Genetic mutations may be clinically silent or result in disease. Germ line mutations may be transmitted to offspring. Mutations in tumor suppressor genes have been likened to a car running on one flat tire. A second mutation results in the loss of function of both alleles, possibly resulting in unregulated growth.

Somatic mutations are of significance in the development of neoplasms via their impact on cell cycle, growth, and differentiation. Certain diseases are associated with a single known mutation, but others, such as cystic fibrosis, are associated with more than 100 mutations and therefore require comprehensive testing. The "gold standard" test would be DNA sequencing in such situations to detect all possible known mutations or new mutations. Cystic fibrosis transmembrane conductance regulator mutation analysis for carrier screening of a panel of 25 mutations is presently recommended by the American College of Medical Genetics (8). Recent studies have attempted the use of oral mucosa cytologic material for screening.

Hereditary and Familial Cancer Syndromes

Hereditary and familial cancer syndromes usually occur in a dominant manner but may also occur through multifactorial inheritance due to the inheritance of multiple low-frequency alleles. Mutations of breast cancer susceptibility genes *BRCA1* and *BRCA2* are identified in about 3% of breast cancer cases (16). Individuals with Li-Fraumeni syndrome (12) inherit one mutant *p53* allele and are therefore predisposed to malignancy, especially when a subsequent hit leads to inactivation of the other allele. They develop tumors at an earlier age than their counterparts without the mutant allele and may have multiple malignancies of the breast and brain, as well as sarcoma and leukemia.

Colorectal cancers can be characterized as those with or without underlying polyposis syndromes. The study of familial adenomatous polyposis has demonstrated the presence of adenomatous polyposis coli gene mutations in 5q21.

Therapeutic Target Detection

The study of molecular pathways of carcinogenesis has highlighted various molecules that are now therapeutic targets. A part of this approach is individualized study of tumor specimens. Clinical trial data on patient outcomes are often put together with protein expression data to determine the thresholds for labeling protein expression as positive or negative. An example of a therapeutic target is HER-2/neu, a member of the tyrosine kinase receptor family. Another

example is epidermal growth factor receptor, also a member of the tyrosine kinase receptor family, which is expressed in colon carcinoma. Recent regimens of treatment of late-stage colon carcinoma with antibodies to epidermal growth factor receptor require immunohistochemical studies of tissue to detect the presence of tumor expression.

Gene Expression Profiling

The ability to test the expression of 1,000 to 40,000 genes simultaneously with microarray technology has significantly changed our approach to the analysis of tumors. Instead of comparing different tumors one gene at a time, advances in bioinformatics have made it possible to find out combinations of genes that characterize a specific tumor. This approach of gene profiling has been successfully used to reclassify tumors according to clusters of gene expression. For example, van de Vijver et al. (24) have found a gene expression "signature" that can serve as a predictor of survival of breast cancer patients much more reliably than histological morphology and individual immunohistochemistry staining. Recently, high-throughput genomic approaches such as gene expression profiling by cDNA microarray have shown promising results in detecting different prognostic groups of soft-tissue tumors. In a pilot study using cDNA microarray and cluster analysis, the gene expression profiles of different types of soft-tissue tumors correctly discriminated patients who survived from those who did not, with P values of less than 0.0001 (10). Notably, none of the existing prognostic factors, including histologic type and response to therapy, were as reliable for predicting the survival of these patients (10). Once gene expression signatures are discovered, there is always a need for subsequent validation. After this is accomplished, commercial companies prepare smaller gene arrays that have only the genes of interest (usually fewer than 100). These specific arrays can be used clinically to predict response to therapy and outcome. The main advantage of this approach is the ability to sort out which patients need additional therapy immediately after surgery and which ones do not. Avoiding excessive therapy for patients who are unlikely to have tumor recurrence would decrease the inconvenience and the side effects of unnecessary treatment.

Microdissection as a Preparative Method for Molecular Testing

It is easy to perform molecular testing with tissues that contain a very large percentage of the cell type of interest. For example, if one is interested in comparing heart muscle with skeletal muscle, there is only a small percentage of contaminating cells such as those of vessels and nerves and therefore there is no need to tease out muscle cells for study. On the other hand, if one is interested in comparing expression patterns of genes in type I and type II skeletal muscles, then a method to separate these cells before analysis becomes necessary. This is also true when one wants to separate stromal cells from epithelial cancer cells in preparation for comparison among different types of cancers. Methods used for obtaining relatively pure cell populations include flow cytometry, density gradient-based cell separation, and for tissues in histological sections, either blunt manual microdissection with an inverted microscope and a lancet or laser microdissection. Several commercial instruments for microdissection are available, and these are capable of isolating even one individual cell from a tissue section. These instruments usually have an inverted microscope, an infrared laser, a control unit for the laser, a controlled mechanical stage for the glass slide, and a digital camera. The cells of interest are cut out of the tissue with the laser and collected in a flask for subsequent RNA, DNA, or protein extraction. One may need to apply nucleic acid amplification to these cells, depending on the number of cells collected and also on the final application. For more-detailed descriptions of methods of and caveats on microdissection, one may refer to several publications and comprehensive monographs on this subject (e.g., reference 15), as well as commercial instrument manuals.

TMAs

A relatively simple method of examining hundreds of tissue sections in one experiment is the use of tissue microarrays (TMAs) (9). TMA has brought histotechnology into the "omics," high-throughput style. Tens to hundreds of minute tissue cores from different patient samples (0.6 to 2.0 mm in diameter) are neatly arranged on each glass slide. For example, slides can be used for immunohistochemical studies and ISH. The advantages of this method are many. Reagents are less expensive, all experiments can be performed in one run, interassay variation is avoided, there is less depletion of paraffin-embedded tissues, tissues can be obtained from departments of pathology from multiple institutions, and the tissue blocks can be returned to the original hospital archives. Studies have shown that adequate sampling is not an issue, and TMAs may even improve sampling by avoiding interpretation bias. A whole section of a tumor may have a small focus of positivity for a marker while the random areas selected for TMA may all be negative. This result correlates better with overall tumor prognosis. However, there are also clear disadvantages of this method over conventional slide methods. These include the initial cost of a tissue microarrayer, the need for a solution to formidable bioinformatics issues that result from increasing the number of samples, and greater difficulty in correlating staining results with the original histological findings. Methods for constructing TMAs from needle biopsy material, cell cultures, and frozen samples have expanded the applications of this technology. These "tissue chips" have helped researchers to keep up with the volume of research data on possible markers generated by genomics and proteomics laboratories. Fulfilling of the promise of TMA is still in its first steps, as methods of high-speed automated quantitative analysis are slowly developed. Important issues to remember when starting to build TMAs are the learning curve associated with using the instrument, the rapid oxidation of antigenic sites when unstained slides are exposed to ambient air, and bioinformatics management of the annotated common data elements for each tissue core, etc. TMA technology is of limited utility in the diagnostic histology laboratory, and TMAs have been mostly used for immunohistochemical slide control samples and for preparation of multi-institutional quality assurance slides.

Detection of Lymphomas and Leukemias

The detection of acute lymphoid leukemias and lymphomas is done in part by determining the clonalities of neoplastic lymphocytes, i.e., rearrangement of immunoglobulin (Ig) heavy-chain and light-chain genes (B-cell clonality) and T-cell receptor (TCR) genes (T-cell clonality) (13). Southern blotting remains the "gold standard" for this type of determination. However, this method requires fresh or frozen tissues or cells, large amounts of DNA, and a long period of hands-on time and has become a second-line test. This method has 1 to 5% sensitivity (i.e., 1 to 5 neoplastic cells/100 nucleated cells can be detected). The most common target genes are those of the Ig heavy chain, the Ig κ light chain, and TCRβ. PCR-based

methodologies with the advantage of using fresh, frozen, or formalin-fixed tissues or cells are faster and less labor-intensive and have become the first-line methods in clinical laboratories for clonality testing. PCR methods use consensus primers targeting highly conserved sequences of different J or V segments of Ig heavy-chain or TCR genes to amplify clonally rearranged Ig heavy-chain or TCR genes. The sensitivity is at 1 clonal B or T cell detected/100 B or T cells with the routine method and can be significantly increased by using clone-specific probes to the range of 1 clonal cell in 10,000 to 1 million normal cells. The major weakness of the PCR method is the tendency for false-negative results due to imperfect consensus primers. Therefore, negative results should be confirmed by Southern blotting whenever possible. The majority of lymphomas and leukemias can be further classified by their characteristic chromosomal lesions (2, 13). Some of these lesions can be detected by immunohistochemical markers as shown in Table 1.

The major limitation of clonality testing using the chromosomal lesions or Ig-TCR gene rearrangement is the false-positive rate. Pseudoclonality associated with Ig gene rearrangement has been seen in cases of small biopsy specimens with a paucity of lymphocytes, helicobacter pylori-induced gastritis, hepatitis C, human immunodeficiency virus infection and other viral infections, Sjögren's syndrome, and rheumatoid arthritis. Pseudoclonality associated with TCR gene rearrangement has been seen in cases of immune system reconstitution post-hematopoietic stem cell transplantation, immune response to tumors, and clonal dermatitis. Furthermore, most of the characteristic chromosomal translocations occurring in hematopoietic malignancies are also observed in healthy individuals when highly sensitive PCR-based assays are applied. Other important limitations include false-negative results due to sampling or technical issues and lineage infidelity (i.e., Ig heavy-chain rearrangement may occur in T-cell malignancies). Therefore, it is necessary to correlate molecular testing results with immunophenotyping results for accurate lineage determination.

Presently molecular diagnostic techniques are considered as second-line tools for clinical detection of hematopoietic malignancies due to the above-mentioned limitations. Morphology analysis and immunophenotyping remain the "gold standards" for diagnosis and classification. However, in difficult cases with inconclusive morphology and immunophenotyping results, molecular diagnostic techniques can be important for reaching an accurate diagnosis. Examples of ambiguous results include atypical reactive interfollicular infiltrate versus T-cell lymphoma (clonal TCR gene rearrangement analysis favoring the latter), follicular lymphoma with marginal zone (monocytoid) differentiation versus marginal zone lymphoma with follicular colonization (IgH-BCL2 translocation favoring the former), and atypical lymphoid infiltrate of gastric mucosa versus extranodal marginal zone B-cell lymphoma [t(11;18) translocation favoring the latter].

Besides being used for diagnostic applications, molecular diagnostic techniques can provide important prognostic information in cases of lymphomas and leukemias. For example, t(8;21), t(15;17), and inv(16) are associated with good prognosis, and t(9;22) is associated with poor prognosis in acute myeloid leukemia (2). The FLT3 mutation has become the most common identifiable genetic abnormality in acute myeloid leukemia and an important poor-prognosis indicator (7). In acute lymphoid leukemia, t(12;21) is not detected by conventional cytogenetics, but with the use of FISH, RT-PCR, or Southern blotting, it is an important good-prognosis indicator while t(9;22) and mixed-lineage leukemia gene rearrangement [t(4;11)] serve as poor-prognosis indicators (2). In B-cell chronic lymphocytic leukemia, patients with mutated IgH genes (correlating with a CD38$^-$, Zap70$^-$ phenotype) have better prognoses than those with IgH genes without mutations, correlating with CD38$^+$ (>30% of neoplastic cells expressing CD38) and Zap70$^+$ (>20% of neoplastic cells expressing Zap70) phenotypes, which have poor prognoses (18).

Detection of Soft Tissue Tumors

Similar to those associated with hematopoietic malignancies, most genetic abnormalities associated with soft-tissue tumors are chromosomal translocations resulting in novel fusion proteins (5). These fusion proteins often affect transcription factors, resulting in a disruption of transcription regulation. This disruption may lead to activation of inappropriate genes or inappropriate repression of some genes. The fusion genes can also serve as targets for the molecular detection of respective tumors and the development of targeted therapy.

Molecular diagnostic techniques, particularly RT-PCR and FISH, have become important tools to detect the characteristic fusion genes associated with soft-tissue tumors. These molecular techniques require only a minimal amount of tissue. This is particularly important when managing needle core biopsy specimens, which are becoming the most common type of specimens in the pathology laboratory. In the majority of cases, the evaluation of morphology and immunohistochemical studies may be sufficient for diagnosis. However, in difficult cases such as that of monophasic synovial sarcoma with a spindle-cell pattern, molecular genetics can be employed.

The specificity of fusion genes, although reasonably high, is not absolute. Thus, most authorities concur that conventional morphological assessment, supplemented by ancillary techniques including molecular studies, remains the standard diagnostic approach. A good example is that of TPM3-ALK and CLTC-ALK gene fusions, which have been recently identified in both inflammatory myofibroblastic tumors and anaplastic large-cell lymphomas.

In addition to their diagnostic applications, molecular studies may further provide important prognostic information for each specific soft-tissue tumor. Anderson et al. reported the translocation t(2;13)/PAX3-FKHR to be an adverse prognostic factor in alveolar rhabdomyosarcoma (1). In contrast, t(1;13)/PAX7-FKHR was associated with a favorable prognosis and was more frequently observed in younger patients with relatively localized disease (1). Sorensen et al. (22) reported that, among the patients with metastatic alveolar rhabdomyosarcoma, bone marrow involvement was significantly higher in PAX3-FKHR-positive patients (22).

PROGNOSTIC SIGNIFICANCE OF DETECTION AND QUANTITATION OF MINIMAL RESIDUAL DISEASE IN LEUKEMIAS, LYMPHOMAS, AND SOFT-TISSUE TUMORS

The sensitivity and specificity of the PCR and RT-PCR protocols have provided evidence for the existence of minimal disease which cannot be detected by physical, morphologic, or radiographic examination. Cumulative data have demonstrated that most patients still harbor a significant tumor burden after resection of tumors or establishment of complete clinical remission of leukemias (4). When patients with Ewing's sarcoma or primitive neuroectodermal tumors were studied using RT-PCR, about 50% of patients with metastatic or relapsed disease had blood or marrow samples positive

for the *EWS–FLI-1* transcripts and approximately 25% of patients without clinically metastatic disease did so as well. Other RT-PCR methods to detect minimal alveolar rhabdomyosarcoma and synovial sarcoma disease and desmoplastic small round cell tumors have also been described (5). In patients with chronic myeloid leukemia, rising or persistently high levels of *BCR-ABL* (*BCR-ABL:ABL* ratio of >0.02% or >100 *BCR-ABL* transcripts/μg of RNA), determined by quantitative RT-PCR, in two sequential specimens obtained more than 4 months following stem cell transplantation are predictive of overt clinical relapse (11). Similarly, by using real-time quantitative PCR to quantify the amount of t(14;18)(q32;q21) cells, it was recently observed that a measurable tumor load of ≥0.01% after stem cell transplantation may predict subsequent relapse of follicular lymphoma (4). Furthermore, studies have shown that treating chronic myeloid leukemia patients before overt clinical relapse of disease can improve survival of such patients after stem cell transplantation (6). Quantification of minimal residual disease may lead to new therapeutic avenues to improve patient outcome. However, the clinical and therapeutic significance of minimal disease remains to be evaluated for most cancers.

Immunohistochemistry: Diagnostic and Prognostic Applications

VINOD B. SHIDHAM AND ANDRÉ A. KAJDACSY-BALLA

47

By revolutionizing the cytomorphological and histomorphological evaluation of human tissue, immunostaining is altering the diagnosis and treatment of an increasing number of diseases. Although initially investigators had only polyclonal antibodies and immunofluorescence as tools, progressive technological advances such as the use of hybridomas, flow cytometry, cytogenetics, and solid-tissue immunostaining have led to reclassification of certain tumors based on the expression patterns of specific cellular antigens. Immunostaining is being applied to aid in the classification and differentiation of neoplasms by using antibodies to lineage-specific proteins such as vimentin, cytokeratin, and S-100 protein.

Advances in production of monoclonal antibodies and techniques for immunostaining sections of formalin-fixed, paraffin-embedded tissue for light microscopy have greatly accelerated these developments (6). Various antigen retrieval methods such as heat-induced epitope retrieval (13) and molecular biology approaches which predict peptide sequences based on the DNA sequences in newly identified target genes have advanced the field further. This chapter highlights the basic principles of immunostaining for light microscopy in brief and discusses the diagnostic and prognostic applications of immunostaining.

ANTIGENS

Computerized programs can predict immunogenic sequences of target molecules to allow for the genetic engineering of peptides for the production of polyclonal antibodies. Semipurified proteins or recombinant proteins are commonly used for producing monoclonal antibodies, which are most commonly reactive with nonlinear conformational epitopes. The epitopes may be destroyed if proteins are digested, denatured, or modified by a cross-linking fixative such as formalin which causes alterations in protein folding patterns.

Formalin fixation is a major barrier for immunohistochemistry. With formalin treatment, methyl group cross-linking frequently destroys the epitope by unfolding the protein. It can also mask the desired epitope by cross-linking it with adjacent proteins. Therefore, many monoclonal antibodies that work well for fresh tissues are frequently rendered useless for paraffin-embedded fixed tissues. Another problem with aqueous formalin solutions is the formation of methoxy alcohol derivative with little aldehyde in the solution, leading to a slowdown of the fixation process (only 1 mm of tissue/h). This slowdown results in the fixation of tissue predominantly along the surface, with autolysis in the central portion, which is eventually fixed by alcohol during the dehydration steps.

Pretreatment of sections (prior to treatment with a primary antibody) with various proteolytic enzymes (papain, trypsin, and pepsin, etc.) may unmask epitopes and facilitate detection. Cross-linking may also be reversed by heating tissue sections in aqueous citrate buffer, resulting in the recovery of epitope reactivity (2, 13). These technical advances have increased the possibility of many monoclonal antibodies to be used with archived tissue sections (23).

The need for immunohistochemical evaluation, including analysis and quantification, is increasing. A quantitative approach to immunostaining is significantly limited because of variations in the types of fixatives, pHs of the fixatives, durations of fixation, temperatures of fixation, and storage conditions. Improved standardization of fixation methods, automated immunostaining, and image analysis are likely to improve the global interpretation of tissue subjected to immunohistochemistry.

ANTIBODIES

Polyclonal rather than monoclonal antibodies are more likely to detect antigens in which some but not all of the epitopes have been masked or denatured. Although wider in their spectrum of reactivity than monoclonal antibodies, polyclonal antibodies usually have less selectivity, resulting in frequent nonspecific staining. The usual practice is to raise polyclonal antibodies against synthetic peptides and increase specificity by peptide absorption. The amount of polyclonal antibodies that can be recovered from any one immunized animal is limited. In addition, there is considerable lot to lot variation in polyclonal antibody reagents.

Murine monoclonal antibodies are uniquely specific in their reactivity with a particular epitope. The recent availability of hybridoma technology for the production of rabbit monoclonal antibodies may further enhance the quality and sensitivity of immunostaining, because rabbit antibodies have stronger affinities than murine antibodies (20). By using a cocktail of several unique monoclonal antibodies, one may enhance the spectrum of reactivity without compromising specificity (18).

