laboratory findings or on pathologic proof of infected valvular vegetations at surgery or autopsy. Echocardiography may play an important role in infective endocarditis in regard to diagnosis, detection of associated cardiac abnormalities and hemodynamic dysfunction, prognosis, and the need for surgery. Vegetations can now be visualized noninvasively in many (but not all) cases of endocarditis and have become the echocardiographic hallmark of this disorder.[396-398] Thus, even though TTE cannot exclude endocarditis, abnormal findings may strongly suggest the disorder, even in the presence of negative blood cultures. Since no single abnormality has 100 percent diagnostic accuracy for infective endocarditis, strategies for diagnosis have been devised based upon a number of criteria,[399399a-399b] and definite echocardiographic vegetations are designated as a major criterion. Both TTE and TEE are valuable in the detection of perivalvular abscesses and prosthetic-valve endocarditis.[147,400] Although there is considerable debate concerning the most accurate diagnostic criteria for endocarditis, echocardiography has become one of the most commonly used techniques for the evaluation of potentially affected patients.[401] Echocardiography (both TTE and TEE) is also useful for evaluation of patients with systemic lupus erythematosus complicated by Libman-Sacks endocarditis.[402,403]

Even though M-mode recordings produced the first echocardiographic description of vegetations,[396] this modality has gradually been largely replaced by 2D imaging. With 2D echocardiography, valvular vegetations typically appear as irregular, usually localized masses of varying echocardiographic density attached to valvular or perivalvular structures (Figs. 13-94 and 13-95) without significantly altering their mobility. The vegetations may be small or quite large and may attach directly to the valve leaflets or the supporting chordal apparatus.[397,398,404,405] Both small, nonmobile vegetations on a normal valve and large vegetations on a markedly abnormal valve may be difficult or impossible to identify with certainty. Aggressive infections often cause perforation or distortion of the affected leaflet, leading to varying degrees of valvular regurgitation. This is distinctly different from most cases of nonbacterial thrombotic (marantic) endocarditis, where the valvular vegetations are usually nondestructive.[406] In cases of infective endocarditis, the presence of vegetations by TTE increases the risk of heart failure, embolic events, and the ultimate necessity of valve replacement.[407-411] Unfortunately, TTE is not 100 percent sensitive in detecting vegetations, and up to 20 percent of patients with proved native-valve endocarditis may have unremarkable examinations.[412] The sensitivity of TTE in prosthetic valve endocarditis has been found to be even lower (approximately 60 percent) due to technical limitations in imaging.[400]

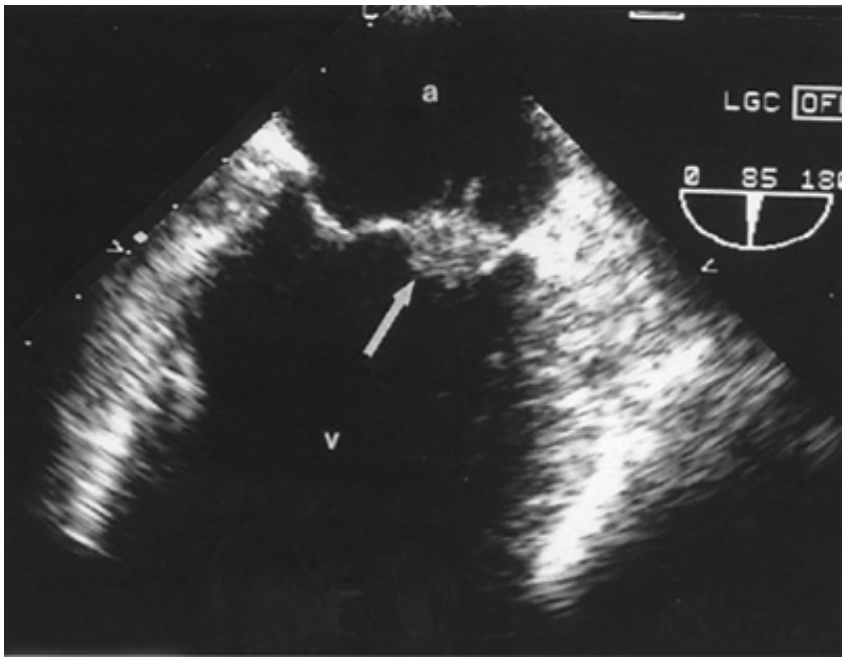

Figure 13-95: Longitudinal TEE view of a large mitral valve vegetation (*arrow*). a = left atrium; v = left ventricle. (Courtesy of William D. Keen, Jr., MD.)

TEE has proved significantly more sensitive than TTE for detection of infective vegetations and is extremely helpful for the diagnosis of perivalvular abscesses, mycotic diverticula, and prosthetic valve involvement.[147,413] The technique is also useful for assessing valvular regurgitation, fistulas (Fig. 13-96), and other hemodynamic complications of endocarditis.[414] Although a negative TEE examination cannot completely exclude infective endocarditis, it confers a relatively good prognosis in those cases where the diagnosis is eventually confirmed.

The optimal use of TEE in suspected endocarditis remains controversial: some authorities recommend routine TEE in all cases, but many do not.[415] A reasonable approach may be to perform TTE as the first screening test in patients with suspected endocarditis. If the study is technically difficult, equivocal, or detects vegetations in patients at high risk for perivalvular complications or hemodynamic compromise, TEE should be performed. If TTE is unremarkable or detects vegetations in patients at low risk for complications, TEE may not be necessary.[149] Exceptions to this last recommendation might include patients with prior antibiotic treatment or those with persistent bacteremia or fever of unknown etiology. In high-risk patients (i.e., with possible prosthetic valve involvement, congenital heart disease, or infection with especially virulent organisms), TEE is recommended even if TTE is normal.[149]

Echocardiographic evaluation of suspected endocarditis is not without pitfalls. It may be quite difficult to detect active vegetations in patients with preexisting valvular abnormalities such as calcification, myxomatous change, rheumatic involvement, and healed vegetations. Despite recent technologic advances, the diagnosis of infective endocarditis remains a clinical one, and over-reliance on echocardiography may cause mistakes. Therefore, *echocardiographic results should be integrated with other clinical information* to diagnose this disorder accurately.[416]

Chapter 13: THE ECHOCARDIOGRAM

ISCHEMIC HEART DISEASE

Echocardiography in Coronary Heart Disease

Although originally of greatest value in valvular heart disease and cardiomyopathy, echocardiography has now become one of the most important techniques for the detection and quantitative assessment of myocardial ischemia and infarction. Cardiac ultrasound-because it is rapid, portable, noninvasive, and inexpensive-is especially well suited to the evaluation of ischemic heart disease. Although visualization of coronary artery structure and flow has been achieved by echocardiography,[417-420] the application of this technique in ischemic heart disease continues to revolve primarily about the assessment of LV function.

Currently, the primary application of echocardiography in patients with coronary heart disease is based upon the detection of the effects of myocardial ischemia and/or infarction upon LV structure and function. Interruption of coronary flow or imposition of an oxygen demand that exceeds oxygen supply quickly leads to impaired systolic thickening and excursion of the affected myocardium. If flow is not restored and transmural infarction occurs, the affected myocardium may become akinetic or dyskinetic and eventually thinned and fibrotic. In addition, myocardial ischemia produces diastolic dysfunction, which may be detected by analysis of transmitral Doppler flow recordings or endocardial expansion profiles. These changes in the structure, contraction, and relaxation of myocardium are often readily detected by echocardiography.

The echocardiographic detection of myocardial ischemia was initially described using M-mode echocardiography, and this modality remains useful because of its excellent sensitivity and temporal resolution.[421] 2D imaging, however, has now become the primary technique for the examination of LV size, wall thickness, myocardial thickening, and regional wall motion, since it enables visualization of all LV wall segments. Thereby, in patients with CAD, standard echocardiographic approaches can be utilized to calculate LV diastolic and systolic volumes as well as ejection fraction.

The echocardiographic manifestations of CAD consist of one or more of the following: reduction in systolic thickening, abnormal segmental wall motion during systole or diastole, and alterations in the acoustic properties of the myocardium (usually termed *tissue characterization*).[422] These abnormalities may be expressed as a disturbance in global LV size and function, an increase in LV volume, and a decrease in LVEF calculated by standard approaches. In addition, using the standard tomographic planes, the LV can be divided into 16 wall segments according to the format recommended by the American Society of Echocardiography (Fig. 13-97).[423] By grading the contraction of each of the 16 segments as hyperkinetic, normal, hypokinetic, akinetic, or dyskinetic (and assigning a numerical value to each grade), a semiquantitative wall motion score can be calculated as the mean numerical value for all segments. Wall motion scores of this kind have been used to assess prognosis in both acute myocardial infarction[424] and chronic coronary artery disease.[425] When LV dysfunction is detected echocardiographically, the specific coronary artery responsible can often be inferred based upon the dyssynergy region(s).[426,427] The echocardiographic findings of akinesis with segmental myocardial thinning can also be used to distinguish CAD from dilated cardiomyopathy, which typically manifests global hypokinesis and decreased wall thickness. There is overlap in the echocardiographic findings between these two groups, however, as severe ischemic disease may cause global hypokinesis and nonischemic

cardiomyopathy may sometimes cause heterogeneous dysfunction.[428]

Myocardial Infarction and Postinfarction Complications

Cardiac ultrasound has achieved an important role in the evaluation of patients with acute myocardial infarction (MI) and is frequently used for diagnosis, quantitative functional assessment, risk stratification, and detection of complications[424429-432] (see also Chap. 47). Echocardiography is especially valuable in *excluding* transmural infarctions, as these are almost always associated with regional akinesis or dyskinesis (Figs. 13-98, 13-99 and 13-100).[433,434] Non-Q-wave infarctions are more difficult to diagnose with certainty, however, as the echocardiogram may show subtle regional hypokinesis or even normal wall motion in some cases. Thus, echocardiography has been used to evaluate chest pain in the emergency department and appears to have a reasonable sensitivity and specificity in the diagnosis of MI.[433,434] It may also help select patients for thrombolytic therapy.[435] In addition, patients without contractile abnormalities who ultimately exhibit signs of MI have a low incidence of complications.[434]

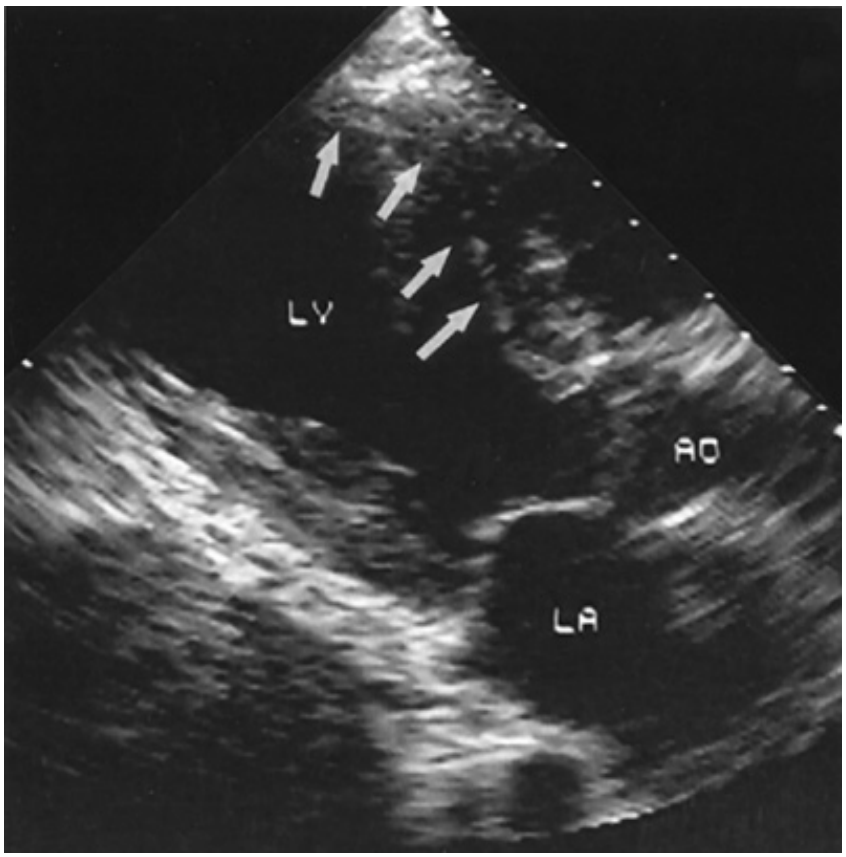

Figure 13-99: Parasternal long-axis view of a large anteroseptal myocardial infarction, with thinning and dyskinesis of the anteroseptal wall (*arrows*). LV = left ventricle; LA = left atrium; AO = aorta.

Echocardiography is now the most commonly utilized approach to assess the effects of MI upon LV function. Ultrasound imaging studies of LV remodeling have demonstrated that infarct expansion occurs commonly with anterior infarctions, often beginning within the first 10 days, and conveys an adverse prognosis.[436,437] Similarly, calculation of the wall motion score has identified a cohort of post-MI patients at markedly increased risk for in-hospital complications.[434] This prognostic marker appears superior to conventional clinical criteria in predicting events.[434]

Echocardiography is probably of greatest value in the assessment of complications associated with acute MI. Most such complications are quickly detected by echocardiography, and the fact that it is portable, rapid, and noninvasive render the technique extremely valuable in these circumstances. As indicated above, severe LV dysfunction resulting in advanced heart failure or shock can be readily identified by echocardiography. In addition, aneurysm formation is usually quite apparent in ultrasonic images.[438] By definition, postinfarction LV aneurysms are recognized as wide-mouthed, thinned-walled myocardial segments that display dyskinetic expansion during systole. Aneurysms are a favored site for development of LV thrombi, which are discussed in detail in the discussion of cardiac masses, below. A less frequent complication is rupture of the LV free wall, which is usually rapidly fatal and therefore rarely imaged by echocardiography.[439] However, the presence of significant pericardial effusion on echocardiography in patients with hemodynamic compromise in the postinfarction period should suggest this condition. If a free wall rupture is sealed off by clot and pericardial inflammation, a pseudoaneurysm is formed[440,441] (Fig. 13-101). This lesion is distinguished from a true aneurysm by its highly localized nature and the presence of a narrow neck connecting it with the ventricle. Pseudoaneurysms frequently have multilayered thrombi within them and exhibit characteristic Doppler flow signals at the junction with the ventricle.[441] Since the risk of rupture is high, accurate diagnosis and prompt surgical repair of pseudoaneurysms is important.

Although postinfarction free wall rupture does not lend itself well to echocardiographic detection, acquired defects of the interventricular septum are more commonly delineated by cardiac ultrasound.[442,443] Acquired ventricular septal defects often consist of a latticework of tissue rather than a discrete orifice, but nevertheless echocardiographic images can depict absence of myocardium and distinct flow jets communicating between the LV and RVs (Fig. 13-102, Plate 68).[444] These color jets are typically high-velocity and aliased, coursing from the septum into the RV. The echocardiographic location of the defect and jet correlate well with the location by cineangiography, surgery, or autopsy, and an apical location is most amenable to surgical correction.[444]

MR is a common sequela of acute MI; if severe, it may result in profound congestive heart failure and shock. Several mechanisms may be responsible for the occurrence of postinfarction MR including dilation of the LV cavity and mitral annulus, papillary muscle dysfunction, and partial or complete rupture of a papillary muscle (Fig. 13-103).[445-447] MR from papillary dysfunction may lead to eccentric color jets within the LA. In general, the recognition and quantitation of MR occurring in the postinfarction period is no different from that of any other type of MR. Acute ischemic MR, however may cause a smaller flow disturbance by color Doppler than comparable grades of chronic MR, particularly with transthoracic imaging. Therefore, TEE may play an important role in the identification and quantitative assessment of this complication, as well as in ensuring adequate operative repair.[447]

In the setting of inferior wall infarction due to occlusion of the proximal right coronary artery, right ventricular MI may occur. The most specific echocardiographic sign of right ventricular infarction is a regional wall motion abnormality, which is usually best visualized in the RV free wall (Fig. 13-104).[448] RV infarction is typically accompanied by RV enlargement and tricuspid regurgitation; associated inferior or posterior left ventricular wall motion abnormalities are virtually always present.

Pericarditis is a common complication of acute MI, typically occurring during the acute phase of the illness and much less often in the late phases as part of Dressler syndrome. Postinfarction pericarditis, however, is not typically associated with marked echocardiographic abnormalities. If a pericardial effusion is present at all, the amount of fluid is usually quite small. Therefore, the absence of pericardial fluid on ECG cannot rule out pericarditis, and the presence of a large effusion with tamponade should raise the suspicion of a LV free wall rupture.

TEE has recently assumed a central role in the evaluation of patients with significant hemodynamic abnormalities in the postinfarction period. When TTE is technically suboptimal, transesophageal images can rapidly identify LV dyssynergy, valvular dysfunction, and other abnormalities associated with infarction. TEE may enable direct visualization of acquired ventricular septal defects when the lesion is not obvious or seen only as a disturbed flow stream in the RV with transthoracic imaging. Perhaps of greatest significance, TEE can provide definitive identification of a ruptured papillary muscle and a quantitative assessment of postinfarction mitral regurgitation.

Echocardiography has been used to evaluate the extent of reperfusion after thrombolytic or interventional therapy for acute MI. Several reports have demonstrated that LV systolic function assessed by 2D imaging improved within 24 h to 10 days of successful thrombolysis.[449,450] More recently, contrast echocardiograms obtained by direct intracoronary injection have shown that reperfusion of the infarct-related epicardial coronary artery by angiography is not necessarily accompanied by evidence of normal flow in the downstream microcirculation. In addition, this "no-reflow" phenomenon on echocardiography heralds a poor prognosis, including failure of improvement of LV performance as well as increased late complications.[208-210,450a]

Stress Echocardiography

Recently, the combination of stress testing and echocardiography (stress echocardiography) has found an important role in the diagnosis of CAD[451-453] (see also Chap. 42). The utility of this technique improved dramatically when technologic advances permitted side-by-side viewing of rest and stress images together in a cine-loop format.[454] The application of stress echocardiography is based upon the concept that a stress-induced imbalance in the myocardial supply/demand ratio will produce regional ischemia and resultant abnormalities of regional contraction, which can be readily identified by echocardiography (Fig. 13-105). The location of wall motion abnormalities may be used to predict the stenosed coronary vessel(s), while the ratio of dyssynergic to normal myocardium can provide a quantitative assessment of LV ischemia.[426,427] Although the digital techniques currently employed limit the number of views available and restrict the examination to eight frames during systole, this process does not seem to impair the ability to identify contractile dysfunction.[455,456]

The types of stress employed fall into two basic groups, exercise and pharmacologic.[426,427] Other forms, such as mental stress and atrial pacing, are not widely used. Exercise testing can be performed either on a treadmill or a stationary bicycle (either upright or supine).[457] Treadmill testing involves a familiar activity, uses equipment that is widely available, and achieves a greater oxygen consumption than bicycle ergometry. Echo imaging usually can be accomplished only before and after treadmill exercise, however, whereas bicycle exertion facilitates the acquisition of images during the exercise protocol. Thus far, treadmill has been the preferred exercise modality. Of importance, all postexertional images should be obtained within a 2-min window following exercise to avoid recording normal contractile function after recovery from ischemia.

Pharmacologic stress has the advantages of reducing the motion artifact of exercise, enabling continuous imaging throughout the protocol, and assessing myocardial viability.[458-469] Pharmacologic stress echocardiography can employ vasodilator agents such as dipyridamole or adenosine, which induce a heterogeneity of myocardial perfusion in ischemic heart disease, or inotropic agents such as dobutamine and arbutamine, which increase myocardial oxygen demand and directly produce ischemia.[458-469] As with exercise stress, diagnostic criteria include induction of regional wall motion abnormalities and LV dilatation. It is important to recognize that the normal response to exercise is hyperkinesis, and wall motion abnormalities may take the form of a lesser degree of hyperkinesis of a given segment in comparison with the rest of the LV myocardium. Dobutamine stress echocardiography appears to be of particular value in detecting

myocardial viability.[455-463,466-469,469a,469b]

The safety and accuracy of stress echocardiography for the diagnosis of myocardial ischemia has been examined in a number of studies.[453,469-472] Both exercise and pharmacologic stress carry an extremely low risk of arrhythmia or infarction, although dobutamine can result in hypotension or *systolic anterior motion of the mitral valve* (SAM) with resultant LV outflow obstruction.[453,473,474] In general, stress echocardiography and nuclear scintigraphy yield similar results, although stress echocardiography may be slightly less sensitive and slightly more specific than scintigraphy.[455,464,475] In a study performed in an institution with high volumes and expertise in both ultrasound and radionuclide stress imaging, the two techniques were found to be comparable in their accuracy of detecting coronary artery disease.[455]

The most common clinical application of stress echocardiography is in the diagnosis of CAD, and it appears especially useful in cases where exercise *electrocardiography* (ECG) may be inaccurate or falsely positive (e.g., abnormal baseline ECG, LV hypertrophy, or chronic digitalis administration).[453,472,476,477] In this regard, stress echocardiography appears especially useful for detection of ischemia in women,[478,478a,478b] in whom stress ECG yields a high incidence of false-positive results. Stress echocardiography also adds independent prognostic information to exercise ECG, even in multivessel CAD.[479] Dobutamine echocardiography may aid in the detection of ischemia in patients with cardiac transplantation and allograft vasculopathy (chronic rejection).[480] In patients with known CAD, exercise echocardiography may facilitate localization and quantitation of ischemia, guide revascularization procedures, and assess the functional severity of coronary artery stenoses.[481] Stress echocardiography can also demonstrate resolution of regional ischemia after successful coronary artery bypass surgery or angioplasty.[482-485]

Stress echocardiography can play an important role in determining the prognosis of patients with CAD.[486-494,494a,494b,494c] Both exercise and pharmacologic stress echocardiography appear superior to exercise ECG for identification of patients at high risk of recurrent ischemic events after MI.[486-491] In addition, dobutamine stress echocardiography is useful in predicting perioperative ischemic complications in patients undergoing noncardiac surgery and appears to have a very strong negative predictive value.[492-494]

In patients with chronic CHD, dobutamine stress echocardiography can identify hypokinetic yet viable myocardium and predicts improvement in function after successful revascularization.[457-463,467,469a,469b,470] Functional improvement in a hypokinetic segment with low-dose dobutamine infusion which then progresses to hypokinesis or akinesis with higher dobutamine dose (the so-called biphasic response) correlates well with the presence of ischemic yet viable ("hibernating") myocardium. Studies have suggested that dobutamine stress echocardiography compares well with positron emission tomography and thallium single-photon emission computed tomography (SPECT) imaging in this regard.[466-468,495-505,501a,501b] It is likely that this application of echocardiography will continue to evolve over time, particularly for pharmacologic stress testing (Chap. 48).

There is evidence that exercise echocardiography can provide useful information regarding the hemodynamic status and functional severity of valvular heart disease.[502-505] Specifically, stress echocardiography has been used to assess the degree of obstruction in patients with MS[503] and to quantitate the severity of AS in patients with advanced LV dysfunction.[505] These data may help guide the timing of surgical valve repair or replacement.

As is true of all diagnostic modalities, stress echocardiography has certain limitations. High-quality ultrasound images may be difficult to acquire in some patients-a situation that may be exacerbated by exertion and the time constraints inherent to exercise stress testing. In addition, considerable expertise is required to interpret stress echocardiographic images accurately, and this

learning curve precludes the use of stress echocardiography by all but experienced echocardiographers. Nevertheless, stress echocardiography has many advantages over alternate diagnostic approaches such as radionuclide scintigraphy and coronary angiography, including its noninvasive and relatively inexpensive nature, rapid acquisition and interpretation times, and freedom from ionizing radiation. Harmonic imaging (both with and without intravenous echocardiographic contrast) has also enhanced endocardial border definition, facilitating stress echo studies in many patients with suboptimal fundamental (nonharmonic) echo images.Therefore it is anticipated that the use of stress echocardiography will continue to increase in the foreseeable future.

Chapter 13: THE ECHOCARDIOGRAM

THE CARDIOMYOPATHIES

The evaluation of cardiomyopathy is complicated by the fact that few specific diagnostic criteria exist, and identification is often a process of exclusion. Further, many potential etiologies may be responsible for the myopathic process, and it may be possible to identify a specific etiology in only the minority of patients. Accordingly, a diagnostic strategy has evolved that initially seeks to place patients into one of three pathophysiologic categories: dilated, hypertrophic, or restrictive; then, the specific etiologies recognized as producing the individual pathophysiologic state are pursued.[506] Thus, dilated cardiomyopathies are associated with myocyte loss and necrosis, a marked increase in LV volume, thinning of the myocardium, and profound systolic dysfunction.[507] *Hypertrophic cardiomyopathy* (HCM) is recognized by increased myocardial thickness, particularly involving the interventricular septum, with preserved systolic function.[508] Restrictive cardiomyopathies may be due to infiltration of the myocardium by abnormal substances or fibrotic tissue; these cause symmetrical degrees of wall thickening with modest or no diminution of systolic function and little change in cavity size.[509] Echocardiography customarily serves as the cornerstone of such evaluations and provides data on cavity size, wall thickness, and systolic function. Thus, on echocardiogram, patients with dilated cardiomyopathy exhibit a marked increase in left LV and volume, little change in wall thickness, and severe contractile dysfunction.[507] Patients with HCM exhibit a dramatic increase in LV wall thickness, with the septum characteristically disproportionate to the posterior wall, and often subaortic stenosis induced by systolic anterior motion of the anterior mitral valve leaflet. Patients with restrictive cardiomyopathy are identified by a symmetrical increase in wall thickness accompanied by modest changes in contractile function and LV cavity size.[509]

Hypertrophic Cardiomyopathy

HCM is a primary abnormality of the myocardium that exhibits myocyte disarray and unprovoked hypertrophy, often affecting the septum disproportionately[508] (see also Chap. 74). The disorder, which is often transmitted in an autosomal dominant pattern, has been linked to a number of abnormalities in genes that code for myocardial proteins.[510,511] A number of classic echocardiographic findings occur in HCM (Fig. 13-106). The fundamental abnormality on echocardiogram in HCM is LV hypertrophy, which is often severe. Although the hypertrophy may be confined to the septum, it may be concentric or involve any other portion of the LV.[512] The customary classic finding is *asymmetrical septal hypertrophy* (ASH), defined as a disproportionate thickness of the interventricular septum compared to the posterobasal wall with a ratio of greater than 1.3 to 1.[513,514] In some cases the entire septum is hypertrophied, while in others the thickening may be localized to the proximal, mid-, or distal (apical) septum.[515] Asymmetric hypertrophy of the proximal interventricular septum may lead to dynamic LV outflow tract obstruction-*hypertrophic obstructive cardiomyopathy* (HOCM) or *idiopathic hypertrophic subaortic stenosis* (IHSS). Although ASH is almost always present in cases of dynamic LV outflow tract obstruction, it is not a specific marker for HCM and may occur in some patients with RV hypertrophy, inferior MI, and a minority with hypertensive LV hypertrophy.[516] In general, the more extensive the hypertrophic process, the more severe the symptoms. Extent of hypertrophy, however, does not appear to correlate well with risk of sudden death, as patients with minimal hypertrophy may still be at significant risk.[517]

The second characteristic finding of HCM is systolic anterior motion of the mitral valve, or SAM,

which usually involves the anterior mitral valve leaflet. Posterior-leaflet SAM also has been reported in HCM, as have a variety of mitral valve deformities.[518,519] Encroachment of the pathologically thickened septum upon the LV outflow tract creates a pressure drop by a Venturi effect, which draws the mitral leaflets toward the septum, creating dynamic (subaortic) LV outflow obstruction (Fig. 13-106). Recent work has also demonstrated the important effects of papillary muscle position and chordal tension on systolic mitral morphology and SAM.[520] Because of distorted mitral coaptation during systole, SAM generally causes MR of variable severity. The severity and duration of SAM directly influence the degree of both outflow tract obstruction and mitral regurgitation.[521] Like asymmetrical septal hypertrophy, SAM (especially systolic motion of the chordae) is not pathognomonic for HCM, having been reported in other conditions such as hypovolemia, anemia, and states where LV outflow tract narrowing and hyperdynamic contraction are present.[522,523]

The third manifestation of classic HCM is midsystolic closure of the aortic valve.[524] This finding is best seen on M-mode recordings, occurs only in the presence of outflow tract obstruction, and is probably a manifestation of the sudden pressure drop during mid- and late systole caused by SAM. As with ASH and SAM, midsystolic aortic closure is not specific for HCM and can occur in MR, aortic root dilatation, ventricular septal defect, and discrete subaortic stenosis.[525,526] When HCM is present, however, midsystolic aortic valve closure suggests significant outflow tract obstruction.

The fourth important abnormality of HCM is observed on Doppler examination of the LV outflow tract (LVOT). Normally, Doppler interrogation of this area produces a spectral tracing that peaks early in systole and has a maximum velocity of less than 1.7 m/s. In many patients, HCM creates a high-pressure gradient coincident with SAM, which is detected by Doppler as a high-velocity systolic jet in the LVOT. As opposed to valvular aortic stenosis, however, the maximal velocity in obstructive HCM peaks late in systole, creating a characteristic "saber-tooth" pattern (Fig. 13-107).[527-530] Although the subaortic gradient can be estimated using the modified Bernoulli equation,[529,530] the assumptions used in this equation may not apply to HCM, as intraventricular gradient calculations can be spuriously high because of the phenomenon of pressure recovery.[531] Similar Doppler patterns also may be seen occasionally within the LV in patients with HCM if systolic obliteration of the hypertrophied LV causes localized areas of high flow velocity in the more distal portions of the ventricular cavity.[527]

Diastolic dysfunction has been long recognized in HCM. Doppler interrogation of LV inflow often reveals a relaxation abnormality, with a reduced early diastolic (E) velocity, a prolonged deceleration slope of the E wave, and an increased velocity of the atrial systolic (A) component.[532,533] Color Doppler imaging can be used to demonstrate intraventricular flow characteristics.[534]

Dilated Cardiomyopathy

In cases of *dilated cardiomyopathy* (DCM), the heart is typically greatly enlarged and systolic function is markedly depressed (see also Chap. 66).[535] Four-chamber dilatation is a common but not uniform finding, as some patients may have relatively preserved RV size (this may confer an improved prognosis).[536] Marked LV enlargement and generalized dysfunction can also be caused by severe ischemic heart disease, chronic alcohol abuse, various infectious myocarditides, anthracyclines and other cardiotoxic agents, nutritional deficiencies, and hereditary myopathies.[537,538] Severe ischemic disease is often segmental and has been reported to spare the posterior wall frequently,[539] while the LV dysfunction of DCM is usually global. The typical constellation of echocardiographic findings in DCM include an increased LV end-diastolic diameter and volume with decreased fractional shortening, thinning of the LV walls (Fig. 13-108), increased E point-septal separation, LA enlargement, and limited mitral and aortic valve opening

(due to low stroke volume).[535,540] Intracardiac thrombi are frequently observed and are most often found in the LV apex.[540] M-mode imaging of the mitral leaflets may demonstrate a "B bump," or notch just before systolic valve closure, indicating elevated LV diastolic pressure (Fig. 13-8). The cardiac valves are usually normal, but mitral annular dilatation and secondary MR are common.

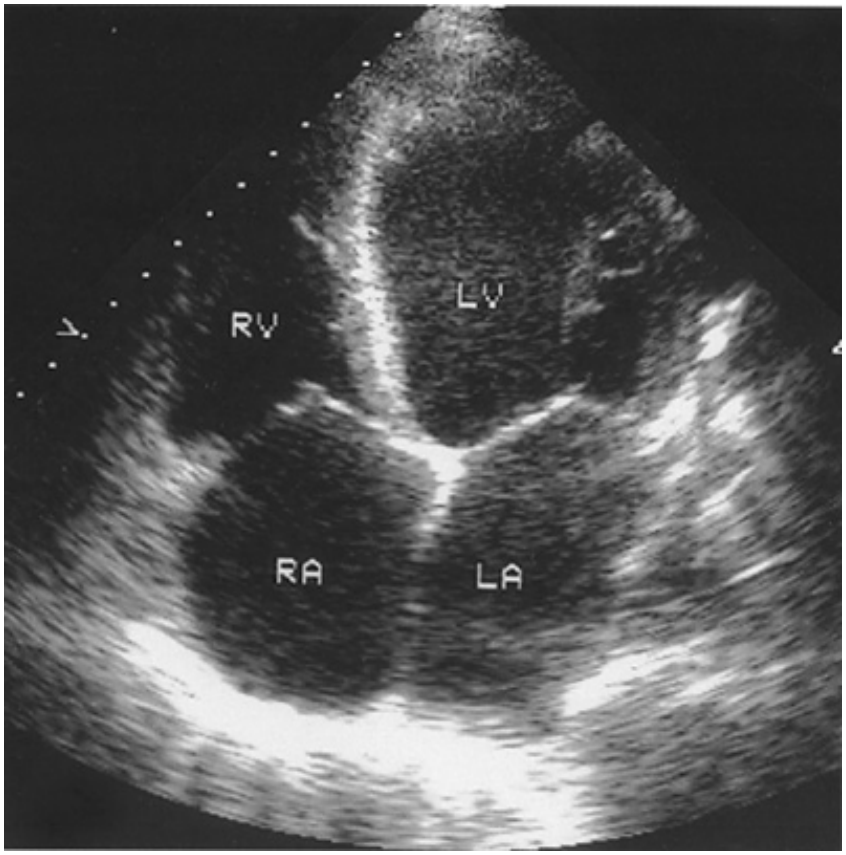

Figure 13-108: Apical four-chamber image of dilated cardiomyopathy. There is four-chamber enlargement as well as left ventricular (LV) spontaneous echo contrast. RV = right ventricle; RA = right atrium; LA = left atrium.

Doppler echocardiography often reveals an abnormally low-velocity time integral in the LV outflow or inflow tracts.[541] Diastolic MR due to elevated LV diastolic pressure also may be present. Diastolic dysfunction is common, and pulsed-wave Doppler interrogation of mitral inflow may show an abnormal relaxation, restrictive, or pseudonormal pattern depending on LV diastolic pressures and loading conditions.[541,541a] A restrictive pattern of mitral inflow Doppler confers a poor prognosis in patients with DCM.[542,543]

Restrictive Cardiomyopathy

Restrictive cardiomyopathy may be idiopathic or secondary to infiltrative diseases such as amyloidosis, hemochromatosis, hypereosinophilic syndrome and Loeffler endocarditis, sarcoidosis, radiation toxicity, glycogen storage diseases, and Gaucher disease[544] (see also Chap. 75). Typical 2D echocardiographic features of these diseases include (1) a diffuse increase of ventricular thickness in the absence of marked ventricular chamber dilation and (2) marked biatrial enlargement[509,545-549] (Fig. 13-109). Systolic function is often modestly decreased. As with the other cardiomyopathies, these echocardiographic findings are nonspecific. Doppler

examination may show a mitral inflow relaxation abnormality early in the course of restrictive cardiomyopathy, but restrictive pattern (E much greater than A, with shortened E deceleration time) is a more classic finding, which often evolves with time and indicates both a high LA pressure and poor prognosis.[550]

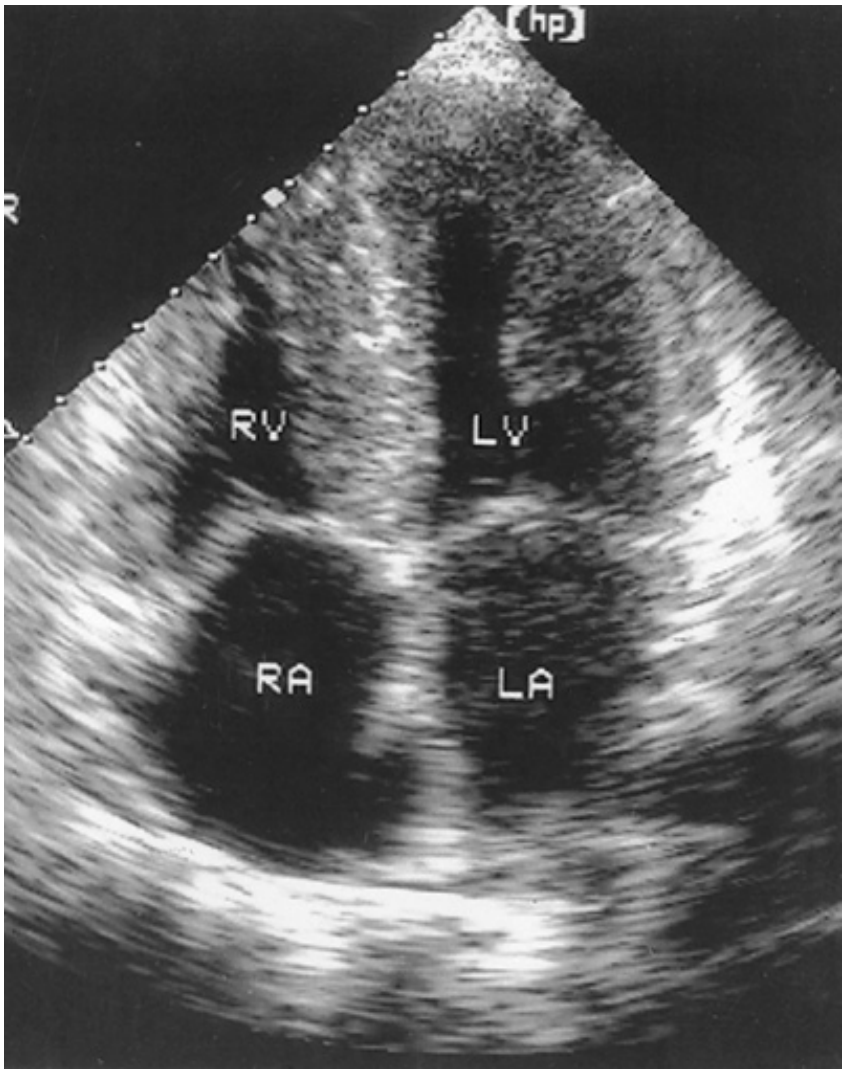

Figure 13-109: Apical four-chamber image of cardiac amyloid. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle.

Amyloidosis is generally the most commonly encountered restrictive cardiac disease. In addition to biventricular hypertrophy, amyloidosis is also associated with diffuse thickening of the interatrial septum and cardiac valves.[549] In advanced disease, depressed systolic function is also common. An abnormal "speckled" pattern or "ground-glass" appearance of the myocardium has been described on 2D echocardiography, but this sign is absent in many cases and therefore has minimal clinical usefulness.[547,549] The finding of a restrictive mitral inflow pattern (and an abnormally high diastolic component of pulmonary vein inflow) on Doppler echocardiography has been identified as a marker of advanced disease and poor prognosis.[551,552] In addition to increased myocardial thickness, endocardial thickening and fibrosis and restricted atrioventricular leaflet motion are common features of Loeffler endocarditis and endomyocardial fibroelastosis.[548] Intraventricular thrombi are also common in these processes.[553]

Chapter 13: THE ECHOCARDIOGRAM

CONGENITAL HEART DISEASE

Echocardiographic Identification of Congenital Cardiac Anomalies

2D and Doppler echocardiography has had a major impact on the diagnosis and management of patients with congenital heart disease (see also Chaps. 63 and 64). From isolated congenital lesions to complex, extensive cardiac malformations, echocardiographic imaging (often with intravenous contrast injection) is usually sufficient to delineate cardiac anatomy. TEE is an important adjunctive technique as well[554]; in many cases, a thorough echocardiographic evaluation may obviate the need for cardiac catheterization and angiography.[555-557]

The ultrasound diagnosis of a simple intracardiac shunt is usually straightforward, but the task of defining complex congenital cardiac abnormalities can be daunting. In these cases, it is useful to remember a few basic anatomic rules. The venae cavae and pulmonary veins generally empty into the morphologic right atrium and LA, respectively. The atrioventricular valves uniformly follow their ventricles through embryologic development: a tricuspid valve accompanies the morphologic right ventricle and a mitral valve accompanies the left. Similarly, the semilunar valves follow the great vessels. The aorta and pulmonary artery can be distinguished, regardless of their position, by the bifurcation of the pulmonary artery.

Several features aid identification of the morphologic right and left ventricles. The right ventricle has a tricuspid atrioventricular valve; in comparison with the mitral annulus, the tricuspid annulus is positioned slightly closer to the cardiac apex.[558] The right ventricle also has a moderator band, coarser trabeculations than those in the left ventricle, and an infundibulum that separates the inlet area from the right ventricular outflow tract.

Cardiovascular Shunts

ATRIAL SEPTAL DEFECT

Most secundum and primum *atrial septal defects* (ASD) are easily visualized by echocardiography, although sinus venous defects are often difficult to detect without TEE.[559,560] Apical echocardiographic views often show artifactual "dropout" in the region of the fossa ovalis, since the interatrial septum is thin in this area and runs parallel to the ultrasound beam. Therefore, the subcostal view provides the optimal imaging plane to detect lesions of the atrial septum.[561] Ostium secundum defects are the most common form of ASD, and 2D imaging shows a localized absence of septal tissue in the midportion of the interatrial septum (Fig. 13-110*A*, Plate 69). Lack of any interatrial septal tissue between the defect and the base of the interventricular septum characterizes an ostium primum defect (Figure 13-110*B*). Although ostium secundum defects are usually isolated, ostium primum (or partial AV canal) defects are often accompanied by other lesions, such as cleft anterior mitral valve leaflet, MR, and atrioventricular canal ventricular septal defect.[562] Sinus venosus defects are strongly associated with partial anomalous pulmonary venous return (for example, drainage of the right upper pulmonary vein into the right atrium or superior vena cava) (Fig. 13-111). Rarely, the atrial septum may be completely absent (Fig. 13-112). With all but small ASDs, the right atrium is enlarged and RV volume overload is present, with a dilated RV and paradoxical septal motion.[563]

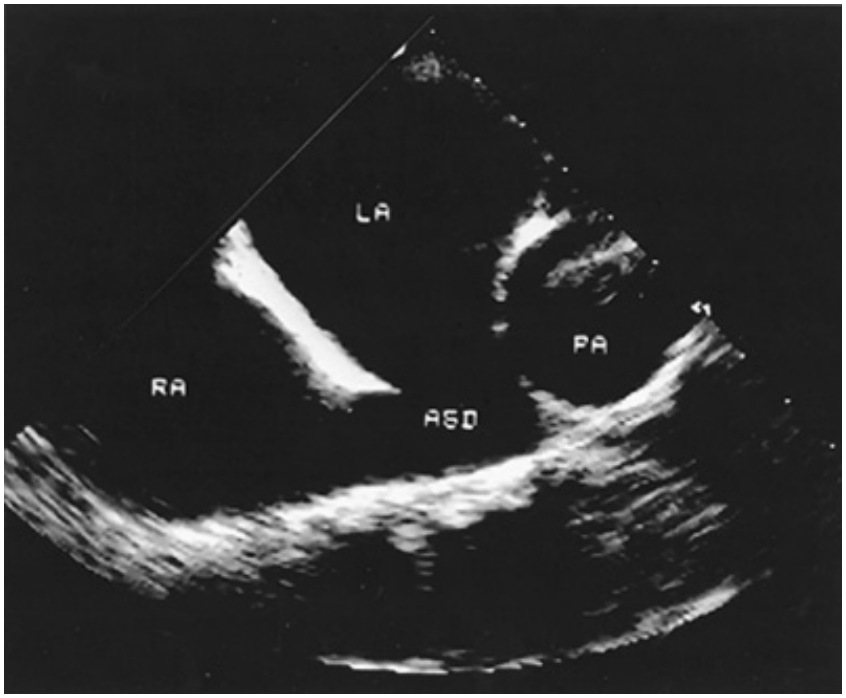

Figure 13-111: Transesophageal image of a sinus venosus atrial septal defect (ASD) (longitudinal plane). The defect is present in the superior portion of the interatrial septum. RA = right atrium; LA = left atrium; ASD = atrial septal defect; PA = pulmonary artery.

Intravenous contrast injection generally demonstrates shunting across the ASD, frequently with bidirectional flow.[564] Therefore, "negative jets" of unopacified flow from the left atrium into the contrast-filled right atrium may alternate with the appearance of contrast bubbles flowing through the defect into the LA. When an ASD is present, contrast should appear quickly (within three to five heartbeats) in the LA after entering the right atrium. Delayed appearance of contrast in the LA may indicate an intrapulmonary shunt rather than an ASD.

Color Doppler imaging is also useful for detecting flow through ASDs (Fig. 13-110*A*, Plate 69), although the pressure drop between atria often does not produce turbulence. Inflow from the inferior vena cava and right-sided pulmonary veins may be prominent in normals and can be misinterpreted as a shunt.[565,566] Pulsed-wave Doppler recordings usually reveal continuous flow, which peaks in late systole. Pulmonary-to-systemic flow ratios can be estimated in ASD (and ventricular septal defects) by comparing volumetric flow measurements through the LV and RV outflow tracts. Such calculations are only moderately accurate in adults.[567,568]

VENTRICULAR SEPTAL DEFECT

Ventricular septal defects (VSDs) may be classified as perimembranous, inlet, outlet, or trabecular. Echocardiography is quite useful for the detection and classification of VSDs.[569-571] The defect itself is sometimes visible with 2D imaging alone (Fig. 13-113*A*), but smaller VSDs are easily missed. Complete absence of the interventricular septum (single ventricle) is quite rare (Fig. 13-113*B*). Pulsed- or continuous-wave Doppler interrogation often reveals discrete areas of high-velocity flow across the interventricular septum. Measurement of the peak CW velocity through the shunt allows calculation of the interventricular pressure gradient (via the modified Bernoulli equation); subtraction of this gradient from the systolic blood pressure (in the absence of aortic valve disease) approximates the RV systolic pressure.

Overall, color-flow imaging is the most useful Doppler technique for the diagnosis of VSDs.[571] Typically, a high-velocity systolic color jet is seen traversing the interventricular septum, although the velocity is lower with large defects and in the presence of pulmonary hypertension (Fig. 13-114, Plate 70). The appearance of the color jet in the standard imaging planes can be used to determine the type of VSD. Intravenous contrast injection may reveal a negative contrast jet in the right ventricle, and contrast may cross the defect and partially opacify the left ventricle. In the absence of MR, contrast will not enter the left atrium, distinguishing an isolated VSD from an ASD. Doppler echocardiography can also be used to detect abnormalities associated with VSDs, such as ventricular septal aneurysm, MR and TR, ASD (especially with inlet VSDs), aortic insufficiency-with outlet (supracristal) VSDs-and "straddling" of the defect by the mitral or tricuspid valve.[572,573] Accurate detection of such lesions is especially critical before surgical intervention.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus originates just to the left of the PA bifurcation and inserts into the aorta slightly distal to and opposite from the ostium of the left subclavian artery. Given this posterior location, it is difficult to image a *patent ductus arteriosus* (PDA) itself with 2D TTE alone, and TEE is usually superior for direct visualization of the lesion[574] (Fig. 13-115*A* and *B*, Plate 71). In most cases, 2D imaging of the communication is not essential, as color-flow Doppler reliably detects high-velocity diastolic flow within the PA in nearly all non-Eisenmenger patients.[575-577] The flow jet characteristically enters the distal left region of the main PA and streams anterior along the medial wall of the vessel (Fig. 13-115*B*, Plate 42*B*). With large shunts, volume overload and subsequent dilation of the left ventricle occurs. Aortopulmonary window is a much rarer shunt involving the great vessels which presents as a communication anteriorly between the ascending aorta and proximal PA.[578,579] It is embryologically distinct from a PDA and more closely related to a truncus arteriosus defect.

Venous Inflow Abnormalities

Anomalous pulmonary venous return (APVR) may be partial or total. Partial APVR is present in 80 percent of sinus venosus ASD cases and is a feature of the Scimitar syndrome.[580,581] The usual finding on TTE is RV volume overload. TEE is quite useful in detecting these abnormal venous connections. In total APVR, the pulmonary veins may empty directly into the right atrium or into a common posterior chamber or vein. This structure and its connection with the right atrium may be visualized echocardiographically, along with the obligatory ASD.[582-585] In some cases, the collecting chamber posterior to the left atrium may mimic the appearance of *cor triatriatum*, an entity characterized by a membrane in the posterior left atrium which may obstruct pulmonary venous inflow, causing symptoms similar to those of mitral stenosis[586] (Fig. 13-116).

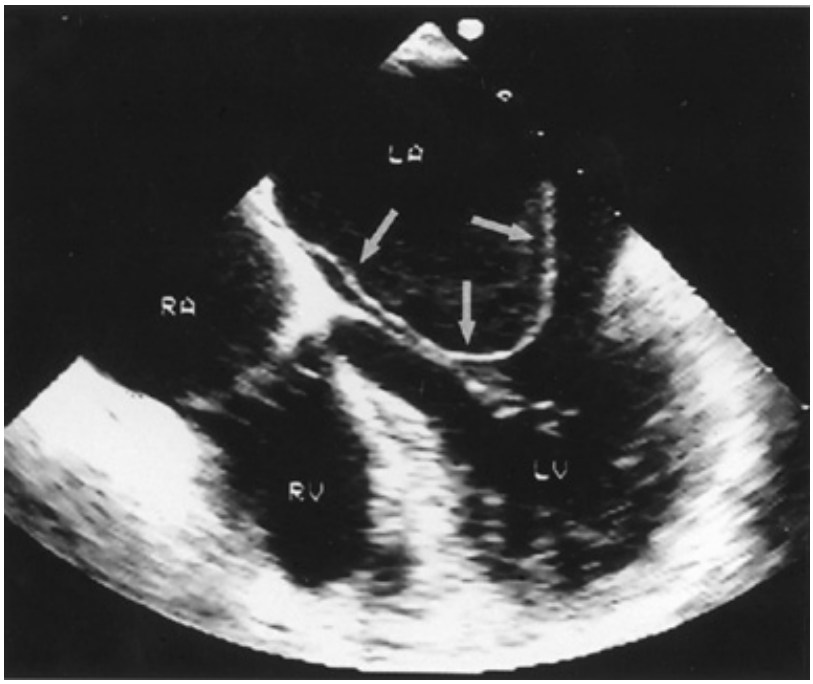

Figure 13-116: Transverse transesophageal image of cor triatriatum. A membrane (*arrows*) is present in the left atrium. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Persistent left superior vena cava occurs in 0.5 percent of the normal population.[587,588] In most cases, the anomalous vein empties into the coronary sinus, which then drains into the right atrium (Fig. 13-117). Unless the coronary sinus is unroofed and drains into the left atrium, no shunting occurs. The typical echocardiographic finding is a large coronary sinus, which is especially well seen on transesophageal or parasternal transthoracic views. The diagnosis may be confirmed by intravenous contrast injection from the left arm, as this will opacify the coronary sinus shortly before filling the right atrium.[587,588]

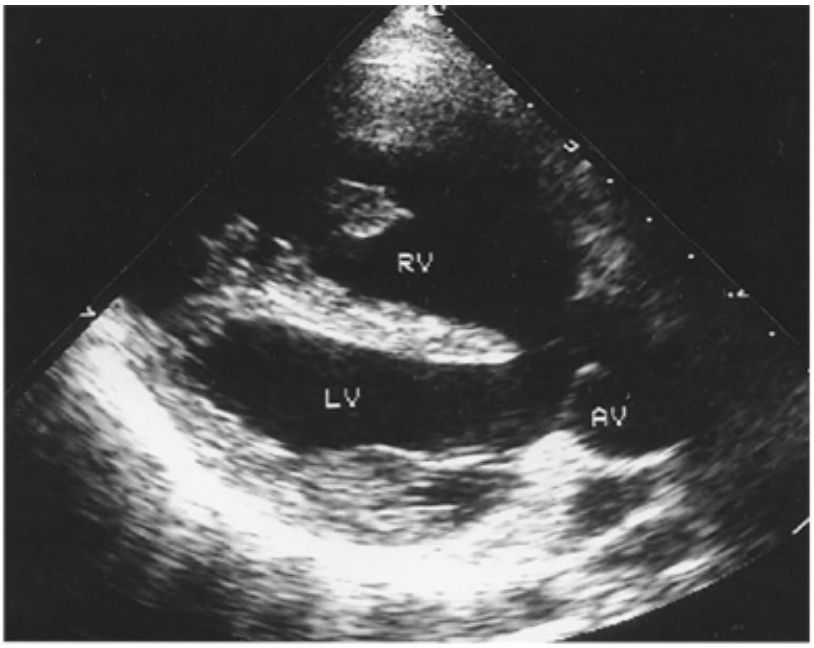
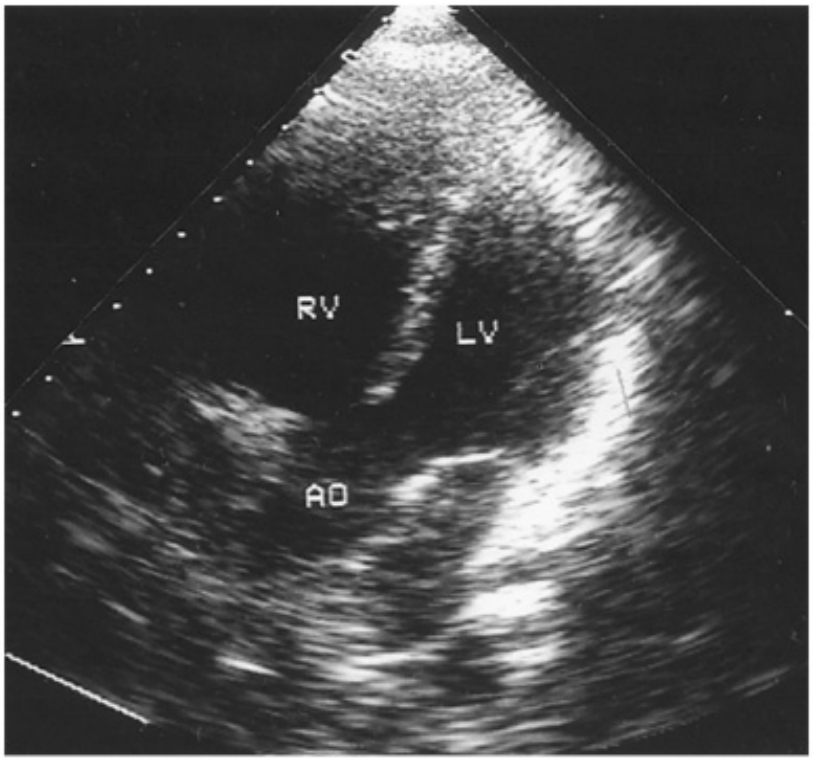
Figure 13-117: *A.* Transesophageal image (transverse plane) from a patient with persistent left superior vena cava. The coronary sinus (CS) is dilated. *B.* After injection of agitated saline into the left antecubital vein, contrast is seen entering the right atrium (RA) via the CS. TV = tricuspid valve; RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Conotruncal and Aortic Abnormalities

Tetralogy of Fallot is one of the more common conotruncal abnormalities, and affected individuals may sometimes survive to adulthood without surgical intervention. The classic echocardiographic features include a large perimembranous VSD, an anteriorly displaced aorta which overrides the VSD, RV enlargement and dysfunction, and pulmonic stenosis (either infundibular, valvular, or suprevalvular) (Fig. 13-118).[589,590] The VSD and aorta are well visualized in the parasternal long-axis view, while the RV outflow tract and proximal PA are best seen in the parasternal short-axis view at the base of the heart. Doppler interrogation can provide evaluation of the severity of pulmonic stenosis, both before and after surgery. Echocardiography may aid detection of infants with tetralogy who will require early surgical intervention as well as patients who are at high risk for sudden death after surgical repair.[591,592]



A



B

B

Figure 13-118: Parasternal long-axis (*A*) and apical four-chamber (*B*) images of tetralogy of Fallot. The right ventricle (RV) is enlarged, and a large VSD is present. The aorta (AO) overrides the interventricular septum. LV = left ventricle. (Courtesy of Reinaldo W. Beyer, MD.)

Although *double-outlet right ventricle* (DORV) shares several clinical characteristics with tetralogy of Fallot (VSD and anterior aortic displacement are invariably present, and pulmonic valvular stenosis and ASD are common in both), it is morphologically distinct (Fig. 13-119). Normal continuity of the posterior aortic wall with the anterior mitral valve leaflet (always present in tetralogy of Fallot) is absent in DORV, and an interposed mass of fibrous tissue between the left atrium and the nearest great vessel is seen on 2D imaging.[593,594] In addition, the great vessels may be transposed in DORV, resulting in a characteristic side-by-side appearance of the aorta and PA on parasternal short-axis images.[595]

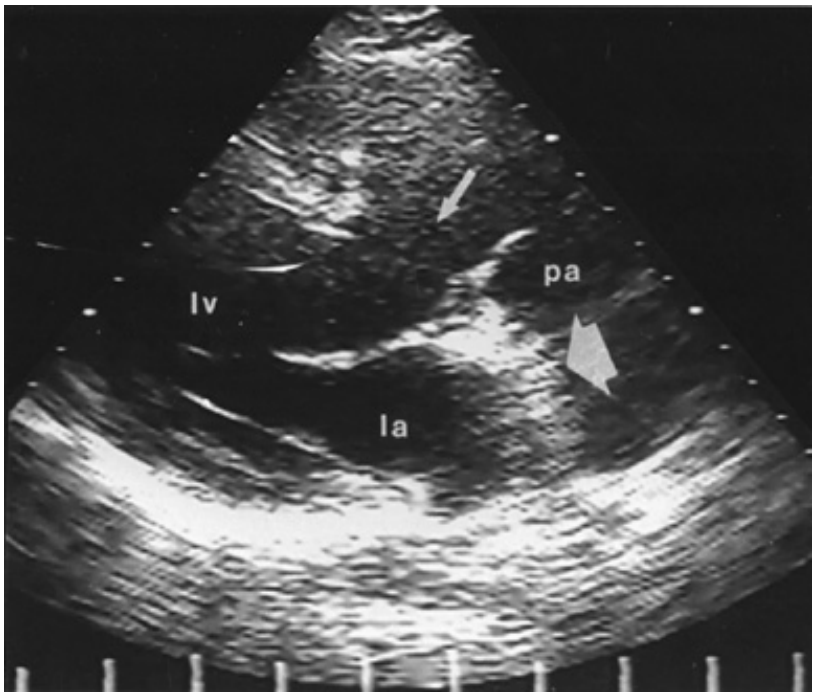


Figure 13-119: Parasternal long-axis image of double-outlet right ventricle. A large VSD is present (*small arrow*) and the normal continuity between the posterior aortic wall and the anterior mitral leaflet is absent. Fibrous tissue is seen (*large arrow*) between the left atrium (LA) and the nearest great vessel (in this case, the pulmonary artery (PA). LV = left ventricle.

Echocardiography has become a valuable tool for detection, management, and postoperative follow-up of patients with *transposition of the great arteries.* Attention to the anatomic rules mentioned earlier is essential for accurate diagnosis of both D (classic) and L ("congenitally corrected") transposition. In D-transposition, the aorta arises from the RV, the PA arises from the LV, and one or more obligatory shunts are present. With L-transposition, the morphologic right and left ventricles are switched, and associated anomalies such as VSD and pulmonic stenosis are common. In both types of transposition, the normal echocardiographic orientation of the great vessels on parasternal short-axis images (a sausage-shaped RVOT and PA draped over a circular aorta) is no longer present, and the two great vessels are typically side by side and parallel (Fig. 13-120).[596,597] In general, the aorta is anterior and to the right of the PA in D-transposition and anterior and to the left in L-transposition. Both TTE and TEE are an important part of continuing

care after surgical repair or palliation of transposition; they can detect valvular regurgitation, outflow tract narrowing, and stenosis of the atrial baffle systems used to palliate D-transposition surgically.[598-600]

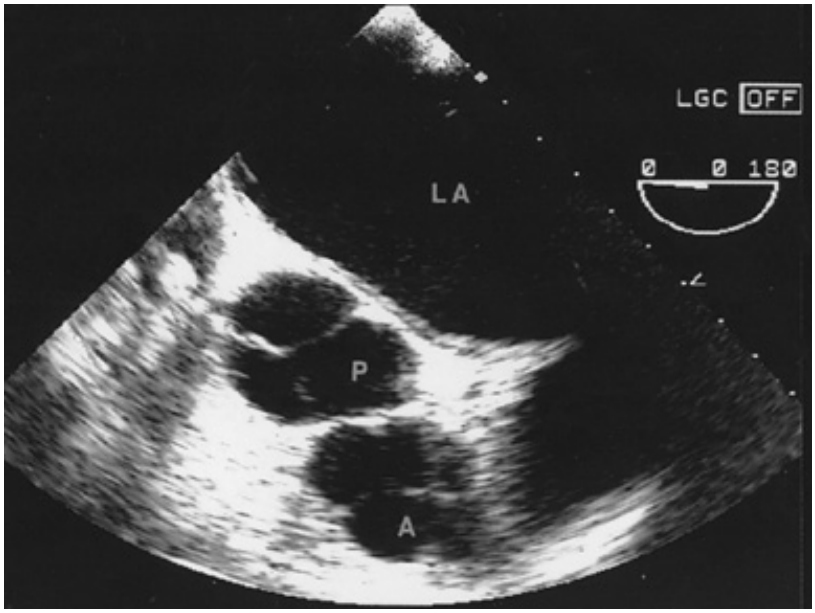

Figure 13-120: Transverse transesophageal image through the semilunar valves in L-transposition. The aortic valve (A) is anterior and to the left of the pulmonic valve (P). LA = left atrium.

Truncus arteriosus is a rare anomaly characterized by a large VSD, a single semilunar valve, and a single great vessel that divides into the ascending aorta and PA.[601,602] Ultrasound imaging can determine the anatomy of the great vessels and assist in defining the various subsets of truncus arteriosus.

Coarctation of the aorta is associated with a bicuspid aortic valve and is best visualized from the suprasternal position. 2D imaging may identify the site of coarctation, but the natural mild curving of the descending aorta can occasionally lead to a false-positive diagnosis. Clear visualization of narrowing in the proximal descending aorta with poststenotic dilatation, however, is pathognomonic of coarctation.[603,604] Doppler interrogation from the suprasternal notch demonstrates increased systolic velocity in the descending aorta and may also reveal a persistent flow gradient throughout diastole in cases of severe coarctation (Fig. 13-121).[605] Color imaging often displays flow acceleration and aliasing proximal to the site of coarctation. The maximum velocity through the coarctation can be used to estimate the pressure gradient, and this measurement can be particularly valuable for the detection of restenosis after surgical repair or percutaneous balloon aortic dilatation.[606,607]

Supravalvular aortic stenosis, either isolated or associated with Williams syndrome (Chap. 10), is generally imaged best from the suprasternal and superior parasternal positions. Echocardiography reveals either an hourglass-shaped stenosis of the aorta above the sinuses of Valsalva, diffuse hypoplasia of the ascending aorta, or a focal fibrous ridge at the sinotubular junction.[608] Doppler imaging can help estimate the gradient across the stenosis, and marked aliasing of color-flow imaging in the ascending aorta should raise suspicion of the diagnosis. Thickening of the aortic valve leaflets and stenoses of the coronary ostia are important associated findings that may be detectable by echocardiography.

Ventricular Outflow Tract and Semilunar Valve Abnormalities

RIGHT VENTRICLE

Infundibular stenosis is rare outside the setting of tetralogy of Fallot and is much less common than valvular PS. On 2D imaging, muscular hypertrophy is often visualized proximal to the pulmonary artery, while Doppler interrogation reveals increased flow velocities through the infundibulum.[609] PS is reasonably common and may be either isolated or associated with other congenital lesions (such as VSD, transposition, and tetralogy of Fallot). Typical echocardiographic features include thickening of the leaflets, restricted leaflet motion, systolic doming of the valve, and elevated systolic flow velocity on Doppler[610] (Fig. 13-85). As with other stenotic lesions, the gradient can be estimated using the modified Bernoulli equation. The pulmonic valve is best visualized in the parasternal short-axis view through the base (or a modified parasternal view of the RVOT). In children, the subcostal position frequently provides excellent visualization of the RVOT and pulmonic valve. When TTE is suboptimal, TEE can provide detailed images of the pulmonic valve. In pulmonic stenosis, the valve leaflets may calcify over time, and poststenotic dilatation of the pulmonary artery is often present.

LEFT VENTRICLE

Subvalvular obstruction may be dynamic or fixed. *Hypertrophic cardiomyopathy*, which may present at any age, is discussed earlier in this chapter. Discrete *subaortic stenosis* may be caused by a thin membrane in the LV outflow tract, a fibromuscular ridge, or diffuse muscular narrowing of the outflow tract (Figs. 13-122*A* and *B*, Plate 72).[611] 2D echocardiographic imaging can distinguish these various forms of discrete subvalvular stenosis, and Doppler analysis permits estimation of the systolic gradient.[612] Color-flow imaging demonstrates increased turbulence in the LVOT as well as aortic valvular regurgitation in about 50 percent of cases. Apical views are sometimes more useful for detecting thin subaortic membranes, as these structures are parallel to the ultrasound beam on parasternal images (Fig. 13-122). Subaortic fibromuscular ridges are sometimes associated with anomalous mitral valve chordae connecting the papillary muscles or the anterior mitral valve leaflet to the septum.[613,614] M-mode imaging may reveal midsystolic partial closure of the aortic valve, differentiating subvalvular from valvular AS.

Bicuspid aortic valve is the most common congenital cardiac lesion in adults and is present in 1 to 2 percent of all individuals (men are affected more often than women).[615,616] Initially, eccentric diastolic coaptation of the aortic cusps was reported on M-mode in patients with bicuspid valves. However, M-mode findings are less accurate than 2D imaging, and the parasternal short-axis view is generally best for defining the fish-mouthed systolic aortic valvular anatomy (Figs. 13-60 and 13-61). Bicuspid valves are sometimes easy to detect in diastole as well, but raphes and remnants of commissures may obscure the diagnosis and mimic a trileaflet valve. In general, asymmetry of the aortic leaflets suggests congenital deformation. In equivocal cases, multiplane TEE is usually diagnostic (Fig. 13-61).

Ventricular Inflow Tract Abnormalities

Ebstein's anomaly is a congenital deformity of the tricuspid valve in which the leaflets are displaced into the right ventricle. Associated findings include TR, right atrial enlargement, and ASD.[617,618] 2D imaging typically shows abnormal apical displacement of the septal leaflet insertion, with variable deformity of the leaflet (Fig. 13-123). The anterior leaflet originates from the tricuspid annulus but is elongated and often tethered to the RV free wall by abnormal chordal attachments. The tricuspid deformity and regurgitation are best visualized in the apical four-chamber view, although the subcostal and modified parasternal views also may be helpful.

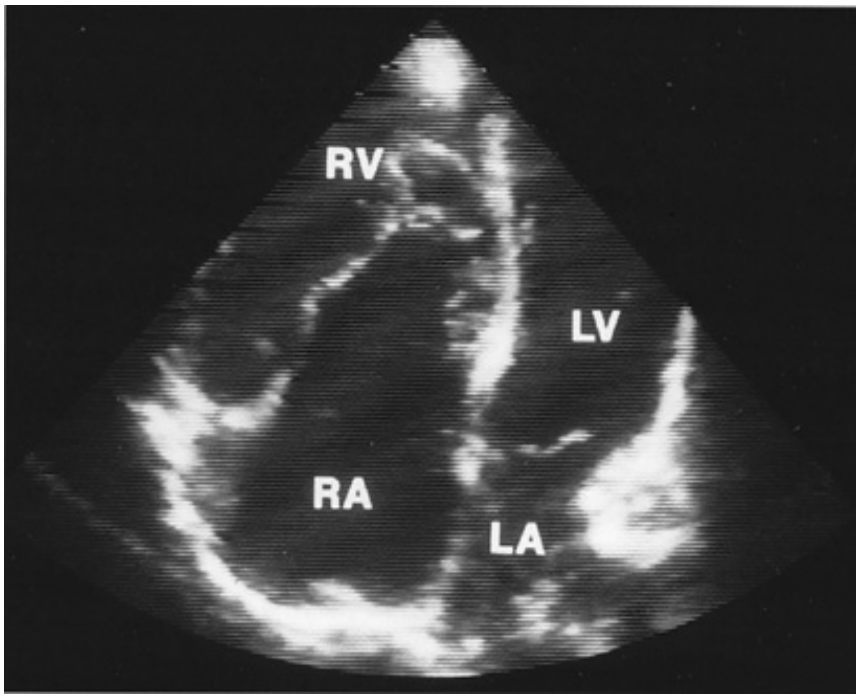

Figure 13-123: Apical four-chamber image of Ebstein's anomaly. The right heart is enlarged, and the insertion of the septal leaflet of the tricuspid valve is displaced apically. The anterior tricuspid leaflet (to the patient's right) is abnormally elongated. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle. (Reproduced with permission of Joseph A. Kisslo, MD.)

Atrioventricular valvular atresia is usually accompanied by hypoplasia of the corresponding ventricle. Echocardiographic images of tricuspid atresia characteristically show a small, nonfunctional right ventricle, an interatrial communication of variable size, and a normally developed left ventricle. Associated lesions include VSD, transposition, and RV outflow obstruction. Echocardiography is an important tool in the management of patients with tricuspid atresia after palliation with the Fontan procedure. Mitral atresia is associated with a hypoplastic LV. Additional rare congenital mitral anomalies imaged by echocardiography include parachute mitral valve and congenital MS.

Fetal Echocardiography

The average risk for significant heart disease in the fetus is approximately 0.4 to 0.8 percent. Fetal echocardiography has evolved over the past 14 years into a sophisticated method for intrauterine detection of cardiac abnormalities[619] (Fig. 13-124). The technique has been advocated for the preterm diagnosis of congenital heart disease, especially in higher-risk cases [for example, maternal congenital heart disease or diabetes mellitus, maternal teratogen exposure or *t*oxoplasmosis, *o*ther intrauterine infections, *r*ubella, *c*ytomegalovirus, and *h*erpes virus (TORCH) infection, and familial syndromes that may affect the heart].[620] Fetal echocardiography has successfully identified a variety of congenital lesions including atrial and ventricular septal defect, pulmonic stenosis, transposition, tetralogy of Fallot, hypoplastic left heart, Ebstein's anomaly, and tricuspid atresia.[621] Prenatal detection of these lesions may improve prognosis and guide therapy. Although some have recommended routine limited fetal echocardiography during the second or third trimester,[620] recent reports have suggested a low yield and limited diagnostic accuracy.[622-624] Like many imaging techniques, fetal echocardiography is evolving, and further study is required to define its optimal clinical use.

Chapter 13: THE ECHOCARDIOGRAM

CARDIAC MASSES, THROMBI, AND TUMORS

Normal Variants and Masses of Uncertain Significance

When an abnormally localized accumulation of dense reflectances appears on the echocardiogram, it is said to represent a mass. Echocardiographic masses may be caused by technical artifacts or anomalous structures, but they are of greatest significance in representing true lesions of the heart such as tumors, thrombi, and vegetations. Echocardiography is the procedure of choice for the detection and evaluation of cardiac mass lesions; often, it is the only modality capable of delineating small lesions such as papillary fibroelastomas.[625] Accordingly, echocardiographic examinations are commonly performed to search for embolic sources, particularly in patients with cerebral ischemic events.

A number of technical artifacts are capable of appearing as masses on echocardiogram. For example, side lobe signals, reverberations, and noise artifact may lead to accumulations of ultrasonic reflectance within the cavities or adjacent to the myocardium of the heart.[20,21] Such structures usually lack distinct borders, do not move appropriately through the cardiac cycle, lack identifiable attachments to endocardial surfaces, and cannot be visualized in all views and at all depth settings. In seeking a way to distinguish artifacts from LV thrombi (a common clinical dilemma) the absence of wall motion abnormalities is of particular value.[626]

Several benign normal variant findings can be observed during echocardiographic examination and must be distinguished from pathologic lesions. Thus, many adults manifest persistence of the eustachian valve (Fig. 13-125), a thin ridge of tissue at the junction of the inferior vena cava and right atrium.[627,628] The eustachian valve appears as a long, linear, freely mobile structure in the right atrium at the mouth of the inferior vena cava and is nearly always benign (although infective involvement has been reported).[629,630] An additional embryonic remnant that may be seen in the posterior right atrium is the Chiari network, which typically appears as a weblike mobile structure.[631,632] In some individuals, RV hypertrophy may produce significant enlargement of the RV moderator band coursing along the interventricular septum to the apex of the RV.[633] Similarly, false chordae tendineae ("heartstrings") can occasionally be visualized as linear structures spanning the LV cavity attached to endomyocardium at both ends (Fig. 13-126).[634,635] Neither of the foregoing lesions has been conclusively associated with morbidity or mortality. On occasion, LV hypertrophy or hypertrophied papillary muscles may simulate cardiac mass lesions.[633] Although TEE provides enhanced sensitivity and resolution in the delineation of cardiac mass lesions, this technique may be associated with variants and artifacts of its own.[636,637]

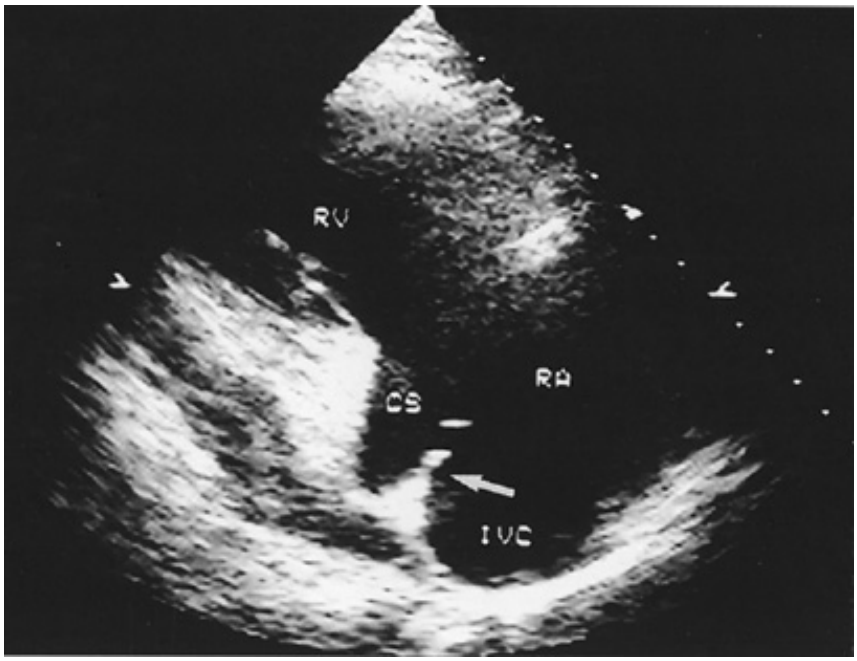

Figure 13-125: Right ventricular inflow view showing a prominent eustachian valve (*arrow*) at the junction of the inferior vena cava (IVC) and the right atrium (RA). RV = right ventricle; CS = coronary sinus. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging,* 2d ed. Philadelphia; Saunders; 1996:452-480, with permission.)

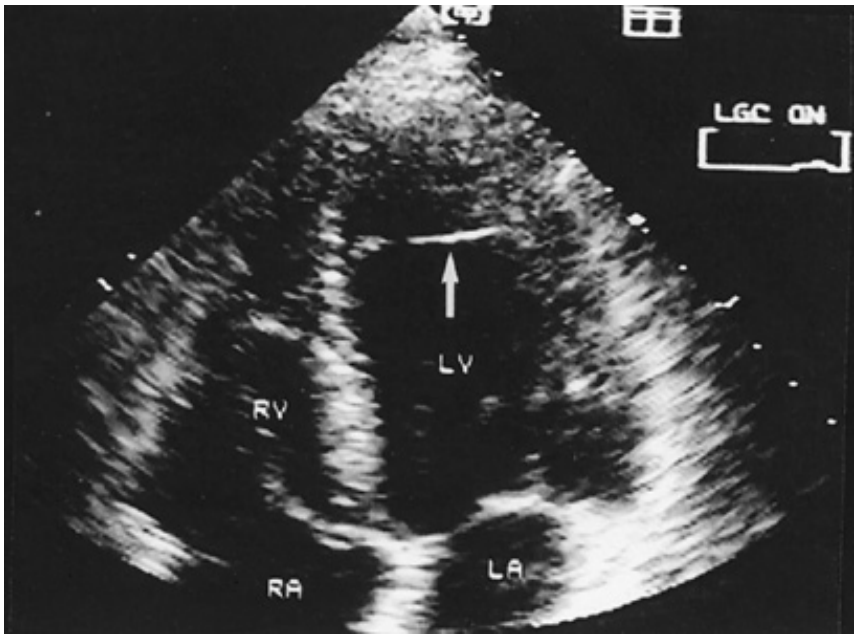

Figure 13-126: Apical four-chamber view demonstrating a false chord (*arrow*) within the left ventricle (LV). LA = left atrium; RA = right atrium; RV = right ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

A variety of foreign bodies and iatrogenically induced anatomic alterations may be visualized on echocardiogram and must be distinguished from pathologic lesions. Intracardiac catheters,

pacemaker leads (Fig. 13-127), prosthetic valves or patches, and atrial suture lines after cardiac transplantation can be visualized during echocardiographic examination.[638,639] These structures are usually easily recognized due to the highly reflective properties of the foreign material, which result in bright echoes, reverberations, and shadowing behind the structures. In this regard, endomyocardial biotomes and pericardiocentesis catheters can be readily visualized by cardiac ultrasound, and echocardiography can be employed to guide procedures utilizing these instruments in lieu of fluoroscopy.[640,641] Last, a variety of manufactured objects that have penetrated the heart have been described on echocardiography, including bullets, pellets, and nails.[642]

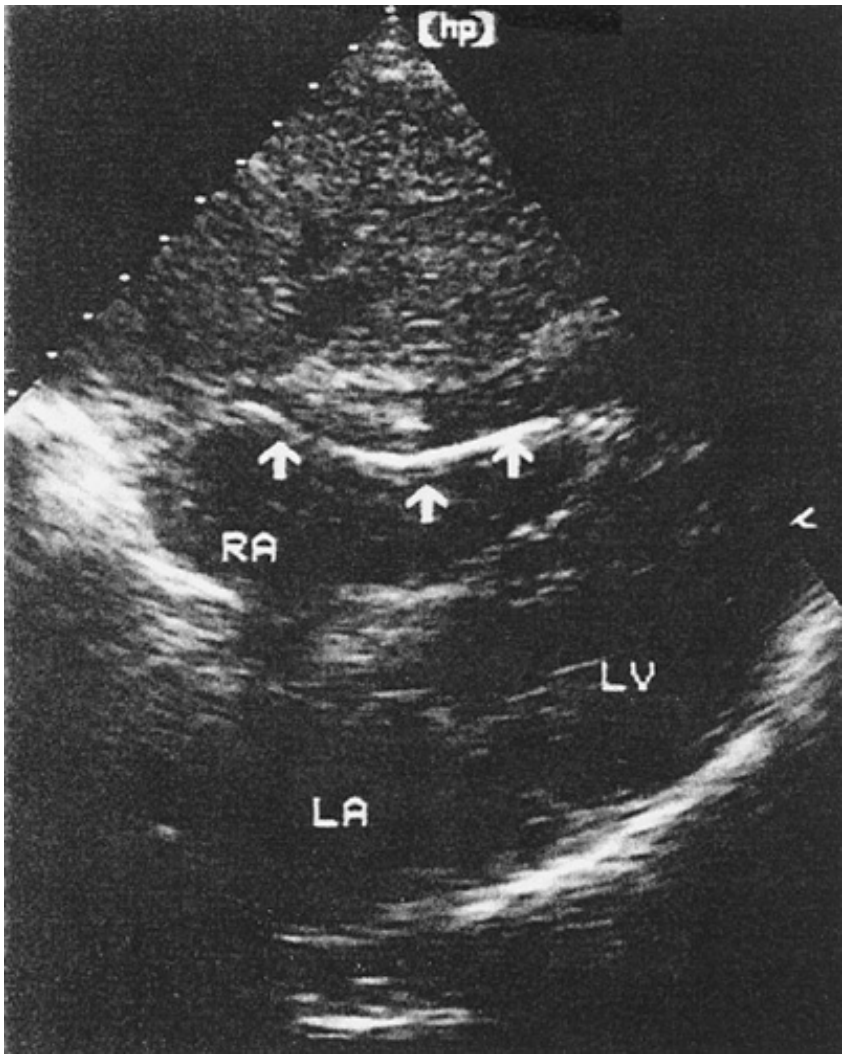

Figure 13-127: Subcostal four-chamber image demonstrating a pacemaker wire (*arrows*) in the right heart. RA = right atrium; LA = left atrium; LV = left ventricle.