DETECTION SYSTEMS

Immunostaining may be performed on tissue sections (immunohistochemistry) or cytology smear specimens (immunocytochemistry). It may be performed as one step, with a primary antibody conjugated directly with an indicator system, or two steps, with a primary antibody followed by a secondary antibody conjugated with an indicator system.

There are a number of methods for the detection of antibodies bound to their specific target antigens. Commonly, heavy-chain-specific, anti-Fc secondary antibodies are conjugated directly with reactive substances, such as biotin. This allows for the detection of numerous specific primary antibodies by using the same secondary antibody system. Biotin is detected by streptavidin, linked to one of several indicator enzymes such as horseradish peroxidase, alkaline phosphatase, or glucose oxidase, which then reacts with a substrate, producing an insoluble colored product visible by light microscopy. It is possible to investigate multiple antigens simultaneously by using primary antibodies of different heavy-chain classes, immunoglobulin A (IgA), IgG, and IgM, with different epitope specificities to first attach to the antigens of interest. Each secondary anti-heavy-chain antibody will have its own detection substances with different visual color development patterns (3, 16).

A polymer backbone labeled with an indicator enzyme such as horseradish peroxidase or alkaline phosphatase may be conjugated to either primary antibodies (Zymed cytokeratin rapid immunohistochemistry kit; Zymed Laboratories, Inc., South San Francisco, Calif.) or secondary antibodies (PowerVision+ [ImmunoVision Technologies Co., Brisbane, Calif.] and EnVision and EnVision+ systems [DakoCytomation, Carpinteria, Calif.]). This provides an amplified biotin-free detection system with high sensitivity and fewer steps than conventional methods.

CONTROLS

As the reagents used and the targets evaluated are mostly proteins, they are subject to nonspecific binding, degradation, and cross-reactivity. It is important to monitor the process with negative and positive controls. There are two methods for negative controls. The antibody to be used may be reacted with the target antigen prior to immunostaining. More commonly, the primary antibody may be replaced by another antibody of the same idiotype but different specificity.

The positive controls may be tissue sections or cytology smear specimens with proven immunoreactivity with the test antigen. The positive controls should ideally be treated in a fashion identical to that of the test material with reference to steps such as fixation, tissue smear specimen processing, and antigen retrieval. Generally, one positive control is sufficient for a particular immunostaining run utilizing automated procedures. In order to avoid errors introduced by failures of mechanical delivery, these positive controls should preferably be placed on the same slide as the test specimen. This is relatively easy for tissue sections but may not be feasible for cytology smear specimens, depending on the method of smear preparation. Tissue "sausages" or tissue microarrays with several control tissues, including ones fixed at different times, are used as positive controls by some laboratories. Positive controls for cytology may be the smear specimens prepared from lesions with known immunoreactivity for a particular antigen or from smear specimens from cell lines with known immunoreactivity patterns. Positive control smear specimens should be processed and fixed using methods identical to those used for test smear specimens. The fixed smears may

then be dehydrated without staining, cleared, and covered with glass coverslips using mounting medium similar to that used for permanent sections (15, 17, 19). Such coverslipped unstained smears are stable at room temperatures of 70 to 80°F as positive controls for commonly used immunomarkers (19).

Ubiquitous antigens may serve as internal controls to establish the stability of antigens after fixation and tissue processing. Vimentin is a stable antigen in formalin-fixed tissue sections and thus may be used to evaluate unevenly fixed tissue blocks by evaluating only those areas with vimentin reactivity for other specific antigens. The lack of reactivity for such an internal control indicates a need to modify the immunostaining protocol by, for example, incorporating pretreatment of the sections by enzyme digestion or heat-induced epitope retrieval. Although vimentin is considered to be a reliable internal control for formalin-fixed, paraffin-embedded tissue sections, it may not be applicable to all methods of fixation and processing. As reported previously (17), vimentin immunoreactivity deteriorates in air-dried smear specimens after rehydration in saline and postfixation in alcoholic formalin but other markers are stable (17).

Nonspecific binding may be reduced by preincubating the sections with milk or with Igs of the same species and type as the secondary antibody used. Preincubation with streptavidin may be necessary for biotin-rich tissues, especially when one is using heat-induced epitope retrieval, which may greatly enhance the intrinsic biotin reactivity (2).

INTERPRETATION

The chromogen's color indicates the presence of the antigen in question. In general, the intensity of immunoreactivity should be comparable to that seen with the positive control. This is important for certain immunomarkers such as CD117 (c-*kit*), which may be interpreted spuriously as positive when only faint immunostaining is seen.

The location of the marker within the cell helps in interpretation. Some examples of immunomarkers with diagnostic nuclear reactivity are estrogen receptor (ER), progesterone receptor (PR), androgen receptor, S-100 protein, microphthalmia transcription factor, thyroid transcription factor 1 (TTF-1), MyoD1, β catenin (for desmoid), and calretinin (for mesothelial cells). The appearance of these markers in the cytoplasm alone may be confusing, but suggests nonspecific or nondiagnostic staining.

Some immunostaining patterns are typical for a particular lesion (see Table 1). Examples include the canalicular immunostaining pattern associated with polyclonal carcinoembryonic antigen (pCEA) in hepatocellular carcinoma, the concentric fibrillar immunostaining pattern associated with cytokeratins in mesothelial cells, the peripheral microvillous immunostaining pattern associated with HBME-1 and epithelial membrane antigen (EMA) in mesothelial cells, the membranous immunostaining pattern associated with Her2/neu in mammary carcinoma, the membranous pattern associated with E-cadherin in mammary ductal carcinoma, and the dot-like paranuclear globular immunoreactivity pattern associated with cytokeratin in desmoplastic small round cell and Merkel cell tumors.

APPLICATIONS

Textbooks (1), journals (e.g., *Applied Immunohistochemistry and Molecular Morphology*), and websites (Immunoquery; http://www.ipox.org) are invaluable tools for keeping up with

TABLE 1 Typical immunoreactivity (antigen expression) patterns of a few types of tumors[a]

Tumor type(s)	Immunoreactivity (antigen expression) pattern(s)
Biliary tract, mucinous ovarian, and transitional cell ca	CyK 20$^+$, CyK 7$^+$
Gastric tumor	CyK 20$^-$, CyK 7$^+$, MUC5AC$^+$
Breast, lung, endometrial, and nonmucinous ovarian ca	CyK 20$^-$, CyK 7$^+$
Colon ca	CyK 20$^+$, CyK 7$^-$, diffuse pCEA$^+$, MUC5AC$^-$
Hepatocellular ca	pCEA$^+$ (canalicular-pattern), AFP$^+$, MUC5AC$^-$
Cholangiocarcinoma	pCEA$^-$ (or diffusely$^+$), AFP$^-$, CyK7$^+$, MUC5AC$^+$
Thyroid, endometrial, mesothelioma, and renal ca	Coexpression of Vim and CyK
Breast and nonmucinous ovarian ca	ER/PR/AR$^+$
Small cell ca	$+$ For neuroendocrine markers (synaptophysin, chromogranin, CD56)
Merkel cell ca	Globular CyK20$^+$, $+$ for neuroendocrine markers
Thyroid ca	Vim$^+$, CyK$^+$, thyroglobulin$^+$
Prostate ca	PSAP$^+$, PSA$^+$, CEA$^-$
Choriocarcinoma	HCG$^+$
Seminoma	PLAP$^+$
Mesothelioma	Vim$^+$, CyK 5$^+$, nuclear calretinin$^+$, CEA$^-$ (or focal)
GIST	CD117$^+$, CD34$^+$
Desmoplastic small round cell tumor	CyK$^+$ (globular), desmin$^+$ (globular), Vim$^{+/-}$
Prostatic adenocarcinoma versus transitional cell ca	PSA/PSA/Leu7$^+$ versus CyK 903 (34βE12)$^+$
Small cell lung ca versus Merkle cell ca	TTF-1$^+$ versus CyK 20$^+$
Thyroid ca versus medulary ca of thyroid	Thyroglobulin$^+$ versus calcitonin$^+$
Stromal tumors versus leiomyosarcoma	CD10$^+$ versus SMA$^+$
Breast ca versus colon ca	ER/PR/AR/CyK 7$^+$ versus CyK 20$^+$
Ovarian mucinous ca versus appendiceal mucinous ca	CyK 7$^+$ versus CyK 20$^+$ and Cdx2$^+$
Hepatocellular ca versus cholangiocarcinoma	pCEA$^+$ (canalicular), hepar$^+$, albumin$^+$ versus pCEA$^-$ (canalicular), hepar$^-$, albumin$^-$
Mesothelioma versus lung ca	Calretinin$^+$ (nuclear) versus TTF-1$^+$ (nuclear)

[a] Ca, carcinoma; CyK, cytokeratin; MUC5AC, mucin 5 subtypes A and C; AR, androgen receptor; PSAP, prostate-specific acid phosphatase; PSA, prostate-specific antigen; Vim, vimentin; HCG, human chorionic gonadotropin; PLAP, placental alkaline phosphatase; SMA, smooth muscle actin; AFP, alpha-1 fetoprotein; $+$, positive; $-$, negative.

the rapidly changing field of immunohistochemistry diagnostic and prognostic applications. The areas in which immunostaining might be used for such applications may be categorized as follows: differential diagnosis, evaluation using therapeutic predictive markers, evaluation using prognostic markers, evaluation for dysplasia and malignancy, and intraoperative evaluation.

Differential Diagnosis

Immunohistochemistry is commonly used to aid in the differential diagnosis of neoplasms, particularly those classified as poorly differentiated. The undifferentiated neoplasms may be grouped morphologically into four categories: small blue cell tumors, large cell tumors, pleomorphic tumors, and spindle cell tumors. Figure 1 shows a simplified algorithm to be applied with reference to morphological features and clinical details (7, 10, 14, 23). This algorithm may be modified and updated further depending on future additions to and improvements in the ever expanding list of immunomarkers.

Up to 20% of neoplasms present as metastases with an unknown primary. The search for the primary site is a time-consuming, expensive, and often fruitless process. In rare cases, it may not be found even after a complete autopsy. Immunomarkers have contributed greatly to the resolution of this challenge. For example, coordinate expression of

cytokeratins 7 and 20 may help in determining the primary sites of metastatic lesions (23). In addition, all epithelial neoplasms express cytokeratins; however, expression of the nontrichogenic cytokeratins follows a site-specific pattern. Similarly, different types of mucins, along with cytokeratins, facilitate the diagnostic algorithm for interpretation of gastrointestinal tract cancers (7).

Immunostaining has also been effectively used for the detection of small metastatic lesions in sentinel lymph nodes (SLNs) for identification of melanoma (16), mammary carcinoma (22), Merkel cell tumor (21), and other tumors. It may also be helpful for identification of surgical margins such as in cases of carcinoma of the stomach and for detection and confirmation of various microorganisms such as cytomegalovirus and polyoma virus and of other substances such as amyloid.

Evaluation Using Therapeutic Predictive Markers

A therapeutic predictive marker is used to help guide therapy. The best known therapeutic predictive makers are ER and PR in breast carcinoma (11), the growth factor receptor Her-2/neu in breast carcinoma (12), CD117 in gastrointestinal stromal tumors (GIST) (8), and epidermal growth factor receptor in several different tumors (9).

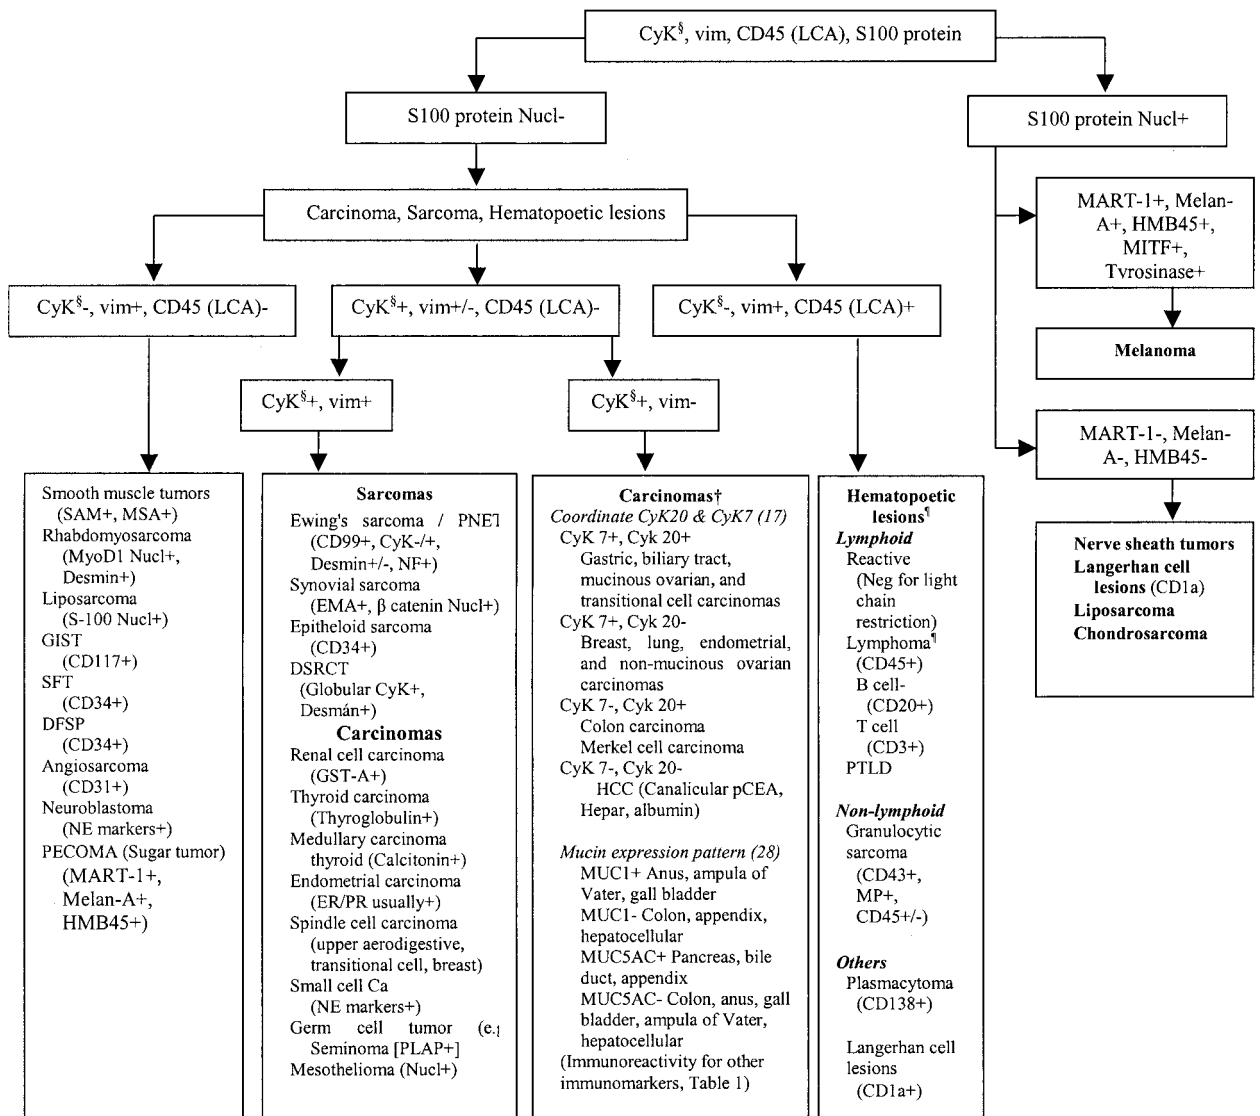
The presence of nuclear ER and PR favors a positive response to estradiol antagonist treatment (12). These markers


FIGURE 1 Algorithm for immuohistochemical evalution of tumors—to be interpreted with reference to morphology and clinical details (7, 14, 23). §, For covering a wider spectrum of cytokeratins (CyK), cytokeratin–Lu-5 or a cocktail of cytokeratin AE1/AE3 and CAM5.2 is preferred. ¶, The list of hematopoietic lesions is partial and abbreviated (for details, see reference 14 and other specific literature). †, For details, see specific references including reference 7 and 23.

are assayed routinely in breast cancers. Patients with tumors with 10% or more nuclei positive for ER or PR are more likely to respond to hormonal therapy. A variety of methods have been used to quantify results by image analysis with evolving automation.

Due to the amplification of the Her-2/neu gene, ErbB-2 (HER-2) tyrosine kinase receptor, a member of the epidermal growth factor family of receptors, is overexpressed in approximately 30% of breast carcinomas. Humanized antibody Herceptin (Genentech, Inc., South San Francisco, Calif.) has demonstrated benefits in women with advanced breast cancer who did not respond to conventional chemotherapy. Although the impact of ErbB-2 has been studied for 20 years, its importance was accelerated when the humanized antibody (Herceptin) was developed. Her-2/neu protein is expressed in

the cell membrane and can be demonstrated by immunohistochemistry as a marker with a membranous immunostaining pattern. In cases with equivocal immunohistochemistry results, gene amplification can be demonstrated by the use of labeled nuclear probes with in situ hybridization, either fluorescent in situ hybridization or chromogenic in situ hybridization.

Virtually all GIST are associated with mutations of the c-kit oncogene with expression of CD117 (c-kit). This association is extremely helpful for the detection of GIST (8). Imatinib mesylate (STI571; Gleevec) is a potent, specific inhibitor of c-kit (CD117) used in chronic myeloid leukemia. It has demonstrated significant therapeutic effects in cases with unresectable and metastatic malignant GIST. The relationship of CD117 to imatinib mesylate in other tumors is being evaluated.

Other agents such as gefitinib (Iressa; ZD1839) and lapatinib (GlaxoSmithKline, Research Triangle Park, N.C.) are inhibitors of epidermal growth factor receptor (ErbB-1 tyrosine kinase receptor) expressed in the cytoplasm and membranes of cells from several different tumors.

Evaluation Using Prognostic Markers

Examples of prognostic markers include proliferation and cell cycle proteins (such as Ki-67, p53, and retinoblastoma protein), various growth factors and their receptors, molecules involved in apoptosis (Bcl-2), proteases and their inhibitors (including tissue metalloproteinase inhibitor), and adhesion molecules (such as cadherins and integrins).

Knowledge about the prognostic significance of each marker will continue to be updated as the follow-up data from an increasing number of studies become available (4). Association such as that of poor prognosis with the immunoexpression of vimentin in breast and renal cell carcinomas is expected to emerge.