Several morphologic changes involving the interatrial septum are often considered under the classification of cardiac mass lesions of uncertain significance. Aneurysms of the interatrial septum have been reported in about 1 percent of the population and are recognized on echocardiogram as a protrusion of the interatrial septum of at least 1.5 cm from its longitudinal plane dividing the left and right atrium (Fig. 13-128).[643,644] Although usually benign, interatrial septal aneurysms are often associated with a patent foramen ovale and have been implicated as a source of cardiogenic emboli.[645] Interatrial septal aneurysms may be detected by TTE, but they are more readily imaged by the transesophageal approach.[644] Lipomatous

hypertrophy of the interatrial septum, or accumulation of adipose tissue within this structure, is not an uncommon finding in elderly individuals. Lipomatous hypertrophy appears as a highly reflective thickening of the interatrial septum that typically spares the foramen ovale, thereby creating a characteristic dumbbell echocardiographic appearance.[646,647] No significant consequences or sequelae have been attributed to lipomatous infiltration of the interatrial septum.

Intracardiac Thrombi

Intracardiac thrombi occur commonly in a variety of cardiovascular disorders, may be visualized in any chamber of the heart, and frequently result in embolic events.[648] The major factors that predispose to the formation of intracardiac thrombi include localized stasis of flow, low cardiac output, and cardiac injury. In addition, migration of venous thrombi may also result in intracardiac clots.[649,650] The appearance of intracardiac thrombi may vary considerably, and although they are typically attached to the endocardium, unrestricted and freely mobile thrombi occasionally may be encountered (particularly in the setting of valvular stenosis which prevents exit of the thrombus from the heart).[651] Thrombi typically have identifiable borders and may be layered and homogeneous or heterogeneous, with areas of central liquefaction (Figs. 13-129 and 13-130).[651,652]

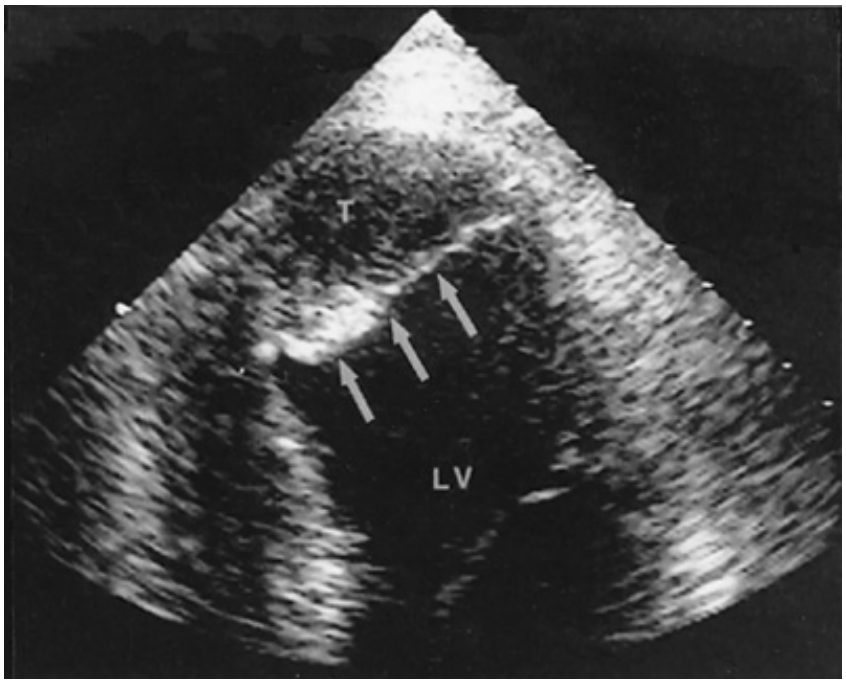

Figure 13-129: Magnified apical view of a large thrombus (T) in the apex of the left ventricle (LV). Although the thrombus is fairly homogeneous, its border is more echo-dense (*arrows*).

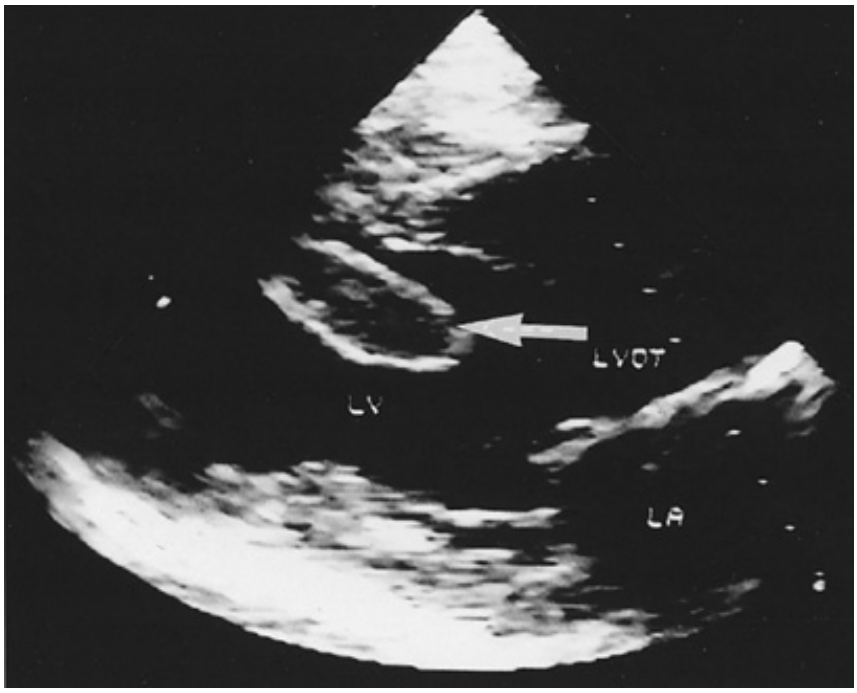

Figure 13-130: Parasternal long-axis view of a large mobile thrombus (*arrow*) attached to the anteroseptal segment of the left ventricle (LV). LVOT = left ventricular outflow tract; LA = left atrium. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

RIGHT HEART

Thrombi within the right heart chambers may form locally or migrate from the venous circulation; they are found most commonly in the RA.[653] As opposed to the laminar, relatively immobile nature of RA thrombi that form in situ, venous thromboemboli trapped in the RA tend to be serpentine and mobile.[649] The potential for pulmonary embolism is high.[654] Thrombi also can be seen within the main pulmonary arteries, although they are less well visualized by TTE than TEE.[655] RV thrombi are rare but may occur with RV infarction and endomyocardial fibrosis.[656,657] Their appearance is similar to that of LV thrombi.

LEFT ATRIUM

Left atrial thrombi occur in the setting of low cardiac output, mitral valvular disease (particularly mitral stenosis), atrial fibrillation, and LA enlargement. Both TTE and TEE can detect thrombi within the main cavity of the left atrium (Fig. 13-131), but TEE is clearly superior for visualizing thrombi within the left atrial appendage.[658-660] Since approximately 50 percent of LA thrombi are limited to the appendage, TEE is the diagnostic procedure of choice to detect this lesion.[652,661] LA thrombi appear as discrete masses, either fixed or mobile, and are usually of homogeneous echo density[659] (Fig. 13-52). On TEE, normal pectinate muscular ridges in the appendage must be distinguished from small thrombi. In addition, the left atrial appendage may occasionally be multilobed. Although this anatomic variant may be a risk factor for appendage thrombi, the atrial tissue separating the lobes should not be mistaken for clot.[662]

Figure 13-131: Apical four-chamber image of a large mobile "ball" thrombus (*arrow*) in the left atrium (LA). LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Left atrial thrombi are often accompanied by spontaneous echo contrast (or "smoke") within the LA. This finding, probably produced by transient aggregation of erythrocytes and plasma proteins,[663] indicates stagnant blood flow and can occur in any cardiac chamber or the aorta. Left atrial spontaneous echo contrast, like LA thrombus, has been associated with embolic events[664,665] and may be a marker of regional prothrombotic activity.[666] On 2D imaging, the contrast signals are in constant motion and can be missed if gain settings are inappropriately low.

LEFT VENTRICLE

Most LV thrombi occur in settings of abnormal systolic contraction (dilated cardiomyopathy, acute myocardial infarction, and chronic LV ventricular aneurysm).[667-669] LV thrombi have been reported in up to one-half of patients with large myocardial infarctions and occur more frequently in anterior infarctions (up to 30 to 40 percent of such patients).[668] Most thrombi are located in the apex[626] and thus are best visualized in the apical views (Fig. 13-129). Although echocardiography is the procedure of choice for detecting LV thrombi,[669] the technique's true sensitivity and specificity remains uncertain, since most patients included in validating studies had LV aneurysms and the echocardiographic criteria applied were subjective.[668-670]

LV thrombi may be laminar and fixed or protruding and mobile, and they may have a

heterogeneous echo density (Figs. 13-129 and 13-130). Studies suggest that "immature" thrombi are often filamentous, with irregular borders, while older thrombi tend to be echodense and fixed.[626,648,671] The echocardiographic characteristics of thrombi may influence the risk of cardiogenic embolization, as irregularly shaped, mobile, and protruding thrombi are more likely to embolize than laminar, immobile clots.[648] True LV thrombi have a density distinct from the underlying myocardium, appear in multiple imaging planes, and move concordantly with the underlying myocardium.[669] Suspected masses in areas of normally functioning myocardium are rarely thrombi.

Chapter 13: THE ECHOCARDIOGRAM

CARDIAC TUMORS

Although diagnosed infrequently, cardiac tumors often are included in the differential diagnosis of cardiac problems because of their protean clinical manifestations. Cardiac tumors may be intracavitary or intramural, and the location determines their echocardiographic appearance. Intracavitary tumors appear as sessile or mobile echo densities attached to the mural endocardium while intramural tumors appear as localized thickening of the LV wall.[672] The pericardium also may be involved with cardiac tumors, with or without the presence of concomitant effusion (Chap. 77).

Myxomas

Myxomas are the most common primary cardiac tumors, accounting for about 25 percent of all such lesions.[673-675] Myxomas can occur in any cardiac chamber, but 75 percent are found in the LA.[675] On 2D imaging, myxomas usually appear as gelatinous, speckled, sometimes globular masses with frond-like projections (Figs. 13-132 and 13-133). Tissue heterogeneity is common, but calcification is rare.[673] Although they may be sessile, myxomas are usually attached to the endocardial surface by a pedicle. Typically, they are attached to the interatrial septum, but they can originate from the posterior or anterior atrial wall, the appendage, or even the cardiac valves.[676,677] Large tumors are almost always mobile to some degree, and a sizable left atrial mass that appears fixed in position is therefore less likely to be a myxoma. Large left atrial myxomas may move back and forth into the mitral valve annulus during the cardiac cycle, entering the orifice in diastole and the left atrium in systole. Accordingly, Doppler interrogation may demonstrate either obstruction of flow, valvular regurgitation, or both.[678,679] Most myxomas are visible on TTE, but TEE is superior for the delineation of tumor attachments and detection of small myxomas.[680] Since approximately 5 percent of myxomas are biatrial, careful evaluation of the RA is mandatory.[675]

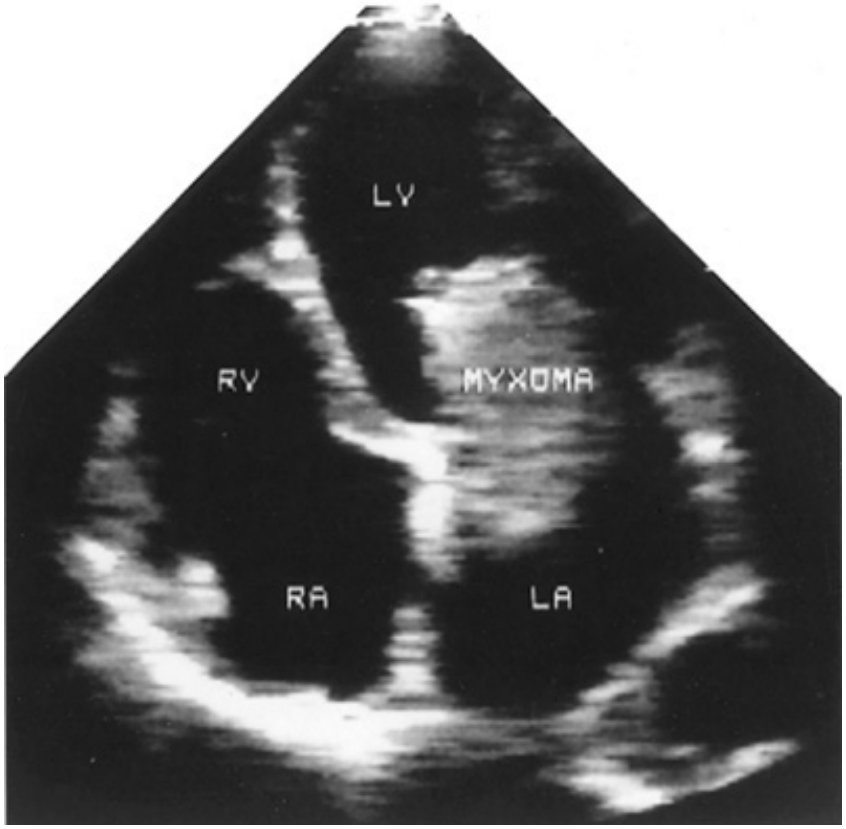

Figure 13-132: Apical four-chamber image of a left atrial myxoma which is attached to the interatrial septum and prolapses through the mitral valve. LA = left atrium; RA = right atrium; RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging,* 2d ed. Philadelphia: Saunders, 1996:452-480, with permission.)

Additional Primary Tumors

Benign

Rhabdomyomas are rare cardiac tumors associated with tuberous sclerosis.[681,682] There is a strong tendency for multiple tumors to occur within an affected heart (90 percent of cases).[681,683] Fibromas are found most often in children and affect the left ventricle most frequently. The tumor may grow within the myocardium rather than expanding into a cardiac chamber.[684,685] Papillary fibroelastomas are usually quite small in size (less than 1 cm in diameter) and often grow on cardiac valves or chordae. These rare tumors typically have multiple small fronds that tend to embolize.[625,686,687] Echocardiographic differentiation from vegetations can be difficult (Chap. 77).

Malignant

Primary malignant cardiac tumors are quite rare and confer a very poor prognosis. Angiosarcoma is the most common and occurs most often in the right atrium. Rhabdomyosarcoma is an additional primary cardiac malignancy.[688] Echocardiography can be useful in monitoring response to therapy, but its diagnostic utility is limited, as most findings are nonspecific.

Metastatic and Secondary Tumors of the Heart and Pericardium

Metastatic tumors to the pericardium and heart occur 20 to 40 times more often than primary cardiac tumors (Fig. 13-134).[689] Tumors that commonly involve the heart and pericardium include breast and lung carcinoma, melanoma, and lymphoma. Involvement may be secondary to hematogenous, lymphatic, or contiguous spread. Tumors such as hepatoma and renal carcinoma can also extend to the heart via the venae cavae.[690] In these cases, tumor is often visible in the inferior vena cava and RA. Metastatic disease affects the pericardium more frequently than the heart itself, and pericardial effusion is the most common echocardiographic manifestation in patients with cardiac metastases.[689,691,692] Intracavitary and pericardial masses are easily visualized with 2D imaging, although intramural tumors are sometimes difficult to image. Echocardiographic findings are nonspecific, and metastatic tumors may be mistaken for primary cardiac neoplasms, vegetations, thrombi, or even prominent muscular trabeculations (Chap. 77).

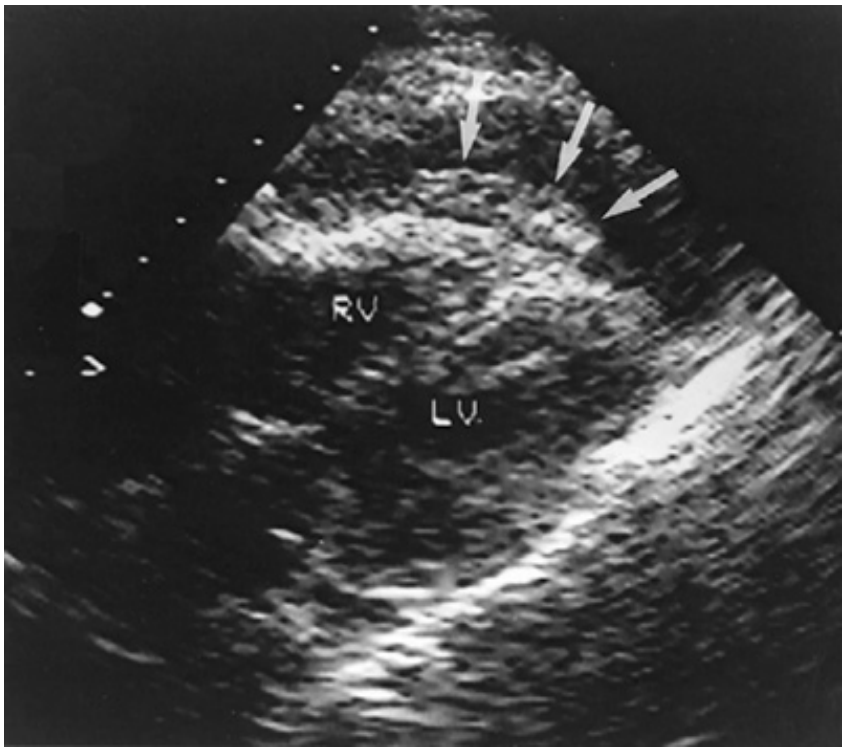

Figure 13-134: Modified subcostal image showing a metastatic tumor on the epicardium (*arrows*) and a malignant pericardial effusion. RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Additional Cardiac Masses

The heart is rarely involved in echinococcal disease (<2 percent of cases), but intracardiac or intrapericardial rupture of a cyst can lead to anaphylaxis and cardiac tamponade, respectively.[693] Echocardiographic detection of a multiseptated cyst in the left ventricle or interventricular septum suggests cardiac echinococcal disease.[694]

Simple pericardial cysts usually occur in the right costophrenic angle (posterior to the right atrium) and have a benign prognosis. The structures are nonseptated and fluid-filled; they do not compress the cardiac chambers.[695]

Chapter 13: THE ECHOCARDIOGRAM

PERICARDIAL DISEASE

In normal subjects, the pericardium is difficult to visualize since the pericardial cavity is only a potential space and visceral and parietal pericardial layers appear as a single echo.[696] In the setting of pericardial effusion, the fluid appears as a sonolucent area (or clear space) separating epicardium from pericardium.[697] Pericarditis may be unaccompanied by pericardial effusion and in such cases may be undetectable by echocardiography.[698] In addition, although thickening and/or calcification of the pericardium may be detectable by echocardiography in patients with constrictive pericarditis, cardiac ultrasound is limited in this capability.[699-700a] Therefore, the evaluation of constrictive pericarditis by echocardiography, primarily involves Doppler flow recordings.[701]

Pericardial Effusion

Echocardiography is the diagnostic procedure of choice for detection of pericardial fluid[696,697] (Fig. 13-135), and early M-mode studies demonstrated that volumes as small as 20 to 30 mL could be detected reliably.[702] As both myocardium and pericardium are echo-reflective and pericardial fluid is not, a sonolucent area between the epicardium and pericardium is diagnostic of a pericardial effusion. Although epicardial-pericardial separation may be seen during systole in normal cases, separation throughout the cardiac cycle is abnormal.[702] Descending aorta, coronary sinus, pleural effusion, pericardial cyst, and LV pseudoaneurysm occasionally may be mistaken for pericardial effusion.[703]

Echocardiography can be used to identify pericardial loculations, fibrous strands, and pericardial tumors as well as to assess the size of effusions[692,696,697,699,700] (Fig. 13-136). Pericardial effusions may be concentric or loculated (the latter type is especially common with postoperative, infective, and malignant effusions). As pericardial tissue reflects upon itself behind the left atrium between the pulmonary veins (the oblique sinus), fluid is rarely seen in this area. Small, nonloculated effusions may move depending on patient position and thus are often drawn posteriorly and inferiorly by gravity during routine imaging. A rim of pericardial fluid surrounding the heart is evidence of a moderate or large effusion, and the heart can sometimes be seen "swinging" back and forth within the pericardial space, creating the mechanism of *electrical alternans.*[704] In general, small effusions are seen posteriorly rather than anteriorly on supine imaging.[696] Moderate-sized (100 to 500 mL) nonloculated effusions are present both anterior and posterior to the heart.[696] Large nonloculated effusions (>500 mL) are circumferential and frequently allow free motion of the heart within the fluid-filled space.[696,697]

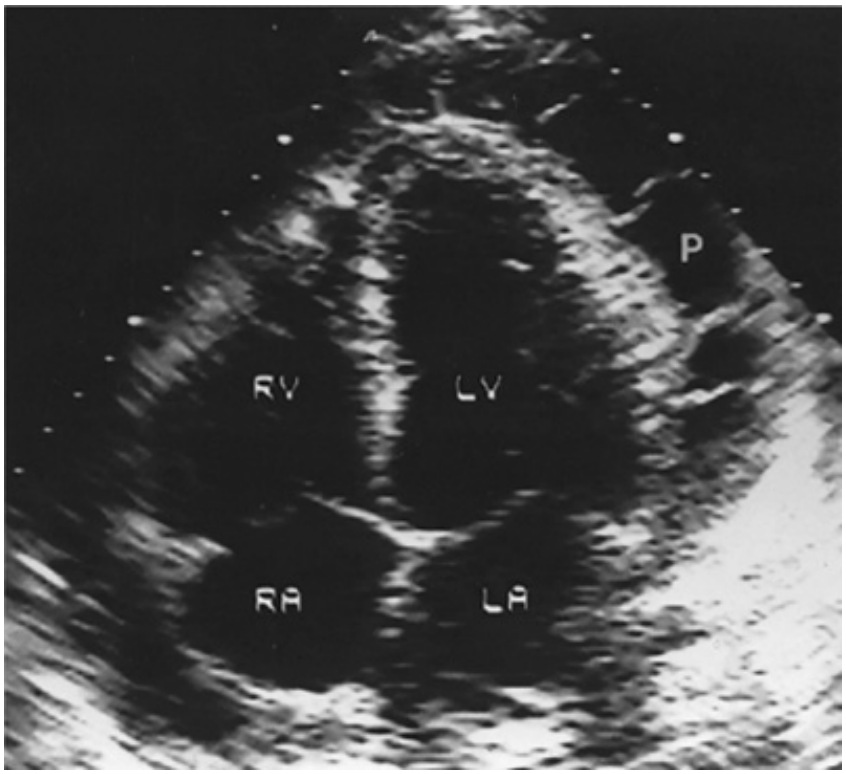

Figure 13-136: Apical four-chamber image in a case of malignant pericardial effusion (P). Numerous fibrinous strands are seen within the effusion. LA = left atrium; RA = right atrium; RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders, 1996:452-480, with permission.)

Distinguishing between pericardial and pleural effusions is occasionally difficult with echocardiography.[705] If these conditions coexist, the pericardium usually can be identified as a linear density separating fluid in the two spaces. The parasternal long-axis view is often helpful in differentiating the disorders. The descending aorta is a mediastinal structure; therefore pericardial effusions will often separate the heart and descending aorta, while pleural effusions are seen inferior and posterior to the aorta[705] (Fig. 13-137). In cases of large pleural effusions, atelectatic lung tissue also may be present (Fig. 13-137). Subcostal views are often valuable and may yield the only satisfactory transthoracic images in postoperative or posttraumatic cases. The inferior vena cava also can be imaged in this view; if the vessel does not display inspiratory collapse greater than 50 percent of its maximum diameter, elevated RA pressure is present.[366]

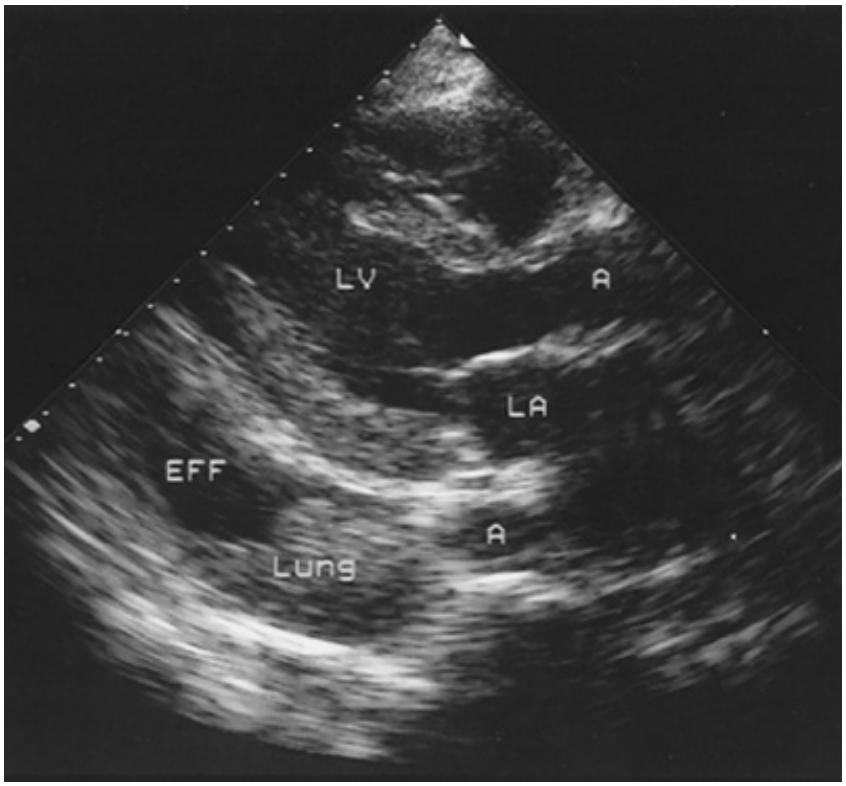

Figure 13-137: Parasternal long-axis view in a patient with a pleural effusion (EFF) posterior to the heart. Atelectatic lung tissue is present within the effusion. LA = left atrium; LV = left ventricle; A = aorta.

On parasternal images, an echolucent space is sometimes visualized anterior to the RV.[706] Although this finding may represent pericardial fluid, it usually is caused by epicardial fat (without effusion) and has no pathologic significance. Therefore the diagnosis of pericardial effusion based solely on the presence of this anterior clear space should be avoided.

Cardiac Tamponade

As the pericardium is a relatively noncompliant membrane that adapts slowly to volume changes, pericardial effusions (especially those that accumulate rapidly) may limit cardiac filling and cause cardiac tamponade. Echocardiography can help diagnose this condition by detecting (1) morphologic signs of increased intrapericardial pressure and (2) abnormal intracardiac flow patterns caused by tamponade and enhanced ventricular interdependence.[707,708]

As diastolic pressures are slightly lower in the right heart than the left, the RA and RV are usually the first chambers to exhibit evidence of increased intrapericardial pressure. High intrapericardial pressure can cause compression or collapse of right heart chambers.[707,709,710] Invagination of the right atrial wall during atrial systole is a sensitive (but not specific) sign of tamponade (Fig. 13-138).[709] Diastolic collapse or "buckling" of the RV free wall is a more specific sign of tamponade, and can be visualized both on 2D and M-mode imaging[707,710] (Fig. 13-135*B* and *C*). In cases of localized tamponade or severe RV hypertrophy, left atrial or ventricular diastolic collapse may be the first sign of tamponade.[711,712]

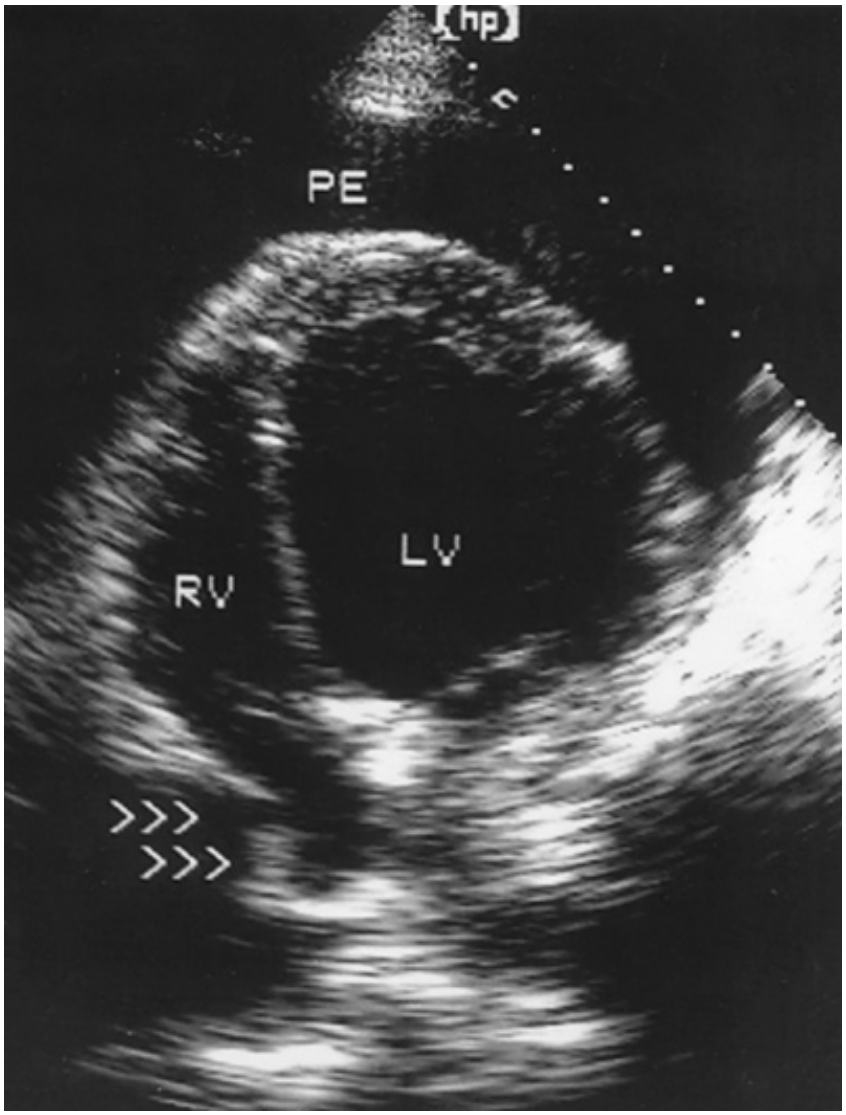

Figure 13-138: Right atrial collapse (*arrows*) in cardiac tamponade. PE = pericardial effusion; LV = left ventricle; RV = right ventricle.

Doppler echocardiographic recordings in patients with tamponade have demonstrated an enhancement or exaggeration of the normal respiratory variation in ventricular inflow and outflow.[708,713] Thus, transmitral and LVOT velocities decrease significantly with inspiration, probably because of enhanced ventricular interdependence and a marked decrease in the transmitral diastolic gradient during inspiration (Fig. 13-139). The latter is caused both by high intrapericardial pressure as well as leftward motion of the interventricular septum from increased RV filling.[708] Although cardiac tamponade remains a clinical diagnosis, echocardiography has significantly improved the detection of hemodynamic effects from pericardial fluid, especially in early and equivocal cases. Studies have also indicated that when echocardiography is used to direct pericardiocentesis to the site of greatest fluid accumulation, the risks associated with blind pericardial puncture are decreased.[714]

Constrictive Pericarditis

The diagnosis of constrictive pericarditis is sometimes difficult to establish, even by cardiac catheterization. 2D and M-mode echocardiography may provide evidence of thickened pericardial tissue by demonstrating increased reflectivity and multiple parallel moving echoes in the area of the pericardium.[699,700] The criteria for pericardial thickening on echocardiogram are imperfect, however, as the normal pericardium is an echodense, highly reflective structure with a gain-

dependent signal.[715] Paradoxical septal motion may be seen on M-mode with constriction, as can an abnormal inspiratory interventricular septal "bounce"[716] and limited diastolic motion of the posterior LV wall.[717] A dilated inferior vena cava that does not collapse on deep inspiration is indicative of high RA pressure and may be observed on 2D imaging in constrictive pericarditis.[716]

The utility of Doppler recordings in evaluating constrictive pericarditis has been shown in several recent studies.[550,701,718-723a,723b] As with cardiac tamponade, pericardial constriction produces exaggerated respiratory variation in the isovolumic relaxation time and in flow velocities within right and left ventricles, pulmonary veins, and hepatic vein.[701,718,722] A respiratory variation of >20 percent in peak mitral E velocity favors the diagnosis of constriction over restrictive cardiomyopathy, while little respiratory variation and a shortened E deceleration time favor restrictive physiology.[701] Doppler echocardiographic criteria for constriction have been validated prospectively and may help predict clinical response to pericardiectomy.[721] Unfortunately, exaggerated respiratory flow variation is not specific for pericardial constriction and also can be seen in chronic obstructive pulmonary disease and asthma.[724] In these cases, Doppler examination of superior vena cava flow is useful: patients with asthma will have increased flow toward the heart during inspiration, while limited forward flow will be seen in constriction (the echocardiographic equivalent of Kussmaul's sign).[724,724a] Recently, respiratory variation in the peak velocity and duration of continuous-wave Doppler TR spectral envelopes has been shown to reflect accurately the enhanced ventricular interaction seen in constrictive pericarditis.[725]

Chapter 13: THE ECHOCARDIOGRAM

IMAGING OF THE CORONARY ARTERIES

The ability to visualize the proximal segments of the left and right coronary arteries was initially demonstrated by Weyman et al.[417] Subsequent studies established the ability of color and spectral Doppler examination to image and record the velocity of flow from TTE and TEE approaches, particularly with regard to the left anterior descending coronary artery.[418-420] However, visualization of the coronary arteries by echocardiography has not achieved a significant role in clinical practice because the resolution of the technique is at the limit of vessel size and the vessels are circuitous and move vigorously, often coursing in and out of the beam path. Despite these limitations, transthoracic imaging has proven useful for the diagnosis and follow-up of patients with Kawasaki disease and coronary involvement[726-728] (Fig. 13-140) and may also help distinguish normal from atherosclerotic coronary arteries.[729]

The coronary arteries are routinely imaged with TEE, which can detect proximal stenoses, atherosclerosis, and congenital abnormalities of the coronaries more accurately than surface imaging.[730-732] Doppler TEE analysis also has been used to determine coronary low reserve.[733,734]

Visualization of mid- and distal coronary arteries is problematic with both TTE and TEE. Recent advances in technology and contrast agents, however, may significantly improve capabilities in this area. Figure 13-141 (Plate 73) shows color flow within a septal coronary artery. This image was produced by an instrument utilizing a carrier frequency range of 5 to 7 MHz, rather than the more commonly used range of 2.5 to 3.5 MHz. This area of echocardiography is expanding rapidly and clinical applications will grow in the future.[735,736]

Chapter 13: THE ECHOCARDIOGRAM

List of Figures

Figure 13-5: Formation of A-mode, B-mode, and M-mode echocardiograms. The transducer emits an ultrasound beam, which reflects at each anatomic interface. The reflected wavefronts can be represented as dots (B mode) or spikes (A mode). The dot brightness and spike magnitude vary with the amplitude of the reflected wave. If the B-mode scan is swept from left to right with time, an M-mode image is produced. CW = chest wall; RV = right ventricle; IVS = interventricular septum; AML = anterior mitral leaflet; PML = posterior mitral leaflet; and PW = posterior wall. (Modified from Hagan AD, DeMaria AN. *Clinical Applications of Two-Dimensional Echocardiography and Cardiac Doppler*. Boston: Little, Brown; 1989, with permission.)

Figure 13-6: *A.* Diagram of an M-mode sweep from apex to base in a normal heart (parasternal view). En = endocardium; PPM = posterior papillary muscle; E,P = epicardial/pericardial interface; ARVW = anterior right ventricular wall; RV = right ventricle; LV = left ventricle; IVS = interventricular septum; Ch = chordae tendineae; PMVL = posterior mitral valve leaflet; AMVL = anterior mitral valve leaflet; LVOT = left ventricular outflow tract; AV Jn = atrioventricular junction; RVOT = right ventricular outflow tract; Ao = aorta; LA = left atrium; AoV = aortic valve; LAW = left atrial wall; RA = right atrium; ATVL = anterior tricuspid valve leaflet; PA = pulmonary artery; PV = pulmonary valve; APS = atriopulmonic sulcus. (From Felner JM, Schlant RC. *Echocardiography: A Teaching Atlas*. New York: Grune & Stratton; 1976, with permission.) *B* to *D*. M-mode sweep from apex to base in a normal individual.

Figure 13-7: Standard M-mode image through the left ventricle at the level of the mitral valve. See text for discussion of nomenclature.

Figure 13-8: M-mode image through the mitral valve showing a "B bump," suggesting high left ventricular diastolic pressure (*arrow*). The E-point septal separation is also increased. (Transducer is in the left parasternal position.)

Figure 13-9: Recommended criteria for M-mode measurement of cardiac dimensions (see text for details). The figure and the elliptical inserts (*a, b, c, d,* and *e*) illustrate the leading-edge method. ARV = anterior right ventricular wall; RV = right ventricle; LV = left ventricle; PLV = posterior left ventricular wall; S = septum; PPM = papillary muscle; AMV and PMV = anterior and posterior mitral valve leaflets, EN: endocardium, EP: epicardium; AV = aortic valve; Ao = aorta; LA = left atrium. Figure 13-60: *A.* Parasternal short-axis image of a bicuspid aortic valve (AV) during systole. RV = right ventricle; RA = right atrium; LA = left atrium. *B.* Transesophageal image of a bicuspid aortic valve (A). LA = left atrium, R = right ventricular outflow tract. (From Blanchard DG, Kimura BJ, Dittrich HC, DeMaria AN. Transesophageal echocardiography of the aorta. *JAMA* 1994; 272:546-551, with permission.)