Evaluation for Dysplasia and Malignancy

Although rare, in some situations immunostaining may facilitate interpretation of dysplasia (through detection of p16 in cervical dysplasia [5]) and malignancy (through detection of monoclonal antibody for CEA in minimal deviation endocervical adenocarcinoma versus normal endocervical mucosa and S-100A6 immunoreactivity in normal nevi versus rare or weak immunoreactivity in melanoma). Other approaches such as the use of p53 immunoreactivity in serous cavity fluids and in urine have been studied for detecting neoplastic cells.

Intraoperative Evaluation

Rapid intraoperative immunocytochemical evaluation facilitates improved management in a variety of clinical situations. The most practical application is the rapid intraoperative immunocytochemical evaluation of SLNs for detection of cutaneous melanoma (19). The imprint smear specimens can be immunostained by using a standardized protocol in 17 min (19). If the SLNs are positive for melanoma micrometastases, the surgeon can proceed with completion of regional lymphadenectomy during the same anaesthetic session, thus eliminating the need for additional surgery at a later date. This has obvious financial and social benefits with improved quality of patient care. If indicated, the same principle may be applied for the evaluation of SLNs for breast carcinoma, Merkel cell tumor, and many other malignancies in the future.

Rapid intraoperative immunocytochemical evaluation can also be applied for the evaluation of the imprint smears of surgical margins of carcinomas, especially in fatty tissues such as breast. Frozen sections of such tissues are technically difficult to assess for micrometastases due to significant artifacts and blank holes in the sections.

Immunofluorescence Methods in the Diagnosis of Renal and Skin Diseases

A. BERNARD COLLINS, ROBERT B. COLVIN, CARLOS H. NOUSARI,
AND GRANT J. ANHALT

48

Immunofluorescence is a well-established technique for the detection of antigens in tissue sections or cell suspensions (6, 7, 11, 29, 40). Since its development in 1941 by Albert Coons at Harvard Medical School to demonstrate the presence of pneumococcal antigens in tissue (15), immunofluorescence has become a crucial tool in the diagnosis and determination of prognoses of immunologically mediated kidney (12, 28, 38–40) and skin (1, 5, 6, 8, 16) diseases. Direct immunofluorescence (defined as the application of specific antibodies to detect specific antigens in tissue) is a sensitive and simple technique for the detection of tissue-bound immunoglobulins (Igs), complement components, and fibrin-fibrinogen in cases of glomerulonephritis and autoimmune or immunologically mediated mucocutaneous disorders. In the kidney, many forms of primary glomerulonephritis are characterized by deposition of immunoreactants in distinctive diagnostic patterns. The primary renal targets are the glomerulus, the proximal tubules, and the interstitium. In many skin diseases, demonstration of Ig or complement deposition in specific structures in the dermis and epidermis is an essential criterion for accurate diagnosis. For the skin, we will focus primarily on the immunofluorescence findings in bullous and connective tissue disorders, vasculitides, and other mucocutaneous conditions, for which this immunohistochemistry technique can provide useful diagnostic information. This chapter will also emphasize the common immunofluorescence techniques used for diagnosis and interpretation with kidney and skin biopsy specimens.

TISSUE FOR IMMUNOFLUORESCENCE

Kidney

Renal tissue submitted for immunofluorescence studies is usually obtained from percutaneous needle biopsies, surgical wedge biopsies, or nephrectomies. A hand lens (magnification, × 7) or dissecting microscope is useful to determine if the tissue specimen contains glomeruli. The complete diagnostic work-up for renal tissue includes electron microscopy (33), direct immunofluorescence (11), and light microscopy studies (40). Percutaneous needle biopsy specimens, which usually range in length from 0.5 to 2.0 cm, can be divided in such a manner as to ensure that adequate tissue is available for the three-part study. The division of a closed and surgical (wedge) renal biopsy specimen is illustrated in Collins

(11). Briefly, a 1-mm portion is cut from each end of the core and placed immediately in Karnovsky's fixative (33) for electron microscopy studies. The remainder of the core is divided longitudinally. One half is frozen for direct immunofluorescence studies, and the other half is placed into 10% buffered formalin for light microscopic studies.

Skin

For skin specimens used for immunofluorescence studies, the proper choice of a biopsy site is critical to maximize the probability of obtaining diagnostic information. In most if not all cases of bullous skin diseases, namely, those autoimmune in nature, biopsy specimens should be obtained from perilesional tissue (Fig. 1). A 3- to 4-mm punch biopsy specimen from inflamed but unblistered skin adjacent to a blister is most useful. Blistered lesional skin is the most common cause of negative results. Skin biopsy specimens from sites too distant from the blistering can also cause negative results. However, there are exceptions when examination of lesional tissue is required (Fig. 2). For the diagnosis of pemphigoid, pemphigus, linear IgA bullous disease, epidermolysis bullosa acquisita (EBA), and dermatitis herpetiformis, the tissue sample should be taken from inflamed but unblistered skin. For the diagnosis of connective tissue diseases, vasculitis, lichen planus, erythema multiforme, and porphyria (55), the biopsy specimen should come from the lesional skin.

While renal tissue obtained at autopsy may be suitable for direct immunofluorescence, skin undergoes postmortem autolysis and nonspecifically traps serum proteins. This leads to difficulty in interpretation due to high background staining.

TISSUE-HANDLING AND -FREEZING PROCEDURE: RENAL AND SKIN BIOPSY SPECIMENS

Tissue for immunofluorescence studies should be obtained fresh and kept moist until rapidly frozen or snap-frozen. If freezing can be performed within 20 to 30 min for renal biopsy specimens and within 24 h for skin biopsy specimens, the tissue can be kept on a saline-moistened piece of gauze or filter paper in a closed vial or small petri dish. For longer delay times (due to transport) or as an alternative to freezing, the specimen can be put into Michel's immunofluorescence transport medium. Increasingly, it is standard practice
FIGURE 1 Direct immunofluorescence of a skin biopsy specimen. There is granular IgG deposition along the basement membrane zone. This pattern is characteristic of that seen in connective tissue disease-associated interface dermatitis, including lupus erythematosus.

to use Michel's medium (41, 45) for all skin biopsy specimens. The medium is composed of an 85% saturated solution of ammonium sulfate, the protease inhibitor N-ethylmaleimide, and magnesium sulfate, in citrate buffer, pH 7.25 (available commercially from Zeus Scientific Inc., Raritan, N.J.). The solution is stable at room temperature but must be kept in a tightly capped container to prevent absorption of CO_2 and acidification. The ammonium sulfate reversibly denatures all proteins in the biopsy specimen. Specimens stored in the transport medium are stable for at least 2 to 4 weeks at room temperature. Immunofluorescence results for the skin are usually identical to those obtained for

snap-frozen tissue (41), but kidney specimens frequently have increased background. When the specimen is received in the laboratory, the ammonium sulfate is removed by placing the tissue into the wash solution (three 10-min washes; Zeus Scientific Inc.). Although it is standard procedure to use repeated, brief washings for other tissues, often in the case of skin specimens, high levels of background fluorescence can be reduced by more-prolonged washes, such as three times for 1 h or overnight at 4°C.

The renatured skin biopsy specimen is then oriented and embedded in optimal cutting temperature (OCT) compound (Tissue-Tek; Miles Laboratories, Inc., Elkhart, Ind.)
FIGURE 2 Direct immunofluorescence of a skin biopsy specimen. There is fine linear wavy IgG deposition along the basement membrane zone. This pattern is characteristic of that seen in bullous pemphigoid.

contained in a small aluminum foil "bullet" formed by wrapping a layer of foil around the bottom of a serum Vacutainer tube. The bullet is frozen by dipping it into liquid nitrogen, the foil is peeled off, and the OCT compound block is mounted on the cryostat chuck.

Renal tissue is frozen by immersing properly oriented tissue into a small amount of OCT compound, a water-soluble resin (Miles Laboratories, Inc., Naperville, Ill.), on a precooled metal chuck in a cryostat and spraying gently with MCB Tissue Freeze (Matheson, Coleman and Bell Manufacturing Chemists, Norwood, Ohio). Tissue is ready for sectioning in less than 3 min.

Many of the difficulties in immunofluorescence studies are related to tissue-handling techniques, suboptimal freezing procedures, or inappropriate frozen storage conditions. If tissue is allowed to freeze too slowly, ice crystal formation can occur, causing structural disruption.

STORAGE CONDITIONS FOR FROZEN SPECIMENS

Frozen specimens should be stored frozen at −70°C in a small plastic bag with as little air as possible. At −70°C, it is possible to store blocks for long periods, often for years, and still obtain adequate results. Tissue can be stored at −20°C, but at this temperature the duration of satisfactory preservation usually does not exceed several months. Frozen tissue deteriorates during storage, usually from ice crystal formation or desiccation.

FIXATION

Most diagnostic studies using direct immunofluorescence techniques are performed with unfixed frozen tissue sections, since many antigens can be altered or destroyed by fixation. However, the demonstration of the presence of some cytoplasmic antigens, such as viral antigens, for diagnostic purposes may require fixation. The optimal fixation conditions must be empirically determined for each antigen of interest. Fixation may also cause the physical redistribution of some antigens. For example, in anti-neutrophil cytoplasmic antibody (ANCA) assays, alcohol fixation of the neutrophil slide preparation causes the myeloperoxidase contained in the primary azurophilic granules of neutrophils to redistribute to a perinuclear or nuclear location (19).

FROZEN-TISSUE SECTIONING

Frozen kidney tissue sections for direct immunofluorescence should be cut in a cryostat at a thickness of 2 to 4 mm. The frozen blocks of tissue should be equilibrated in the cryostat at −25 to −20°C before frozen sectioning. The tissue sections are picked up on single-end SuperFrost/Plus glass slides (Fisher Scientific, Pittsburgh, Pa.) to facilitate labeling and decrease the chance that tissue will be lost by wiping off of the wrong side. The tissue attaches because the slides are at a higher temperature than the tissue and are positively charged, reducing the likelihood of washing off the tissue. Furthermore, the Plus slide pretreatment eliminates the time-consuming need for coating slides with albumin, glue, poly-L-lysine, or 3-aminopropyltriethoxysilane (27, 30). An initial frozen tissue section is stained using a 1% toluidine blue solution in order to determine whether glomeruli are contained in the tissue section. If so, sections are cut for the routine direct immunofluorescence panel. If the specimen is small, a circle is cut around the tissue with a diamond or aqueous insoluble pencil,

since it can be difficult to find the tissue on the slide after coverslips are placed on the tissue sections.

Three sections are placed on each slide and either air dried and stained immediately or stored frozen at −20°C in a slide box covered with aluminum foil or plastic wrap. Storing slides overnight allows more effective organization of technical time. Frozen skin biopsy specimens are sectioned at a thickness of 5 μm in a cryostat at −20°C, stained with a rapid tissue stain (such as Multiple Stain; Polysciences, Warrington, Pa.) to ensure proper orientation, and mounted on albumin-coated slides. For skin biopsy specimens, five slides are prepared with three tissue sections on each slide.

DIRECT IMMUNOFLUORESCENCE

Principle

In the direct immunofluorescence technique, frozen tissue sections are incubated at room temperature in a moist chamber using well-characterized fluorochrome-conjugated antibodies. After incubation, the unbound labeled antibody is washed from the tissue sections, the slides are placed on coverslips, and the bound labeled antibody is detected by examination and interpretation using a fluorescence microscope.

Evaluation of skin and renal tissues by direct immunofluorescence usually entails examination of the frozen sections of specimens for deposition of Igs, complement components, and fibrin detected by using fluorescein-labeled monospecific antibodies directed against these immunoreactants. However, in 1989 Fogazzi et al. (20) reported a method for performing direct immunofluorescence with formalin-fixed, paraffin-embedded renal tissue after treatment of the sections with the proteolytic enzyme pronase. They found comparable results when the intensities, distribution patterns, and locations of immunoreactants were compared to those obtained with direct immunofluorescence performed with frozen tissue sections from patients with the same disorders, namely, IgA nephropathy and membranous and proliferative lupus nephritis. Subsequently, they studied more than 500 renal cases with this technique and found good correlation between the direct immunofluorescence results obtained with the two methods. In our laboratory, we have confirmed the results obtained with the technique in cases of IgA nephropathy, membranous postinfectious glomerulonephritis, and lupus nephritis. The technique is more time-consuming, expensive, and complex than using frozen tissue but provides a sensitive alternative when only paraffin-embedded material is available for diagnostic studies.

Immunoperoxidase techniques have been explored as an alternative methodology, but in almost all bullous diseases and cases of glomerulonephritis, immunofluorescence techniques are more sensitive and accurate (6, 40).

Staining Procedure

Renal and skin biopsy specimens are routinely stained with a panel of IgG fractions of fluorescein-labeled monospecific antisera to IgG, IgA, IgM, C3, C1q, fibrin-fibrinogen, κ and λ light chains, and, in the case of renal biopsy specimens, albumin as a negative control.

1. Prior to staining, cryostat sections (2 to 5 μm) are air dried for 30 min at room temperature to maximize adherence. Afterward, slides are washed for 5 min in 0.01 M sodium-phosphate buffered saline (PBS)–0.15 M NaC1 (pH 7.3) to remove unbound serum proteins which contribute to background staining. The slides are loaded into a staining rack of a Tissue-Tek II (Miles Laboratories) slide-staining

unit, which is placed on a clinical rotator adjusted to give gentle stirring.

2. After washing, one slide at a time is removed, the excess PBS is blotted from around the tissue section, and 50 to 100 μl of appropriately diluted fluorescein conjugate is applied to the tissue section while it is still moist. A drop of conjugate should be added just above the tissue section, and to ensure that the conjugate covers the entire specimen, the slide should be gently tipped to one side and then the other. The slides are then incubated for 30 min at room temperature in a moist, level chamber or in petri dishes containing a moistened piece of filter paper. It is essential that tissue remain moistened after being hydrated to avoid problems with background staining.

3. After incubation, the slides are tipped to one side to allow the excess conjugate to run off and the slides are washed as in step 1 in PBS four times for 5 to 10 min each time to remove unbound fluorochrome-labeled conjugate from the section.

4. The excess PBS is blotted from around the specimen, and the moistened tissue is placed on a coverslip with mounting medium. For skin tissue sections, it is necessary to mount the sections with a medium containing compounds to reduce fluorescence burnout, such as Permafluor (Shandon Lipshaw, Pittsburgh, Pa.), mixed with 0.3 M diazabicyclooctane and triethylenediamine (Sigma Chemical Co., St. Louis, Mo.) and buffered to pH 10.00 with 2 M glycine (31). For kidney tissue sections, Aqua-Mount (Lerner Labs, Pittsburgh, Pa.) is used as a mounting medium.

5. The slides are examined using a fluorescence microscope with epi-illumination equipment, which consists of barrier and excitation filters contained in a dichroic mirror package, to allow the visualization of fluorescein.

C4d Staining of Renal Allografts

In addition to being stained with the routine direct immunofluorescence panel, allograft kidney biopsy specimens are stained for C4d as a marker of antibody-mediated rejection by using a three-step immunofluorescence technique (14). Diffuse staining of C4d in peritubular capillaries (Fig. 3) has been shown to be associated with circulating antibodies to donor HLA class I and class II antigens in acute and chronic rejection (14, 36, 37).

Use of NaCl-Induced Split-Skin Biopsy Specimens

In subepidermal blistering diseases, it is often possible to infer precise diagnoses from localization of the in vivo bound Igs. Most commonly, this involves differentiating bullous pemphigoid and its variants (in which IgG is bound to epidermal hemidesmosomal proteins) from EBA (in which IgG is bound to dermal type VII collagen) or antiepiligrin mucous membrane pemphigoid (in which IgG is bound to laminin type V and epiligrin and also localized to the dermal surface) (22).

This procedure may be useful when IgG is detected along the epidermal basement membrane zone after standard preparation of a punch biopsy specimen. The biopsy specimen is thawed at room temperature from the OCT compound block, and the dermis is trimmed to a thickness of <1 mm. (It is important to have as thin a dermal remnant as possible to aid in the salt splitting step.) The punch biopsy specimen is then placed in 20 to 30 ml of 1M NaCl dissolved in water for 48 to 72 h at 4°C. At the end of this time, the biopsy specimen is washed briefly in tissue wash solution to remove excess salt and separation through the lamina lucida may be induced by manually peeling the epidermis from the dermis. The epidermis is then placed back on top of the dermis, reembedded in OCT compound, and stained using the routine immunofluorescence technique. Occasionally, even after adequate incubation in 1 M NaCl, the epidermis will not easily separate from the dermis. In such cases, the biopsy specimen should be immersed in PBS at 56°C for 30 to 45 s and cooled and afterward the epidermis should be easily separated. Care must be taken to keep the temperature at 56°C, since at 60°C Igs will be irreversibly denatured.

In bullous pemphigoid, the IgG will localize to the basilar surfaces of the epidermal cells, on the roof of the induced
FIGURE 3 Acute humoral rejection of a renal allograft. A three-step immunofluorescence technique shows diffuse C4d deposition (arrow) in peritubular capillaries.

blister; in EBA and antiepiligrin cicatricial pemphigoid, IgG will be found solely on the dermal side after the induced separation (22, 34, 61). This split-skin technique cannot distinguish between EBA and antiepiligrin cicatricial pemphigoid, because dermal staining is observed in both disorders (18). However, because bullous pemphigoid is far more common than these other two diseases, this technique often helps determine if the deposits are epidermal or dermal, thus eliminating the need for less readily available immunochemical techniques (such as immunoblotting, antigen-specific enzyme-linked immunosorbent assay [ELISA], and immunoprecipitation of epidermal extracts, which employ serum autoantibodies). Additionally, in pemphigoid and EBA, circulating serum autoantibodies are not detectable in as many as 50% of cases and immunochemical techniques cannot be performed (34, 42, 61). In cases without circulating autoantibodies, the only way of differentiating these disorders would be the far more difficult and expensive technique of direct immunoelectron microscopy. In some cases, when autoantibodies are not detectable by routine techniques, they can be detected by antigen-specific ELISAs. ELISAs for the detection of circulating antibodies to desmogleins 3 and 1 in pemphigus vulgaris and foliaceus patients (2, 10, 26) as well as those for the detection of antibodies to the NCA16 epitope of the BP180 antigen in bullous pemphigoid patients (35, 51) have been recently and rapidly used as an important complementary tool for management of these diseases. However, a critical correlation of ELISA results with the clinical findings and results of routine histology and immunofluorescence testing, direct and indirect, is essential to rendering an accurate diagnosis and prognosis (4, 9, 23, 62).

INDIRECT IMMUNOFLUORESCENCE

Indirect immunofluorescence is used to detect circulating autoantibodies with tissue specificity. These include anti-glomerular basement (anti-GBM) and anti-tubular basement antibodies in renal disease (13, 40, 59) and bullous pemphigoid and pemphigus antibodies in skin disease (5, 7). Anti-GBM antibodies are now detected in our laboratory using Western blot analysis (see chapter 125, this volume) and/or ELISA. Patterns of reactivity of ANCA, both cytoplasmic ANCA and perinuclear ANCA, can be detected by indirect immunofluorescence, but confirmation using antigen-specific immunoassays for proteinase 3 and myeloperoxidase is required (44).

MOUNTING MEDIUM

The simplest mounting medium for immunofluorescence preparations is the one described by Coons et al. (15), which contains 9 parts glycerol and 1 part PBS. One disadvantage is that it requires that the perimeter of the coverslip be sealed using nail polish or permount, which can be troublesome to contain.

Another mounting medium, preferred by many laboratories, is polyvinyl alcohol-glycerol-PBS (50). It immobilizes the coverslip by forming a semisolid gel when it sets and allows storage for several weeks at 4°C without significant loss of fluorochrome intensity. Polyvinyl alcohol (Monsanto, St. Louis, Mo.) is a water-soluble resin. Available as Gelvatol, grade 20 to 30, it was previously referred to as Elvanol (E. I. Du Pont de Nemours and Company, Wilmington, Del.) by Goldman (24). This preparation is available commercially under the name of Aqua-Mount (Lerner Laboratories).

For most purposes, the pH of mounting medium should be neutral. However, the pH of mounting medium can be adjusted to achieve more intense fluorescence or to emphasize one color over another, which is particularly helpful in performing double staining. The green fluorescence of fluorescein is quenched at lower pHs, which accents the visualization of the red fluorescence of rhodamine; at high alkaline pHs, both fluorochromes fluoresce yellow. If slides are mounted in Gelvatol or Aqua-Mount and stored without light exposure at 4°C or frozen, the fluorescence can be preserved for at least 4 to 8 weeks and longer if the staining is intense.

Rapid fading of fluorescence after excitation is a serious limitation of immunofluorescence preparations, since it restricts reexamination of slides for further evaluation. To ensure that sufficient sections are available for interpretation and reevaluation, several can be placed on the same slide or staining can be done in duplicate. Photography can also be used to document results.

The fading of immunofluorescence slides is related to a combination of factors, including photochemical reactions, fluorochrome oxidation, and the physical and chemical properties of the fluorescein isothiocyanate (FITC) conjugate. As mentioned previously, it may be necessary to mount the specimens with a medium containing compounds to reduce fluorescence burnout, such as Permafluor (Shandon Lipshaw). The addition of reducing agents such as p-phenylenediamine and n-propylgallate to the mounting medium also retards fading (48, 56). These reducing agents are thought to suppress photodecomposition in the excited state of the fluorochrome. They have little quenching effect on rhodamine emission, which is an important consideration in double-labeling studies.

QUALITY CONTROL

Fluorescein-conjugated antibodies are available from commercial sources. The conjugate should be diluted according to the manufacturer's recommendations. Optimal dilutions of the fluorochrome conjugates are determined empirically using known positive and negative controls. The range of working dilutions for direct immunofluorescence studies using fluorochrome-labeled conjugates is usually 1:5 to 1:40 (or about 50 to 150 mg of protein/ml). The range of working dilutions for direct immunofluorescence is usually lower than that for indirect immunofluorescence because of the amplification effect. The appropriate dilution should be determined by checkerboard titrations as described by Beutner et al. (6). The correct dilution of individual lots of antibody conjugates can be estimated by determining the end-point precipitation against normal serum in Ouchterlony double immunodiffusion. The working dilution should be two to four times that of the greatest dilution that produces a precipitin line in the Ouchterlony plate after 24 h. If the dilution estimated by this method varies greatly from the manufacturer's recommendations, dilutions of the conjugate can be tested with a known positive biopsy specimen and visually inspected for optimal signal-to-background fluorescence. In any case, the laboratory should run known positive and negative tissue controls to validate the working dilutions.

The negative tissue controls for skin biopsy specimens should be sections from normal skin and should be incubated with each of the fluorescein conjugates. An additional single control specimen of normal skin, washed only with PBS and viewed without exposure to any fluorescein conjugate,

should be prepared. This helps in evaluation of nonspecific fluorescence and autofluorescence from the tissue, usually not necessary in direct immunofluorescence with kidney specimens.

ANTIBODY SPECIFICITY

Specificity is an important prerequisite for the FITC-labeled antisera or antibodies used in immunofluorescence studies. Many commercial suppliers sell monospecific fluorochrome-labeled reagents that produce satisfactory results. However, confirmation of specificity and sensitivity is the responsibility of the user. Commercial suppliers of antibodies usually provide information about the specificity and sensitivity of the fluorochrome-labeled antisera, including the results of Ouchterlony immunodiffusion studies or immunoelectrophoresis analysis (46, 54). It should be noted that these techniques are not sufficiently sensitive to detect minor contaminating antibodies.

The best method for determining the specificities of FITC-labeled antisera used in diagnostic immunofluorescence kidney studies is to assess their reactivities with known positive and negative tissue controls. For example, a renal biopsy specimen from a patient with membranous glomerulonephritis that has previously been shown to contain only IgG but not IgA is very helpful in defining the specificity of a new lot of FITC-labeled anti-human IgA. Specificity can sometimes be established by blocking or absorption studies (46, 54). To block staining, the tissue is incubated with unlabeled specific antibody prior to being incubated with the specific fluorochrome-labeled antibody. Although this sometimes results in diminished fluorescence, complete prevention of staining is rarely seen. In the second approach, the tissue is incubated with specific conjugated antibody after it has been absorbed with antigen coupled to an insoluble matrix such as cyanogen-bromide-activated Sepharose-CL4B particles (21). Positive controls for Igs can include touch preparations and frozen tissue sections of tonsil or small intestine. Another useful approach is to compare old lots of antisera to new ones with respect to their abilities to detect a known antigen in archival positive cases. Rigorous proof of antibody specificity, although often required in research applications, is usually not necessary in diagnostic studies, particularly if one has evidence of specificity of a particular reagent by either immunodiffusion or electrophoresis and the reactivity and the lack of reactivity with positive and negative tissue controls, respectively.

Polyclonal antibody preparations may contain extraneous antibodies, such as anti-nuclear antibodies, because the antigenic preparation used for immunization can be contaminated with nuclear fragments. Unwanted antibodies can be removed by incubation of the antiserum with appropriate insoluble preparations, such as tissue homogenates or washed red blood cells (43). It is necessary to use insoluble antigens, since soluble complexes cannot be removed effectively by centrifugation and may bind to the tissue. One method of insolubilizing proteins is to conjugate them to cyanogen-bromide-activated Sepharose particles (Pharmacia, Uppsala, Sweden) (21).

Even antibodies directed against a purified macromolecular protein may have undesirable reactivities. For example, if intact human IgG is used to immunize an animal, the resultant antiserum will usually detect all classes of Igs because they share light chains. Such reactivity can be removed by absorbing the antibody with a preparation of light chains, as is done in the preparation of commercially available heavy-chain-specific antisera (21, 43). Cross-species antigenic similarity of Igs can result in problems in indirect immunofluorescence studies: for instance, goat anti-rabbit IgG may cross-react with human IgG. If, for example, one is attempting to detect human IgG in immune deposits by using antibodies of rabbit and goat origin as the primary and secondary antibodies, respectively, it is essential that the goat anti-rabbit IgG be absorbed with human IgG until no cross-reactivity remains. It is wise to include a control slide with deposits of human IgG, which is incubated with normal rabbit serum (diluted to the same extent as the antiserum) followed by FITC-labeled goat anti-rabbit IgG. Positive staining indicates that the goat antibodies have not been properly absorbed.

FLUORESCENCE MICROSCOPES

Fluorescence microscopy depends on the principle that certain molecules, such as fluorescein, have electrons that are readily excited to unstable higher energy states by absorbing photons of light of certain energies (32, 43). When these electrons return to a more stable energy state, they release the stored energy as light, but at a lower energy level and a longer wavelength.

This loss of energy is emitted as fluorescent light. An excitation filter is chosen to provide incident photons of optical energy at the correct wavelength, and a barrier filter is chosen to block most of the photons of excitation energy and allow only those with lower energies (the fluorescent or emitted photons) to pass through. Fluorescein is maximally excited at around 490 nm and has a peak emission at around 510 to 517 nm. FITC interference and excitation filters take advantage of the strong absorption of fluorescein at 490 nm, and when combined with a barrier filter, they block energy with a wavelength of less than 500 nm. This combination of filters results in an apple green color with fluorescein-labeled antibodies. Rhodamine is maximally excited at 500 nm, with peak emission at 580 nm, and appears cherry red with the appropriate corresponding excitation and barrier filters (24, 43).

Tissues or cells stained with fluorescein conjugates can be examined with fluorescence microscopes equipped with appropriate excitation and barrier filters. The optics is fully described by Nairn (43). The most commonly used system is that of epi-illumination, composed of a vertical illuminator and dichroic mirrors, developed by Ploem (49). The dichroic mirrors serve as both excitation and barrier filters, since they allow the passage of excitation energy in one direction and emission energy in the other. One limitation of epi-illumination is that the intensity of light at lower magnifications is considerably less than with a dark-field condenser. Another problem is that fluorescence signals of structures above or below the plane of focus result in a background glow or halo effect. This can interfere with interpretation and is frequently more of a concern with cell suspension preparations than with tissue sections. Reduction of these out-of-focus signals can be accomplished by using laser confocal microscopy (57, 58, 60) and digital deconvolution immunofluorescence studies (3, 17, 52, 53), usually not necessary for diagnostic applications but more useful for research purposes. Despite these disadvantages, there are several advantages of epi-illumination over transmitted illumination using a dark-field condenser: (i) no oil is needed; (ii) the intensity of illumination is constant, once the objective is focused so that the brightnesses of staining of different specimens can be more reliably compared; and (iii) viewing can be combined with standard-phase microscopy, which is important

for cell suspension studies and for definition of morphological detail in tissue sections, and examination in double-staining studies is easier because of interchangeable FITC and rhodamine dichroic filter systems.

The light source for most fluorescence microscopes is a high-pressure mercury lamp. Illumination is very important, since the brightness of fluorescence depends on the light source, the efficiency of the fluorochrome in converting incident light into fluorescent light, and the concentration of the fluorochrome in the specimen.

EXAMINATION OF SLIDES AND EVALUATION AND RECORDING OF STAINING RESULTS

Preferably, slides should be examined on the day of staining, and a detailed record of the results should be kept on worksheets. Positive and negative controls should be run with each biopsy specimen until one gains confidence in the specificity of staining with a given fluorochrome-labeled reagent. Unexpected findings should always be confirmed before results are reported.

The fluorescence staining should be described according to location, extent, pattern, and intensity. For the glomerulus, examples of location are the mesangium (Color Plate 4) and the capillary wall, and for the skin, examples are the basement membrane zone and the intraepidermal layer. The extent of the staining should be described, usually by the terms focal or diffuse in immunofluorescence studies of the kidney. Sometimes it may be necessary to counterstain the section with 0.01% Evans blue or to stain adjacent sections with toluidine blue in order to determine the exact location of immunofluorescence staining, since morphology can sometimes be difficult to visualize. In addition to location and extent of staining, the pattern must be described. A granular pattern (Color Plate 5) is suggestive of immune complex deposition, whereas a linear pattern (Color Plate 6) is characteristic of autoantibodies bound to basement membranes, as in anti-GBM disease or bullous pemphigoid. Intensity is assessed in a subjective manner, usually on a graded scale of 0 to 4+. There is often a need to compare relative intensities of positive and background staining in control slides, particularly in screening for autoantibodies. Many factors affect intensity, principally the antiserum characteristics (dilution, avidity, and fluorescein/protein [F/P] ratio), the thickness of the section, and the light path and filter system of the fluorescence microscope.

PHOTOGRAPHY

Photography is the only permanent record one has of the immunofluorescence findings. Many immunopathology laboratories are now using a digital camera interfaced with a computer to capture fluorescence images for documentation of results. One of the most significant advantages digital imaging offers over 35-mm photography is permanent electronic storage of the image. Fewer images are required for documentation, and the costs of photographic and dark-room supplies are eliminated. Alternatively, a 35-mm camera interfaced with the fluorescence microscope can be used for documentation. Black-and-white Tri-X film (American Standards Association [ASA] 400) and high-speed Ektachrome film (ASA 400, 800, or 1,000) for color slides are recommended. Rapid processing and pushing to a higher ASA rating is possible for Ektachrome film. Exposure time is determined empirically. Cameras with automatic exposure

meters should have spot metering. Average exposure times vary from 5 to 10 s for fast (ASA 400) black-and-white film and from 30 to 60 s for ASA 400 color film. A log book in which exposure times are recorded may be useful in determining subsequent correct exposure times.

PROBLEMS AND PITFALLS

Fluorescent Reagents

High background staining often results from antibodies that are too heavily conjugated with fluorescein (F/P molar ratio, >4); these molecules adhere nonspecifically to tissue because of their net negative charge. High background staining may also be the result of partial drying of tissue sections after the staining procedure has begun. The best reagents for tissue staining are IgG fractions of FITC- or tetramethyl rhodamine isocyanate-labeled antisera recovered by DEAE-cellulose chromatography from the sera of animals that have been immunized with highly purified immunogens (25). They should contain two to four molecules of FITC per molecule of IgG. More highly labeled antisera, with F/P ratios greater than 2, are usually more suitable for detecting cell surface antigens in cell suspension studies using flow cytometry analysis.

Polyclonal monospecific fluorescein-labeled IgG antisera are available from a number of commercial companies and are generally satisfactory for diagnostic purposes. If conjugation is necessary, the dialysis method of Goldman (24) is recommended. This method of conjugation results in conjugates with low F/P ratios. Commercial conjugates are sometimes supplied in a lyophilized form and require reconstitution with distilled water or in a diluent supplied by the manufacturer, or they may come already reconstituted. Data from the supplier should include documentation of specificity, total protein concentration, antibody concentration, and the F/P ratio.

The undiluted stock antisera or antibodies can be stored at 4°C or aliquoted into volumes of 0.1 to 0.5 ml and stored frozen at −20°C until ready to be diluted. Storage should be according to the conditions specified by the manufacturer. Monoclonal antibodies are particularly sensitive to denaturation due to freeze-thawing and should be stored at 4°C or aliquoted and stored at −70°C. It is necessary to centrifuge conjugates just before using (10,000 × g for 15 min) to remove the aggregates that form as a result of storage.

Interpretation, Nonspecific Fluorescence, Autofluorescence, and Specific Fluorescence

Many proteins and structures in skin autofluoresce, and recognizing this background fluorescence is an important acquired interpretive skill. For example, elastin, elastin microfibrils, and collagen autofluoresce rather strongly. In skin, actinic damage causes a progressive increase in background fluorescence, especially along the basement membrane and around dermal blood vessels, that can obscure or even mimic specific Ig deposition. Lipofuscin granules in the sweat gland epithelium also autofluoresce orange, and the quantity of lipofuscin increases with age. In inflammatory skin lesions, vascular leakage can cause granular deposition of Igs and complement components that can mimic the findings in vasculitis cases. These changes are especially frequent in biopsy specimens from the lower extremities, presumably due to increased venous hydrostatic pressure.

Autofluorescence, caused by fluorescence found intrinsically in the tissue, is usually recognized by its color, which is

generally yellow or orange with the usual FITC filter system and is easily distinguishable from the apple green of fluorescein. Examination of an unstained section can be helpful in judging autofluorescence.

As already noted, nonspecific fluorescence from a non-immunologic reaction of fluorescein-conjugated antibody with the tissue most often results from the use of FITC-labeled antibodies that are too heavily conjugated with fluorescein. Several methods can be used to remove highly charged negative molecules. The simplest involves absorption of the conjugate with tissue powder, prepared by acetone treatment and drying at 37°C (43). Alternatively, highly conjugated molecules can be removed by anion exchange (DEAE) chromatography (24, 43). Further fractionation is usually not necessary, since commercial conjugates that have already been chromatographed to obtain fractions with F/P ratios of 2 to 4 are available from a number of sources. Highly charged molecules usually precipitate in conjugates during storage at 4°C, and background or nonspecific staining may disappear in time. Other methods that can be used to prevent nonspecific fluorescence include the addition of a negatively charged molecule, such as bovine serum albumin, which competes with the conjugate for binding sites in the tissue, and prestaining of the tissue with a negative dye, such as Evans blue. Usually these procedures are not necessary for diagnostic studies. Nonspecific fluorescence can also be due to the presence of free fluorochrome in the conjugate, which can be removed by dialysis against PBS or by gel filtration using a Sephadex G-25 column (24). Another mechanism by which antibodies can bind nonspecifically to tissues or to cells in suspensions is by reaction of the Fc receptor on the surfaces of cells or of anti-IgG antibodies with aggregated IgG. Aggregated protein can be removed by ultracentrifugation (100,000 × g for 45 min). Binding by Fc receptor activity can be excluded by the use of F(ab')₂ or Fab fragments, both of which are available commercially for a variety of antisera. Alternatively, these fragments can be prepared by either pepsin or papain digestion, respectively, according to the method of Parham (47). F(ab')₂ or Fab fragments are only occasionally required for tissue immunofluorescence studies.

Specific fluorescence observed in tissue is reported with consideration of the following features: (i) the morphology and distribution of the deposits (most important is distinguishing true linear deposition from granular or globular deposits, and less important is the focal or continuous distribution of the deposition); (ii) the nature of the immunoreactant(s) detected, for example IgG versus IgA; and (iii) the localization of the deposition (for example, it is critical to distinguish between deposition of IgG on the epidermal cell surface as seen in pemphigus and deposition along the basement membrane as seen in bullous pemphigoid). As described previously, for basement membrane zone deposition, the ultrastructural localization of the immunoreactant can be inferred by salt splitting the biopsy specimen and observing the localization after epidermal separation. For a more complete description of specific fluorescence findings in skin diseases, see chapter 123, this volume.

Introduction

HARRY E. PRINCE

49

The chapters in this section describe a variety of methods and their applications for detecting infections caused by bacteria, mycoplasmas, chlamydiae, rickettsiae, and bartonellae. Most of these methods are designed to measure organism-specific antibodies; in many situations, antibody detection is still one of the most effective tools available for identifying the infecting pathogen (e.g., *Borrelia burgdorferi, Bartonella henselae,* and *Legionella pneumophila*). Similarly, assessment of vaccine efficacy still relies heavily on demonstrating the post-vaccination presence of antibodies recognizing intrinsic components (e.g., polysaccharides of *Streptococcus pneumoniae* and *Neisseria meningitidis*) or secreted products (e.g., tetanus and diphtheria toxins) of the relevant organisms. The methods cover the entire historical range of antibody assays, ranging from gel diffusion and agglutination to complement fixation and indirect immunofluorescence to enzyme-linked immunosorbent assays and Western blotting (2).