Figure 13-61: Transesophageal image of a stenotic bicuspid aortic valve (*A*) with superimposed planimetry of the valve area (approximately 1 cm2).

Figure 13-62: Continuous-wave Doppler tracing (from the apical transducer position) through the aortic valve in a case of combined aortic stenosis and insufficiency. The peak systolic velocity approaches 5 m/s.

Figure 13-63: M-mode tracing (from the parasternal position) in a patient with acute severe aortic regurgitation. The mitral valve leaflets close (*arrow*) before ventricular contraction begins. P = p wave, R = QRS complex.

Figure 13-64: (Plate 60) *A.* Parasternal long-axis plane showing a multicolor jet (indicating turbulent flow) of aortic regurgitation in the left ventricular outflow tract. The jet is narrow in width, suggesting mild regurgitation. AO = aorta; LA = left atrium; LV = left ventricle. *B.* Parasternal long-axis plane with color-flow Doppler imaging. The aortic regurgitant (AR) color jet is as wide as the left ventricular outflow tract, suggesting severe AR. AO = aorta; LA = left atrium; LV = left ventricle. *C.* Parasternal long-axis image of acute severe aortic insufficiency (AI). The accompanying marked elevation of left ventricular (LV) diastolic pressure causes diastolic mitral regurgitation (MR). AO = aorta; LA = left atrium.

Figure 13-65: Continuous-wave Doppler tracing (from the apical transducer position) of severe AR. The pressure half-time of the AR envelope is approximately 200 ms.

Figure 13-66: Pulsed-wave Doppler tracing (from the suprasternal transducer position) in a case of severe aortic regurgitation. The sample volume is in the descending thoracic aorta, and holodiastolic flow reversal (*arrow*) is present.

Figure 13-67: Transthoracic parasternal long-axis plane demonstrating a dissection of the descending thoracic aorta. The aortic root is dilated, the aortic valve is thickened, and an intimal flap is present in the descending aorta (*arrows*). LV = left ventricle; LA = left atrium.

Figure 13-68: Longitudinal TEE view of an ascending aortic dissection in a patient with a porcine prosthetic valve in the aortic position (*large arrow*). The false (F) and true (T) lumens are separated by an intimal flap (*small arrow*). (From Blanchard DG, Kimura BJ, Dittrich HC, DeMaria AN. Transesophageal echocardiography of the aorta. *JAMA* 1994; 272:546-551, with permission.)

Figure 13-69: (Plate 61) Transverse TEE view of an aortic dissection. The false (F) and true (T) lumens are separated by an intimal flap (*large arrow*). The communication between the two channels is visible (*small arrow*).

Figure 13-71: (Plate 63) Transverse TEE view of penetrating ulceration in the proximal portion of the descending aorta (A). The mouth of the ulcer crater is visible (*large arrowhead*), as is blood flow within the atheroma (*arrow*).

Figure 13-72: Transverse TEE image of traumatic aortic disruption and partial transection (*arrows*) involving the distal portion of the aortic arch.

Figure 13-73: *A.* Parasternal long-axis view of mitral stenosis. The left atrium (LA) is enlarged, mitral opening is limited, and "doming" of the anterior mitral leaflet is present. LV = left ventricle; RV = right ventricle; AO = aorta. *B.* Apical four-chamber view in mitral stenosis. The left artium is markedly dilated. RA = right atrium. *C.* Parasternal short-axis plane in mitral stenosis.

Figure 13-74: Parasternal M-mode image through the mitral valve in a patient with mitral stenosis. The normal rapid downslope of the anterior mitral leaflet after early rapid diastolic filling is absent.

Figure 13-75: Pressure half-time method for calculation of mitral valve area (MVA). (From Hagan AD, DeMaria AN. *Clinical Applications of Two-Dimensional Echocardiography and Cardiac Doppler.* Boston: Little, Brown; 1989, with permission.)

Figure 13-76: Continuous-wave tracing of mitral regurgitation with calculation of *dP/dt* (apical transducer position). The time period between velocities of 1 and 3 m/s is 0.07 s; the calculated *dP/dt* is approximately 460 mmHg/s. See text for details.

Figure 13-77: (Plate 64) *A.* Mitral regurgitation. *Left:* apical three-chamber plane. Right: same plane with color Doppler imaging. A large jet of mitral regurgitation (*arrow*) is present. AO = aorta; LA = left atrium; LV = left ventricle. *B.* Parasternal long-axis view from a patient with angiographically proved severe mitral regurgitation. The color Doppler jet in this case is directed posteriorly and eccentric (*black arrows*). The jet hugs the wall of the left atrium (LA) and wraps around all the way to the aortic root (*white arrows*). LV = left ventricle.

Figure 13-78: (Plate 65) TEE images from a case of severe mitral regurgitation secondary to a flail posterior mitral valve leaflet. *A.* abnormal coaptation and prolapse of the posterior leaflet is apparent. *B.* Color Doppler imaging demonstrates an eccentric jet of MR directed anteriorly toward the aortic root (AO). LA = left atrium; LV = left ventricle.

Figure 13-79: Pulmonary venous pulsed-wave Doppler in severe mitral regurgitation. Systolic flow reversal (i.e., systolic flow into the pulmonary vein) is present (*arrows*).

Figure 13-80: (Plate 66) *A.* Proximal isovelocity surface area (PISA). See text for details. Q = flow; FCR = flow convergence region; r = radius of isovelocity hemisphere; Vr = velocity of flow at distance r from the orifice. (From Bargiggia GS, Tronconi L, Sahn DJ, et al. A new method for quantitation of mitral regurgitation based on color flow Doppler imaging of flow convergence proximal to regurgitant orifice. *Circulation* 1991; 84:1481-1489, with permission.) *B.* Magnified view (from the apical four-chamber plane) of mitral regurgitation (MR) demonstrating color Doppler flow convergence proximal to the mitral valve (PISA).

Figure 13-81: (Plate 67) Apical four-chamber plane in mitral stenosis. Color flow imaging in the mitral valve region shows flow convergence (PISA) proximal to the valve during diastole. LA = left atrium; RA = right atrium; RV = right ventricle.

Figure 13-82: *A.* Parasternal long-axis plane through the mitral valve in late systole. The plane of the mitral annulus (A) is drawn in a dotted line. The posterior mitral leaflet prolapses past the level of the annulus into the left atrium (LA). AO = aorta; LV = left ventricle. *B.* Diagram of true mitral valve prolapse. The mitral leaflets clearly prolapse (*arrows*) posterior to the plane of the mitral annulus (*straight dotted line*). Ao = aorta; LV = left ventricle; LA = left atrium; M = m-mode imaging beam. (From Devereux RB, Kramer-Fox R, Kligfield P. Mitral valve prolapse: Causes, clinical manifestations, and management. *Ann Intern Med* 1989; 111:305-317, with permission.) C. M-mode image through the plane of the mitral valve demonstrating posterior prolapse of the leaflets during systole (*arrow*). E = early diastolic filling; A = atrial component.

Figure 13-83: *A.* Apical four-chamber image of a flail posterior mitral valve leaflet (pmvl). The mitral valve is thickened and myxomatous. amvl = anterior mitral valve leaflet. *B.* Transesophageal echocardiography image (transverse four-chamber plane) of a flail posterior mitral valve leaflet (*arrows*) secondary to ruptured chordae. LA = left atrium; RA = right atrium; LV = left ventricle.

Figure 13-84: Parasternal long-axis plane demonstrating mitral annular calcification (*white arrow*) with ultrasonic shadowing posteriorly (*black arrows*). AO = aorta; LV = left ventricle; LA = left atrium. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelber HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-85: *A.* Pulmonic stenosis. The pulmonic valve leaflet is thickened and echo-reflective (*arrow*). RA = right atrium; LA = left atrium; AO = aorta; PA = pulmonary artery; RV = right ventricle. *B.* Doppler interrogation reveals increased flow velocity (4 m/s) through the valve orifice.

Figure 13-86: Continuous-wave Doppler tracing through the right ventricular outflow tract and pulmonary artery (left parasternal transducer position). Mild pulmonic regurgitation is present (*arrows*).

Figure 13-87: Pulsed-wave Doppler tracing of the hepatic vein in severe tricuspid regurgitation (TR) (subcostal transducer position). Systolic flow reversal into the hepatic vein is present.

Figure 13-88: *A.* Parasternal short-axis view in severe pulmonary hypertension with marked enlargement of the right ventricle (RV). The left ventricle (LV) is small, and the interventricular septum is flattened. *B.* Apical fourchamber view in pulmonary hypertension. The right atrium (RA) and right ventricle (RV) are much larger than the left-sided chambers. LA = left atrium; LV = left ventricle.

Figure 13-89: M-mode in severe pulmonary hypertension. The dimension of the right ventricle (RV) is larger than that of the left ventricle (LV). The interventricular septum (IVS) moves paradoxically-i.e., *toward* the mitral valve (MV) during diastole rather than away. TV = tricuspid valve.

Figure 13-90: M-mode image of the pulmonic valve in severe pulmonary hypertension (parasternal transducer position). The a dip is absent, and a characteristic W-shaped motion of the leaflet is present during systole, indicating partial closure of the valve during midsystole followed by reopening prior to diastole.

Figure 13-91: Apical two-chamber view of a mechanical prosthetic valve (mitral position) during systole. The left atrium is completely obscured by ultrasonic shadowing (*arrows*). LV = left ventricle.

Figure 13-92: Apical view of a bioprosthetic valve (*arrow*) in the mitral position (two of the three prosthetic valve struts are apparent). Spontaneous echo contrast (SEC) is also present, secondary to systolic dysfunction and enlargement of the left ventricle (LV); LA = left atrium.

Figure 13-93: TEE images from a patient with a St. Jude prosthetic valve in the mitral position. *A.* Diastolic image. The two struts of the open valve are seen (*large arrows*) as well as their ultrasonic shadows (*small arrows*). LA = left atrium; LV = left ventricle. *B.* Systolic image. The two prosthetic leaflets are closed (*arrows*) and cast a dense ultrasonic shadow, obscuring the left ventricle.

Figure 13-94: *A.* Apical four-chamber view demonstrating a large tricuspid valve vegetation (*arrow*). RA = right atrium; LA = left atrium; LV = left ventricle; RV = right ventricle. *B.* Parasternal long axis view demonstrating a vegetation (*arrow*) on the anterior valve leaflet; AO = aorta.

Figure 13-95: Longitudinal TEE view of a large mitral valve vegetation (*arrow*). a = left atrium; v = left ventricle. (Courtesy of William D. Keen, Jr., MD.)

Figure 13-96: Longitudinal TEE image demonstrating a fistula between the aorta (A) and left atrium (LA) in a patient with endocarditis. AV = aortic valve; P = pulmonary artery; LV = left ventricle; M = mitral valve. (From Sobel J, Maisel AS, Tarazi R, Blanchard DG. Gonococcal endocarditis: Assessment by transesophageal echocardiography. *J Am Soc Echocardiogr* 1997; 10:367-370.)

Figure 13-97: Sixteen-segment format for identification of left ventricular wall segments. Coronary arterial territories are also included. LAX = parasternal long axis; SAX PM = short axis at papillary muscle level; 4C = apical four-chamber; 2C = apical two-chamber; ANT = anterior; SEPT = septal; POST = posterior; LAT = lateral; INF = inferior. (From Segar D, Brown S, Sawada S, et al. Dobutamine stress echocardiography: Correlation with coronary lesion severity as determined by quantitative angiography. *J Am Coll Cardiol* 1992; 19:1197, with permission.)

Figure 13-98: Diastolic (*left*) and systolic (*right*) images (apical two-chamber plane) from a patient with an inferior wall myocardial infarction. The inferobasal segment is dyskinetic (*arrows*). LV = left ventricle; LA = left atrium.

Figure 13-99: Parasternal long-axis view of a large anteroseptal myocardial infarction, with thinning and dyskinesis of the anteroseptal wall (*arrows*). LV = left ventricle; LA = left atrium; AO = aorta.

Figure 13-100: Apical four-chamber images of a large apical infarction. Diastole (D) is displayed on the left, systole (S) on the right. During systole, the base of the ventricle contracts, but the apex is dyskinetic (*arrows*).

Figure 13-101: Modified apical four-chamber view of a large pseudoaneurysm (PAN) communicating with the left ventricle (LV). The rupture site is apparent (*arrow*); clot (C) is present within the aneurysm. (From Yucel G, Steinberg E, O'Reilly M, Kronzon I. Giant left ventricular pseudoaneurysm. *Circulation* 1996; 94:848, with permission.)

Figure 13-102: (Plate 68) Modified apical four-chamber image of a distal septal ventricular septal rupture. With 2D imaging (*left*), the distal septum is incompletely visualized. With color Doppler imaging, however, a high-velocity aliased color jet is seen in the right ventricle (RV). In addition, an area of flow convergence is seen on the left ventricular (LV) side of the rupture (*arrow*).

Figure 13-103: Transverse four-chamber TEE image of a posterolateral infarction causing posterior papillary muscle ischemia and partial rupture. The posterior mitral leaflet (*large arrow*) is poorly supported (but not actually flail) and prolapses into the left atrium (LA). The basal lateral wall segment (*small arrows*) of the left ventricle (LV) is dyskinetic.

Figure 13-104: Diastolic (*A*) and systolic (*B*) subcostal four-chamber images of right ventricular (RV) myocardial infarction. The RV free wall is dyskinetic (*arrows*) during systole (*B*).

Figure 13-105: *A.* Digitized parasternal views during diastole (*left*) and systole (*right*) from a normal individual. *Upper panels:* long-axis plane; *lower panels:* short-axis plane. *B.* Digitized apical views during diastole (*left*) and systole (*right*) from a normal individual. *Upper panels:* four-chamber plane; *lower panels:* two-chamber plane. *C.* Digitized parasternal long-axis views at peak systole before (*left*) and immediately after exercise (*right*). The anteroseptal wall moves normally at rest (*arrows*) but becomes dyskinetic with exercise. LV = left ventricle; LA = left atrium; AO = aorta. *D.* Digitized apical four-chamber views at peak systole before (*left*) and immediately after exercise (*right*). The apical septal, apical, and apical lateral walls become dyskinetic with exercise, suggesting inducible ischemia in the left anterior descending artery territory. LA = left atrium; LV = left ventricle. *E.* Digitized parasternal short-axis views (all recorded at peak systole) during dobutamine echocardiography in a patient with three-vessel coronary artery disease. At baseline (*upper left panel*), the left ventricular systolic function is normal. With low-dose dobutamine (5 μg/kg/min, *upper right panel*), function improves. With 10 μg/kg/min, however (*lower left panel*), function is similar to that at baseline. At 20 μg/kg/min (*lower right panel*), systolic function deteriorates and the left ventricle dilates. This response suggests global ischemia induced by dobutamine infusion.

Figure 13-106: *A.* Parasternal long-axis view (during systole) of hypertrophic cardiomyopathy (HCM). Asymmetrical septal hypertrophy is present, as is systolic anterior motion of the anterior mitral valve leaflet (*arrow*). LV = left ventricle; LA = left atrium; RV = right ventricle; AO = aorta. *B.* Parasternal short-axis view of HCM. Asymmetrical septal hypertrophy is present (*arrows*). RV = right ventricle; LV = left ventricle. *C.* Parasternal M-mode image from a patient with HCM, demonstrating systolic anterior motion of the anterior mitral valve leaflet (*arrows*). RV = right ventricle; IVS = interventricular septum; LV = left ventricle.

Figure 13-107: Continuous-wave Doppler tracing through the left ventricular outflow tract (from the apical transducer position) in hypertrophic obstructive cardiomyopathy (HOCM). In comparison to valvular aortic stenosis, the rise in velocity is delayed (reflecting dynamic rather than fixed outflow obstruction).

Figure 13-108: Apical four-chamber image of dilated cardiomyopathy. There is four-chamber enlargement as well as left ventricular (LV) spontaneous echo contrast. RV = right ventricle; RA = right atrium; LA = left atrium.

Figure 13-109: Apical four-chamber image of cardiac amyloid. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle.

Figure 13-110: (Plate 00) *A.* Apical four-chamber view of an ostium secundum atrial septal defect (ASD). On the left, a defect in the mid atrial septum is apparent (*arrow*). On the right, there is color flow through the shunt. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle. *B.* Subcostal four-chamber view of a large ostium primum atrial septal defect (*arrow*). RA = right atrium; LA = left atrium; LV = left ventricle; RV = right ventricle. (Reproduced with permission of Joseph A. Kisslo, MD.)

Figure 13-111: Transesophageal image of a sinus venosus atrial septal defect (ASD) (longitudinal plane). The defect is present in the superior portion of the interatrial septum. RA = right atrium; LA = left atrium; ASD = atrial septal defect; PA = pulmonary artery.

Figure 13-112: Transverse transesophageal image of single atrium. RV = right ventricle; LV = left ventricle. (From Blanchard DG, Scott ED. Single atrium. *Circulation* 1997; 95:273, with permission.)

Figure 13-113: *A.* Apical four-chamber image of an inlet ventricular septal defect (VSD). The defect (*arrows*) is situated more inferiorly than the typical position of a perimembranous VSD. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle. *B.* Apical image of single ventricle. RA = right atrium; LA = left atrium.

Figure 13-114: (Plate 70) Parasternal short-axis images of a large perimembranous ventricular septal defect (VSD) (*arrow*) without (*left*) and with (*right*) superimposed color flow Doppler. A large, turbulent color jet crosses the VSD during systole (*right*). RVOT = right ventricular outflow tract; RA = right atrium; LA = left atrium; LVOT = left ventricular outflow tract.

Figure 13-115: (Plate 71) *A.* Transesophageal image of a patent ductus arteriosus (PDA). Color Doppler imaging shows flow from the descending aorta (DESC AO) into the PDA. (Courtesy of Bruce J. Kimura, M.D.) *B.* Parasternal short-axis images at the aortic valve level. On the left, the pulmonary artery (PA) is somewhat enlarged. On the right, color imaging reveals diastolic flow within the PA, consistent with a patent ductus arteriosus. RV = right ventricle; RA = right atrium; LA = left atrium; AO = aorta.

Figure 13-116: Transverse transesophageal image of cor triatriatum. A membrane (*arrows*) is present in the left atrium. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-117: *A.* Transesophageal image (transverse plane) from a patient with persistent left superior vena cava. The coronary sinus (CS) is dilated. *B.* After injection of agitated saline into the left antecubital vein, contrast is seen entering the right atrium (RA) via the CS. TV = tricuspid valve; RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-118: Parasternal long-axis (*A*) and apical four-chamber (*B*) images of tetralogy of Fallot. The right ventricle (RV) is enlarged, and a large VSD is present. The aorta (AO) overrides the interventricular septum. LV = left ventricle. (Courtesy of Reinaldo W. Beyer, MD.)

Figure 13-119: Parasternal long-axis image of double-outlet right ventricle. A large VSD is present (*small arrow*) and the normal continuity between the posterior aortic wall and the anterior mitral leaflet is absent. Fibrous tissue is seen (*large arrow*) between the left atrium (LA) and the nearest great vessel (in this case, the pulmonary artery (PA). LV = left ventricle.

Figure 13-120: Transverse transesophageal image through the semilunar valves in L-transposition. The aortic valve (A) is anterior and to the left of the pulmonic valve (P). LA = left atrium.

Figure 13-121: Continuous-wave Doppler tracing of the descending aorta (from the suprasternal position) in aortic coarctation. Peak systolic velocity is approximately 3.6 m/s, and there is persistent flow during diastole, suggesting severe coarctation. D Ao = descending aorta.

Figure 13-122: (Plate 72) Apical three-chamber view of discrete subaortic stenosis. *A.* Fibromuscular ridge (*arrow*) is present in the left ventricular outflow tract. LV = left ventricle; LA = left atrium; A = aortic root. *B.* Apical five-chamber view of discrete subaortic stenosis with color-flow Doppler, demonstrating aliasing and proximal flow convergence in the left ventricular outflow tract. LV = left ventricle; LA = left atrium.

Figure 13-123: Apical four-chamber image of Ebstein's anomaly. The right heart is enlarged, and the insertion of the septal leaflet of the tricuspid valve is displaced apically. The anterior tricuspid leaflet (to the patient's right) is abnormally elongated. RV = right ventricle; RA = right atrium; LA = left atrium; LV = left ventricle. (Reproduced with permission of Joseph A. Kisslo, MD.)

Figure 13-124: Fetal echocardiogram (four-chamber view). LV = left ventricle; RV = right ventricle.

Figure 13-125: Right ventricular inflow view showing a prominent eustachian valve (*arrow*) at the junction of the inferior vena cava (IVC) and the right atrium (RA). RV = right ventricle; CS = coronary sinus. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia; Saunders; 1996:452-480, with permission.)

Figure 13-126: Apical four-chamber view demonstrating a false chord (*arrow*) within the left ventricle (LV). LA = left atrium; RA = right atrium; RV = right ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-127: Subcostal four-chamber image demonstrating a pacemaker wire (*arrows*) in the right heart. RA = right atrium; LA = left atrium; LV = left ventricle.

Figure 13-128: Transverse transesophageal image of an interatrial septal aneurysm (*arrow*). RA = right atrium; LA = left atrium. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-129: Magnified apical view of a large thrombus (T) in the apex of the left ventricle (LV). Although the thrombus is fairly homogeneous, its border is more echo-dense (*arrows*).

Figure 13-130: Parasternal long-axis view of a large mobile thrombus (*arrow*) attached to the anteroseptal segment of the left ventricle (LV). LVOT = left ventricular outflow tract; LA = left atrium. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-131: Apical four-chamber image of a large mobile "ball" thrombus (*arrow*) in the left atrium (LA). LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-132: Apical four-chamber image of a left atrial myxoma which is attached to the interatrial septum and prolapses through the mitral valve. LA = left atrium; RA = right atrium; RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging*, 2d ed. Philadelphia: Saunders, 1996:452-480, with permission.)

Figure 13-133: Apical four-chamber image of a large left atrial myxoma (*arrows*), which is attached to the lateral wall of the atrium. LA = left atrium; RA = right atrium; RV = right ventricle; LV = left ventricle; PE = pericardial effusion; PL = pleural.

Figure 13-134: Modified subcostal image showing a metastatic tumor on the epicardium (*arrows*) and a malignant pericardial effusion. RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging,* 2d ed. Philadelphia: Saunders; 1996:452-480, with permission.)

Figure 13-135: *A.* Moderate pericardial effusion (PE) on parasternal long-axis imaging. AO = aorta; LV = left ventricle; LA = left atrium. *B.* Right ventricular compression in cardiac tamponade (subcostal plane). RA = right atrium; LV = left ventricle; PE = pericardial effusion. *C.* M-mode image of cardiac tamponade and right ventricular diastolic collapse. The right ventricular (RV) free wall (*arrows*) moves posteriorly toward the interventricular septum during diastole. E = effusion; LV = left ventricle.

Figure 13-136: Apical four-chamber image in a case of malignant pericardial effusion (P). Numerous fibrinous strands are seen within the effusion. LA = left atrium; RA = right atrium; RV = right ventricle; LV = left ventricle. (From Blanchard DG, DeMaria AN. Cardiac and extracardiac masses: Echocardiographic evaluation. In: Skorton DJ, Schelbert HR, Wolf GL, Brundage BH, eds. *Marcus' Cardiac Imaging,* 2d ed. Philadelphia: Saunders, 1996:452-480, with permission.)

Figure 13-137: Parasternal long-axis view in a patient with a pleural effusion (EFF) posterior to the heart. Atelectatic lung tissue is present within the effusion. LA = left atrium; LV = left ventricle; A = aorta.

Figure 13-138: Right atrial collapse (*arrows*) in cardiac tamponade. PE = pericardial effusion; LV = left ventricle; RV = right ventricle.

Figure 13-139: Pulsed-wave Doppler tracing of left ventricular inflow in cardiac tamponade (apical transducer position). There is abnormal respiratory variation in the peak E wave velocity (which varies from 60 to 80 cm/s). E = expiration; I = inspiration.

Figure 13-140: Parasternal short-axis images of coronary artery aneurysms associated with Kawasaki's disease. *A.* The proximal left coronary artery (LCA) is seen to be diffusely dilated and aneurysmal. *B.* A proximal right coronary artery aneurysm (*arrow*) is shown. AO = aorta, LA = left atrium. (Courtesy of Victor Lucas, MD and Paul Grossfeld, MD.)

Figure 13-141: (Plate 73) Transthoracic short-axis image of a coronary artery within the interventricular septum (*arrows*). LV= left ventricle; RV = right ventricle.

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 14:

ECG EXERCISE TESTING

Author: Victor F. Froelicher

The exercise test continues to have an integral place in cardiovascular medicine because of its high yield of diagnostic, prognostic, and functional information.[1] When conducting an exercise test, the method and analysis of the data should be determined by the objective of the test. In the clinical setting, the major indications for exercise testing are the diagnosis and prognostication of heart disease. The determination of exercise capacity is helpful in quantifying disability, estimating prognosis, and monitoring the disease state of patients with chronic obstructive pulmonary disease, chronic heart disease, and known coronary heart disease. However, the major emphasis is on the analysis of the electrocardiogram (ECG) in the majority of clinical tests. Also, the reproduction of symptoms such as angina or presyncope is vital for clinical purposes.

METHODS

Excellent guidelines have been updated by organizations such as the American Heart Association, the American Association of Cardiovascular and Pulmonary Rehabilitation, and the American College of Sports Medicine that are based on a multitude of research studies over the last 20 years and have led to greater uniformity in methods.[2-4] These should be followed as closely as possible. General concerns prior to performing an exercise test include safety precautions and equipment needs, patient preparation, choosing a test type, choosing a test protocol, patient monitoring, reasons to terminate a test, and posttest monitoring.

Safety Precautions and Equipment

The safety precautions outlined by the American Heart Association are very explicit in regard to the requirements for exercise testing. Everything necessary for cardiopulmonary resuscitation must be available, and regular drills should be performed to ascertain that both personnel and equipment are ready for a cardiac emergency. The first survey of clinical exercise facilities by Rochmis and Blackburn[5] showed exercise testing to be a safe procedure, with approximately 1 death and 5 nonfatal complications per 10,000 tests. Perhaps due to an expanded knowledge concerning indications, contraindications, and end points, maximal exercise testing appears safer today than 20 years ago.[6] Gibbons et al.[7] reported the safety of exercise testing in 71,914 tests conducted over a 16-year period. The complication rate was 0.8 per 10,000 tests. The authors suggested that the low complication rate may be due to a cool-down walk, but we have observed a low complication rate despite laying patients supine immediately after the test and exercising higher-risk patients.[7]

Besides emergency equipment, the safety and accuracy of the testing equipment should be considered. The treadmill should have front and side rails for subjects to steady themselves. It should be calibrated monthly. Some models can be greatly affected by the weight of the subject and will not deliver the appropriate workload to heavy individuals. An emergency stop button should be readily available to the staff only. A small platform or stepping area at the level of the belt is advisable so that the subject can start the test by "pedaling" the belt with one foot prior to stepping on.

Although numerous clever devices have been developed to automate blood pressure measurement during exercise, none can be recommended. The time-proven method of holding the subject's arm with a stethoscope placed over the brachial artery remains most reliable. The subject's arm should be free of the handrails so that noise is not transmitted up the arm. It is sometimes helpful to mark the brachial artery. An anesthesiologist's auscultatory piece or an electronic microphone can be fastened to the arm. A device that

inflates and deflates the cuff on the push of a button can be helpful also.

Exercise Testing

PRETEST PREPARATIONS

During the pretest evaluation, the physician should establish an understanding of any patterns of cardiopulmonary compromise associated with exercise and the patient's usual level of exercise tolerance. The patient should be asked whether he or she has ever become light-headed or fainted while exercising and whether anyone in the family has died suddenly during exercise. The physician also should ask about family history and general medical history, making note of any conditions that may increase the risk of sudden death.

A brief physical examination always should be performed prior to testing to rule out significant outflow obstruction. In some instances, such as when asymptomatic, apparently healthy subjects are being tested for exercise capacity or a repeat treadmill test is being done on a patient whose condition is stable and established, a physician need not be present but should be in close proximity and prepared to respond promptly. The response to signs or symptoms should be moderated by the information the patient gives regarding his or her usual activity. If abnormal findings occur at levels of exercise that the patient usually performs, then it may not be necessary to stop the test because of them. Also, the patient's activity history should help determine appropriate target workload for testing.

Table 14-1 lists the absolute and relative contraindications to performing an exercise test, as well as the factors to consider in assessing the degree of exercise.

Table 14-1: Contraindications to Exercise Testing

ABSOLUTE
Acute myocardial infarction (within 2 d)
Unstable angina not previously stabilized by medical therapy*
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
Symptomatic severe aortic stenosis
Uncontrolled symptomatic heart failure
Acute pulmonary embolus or pulmonary infarction
Acute myocarditis or pericarditis
Acute aortic dissection
RELATIVE†
Left main coronary artery stenosis
Moderate stenotic valvular heart disease
Electrolyte abnormalities
Severe arterial hypertension‡
Tachyarrhythmias or bradyarrhythmias
Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Mental or physical impairment leading to inability to exercise adequately

High-degree atrioventricular block

*Appropriate timing of testing depends on level of risk of unstable angina, as defined by the Agency for Health Care Policy and Research Unstable Angina Guidelines.
†Relative contraindications can be superseded if the benefits of exercise outweigh the risks.
‡In the absence of definitive evidence, the committee suggests a systolic blood pressure of >200mmHg and/or diastolic blood pressure of >110 mmHg.

SOURCE: Modified from Fletcher GF, Balady G, Froelicher VF, et al. Exercise standards: A statement for healthcare professionals from the American Heart Association. Special report. *Circulation* 1995; 91:580-615.

Preparations for exercise testing include the following:

1. The subject should be instructed not to eat or smoke at least 2 hours prior to the test and to come dressed for exercise.
2. A brief history and physical examination (particularly noting systolic murmurs) should be accomplished to rule out any contraindications to testing (see Table 14-1).
3. Specific questioning should determine which drugs are being taken, and potential electrolyte abnormalities should be considered. The labeled medication bottles should be brought along so that medications can be identified and recorded. Because of a greater potential for cardiac events with the sudden cessation of β blockers, they should not be automatically stopped prior to testing but done so gradually under physician guidance, only after consideration of the purpose of the test.
4. Pretest standard 12-lead ECGs are necessary in both the supine and standing positions. Good skin preparation must cause some discomfort but is necessary for good conductance and to avoid artifacts. The changes caused by exercise electrode placement can be kept to a minimum by keeping the arm electrodes off the chest, placing them on the shoulders, and by recording the baseline ECG supine[8] (Fig. 14-1). In this situation, the modified exercise limb lead placement can serve well as the reference resting ECG prior to an exercise test.
5. Hyperventilation is not necessary prior to testing. Subjects both with and without disease may or may not exhibit **ST**-segment changes with hyperventilation; the value of this procedure in lessening the number of false-positive responders is no longer considered useful.

DURING THE TEST

Most problems can be avoided by having an experienced physician, nurse, or exercise physiologist standing next to the subject, measuring blood pressure, and assessing appearance during the test. The exercise technician should operate the recorder and treadmill, take the appropriate tracings, enter data on a form, and alert the physician to any abnormalities that may appear on the monitor scope.

Subjects should be reminded not to grasp the front or side rails because this decreases the work performed and creates noise in the ECG. Hanging on increases exercise time, resulting in an overestimation of exercise capacity.

Target heart rates based on age should not be used because the relationship between maximal heart rate and age is poor, and a wide scatter exists around the many different recommended regression lines. Such heart rate targets result in a submaximal test for some individuals, a maximal test for some, and an unrealistic goal for others. The Borg scales are an excellent means of quantifying an individual's effort. At 1- to 2-min intervals, subjects should be monitored for perceived effort level by using the 6 to 20 Borg scale or the nonlinear 1 to 10 scale of perceived exertion.[9,10]

INDICATIONS FOR TEST TERMINATION

The absolute and relative indications for termination of an exercise test listed in Table 14-2 have been derived from clinical experience. Absolute indications are clear-cut, whereas relative indications sometimes

can be disregarded if good clinical judgment is used. Absolute indications include a drop in systolic blood pressure despite an increase in workload, anginal chest pain becoming worse than usual, central nervous system symptoms, signs of poor perfusion (such as pallor, cyanosis, and cold skin), serious dysrhythmias, technical problems with monitoring the patient, patient's request to stop, and marked electrocardiographic changes, e.g., more than 0.3 mV of horizontal or downsloping ST-segment depression or 0.2 mV of ST-segment elevation. Relative indications for termination include other worrisome ST-segment or QRS changes such as excessive junctional depression; increasing chest pain; fatigue, shortness of breath, wheezing, leg cramps, or intermittent claudication; and worrisome appearance, hypertensive response (systolic pressure >260 mmHg, diastolic pressure >115 mmHg), and less serious dysrhythmias including supraventricular tachycardias. If more information is required, the test can be repeated later after symptoms have been stabilized.

Table 14-2: Indications for Terminating Exercise Testing

ABSOLUTE INDICATIONS
Drop in systolic blood pressure (persistently below (baseline) despite an increase in workload
Onset of new or increasing anginal chest discomfort
Central nervous system symptoms (ataxia, dizziness, or near syncope)
Evidence of poor peripheral perfusion (cyanosis or pallor)
Serious arrhythmias (i.e., high-grade ventricular, such as multiform complexes, triplets, and runs)
Technical difficulties in monitoring the ECG or systolic blood pressure
Patient's request to stop
RELATIVE INDICATIONS
ST or QRS changes such as excessive (≥3-4 mm) St-segment displacement, junctional depression, or marked QRS axis shift
Increasing chest discomfort
Fatigue, shortness of breath, wheezing, leg cramps, or intermittent claudication
General appearance (see discussion)
Less serious arrhythmias, including supraventricular tachycardias
Development of bundle branch block thar cannot be distinguished from ventricular tachycardia

AFTER EXERCISE

If maximal sensitivity for ischemic markers is to be achieved with an exercise test, patients should be supine during the postexercise period. It is advisable to record about 10 s of electrocardiographic data while the patient is standing motionless but still experiencing near-maximal heart rate and then have the patient lie down. Having the patient perform a cool-down walk after the test can delay or eliminate the appearance of ST-segment depression.[11] According to the law of LaPlace, the increase in venous return and thus ventricular volume in the supine position increases myocardial oxygen demand. Data from our laboratory[12] demonstrate that having patients lie down enhances ST-segment abnormalities in recovery.

Monitoring should continue for at least 5 min after exercise or until changes stabilize. An abnormal response occurring only in the recovery period is not unusual. All such responses are not false-positive results, as has been suggested. Experiments confirm mechanical dysfunction and electrophysiologic abnormalities in the ischemic ventricle following exercise. A cool-down walk can be helpful when performing tests on patients with an established diagnosis undergoing testing for other than diagnostic

reasons, when testing athletes, or when testing patients with dangerous dysrhythmias. When this is the case, it may be preferable to walk slowly (1.0-1.5 mi/h) or continue cycling against zero or minimal resistance (0-25 W when testing with a cycle ergometer) for several minutes following the test.

Exercise Test Modalities

Three types of exercise can be used to stress the cardiovascular system: isometric, dynamic, and a combination of the two. *Isometric exercise*, defined as constant muscular contraction without movement (such as handgrip), imposes a disproportionate pressure load on the left ventricle relative to the body's ability to supply oxygen. *Dynamic exercise* is defined as rhythmic muscular activity resulting in movement, and it initiates a more appropriate increase in cardiac output and oxygen exchange. Since a delivered workload can be calibrated accurately and the physiologic response measured easily, dynamic exercise is preferred for clinical testing.

Numerous modalities have been used to provide dynamic exercise for exercise testing, including steps, escalators, and ladder mills. Today, however, the bicycle ergometer and the treadmill are the most commonly used dynamic exercise devices. In cases of spinal cord injury, peripheral neuropathy, or orthopedic disorders, arm ergometry is also performed for exercise testing. A wheelchair ergometer has been developed for spinal cord-injured patients.[13]

BICYCLE ERGOMETER VERSUS TREADMILL

The bicycle ergometer is usually cheaper, takes up less space, and makes less noise. Although bicycling is a dynamic exercise, most individuals perform more work on a treadmill because a greater muscle mass is involved, and most subjects are more familiar with walking than cycling. Upper body motion is usually reduced, but care must be taken so that the arms do not perform isometric exercise. The workload administered by the simple bicycle ergometer is not well-calibrated and depends on pedaling speed. It is too easy for a subject to slow pedaling speed during exercise testing and decrease the administered workload. More expensive electronically braked bicycle ergometers keep the workload at a specified level over a wide range of pedaling speeds.

In most studies comparing upright cycle ergometer with treadmill exercise, maximal heart rate values have been demonstrated to be roughly similar, whereas maximal oxygen uptake has been shown to be 6 to 25 percent greater during treadmill exercise.[14-16]

ARM ERGOMETRY

For a given submaximal workload, arm exercise requires a greater myocardial oxygen demand than leg exercise. At maximal effort, however, physiologic responses generally are greater in leg exercise than in arm exercise. At a given power output [expressed as kilopound-meters per minute (kpm/min) or watts (W)], heart rate, systolic and diastolic blood pressure, the product of heart rate times systolic blood pressure, minute ventilation (V_E), and blood lactate concentration are higher during arm exercise. In contrast, stroke volume and the ventilatory threshold (the latter expressed as a percentage of aerobic capacity) are lower during arm exercise compared with leg exercise.[17-20] Since cardiac output is nearly the same in arm and leg exercise at a given oxygen uptake,[21] the elevated blood pressure during arm exercise is due to increased peripheral vascular resistance. Maximal oxygen uptake ($_{O_2max}$) during arm ergometry in men generally varies between 64 and 80 percent of leg ergometry Vdot;$_{O_2max}$. Similarly, maximal cardiac output is lower during arm exercise compared with leg exercise, whereas maximal heart rate, systolic blood pressure, and rate-pressure product are comparable[22] or slightly lower[23] during arm exercise.

Exercise Protocols

The many different exercise protocols in use have led to some confusion regarding how physicians compare tests between patients and serial tests in the same patient. The most common protocols, their stages, and the predicted oxygen cost of each stage are illustrated in Fig. 14-2. When treadmill and cycle ergometer testing were first introduced into clinical practice, practitioners adopted protocols used by major researchers.[24-28] The large and uneven work increments in some of these protocols have been shown to

result in a tendency to overestimate exercise capacity.[29] Investigators have since recommended protocols with smaller and more equal increments.[30,31] Recent guidelines suggest that protocols should be individualized for each subject such that test duration is approximately 8 to 12 min.

RAMP TESTING

An approach to exercise testing that has gained interest is the ramp protocol, in which work increases constantly and continuously (Fig. 14-3). The recent call for "optimizing" exercise testing would appear to be facilitated by the ramp approach, since work increments are small, and since it allows for increases in work to be individualized, a given test duration can be targeted.

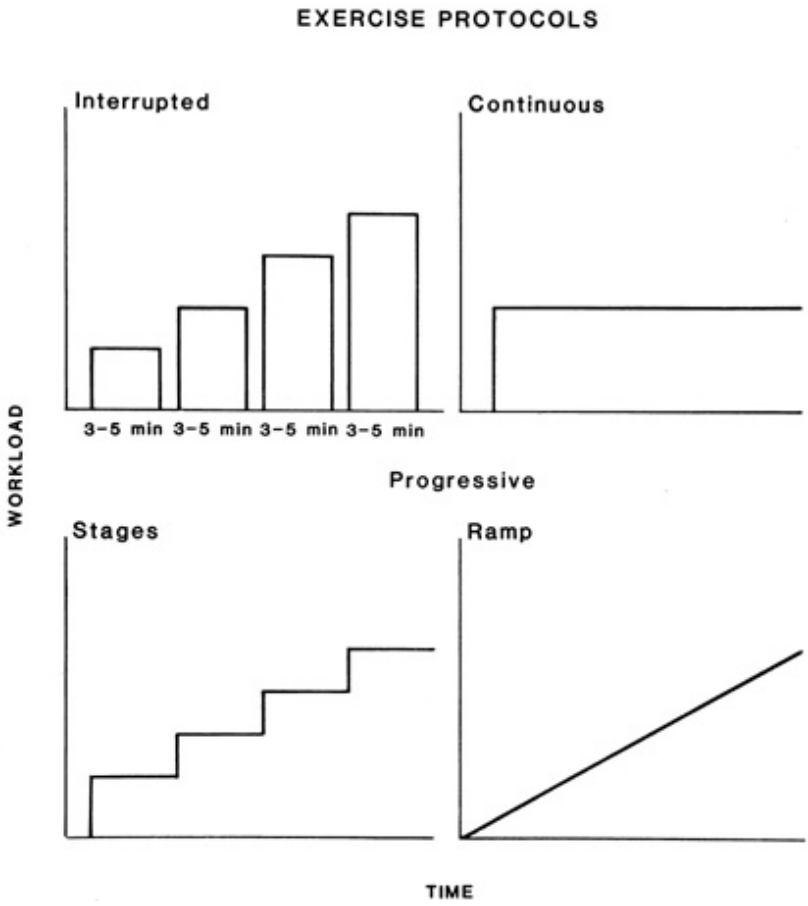

Figure 14-3: An approach to exercise testing that has gained interest is the ramp protocol, in which work increases constantly and continuously, as shown in this illustration.

To investigate this, our laboratory compared ramp treadmill and bicycle tests with protocols used more commonly clinically.[32] Ten patients with chronic heart failure, 10 with coronary artery disease who were limited by angina during exercise, 10 with coronary artery disease who were asymptomatic during exercise, and 10 age-matched normal subjects performed three bicycle tests (25 W/2-min stage, 50 W/2-min stage, and ramp) and three treadmill tests (Bruce, Balke, and ramp) in randomized order on different days. Maximal oxygen uptake was significantly higher (18 percent) on the treadmill protocols versus the bicycle protocols collectively, confirming previous observations. Only minor differences in maximal oxygen uptake, however, were observed among the treadmill protocols themselves or among the cycle ergometer protocols themselves. Our observations suggest that (1) oxygen uptake is overestimated from tests that contain large increments in work, and (2) the variability in estimating oxygen uptake from work rate is markedly greater on these tests than for an individualized ramp treadmill test.

Chapter 14: ECG EXERCISE TESTING

HEMODYNAMIC RESPONSES

Monitoring hemodynamic responses while conducting a treadmill test is vital to assessing the patient's response to exercise. Measurements are used for diagnosis and prognosis and can necessitate test termination.

Maximal Heart Rate

METHODS OF RECORDING

Although measuring a patient's maximal heart rate (HR_{max}) should be a simple matter, the different ways of recording rate and differences in the type of exercise used may affect its measurement. Heart rate drops quickly in recovery and can climb steeply even in the last seconds of exercise. Premature beats can affect averaging and must be eliminated in order to obtain the actual heart rate. Cardiotachometers are incorporated into most exercise test devices but may fail to trigger or may trigger inappropriately on T waves, artifacts, or aberrant beats, thus yielding inaccurate results.

FACTORS LIMITING MAXIMAL HEART RATE

Several factors may affect the HR_{max} during dynamic exercise. HR_{max} declines with advancing years and is affected by gender. Height, weight, and even lean body weight apparently do not affect HR_{max} very much. The physiologic limits on HR_{max} in normal men are determined by rapidity of sinus node recovery, cardiac dimensions, left ventricular filling, and contractile state. Systole has a relatively fixed time interval; in contrast, relatively less time of the cardiac cycle is spent in diastole when heart rate increases. Many studies have reported HR_{max} during treadmill testing in a variety of patients. Regressions with age have varied depending on the population studied and other factors. Figure 14-4 summarizes these studies of HR_{max}.[33,34] In an effort to clarify the relationship between HR_{max} and age, Londeree and Moeschberger[35] performed a comprehensive review of the literature compiling over 23,000 subjects aged 5 to 81 years. A stepwise multiple regression revealed that age alone accounted for 75 percent of the variability; other factors added only about 5 percent and included mode of exercise, level of fitness, and continent of origin but not sex. The 95 percent confidence interval, even when accounting for these factors, was 45 beats per minute (Fig. 14-5). Heart rates at maximal exercise were lower on bicycle ergometry than on the treadmill and lower still with swimming. Their analysis revealed that trained individuals had significantly lowered maximal heart rates. Graettinger et al.[36] from our laboratory presented clinical, echocardiographic and functional determinants of HR_{max}. Despite controlling for age, activity status, sex, and hypertension, measures of cardiac size and function added little to the prediction of HR_{max}. Most of the variance in HR_{max} was accounted for simply by age. Given the large degree of individual variability in cardiac variables, as well as the HR_{max}/age relationship, HR_{max} always may be a difficult variable to explain.

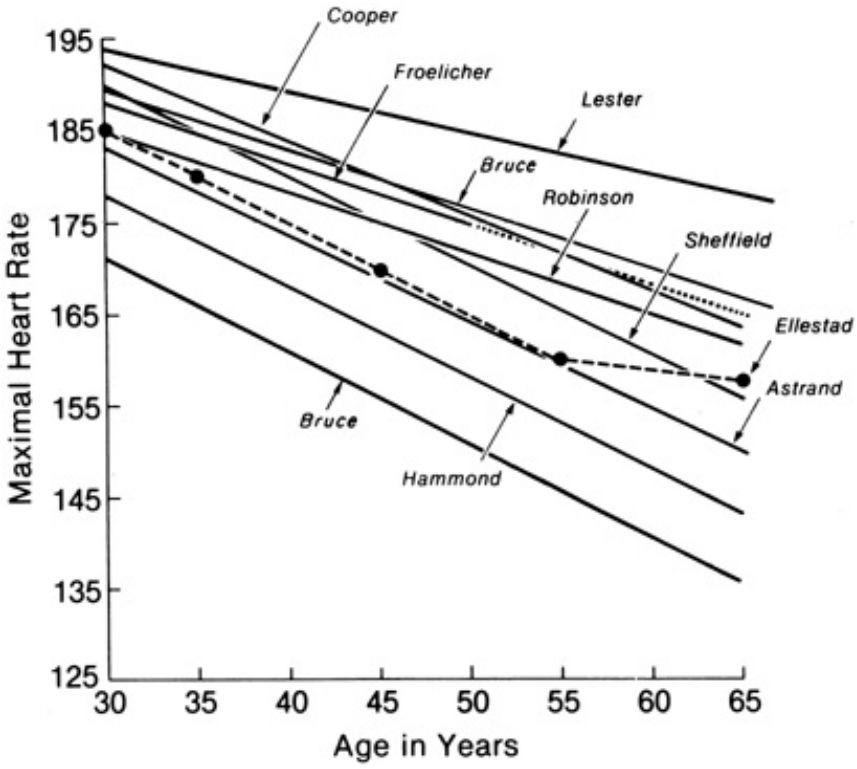

Figure 14-4: Many studies, as shown in this illustration, have reported HR_{max} during treadmill testing in a variety of patients. Regressions with age have varied depending on the population studied and other factors.

Another factor that affects HR_{max} and which is important to clinical medicine is bed rest.[37] Altitude may affect the heart rate response to exercise.[38] Some investigators report substantially lower maximal heart rates in well-trained athletes. A final factor determining maximal exercise heart rate is motivation to exert oneself maximally. Older patients may be restrained by poor muscle tone, pulmonary disease, claudication, orthopedic problems, and other noncardiac causes of limitation. The usual decline in HR_{max} with age is not as steep in people who are free from myocardial disease and stay active, but it still occurs. Recent work from the Cleveland Clinic emphasizes the prognostic importance of chronotropic incompetence or heart rate impairment and demonstrates that such a response does not make a test "inadequate."[39]

Blood Pressure Response

Systolic blood pressure should rise with increasing treadmill workload, whereas diastolic blood pressure usually remains about the same (Fig. 14-6). A rising diastolic blood pressure can be associated with coronary heart disease; however, it is more likely a marker for labile hypertension, which leads to coronary disease. A drop in systolic blood pressure below preexercise values is the most ominous criterion, whereas a drop of 20 mmHg or more without a fall below preexercise values appears to have less predictive value.[40] Exercise-induced hypotension (EIH) can be due to either left ventricular dysfunction (as reflected by myocardial infarction status), ischemia, or outflow obstruction. When EIH occurs without association with either of these two factors, EIH appears to be benign.

The highest systolic blood pressure should be achieved at maximal workload. When exercise is stopped, approximately 10 percent of people tested will abruptly drop their systolic blood pressure owing to peripheral pooling. To avoid fainting, patients should not be left standing on the treadmill. The systolic blood pressure usually normalizes on resuming the supine position during recovery but may remain below normal for several hours after the test. Irving et al.[41] examined

variations in clinical noninvasive systolic pressure at the point of symptom-limited exercise on a treadmill. Lower maximal systolic pressures often were associated with two- or three-vessel disease or reduced ejection fraction or both. The annual rate of sudden cardiac death decreased from 98 per 1000 men to 25 and 7 per 1000 men as the range of maximal systolic pressure increased from less than 140 to 140 to 199 to 200 mmHg or more, respectively.

The 3-min systolic blood pressure ratio is a useful and readily obtainable measure that can be applied in all patients who are undergoing exercise testing for the evaluation of known or suspected ischemic heart disease.[42] The ratio is calculated by dividing the systolic blood pressure 3 min into the recovery phase of a treadmill exercise test by the systolic blood pressure at peak exercise. A 3-min systolic blood pressure ratio greater than 0.90 is considered abnormal. Higher values for the ratio are associated with more extensive coronary artery disease, as well as an adverse prognosis after myocardial infarction.

Chapter 14: ECG EXERCISE TESTING

EXERCISE CAPACITY

Maximal ventilatory oxygen uptake (Vdot;$_{O_2max}$) is the greatest amount of oxygen that a person can extract from inspired air while performing dynamic exercise involving a large part of the total-body muscle mass. Since maximal ventilatory oxygen uptake is equal to the product of cardiac output and arteriovenous oxygen difference (aV_{O_2}), it is a measure of the functional limits of the cardiovascular system. Maximal a V_{O_2} difference is physiologically limited to roughly 15 to 17 mL/dL. Thus maximal a V_{O_2} difference behaves more or less as a constant, making maximal oxygen uptake an indirect estimate of maximal cardiac output.

Maximal oxygen uptake depends on many factors, including natural physical endowment, activity status, age, and sex, but it is the best index of exercise capacity and maximal cardiovascular function. As a rough reference, the maximal oxygen uptake of the normal sedentary adult is often considered approximately 30 mL O_2/kg per minute, and the minimal level for physical fitness is often considered roughly 40 mL O_2/kg per minute. In general, aerobic training can increase maximal oxygen uptake by up to 25 percent. This increase depends on the initial level of fitness and age as well as the intensity, frequency, and length of training sessions. Individuals performing aerobic training such as distance running can have maximal oxygen uptakes as high as 60 to 90 mL O_2/kg per minute. For convenience, oxygen consumption is often expressed in multiples of basal resting requirements. The metabolic equivalent (MET) is a unit of basal oxygen consumption equal to approximately 3.5 mL O_2 per kilogram of body weight per minute. This is the amount of oxygen required to sustain life in the resting state. Table 14-3 lists clinically meaningful METs for exercise, prognosis, and maximal performance.

Table 14-3: Clinically Significant Metabolic Equivalents for Maximum Exercise

1 MET*	Resting
2 METs	Level walking at 2 mi/h
4 METs	Level walking at 4 mi/h
<5 METs	Poor prognosis; usual limit immediately after myocardial infarction, peak cost of basic activities of daily living
10 METs	Prognosis with medical therapy as good as coronary artery bypass surgery
13 METs	Excellent prognosis regardless of other exercise responses
18 METs	Elite endurance athletes
20 METs	World-class athletes

*MET = metabolic equivalent, or a unit of sitting resting oxygen uptake. 1 MET = 3.5 mL/kg/min oxygen uptake.

SOURCE: From Fletcher GF, Balady G, Froelicher VF, et al. Exercise standards: A statement for health professionals from the American Heart Association Writing Group. *Circulation* 1995; 91:580-615. Reproduced with permission from the publisher and authors.

It is preferable to estimate an individual's maximal oxygen uptake from the workload reached while performing an exercise test. Maximal oxygen uptake is, of course, most precisely determined by direct measurement using ventilatory gas-exchange techniques. Thus, if quantifying work with precision is an important objective, such as in athletics, research studies, and patients considered for cardiac transplantation, a direct measurement is essential. *Clinical exercise test results always should be reported in METs and not minutes of exercise.* In this way, the results from different protocols and exercise modalities can be compared directly.

NORMAL VALUES FOR EXERCISE CAPACITY

Maximal oxygen uptake declines with increasing age, and higher values are observed among men compared with women. Thus, when measuring or estimating maximal oxygen uptake, it is useful to have reference values for comparison. Many clever attempts have been made to improve the prediction of what represents a "normal" exercise capacity by including height, weight, body composition, activity status, exercise mode, and such clinical and demographic factors as smoking history, heart disease, and medications.[43] It is important to note that a "normal" value is only a number that has been inferred from some population. A predicted normal value usually refers to age and gender, but many other factors affect one's exercise capacity. In addition to those just mentioned, such factors include some that are not so easily measured, such as genetics and the type and extent of disease.

Regression Equations

The following are commonly used generalized equations based on data published[44-47] in North America and Europe in the 1950s, 1960s, and 1970s:

Males:

$$\dot{V}O_2max\ (L/min) = 4.2 - 0.032\ (age)\ (SD \pm 0.4)$$
$$\dot{V}O_2max\ (mL/kg/min) = 60 - 0.55\ (age)\ (SD \pm 7.5)$$

Females:

$$\dot{V}O_2max\ (L/min) = 2.6 - 0.014\ (age)\ (SD \pm 0.4)$$
$$\dot{V}O_2max\ (mL/kg/min) = 48 - 0.37\ (age)\ (SD \pm 7.0)$$

Application of Nomograms

Morris et al.[48] developed a nomogram from 1388 male veteran patients (Fig. 14-7). The regression equations derived from the group were:

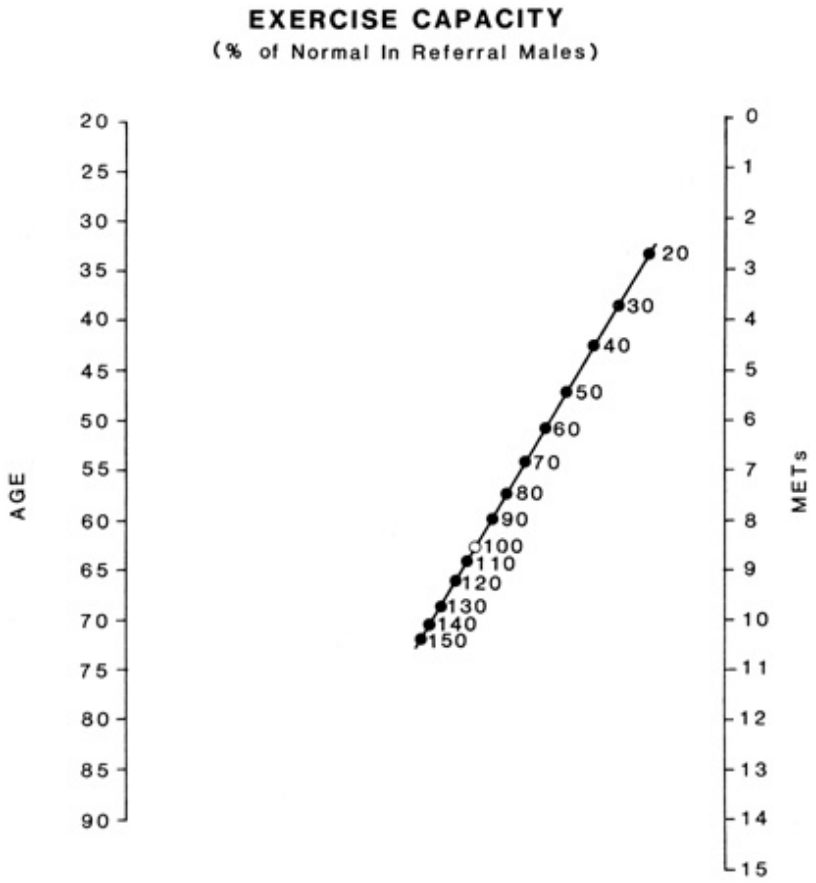

Figure 14-7: The exercise capacity nomogram providing a relative estimate of normal for age, with 100 percent being as expected for age in a clinical population.

All subjects:

$$\text{METs} = 18.0 - 0.15(\text{age}), \text{SEE} = 3.3, r = -0.46, p < 0.001$$

Active subjects:"

$$\text{METs} = 18.7 - 0.15(\text{age}), \text{SEE} = 3.0, r = -0.49, p < 0.001$$

Sedentary subjects:

$$\text{METs} = 16.6 - 0.16(\text{age}), \text{SEE} = 3.2, r = -0.43, p < 0.001$$

When using regression equations or nomograms for reference purposes, it is important to consider several points. First, as mentioned, the relationship between exercise capacity and age is rather poor (r = 0.30 to 0.60). Second, nearly all equations are derived from different populations using different protocols. Thus, to some extent, they are both population- and protocol-specific. Moreover, since treadmill time or workload tends to overpredict maximal METs, it is important to consider whether gas-exchange techniques were used in developing the equations. For example, the equations developed by Morris et al.[48] were derived from a large group of veterans referred for testing for clinical reasons. Thus they had a greater prevalence of heart disease than patients in the other studies, and it is not surprising that a steeper slope was present with a faster decline in $_{O_2max}$ with age.

To account for the differences in measured versus predicted oxygen uptake, a nomogram also was developed using measured oxygen uptake among 244 active or sedentary apparently healthy males (Fig. 14-

8). The MET values are shifted downward roughly 1.0 to 1.5 METs for any given age, reflecting the lower but more precise measures of exercise capacity:

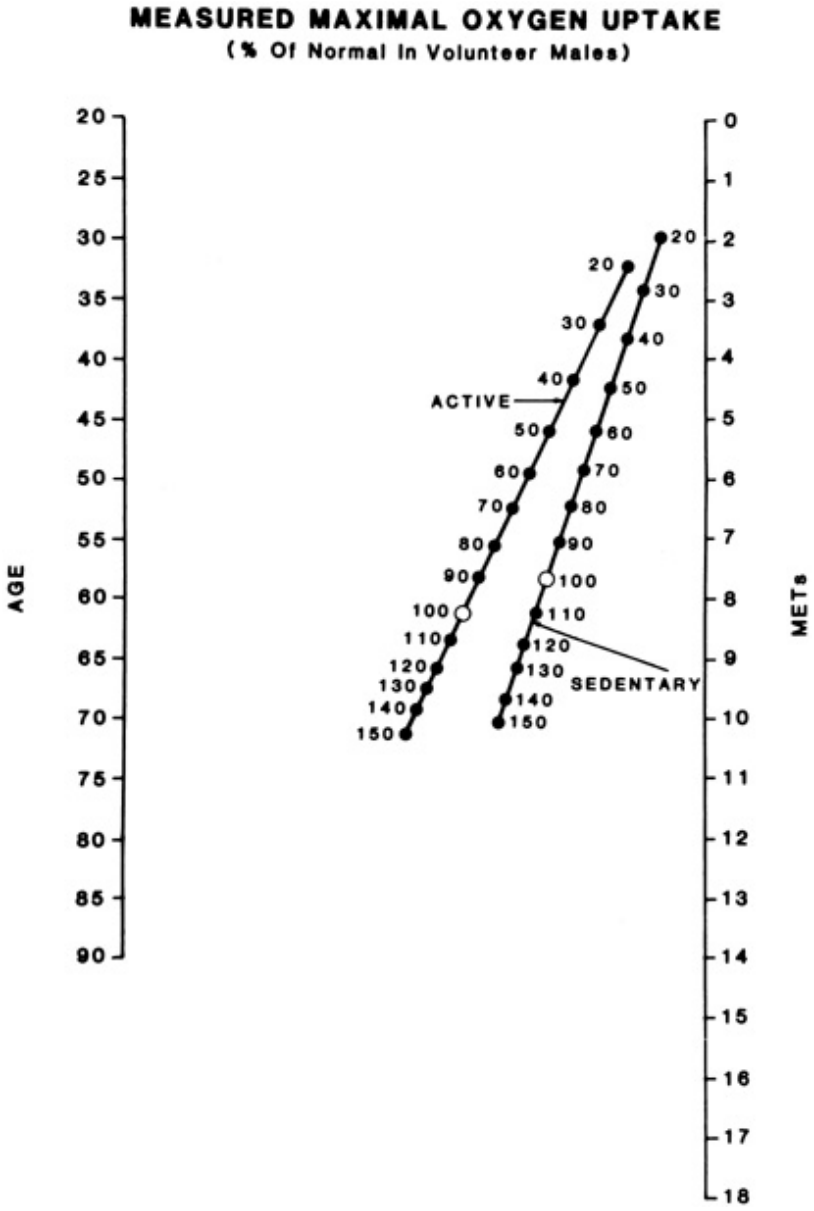

Figure 14-8: The exercise capacity nomogram for estimating aerobic impairment in normal male volunteers.

All subjects:

$$METs = 14.7 - 0.11(age)$$

Active subjects:"

$$METs = 16.4 - 0.13(age)$$

Sedentary subjects:

$$METs = 11.9 - (-0.07)(age)$$

Thus such scales are specific to both the population tested and to whether oxygen uptake was measured directly or predicted. Within these limitations, these equations and the nomograms derived from them can provide reasonable references for normal values and can facilitate communication with patients and between physicians regarding their level of exercise capacity in relation to their peers.

Chapter 14: ECG EXERCISE TESTING

ECG INTERPRETATION

ST Analysis

ST-segment depression is a representation of global subendocardial ischemia, with a direction determined largely by the placement of the heart in the chest. ST-segment depression does not localize coronary artery lesions. V_5 is the lead predominating in significant ST-segment depression. Depression isolated to other leads is usually due to Q-wave distortion of the resting ECG. ST-segment depression in the inferior leads (II, aV_F) is most often due to the atrial repolarization wave that begins in the PR segment and can extend to the beginning of the ST segment. When ST-segment depression is isolated to these leads and there are no diagnostic Q waves, it is usually a false-positive response.[48] ST-segment depression limited to the recovery period does not generally represent a false-positive response. Inclusion of analysis during this time period increases the diagnostic yield of the exercise test.

When the resting ECG shows Q waves of an old myocardial infarction, ST-segment elevation is due to wall-motion abnormalities, whereas accompanying ST-segment depression can be due to a second area of ischemia or reciprocal changes. When the resting ECG is normal, exercise-induced ST-segment elevation is due to severe ischemia (spasm or a critical lesion), although accompanying ST-segment depression is reciprocal. Such ST-segment elevation is uncommon and very arrhythmogenic, and it localizes the involved coronary artery. Exercise induced ST-segment elevation (not over diagnostic Q waves) and ST-segment depression both represent ischemia, but they are quite distinctive: Elevation is due to transmural ischemia, is arrhythmogenic, has a 0.1 percent prevalence, and localizes the artery where there is spasm or a tight lesion, whereas depression is due to subendocardial ischemia, is not arrhythmogenic, has a 5 to 50 percent prevalence, is rarely due to spasm, and does not localize. Figure 14-9 illustrates the various patterns. The standard criterion for abnormal is 1 mm of horizontal or downsloping ST-segment depression below the PR isoelectric line or 1 mm further depression if there is baseline depression. While computer analysis can help interpretation, the raw data always should be considered first because processing can cause artifacts.[49] Also, though numerous computerized ST-segment scores have been recommended, they only appear to be equivalent to visual interpretation using standard criteria. Most information is available in lead V_5, with maximal exercise and 3 min of recovery being the most important times to look for ST-segment depression.[50] ECG recordings should continue for 5 min in recovery or until any new changes from baseline stabilize.

Nonsustained ventricular tachycardia is uncommon during routine clinical treadmill testing (prevalence <2 percent) and is well tolerated, and its prognosis is determined by the accompanying ischemia and left ventricular damage.[51]

Chapter 14: ECG EXERCISE TESTING

THE ACC/AHA GUIDELINES FOR THE USE OF THE STANDARD EXERCISE TEST

The task force to establish guidelines for the use of exercise testing produced guidelines in 1986 and 1997.[52] The most recent publication had some dramatic changes from the first, including the recommendation that the standard exercise test be the first diagnostic procedure in women and in most patients with resting ECG abnormalities rather than performing imaging studies. The following classifications were used to summarize the indications for exercise testing:

- *Class I:* Conditions for which there is evidence and/or general agreement that the exercise test is useful and effective (appropriate).
- *Class II:* Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of the exercise test.
- *Class IIa:* Weight of evidence/opinion is in favor of usefulness/efficacy (probably appropriate).
- *Class IIb:* Usefulness/efficacy is less well established by evidence/opinion (maybe appropriate).
- *Class III:* Conditions for which there is evidence and/or general agreement that the exercise test is not useful/effective and in some cases may be harmful (not appropriate).

Patients who are candidates for exercise testing may have stable symptoms of chest pain, may be stabilized by medical therapy following symptoms of unstable chest pain, or may be postmyocardial infarction or postrevascularization patients. The indications provided in the guidelines are summarized below.

For Diagnosis of Coronary **Artery** Disease

Exercise testing for the diagnosis of obstructive coronary artery disease is one of the most common uses of exercise testing. Most relative evidence for this use has been gathered in patients presenting with chest pain, although it has been logically extended to those with other symptomology or ECG changes possibly due to coronary artery disease. Appropriate evidence-based use of the test for this application (class I) is in adult patients (including those with complete right bundle branch block or less than 1 mm of resting ST-segment depression) with an intermediate pretest probability of coronary artery disease based on gender, age, and symptoms (Table 14-4) (see also Chap. 40). A probable diagnostic use of the test (less evidence) is in patients with vasospastic angina (class IIa). The efficacy is less well established by evidence/opinion (class IIb) in patients with a low or high pretest probability of coronary artery disease by age, symptoms, and gender and in patients with less than 1 mm of baseline ST-segment depression and taking digoxin or with left ventricular hypertrophy. The exercise ST-segment analysis should not be used for diagnosis (class III) in patients with Wolff-Parkinson-White syndrome, left bundle-branch block, electronic pacemakers, or greater than 1 mm of resting ST-segment depression. Patients with a documented myocardial infarction or prior coronary angiography or intervention demonstrating significant disease should not be tested for diagnosis because they have an established diagnosis of coronary artery disease; however, ischemia and risk can be determined by testing.

Table 14-4: Pretest Probability of Coronary Artery Disease by Symptoms, Gender, and Age

Age	Gender	Typical/Definite Angina Pectoris	Atypical/Probable Angina Pectoris	Nonanginal Chest Pain	Asymptomatic
30-39	Males	Intermediate	Intermediate	Low (<10%)	Very low (<5%)
	Females	Intermediate	Very low (<5%)	Very low	Very low
40-49	Males	High	Intermediate	Intermediate	Low
	Females	Intermediate	Low	Very low	Very low
50-59	Males	High (>90%)	Intermediate	Intermediate	Low
	Females	Intermediate	Intermediate	Low	Very low
60-69	Males	High	Intermediate	Intermediate	Low
	Females	High	Intermediate	Intermediate	Low
High = >90%		Intermediate = 10-90%		Low =<10%	Very Low = <5%

NOTE: There are no data for patients or athletes younger than age 30 or older than age 69, but it can be assumed that coronary artery disease prevalence increases with age.

Diagnostic testing is most valuable in patients with an intermediate pretest probability. Exercise testing for the diagnosis of coronary artery disease is expressed most commonly by sensitivity and specificity. Results of correlative studies have been divided over the use of 50 or 70 percent luminal diameter occlusion. Metaanalysis of 58 consecutively published reports involving 11,691 patients without prior myocardial infarction who underwent coronary angiography and exercise testing revealed a wide variability in sensitivity and specificity.[53] Mean sensitivity was 67 percent, and mean specificity was 72 percent. In the studies where workup bias was avoided by having the patients with chest pain agree to undergo both procedures, the approximate sensitivity and specificity of 1 mm of horizontal or downsloping ST-segment depression for diagnosis of coronary artery disease were 50 and 90 percent, respectively.[54] The true diagnostic value of the exercise ECG lay in its relatively high specificity, but the sensitivity can be enhanced by consideration of clinical and hemodynamic variables in scores.

Screening for Silent Coronary Artery Disease in Asymptomatic Individuals

A diagnostic test such as the exercise ECG can be used to screen asymptomatic individuals for coronary artery disease. As mentioned previously, there are 12 studies using the exercise test to do such.[55] Patients were screened for silent heart disease using the exercise test and followed for 5 to 10 years for cardiac events. Considerably different results were obtained in these studies according to the end points considered. When angina is included as an end point, nonspecific symptoms in a subject with an abnormal test are more likely to be called coronary artery disease during the follow-up period. Hard end points, such as death or myocardial infarction, eliminate this misclassification and are more appropriate. The first eight screening studies included angina as an end point; the last four have used only hard end points. In Table 14-5, the first eight studies tested 5000 subjects and ranged in size from 113 to 1390 individuals. Sensitivity was 50 percent, specificity was 90 percent, the risk ratio was 9, and the predictive value of a positive response was 25 percent. This means that 1 of 4 patients with abnormal tests went on to have a cardiac event. Remember that some of these events will be angina, which probably was not actually due to coronary artery disease or truly angina. The last four studies have been larger in size and have included only hard end points. The sensitivity of the test has been about 25 percent, specificity about 90 percent, the risk ratio was 4, and the predictive value of a positive response was only 5 percent. This means that only 1 of 20 people with an abnormal test went on to a cardiac event. Because of this very limited predictive value, in any asymptomatic population, screening has not been recommended. It will lead to many other unnecessary tests. Attempts to raise the pretest probability by considering risk factors have not been able to limit the

false-positive results and improve the predictive value. Theoretically, this should be possible by using a risk factor score.

Table 14-5: The Twelve Screening Studies

Study	No. of Patients	Sensitivity	Specificity	Relative Risk	Predictive Value (+)
First 8 (soft end points)	5526	50%	90%	9×	25%
Last 4 (hard end points)	12,212	25%	90%	4×	5%

Using soft end points exaggerates the sensitivity and predictive value of the test. This could be avoided by blinding all parties to the test result, but this has been considered unethical. Since some of the asymptomatic individuals developing chest pain really have angina due to coronary artery disease, the sensitivity probably lies between the 25 and 50 percent obtained in the studies that used respectively hard and hard plus soft end points. While soft end points are very appropriate for intervention studies, they can result in important prediction errors in studies of diagnostic procedures.

Screening studies have other important population selection considerations. First, the population should truly be asymptomatic and should represent a random sample of the target population. Volunteers are not appropriate because they usually represent the extremes of the population: the healthiest and those who are concerned for personal reasons regarding their health (i.e., family history, symptoms they chose to deny, etc.). Volunteers represent a subtle form of limited challenge.

There is no class I indication for the use of the exercise test in asymptomatic persons without known coronary artery disease because the available evidence demonstrates a large number of false-positive results in low-prevalence populations.

The efficacy of using the exercise test in evaluation of persons with multiple risk factors or of asymptomatic men older than 40 years and women older than 50 years who plan to start vigorous exercise (especially if sedentary) or who are involved in occupations in which impairment may have an impact on public safety or who are at high risk for coronary artery disease due to other diseases (e.g., chronic renal failure) is possibly but not definitely supported by evidence (class IIb).

The test should not be used for routine screening (class III) of asymptomatic men or women.

COMPARISON WITH OTHER DIAGNOSTIC TESTS

While the studies of the standard exercise test have been helpful in illustrating the problems in demonstrating test characteristics, newer technologies often have been evaluated by studies with the same limitations. Nonetheless, it is appropriate to compare the newer diagnostic modalities with the standard exercise test because it is a mature, established technology. The equipment and personnel for performing it are readily available. Exercise testing equipment is relatively inexpensive, so replacement or updating is not a major limitation. The exercise test can be performed in the doctor's office and does not require injections or exposure to radiation. It can be an extension of the medical history and physical examination, providing more than simply diagnostic information. Furthermore, it can determine the degree of disability and impairment to quality of life as well as be the first step in rehabilitation and altering a major risk factor (physical inactivity).

Some of the newer add-ons or substitutes for the exercise test have the advantage of being able to localize ischemia as well as diagnose coronary artery disease when the baseline ECG negates ST-segment analysis (more than 1 mm of ST-segment depression, left bundle branch block, Wolff-Parkinson-White syndrome). The substitutes for exercise also have the advantage of not requiring the patient to exercise and are particularly valuable clinically for those unable to ambulate. However, while the newer technologies appear to have better diagnostic characteristics, this is not always the case, particularly when more than the ST segments from the exercise test are used in scores.

Test evaluation has been advanced by the critical analysis of Feinstein[56,57] and Guyatt.[58] A number of researchers have applied these guidelines along with meta-analyses to reach a consensus on the diagnostic characteristics of the available tests for angiographic coronary **artery** disease.[59,60] Table 14-6 presents some of the results from meta-analyses and from multicenter studies. Techniques listed include electron-beam computed tomography (EBCT), a radiographic technique that can make a quantitative measurement of coronary artery calcification.[61,62] Nuclear perfusion imaging includes both the early studies mainly using thallium radiographic images and the more modern use of single-photon-emission computed tomography (SPECT), which requires computer enhancement of the emissions of thallium and other agents.

Table 14-6: Comparison of Exercise Testing and Add-Ons or Other Test Modalities

Grouping	No. of Studies	Total No. of Patients	Sensitivity	Specificity	Predictive Accuracy
Meta-analysis of standard exercise ECG	147	24,047	68%	77%	73%
Excluding myocardial infarction patients	58	11,691	67%	72%	69%
Limiting workup bias	2	>1,000	50%	90%	69%
Meta-analysis of exercise test scores	24	11,788			80%
Thallium scintigraphy	59	6,038	85%	85%	85%
SPECT without myocardial infarction	27	2,136	86%	62%	74%
Exercise ECHO	58	5,000	84%	75%	80%
Exercise ECHO excluding myocardial infarction patients	24	2,109	87%	84%	85%
Nonexercise stress tests					
Persantine thallium	11	<1,000	85%	91%	87%
Dobutamine ECHO	5	<1,000	88%	84%	86%
Electron-beam computed tomography (EBCT)	5	2,373	90%	45%	61%

Since sensitivity and specificity are inversely related and altered by the chosen cut point for normal/abnormal, the predictive accuracy (percentage of patients correctly classified as normal and abnormal) is a convenient way to compare tests. For instance, while the sensitivity and specificity for exercise testing and EBCT are nearly opposite, the predictive accuracy of the tests is similar. This means that altering their cut points (i.e., lowering the amount of ST-segment depression or raising the calcium score) would result in similar sensitivities and specificities. Since predictive accuracy can be thought of as the number of individuals correctly classified out of 100 tested, simply subtracting predictive accuracy provides an estimate of how many more patients are classified by substituting one test for another test. However, this does assume a disease prevalence of 50 percent that is the intermediate probability for appropriateuse of diagnostic tests (i.e., predictive accuracy is affected by disease prevalence).

While the nonexercise stress tests are very useful, the results shown in Table 14-6 are probably better than their actual performance because of patient selection. For studies of diagnostic characteristics, patients with

a prior myocardial infarction should be excluded because diagnosis of coronary artery disease is already known to be present.

EXERCISE TEST SCORES

The exercise testing studies that have considered additional information besides the ST-segment response have been reviewed and demonstrate the improved test characteristics obtained using this approach.[63] Recent publications have extended the Duke prognostic score to diagnosis,[64] and a consensus approach that uses a number of equations appears to make the scores more applicable to other populations.[65]

EXERCISE NUCLEAR PERFUSION AND ECHOCARDIOGRAPHY

A review of the contemporary literature compared the diagnostic performance of exercise echocardiography and exercise nuclear perfusion scanning in the diagnosis of coronary artery disease (see Chaps. 13 and 16).[66] Studies published between January 1990 and October 1997 were identified from MEDLINE search, bibliographies of reviews and original articles, and suggestions from experts in each area. Articles were included if they discussed exercise echocardiography and/or exercise perfusion imaging for detection and/or evaluation of coronary artery disease, if data on coronary angiography were presented as the reference test, and if the absolute numbers of true-positive, false-negative, true-negative, and false-positive observations were available or derivable from the data presented. Studies performed exclusively in patients after myocardial infarction, with coronary interventions, or with recent unstable coronary syndromes were excluded. Two reviewers used a standardized spreadsheet to independently extract data with discrepancies and resolve them by consensus. Forty-four articles met inclusion criteria: 24 reported exercise echocardiography results in 2637 patients with a weighted mean age of 59 years, 69 percent men, 66 percent with angiographic coronary artery disease, and 20 percent with prior myocardial infarction, and 27 reported exercise SPECT in 3237 patients, 70 percent men, 78 percent with angiographic coronary artery disease, and 33 percent with prior myocardial infarction. In pooled data weighted by the sample size of each study, exercise echocardiography had a sensitivity of 85 percent (95% CI, 83-87 percent) with a specificity of 77 percent (95% CI, 74-80 percent). Exercise perfusion yielded a similar sensitivity of 87 percent (95% CI, 86-88 percent) but a lower specificity of 64 percent (95% CI, 60-68 percent).

ELECTRON-BEAM COMPUTED TOMOGRAPHY

Of the angiographic correlative studies of EBCT, we selected the five with more than 200 subjects without overlapping populations. One hundred and sixty men and women with coronary artery disease (45-62 years of age), of whom 138 had obstructive coronary artery disease and 22 had normal coronary arteries, and 56 age-matched healthy control subjects underwent double-helix CT.[67] Sensitivity in detecting obstructive coronary artery disease was high (91 percent); however, specificity was low (52 percent) because of calcification in nonobstructive lesions. A multicenter study evaluated patients referred for angiography.[68] Four hundred and ninety-one symptomatic patients underwent coronary angiography and EBCT at five different centers between 1989 and 1993. Sensitivity of any detectable calcification by EBCT as an indicator of significant stenosis (>50 percent narrowing) was 92 percent, and specificity 43 percent. When these CT images were reinterpreted in a blinded and standardized manner, however, specificity was only 31 percent. In another multicenter study[69] of 710 enrolled patients, 427 had significant angiographic coronary artery disease, and coronary artery calcification was detected in 404, yielding a sensitivity of 95 percent. Of the 283 patients without angiographically significant disease, 124 had negative EBCT studies, for a specificity of 44 percent. Ultrafast CT was used to detect and quantify coronary artery calcium levels in 584 subjects, 19 percent of whom had clinical coronary artery disease.[70] Sensitivity, specificity, and predictive values for clinical coronary artery disease were calculated for several total calcium scores in each decade. For age groups 40 to 49 and 50 to 59 years, a total score of 50 resulted in sensitivities of 71 and 74 percent, respectively, and specificities of 91 and 70 percent, respectively. For the age group 60 to 69 years, a total score of 300 gave a sensitivity of 74 percent and a specificity of 81 percent. Three hundred and sixty-eight symptomatic patients underwent coronary angiography and EBCT at four different centers between April 1989 and December 1993.[71] One hundred and fifty-eight patients (43 percent) had angiographically obstructive coronary artery disease (>50 percent), and 297 (81 percent) had coronary calcification. It appears that even the best studies of EBCT suffer from limited challenge and workup bias so that the true characteristics of this procedure are not known. However, the five studies averaged in the table

demonstrated a high sensitivity and a low specificity, with a predictive accuracy of about 61 percent. While adjusting the cut point for calcium density can alter the sensitivity and specificity, EBCT is not more diagnostic for angiographic coronary artery disease than the standard exercise test (see Chaps. 17 and 40).