In addition to antibody detection methods, procedures for assessing cellular immune responses to selected pathogens (e.g., *Mycobacterium tuberculosis*) are discussed. Both in vivo assays (e.g., skin testing) and in vitro assays (e.g., gamma interferon secretion) for detecting cell-mediated immune reactivity are presented.

Also described in this section are antigen detection assays, which utilize organism-specific polyclonal or monoclonal antibodies as capture and/or indicator reagents. Such assays range from direct fluorescent assays for visualization of whole organisms (e.g., *Treponema pallidum*) to enzyme immunoassays for detecting specific antigens (e.g., *Helicobacter pylori* and *Vibrio cholerae* antigens in stool).

Molecular methods for pathogen detection are increasingly performed under the auspices of the clinical immunology laboratory. Thus, relevant descriptions of such procedures are presented in this section where appropriate. Of particular note are the clinically relevant assays for detecting mycoplasmas and ureaplasmas, toxin-producing strains of *Escherichia coli*, and rickettsial infections.

A notable addition to section H in this edition is the inclusion of a chapter discussing laboratory tools useful for diagnosing *Bordetella pertussis* infections. Over the last several years, we have witnessed a profound increase in the number of recognized pertussis cases, particularly in adults (3). As increased awareness of the prevalence of pertussis reaches the general physician community, it is important to provide information on the serologic tests useful in diagnosing the illness and how these tests are interpreted.

Section H also contains a new chapter reflecting changes in our world since the last edition was published, namely, the use of anthrax as an agent of bioterrorism in the autumn of 2001 (1). This new chapter discusses assays performed at facilities that are part of the Laboratory Response Network and provides valuable practical information on specimen collection and transport.

Diagnostic Methods for Group A Streptococcal Infections

ANITA SHET AND EDWARD KAPLAN

50

Group A streptococcus, previously known as *Streptococcus pyogenes,* is a major human pathogen orchestrating a litany of infections, including common illnesses such as pharyngitis, impetigo, and scarlet fever, as well as life-threatening conditions like rheumatic fever, necrotizing fasciitis, and streptococcal toxic shock syndrome. Unique to group A streptococci is the predilection of the organisms to promote autoimmunity that results in serious nonsuppurative sequelae such as rheumatic fever/rheumatic heart disease and acute glomerulonephritis. An unexplained resurgence of severe group A streptococcal infections has been observed in the United States and Europe since the mid-1980s (1, 3) and has heightened public concern, largely because no vaccine is available, and resistance to certain antibiotics, such as macrolides, has recently emerged. Thus, there is great emphasis on the importance of accurate diagnosis of group A streptococcal infections.

Group A streptococci belong to the genus *Streptococcus,* which consists of gram-positive aerobic bacteria that microscopically appear as pairs or chains. Common to these organisms is a peptidoglycan cell wall. Based on carbohydrate antigens associated with this cell wall, Rebecca Lancefield classified beta-hemolytic streptococci into 20 serogroups, A to H and K to V (25). Furthermore, in 1928, Lancefield devised an elegant serotyping system for classifying group A streptococci based on a heat-stable surface protein called M protein (22). The ability to differentiate serotypes (and later *emm* types) of M protein allowed epidemiological association with specific infections. For example, the concept of distinct throat and skin strains arose from epidemiological studies during which it became evident that there are certain M types with a tendency to cause throat infection and rheumatic fever (M1, M3, M5, M6, M18, and M19 are termed "rheumatogenic") (14, 33), others with the propensity to cause impetigo/pyoderma and glomerulonephritis (M2, M12, M49, M57, M59, and M60 are termed "nephritogenic"), and many that are associated with invasive streptococcal infections.

Following careful clinical observation, the laboratory confirmation of acute group A streptococcal infections may be accomplished by the following:

- Microbiological culture and identification
- Rapid streptococcal antigen detection tests
- Group A streptococcal antibody tests

MICROBIOLOGICAL CULTURE AND IDENTIFICATION

A properly obtained and adequately processed culture (e.g., throat or wound swab) remains the "gold standard" for confirming the presence of group A streptococci. Typical group A streptococcal colonies grown in standard 5% sheep blood agar plates are surrounded by a clear hemolytic (beta-hemolytic) zone. Presumptive identification of group A streptococci is made by demonstrating a clear zone of inhibition around special bacitracin disks containing 0.04 IU of bacitracin. Definitive identification is done by cell wall carbohydrate grouping, which involves group A carbohydrate extraction using formamide or hydrochloric acid, followed by an antigen-antibody reaction. This precipitation reaction is done in capillary tubes using streptococcal antigen extract and group-specific antisera (commercially available or obtained from reference laboratories) (15). Rapid grouping methods involving the principle of latex agglutination (Streptex; Wellcome Diagnostics) have now largely replaced traditional grouping techniques.

M-Protein Serotyping

The M protein is a major virulence factor of group A streptococci. Antigenic differences within the hypervariable region at the N terminus constitute the basis for the Lancefield serological classification for group A streptococci. Identification of M types is accomplished using a precipitation reaction between M-protein antigen and type-specific antiserum. The antisera against the M-protein antigens are produced with whole-cell streptococcal (killed) vaccines used to immunize rabbits. M-protein antigen is extracted from streptococci using Lancefield's hot hydrochloric acid method (15). More than 80 different M types were identified by this method (23). Many group A streptococcal isolates were deemed nontypeable because of lack of expression of M protein, because of lack of reactivity of the M protein with available antisera, or, importantly, due to previously unidentified M proteins. Alternate methods for group A streptococcal characterization include the use of T-antigen agglutination and opacity factor type determination (13, 35).

Molecular Approaches to Characterization of Group A Streptococci

emm Typing

The labor-intensive nature of traditional M serotyping and the presence of nontypeable strains have led to widespread

utilization of *emm* sequence typing as a method of identification of M-protein types. *emm* typing consists of sequencing the 5′ end of the group A streptococcal *emm* gene (which encodes M protein) by rapid PCR analyses using nucleotide primer pairs. The standard detailed procedure may be obtained at the Centers for Disease Control and Prevention website, http://www.cdc.gov/ncidod/biotech/strep/protocols.htm. Studies have shown excellent correlation between known M serotypes and *emm* types identified by this approach (9). There are currently 124 recognized M genotypes (9).

PFGE

Pulsed-field gel electrophoresis (PFGE) is a useful method of molecular analysis that has been used for epidemiological studies (16). Group A streptococcal DNA is treated with a restriction enzyme (*Sma*I is typically used) to generate DNA fragments, which may be separated by alternating electric fields to obtain unique patterns. These patterns may be compared during an epidemiological outbreak to study clonality or relatedness. However, there is no universally accepted PFGE typing nomenclature.

RAPID STREPTOCOCCAL ANTIGEN DETECTION TESTS FOR GROUP A STREPTOCOCCI

Rapid streptococcal antigen tests have overcome the inherent overnight delay associated with the culture method for identification of group A streptococci and have allowed clinicians to make management decisions based on laboratory data shortly after examining the patient (12). The principle of rapid antigen tests involves an acid extraction step to solubilize streptococcal group-specific cell wall carbohydrate, followed by an antigen-antibody reaction step to identify its presence. Early rapid tests used the principle of latex agglutination; in these cases group-specific rabbit immunoglobulin G (IgG) was bound to latex particles. When extracted streptococcal group antigen is mixed with these IgG-coated latex particles, visible agglutination is detected and recorded as a positive test for the presence of group A streptococcus. Further development led to more sensitive tests using the enzyme immunoassay method. Another technique for rapid antigen tests uses optical immunoassay technology and has been reported by some to offer increased sensitivity (12).

Molecular Approach to Rapid Streptococcal Antigen Detection Tests

The two latest commercially available rapid antigen detection tests employ molecular biology methods. The first is a chemiluminescent single-stranded DNA probe that detects specific rRNA sequences unique to group A streptococci and is a nucleic acid hybridization test (Group A Streptococcus Direct Test; Gen-Probe, Inc., San Diego, Calif.) (11). The second molecular rapid test combines the features of rapid PCR and real-time detection of amplified target streptococcal DNA (LightCycler Strep-A assay; Roche Applied Science, Indianapolis, Ind.) (32).

SEROLOGICAL TESTS: THE HUMAN IMMUNE RESPONSE TO GROUP A STREPTOCOCCAL ANTIGENS

The human host infected with group A streptococci produces a plethora of specific antibodies directed against both somatic and extracellular streptococcal antigens. These immune responses are summarized in Table 1. The extracellular antigens are products released by group A streptococci, whereas the cellular (or somatic) antigens form an integral part of the organism and are usually exposed on its surface (Fig. 1). Most authorities believe that compared to only a single titer of a particular streptococcal antibody, a rising titer from an acute-phase to a convalescent-phase serum sample is a more accurate reflection of a previous streptococcal infection (8). Ideally, the paired sera, obtained approximately 4 weeks apart, should be assayed simultaneously in order to demonstrate a significant rise in titer. As paired sera may be more difficult to obtain in practice, a single serum sample obtained during the illness that exceeds the upper limit of normal (ULN) is considered strongly supporting evidence of a preceding group A streptococcal infection. The ULN is defined as that titer exceeded by 20% of a normal population (34). The immune response is also influenced by myriad factors, and these are reviewed in Table 2 (17, 29).

ASO

Of the two hemolysins produced by group A streptococci, streptolysin S and streptolysin O, only the latter is antigenic. Streptolysin O acts on red blood cell membranes, inducing lysis of cells, but it also can bind to cholesterol in membranes of all eukaryotic cells. Antibody to this enzyme neutralizes its hemolytic activity. Although the anti-streptolysin O (ASO) antibody is thought to be composed of IgG, IgA (5), and IgM during the initial streptococcal infection stage (31), this has not been carefully examined in recent years. This antibody has not been shown to have a protective role against future group A streptococcal infections in the host.

Clinical Indications

The ASO test measures the host immune response to streptolysin O produced by group A streptococci and provides

TABLE 1 Host immune response to group A streptococcal infection

Streptococcal serological test	Antigen
Extracellular streptococcal antigen response	
ASO	Streptolysin O
Anti-DNase B	DNase B
Anti-streptococcal hyaluronidase[a]	Hyaluronidase
Antistreptokinase[a]	Streptokinase
Anti-NADase[a]	NADase
Cellular (somatic) antigen response	
M-protein antibody[a]	Type-specific M protein
Anti-A-carbohydrate[a]	Group A carbohydrate
Anti-streptococcal C5a peptidase[a]	Streptococcal C5a peptidase (group A)

[a] Not commercially available but currently used in research and reference laboratories.
FIGURE 1   Schematic diagram of cellular and extracellular antigens of group A streptococci.

serological evidence for preceding group A streptococcal infection. The ASO test is primarily used to provide evidence of preceding streptococcal infection in patients suspected of having acute rheumatic fever or acute glomerulonephritis following throat infections. However, in acute glomerulonephritis following skin infections, it is uncommon to see an immune response to streptolysin O. The use of the ASO titer for diagnosis of an acute uncomplicated group A streptococcal infection is rarely, if ever, indicated.

ASO: Classic Hemolytic Method

The classic ASO test is based on neutralization of the hemolytic activity of the streptolysin O toxin in the presence of erythrocytes by specific ASO antibodies in the serum. The absence of specific serum antibodies or a negative ASO test would result in persistence of residual unneutralized streptolysin O and is demonstrated by hemolysis of added erythrocytes.

Specimens

Peripheral blood collected in a plain glass tube is allowed to clot. Serum is separated from clotted blood and further clarified by centrifugation of erythrocytes at $500 \times g$ for 5 min. Clear serum is transferred to a sterile storage vial and may be stored at 4°C for up to a week. For longer storage, a temperature of −70°C should be used. For shipping purposes, it is preferable to separate the serum prior to shipping.

Equipment

Equipment includes 96-well microtiter plates, micropipette and tips, multichannel pipette, test tubes, conical centrifuge tubes, and microtiter plate reading platform with mirror.

Reagents

ASO buffer: phosphate-buffered saline (commercially available, or prepare by dissolving 7.4 g of NaCl, 3.17 g of KH_2PO_4, and 1.8 g of Na_2HPO_4 in 1,000 ml of distilled water). Add 1 g of gelatin and heat to dissolve. When cooled, adjust pH to 6.5 to 6.7. Autoclave and store at 4°C.

Streptolysin O reagent (commercially available): Rehydrate using manufacturer's instructions, and use within 15 min.

ASO standards: three internal control human sera of known antibody titer (high, medium, and low titers). These can be obtained from reference laboratories.

Defibrinated erythrocytes: rabbit erythrocytes or human type O/Rh-negative fresh erythrocytes. Wash cells twice with normal saline and then with ASO buffer. Centrifuge after each wash for 10 min at $400 \times g$. Draw off supernatant and continue washing until supernatant is clear. After the final wash, resuspend erythrocytes in ASO buffer to make a 5% suspension (0.75 ml of erythrocytes and 14.25 ml of ASO buffer).

Serum dilutions: Stock dilution of 1:25 may be made by adding 0.1 ml of test or control sera and 2.4 ml of ASO buffer. This stock is inactivated at 56°C for 30 min. Further dilutions of 1:30 and 1:40 may be made as follows: 1:30 dilution, add 0.2 ml of ASO buffer and 1 ml of 1:25 stock serum dilution, and 1:40 dilution, add 0.3 ml of ASO buffer and 0.5 ml of 1:25 stock serum dilution.

TABLE 2   Factors that can influence serological response to group A streptococcal infection

Specific influence	Comment
Age of patient	Highest titers seen in children between ages 6 and 12 yr
Geography	Populations living in areas with a high incidence of streptococcal infections have higher titers (20, 21)
Site of infection (ASO only)	Higher ASO response seen in poststreptococcal upper respiratory infections than in poststreptococcal skin infections (17)
Season of the year	Titers are higher during winter and early spring months
Prompt antibiotic treatment	Reduces the streptococcal antibody response (29)

Procedure

The microtiter plate may be divided into eight sections of three by four wells, which would enable seven different serum samples to be assayed. Add 25 μl of ASO buffer to each well, except the erythrocyte control well, which should receive 50 μl. Now add 25 μl of patient's serum dilutions (1:25, 1:30, and 1:40) to the first three wells of the first row. Complete loading of all seven serum samples and control sera in the corresponding first row may be done at this point. Then make twofold serial dilutions with a multichannel pipette by transferring 25 μl row by row down the plate, discarding the 25 μl that is removed from the last row of wells. After the twofold dilutions have been completed, add 25 μl of ASO buffer to every well. Then add 25 μl of the freshly reconstituted streptolysin O reagent to all wells except the erythrocyte control well. Incubate the plate for 30 min at 37°C. Then add 25 μl of the erythrocyte suspension to every well, and reincubate for 45 min at 37°C. Centrifuge the plate at $400 \times g$ for 5 min. Place the plate on the plate reader, using a fluorescent lamp as a source of light, and examine wells for hemolysis. The last well (highest dilution) without hemolysis is noted. The ASO titer of a serum sample is equal to the reciprocal of this dilution and is expressed as Todd units or international units (depending on whether the streptolysin reagent used is the Todd standard or the World Health Organization international standard, respectively).

Interpretation

The ASO test result is considered interpretable only if the streptolysin O control well shows total hemolysis or if the erythrocyte control well shows no hemolysis, and if the reference serum standards yield titers that differ by no more than 1 dilution from the designated titer for that serum. The assay endpoint is the last well with the highest dilution showing no hemolysis. For paired acute- and convalescent-phase sera assayed simultaneously, a difference of 0.2 log or a difference of two wells between the titers of the two sera is accepted as a minimum for a significant difference. If one serum sample is assayed, the elevated titer should exceed the ULN, as described above. Table 3 shows the age-stratified ULNs of ASO and anti-DNase B in children and adults residing in the United States (20, 21). Ideally, these values must be established separately within each population and geographic area. In patients with group A streptococcal infections, the ASO response can usually be demonstrated after 1 week, with the maximal response being reached 3 to 6 weeks after the infection (19). The ASO titer may begin to decline 6 to 8 weeks after infection, although in some patients the titer may remain elevated for indefinite periods (19). About 20% of infected individuals do not respond with elevated ASO titers (34). Thus, a negative ASO test alone cannot be used to rule

TABLE 3 Examples of age-stratified ULNs of ASO and anti-DNase B in children and adults residing in United States: a guideline

| Age (yr) | ULN | |
	ASO	Anti-DNase B
2–5	120–160[a]	240–320[a]
6–9	240[a]	480–640[a]
10–12	320[a]	480–640[a]
13–15	170[b]	170[b]
Adult	85[b]	85[b]

[a] From reference 20.
[b] From reference 21.

out rheumatic fever or other streptococcal sequelae, and additional antibody tests (e.g., anti-DNase B test) may be used. False elevation of ASO titer may occur due to the presence of lipids in serum, which can act as nonspecific inhibitors of streptolysin O. Freezing and thawing of sera may destabilize lipoproteins, which may alter the titer. Group C and G streptococcal infections can also result in elevated titers, as these groups produce streptolysin O.

More recently, alternative methods for ASO determination have become commercially available. Latex agglutination is one such method, in which latex particles coated with streptolysin O can react with ASO antibodies in the serum. Agglutination occurs when the level of antibody in serum is greater than 200 IU/ml. The advantages of this method include quick testing time and decreased complexity in its execution. However, documentation on the accuracy and precision of the assay is incomplete.

ASO Determinations Using Nephelometry

Nephelometry has been introduced as a simple, rapid procedure for quantitative measurement of ASO titers. The principle of nephelometry is based on the ability to measure the rate of increase in light intensity scattered from particles suspended in solution as a result of complexes formed during an antigen-antibody reaction (6, 7, 28). In the performance of the ASO test, purified recombinant streptolysin O is added to the patient's serum. ASO in the serum sample binds with recombinant streptolysin O, forming complexes resulting in an increase in light scatter that is converted into a peak rate signal. This signal is a function of the serum ASO concentration. Following calibration, the signal is converted to concentration units by the analyzer. All reagents and instrumentation are supplied by the manufacturer (Beckman Coulter IMMAGE Immunochemistry System) (6, 7). Results are reported in ASO international units (per milliliter) and are extrapolated from values measured by the classic hemolytic method previously described.

Comment: Nephelometry has replaced the classic hemolytic method for streptococcal antibody determination in many clinical laboratories. This is an automated method, and less technical expertise is required in its performance. It is also less expensive when performed in large numbers. At present, data regarding correlation between the nephelometric and hemolytic methods are incomplete (17, 27). Furthermore, comprehensive definition of a significant rise in ASO titer and data regarding the ULNs for different populations have yet to be determined independently using nephelometry.