For Risk Assessment and Prognosis

Risk assessment (prognostication) and postmyocardial infarction are the next two applications of the standard exercise ECG. The test should not be performed in these situations in patients with severe comorbidity likely to limit life expectancy and/or candidacy for revascularization (class III).

The second major application of the exercise ECG test is for assessment of risk and prognosis in patients with symptoms or a prior history of coronary artery disease. Appropriate evidence-based use of the test for this application (class I) is in patients undergoing initial evaluation or in patients with significant change in clinical status with suspected or known coronary artery disease.

Exercise testing may be useful for prognostic assessment of patients on digoxin or with abnormal resting ECGs, but its usefulness is less well established in this setting (class IIb). Also, the exercise test may still provide prognostic information (particularly exercise capacity) in patients with preexcitation, ventricular paced rhythm, more than 1 mm of ST-segment depression, and left bundle-branch block but cannot be used to identify ischemia. The test also may be used in patients with a stable clinical course who undergo periodic monitoring to guide treatment. The Duke treadmill score (see nomogram in Fig. 14-10) incorporates two of the major prognostic markers (i.e., exercise capacity[72] and exercise-induced ischemia) and was strongly recommended.[73]

After Myocardial Infarction

The third major application of the exercise ECG is for patients within 2 months of a myocardial infarction.[74] Appropriate evidence-based uses of the test for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation of these patients (class I) are (1) before discharge for prognostic assessment, activity prescription, or evaluation of medical therapy (submaximal at about 4-7 days), (2) early after discharge if the predischarge exercise test was not done (symptom-limited, about 14-21 days), and (3) late after discharge if the early exercise test was submaximal (symptom-limited, about 3-6 weeks). A probable postmyocardial infarction use of the test (less evidence) is for activity counseling and/or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization (class IIa). The efficacy is less well established by evidence/opinion (class IIb) before discharge in patients who have undergone cardiac catheterization to identify ischemia in the distribution of a coronary lesion of borderline severity or in those with the above-mentioned ECG abnormalities that interfere with the recognition of ischemia or for periodic monitoring in patients who continue to participate in exercise training or cardiac rehabilitation.

A meta-analysis of 28 studies involving 15,613 patients found that markers of ventricular dysfunction were more accurate predictors of adverse cardiac events after myocardial infarction than measures of exercise-induced ischemia.[75] A similar study in the postthrombotic age considered other test modalities and validated these conclusions.[76-78]

Exercise Testing Using Ventilatory Gas Analysis

Evidence supports the addition of ventilatory gas analysis to the exercise test (class I) for the evaluation of exercise capacity and response to therapy in patients with heart failure who are being considered for heart transplantation and when assistance is needed in differentiating cardiac versus pulmonary limitations as a cause of exercise-induced dyspnea or impaired exercise capacity.

A probable reason to add gas analysis to the exercise test (less evidence, class IIa) is for the evaluation of exercise capacity when indicated for medical reasons in patients in whom subjective assessment of maximal exercise is unreliable.

The efficacy of adding gas analysis is less well established by evidence/opinion (class IIb) for evaluation of the patient's response to specific therapeutic interventions in which improvement of exercise tolerance is an important goal or end point or for determination of the intensity for exercise training as part of comprehensive cardiac rehabilitation.

Expired gas analysis is not indicated (class III) routinely to evaluate exercise capacity.

Valvular Heart Disease

There is no evidence-based class I indication for testing patients with valvular heart disease. The test possibly can be used, although there are no convincing data to evaluate exercise capacity in patients with valvular heart disease (class IIb). The exercise ECG should not be used to diagnose coronary artery disease in patients with valvular heart disease (class III).

Before and After Revascularization

The evidence supports the use of the exercise ECG test to demonstrate ischemia before revascularization and to evaluate patients with recurrent symptoms suggesting ischemia after revascularization (class I).

A probable use of the test (less evidence) is after discharge for activity counseling and/or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization (class IIa). The efficacy is less well established by evidence/opinion (class IIb) for detection of restenosis in selected high-risk asymptomatic patients within the first months after angioplasty or for periodic monitoring of selected high-risk asymptomatic patients for restenosis, graft occlusion, or disease progression.

The test should not be used to localize ischemia for determining the site of intervention or for routine periodic monitoring of asymptomatic patients after percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass grafting without specific indications (class III).

Since the guidelines were published, investigators have found nuclear perfusion exercise testing to be important in prognostication in patients after coronary artery bypass grafting.[78]

Investigation of Heart Rhythm Disorders

The exercise test should be used to identify the appropriate settings in patients with rate-adaptive pacemakers (class I).

A probable use of the test (less evidence) is for evaluation of patients with known or suspected exercise-induced arrhythmias or for evaluation of medical, surgical, or ablative therapy in patients with exercise-induced arrhythmias (including atrial fibrillation) (class IIa). The efficacy is less well established by evidence/opinion for investigation of isolated ventricular ectopic beats in middle-aged patients without other evidence of coronary artery disease (class IIb).

The test should not be used to investigate isolated ectopic beats in young patients (class III).

Chapter 14: ECG EXERCISE TESTING

SUMMARY

While cardiologists are frequently relinquishing the performance of the standard exercise test to internists and family practitioners, it is important that the latter be properly trained to do it correctly and have expertise in its interpretation. However, the addition of echocardiography or myocardial perfusion imaging does not negate the importance of the ECG or clinical and hemodynamic responses to exercise. The exercise test complements the medical history and the physical examination, and it remains the second most commonly performed cardiologic procedure next to the routine ECG. The renewed efforts to control costs undoubtedly will support the role of the exercise test. Convincing evidence that treadmill scores enhance the diagnostic and prognostic power of the exercise test certainly has cost-efficacy implications. In addition, there is also evidence that measurement of expired gases improves the prognostic power of the test in certain groups of patients and helps to determine if exercise intolerance is due to the heart or the lungs.

Use of proper methodology is critical for safety and obtaining accurate and comparable results. The use of specific criteria for exclusion and termination, interaction with the subject, and appropriate emergency equipment are essential. The exercise protocol should be progressive, with even increments in speed and grade whenever possible.

The following rules are important to follow for getting the most information from the standard exercise test:

- The treadmill protocol should be adjusted to the patient, and one protocol is not appropriate for all patients; consider using a manual or automated ramp protocol.
- Report exercise capacity in METs, not minutes of exercise.
- Hyperventilation prior to testing is not indicated.
- ST-segment measurements should be made at ST0 (J-junction) and ST-segment depression should only be considered abnormal if horizontal or downsloping.
- Raw ECG waveforms should be considered first and then supplemented by computer-enhanced (filtered and averaged) waveforms when the raw data are acceptable.
- Patients should be placed supine as soon as possible after exercise, with a cool-down walk avoided in order for the test to have its greatest diagnostic value.
- The 3-min recovery period is critical to include in analysis of the ST-segment response.
- Measurement of systolic blood pressure during exercise is extremely important, and exertional hypotension is ominous; at this point, only manual blood pressure measurement techniques are valid.
- Age-predicted heart rate targets are largely useless because of the wide scatter for any age; a relatively low heart rate can be maximal for a patient of a given age and submaximal for another. Thus a test should not be considered nondiagnostic if a percentage of age-predicted maximal heart rate (i.e., 85 percent) is not reached. In fact, chronotropic incompetence or heart rate impairment has important prognostic implications.
- Calculation of the Duke treadmill score for every patient should be considered.
- Other predictive equations should also be considered as part of the treadmill report.

To ensure the safety of exercise testing, the following list of the most dangerous circumstances in the exercise testing laboratory should be recognized:

- Testing patients with aortic valvular disease should be done with great care because they may develop severe cardiovascular complications. Thus, a physical examination including assessment of systolic murmurs should be done before all exercise tests. If a significant murmur is heard, an echocardiogram should be considered.
- When patients exhibit ST-segment elevation without diagnostic Q waves due to transmural ischemia, this can be associated with dangerous arrhythmias and infarction. The incidence is about 1 in 1000 clinical tests and usually occurs in V_2 or aV_F rather than V_5.
- When a patient with an ischemic cardiomyopathy exhibits severe chest pain due to ischemia (angina pectoris), a cool-down walk is advisable because the ischemia can worsen in the recovery period.
- When a patient develops exertional hypotension accompanied by ischemia (angina or ST-segment depression) or when it occurs in a patient with a history of congestive heart failure, cardiomyopathy, or recent myocardial infarction, safety is a serious issue.
- When a patient with a history of sudden death or collapse during exercise develops premature ventricular contractions that become frequent, a cool-down walk is advisable because the premature ventricular contractions can increase in recovery, particularly after an abrupt cessation of exercise.

The ACC/AHA guidelines for exercise testing clearly indicate the correct uses of exercise testing. Since the last guidelines, it has been extended as the first diagnostic test in women and in individuals with right bundle branch block and resting ST-segment depression. The Duke prognostic nomogram and scores increase the value of the exercise test. In fact, the use of scores results in test characteristics that approach the nuclear and echocardiographic add-ons to the exercise test.

Part 2: GENERAL EVALUATION OF THE PATIENT
Chapter 15:

CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

Authors: Robert H. Franch, John S. Douglas, Jr., Spencer B. King III, Morton J. Kern

In 1929, Werner Forssman, a resident surgeon at Eberswalde, catheterized his right atrium from a left antecubital vein cutdown using self-fluoroscopy with a mirror. The position of the catheter tip was verified by a roentgenogram.[1] The extensive use of the right heart catheter by Cournand in the early 1940s in the study of human cardiovascular physiology led his group and others to explore the use of this technique for the study of heart disease.[2] In 1945, Brannon, Weens, and Warren described the hemodynamics of atrial septal defect in four patients. From these beginnings, steady advances in methods occurred.[3,4] Catheterization then spread from the laboratory to the bedside, to yield physiologic data and to guide treatment.[5] Now, palliative and corrective interventions involving valves, arteries, veins, and septal defects may accompany the catheterization study.[6]

PREPARATIONS FOR CARDIAC CATHETERIZATION

A relaxed meeting with the patient and the patient's family serves to lessen apprehension, correct any misunderstanding, and establish rapport. Since catheterization is frequently the first major step on the road to cardiac surgery, a tolerable experience fosters an optimistic attitude in the patient and family toward future events. The patient should be examined, and the history, a current chest x-ray, an electrocardiogram, and past catheterizations should be reviewed, along with surgical records, angiocardiograms, and echocardiograms. The site of optimal vascular access is chosen. Nearly all balloon catheters and many gloves contain latex, and it should be added to the list of allergens sought in the history.[7] Old operative notes are examined, especially for complex palliation or repair. A clinical diagnosis is made, and a catheterization protocol is designed to answer pertinent specific questions. The catheterization protocol also may be modified as data become available during the procedure. The patient's education booklet about the procedure is usually read by the patient and the family prior to securing informed consent. Absolute contraindications include the refusal of a competent adult or the absence of a qualified operator and/or a suitable facility[8] (Table 15-1). Anticoagulants are stopped, and the prothrombin time is brought to less than 18 s (INR <2) before a percutaneous arterial catheterization. Dimethyl biguanide, an oral hypoglycemic drug, is not given for 2 days prior to angiography. Serum levels of creatinine, urea nitrogen, and potassium are noted. A patient with chronic renal disease is hydrated; prophylaxis for past allergy to contrast material is given.[9] Breakfast is withheld for a morning procedure; for an afternoon procedure, coffee or juice is permitted, and lunch is withheld. In our experience, prophylactic antibiotics are not necessary. Conscious sedation for diagnostic catheterization involves the incremental use of intravenous drugs that are titrated to each patient's response. Pulse oximeter monitors require accuracy to within 3 percent in the 70 to 100 percent saturation range. Diazepam (Valium) or midazolam (Versed) is given intravenously; intravenous fentanyl may be added for more sedation. Intravenous hydromorphone (Dilaudid) is used if analgesia is required. Subcutaneous 1% lidocaine (Xylocaine) is used locally. If there is a history of allergy, intradermal or subcutaneous testing is done with serial dilutions of a preservative-free local anesthetic agent.[10] Occasionally, particularly in adults, vagal slowing of the pulse, nausea, and perspiration are noted, for which intravenous atropine is the antidote. Systemic anticoagulation is achieved via a bolus of heparin at the start of a diagnostic study that uses the brachial artery but not routinely if the femoral artery is used.

Table 15-1: Contraindications to Cardiac Catheterization

THE ONLY ABSOLUTE CONTRAINDICATIONS
1. Refusal of a mentally competent adult (>16 years of age) patient, or of the parent(s) (guardians) of children, infants, or neonates to consent to the procedure
2. Absence of an experienced cardiac angiography and/or suitable laboratory facilities
RELATIVE CONTRAINDICATIONS TO BE CAUTIOUSLY APPLIED TO INDIVIDUAL PATIENT
1. Significant electrolyte abnormalities or digitalis toxicity
2. Uncontrolled hypertension
3. Febrile illness (not related to endocarditis)
4. Decompensated congestive heart failure
5. Bleeding diathesis: includes patients receiving anticoagulation therapy whose prothrombin time is >18 s (INR >2)
6. Presence of a noncardiac disease that precludes long-term survival
7. Refusal to undergo surgical or interventional curvative or palliative procedures regardless of the outcome of the catheterization (angiogram)
8. Previous history of severe contrast reaction
9. Active gastrointestinal bleeding
10. Pregnancy, especially during first trimester

SOURCE: From Ruiz et al.,[8] with permission from the authors and publisher.

It is desirable that the laboratory be fully involved daily in diagnostic work. General efficiency is increased, costly equipment and space are used, and most important, all personnel become confident and knowledgeable with experience. Certainly the most important ingredient in the laboratory is the thoroughly experienced technical-professional team. The primary objective is to make an accurate diagnosis at one sitting, with the least possible risk and discomfort to the patient. After the procedure, a preliminary, labeled single-page diagram in the patient's chart can accurately present the essence of the catheterization findings.

Outpatient left-sided heart and coronary artery studies require careful selection of patients and an experienced support team.[11,12] The clinical profiles of patients who are not suitable candidates for outpatient catheterization have been published.[13] Others have stated that if a patient is stable enough to be at home before cardiac catheterization, an outpatient catheterization can be considered and a decision following the procedure can be made based on the patient's tolerance of the procedure and the catheterization findings. This approach is most relevant when a catheterization laboratory is in or adjacent to a hospital. The cost savings per patient with outpatient procedures remain significant. Although some physicians have performed cardiac catheterization of stable, low-risk patients in freestanding facilities, the lack of support in this environment is a potential liability, and thus the procedure is not recommended.

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

TECHNIQUES

Catheterization of the Right Side of the Heart: Percutaneous Venous

Percutaneous femoral or median cubital vein catheterization usually permits reuse of the vein. The femoral vein is entered medial to the common femoral artery pulse. Puncture may be facilitated by a Valsalva maneuver to increase femoral vein size. To extend the range of the percutaneous technique, a thin tubular sheath is advanced over a short introducer catheter into the lumen of the vein. This temporary conduit then may be used to introduce a variety of catheters. Two catheters can be inserted through a single femoral vein puncture site by initially placing two guidewires through the femoral vein sheath; the maneuver is repeated to insert an additional catheter. If the hepatic portion of the inferior vena cava (IVC) is absent, the azygos vein channels the catheter tip into the right superior vena cava (SVC) and then into the right atrium (Fig. 15-1), or the azygos vein may enter a persistent left SVC and then through the coronary sinus to the right atrium (Fig. 15-2). In order to cross the tricuspid valve from the IVC, bending the catheter tip against the right atrial wall may be required. If atrial ectopy occurs, the catheter tip can be looped in a hepatic vein and then advanced into the right atrium. The tip is then rotated from the lateral right atrial wall clockwise across the anterior atrial wall and through the tricuspid valve, followed by a slight counterclockwise turn to the anterolateral position in the right ventricle and then clockwise to place the tip via the outflow tract into the main pulmonary artery and then into the left pulmonary artery, its direct continuation. The foramen ovale is entered with the tip pointed leftward and 45° posteriorly. The SVC lies posteriorly and is entered by making a 60° counterclockwise turn from the lateral right atrial border with a straight catheter tip. The foramen ovale is probe-patent in approximately 20 to 35 percent of adults.

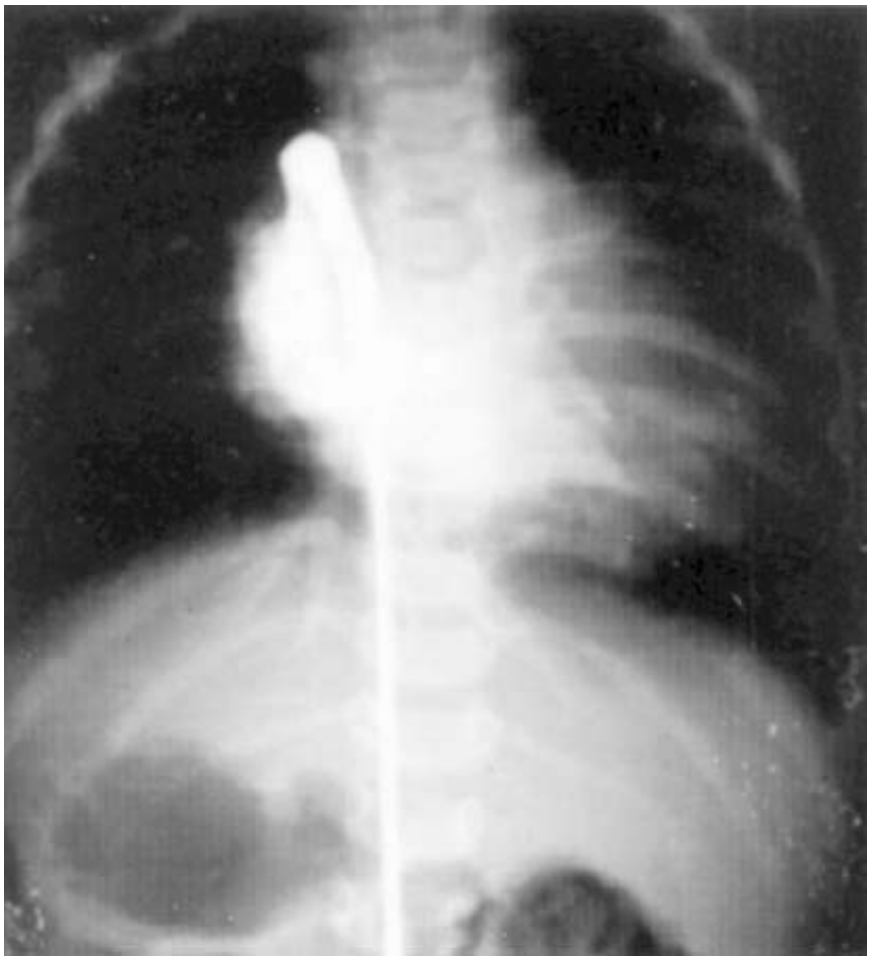

Figure 15-1: Selective injection of a right azygos vein. The hepatic portion of the IVC is absent. The catheter tip enters the right atrium superiorly through the right SVC via the azygos vein.

The internal jugular vein or the subclavian vein also may be used to insert a balloon catheter percutaneously. The latter catheter produces little ectopy because the advancing force is distributed over the surface of the balloon. The tricuspid valve is crossed easily with this approach. If a right-to-left shunt is present, the balloon should be filled with CO_2 and the sidearm of the sheath flushed regularly. In children who lack conventional venous access, transhepatic venous catheterization via a right midaxillary approach is safe and effective.[14]

Rarely, if a venous cutdown is necessary, the right basilic or right median cubital (but not the cephalic) vein is preferred. Care should be taken not to mistake the superficial radial, ulnar, or accessory brachial arteries for veins. From the left arm, the catheter tip may enter a persistent left SVC, exiting via the coronary sinus into the right atrium in an awkward position for entering the right ventricle. A deep inspiration often enables the catheter tip to pass the subclavian vein-brachiocephalic vein junction. The seating of a conventional catheter tip in the pulmonary artery wedge position may be difficult if severe pulmonary artery hypertension or extreme enlargement of the right side of the heart is present. A flow-directed balloon catheter may then be used. Clues to inadvertent coronary sinus catheterizations are (1) the acute angle that the catheter shaft makes as it enters the coronary sinus, especially in the right anterior oblique position, (2) the marked desaturation of coronary sinus blood, and (3) the posterior position of the catheter in the lateral view.

In order to enter the pulmonary artery in patients with transposition of the great arteries and an intact ventricular septum, a balloon catheter is passed across the inevitably present interarterial communication to the left atrium and then superiorly looped in the left ventricular (LV) outflow

tract, from which it enters the pulmonary artery readily. In postoperative patients with pulmonary valve atresia, the pulmonary artery also may be entered via a subclavian (Blalock) or aorticopulmonary (Waterston or Potts) shunt.

Catheterization of the Left Side of the Heart

PERCUTANEOUS TECHNIQUE

In 1953, Seldinger described the use of a flexible metal leader to introduce a polyethylene tube into the artery. The Seldinger technique is used in the common femoral and less often in the axillary radial or brachial arteries in carrying out catheterization of the left side of the heart.[15] The common femoral artery, 4 cm in length, begins at the inguinal ligament and ends at its bifurcation into the deep and superficial femoral arteries at the inferior cortical margin of the head of the femur. The inguinal crease, especially in an obese patient, tends to be inferior to the ligament. In this case, a puncture at or below the crease may involve the superficial femoral artery, and lack of posterior bony support results in poor compression with the chance of bleeding and pseudoaneurysm formation[16] (Fig. 15-3). A skin puncture site chosen 3 cm below the inguinal ligament (not the crease) allows the common femoral artery to be entered at a point where it is compressible against the head of the femur. External rotation of the leg and slight adduction help fixate the artery. The artery is punctured with a nonstylet needle at a 45° angle, transfixing the anterior wall. The guidewire is inserted only when the needle spurt is maximal. Resistance to insertion usually indicates an intramural or extravascular position of the needle or entry into a side branch artery by the guide. The catheter is inserted into the artery over the guidewire, or a sheath assembly may be used, facilitating catheter introduction in a very obese patient or if scar tissue is superficial to the artery. The catheter sheath reduces bleeding during manipulation and reduces discomfort during catheter changes. Arterial pressure may be monitored through a side port in the sheath. Guidewires with torsional control of a flexible distal tip aid passage through a tortuous iliac artery, as does a right Judkins catheter, alone or with a guide. The guide tip is kept at the level of the diaphragm, and the catheter is advanced to this level. The catheter is aspirated and then flushed with heparinized saline solution. To avoid added manipulation of the catheter tip in the transverse arch, the guidewire is placed in the aortic root.[17] The femoral and foot pulses are palpated prior to withdrawal. The artery is compressed for 10 to 15 min, maintaining normal ankle pulses. Devices deployed for sealing the femoral artery puncture site include a collagen plug, a collagen plug with anchor, thrombin with collagen or with fibrin, and a percutaneous suture technique.[18,19] The brachial artery is punctured with an 18-gauge needle, a sheath is inserted, and a no. 6 French 80-cm multipurpose catheter is advanced to the ascending aorta over a 0.032-in. J-guide. Then 5000 units of heparin is given. An arm board is applied for 6 h. Rarely, the right subclavian artery will rise aberrantly as the last root vessel of a left aortic arch, precluding access to the ascending aorta from the right brachial artery. Percutaneous left-sided heart catheterization via an aortofemoral or axillary-femoral synthetic bypass graft has been surprisingly free of complications.[20] A potential hazard is disruption of the pseudointima with subsequent thrombosis.

Figure 15-3: The femoral arteriogram shows the neck (*arrow*) of an oval pseudoaneurysm (pulsating hematoma) arising from the right superficial femoral artery (*arrow*) at the site of the previous catheter entry. (Reproduced with permission from Rapoport et al.[16] and the Radiological Society of North America, Inc.)

The normal aortic valve is easily crossed retrogradely with the catheter tip. Even in aortic valve stenosis, the left ventricle can be entered in nearly all cases. By slowly withdrawing the catheter tip from its looped position in the left aortic sinus, one may perform wall-to-wall exploration of the severely stenotic valve. A straight-tip guidewire may enhance this maneuver. Left and right Judkins, left Amplatz, and pigtail catheters have all been used to center the guidewire in the aortic root to achieve more effective probing of the stenotic orifice.[21,22]

In selected patients who have aortic and mitral valve disk or ball-valve prostheses, a brief direct percutaneous puncture through the palpable apex of the left ventricle is surprisingly free of complications.[23] LV angiography can be performed through the sheath or a catheter. Retrograde catheterization of the left ventricle via a prosthetic aortic disk valve should be avoided. Valvular incompetence is induced, and the catheter may become entrapped in the disk valve mechanism. In contrast, tissue valves can be crossed without significant hazard. In patients with both femoral and

axillary artery disease, selective coronary arteriography can be performed via a translumbar aortic approach, using a sheath,[24] or via a transseptal approach.[25]

ARTERIAL CUTDOWN

The cutdown technique for left-sided heart study usually uses the brachial artery. After the administration of 100 units/kg of heparin intravenously, the anterior wall of the exposed artery is punctured with the tip of an 18-gauge needle. The opening is enlarged slightly with a small forceps, permitting insertion of the tapered catheter. The arteriotomy is closed either by a previously placed, very small purse-string loop or by one or two interrupted sutures. If brisk bleeding does not occur from both proximal and distal artery segments, thrombectomy is performed with a balloon catheter.

Transseptal Approach

Transseptal catheterization may be used to enter the left atrium.[26] From the right femoral vein percutaneously, a 71-cm-long needle is advanced inside a dilator catheter-sheath system to a position beneath the ledge of the limbus fossae ovalis in the right atrium. The needle is then bared to puncture the atrial septum.[27-29] Entry into the left atrium is confirmed by a clear continuous pressure tracing. The dilator is then pushed across the septum. The needle tip is pulled back into the dilator, and when both are well in the left atrium (Fig. 15-4), the sheath is slid over them to also enter the left atrium; needle and dilator are then withdrawn. The sheath permits various preformed open- or closed-tip catheters or large guidewires to be passed into the left atrium and left ventricle. A CO_2-filled balloon catheter may be passed from the left atrium to the left ventricle to the ascending aorta. Biplane fluoroscopy, continuous pressure recording, a catheter in the aortic root, and knowledge of the size and position of the left atrium following pulmonary artery angiography are helpful in positioning the transseptal needle. The left atrium is difficult to enter if there is deformity of the thoracic or lumbar spine or if there is a very large right atrium. Other relative contraindications to transseptal catheterization include marked dilatation of the aortic root and other anatomic distortions of the IVC or atria. The procedure is not done if there is intraatrial thrombus or tumor.

Retrograde catheterization of the left atrium from the left ventricle in the right anterior oblique (RAO) projection uses a tapered flexible catheter that forms a clockwise loop in the left ventricle as it passes to the left atrium. A pigtail catheter has been used similarly.[29]

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

EQUIPMENT

Catheters

Disposable single-use catheters in a wide range of sizes, shapes, and lengths with end and/or side holes are available for diagnostic use. The ideal nonpreformed catheter is soft enough to permit bending as required, has "memory" to hold its shape, and has enough strength or body to permit the curve of the tip to be advanced intact. Torque control is improved by incorporating a thin wire braid in the walls. Transmission of torque to the catheter tip in the ascending aorta is damped by a tortuous iliac artery. The torque is received instead by the proximal part of the catheter, resulting in coiling or potential knotting in the iliac artery. Preformed catheters are made to serve a specific function with a minimum of manipulation. Catheters should have smooth, regular surfaces to reduce thrombogenicity. Atrial septostomy with a fluid-filled balloon catheter or with a controlled folding surgical blade at the catheter tip improves shunting and increases systemic arterial saturation in patients with transposition of the great arteries.[30] A precompressed Ivalon plug or thrombogenic coils inserted by catheter have been used to close the patent ductus arteriosus. Loop-snare or jawed biopsy catheters are used for nonthoracotomy retrieval of intraluminal cardiovascular foreign bodies. A small Doppler crystal mounted on a thin guidewire serves as an intraluminal probe to measure coronary artery blood flow velocity.[31] A catheter-tip electromagnetic probe can be used to measure aortic blood flow velocity. A Doppler pulmonary artery catheter can provide continuous instantaneous stroke output values,[32] assuming a flat velocity profile. An intracoronary artery ultrasound imaging catheter system can provide a cross-sectional, two-dimensional image of good anatomic detail (see Chap. 47). The coronary artery lumen also may be visualized by fiberoptic angioscopic catheters.[33] Inhaled hydrogen gas is detected within 4 s of inhalation with extreme sensitivity by a pacing catheter electrode positioned at the site of a left-to-right shunt or downstream from it.

Used in treating valvular pulmonic stenosis and coarctation of the aorta,[34,35] pulmonary valvuloplasty and aortic angioplasty balloons up to 4 cm long with an inflation diameter up to 20 mm are made of high-tensile-strength polyethylene. Inflation to 3 to 4 atm with a 20-mL plastic syringe is usual. The lumen between the no. 8 or 9 French catheter and the balloon is large, permitting deflation in less than 7 s, decreasing the occlusion time. A short bilobed balloon catheter (two layers with a polyester micromesh between) permits stable positioning across the stenotic valve, stepwise dilation, and a short deflation time.[36] A catheter can be used to deliver a device to close a secundum atrial septal defect as large as 2 cm. Test balloon occlusion of aortopulmonary collaterals mimics the effects of planned surgical closure. In patients with pulmonary atresia and **an** intact ventricular septum who have had surgical relief of the pulmonary atresia, the atrial septal defect can be closed temporarily with a balloon catheter in order to direct all the systemic venous return to the small right ventricle, testing its response. Transcatheter pulmonary artery dilation and stent implantation are especially useful in surgically inaccessible sites.[37]

Radiation Exposure

A qualified radiologic physicist should check the catheterization facilities, and secondary or scattered radiation should be minimized.[38-40] Radiation intensity varies inversely with the square

of the distance; i.e., if the distance to the source is doubled, the amount of radiation will be only one-quarter as much. One should select the smallest possible collimation and keep the image intensifier as close to the patient as possible. The U-arm position that places the x-ray tube to the examiner's side of the table causes the greatest exposure as a result of scattered radiation from the patient. Two film badges should be worn, one at the belt beneath the 0.5-mm equivalent lead apron and the other at the collar level outside the apron. The eyes, gonads, and red bone marrow have a whole-body limit of 5 rem (roentgen equivalent man) per year; any specific organ, such as the thyroid or skin, has a yearly limit of 15 rem. Lead glass spectacles and a thyroid collar reduce radiation to the eye and to the thyroid. Both a floating and a table-to-floor screen are needed for added shielding. The maximal permissible dose, or "safe" exposure, for catheterization laboratory personnel is 100 mrem per week monitored by an unshielded left collar badge. If possible, women of childbearing age should have studies done within 10 days after the onset of menstruation.

Pressure-Recording System

If the heart rate is 60 to 120 beats per minute, the fundamental frequency of the basic wave is 1 to 2 per s. The tenth harmonic or sine-wave component of the pressure wave then occurs at a frequency of 10 to 20 Hz; it is important to detect these components without phase lag or amplitude distortion because their sum represents the rising and falling contours of the native pressure curve. A properly responding pressure-recording system should have a high natural frequency and optimal damping. A high natural frequency is obtained by using a bubble-free, saline solution-filled system of minimum length whose catheter and connector tubings have stiff walls and wide bores. Many catheter-tubing transducer systems are underdamped. To achieve optimal damping, a damping needle or tube is placed between the catheter and the transducer. This extends the output-input ratio of the pressure wave in a nearly uniform manner (unity + 5 percent) to as close as possible to the natural frequency of the system. The values for both frequency response and damping coefficient are obtained by introducing a square-wave pressure input to the catheter system and by measuring the amplitude ratio of any two successive peak pressure amplitudes and the time interval between peaks (Fig. 15-5). For clinical cardiac catheterization, a manometer system with a uniform dynamic response of greater than 20 Hz is desirable.

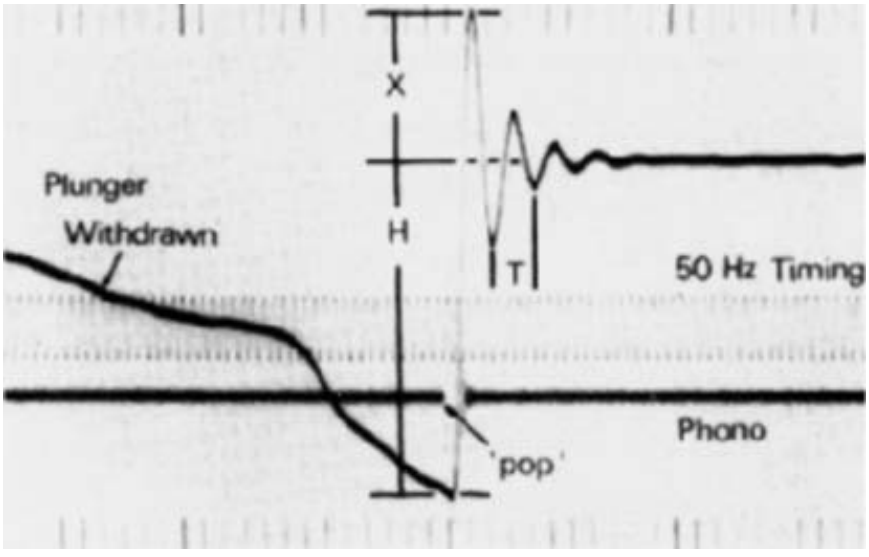

Figure 15-5: In order to measure the dynamic frequency response of a catheter transducer system, an abrupt transient input dynamic pressure is applied to the catheter tip (a plunger is pulled free of an air-filled syringe); the pressure oscillations are recorded at a fast paper speed and measured. X, height of the initial overshoot; H, end height of the recorded deflection; T, period of a free

oscillation, 0.08 s. The natural frequency is 13 Hz; the useful range is 4 Hz. The amplitude ratio of two successive peak amplitudes is 0.59, and the damping coefficient is 0.17. This underdamped system is optimally damped to a coefficient around 0.64 by the addition of a narrow-bore tube between catheter and transducer. (Reproduced with permission of Irex Corporation.)

Clinically, the zero position for an external pressure transducer is set at the lateral midchest level. Specifically, hydrostatic zero is considered to be at the level of most anterior surfaces of the LV blood pool.[41] An additional limiting factor in pressure recording is the superimposition of artifacts on the pressure pulse by the accelerating and decelerating movements imparted to the fluid-filled cardiac catheter by the beating heart. Distortion of the catheter-obtained phasic pressure waveform by motion or damping artifact can be avoided with the use of a catheter-tip, side-mounted, ultraminiature semiconductor gauge. This manometer system is required for first- or second-derivative measurements of the pressure curve.

Oxygen Analysis

The total oxygen content of the blood, once determined by the classic Van Slyke manometric technique, is now obtained by gas chromatography or mass spectrometry. The percent oxyhemoglobin saturation is measured from a small sample of whole blood in a disposable plastic curvette by direct photooximetry or, after hemolysis, by a precision spectrophotometer.[42] Analysis of expired air, from collecting bag or breath by breath, for oxygen and carbon dioxide may be made by gas analyzers or infrared or mass spectroscopy. Oxygen consumption also can be measured throughout the procedure using a flow-through hood technique.[43] Oxygen consumption also can be estimated with a 10 to 25 percent variation from measured values.

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

DATA OBTAINED AT CATHETERIZATION

Pressure Measurements

High-fidelity phasic pressure curves are not obtained from the ventricles or great arteries by fluid-filled catheter recording systems. The underdamped curve gives falsely high systolic and falsely low diastolic readings, and the overdamped curve has a smooth shape with disappearance of the incisura. The shape of the ventricular or great artery pressure trace is occasionally of diagnostic aid. An abrupt fall in pressure in early diastole (early diastolic dip) followed by a sudden rise to a high end-diastolic pressure plateau occurs in both ventricles in abnormal compliance states such as constrictive pericarditis and restrictive cardiomyopathy. In patients with constriction, the LV and right ventricular (RV) pressures have a respiratory reciprocal (discordant) relationship, whereas with heart failure, the relationship is concordant.[44,45] In isolated pulmonary stenosis, the configuration of the RV pressure curve is frequently peaked or triangular.

In valvular pulmonary stenosis, the pulse pressure is frequently greater in the left pulmonary artery than in the right pulmonary artery because flow is preferentially directed into the left pulmonary artery and kinetic energy is translated into lateral pressure. A systolic dip is noted in the main pulmonary artery due to pressure loss from the Bernoulli effect (Fig. 15-6). In bilateral branch pulmonary artery stenosis, the proximal main pulmonary artery shows a wide pulse pressure with a low dicrotic notch. In supravalvular aortic stenosis, the coanda effect makes the right brachial and right carotid artery peak pressures greater than those on the left. A large *a* wave in the right atrium is characteristic of valvular pulmonary stenosis but not of tetralogy of Fallot. A large *v* wave on the pulmonary artery wedge ("pulmonary capillary") pressure tracing may or may not mean that severe mitral regurgitation is present.[46]

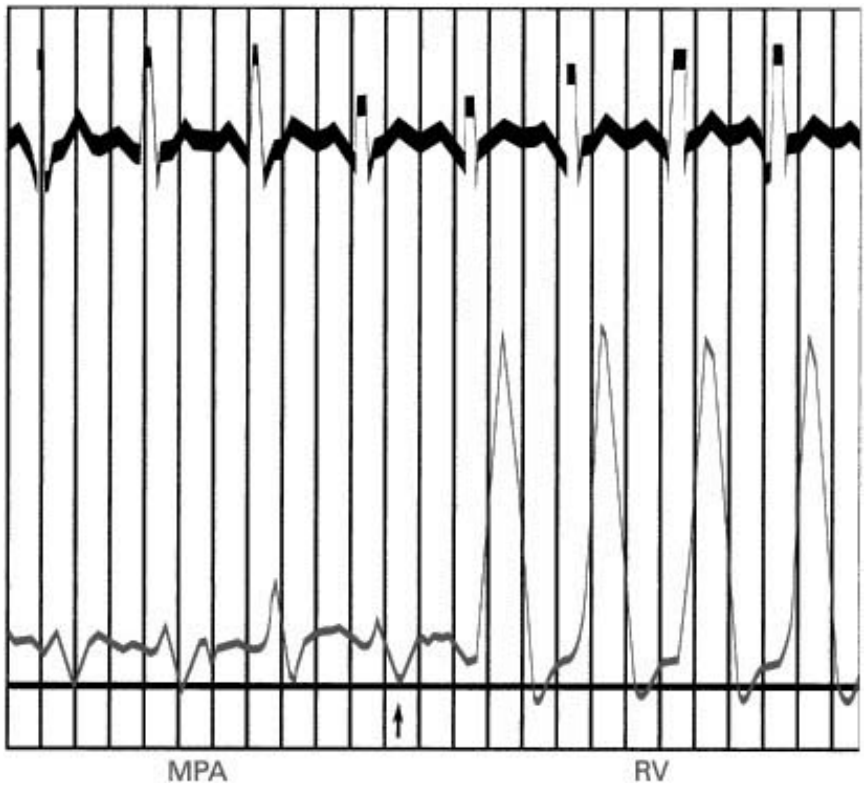

Figure 15-6: Pullback continuous pressure tracing from the main pulmonary artery (MPA) to the right ventricle (RV) recorded in a 27-year-old male with moderate valvular pulmonic stenosis. RV systolic pressure is 84 mmHg. MPA pressure is 16/7 mmHg. Note the systolic dip (*arrow*) in the MPA pressure tracing, due to the pressure loss from the Bernoulli effect. (From Franch RH. Recognition and management of valvular pulmonic stenosis. *Heart Dis Stroke* 1994; 3:365-370. Reproduced with permission from the author and publisher.)