Anti-DNase B Test

Of the four DNases (DNases A, B, C, and D) produced by group A streptococci, DNase B is the most immunogenic following infection (34). Clinical indications for the performance of the anti-DNase B test are essentially those cited for the ASO test. However, unlike ASO, infection of the skin produces a brisk anti-DNase B response. Thus, the anti-DNase B test is more reliable than the ASO test in providing evidence for a preceding streptococcal infection in patients with sequelae following pyoderma (17). The anti-DNase B test is also used as an additional streptococcal antibody test for patients with suspected rheumatic fever who may show no ASO response after upper respiratory tract infection.

Classic Methyl Green Dye anti-DNase B Test

The classic anti-DNase B assay is based on the fact that antibodies to DNase B neutralize the enzymatic activity of DNase B, preventing it from depolymerizing DNA that has

been coupled to an indicator dye. DNase activity can be detected by incubating the enzyme with calf thymus DNA, which is conjugated to methyl green dye. The DNA-dye complex remains greenish unless the enzyme degrades the DNA, in which case the substrate then turns colorless. The reciprocal of the highest dilution of serum that shows definite inhibition of enzyme activity represents the antibody titer for that serum.

Reagents

Tris dilution buffer: Dissolve 1,021 g of Tris, 362 mg of $MgSO_4$, 333 mg of $CaCl_2$, and 1 g of gelatin in 1,000 ml of distilled water. Heat to dissolve gelatin, cool, and adjust pH to 7.6.

Tris inactivation buffer: Add 0.6 g of NaCl to 100 ml of Tris buffer, mix, and filter with a Millipore membrane. Store at 4°C.

Anti-DNase B standards, DNase B, calf thymus DNA, methyl green dye, and imidazole: commercially available.

Serum dilutions: as described for the ASO method using Tris buffer. Stock dilution may be inactivated at 63°C for 30 min.

Procedure

The microtiter plate may be divided into eight sections of three by four wells, which would enable six test sera and two control sera to be assayed. Add 25 µl of Tris buffer to each well, except the DNA substrate control well, which should receive 50 µl. Now add 25 µl of patient's serum dilutions (1:25, 1:30, and 1:40) to the first three wells of the first row. Complete loading of all six test sera and control sera in the corresponding first row may be done at this point. Then make twofold serial dilution with a multichannel pipette by transferring 25 µl row by row down the plate, discarding the 25 µl that is removed from the last row of wells. After the twofold dilutions have been completed, add 25 µl of DNase B to all wells except the DNA-methyl green substrate well. Incubate the plate for 15 min at 37°C. Then add 50 µl of DNA-methyl green substrate to every well, and reincubate for 20 h at 37°C. Read and record the results.

Interpretation

DNase activity on the DNA-methyl green conjugate is reflected by digestion of DNA and depolymerization of the colored complex, resulting in loss of blue-green color in the substrate. This represents the end point of antibody neutralization (27). The color gradation is assigned a range from 0 (no color) to 4+ (strongest color). The enzyme control should be 0 and the substrate control should be 4+. The last well (highest dilution) with a reading of 4+ or 3+ is the end point, and the reciprocal of its titer represents the anti-DNase B value in units per milliliter.

Anti-DNase B: Nephelometry

Anti-DNase B can also be quantitated by nephelometry. The principles are the same as described above; purified DNase B is added to serum to form immune complexes that result in change in light scatter, which is subsequently measured (6, 7). As before, the results are reported in units per milliliter, which are extrapolated from values obtained by the classic method. As with ASO measurements, further studies to correlate the two methods for anti-DNase B measurement need to be performed, especially in defining a ULN and a significant rise in anti-DNase B titer.

Anti-A-Carbohydrate Test

Studies have suggested a specific correlation between persistence of serum antibody against group A carbohydrate and the presence of rheumatic carditis and rheumatic mitral valve disease, with elevated levels of anti-A-carbohydrate being reported for individuals with rheumatic heart disease (2). At present only a very few laboratories are performing this test, and these determinations are for research purposes. Information about required reagents and the procedure for performing the anti-A-carbohydrate test may be obtained from the literature (4).

Group A Streptococcal Antihyaluronidase Test

The streptococcal antihyaluronidase determination is an enzyme neutralization test in which the antigen used is streptococcal hyaluronidase elaborated by the bacteria (26). However, this test is no longer commercially available and is now usually performed only in reference or research laboratories.

Anti-M-Protein Antibodies

Following group A streptococcal infection, the host produces antibodies against type-specific streptococcal M protein. These antibodies have opsonic properties and have been shown to correlate with protection against group A streptococcal infection (24). M-protein antibodies appear slowly, over a period of several months. These antibodies have been shown to consist of both IgA and IgG subclasses that play a role in inhibiting streptococcal adherence to pharyngeal cells and in preventing internalization of the organism into pharyngeal epithelial cells, respectively (10). The indirect bactericidal test is used for detecting the antibodies and is based on the antiphagocytic effect of streptococcal M protein and its neutralization by type-specific antibody (15). This test is used only in research laboratories, especially in studies of M-protein vaccines, and has limited clinical use.

Other streptococcal antibody tests are streptokinase and NADase, but the availability of these is limited to research laboratories. The recently reported antibody to group A streptococcal C5a peptidase (30) has been shown to parallel the rise of ASO during acute streptococcal pharyngitis, but at the present time this is a research test with limited clinical applicability.

CONCLUSION

Several microbiological tests are available for accurate diagnosis of group A streptococcal infection. While classic culture methods remain the "gold standard" for determining the presence of group A streptococci, rapid antigen detection methods have gained popularity in many clinical settings due to their efficiency and ease of performance. However, a confirmatory group A streptococcal culture is still recommended as a backup for a negative rapid antigen test result. It should be emphasized that the most common clinically used streptococcal antibody tests (ASO and anti-DNase B) provide evidence only for a preceding group A streptococcal infection. Together with clinical findings the tests may support the diagnosis of sequelae to group A streptococcal infection, but they are not by themselves diagnostic of these clinical conditions.

Immune Responses to Polysaccharide and Conjugate Vaccines

CARL E. FRASCH

51

Most invasive bacterial disease in humans results from encounters with encapsulated bacterial pathogens. For this reason polysaccharide (PS) vaccines have been licensed for protection against several serious bacterial infections, including those caused by *Neisseria meningitidis, Streptococcus pneumoniae, Haemophilus influenzae* type b (Hib), and *Salmonella enterica* serovar Typhi. A problem with most native PSs is that they induce a poor immune response in children under 2 years of age, making young children particularly susceptible to invasive disease caused by these organisms. For this reason, conjugate vaccines were developed. The first conjugate against Hib was licensed in 1987. While Hib, meningococcal, and pneumococcal conjugate vaccines are now in general use in young children, PS vaccines are still widely used in older children and adults. The antibody responses to the Hib, meningococcal, pneumococcal, and typhoid Vi PSs are discussed below, whether induced by immunization with PS or conjugate vaccines.

The presently U.S.-licensed bacterial PS and conjugate vaccines are listed in Tables 1 and 2 and are the focus of this chapter. Estimation of antibody concentrations and measurements of functional antibody are critical to our understanding of PS-induced immunity. Information on quantitative immunoassays for anti-PS antibodies is presented. Discussions of methods for functional assays are presented in another chapter of this book.

IMMUNOLOGY OF THE ANTIBODY RESPONSE TO BACTERIAL PSs

Serum antibody in concert with the complement system plays a central role in protection against invasive diseases caused by encapsulated bacterial pathogens, whether primarily by direct killing (bactericidal antibody) or by opsonophagocytosis (opsonic antibody).

The humoral immune response to bacterial PSs is clonally restricted compared to the response to protein antigens. Within individual adults the serum antibody response to pneumococcal and other PSs derives from a small number of dominant B-cell clones. The reason is likely that PSs express relatively few epitopes that would not be recognized as self. A clonally restricted immune response means that any one individual will likely have an antibody response restricted to a very small number of epitopes on any given PS.

A widely held premise is that PSs are T-cell-independent immunogens and thus do not induce immunologic memory. This is based largely upon studies with short-lived animal species (mostly mice) and young children. While a single exposure to a PS vaccine may not induce immunologic memory, there is evidence for immunologic memory responses to bacterial PSs in adults (5). Epitopes present on a bacterial PS can be widely shared among different cross-reactive PS structures, and repeated exposure to epitopes on these PS structures can induce immunologic memory. Unlike children, adults have had repeated exposure to meningococcal and pneumococcal PSs complexed with other bacterial components, and this repeated exposure appears to induce B-cell memory. In children, immunization with a PS-protein conjugate vaccine primes for a booster response upon reexposure to the bacterium-associated PS (43, 70). By comparison, adults generally respond to a similar magnitude to PS presented as either the native PS or a conjugate, though conjugates generally stimulate somewhat higher antibody concentrations (68).

QUANTITATION OF ANTI-PS ANTIBODIES BY ELISA

In an assessment of naturally occurring levels of antibody to encapsulated bacteria and evaluation of the immune response to PS or conjugate vaccines, one should consider both antibody quantitation and measures of biological (functional) activity. Quantitation of anti-PS antibody is important, because as the type-specific antibody concentration increases, the risk of invasive disease on a population basis due to that bacterial strain decreases. The functional activity measured should correlate with a known mechanism of protection.

Antibody concentrations should be determined using conditions such that immunoglobulin G (IgG) specific for a serogroup or serotype is measured. This requires careful control of assay conditions, use of purified PSs, and application of cross-absorptions to verify antibody specificity. The enzyme-linked immunosorbent assay (ELISA) is now the most commonly used method for quantitation of antibody concentration. Where possible these concentrations should be measured as micrograms of specific antibody per milliliter. To facilitate accurate and comparable quantitative anti-Hib, antimeningococcal, and antipneumococcal antibody measurements in different laboratories, reference sera have been produced and characterized (21, 46, 54), and they are now in international use. Antibody concentrations in these reference sera are shown in Table 3.

TABLE 1 Bacterial PS vaccines licensed in the United States

Vaccine type	Manufacturer	PS(s) included	Dose
Meningococcal	Aventis Pasteur	A, C, Y, W135	50 µg/PS
Pneumococcal	Merck & Co.[a]	1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17A, 18C, 19F, 19A, 20, 22F, 23F, 33F	25 µg/PS
Typhoid	Aventis Pasteur	Vi	25 µg

[a] In December 2002, Wyeth Vaccines discontinued production of their pneumococcal 23-valent PS vaccine.

TABLE 2 Bacterial PS-protein conjugate vaccines licensed in the United States

Vaccine type	Manufacturer	PS(s) included	Dose
Hib	Aventis Pasteur Wyeth Merck & Co.	b	7.5–10 µg/PS
Pneumococcal	Wyeth	4, 6B, 9V, 14, 18C, 19F, 23F	2 µg/PS (4 µg for 6B)
Meningococcal[a]	Baxter Chiron Wyeth	C	10 µg
	Aventis Pasteur	A, C, Y, w13S	4 µg/PS

[a] The meningococcal conjugate was first licensed in the United Kingdom, and only the 4-valent conjugate is licensed in the United States.

TABLE 3 Human reference sera for ELISA[a]

Bacterial species	Serum designation	PS type/group	Antibody concn (µg/ml)			Reference
			IgG	IgM	IgA

[a] Internationally recognized sera used for quantitation of anti-PS antibodies in human sera.

The human Hib reference serum, lot 1983, is a serum pool from 15 adult plasma donors who were immunized with the purified Hib PS (61). These adults received the Hib PS vaccine as part of a three-vaccine immunization series for preparation of bacterial PS immune globulin, also called BPIG. Plasma recovered from these individuals was converted to serum and then pooled. The resulting pool contained 70.0 μg of total anti-Hib PS antibody per ml, determined by comparison with an earlier Hib reference serum, Stan Klein, using a radioimmunoassay method.

The meningococcal PS reference serum pool, CDC1992, was prepared from plasma obtained from 18 adults that received the ACYW135 PS vaccine (21). A total of 24 adults at the Centers for Disease Control and Prevention were immunized with the Aventis Pasteur PS vaccine Menomune. Test sera were obtained after vaccination and assayed for anti-meningococcal PS antibody by ELISA. Eighteen of the individuals were then subjected to plasmapheresis. The pooled plasma was converted to serum. Antibody assignments were made using the cross-standardization method described by Concepcion and Frasch (15).

The pneumococcal PS reference serum pool, 89SF (also called 89S), was prepared from plasma obtained from 17 adults immunized with the 23-valent pneumococcal PS vaccine produced by Lederle Laboratories. These plasma units were selected from among units from 68 immunized plasma donors as being high in anti-pneumococcal PS antibody. The donors were originally immunized to produce BPIG (61), but their plasma units were used instead to produce the reference serum 89S described by Quataert et al. (54). The plasma units were pooled and then converted to serum. Antibody assignments were made by using a reference antigen capture ELISA, the reference antigen being immunoglobulin molecules from the U.S. National Reference Preparation of serum proteins, batch IS 1644, which were captured by light chain-specific antibody previously attached to the ELISA plates. Isotype-specific second-antibody–enzyme conjugates were used. Some antibody concentrations for selected pneumococcal types were confirmed by quantitative precipitation (54). Concepcion and Frasch later confirmed most of the results of Quataert et al. using a cross-standardization ELISA method (15).

General ELISA Method for Bacterial PS

It is important to absorb the PS to the plastic surface of the microtitration plate such that the PS retains its native conformation. Pyrogen-free water should be used for preparation of the antigen coating solution to avoid nonspecific antibody binding to lipopolysaccharides. The most straightforward approach would be to use the native PS as the coating antigen, but PSs do not absorb to plastic surfaces as efficiently as proteins. Since PSs are essentially never 100% pure, one should use the minimum amount necessary for antigen coating to obtain sufficient signal and sensitivity. To be able to use low concentrations of the native PS and yet have uniform attachment, Arakere and Frasch utilized methylated human serum albumin (mHSA) to facilitate attachment of negatively charged PSs and those having hydrophobic groups. The chemical treatment used to prepare the mHSA converts nearly all free carboxyl groups to methyl groups, leaving the protein positively charged and hydrophobic due to the methyl groups (3). One to 5 μg of PS per ml can be used when a negatively charged PS is admixed with mHSA for plate coating, whereas direct absorption of the PS may require 10 to 20 μg of PS per ml and uniform well-to-well attachment may not be achieved.

Another approach to attaching bacterial PSs to ELISA plates with high binding efficiency is to use chemically modified PSs (conjugates), as has been done for Hib (52). However, a potential problem with this approach is possible generation of new antibody-reactive epitopes. This has been shown to be the case with some pneumococcal PSs and the group B streptococcal type III PS (7). In general it is best to avoid activation methods that have the potential to break carbon-carbon bonds, as occurs when sodium periodate is used to create the reactive aldehyde groups needed for attachment of the PS to the amino groups of a protein or peptide.

Historically, Hib PS antibodies have been measured by radioimmunoassay, but the recommended assay method is now an ELISA based upon the method described by Phipps et al. (52). This ELISA utilizes Hib oligosaccharides conjugated by reductive amination to human serum albumin (also called HbO-HA) and has been standardized (45). The reference serum is lot 1983 with 70 μg of total anti-Hib PS antibody per ml. The isotype breakdown within the total antibody is as follows: IgG, 60.9 μg/ml; IgA, 5.6 μg/ml; and IgM, 3.5 μg/ml.

The limit of antibody detection using the HbO-HA ELISA is approximately 0.05 μg/ml. An alternative approach for coating the 96-well ELISA plate is to use a mixture of 5 μg of native Hib PS per ml and 2.5 μg of mHSA per ml in phosphate-buffered saline, pH 7.4. The mechanism of PS attachment using mHSA is a combination of hydrophobic and charge interactions between the PS and mHSA (3). Using the mHSA method with the native PS, the limit of anti-PS antibody quantitation is approximately 0.15 μg/ml.

PS antigens used in ELISA are often taken from bulk PS stocks used in production of licensed PS vaccines and are thus purified to the purity requirements for the vaccine. In general, the requirements are <1 to 2% contamination for both protein and nucleic acids. The Hib, meningococcal, and serovar Typhi PSs will also contain small amounts of lipopolysaccharide, while the pneumococcal PSs will contain about 5% of a common PS, the C PS, relative to the type PS content. For this reason it is critical that an anti-PS ELISA be carefully evaluated for specificity. This should be done by absorption with a heterologous type PS from the same bacterial species. For example, one can use meningococcal group Y PS to determine the specificity of meningococcal group C PS antibodies. The heterologous PS should remove less than 20% of the antibody reactivity. To achieve the required specificity it may be necessary to preabsorb the sera with the heterologous PS. It is likely that the specificity of measurements of antibody to the meningococcal and Vi PSs could be improved by preabsorption with meningococcal and serovar Typhi lipopolysaccharides, respectively.

To achieve the needed specificity in the pneumococcal ELISA it is necessary to absorb test sera with purified C PS and with a heterologous pneumococcal PS (16). The heterologous PS that has generally been used is the type 22F PS. C PS absorption removes most of the non-type-specific cross-reacting antibody, but the 22F PS removes antibodies to another common antigen, possibly the site of covalent attachment of the C PS to the type PS. In my laboratory, I am able to avoid the preadsorption steps by the addition of about 1 to 2 μg of the absorbent(s) per ml to the buffer used to dilute the serum samples, with subsequent overnight incubation of the test sera on antigen-coated plates. A detailed ELISA protocol for the pneumococcal ELISA can be downloaded from the website http://www.vaccine.uab.edu.

FUNCTIONAL ASSAYS FOR ANTI-PS ANTIBODY

Use of functional assays is important, and the functional assay used should be a surrogate for the known protective function of anti-PS antibodies, either naturally induced or stimulated by vaccination. The methodology for the bactericidal and opsonophagocytic assays is described by Nahm and Lorenz in chapter 37 of this volume.

Although the words *correlate* and *surrogate* are at times used interchangeably, this is not correct. A correlate is when two variables are related where variation in one is accompanied by a linear variation in the other. A surrogate takes the place of something else. In the case of meningococcal disease it is clear that protection is mediated by the presence of bactericidal antibody, but not necessarily only by such antibodies, and that anti-PS antibodies are sufficient to protect against disease. Thus, in vitro measurements of bactericidal antibody can be considered a surrogate for in vivo protection. Furthermore, we know that anti-PS antibody is bactericidal in vitro and that these antibodies are largely IgG. From this, measuring the amount of anti-PS IgG antibody by ELISA is a correlate of protection and will correlate with bactericidal antibody titers.

The presence or induction of bactericidal antibody is predictive of protection against meningococcal disease. The studies by Goldschneider et al. showed that the presence of detectable bactericidal antibodies using human serum as the complement source was sufficient to protect against invasive serogroup-specific meningococcal disease (26). A group C meningococcal conjugate vaccine is licensed in a number of countries (not the United States) for use in infants and children. The approval was based upon the ability of the group C conjugate vaccine to induce bactericidal antibodies (10). During the United Kingdom clinical evaluation of the vaccine, the investigators utilized a bactericidal assay using baby rabbit serum as the complement source and were able to define bactericidal titers that predicted protection against group C meningococcal disease. Bactericidal titers of <1:8 reliably predicted susceptibility, and titers of 1:128 or greater were highly predictive of protection. Prevalence studies of meningococcal serogroup C bactericidal antibody in the United Kingdom showed an inverse relationship between disease incidence and prevalence of bactericidal antibody akin to the classic studies by Goldschneider et al. (26, 66). Thus, using rabbit complement, antibody titers of 1:8 or greater correlated best on a population basis with low disease incidence.

Serotype-specific opsonic antibodies protect against invasive pneumococcal disease, but little information is available regarding the amount of opsonic antibody needed for protection. Similarly, it is likely that serum bactericidal antibody against the Vi PS protects against typhoid fever, but the relevant titer has not been established (56).

INTERPRETATION OF ANTIBODY RESPONSE DATA FOR SPECIFIC BACTERIAL PSs

Hib PS

Hib was the leading cause of invasive bacterial disease in children under the age of 5 years in most industrialized countries prior to the introduction of conjugate vaccines in 1987 (9, 60). Then approximately 1 in 200 children by the age of 5 years had developed Hib meningitis, septicemia, or epiglottitis and 5 to 8% died, despite effective antimicrobial therapy. Of the survivors, 20 to 30% had some form of lasting sequelae. More than half of all children who develop invasive Hib disease in industrialized countries have meningitis. Hib disease is now rare in the United States and other countries.

A number of investigators have shown the Hib capsule to be a major virulence factor. Antibodies to the capsular PS are bactericidal and opsonize the bacteria for phagocytic killing (17). In a field trial performed in Finland in 1974, the presence of antibodies induced by a Hib PS vaccine correlated with protection (51). The Finnish trial helped show that the minimum protective level of anti-Hib PS antibodies at the time of exposure was about 0.15 µg/ml. This estimate was originally based on calculations of the amount of anti-Hib antibody in agammaglobulinemic children just prior to receipt of an immune globulin injection (55). In the Finnish trial an anti-Hib PS antibody titer of ≥1.0 µg/ml following vaccination with unconjugated Hib PS vaccine was associated with long-term protection against invasive Hib disease (9, 51). Although the relevance of this antibody threshold to clinical protection after immunization with a conjugate vaccine is not known, this level continues to be considered indicative of long-term protection. Although both the geometric mean titer using a standardized ELISA and the rate of seroconversion to 1 µg/ml are used to compare different Hib conjugate vaccines, the seroconversion rate is more important since it is an indication of the percentage of vaccinees expected to have long-term protection.

The nonconjugated Hib PS, like most PSs, is capable of stimulating B lymphocytes to produce antibody without help of T lymphocytes (T-cell-independent response) (64). Responses to protein antigens are augmented by helper T lymphocytes (T cell dependent). Covalent attachment of the Hib PS to a protein carrier converted the T-cell-independent PS into a T-cell-dependent antigen. The ability of a conjugate to recruit helper T lymphocytes into the immune response helps explain why an infant responds to the Hib conjugate vaccine but not to the PS on primary immunization (18). The T-cell-dependent nature of the immune response also results in induction of immunologic memory, leading to an anamnestic or booster response on reexposure to the native PS (28). Other features of a T-cell-dependent response, such as predominance of IgG1 in young children and affinity maturation, are also seen with conjugate vaccines (64).

Bactericidal titers in postvaccination sera against Hib are strongly correlated with the affinity or functional avidity of the sera (59). Those children with low-affinity antibody after immunization showed little increase in bactericidal activity. Although there was a direct and significant correlation between bactericidal activity and functional avidity, a wide range of anti-Hib PS antibody concentrations were found to have equivalent bactericidal titers, indicating that multiple factors contribute to the observed bactericidal titer (59). However, the in vivo biological importance of antibody avidity is not clear.

Meningococcal PS

N. meningitidis is a leading cause of bacterial meningitis in the United States, with an incidence of about 1/100,000 population, and is the leading cause of meningitis in Europe and Africa. The endemic rates in Europe are about 4 or 5/100,000 and about 20/100,000 in sub-Saharan Africa. The rates are highest in young children. In the United Kingdom the rate in 1999, prior to introduction of the group C conjugate vaccine, was 50/100,000 in children 1 to 4 years of age (47). Meningococcal meningitis and meningococcemia have a case fatality rate of about 10%. Serogroups A, B, C, and Y account for more than 90% of meningococcal disease worldwide, and

nonencapsulated strains are essentially avirulent. The major problem that *N. meningitides* presents is its ability to cause outbreaks and epidemics. This is particularly a problem in sub-Saharan Africa, where in 1996 an epidemic in the West African countries of Burkina Faso, Mali, Niger, and Nigeria resulted in over 200,000 cases, with 20,000 deaths (14). In addition, about 20% of survivors have permanent sequelae such as deafness or loss of extremities.

Meningococcal PS vaccines were developed in the 1960s and licensed in the United States and France in 1975. These vaccines were the first purified component bacterial vaccines. The two formulations generally available are the AC vaccine, produced in Europe, and the ACYW135 vaccine, produced mostly in the United States by Aventis Pasteur. These vaccines are recommended for use in individuals 2 years of age and older who may be at increased risk of meningococcal disease.

A problem with the group C PS vaccine component, not evident with the group A PS, is that reimmunization induces lower antibody concentrations than does primary immunization. This hyporesponsiveness was evident in toddlers and adults when age-matched groups received a second compared to a primary group C PS immunization (27, 42).

Each of the four meningococcal PSs included in the vaccine contains *O*-acetyl groups. The critical role of the *O*-acetyl groups in the group A PS for induction of bactericidal antibodies has now been shown (6). De-*O*-acetylated group A PS no longer reacted with antibodies in postvaccination sera, and a de-*O*-acetylated group A PS-tetanus toxoid vaccine induced only low levels of bactericidal antibody.

The presence of *O*-acetyl groups is not important for induction of bactericidal antibodies to group C (24), and unpublished studies from the 1970s by investigators at the National Institute of Public Health in The Netherlands indicated the same for the Y and W135 PSs. About 10% of clinical isolates of group C meningococci are *O*-acetyl negative (3). Studies comparing *O*-acetyl-positive and -negative group C conjugate vaccines showed the *O*-acetyl-negative vaccine to be more immunogenic (11).

Protection against meningococcal disease is mediated largely by serum bactericidal antibodies. Prior to development of antibiotics and effective vaccines, the mortality rate of untreated meningococcal disease was between 60 and 80% (23). Introduction of serum therapy shortly after 1900 using hyperimmune horse sera reduced the mortality to between 13 and 30% in treated patients, depending upon how promptly serum therapy was initiated. The success of this therapy demonstrated very early the central role of humoral antibody in protection against meningococcal bacteremia and meningitis.

The critical role of bactericidal antibodies has been further demonstrated in a number of ways. (i) The highest incidence of meningococcal disease occurs in individuals between 6 and 12 months of age. This age has the lowest bactericidal antibody levels. (ii) Studies with U.S. Army recruits in the mid-1960s showed a direct correlation between susceptibility to meningitis and absence of serum bactericidal antibodies (26). In prospective studies, Goldschneider et al. (26) showed that disease occurred only among individuals lacking measurable bactericidal antibodies. (iii) Individuals deficient in complement component C5, C6, C7, or C8 have a significantly increased susceptibility to invasive meningococcal infection, even though they may have high levels of antimeningococcal antibodies. (iv) A correlation has been shown between the efficacy of meningococcal PS vaccines and induction and persistence of bactericidal antibodies.

Meningococcal PSs induce opsonic antibodies. In fact, the earliest name for the organism was *Diplococcus intracellularis meningitidis*, based upon the frequent observation of meningococci within polymorphonuclear leukocytes in Gram-strained cerebrospinal fluid samples. Roberts showed that immunization of adults with the group AC PS vaccine induced opsonic antibodies and that these antibodies were mostly IgG (57).

The antibody response to the meningococcal PSs is age dependent. Like other PSs, they are T-cell-independent immunogens, and the ability to respond to such immunogens shows age maturation. The natural development of antibodies to the group A and C meningococcal PSs showed a progressive increase with age, antibodies to group A developing more rapidly, due in large part to more prevalent cross-reacting PSs (25). Adult levels of naturally acquired antibodies to group A are achieved by 12 to 14 years of age. Naturally occurring peak levels of antibody to the group C PS occur at an older age. With administration of AC PS vaccines to children, mature adult-type responses were seen by 10 to 12 years of age (25, 36).

A single dose of either the meningococcal group A or group C PS does not induce protective antibody responses in the majority of infants until about 2 years of age. The group A PS does, however, prime for a booster-type response when given to infants, and a two-dose immunization schedule induced complete protection in children under 1 year of age in New Zealand (38).

The minimum protective concentration of antimeningococcal PS antibodies has not been determined, but Gold estimates the level to be about 2 μg/ml (25). He based this estimation on a number of observations: (i) most adults have >2 μg/ml and have bactericidal activity, (ii) patients at the time of hospital admission with meningococcal disease have <2 μg of anti-PS antibody per ml, and finally (iii) protection against group A meningococcal disease was observed in infants in whom vaccination induced a geometric mean anti-A PS concentration of 2 μg/ml or more. Burian et al. have estimated the protective level of naturally acquired group A meningococcal PS antibody to be 1 μg/ml or greater, by comparing antibody levels by age with age-specific incidence of disease and with antibody levels in acute-phase sera from patients with meningococcal group A (12). The antibody assays for the studies of both Gold and Burian et al. were done by radioimmunoassay in the laboratory of Emil Gotschlich.

Relatively little has been done to ascertain the relative importance of IgG versus IgM antibodies in protection against meningococcal disease, but most of the bactericidal antibody resides in the IgG fraction (62).

Pneumococcal PS

S. pneumoniae (pneumococcus) is a pathogen that affects both children and adults worldwide, but it is particularly a problem at the extremes of life. The pneumococcus colonizes the upper respiratory tract and can cause disseminated disease (bacteremia and meningitis), pneumonia, upper respiratory infections (including sinusitis), and otitis media. In children, the peak incidence of invasive disease occurs by 12 to 15 months of age. It is the most common cause of bacterial pneumonia and otitis media. Annually, an estimated 1.2 million deaths due to pneumococcal pneumonia occur worldwide in children less than 5 years of age (49). Prior to introduction of the pneumococcal conjugate vaccine in the United States, there were an estimated 3,000 cases of meningitis, 50,000 cases of bacteremia, 500,000 cases of pneumonia, and 7 million cases of otitis media each year (13).

Pneumococci are subdivided into more than 90 different serotypes based upon antigenic and structural differences among the surface capsular PSs. According to the Danish identification system, these types are included within 47 groups, members of each group being antigenically related. Some groups, such as 1, 3, 5, and 14, contain a single serotype, while other groups, such as 19, contain multiple serotypes, for example, 19F, 19A, 19B, and 19C. While there are many different serotypes, about 30 types account for most pneumococcal disease. Among young children in the United States, 7 types account for over 80% of invasive pneumococcal disease, while 11 types account for most invasive disease in children worldwide.

Protection against pneumococcal disease is antibody mediated. The critical role of antibody and opsonophagocytosis in protection against pneumococcal disease can be deduced from those defects in host immunity that predispose individuals to invasive pneumococcal infection (31). Defects in antibody production (hypogammaglobulinemia), complement activity (C2 or C3 deficiency), or phagocytic function (anatomic or functional asplenia, as in sickle cell disease) all result in increased susceptibility to pneumococcal disease.

Antibody to the capsular PS is protective, and antibody to one serotype PS does not provide protection against another, except among some serotypes within a group. Zysk et al. found that anti-C PS antibodies were significantly lower among patients (median age, 54 years) with invasive pneumonia and meningitis than in healthy adults (71). However, the predisposition to develop invasive pneumococcal disease in those lacking an immune response to C PS is not clear, because others have shown that anti-C PS antibody is not opsonic (69).

The first well-controlled pneumococcal vaccine efficacy trial was conducted by MacLeod et al. and published in 1945 (44). Their vaccine contained 50 to 70 μg of each of four pneumococcal types, and 8,500 military recruits received the vaccine while 8,500 received saline. Within 2 weeks there were no more cases of pneumonia due to the four types in the immunized group. The two vaccine groups had the same number of cases of pneumonia due to types not immunized against, showing that protection was type specific.

The currently licensed 23-valent pneumococcal PS vaccine was approved in 1983 for use in individuals 2 years of age and older. The primary recommendation was for use in adults aged 65 years and older and in high-risk children, especially those with sickle cell disease. The vaccine contains 25 μg of each serotype PS per dose (575 μg of total PS). See Table 1 for pneumococcal type PSs included in the vaccine.

As seen with other PS vaccines, there is a clear age-related maturation apparent in the ability to respond to the pneumococcal 23-valent PS vaccine. The pneumococcal PSs are poorly immunogenic and fail to induce protective antibody levels in children <2 years of age. Those serotypes most associated with disease in young children, types 6A/6B, 14, 19F, and 23F, are the least immunogenic in this age group (37). For this reason conjugate vaccines were developed against the 7 to 11 most common pediatric pneumococcal types. The first pneumococcal conjugate vaccine was the 7-valent (4, 6B, 9V, 14, 18C, 19F, and 23F) product Prevnar, produced by Wyeth Vaccines, and was licensed in the United States in 2000.

The ability to respond to the different native pneumococcal PS types increases with age. Studies on age-related development of pneumococcal PS antibodies show that there is a marked increase in antibody synthesis between 12 and 18 months of age (63). For most pneumococcal types, adult level responses are generally observed by 15 years of age (Fig. 1). However, for some types, adult level responses to pneumococcal PSs occur by 8 to 10 years of age (19, 50). The antibody responses to types 14 and 23F reach adult levels by 13 to 15 years of age.

The pneumococcus is associated with high morbidity and mortality among the elderly. The ability of the pneumococcal PS vaccine to elicit a functional antibody response was found to be markedly reduced in the elderly compared to young adults (58). In the study by Romero-Steiner et al., a group of
FIGURE 1 Age-related maturation in antibody response to PSs. Antibody response to four serotypes upon immunization with the pneumococcal PS vaccine in children from 1 to 15 years of age was measured.

mostly female elderly subjects (mean age, 85 years) was immunized with the 23-valent PS vaccine. Their immune responses were measured by ELISA and opsonophagocytic assays and compared to those of a control group of younger adults (mean age, 37 years). As observed in other studies, the ability to respond decreased with age, but those 63 to 79 years of age had an IgG antibody response to vaccination very similar to that of younger adults. However, a striking difference was seen in that the elderly had much lower opsonophagocytic titers following immunization than did younger adults. The IgG antibodies from elderly individuals were found to have a much lower avidity than those from young adults. Thus, the critical measure is not total antibody but functional antibody titers.

Antibody avidity affects the antibody concentration needed to induce opsonophagocytic killing of pneumococci (67). High-avidity IgG antibodies against pneumococcal types 6B and 23F were significantly more effective in mediating opsonophagocytosis on a weight basis than lower-avidity antibodies.

An efficacy trial was conducted in northern California for the 7-valent pneumococcal conjugate vaccine Prevnar (8). The vaccine contains 2 μg/dose for types 4, 9V, 14, 18C, 19F, and 23F and 4 μg/dose for type 6B. The trial involved about 37,000 infants, approximately half of whom received Prevnar. The efficacy against serotypes included in the vaccine was 97.4% (95% confidence interval, 83 to 100%) compared to the control group that received a meningococcal group C conjugate vaccine. To obtain an estimate of protective IgG antibody levels the 97% efficacy was compared to antibody concentrations achieved by approximately 97% of the infants after dose 3 at 7 months of age (30). Most vaccinated infants had >0.18 μg of IgG antibody per ml.

For most of the serotypes in Prevnar there is a good correlation between IgG antibody concentrations determined by ELISA and opsonic titers when the sera were preadsorbed with both C PS and 22F PS (16, 30). The proportion of vaccinated individuals achieving a threshold IgG antibody concentration can be used as a correlate of protection. However, serological criteria that may predict efficacy against invasive pneumococcal disease are not precise concentrations, but rather estimates or threshold levels that predict protection on a population basis. It is likely that higher antibody concentrations are needed to protect against pneumonia or otitis media (22).

In the absence of serotype-specific efficacy estimates for invasive pneumococcal disease, it is not possible to define specific serological criteria for each serotype. For this reason we must rely upon one antibody threshold applicable to all serotypes. Since there were vaccine failures for serotype 19F, an antibody threshold of 0.4 μg/ml has been derived for this serotype (30). Thus, a conservative threshold estimate applicable to most pneumococcal serotypes causing invasive disease in young children can be 0.5 μg of IgG per ml as predictive of protection at the time of exposure.

Comparing the immunoglobulin isotypes, IgG is clearly the predominant protective antibody against invasive pneumococcal infections. The major anti-pneumococcal PS IgG isotype in adults is IgG2, while the response in young children is IgG1 (2, 41). The switch from a predominantly IgG1 to a IgG2 response begins after 2 years of age, and older adults have a negligible IgG1 response to the pneumococcal PS vaccine (41). Adults possessing the G2m(n) immunoglobulin allotype have significantly higher postimmunization levels of antibody to various pneumococcal serotypes than do individuals lacking this allotype (41). G2m(n) is an allotype antigen of IgG2 subclass heavy chains. Interestingly, IgG2 makes up only about 20 to 30% of total serum IgG but accounts for the majority of pneumococcal PS-specific antibody.

Substantial IgM antibody is induced by vaccination with the pneumococcal PS vaccine, even in the face of a strong IgG response (29). Anti-pneumococcal IgM antibodies are opsonic.

A recent report documents that the pneumococcal PS vaccine induced capsular serotype-specific mucosal secretory IgA (sIgA) in breast milk is opsonic (22a). The sIgA induced complement-dependent killing of pneumococci by phagocytosis, but it is not clear how the sIgA activates complement. Janoff et al. showed that the majority of pneumococcal PS-specific serum IgA was polymeric and this polymeric IgA induced type-specific complement-dependent killing of pneumococci (4, 29).

Typhoid Vi PS

S. enterica serovar Typhi is the etiologic agent of typhoid fever and is the only *Salmonella* serovar that has a capsular PS. Further, only Vi-positive strains of serovar Typhi invade the blood and cause typhoid fever. Approximately 33 million cases of typhoid fever, with 500,000 deaths, are estimated to occur each year worldwide, mostly in developing countries (20).