Left ventricular end-diastolic pressure (LVEDP) is recorded on a high-sensitivity scale and is measured where the downslope of the *a* wave in the left ventricle coincides with the initial upstroke of the LV pressure. The LVEDP also may be measured at the peak of the R wave of the electrocardiogram. An elevated LVEDP reflects an alteration in the ventricular pressure-volume relation or a decrease in diastolic compliance of the ventricle. An increased LVEDP occurs commonly with a dilated failing left ventricle but also may be noted in a small ventricular cavity with thick walls or in a normal-size LV cavity during an acute ischemic attack.

In order to measure the maximal rate of rise of LV pressure, or peak *dP/dt*, a high-fidelity pressure record is needed, obtained ideally via a catheter-tip transducer. This value is influenced by preload and afterload in addition to the contractile state. The preejection phase index (*dP/dt*)/*P*, where *P* is the LV pressure during isovolumic systole, reflects the velocity of shortening of contractile elements but also responds to changes in preload. In daily practice, ejection-phase indexes derived from the conventional LV angiogram are used to assess LV function.[47] The ejection fraction is commonly employed as an index of ventricular contractility but is sensitive to changes in preload and afterload as well (see Chap. 22).

A satisfactory pulmonary artery wedge mean pressure provides a good estimate of left atrial mean pressure. Some damping in waveform and phase shift (0.06-s time delay) occurs in the transmitted wedge pressure when compared with the direct left atrial pressure record. During diastole, pulmonary artery wedge diastolic mean pressure tends to be higher than the left atrial diastolic mean pressure, especially in the presence of a prosthetic or abnormal mitral valve. End-expiratory pulmonary artery diastolic pressure agrees within 2 to 4 mmHg with mean pulmonary artery wedge pressure in the absence of increased pulmonary arteriolar resistance. In contrast, pulmonary

vein wedge pressure does not give an accurate estimate of the pulmonary artery pressure in the presence of pulmonary artery hypertension.

Pressure recording permits measurement of either the peak or the mean pressure differential across a stenotic semilunar or atrioventricular (AV) valve or a segmentally narrowed blood vessel. If possible, simultaneous pressure recordings across a valve should be obtained, especially if there is atrial fibrillation. If the pulmonary artery wedge is used as an estimate of left atrial mean pressure, the waveform and amplitude should be confirmed at a second site. The error in assessing the mitral valve area in mitral stenosis can be large when the measured pressure differential is small. Because of the slow fall of the *y* descent in the wedge position, the mitral valve gradient may be overestimated by 3 to 4 mmHg when compared with the gradient obtained with a direct left atrial pressure.[48,49] A pullback record across the semilunar valve performed with a catheter having multiple paired side holes may show a false zone of composite ventricular and great artery pulses resulting from the simultaneously recorded pressures through proximal and distal side holes. Occasionally, a gradient may be overlooked if the catheter tip cannot be advanced well into the ventricle so that it washes into the aorta in systole and falls into the left ventricle in diastole. The ascending aortic pressure should be recorded at the level of the coronary ostia to avoid the effects of pressure recovery,[50,51] i.e., the increase in lateral pressure downstream from a stenosis as the narrow, high-velocity flow field broadens and slows, losing kinetic energy.[52-54] The LV pressure in aortic valve stenosis is recorded well in the LV cavity to avoid systolic pressure loss due to tapering high-velocity flow in the subaortic area. In a case of proximal infundibular pulmonary stenosis, if the pullback is at the cranial aspect of the tricuspid valve, the catheter may fall back into the right atrium from the RV outflow tract very quickly, missing the gradient.

LV cavity obliteration with catheter entrapment may result in spurious pressure gradient. To detect an intraventricular gradient, the LV pressure should be checked in the inflow and outflow (i.e., submitral and subaortic) positions simultaneously and in the apical versus the inflow or outflow positions simultaneously. These recordings enable one to detect any delay in the fall of LV systolic pressure that may occur when the catheter is entrapped.

Interventions during Catheterization

We use a bicycle ergometer that provides loads of 0 to 450 W in steps of 5 W; the level of effort remains constant by maintaining a monitor pointer at a neutral position. The regression equation for oxygen consumption in milliliters per minute for a given load in watts on this ergometer is V_{O_2} = 13.16 W + 254 mL. An increase in cardiac output of 0.6 L/min or greater for each 100 mL of oxygen consumed presumes a normal response. If the oxygen consumption is increased 200 to 250 mL/min by supine use of a bicycle ergometer, an increase in arteriovenous oxygen content difference greater than 30 mL/L is considered abnormal. When the pulmonary artery oxygen saturation falls to substantially less than 30 percent during exercise, the upper limit of circulatory stress is being approached. Normally, during moderate exercise, LVEDP actually falls, and stroke work increases; if LV performance is only moderately impaired, LVEDP rises, and stroke work rises; but in severe dysfunction, stroke work fails to increase despite an increase in LVEDP. Isometric hand-grip exercise increases heart rate, systemic mean pressure, and cardiac output. A fall in LV stroke work and a sharp rise in LVEDP during the grip test is evidence of poor LV reserve. All patients with mitral stenosis who have normal or mildly increased pulmonary artery and wedge pressures at rest should have the mitral gradient and cardiac output rechecked during exercise. In normal patients during exercise, pulmonary artery pressure rises minimally, usually no higher than 25 mmHg mean. In a patient with a repaired ventricular septal defect and residual pulmonary vascular disease, the pulmonary artery pressure may be at the upper limits of normal or slightly increased at rest but may double with low-level exercise.

Rapid atrial pacing also may be used as a stress intervention. In normal individuals, LVEDP falls

as the heart rate is increased. If a paced patient with coronary artery disease is unable to meet the increased myocardial oxygen demand, the LVEDP rises in the early postpacing period, and excess lactate is noted in coronary sinus blood. In patients with tetralogy of Fallot, spontaneous or drug-induced increases in heart rate or atrial pacing produce a drop in arterial oxygen saturation and an increase in right-to-left shunting by increasing dynamic RV outflow tract obstruction.

In hypertrophic obstructive cardiomyopathy, isoproterenol, amyl nitrite, exercise, tilting, and the Valsalva maneuver, which tends to decrease diastolic ventricular volume, can intensify or provoke a systolic outflow tract pressure gradient, whereas a purely vasopressor amine, phenylephrine, which enlarges ventricular volume, tends to decrease the outflow tract pressure gradient[53] (see Chap. 67).

The response of cardiac output to vasodilator drugs in a patient with heart failure can be assessed. In patients with primary pulmonary artery hypertension (see Chap. 59), a 30 percent decrease in pulmonary vascular resistance and a 10 percent decrease in mean pulmonary artery pressure are the usual criteria for a positive response to pulmonary vasodilator drugs.[55]

Blood Oxygen Measurements

An increase in the oxygen content of blood from the chambers of the right side of the heart in excess of the normal variation in oxygen content on serial sampling is used as evidence of a left-to-right shunt.[56] Thus an oxygen step-up from the SVC to the right atrium of more than 1.9 vol% indicates shunting into the right atrium; a step-up from the right atrium to the right ventricle of 0.9 vol% or more and a step-up from the right ventricle to the pulmonary artery of 0.5 vol% or more indicates a left-to-right shunt at the RV and pulmonary artery levels, respectively. By these criteria, false-positive results are rare, but false-negative results can occur in patients with small shunts. In an anemic or polycythemic patient, the detection of shunting is best reflected by the step-up in percentage oxygen saturation rather than the step-up in volume percent, since the latter depends on the hemoglobin concentration.[57]

Studies show that sensitivity in detecting left-to-right shunts is improved if numerous serial blood samples are withdrawn in rapid succession for oximetry. If two sets of interrupted samples are taken from the SVC, right atrium, right ventricle, and pulmonary artery, a 9 percent saturation increase between the SVC and the right atrium indicates a large atrial shunt, a 5 percent saturation increase between the right atrium and the right ventricle indicates a ventricular shunt, and a 3 percent saturation increase between the right ventricle and the pulmonary artery indicates a pulmonary artery shunt. Sensitivity can be improved if blood samples are obtained in multiple pairs in a rapid serial sweep without flushing with saline solution between samples. The rise in oxygen saturation step-up for a given left-to-right shunt is related to the saturation of mixed venous blood (MVB). For example, if the MVB is 85 percent, a 5 percent step-up represents a 2:1 shunt; if MVB is 75 percent, a 10 percent step-up is needed; if the MVB is 65 percent, a 15 percent step-up indicates a 2:1 shunt. The results of the blood oxygen analysis should be reviewed before the catheterization is completed. Left-to-right shunts of less than 20 percent of pulmonary flow are not detectable by oximetry. Since no oximetric criteria exist for exclusion of a shunt, selective angiography and/or the use of a hydrogen (platinum) electrode provide maximal sensitivity and reliability in excluding small shunts.[58] The presence of an increased oxygen step-up in the right side of the heart should be correlated closely with angiographic findings.

Catheter Position

The catheter position may be useful in identifying the anatomic location of an intracardiac defect or an anomalous vein (Fig. 15-7). In crossing a membranous ventricular septal defect in the anteroposterior view, the catheter inserted from the arm passes into the ascending aorta from the

right ventricle in a hairpin loop and enters the pulmonary artery from the right ventricle in a wider U loop. A patent ductus arteriosus is entered by pointing the tip of the catheter toward the "roof" of the junction of the main and left pulmonary arteries. Failing direct catheter passage, a flexible-spring guidewire, introduced while the venous catheter tip rests in the main pulmonary artery, readily passes through the ductus into the descending aorta; in aorticopulmonary septal defect, the tip passes directly up the ascending aorta from the main pulmonary artery. When the catheter tip enters a pulmonary vein within the heart shadow, angiography is necessary to ascertain whether the pulmonary vein drains into the left or the right atrium. A secundum atrial septal defect is more easily crossed from the leg approach, a sinus venosus defect from an arm approach, and an ostium primum defect from either approach. If the tricuspid valve is congenitally displaced into the right ventricle, the pressure transition from the right ventricle to the right atrium may occur while the catheter tip is far to the left of the spine. Simultaneous intracardiac electrocardiography is confirmatory (see also Chap. 70).

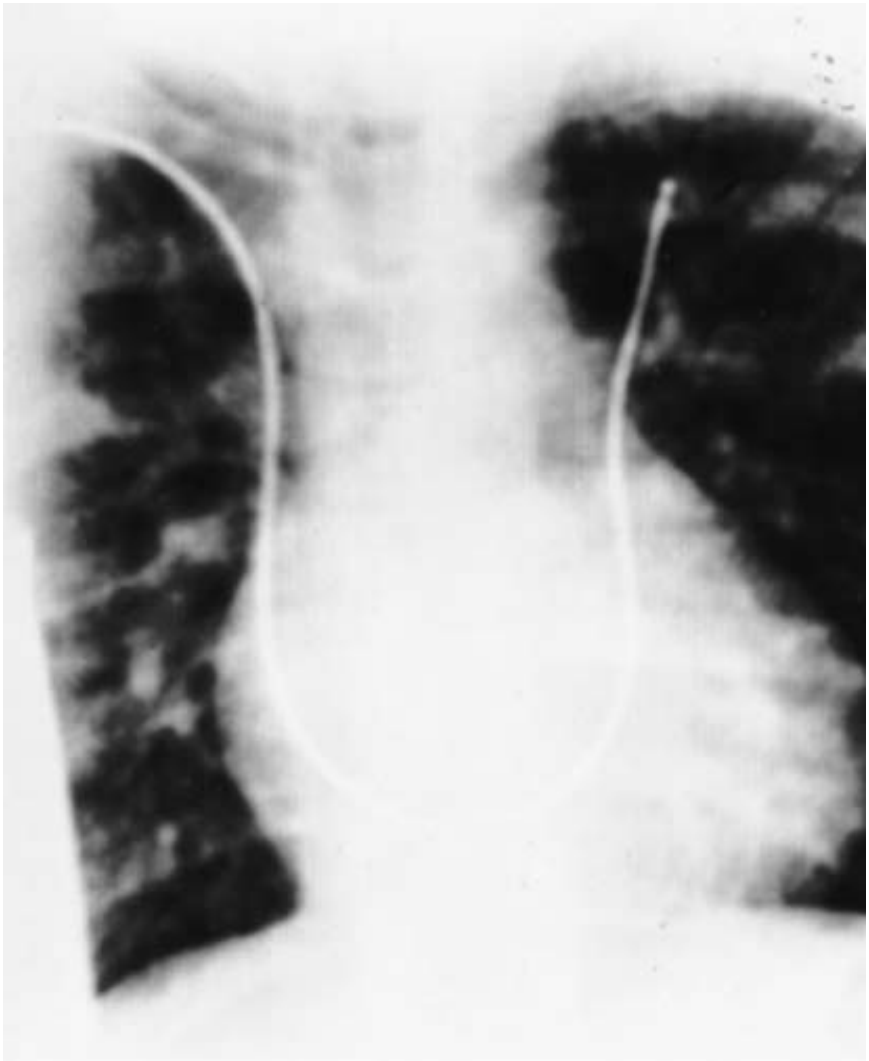

Figure 15-7: The catheter tip passes from the right SVC to the right atrium and then to the coronary sinus, the left SVC, and an anomalous left upper lobe pulmonary vein.

Flow and Shunt Calculations

FICK METHOD: CARDIAC OUTPUT

In 1870, Adolph Fick expounded a theory for the measurement of blood flow that he never used in the laboratory: "The total uptake or release of a substance by an organ is the product of the blood flow to the organ and of the arteriovenous concentration of the substance." In the following example, the cardiac output may be calculated given the following three values: total oxygen consumption of 300 mL/min, arterial blood oxygen content of 19 mL per 100 mL of blood, and mixed venous blood oxygen content of 14 mL per 100 mL of blood. The cardiac output, in liters per minute, is equal to the oxygen consumption divided by the arteriovenous oxygen difference multiplied by 10 (to convert the latter to liters). In this case, the cardiac output equals 6.0 L/min. Cardiac output may be related to the body surface area (BSA) as the *cardiac index*. If one assumes a BSA of 2.0 m^2, the cardiac index would be 3 L/min per square meter. Because of laminar flow from the coronary sinus and the cavae and in the right atrium, MVB is best obtained from the pulmonary artery. Under conditions of exercise, a minimum of 3 min is usually required to obtain a steady-state preliminary to expired air and blood collection. In a given person, repeated measurements of the cardiac output at rest by the Fick technique may vary to a maximum of ±17 percent, presuming a continued steady state.

SHUNT CALCULATIONS

Shunt calculations using the Fick principle tend to be approximations, since complete mixing of venous and shunted blood may not occur. Also, as the arteriovenous oxygen narrows, small errors in the analysis or in the collection of blood samples make large variations in the calculated pulmonary blood flow possible. The calculation of shunt flow, however, is useful; it provides a quantitative index that is combined with clinical findings to determine whether or not surgery is advisable.

Numerous formulas have been developed, but those listed below are the ones used most often. The *oxygen capacity* is the maximal amount of oxygen that will combine with hemoglobin and that will be dissolved in plasma at a high P_{O_2}. One gram of hemoglobin can combine with 1.36 mL of oxygen. The amount of oxygen dissolved in plasma depends on the solubility coefficient of oxygen, the temperature, and the partial pressure of oxygen. At 37°C, the solubility coefficient is such that the amount of oxygen dissolved in plasma is 0.03 mL/mmHg per liter. With an oxygen tension of about 100 mmHg, about 3 mL of oxygen is dissolved per liter of blood. This small amount is usually ignored, although when the patient is breathing 100% oxygen, a considerable amount of oxygen can be dissolved in plasma. Oxygen content is related to both the hemoglobin concentration and the oxygen saturation. The oxygen content equals 1.36 × Hb (g/dL) × Sa_{O_2} (%)/100.

1. A sample calculation of left-to-right shunt:

Total oxygen consumption (V_{O_2})	240 mL/min
Pulmonary artery blood oxygen content ($P_{A_{O_2}}$)	17 mL/100 mL
Mixed venous blood oxygen content (MV_{O_2})	15 mL/100 mL
Arterial blood oxygen content (Sa_{O_2}) (assumed to equal pulmonary venous oxygen content)	19 mL/100 mL

$$\text{Pulmonary flow } (Q_p) = \frac{V_{O_2}}{Sa_{O_2} - P_{AO_2}}$$

$$= \frac{240}{19 - 17(10)}$$

$$= 12 \text{ L/min}$$

$$\text{Systemic flow } (Q_s) = \frac{V_{O_2}}{Sa_{O_2} - MV_{O_2}}$$

$$= \frac{240}{19 - 15(10)}$$

$$= 6 \text{ L/min}$$

Pulmonary flow/systemic flow ratio = $Q_p/Q_s = 12/6 = 2$.

If one substitutes for Q_s and Q_p in the preceding formula and reduces to a common denominator, the *pulmonary flow-systemic flow* ratio is obtained from a formula requiring only the oxygen saturation. Assuming an oxygen capacity of 20 vol%, the following blood oxygen saturations for the preceding samples are Sa = 95 percent, P_A = 85 percent, and MV = 75 percent.

Left-to-right shunt also may be expressed as the percentage of total pulmonary flow that is shunted blood. The 2:1 Q_p/Q_s ratio above then represents a 50 percent left-to-right shunt.

2. Calculation of right-to-left shunt:

$$\frac{Q_p}{Q_s} = \frac{Sa_{O_2}\% - MV_{O_2}\%}{Sa_{O_2}\% - Pa_{O_2}\%} = \frac{95 - 75}{95 - 85} = 2$$

$$V_{O_2} = 240 \text{ mL/min}$$
$$MV_{O_2} = 13 \text{ mL/100 mL blood}$$
$$Sa_{O_2} = 17 \text{ mL/100 mL blood}$$

Pulmonary vein blood oxygen content is as follows:

$$PV_{O_2} = 19 \text{ mL/100 mL blood}$$

(assumed to be 98 percent of oxygen capacity + 0.3 mL of dissolved oxygen).

$$Q_p = \frac{V_{O_2}}{PV_{O_2} - MV_{O_2}} = \frac{240}{19 - 13(10)}$$

$$= 4 \text{ L/min}$$

$$Q_s = \frac{V_{O_2}}{Sa_{O_2} - MV_{O_2}} = \frac{240}{17 - 13(10)}$$

$$= 6 \text{ L/min}$$

Pulmonary/systemic flow ratio = Q_p/Q_s = 0.7. Right-to-left shunt also may be expressed as the percentage of total systemic flow that is shunted blood. The 0.66 Q_p/Q_s ratio above represents a 33 percent right-to-left shunt.

3. Calculation of bidirectional shunt:

$$V_{O_2} = 240 \text{ mL/min}$$
$$P_{AO_2} = 15 \text{ mL/100 mL blood}$$
$$MV_{O_2} = 13 \text{ mL/100 mL blood}$$
$$Sa_{O_2} = 18 \text{ mL/100 mL blood}$$
$$PV_{O_2} = 19 \text{ mL/100 mL blood}$$

$$Q_p = \frac{V_{O_2}}{PV_{O_2} - P_{AO_2}} = \frac{240}{19 - 15(10)}$$

$$Q_s = \frac{V_{O_2}}{Sa_{O_2} - MV_{O_2}} = \frac{240}{18 - 13(10)}$$

$$= 4.8 \text{ L/min}$$

$$Q_{ep} = \frac{V_{O_2}}{PV_{O_2} - MV_{O_2}} = \frac{240}{19 - 13(10)}$$

$$= 4.0 \text{ L/min}$$

$$\text{Left-to-right shunt} = Q_p - Q_{ep} = 6 - 4$$
$$= 2 \text{ L/min}$$
$$\text{Right-to-left shunt} = Q_s - Q_{es} = 4.8 - 4.0$$
$$= 0.8 \text{ L/min}$$

Note that effective pulmonary flow Q_{ep} is that volume of systemic venous blood which, after returning to the right atrium, actually reaches the pulmonary capillaries. It is equal to effective systemic blood flow Q_{es}.

INDICATOR-DILUTION TECHNIQUE

Cardiac Output: Dye Method

The cardiac output, or the mean volume rate of flow, may be determined by using a modification of the standard concentration equation employed for the determination of a static fluid volume

such as the blood volume:

$$V = \frac{I}{C}$$

where V = fluid volume, mL
I = indicator added to fluid, mg
C = concentration of indicator in each milliliter of fluid, mg/mL

For determination of a moving fluid volume,

$$\text{Cardiac output} = \frac{I}{Ct}$$

where t = time required for all indicator-fluid mixture to pass sampling site once

If the indicator particles are injected into the circulation as a bolus and measured in the initial passage at a downstream site, they distribute themselves in a time-concentration plot of grossly predictable form called an *indicator-dilution curve* (Fig. 15-8). The descending limb of the indicator-dilution curve is distorted by indicator-blood mixture that has begun a second circulation. To exclude recirculating indicator, the concentration is plotted logarithmically against time. The early portion of the disappearance slope is extrapolated linearly on semilogarithmic paper to obtain a primary curve, on the premise that if indicator-blood mixing is complete, the washout of indicator is an exponential function of time. A cuvette densitometer is used to obtain a continuous arterial time-concentration curve. Thus

$$\text{Cardiac output (in L/min)} = \frac{I \times 60\ \text{s}}{Ct}$$

where C = mean concentration of indicator in one circulator passage, mg/L
t = time, s

The cardiac output is falsely high if an indicator is lost. If an indicator is counted twice, i.e., if undetected recirculation occurs, the cardiac output is falsely low. An analogue computer provides rapid calculation of cardiac output from dye-dilution curves and detects whether or not logarithmic decay of indicator concentration has occurred. The Stewart-Hamilton formula assumes constant heart rate and stroke volume and a linear runoff in the pulmonary artery. Values for cardiac output obtained with the indicator-dilution technique compare closely with those obtained by the Fick method.[59]

In the absence of shunt, the indicator-dilution curve shows an uninterrupted buildup slope, a sharp concentration peak, a steep disappearance slope, and a prominent recirculation peak. Two major types of distortion are produced by central shunting. In a left-to-right shunt, there is decreased peak concentration of dye, a gentle disappearance slope (prolonged disappearance time), and absence of the recirculation peak. These alterations are produced by the recirculation of indicator particles through the lungs, resulting in a slow release of indicator to the peripheral circulation. The typical curve produced by a venoarterial, or right-to-left, shunt shows deformity of the buildup slope by an abnormal or early-appearing hump, or reflection, representing indicator that

has been shunted from right to left. The distortion in contour of the indicator-dilution curve in valvular regurgitation is similar to that occurring with left-to-right shunts. Efforts have been made to predict all or part of the curve from certain other curve components. The cardiac output obtained by the forward-triangle method compares favorably with the classic Hamilton method. In this technique, the initial portion of the indicator-dilution curve is considered to be a triangle. The area of this triangle multiplied by a constant gives the area of the primary dilution curve. Intracardiac shunts can be detected and quantified by indicator-dilution curves.[61]

Cardiac Output: Thermodilution Technique

The thermodilution technique was introduced by Fegler in 1953 to measure volume flow rate.[61,62] A multiple-lumen, balloon-tipped flow-directed thermistor catheter is placed in the pulmonary artery. Ten milliliters of room-temperature (22°C) 5% dextrose or normal saline solution is injected rapidly (<4 s) through a second lumen into the right atrium. As the injectate blood mixture initially passes from the right ventricle, the pulmonary artery blood temperature drops maximally and then progressively rises in a beat-to-beat disappearance slope as the residual injectate-blood mixture is washed out of the right ventricle. The recirculation phase is negligible. Recording the curve allows assessment of the technical adequacy of the study. The area under the time-temperature curve is electronically integrated, and the cardiac output is computed by the Stewart-Hamilton formula. The difference between successive determinations should be less than 10 percent. Since there is no "gold standard" for cardiac output, the results have been compared with the dye-dilution and Fick techniques and have been noted to correlate well, except in low cardiac output states, where the Fick method is preferable. If severe tricuspid or pulmonary regurgitation or significant left-to-right shunting is present, the peak is attenuated and the downslope of the curve is prolonged, so the thermal dilution cardiac output likely will be unreliable.[63] In general, when one uses thermal dilution, a true directional change in cardiac output is reflected by an observed change of ±10 percent.

Ventricular Volume Measurements

LV volume is estimated by selective injection of contrast medium into the left ventricle or left atrium. The image of the opacified LV cavity is obtained by cineventriculography. Biplane view image pairs used include frontal and lateral, right and left anterior oblique, or half-axial left anterior oblique and conventional RAO.[64,65] A single-plane mode using the frontal or RAO projection often is adequate.[66,67] In the classic biplane technique, each shadow of the LV cavity is treated as an ellipse. The long axis of the ventricle (L_m) and the two mutually perpendicular short axes at its midpoint (D_a and D_l) are measured, and the volume (V) is calculated from the formula for volume of an ellipsoid:

$$V = \frac{4}{3}\pi \times \frac{D_a}{2} \times \frac{D_l}{2} \times \frac{L_m}{2}$$

or

$$V = \frac{\pi}{6} \times D_a \times D_l \times L_m$$

In the single-plane method, the long axis and one short axis are measured; the second nonvisible short axis is assumed to equal the first; thus

$$V = \frac{\pi}{6} \times L_m \times D_l^2$$

More often, in either the biplane or single-plane method, the short-axis dimension is derived from the measured long axis and the area (*A*) of the LV shadow, treated as an ellipse (area-length method of Dodge) (Fig. 15-9):

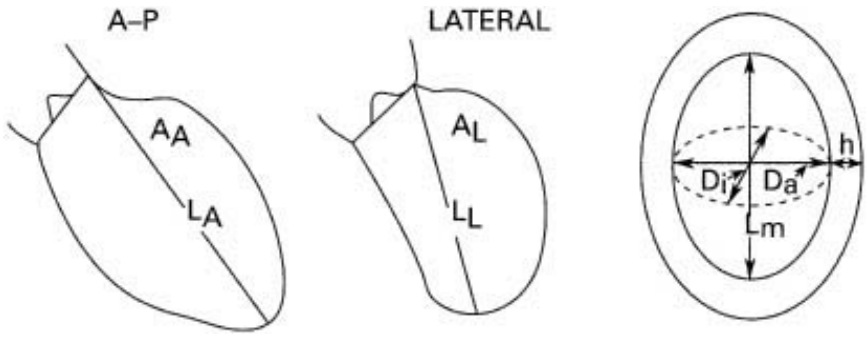

Figure 15-9: Dimensions of the left ventricular (LV) cavity in end-diastole used for the calculation of the ventricular volume by the area-length method, biplane technique. A-P, anteroposterior plane; A_a, A_l, area, A-P and area lateral plane (planimetry); L_a, L_l, length or long axis of the left ventricle (measured); D_a, D_l, diameter of short axis, A-P lateral plane (derived; L_m, maximum length or long axis whether from the lateral A-P or lateral plane; *h*, wall thickness, LV. See text for formulas. (Left and middle portion of figures from Sandler and Dodge.[66] Right portion of figure from Dodge HT. Hemodynamic aspects of cardiac failure. *Hosp Pract* 1971; January:91. Illustration by B. Tagawa and A. Miller. Reproduced with permission from the publishers and authors.)

$$A = \pi L_m \frac{D}{4}$$

Corrections are made for magnification due to the divergence of the x-ray beam.[68] A calibrated grid or circular reference marker is filmed at the estimated level of the left ventricle. The true grid size equals the size measured on the projected film times a correction factor. More magnification may occur in the periphery than in the center of the field (pincushion effect) due to spherical aberration in the lens system. Digital ventriculography provides rapid, computer-derived ventricular volumes. Geometric and nongeometric count-based radionuclide techniques for calculation of ventricular volumes are well validated.

By the use of magnetic resonance imaging (MRI) in each case, LV volume obtained by the biplane long-axis method and LV volume obtained from multiple short-axis plane images (using Simpson's rule) agree closely.[69] If the left ventricle of a postmortem heart specimen is filled with contrast material and filmed, the calculated estimate of the volume of the left ventricle is higher than the known volume of the left ventricle. An appropriate regression equation for both single-plane[66,67] and biplane[64,65] techniques has been derived to adjust for this initial overestimate. The LVEDV is normally 70 ± 20 mL/m^2, and the end-systolic volume is 24 ± 10 mL/m^2. The forward stroke volume obtained by left ventriculography agrees well with indicator-dilution and Fick determinations. The ejection fraction of the left ventricle is 0.67 ± 0.08; values below 0.55 are usually considered abnormal. Diastolic LV wall thickness measured by angiography is 9 mm for women and 12 mm for men, and LV wall mass is 76 g/m^2 for women and 99 g/m^2 for men.[70]

The total stroke volume obtained by left ventriculography is used to assess the severity of mitral and aortic valve regurgitation. Total stroke volume minus forward stroke volume equals regurgitant stroke volume. The regurgitant fraction equals regurgitant stroke volume divided by total stroke volume. Severe valvular regurgitation has a regurgitant fraction of 0.50 or greater. Direct measurement of aortic regurgitation in milliliters per stroke in a pulsatile circulation model agrees closely with MRI-derived phase velocity encoding data in the model. The technique is clinically applicable (Fig. 15-10).

RV volume is estimated by applying Simpson's rule or the area-length method to the cavity silhouettes after biplane angiography.[71] The end-diastolic volume of the right ventricle in normal persons is 81 ± 12 mL/m^2. The opacified left atrial shadow is represented as an ellipsoid, so the left atrial volume also can be calculated in the biplane mode; the normal left atrial maximal volume is 63 ± 16 mL with a mean volume of 35 ± 8.7 mL.

Resistance

By Poiseuille's law, the flow varies directly with the fourth power of the radius of a tube; resistance varies inversely with the fourth power of the radius. Vascular resistance to blood flow in systemic, pulmonary, or regional vascular beds is estimated by analogy to Ohm's law:

$$\text{Resistance} = \frac{\text{pressure (or volts)}}{\text{mean blood flow (or amperes)}}$$

or resistance = mean pressure differential across the vascular bed divided by the blood flow (see also Chap. 3).

To obtain the pressure difference across the pulmonary bed, subtract the pulmonary artery wedge (or left atrial) pressure from the pulmonary artery mean pressure; for the systemic pressure difference, subtract the mean central venous or right atrial pressure from the mean aortic pressure. Conversion into centimeter-gram-second (cgs) units (dyn·s/cm^5) is usual, but it does not add to the intrinsic significance of the measurements. Resistance also can be expressed simply as *R* in units = mean pressure difference (mean flow in millimeters of mercury) divided by the cardiac output (in liters per minute). In infants and children, the pressure drop is related to the flow index; thus *R* in units × m^2 = pressure difference divided by cardiac index. Pulmonary resistance calculations in adults are usually not indexed, although there is an increasing tendency to do so. The normal pulmonary vascular resistance index is 1 to 2 units. Generally, 1 resistance unit is approximately equal to 80 dyn·s/cm^5. In a physiologic sense, the term *resistance* avoids specific definition. A change in resistance usually implies a change in a cross-sectional area of the vascular bed but does not indicate the mechanism behind the change. Passive widening of the vessels by increases in intravascular flow as well as the opening of previously closed channels may produce changes in resistance similar to those of active vasomotion. Subnormal calculated pulmonary vascular resistance is found in the patient who has a large atrial septal defect with normal pulmonary artery pressure. Clinically, the resistance figure is useful in quantitating the extent of pulmonary vascular disease; thus a patient with a pulmonary vascular resistance of 10 units/m^2 probably would not benefit from closure of a septal defect (see Chap. 70). The total resistance to blood flow in a pulsatile system is defined as *impedance*. Its clinical use is limited, however, since the accurate calculation of impedance requires high-fidelity pressure and velocity or flow recordings.

Calculation of Valve Areas

The equation for calculation of valve area (Torricelli's orifice equation) uses a standard hydrokinetic formula for a rounded-edge orifice or a short tube. When flow occurs across a

narrow orifice, the pressure differential is related to the conversion of pressure energy into kinetic energy. The Gorlin formula for calculation of valve area is derived by combining two standard orifice formulas, one describing the volume rate of flow and the second, the velocity of flow.[72,73]

FORMULA I

$$F = AVC_c$$

where F = volume rate of flow during the time the valvular orifice is open, mL/s of diastole or systole
A = area of fixed orifice, cm^2
V = velocity flow, cm/s
C_c = coefficient of orifice contraction compensating for the physical phenomenon of reduction of the orifice stream to an area less than the area of the actual orifice

FORMULA II

$$V^2 = C_v^2 2gh \quad \text{or} \quad V = C_v\sqrt{2gh}$$

where V = as above
C_v = coefficient of velocity (allowing for some loss in conversion of pressure energy to velocity)
g = gravity acceleration (980 cm/s per second)
h = pressure head or differential across the orifice, cmH_2O

COMBINING I AND II

$$A = \frac{F}{C_c \times C_v\sqrt{2gh}} \qquad A = \frac{F}{C \times 44.3\sqrt{P_1 - P_2}}$$

where C = discharge coefficient (an orifice constant obtained by comparing calculated with measured valve areas at postmortem, which combines C_c, C_v, conversion factor, mmHg to cmH_2O, other unknown factors)

$44.3 = \sqrt{2g} = \sqrt{1960}$
$h = P_1 - P_2$
= pressure differential across the orifice, mmHg

The duration of ventricular filling or emptying is calculated in seconds per minute from pullback or simultaneous pressure records obtained immediately upstream and downstream from the valve. The systolic or diastolic time per beat multiplied by the heart rate gives the number of seconds in each minute during which either filling or emptying occurs across the AV or semilunar valve, respectively. Thus the volume rate of flow in milliliters per second of systole or diastole is the mean volume rate of flow (cardiac output in milliliters per minute) divided by the filling or

emptying time in seconds per minute. A sample calculation of mitral valve area is as follows:

$$\begin{aligned}\text{Cardiac output (CO)} &= 5000\ \text{mL/min}\\ \text{Diastolic filling period (DFP) beat} &= 0.38\ \text{s/beat}\\ \text{Pulse rate} &= 90\ \text{beats/min}\\ \text{DFP/min} &= 34\ \text{s/min}\\ \text{Left atrial mean diastolic pressure (LAP)} &= 30\ \text{mmHg}\end{aligned}$$

The calculation for the aortic valve area is as follows:

$$\begin{aligned}\text{Left ventricular mean diastolic pressure (LVDP)} &= 5\ \text{mmHg}\\ C &= 0.85\ \text{(orifice constant for the mitral valve)}^{77}\end{aligned}$$

$$\begin{aligned}\text{Mitral valve flow (MVF)} &= \frac{\text{CO}}{\text{DFP/min}}\\ &= \frac{5000\ \text{mL/min}}{34\ \text{s/min}}\\ &= 147\ \text{mL/s of diastole}\end{aligned}$$

$$\begin{aligned}\text{Mitral valve orifice area (MAV)} &= \frac{\text{MVF}}{0.85 \times 44.5\sqrt{\text{LAP} - \text{LVDP}}}\\ &= \frac{147}{38\sqrt{25}} = 0.8\ \text{cm}^2\end{aligned}$$

If the femoral artery is used, the aortic gradient from the simultaneous left ventricular-femoral artery pressure tracing should be averaged with the gradient obtained from the tracing that is realigned to correct for the central to peripheral time lag of the femoral pulse.[74] Other modifications also have been proposed.[75,76]

Similarly, orifice areas may be calculated for the tricuspid and pulmonary valves, using an orifice constant of 1.0. In a pulsatile flow model, the Gorlin valve area predicted the severity of aortic stenosis better than valvular resistance or stroke-work loss measurements.[77] The approximations and systemic errors in the formula do not detract from its usefulness in providing objectivity in the classification of patients with valvular disease.[78] The valve orifice, and thus the calculated valve area, may not be fixed and may be flow- and pressure-dependent. The orifice constant, too, may vary with the square root of the mean pressure gradient. Modifications of the widely used Gorlin formula have been made. To estimate aortic valve area, the Bache formula uses either the peak-to-peak or the maximum systolic gradient, thus avoiding planimetry.[79] Hakki omits the ejection or filling period and the empirical constant. He uses the square root of either the mitral mean, aortic mean, or aortic peak pressure gradients divided into the cardiac output. The Hakki mitral or aortic valve area generally agrees with the Gorlin areas[80]; a correction factor for heart rate has been proposed.[81] If flow is normal, reducing a valve orifice diameter to less than half or the cross-sectional area to one-fourth is generally required to offer significant obstruction. A significantly reduced mitral valve area is 1 cm^2; aortic valve area is 0.7 cm^2 (see Chap. 57). The transmitral pressure gradient is somewhat overestimated if the pulmonary artery wedge pressure is used rather than the left atrial pressure.[82] Calculation of the orifice area of a stenotic valve in the presence of associated valvular regurgitation must take into consideration the added regurgitant flow or the severity of the stenosis will be overestimated. To obtain an estimate of mitral or aortic regurgitant

volume, the forward stroke volume should be subtracted from total angiographic LV stroke volume.

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

SELECTIVE ANGIOGRAPHY

Contrast medium was first injected through a rubber catheter placed in the right ventricle by Chavez in 1947. The technique of selective angiography has been continually refined. In the patient with valvular or congenital heart disease, the diagnosis is often made initially by noninvasive imaging. Catheterization and angiography are then performed as directed studies to provide histologic data and additional anatomic detail. A catheter with a large lumen facilitates rapid low-pressure delivery of a single bolus of the contrast agent. A catheter with a coiled open tip and multiple laterally directed openings reduces recoil. A balloon-tipped angiographic catheter with proximal side holes is easy to manipulate and induces less ectopy than do conventional catheters. A power injector delivers the desired volume of contrast medium at a preselected maximal flow rate. In adults with complex cyanotic congenital heart disease, a large closed-end catheter with multiple side holes inserted via the femoral vein can deliver 70 mL of contrast medium in 2 s without recoil. Positioning the catheter in the apex of the right ventricle is done by using a guidewire or a tip deflector wire when a large-diameter catheter is used.

Contrast Media

In 1923, Osborn noted that the urinary bladder of luetic patients treated with oral and intravenous sodium iodide became opaque to x-rays because of the absorption of photons by iodine. All contrast media contain three iodine molecules attached to a fully substituted benzene ring. The fourth position in the standard ionic agent is taken up by sodium or methylglucamine as cation; the remaining two positions of the benzene ring have side chains of diatrizoate, metatrizoate, or iothalamate. All media are excreted predominantly by glomerular filtration. The normal half-time of excretion is 20 min; biliary excretion is 1 percent. A dose of 0.5 to 1.0 mL/kg of medium may be scaled up or down in relation to total body weight, size of the heart chambers, systemic blood flow, degree of left-to-right shunting, severity of pulmonary vascular disease, and clinical status of the patient. If significant hemodynamic changes rapidly follow the administration of contrast medium, subsequent large-volume injections ideally should be spaced in time as the clinical status of the patient dictates. The vasodilator effect and the transient decrease in systemic vascular resistance are directly related to the degree of osmolality of the contrast medium used. Transient hypervolemia and depressed contractility are in part responsible for the elevation of left atrial and LV end-diastolic pressure.

To reduce the osmotic effects of contrast medium, the number of dissolved particles must be decreased or the molal concentration of iodine per particle must be increased (Fig. 15-11). New-generation, nonionic, monomer, and ionic dimer contrast agents have approximately the same viscosity and iodine concentration but have only one-half or less of the osmolality of the ionic agents, e.g., iopamidol and ioxaglic acid (ioxaglate), 796 and 560 mosmol/kg H_2O, respectively, versus 1689 mosmol/kg H_2O for diatriozate sodium.[83] The advantages of the new agents include less hemodynamic loading,[84] patient discomfort, binding of ionic calcium, depression of myocardial function and blood pressure,[85] and possibly fewer anaphylactoid reactions. A disadvantage is the high cost that leads to a policy of selected use.[86] Also, while standard contrast media have a moderate anticoagulant effect, some nonionic media have only a slight anticoagulant effect, and the catheter and syringe containing them should thus be kept free of blood.[87] The principal use of the new agents may be in very ill patients, especially in adults with extremely

poor LV function, in patients with renal disease, especially those with diabetes, and in patients with a history of serious reaction to contrast media or with multiple allergies. If standard high-osmolality agents are used, those which are non-calcium binding may produce less negative inotropic effect and less ventricular fibrillation.[88]

CONTRAST MEDIA

	Standard Agents	New Generation Agents	
	High Osmolality	Low Osmolality	
Structure	Ionic Monoacid Monomer	Non-Ionic Monomer	Ionic Monoacid Dimer
Benzene Rings	One	One	Two
Cation	One	None	One
Moles of Iodine	Three	Three	Six
Particles in Solution	Two	One	Two
Molal Concentration Of Iodine Per Particle	1.5	3.0	3.0
Side Chains	Ditrizoate[1] Metrizoate[2] Iothalamate[3]	Metrizamide[4] Iopamidol[5] Iohexol[6]	Ioxaglate[7]
Proprietary Names	[1]Renografin 76 Angiovist Hypaque [2]Isopaque [3]Conray	[4]Amipaque [5]Isovue [6]Omnipaque	[7]Hexabrix

Figure 15-11: Comparison of structure, iodine per particle, and side chain between standard and new contrast media. The number next to the proprietary name identifies the side chain it contains.

Filming Methods

Cineangiography uses intensification and amplification fluoroscopy and filming by a 35-mm movie camera as well as television monitoring and disk recording.[89] Perfection in image quality is achieved when each point in the object is recorded as a point on the film. In practice, this reproduction is hindered by the diffusion of light by intensifying screens interfering with sharpness and resolving power. Although the detail of the individual cine frame lacks the spatial resolution of the cut-film screen angiogram, the motion itself increases visual perception by noise averaging and use of the integrating (5 frames per second) or persistence ability of the eye (0.2 s). The circular image of the phosphor is usually overframed on relatively slow 35-mm film with an 18 × 24 mm useful film area. Meticulous attention to film processing and the film type is essential to obtain the desired contrast and image detail. Radiographic contrast, or the difference in density or grayness between areas, depends in part on the proper x-ray photon penetration of the subject, film contrast, and scatter radiation. The latter is minimized by a collimation of the x-ray beam. For

coronary angiography, short-scale, high-contrast, sharp white images on a dark gray background are desired; in the congenital heart patient, a long scale of shades of gray helps to define the entire cardiac anatomy. Biplane cineangiography is highly desirable in the study of complex congenital heart defects, especially in infancy. The total amount of contrast medium is significantly reduced, and chamber and great vessel relations are better defined.

To perform computer-enhanced digital angiography, the catheterization laboratory image intensifier and video camera are linked to an analogue-to-digital converter, computer system, and digital storage device. The analogue video signal is digitized into a series of discrete numerical values that represent continuous voltage fluctuation and can be stored on disks. The images are acquired in the standard cineradiographic mode and simultaneously are stored on film via the cine camera and digitized from the video image. The digital information is enhanced for display by a real-time image processor and is stored on a digital disk for further processing. In single-plane acquisition, exposure rates of 15, 30, and 60 frames per second in a 512 × 512 or 1024 × 1024 matrix are available. In simultaneous biplane acquisition, 7.5, 15, and 30 frames per second are possible. Enhanced images can be recalled and reviewed to allow selection of a freeze frame. The selected image can be stored and displayed on a separate monitor. A real-time image processor enhances and smooths the fluoroscopic image. For difficult projections, pulsed fluoroscopy is available on demand at approximately half the cine dose level, the last 5 s of which can be stored on digital disk for instant review. Varying degrees of enhancement, frame rates, and exposure times can be selected from a preprogrammed push-button module. Analytical programs include subtraction capabilities, ventricular ejection fraction, edge enhancement, and regional and global wall motion. An image mask is made electronically by reversing the polarity of the background image of bone and tissue. The mask is then superimposed on the angiographic image. The positive and negative images of the competing tissue background cancel, leaving the digital subtraction angiogram. Arterial stenosis quantification and 2× zoom magnification can be performed in postprocessing. A hand-held infrared control device permits image review and freeze-frame storage during the study. It can be placed in a sterile bag and operated by the cardiologist at tableside. Postcase review and additional image processing are accomplished via the view panel. Hard-copy images of selected frames, which are particularly useful for interventional procedures, can be recorded via video paper, x-ray film, or laser copier. In practice, the resolution of the digital arteriogram from the hard disk approaches that of cine film. Unacceptable image degradation occurs when the digital angiogram is transferred to videocassette tape. Thus, once a practical way of permanent digital image archiving is established and if a standard compatible system for exporting image data is developed, digital angiography is likely to replace film in the catheterization laboratory.[90] The compact disc-recordable (CD-R) format and a universal interchange standard set by users and makers, i.e., Digital Imaging and Communications in Medicine (DICOM), appears promising.

Positioning

Universal positioning capability of the x-ray and intensifier tubes by using stands of L-, U-, or C-arm configuration permits angled views of a supine patient. Two profile views of the curved ventricular septum are needed. They are made in degrees of axial obliquity and cranial angulation as follows: (1) The 40° left anterior oblique (LAO) and 30° cranial position (four-chamber view) outlines the posterior third of the ventricular septum, the valve plane in AV canal defects, and the four heart chambers without superimposition. (2) The 60° LAO and 30° cranial position (long-axial view) outlines the anterior two-thirds of the ventricular septum, the membranous ventricular septal defect, and the LV outflow tract (Fig. 15-12*A*, *B*). An elongated RAO view, which is useful for seeing the RV infundibulum and supracristal ventricular septal defect, is obtained by 30° axial RAO and 40° cranial angulation. The main pulmonary artery and its bifurcation are seen in the frontal position with 30° of cranial angulation; a steep LAO position with marked cranial angulation is also used.[91]

A successful procedure results when a rapid injection of the proper volume of contrast medium is made through an adequate-sized catheter, properly positioned, with detailed attention to radiologic technique and to the position of the x-ray tube or tubes. Complete opacification of the LV cavity without inducing ventricular ectopy defines a satisfactory LV angiogram.[92]

Uses of Angiography

Right atrial angiography is useful in defining the following: (1) the tricuspid valve in Ebstein's anomaly and tricuspid atresia or stenosis, (2) myxoma or thrombus, (3) juxtaposition of right atrial appendage in cyanotic congenital heart disease, (4) the right atrial border in pericardial effusion or tumor, and (5) atrial septal defect with right-to-left shunting or occasionally the site entrance of an anomalous pulmonary vein by reflux. In the lateral position, an RV injection is used to study the caliber and the level of obstruction to RV outflow and the relation of the great vessels to the right ventricle (Fig. 15-13). A pulmonary artery injection may be used to fill the left side of the heart to detect a left-to-right shunt and to detect the site of partial (Fig. 15-14) or total anomalous venous drainage of the pulmonary veins and to visualize the pulmonary artery and its branches (Fig. 15-15). An atrial septal defect is best defined by selectively injecting the right upper-lobe pulmonary vein rather than the left atrium itself. In patients with an endocardial cushion defect and an ostium primum atrial defect, selective LV angiography shows relative elongation (Swan's neck) of the LV outflow tract and shortening of the LV inflow tract due to deficiency of the upper part of the inlet ventricular septum (Fig. 15-16). To identify the pulmonary arteries in cases of pulmonary atresia with ventricular septal defect or to identify one pulmonary artery in cases where a shunt procedure has inadvertently produced discontinuity between right and left branches, a hand injection of contrast medium into an end-hole balloon catheter occluding a pulmonary vein or into a conventional catheter in the pulmonary vein wedge position frequently will opacify the ipsilateral pulmonary artery retrogradely back to its main confluence.[93] The size and origin of systemic artery-to-pulmonary artery collaterals arising from the descending aorta, the patent ductus, and the subclavian arteries should be defined in the patient with pulmonary atresia (Fig. 15-17).

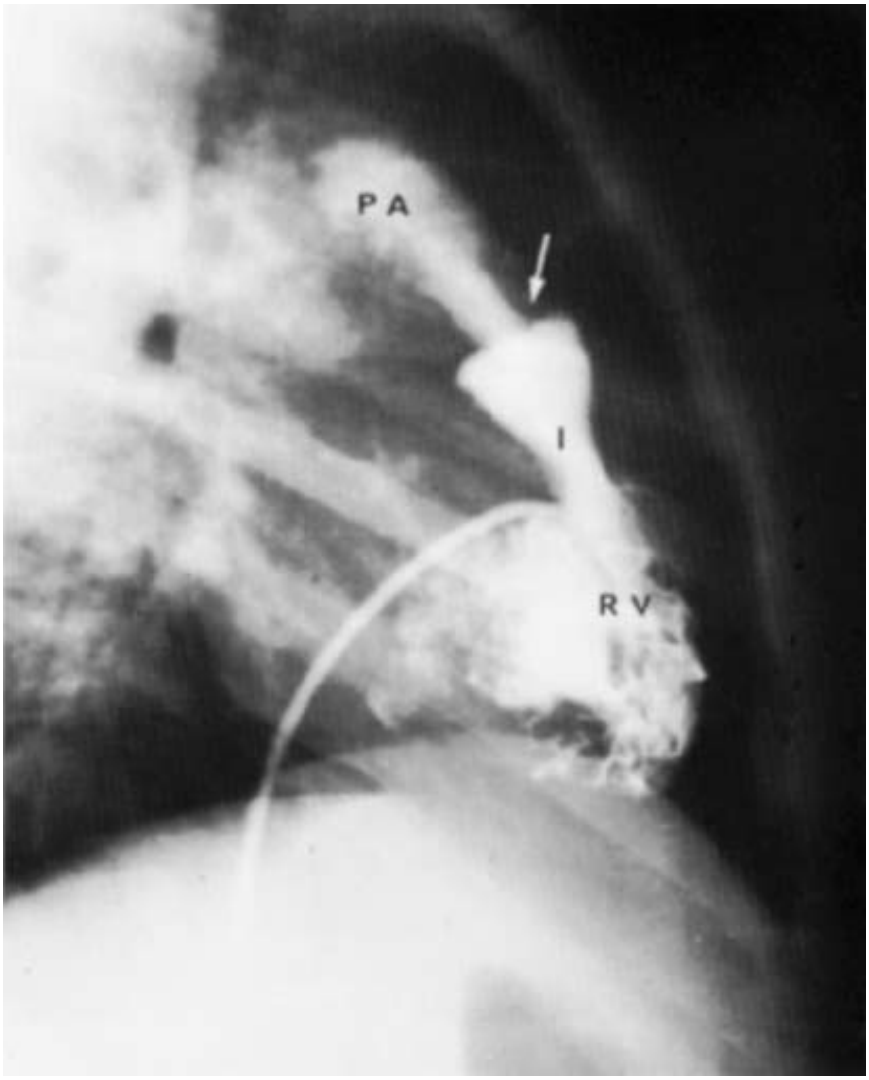

Figure 15-13: Valvular pulmonary stenosis (lateral view). Right ventricular injection of opaque medium. Contrast material exits through central orifice of pulmonary valve in form of a jet (*arrow*). RV, right ventricle; I, infundibulum of right ventricle; PA, pulmonary artery.

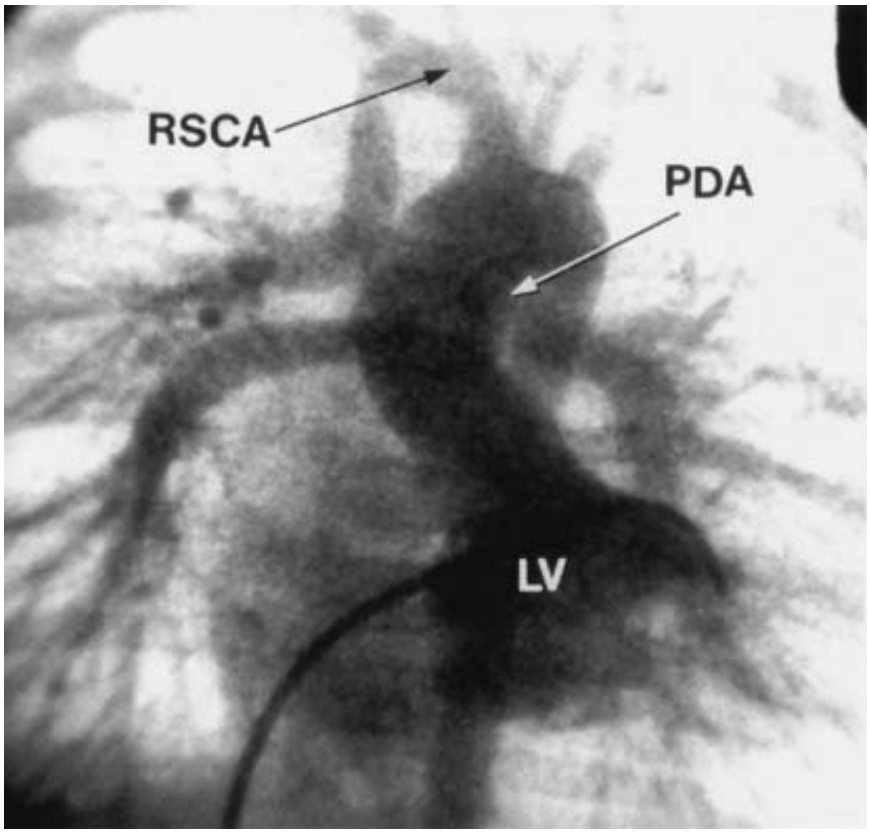

Figure 15-17: Selective LV angiogram in a patient with ventricular septal defect and pulmonary atresia, frontal view. The right and left pulmonary arteries are supplied by a patent ductus arteriosus (PDA). A branch from the right subclavian artery (RSCA) fills a separate right pulmonary artery supplying the right middle and upper lobe.

Valve Regurgitation

Injections made above the aortic valve serve to detect and qualitatively assess aortic regurgitation. In milder degrees of aortic regurgitation, a fine regurgitant jet or puff is noted; opacification is limited to the LV outflow tract, clearing with each systole (grade 1), or faint, persistent, incomplete opacification of the LV cavity (grade 2) occurs. In grades 3 and 4, no distinct jet is seen, and dense complete opacification of the left ventricle occurs either progressively or in one or two diastolic cycles, and LV density exceeds aortic density in the severe case. After an aortic injection, the size and mobility of a stenotic aortic valve may be visualized by negative-contrast washout of the opacified aorta with nonopaque ventricular blood. In the LAO view, the mouthlike opening of a bicuspid aortic valve is seen when fusion of the commissure between the right and the left aortic sinus leaflets occurs. An LV injection may display the level of subaortic obstruction to LV outflow. In patients with endocardial cushion defect, the frontal view may show a radiolucent notch in the anterior mitral valve leaflet or between the superior and inferior bridging leaflets of the AV valve.

LV injection in the RAO view is used to detect and grossly quantitate mitral regurgitation. Forty-five milliliters of contrast medium is delivered at 15 mL/s via a pigtail catheter positioned to avoid ventricular ectopy. The angiographic criteria for grading mitral regurgitation are somewhat subjective, so disagreement may arise between observers in assessing the degree of reflux. In grades 1 and 2 mitral regurgitation, a narrow- to moderate-width regurgitant jet of slight to moderate density is noted; minimum to moderate opacification of the left atrium clears quickly. In grades 3 and 4, a well-defined jet is absent, and left atrial opacification is intense, immediate, and lingering; thus the left atrium appears denser than the left ventricle or aorta in grade 4 mitral

regurgitation. In mitral valve prolapse, which is shown best in a lateral projection with slight cranial angulation, all or a portion of one or both leaflets balloons above the mitral annulus in systole, with or without associated mitral valve regurgitation. A normal mitral valve may leak if ectopic beating occurs. Unlike disk or ball valves, prosthetic tissue valves can be crossed with the catheter tip without interfering with valve function. Selective RV angiography in the RAO or lateral position via a pigtail catheter lying in the apex of the right ventricle gives adequate evaluation of tricuspid regurgitation.[94] Reflux into the SVC and IVC is associated with severe tricuspid regurgitation. A properly placed main pulmonary artery catheter will detect significant pulmonary regurgitation.

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

COMPLICATIONS OF CARDIAC CATHETERIZATIONAND ANGIOGRAPHY

An experienced operator can carry out catheterization of the right side of the heart without difficulty in practically all cases. Complications may include knotting of the catheter; breakage of the guidewire; perforation of the atrium, ventricle, or coronary vein; and pulmonary infarction or pulmonary artery rupture associated with balloon catheter inflation.[95] Complete heart block may be induced if left bundle-branch block is already present or if prolonged catheter manipulation is required in a cyanotic patient. Prolonged ventricular or atrial arrhythmia may occur.

In the catheterization of the left side of the heart, thrombosis or hematoma may occur at the percutaneous arterial puncture site, and blood may migrate into fascial and retroperitoneal planes.[96] Perforation may occur at a tortuous subclavian or pelvic arterial site. The most common vascular complication is femoral arterial pseudoaneurysm or pulsating hematoma, in part due to the increased use of heparin after catheterization (see Fig. 15-3). Pseudoaneurysm following catheterization may be detected by color Doppler flow imaging. In systole, a high-velocity flow signal moves into the sac of the pseudoaneurysm from the small puncture site in the superficial or common femoral artery; in diastole, there is a low flow velocity from the sac into the femoral artery retrogradely. In the presence of the femoral artery-to-femoral vein fistula, there is a constant-flow signal from the artery to the vein.[97,98] Ultrasound-guided compression obliteration of these communications has been helpful. Among approximately 23,000 patients (72 percent males) at Emory University Hospital who had coronary artery angiography via the percutaneous femoral approach using a no. 8 French multipurpose catheter, 14 patients (12 females and 2 males) required femoral artery thrombectomy. The smaller femoral artery of the female is more prone to thrombotic occlusion than is that of the male. Cerebral embolism results primarily from plaque material dislodgment in the ascending aorta and less often from a fibrin clot on catheters.[99] Isolated persistent diplopia or hemianopia may occur. In 30,000 coronary artery and LV catheterizations, 35 patients had central nervous system complications (carotid distribution in 15, vertebrobasilar in 20, and diffuse encephalopathy in 2). The deficit resolved in one-half of all patients and persisted in one-half. There were two deaths. Cholesterol crystal embolization shower syndrome may follow catheter manipulation in the aorta and can result in progressive renal failure. Transseptal puncture may result in inadvertent perforation of the aorta or the free wall of the atrium, with resulting cardiac tamponade.

Nausea with or without vomiting may develop immediately after the initial injection of contrast medium, probably related to direct stimulation of serotonin receptors in the brain. Adverse reactions also include sneezing, chills, low-grade fever, hives, itching, angioedema, bronchospasm, and shock. Since no anti-contrast medium immunoglobulin E (IgE) is found, these reactions are anaphylactoid rather than being true anaphylaxis. The mechanism may be related to activation of the kallikrein, classic or alternate complement, or intrinsic coagulation systems or to direct hyperosmolar or chemical cytotoxicity.[100] Rare reactions include parotitis (iodide mumps), glossitis, and pancreatic edema. A two-dose oral glucocorticoid regimen (methylprednisolone, 32 mg) given 12 and 2 h before standard contrast medium injection significantly reduces acute allergic reactions. Diphenhydramine hydrochloride, cimetidine hydrochloride, epinephrine, and hydrocortisone, singly or combined, have been added to a treatment protocol outlined in Table 15-2. Patients at high risk for contrast medium nephropathy usually have preexisting renal insufficiency and diabetes. An increase in serum creatinine levels of 0.5 to 1.0 mg/dL or a rise of

25 to 50 percent over baseline at 24 to 48 h after angiography is noted in 2 to 7 percent of an unselected population and is considered to reflect contrast medium-induced renal injury. Good hydration is essential in preventing or diminishing renal injury: 0.45% normal saline at a rate of 1 mL/kg per hour is begun 12 h before and is continued for 12 h after the procedure.[101] The mechanism of contrast nephrotoxicity is related in part to renal cortical vasoconstriction and to tubular cell toxicity[102,103] (Fig. 15-18). Renal insult in a high-risk-group subset in a randomized trial was diminished with the use of low-osmolality media. There is little difference in the rate in serum creatinine levels after angiography in low-risk groups whether ionic or nonionic contrast media are used.[104,105] Pulmonary edema following angiography may be caused by volume overload and a negative inotropic effect.

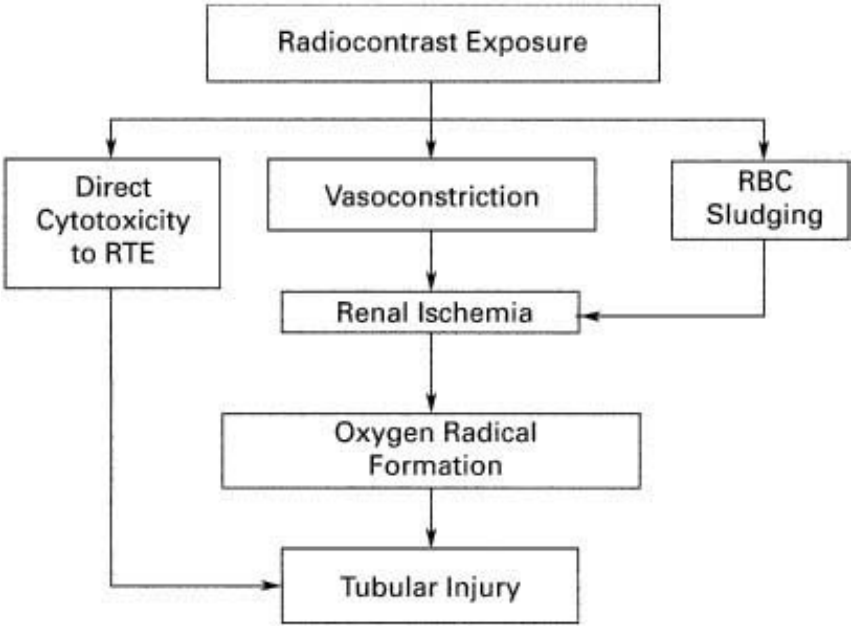

Figure 15-18: Proposed mechanisms of contrast media-induced acute renal injury. RBC, red blood cells; RTE, renal tubular epithelial cells. (From Rocher.[102] Reproduced with permission of the author and publisher.)

In desperately ill patients and in those with marked ventricular dysfunction or severe valvular obstruction, the desire for films that display the cardiac anatomy spectacularly should be tempered by the potential consequences of large doses of contrast medium in this setting.[106]

Chapter 15: CARDIAC CATHETERIZATION, CORONARY ARTERIOGRAPHY, AND CORONARY BLOOD FLOW AND PRESSURE MEASUREMENTS

CORONARY ARTERIOGRAPHY AND LEFT VENTRICULOGRAPHY

Coronary arteriography remains the standard by which all methods of diagnosing coronary artery disease are measured. It is the primary method of defining coronary anatomy in living patients. To accomplish this in a safe, reliable, and reproducible manner, adherence to certain principles of performance and interpretation is required.[107-109]

Coronary arteriography provides not only an anatomic map of the coronary arteries, including the site, severity, and shape of stenotic lesions, but also the characteristics of distal vessels in terms of size, presence of atherosclerotic disease, mass of myocardium served, a rough index of differential coronary flow, identification of collateral vessels, and an estimate of their functional importance.[110-113] Intracoronary thrombi can be recognized, although it is clear from angioscopic studies that coronary arteriography is relatively insensitive in the detection of thrombi. In addition, the presence of coronary spasm can be ascertained by using provocative maneuvers.[114-116] The functional significance of a coronary stenosis can be assessed by measuring coronary flow directly, both at rest and during an intense coronary dilator stimulus. The difference between resting and maximal coronary flow is the coronary flow reserve capacity of the coronary bed. Coronary flow reserve can be measured in the coronary arteriography laboratory by using digital subtraction or intracoronary Doppler techniques.[117]

LV catheterization makes possible measurements of LV pressure at rest, with exercise, or after pharmacologic agents. Left ventriculography enables one to make a visual analysis of wall motion. Ventricular systolic and diastolic volume andejection fraction can be calculated. Careful correlation of the coronary arteriogram and left ventriculogram permits identification of stenotic and potentially bypassable arteries serving viable myocardium. LV wall motion can be further evaluated by the addition of stress such as atrial pacing, pharmacologic agents, or exercise. Augmenting LV contraction by the use of nitrates, catecholamines, or postextrasystolic beats may permit the identification of LV wall segments that have a potential for improved function after revascularization surgery.[118-120] The presence of associated valvular heart disease may be determined. In patients who have previously undergone surgery, patency of grafts and status of the native coronary arteries can be ascertained. In certain children with congenital heart disease, the location of the coronary arteries can be determined as an aid to planning surgical correction.[121]

Techniques of Coronary Arteriography

Sones ushered in the modern era of coronary arteriography in 1958 when he developed a safe and reliable method of selective coronary arteriography.[110] The Sones technique uses an antecubital incision over the brachial artery. The artery is exposed, and a woven Dacron catheter (Sones USCI) is passed into the brachial artery and maneuvered through the axillary and subclavian arteries into the ascending aorta. Manipulation techniques depend on deflecting the soft, tapered catheter tip off the aortic valve cusps up to the coronary orifices. The Sones technique has stood the test of time. The advantages are that it requires only one catheter, aortoiliac disease is avoided, and the operator is close to the aortic root and therefore has a good feel of the catheter tip. The disadvantages of antecubital dissection, arteriotomy, and arterial closure have been nearly entirely overcome by percutaneous entry of the brachial artery and, in recent years, the radial artery. Manipulation skills and precise knowledge of the aortic root anatomy are required. A detailed description of the Sones technique has been published.[122]

Percutaneous arterial catheterization, described in 1953 by Seldinger,[123] was first used to study the coronary arteries, as reported by Ricketts and Abrams in 1962.[124] Modification of catheters was made by Amplatz et al.[125] and by Judkins[126] in 1967. The Judkins technique requires three preformed catheters: one for each coronary artery and a pigtail catheter for the LV injection. The Judkins technique is much easier to

learn; paradoxically, this may be its major drawback. The femoral artery is punctured below the inguinal ligament, and a left coronary artery catheter is passed over the guidewire into the aorta. After the catheter is flushed and good pressure tracings are obtained from the tip, the catheter is advanced until it engages the left coronary orifice. The preformed shape of the catheter holds it against the inside of the aortic curve, enabling the tip to spring into the left coronary orifice. The tip is made in four lengths for use with different-sized aortic roots. After the left catheter is removed, the appropriate-sized right coronary catheter is inserted over a guidewire and positioned above the right coronary orifice, where it is rotated clockwise. The tip will descend and will be held against the outside curve of the aorta, causing it to spring into the right coronary orifice. LV studies are performed by replacing the coronary catheters with the pigtail catheter. A detailed description of the Judkins technique also has been published.[127]

This technique has the advantages of a percutaneous approach; the disadvantages are the requirement for multiple catheter exchanges and a potential increased risk of emboli to the coronary or cerebral circulation. Complications may arise from the ease of entry of the catheter tip into the coronary arteries. Some poorly trained angiographers have applied this technique without proper appreciation of the devastating consequences of catheter obstruction of the left main coronary artery. Methods of avoiding serious complications of catheter emboli, including systemic heparinization and catheter-debriding techniques, have reduced complications in active centers. In an attempt to combine the advantages of the Sones and Judkins techniques, the single-catheter percutaneous femoral approach was first applied by Schoonmaker in 1968, and use of this technique was reported by Schoonmaker and King.[128] This technique has been employed at Emory University Hospital in over 80,000 studies since 1972.

Performance of Coronary Arteriography

The description of our technique of coronary arteriography is brief; a more detailed description has been published.[129] It is our belief that one cannot become expert in performing coronary arteriography by reading. Only through training in an active laboratory and performing hundreds of coronary arteriograms under close supervision can the physician gain a proper appreciation of the potential hazards of coronary arteriography so that they can be avoided.[130] A close physician-patient relationship is essential to reduce fear of the examination. The patient is seen before the procedure, and a thorough history, physical examination, and description of the procedure are completed. Patients with mild or stable symptoms may undergo coronary arteriography as outpatients, unless noninvasive studies indicate the likely presence of severe anatomic problems such as left main coronary artery stenosis. In most laboratories, outpatient catheterization studies are performed with smaller-diameter catheters of a no. 5 or no. 6 French size. Cardiac medications are usually continued up to and through the procedure. An intravenous line is routinely started for administration of midazolam for conscious sedation. The intravenous line is also essential as a port for the administration of additional drugs during the procedure, as needed, if pain or hypotension occurs or if congestive failure is aggravated. Electrocardiographic and pulse oximetry monitoring is performed throughout the procedure. Atropine, lidocaine, propranolol, furosemide, glucocorticoids, an antihistamine, nitroglycerin, epinephrine and other vasopressors, and a narcotic should be readily available for intravenous administration. Heparin and antibiotics are not administered routinely in our laboratory. Patients with a history of anaphylactoid reactions to contrast media are pretreated with antihistamines and glucocorticoids.

A three-way stopcock manifold is connected to lines for pressure monitoring, contrast medium, and heparinized saline solution. A clear catheter is maintained by intermittent flushing with saline solution and contrast medium. The femoral artery is catheterized by the Seldinger technique, and a multipurpose polyurethane catheter is inserted into the descending aorta, where it is flushed before being advanced around the aortic arch without a guidewire. The catheter is advanced to the left ventricle, where, following pressure measurements and test injections to exclude catheter-tip entrapment, 10 to 20 mL of contrast medium is injected over 3 s. This slow injection allows adequate visualization without recoil of the end-hole and side-hole catheter. Filming is done routinely in the RAO view or in a biplane mode using RAO and LAO views.

Essential to any coronary arteriographic technique is a thorough knowledge of aortic root anatomy (Fig. 15-19). Usually the left coronary orifice arises from the left sinus of Valsalva, which is posterior and to the left. The right coronary artery usually arises from the right sinus of Valsalva, which is anterior. Because of extensive variation in the position, size, and number of orifices, considerable experience is required to

avoid failure to identify and study one of the arteries. Left coronary cannulation is performed in the following manner: The tip of the catheter is placed in the noncoronary cusp, which lies posterior and to the left (toward the spine in the RAO view). As the catheter is advanced with a slight clockwise rotation, the tip flips up into the left coronary ostium or into the left cusp. From the left coronary cusp, the catheter tip can be rotated posteriorly and advanced superiorly into the left coronary ostium (see Fig. 15-19). Right coronary artery catheterization is done by positioning the tip of the catheter above the left coronary cusp and rotating clockwise so that the tip sweeps along the anterior aortic root until it reaches the right coronary ostium (see Fig. 15-19). An alternative method is to advance the catheter tip in the right cusp; it curves into the right orifice. When the operator is unsuccessful in reaching one or the other coronary orifices, the catheter is removed and replaced by an appropriate Judkins or other preformed catheter.

(From Schoonmaker and King.[128] Reproduced with permission from the American Heart Association, Inc., and the authors.)

All injections into the coronary arteries are preceded by aspiration of a small amount of contrast medium into the hand-held syringe (to exclude the possibility of air embolism) and are monitored visually until the contrast medium clears. Pressure monitoring is done after these injections. Hypotension following coronary injection usually clears spontaneously or with coughing, which transiently increases aortic pressure and enhances clearing of contrast medium. If hypotension lasting more than a few seconds occurs, especially in a patient with severe proximal coronary artery disease, a pressor agent in an adequate dose to obtain a quick response is started promptly. Adequate coronary perfusion pressure is essential. If congestive heart failure is aggravated by the effect of contrast medium, the first drug used is sublingual nitroglycerin; furosemide may be needed, however. When chest pain occurs, nitrates are given sublingually or intravenously, and the catheter is repositioned in the left ventricle to monitor LVEDP. If pain continues or ST-segment elevation occurs, coronary injection may reveal coronary spasm. Intracoronary nitroglycerin usually provides prompt relief. If severe elevation of end-diastolic pressure occurs, the patient may be propped up and given additional nitrates and oxygen. When tachycardia accompanied by adequate or elevated blood pressure develops during angina, 1-mg increments of propranolol or metroprolol may be given intravenously, producing dramatic relief. Narcotics are used for pain that is not relieved promptly by nitroglycerin and propranolol. Ventricular fibrillation, a rare occurrence, is corrected promptly with the defibrillator. All laboratory personnel must be thoroughly trained in cardiopulmonary resuscitation, since unstable patients may develop life-threatening arrhythmias before, during, and after angiography.[130] Minor anaphylactoid reactions are treated with antihistamines; more serious reactions are treated with the addition of epinephrine and glucocorticoids.[131] Maximal safety is obtained when an expert angiographer performs a brief but complete study, obtaining all clinically pertinent information with a minimal number of injections. Because of the osmotic diuresis induced by the contrast media, intravenous and oral fluid supplements are required after catheterization, and postural hypotension must be checked for when the patient is allowed up.

Interpretation of the Coronary Arteriogram

Once of interest to angiographers and surgeons only, the viewing and interpretation of coronary arteriograms should now be of vital interest to cardiologists if they are to make informed decisions about their patients. The coronary arteriogram should be viewed in a systematic fashion. Because coronary anatomy can be quite variable, one needs to view the films with an eye toward making sure the entire LV epicardial surface and septum are adequately supplied and that no gaps exist. If significant gaps are found, an occluded or anomalous artery is likely. The coronary arteries should be viewed one at a time, and some division of arterial segments such as the one suggested by the American Heart Association[132] should be made (Fig. 15-20). Areas of foreshortening and overlap should be examined in other views to convince the observer that there is not a hidden lesion. It is helpful for several observers to study the arteriogram. As each segment is viewed, a systematic scoring and recording system is mandatory if consistency is to be maintained and no segments are to be overlooked.

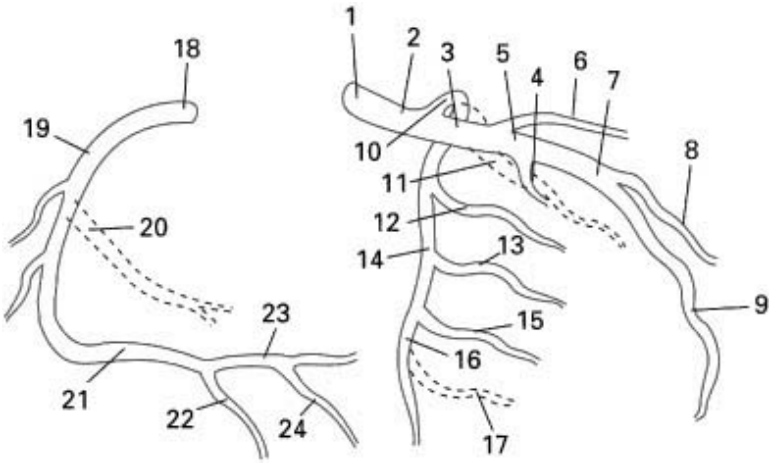

Figure 15-20: Diagram of the coronary circulation. Each arterial segment is evaluated carefully in all views and the degree of stenosis is determined. Left main coronary artery, 1, 2; left anterior descending coronary artery, 3, 5, 7, 9; diagonal branches, 6, 8; major septal perforating branch, 4; circumflex coronary artery in the atrioventricular groove, 10, 14, 16; ramus intermedius, 11; obtuse marginal branches, 12, 13, 15; posterior descending branch of the circumflex coronary artery, if present, 17; right coronary artery in the atrioventricular groove, 18, 19, 21, 23; large right ventricular branch of the right coronary artery, 20; posterior descending branch of the right coronary artery, 22; left ventricular branch of the right coronary artery, 24. Angiographic Views

Filming is done in a number of projections so that all coronary arteries can be visualized throughout their lengths and significant disease can be detected and quantified. Multiple views in the transverse plane (Figs. 15-21, 15-22 and 15-23) were used until 1973, when Bunnell reported the advantages of obtaining views incorporating sagittal angulation of the x-ray beam along the long axis of the body (Fig. 15-24). Use of these views (Figs. 15-25 and 15-26) greatly enhances the ability to visualize the proximal left coronary artery, unmasking lesions that otherwise would be missed in up to 20 percent of patients and significantly improving diagnosis in an additional 30 to 40 percent.[133-135] The evolution of a new generation of x-ray equipment to obtain these views has revolutionized coronary arteriography. In most laboratories, standard views of the left coronary artery are the frontal view, 30° RAO, 45° LAO, 45° LAO with 30° of cranial angulation, 30° RAO with 30° of cranial angulation, and 30° RAO with 15° of caudal angulation. Other views may be needed to separate overlapping vessels or to focus on a particular problem area. The right coronary artery usually is visualized in the right and left oblique projections, and sagittally angulated views frequently are helpful in evaluating the proximal posterior descending artery (Figs. 15-27 and 15-28). The use of sagittally angulated views also provides for improved visualization of LV wall motion and mitral valve motion and for evaluation of the LV outflow tract.[136]

Figure 15-26: Diagrammatic illustration of the direction of the x-ray beam and the left coronary angiogram in the 15° RAO with 30° of cranial angulation. This view is particularly helpful in analyzing the mid-left anterior descending artery and the diagonal branch points. Overlap with diagonal branches is usually avoided. The origin of the circumflex artery may be well seen, as in this illustration. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)

Figure 15-27: Diagrammatic illustration of the direction of the x-ray beam and the right coronary artery in the 45° LAO projection. This view is excellent for visualizing the proximal mid and distal right coronary artery in the AV groove since the direction of the x-ray beam is perpendicular to these arterial segments. Ostial lesions of the right coronary artery are now well visualized if the proximal right coronary artery takes an anterior direction from the aorta and therefore originates in a direction parallel to the x-ray beam. This usually can be overcome by turning to a more severe left oblique projection. The posterior descending and LV branches of the right coronary artery, which pass down the posterior aspect of the heart toward the

apex, are severely foreshortened because the long axis of these vessels is in the same direction as the x-ray beam. The proximal posterior descending branches can be visualized by cranial angulation of the overhead intensifier (see Fig. 15-28) or from a right oblique view. The image intensifier is in the standard LAO position. (From King et al.[136] Reproduced with permission from the publisher, editor, and authors.)