The Vi PS typhoid vaccine is produced as a liquid vaccine by Aventis Pasteur. The recommended dose is 25 μg. It is recommended for individuals as a traveler's vaccine beginning at 2 years of age. Studies showed that either 25 or 50 μg of Vi PS elicited fourfold or greater rises in serum antibody concentrations in 95% of adults from either the United States or France (1, 33), where preimmunization levels were low, whereas in South Africa the seroconversion rate was 75% (33). A booster immunization basically restored post-first-dose antibody levels. These Vi PS antibody levels were all measured by radioimmunoassay.

In Nepal, where the attack rate in individuals 5 to 44 years of age was 16.2/1,000, the Vi PS vaccine given as a single 25-μg dose had an efficacy of 75% measured 17 months after vaccination (1). This study clearly showed that serum antibodies to the Vi PS were sufficient to protect against typhoid fever. In South Africa the protective efficacy was measured out to 3 years postvaccination (34).

The Vi PS vaccine is clearly superior to the old inactivated whole-cell vaccines, based upon both safety and effectiveness against typhoid fever. The efficacy of the whole-cell vaccine was 50 to 60% and of relatively short duration (53). The other currently available typhoid vaccine is the attenuated live oral Ty21a strain of serovar Typhi, formulated as enteric coated capsules. This vaccine requires three doses to achieve 60 to 70% protection in children and adults (39).

Keitel and colleagues have estimated that the protective level of Vi PS serum antibodies is 1.5 μg/ml (32). A single dose induced about 80% seroconversion to this level in healthy American adults. About 3 years after immunization the percentage of vaccinees with 1.5 μg or more of antibody per ml declined to 38%, compared to 1% of individuals having 1.5 μg/ml or more before immunization. Reimmunization restored the initial postvaccination antibody levels (32).

Concerning the age-related immune response to the Vi PS, immunogenicity studies in areas of endemicity, including Nepal and Indonesia, show little evidence of an age-related antibody response down to 2 years of age (1, 53). Interestingly, adults in the United States developed increases (fourfold) in antibody similar to those in adults in areas of endemicity, suggesting that previous exposure to the Vi PS does not seem to be necessary for a good immune response.

The mechanism by which the anti-capsular PS antibodies protect against typhoid fever is not entirely clear (56). Typhoid fever is not a diarrheal disease, but a blood infection. The bacteria must invade the blood and to do so must be encapsulated (54). Antibodies to the Vi PS likely protect by complement-mediated lysis, as is found with other blood-invasive gram-negative bacteria (39). The most important antibody isotype is IgG. It is known that the presence of O-acetyl groups on the Vi PS is essential for induction of protective antibody (65).

Subsequent to licensure of the typhoid Vi Ps vaccine, a Vi PS-protein conjugate vaccine was developed (35). This vaccine was shown to be more immunogenic in young children than the Vi PS vaccine. The conjugate was evaluated for efficacy in Vietnamese children 2 to 5 years of age (40). The efficacy was 91.5% (95% confidence interval, 77.1 to 96.6%) in these children.

Corynebacterium diphtheriae and *Clostridium tetani:* Immune Response and Diagnostic Methods

MARTHA L. LEPOW AND PATRICIA A. HUGHES

52

Corynebacterium diphtheriae and *Clostridium tetani* are responsible for important diseases. Tetanus is caused by introduction of *C. tetani* from soil through contaminated wounds, while diphtheria results from airborne infection from infected cases. In both instances it is a potent exotoxin that is responsible for clinical disease. The toxin of *C. tetani* is so potent that the lethal dose may not be of sufficient strength to stimulate antibody production. In both instances formalin-inactivated toxins have been used for universal immunization. For children they are combined with pertussis vaccine, and adults are given both together at a reduced dose of diphtheria toxoid. In September 2005, two new vaccines containing combined acellular pertussis, diphtheria, and tetanus vaccines were licensed.

DIPHTHERIA

Diphtheria is an acute communicable disease of the nasopharynx, larynx, and trachea with complications involving the heart and peripheral nerves and kidney; it has been known since antiquity. Although largely controlled through immunization in the United States, cases do occur sporadically in the United States and elsewhere in the Western world. Recent epidemics have occurred in some countries of the former Soviet Union (9, 12).

The Organism and Pathogenesis

C. diphtheriae is a gram-positive rod with one end being wider, giving it a club-shaped appearance. On culture, characteristic bands or granules appear. On smears the organisms assume a parallel appearance. There are four different biotypes, but no difference in disease is noted among them.

The exotoxin produced by *C. diphtheriae* is the most important pathogenic factor. Toxin production which results from a nonlytic infection by one of a series of related bacteriophages containing a genetic sequence encoding toxin transmission may be facilitated by local tissue damage resulting from the toxin. The *tox* gene is part of a multiple bacterial gene operon, and the entire operon is under the control of a repressor gene, *dtx*, which in the presence of iron binds to and inhibits the *tox* gene. Toxin is produced only under low-iron conditions.

Diphtheria toxin is a polypeptide with a molecular weight of approximately 58,000. It is secreted as a proenzyme requiring enzymatic cleavage into fragments A and B to become active. Fragment B is responsible for attachment to

and presentation of the host cell, and although it is not toxic by itself, it is the antigen responsible for clinical immunity. After penetration of the cell, fragments A and B are detached and fragment A, the toxin, inhibits protein synthesis and results in cell death.

On mucous membranes, the toxin causes local cell death with membrane formulation and remote manifestations in the myocardium, central nervous system, and kidney. Clinical immunity is dependent upon antibodies to the toxin, and formalinized toxin (toxoid) is the active immunizing agent.

Assays for Antitoxin Levels

Several laboratory assays are available. In vitro neutralization assays are based on capabilities of serum containing diphtheria toxin antibodies to neutralize the cytopathogenic effect of diphtheria toxin on the tissue culture system of Vero cells derived from African green monkey kidney cells (7). Neutralization assays are very accurate in this system but are available only in research laboratories. Levels of 1.0 IU and above are associated with long-term protection.

Several enzyme-linked immunosorbent assays (ELISAs) capable of detecting specific immunoglobulin G (IgG) have been developed; however, false-positive results may occur due to recognition of nonneutralizing antibodies. Results of ELISAs may not correlate well with toxin-neutralizing assays.

Recently a delayed-fluorescence immunoassay has been used to determine diphtheria antitoxin levels in human serum. This has been evaluated in vivo in neutralization tests performed with rabbits and has been shown to be superior to Vero cells on sera with titers below 0.02 µg/ml (3).

In the first international meeting of the WHO European Laboratory Working Group on Diphtheria in 1994, it was agreed that the in vitro toxin neutralization assay on Vero cells is the most appropriate method for measurement of diphtheria antitoxin antibodies. In vitro assays such as ELISA and passive hemagglutination (PHA) assays are required to provide comparison with toxin neutralization assays.

Clinical Manifestations

The disease most commonly presents with gradual onset over 1 to 2 days as a membranous pharyngitis with confluent exudate over the tonsils and soft palate, with a moderate fever. Laryngeal diphtheria occurs concomitantly with inspiratory stridor and hoarseness. Transmission is through the respiratory route. Nasal and cutaneous diphtheria are rare

manifestations. Cases of diphtheria are reportable to local health departments.

Complications associated with the toxin occur within a few days, and it is important to establish a diagnosis quickly with culture so that treatment can be instituted. Effective treatment includes early administration of an equine diphtheria antitoxin (DAT), although toxin which has already entered the host cell cannot be affected by antitoxin. The Centers for Disease Control and Prevention has recently procured an equine DAT product from Instituto Butantan in Brazil. It can be provided to physicians caring for patients with respiratory diphtheria under a Food and Drug Administration investigational new drug protocol. Skin testing is mandatory, and treatment for acute reactions must be available. Serum sickness can occur with large doses of antitoxin. A novel approach to passive immunity may be the development of a modified diphtheria toxin receptor molecule to bind diphtheria toxin (4).

Penicillin or erythromycin can be given to clear the organisms from cases or for eradication of the carrier state. There is little evidence for use of antitoxin in carriers.

Active Immunization

In the early 20th century, it was discovered that a balanced mixture of toxin and antitoxin could be used to successfully immunize susceptible persons. Diphtheria toxoid was subsequently developed, and by the mid-1940s diphtheria toxoid was combined with tetanus toxoid and whole-cell pertussis vaccines (DPT). Adsorption of all three onto an aluminum salt for intramuscular use came soon after, which enhanced immunogenicity. Universal immunization with the combined vaccine was well under way in the 1950s. Recently, acellular pertussis vaccine has replaced whole-cell pertussis vaccine, and a schedule of five doses, with administration at 2, 4, 6, and 15 to 18 months and 4 to 6 years constitutes the childhood schedule (1). Older children and adults receive DT with a lower concentration of diphtheria toxoid in order to prevent more severe local reactions.

After three doses of diphtheria toxoid almost all infants will have developed anti-diphtheria toxoid titers at 0.01 IU/ml, which is the minimal protective level. During the past few years immunization programs in the former Soviet Union have resulted in 90% efficacy (7).

A combined vaccine consisting of DT acellular pertussis (DTACP) together with inactive poliovirus vaccine and hepatitis B virus vaccine has become available for immunization of infants up to 6 months of age, and others may be in the pipeline to decrease the number of injections required for young infants. In the future efforts will be made to reduce reactogenicity of components of DTACP (8).

A diphtheria toxoid from CR 197, a mutant nontoxogenic strain of *C. diptheriae*, has been conjugated to capsular polysaccharides of *Haemophilus influenzae* type b, seven types of pneumococcus, and four types of meningococcus, resulting in enhanced immunity to the antigens and longer persistence of antibody. A booster effect has been observed for diphtheria antibody following administration of the polyvalent pneumococcal conjugate vaccines.

TETANUS

Introduction

The Organism and Its Exotoxins

C. tetani is a gram-positive, spore-forming motile anaerobic bacillus. Although considered a strict anaerobe, it can be cultured in a range of temperatures and in a variety of media used in growing anaerobes. Spores may persist in soil for months or years. Animals can carry *C. tetani* in their feces.

Exotoxins of *C. tetani*

C. tetani produces two exotoxins, tetanolysin and the neurotoxin tetanospasmin, which is responsible for the manifestations of the disease. It is one of the most potent known toxins, and the minimal lethal dose in humans is estimated to be <2.5 μg/kg of body weight. Formalinization detoxifies the toxin while retaining its immunogenicity.

Pathogenesis

Infection usually begins with the inoculation of spores through the epithelium. Wounds accompanied by tissue injury and necrosis (with or without aerobic organisms) leading to low oxygen concentration allow spores to germinate and bacilli to replicate. Toxin produced locally reaches the central nervous system via lymphatics and along neurons.

Diagnosis

The diagnosis is clinical, supported by an appropriate epidemiological setting. The illness presents as trismus, nuchal rigidity, and dysphagia accompanied by spasms of major muscle groups. Today with universal effective immunization, clinical tetanus rarely occurs and is seen in the elderly and in neonates in parts of the world where the umbilical stump is treated with soil which then constitutes a portal of entry for spores. Antitoxic antibodies are protective in prevention of infection, and treatment is mainly supportive.

Methods for Measuring Antitoxin

Although reliable methods of measuring antitoxic neutralizing antibodies have existed for many years for tetanus antitoxin, regular clinical laboratories rarely maintain the capability of determining tetanus antitoxin levels because they are of no use in diagnosis or treatment of the acute disease. They are also time-consuming and are mainly used as research tools.

The most reliable method for determining tetanus antitoxin levels is in vivo neutralization of toxin which depends upon antibodies of the IgG class. The mouse neutralization assay is the most widely used (2), and this method is described below.

PHA has good correlation with neutralization tests. This detects IgM and IgG antibodies, and since only IgG is active in neutralization tests, low levels of early antibody (IgM) may not be active (8).

An ELISA can be used for the determination of serum tetanus antitoxin levels (10). It is a simple test, is relatively inexpensive, and can detect antitoxin of specific immunoglobulin types. The titer may be higher with ELISA than with neutralization assays, especially for recently immunized people, suggesting the presence of low-avidity antibodies.

ELISA has in some hands proven to be as sensitive as the neutralization test for the detection of antitoxin, but there are problems in reproducibility. Despite the ability of the ELISA to detect IgG antitoxin, which presumably contains all of the toxin-neutralizing activity, differences in binding activity and neutralization have occurred. At this time, ELISAs should be employed for screening but not for determining the specific titer of antibody.

Counterimmunoelectrophoresis can be used for the detection of tetanus antitoxin (13), but because of its relative insensitivity, this method is useful only in screening sera containing relatively high levels (>7.0 IU/ml) of antitoxin. A solid-phase radioimmunoassay has also been described for

the detection of tetanus antitoxin (5), but no comparisons with in vivo neutralization tests have been reported.

It is recommended that in a clinical laboratory, where values for individual patients are important, the more reliable mouse neutralization test should be used. There is no tissue culture method available for the titration of tetanus toxin or antitoxin.

Natural Immunity and Response to Disease

It is unclear whether humans can develop circulating antibody to tetanus in the absence of vaccination or disease. Intestinal colonization could result in such protection. The exotoxin of *C. tetani* is so potent and the lethal dose so small that survivors of the disease will rarely develop significant antibody titers.

Immune Response to Tetanus Toxoids

Injection of tetanus toxoid, which is one of the most effective immunizing agents in use today, regularly evokes antitoxic antibodies. A circulating neutralizing antibody titer of 0.01 IU/ml is protective against disease.

In 1944, following success of tetanus toxoid immunization during World War II, routine inoculation in childhood was recommended by the American Academy of Pediatrics. Shortly thereafter, tetanus toxoid was combined with diphtheria toxoid and whole-cell inactivated pertussis organisms (DTP), and this combination became the standard immunization protocol for infants and children up to 7 years of age. As of January 2000 acellular pertussis vaccines have replaced whole-cell vaccine in formulations with diphtheria and tetanus (6). For older children and adults, only diphtheria and tetanus toxoid are recommended, and the quantity of diphtheria toxoid is lower (Td) in order to avoid serious reactions. In the United States aluminum hydroxide, aluminum phosphate, or alum is used as an adjuvant. These allow an adequate immune response with fewer doses than with fluid preparations.

Infant Immunization Schedule

Three doses of vaccine at 2, 4, and 6 months are recommended, with a booster at age 12 to 18 months and again at 5 years. This regimen will ensure nearly 100% durable protection. A minimum of two doses is necessary for stimulation of measurable protective levels of tetanus antibody.

For unimmunized older children and adults, two doses four or more weeks apart will produce tetanus antitoxin levels of >0.01 IU/ml, but a booster dose should be given 6 to 12 months later. Td vaccination is recommended every 10 years to maintain immunity to both tetanus and diphtheria. With these regimens, tetanus has largely been eliminated. Persons who have recovered from tetanus should be immunized because the natural disease may not be protective. The World Health Organization recommendation for tetanus immunization of women of childbearing age is two doses 2 months apart in parts of the world where neonatal tetanus still occurs.

Care of Tetanus-Prone Wounds

For wounds contaminated with soil or feces or where there is devitalized tissue (e.g., burns or puncture wounds), a booster dose of vaccine is usually given if the immunization status is unknown or more than 5 years has elapsed since the last dose.

Passive antibody is also recommended as a single dose of human tetanus immune globulin (TIG) (250 U) in a separate site if the immunization status of the patient is not known. If TIG is unavailable, equine antitoxin (3,000 to 5,000 U) can be used after skin testing. Epinephrine must be available in case of anaphylaxis, and if the skin test is positive, desensitization may be required. This product is not available in the United States. Because of a variable immune response, individuals with symptomatic human immunodeficiency virus infection should receive passive antibody (TIG) for all tetanus-prone wounds regardless of immunization status (11).

Treatment of Disease

Currently a single dose of human TIG is given at diagnosis to bind circulating toxin. Wound debridement and antibiotics as well as supportive care are needed.

Standardization of Commercially Produced Tetanus Toxoid

In North America the available preparations are given as 0.5-ml doses intramuscularly. The toxoid content of commercial products is assessed by flocculation with standard antitoxin and is measured in units termed the limits of flocculation. Potency is determined by animal bioassays: for the fluid preparation, immunized guinea pigs are tested for survival after a toxin challenge; for precipitated toxoid, a serum pool from immunized guinea pigs must exceed 2 IU/ml (8).

CLINICAL USE OF ANTITOXIN LEVELS

There are few indications for the determination of tetanus antitoxin levels. Diagnosis and therapy are determined on the basis of clinical symptoms and exposure history. A possible clinical use could be to determine the antitoxin level before using tetanus antitoxin for therapy. If 0.01 IU of antitoxin is present prior to treatment, the diagnosis of tetanus would surely be in doubt. On the other hand, the absence of antitoxin in serum after a clinical illness compatible with tetanus does not rule out the diagnosis because the quantity of toxin producing disease may not be sufficient to stimulate antibody formation.

For population surveys of immune status to tetanus, one of the more rapid but less quantitative tests commercially available such as PHA or ELISA can be used (8). Probably the most frequent need for these assays today is in connection with studies of immunocompetence in infants and young children. The response to tetanus toxoid after three or four doses is of practical use where B-cell activity is being measured.

METHOD FOR ANTIBODY DETERMINATION

Titration of Tetanus Antitoxin by the Mouse Toxin Neutralization Test

The procedure for titration of tetanus antitoxin is based on the capacity of tetanus antitoxin to protect mice from death after subcutaneous injection of tetanus toxin. The following procedure is based on the method of Barile et al. (2).

The sample of tetanus toxin to be used must first be titrated against a standard tetanus antitoxin to determine the L+/1,000 toxin dose. The L+/1,000 dose is the least amount of tetanus toxin which when mixed with 0.001 U of antitoxin and injected subcutaneously into mice in a volume of 0.5 ml causes the death of all mice by 96 h.

Female mice, 15 to 18 g, are used since males tend to fight. Any strain may be used, but strain and source should not be changed once the titration procedure has been established. Preliminary estimation of the L+/1,000 dose of toxin

can be made in groups of four to six mice. In all mouse tests, pool all mice needed for the test, including the controls, and distribute them randomly into the groups required.

Phosphate-buffered saline (0.067 M, pH 7.4) containing 0.2% gelatin is used as the diluent for all reagents.

For the initial screening test to estimate the L+/1,000 dose of toxin, add constant volumes of standard antitoxin containing 0.004 antitoxin units (AU)/ml to a series of 8 to 10 tubes. Prepare a series of three- to fivefold dilutions of tetanus toxin, and add an equal volume to each tube of antitoxin. Shake the mixtures gently, incubate them for 1 h at room temperature, and then keep the mixtures at 4 to 8°C until the time of injection.

Inject 0.5 ml of each toxin-antitoxin mixture subcutaneously in the right inguinal fold of 4 to 10 mice per dose, using 26-gauge, 3/8-in. needles. Each injection contains 0.001 AU. Observe for 96 h and record the number of deaths. The smallest dose of toxin which kills all mice is the approximate L+/1,000 dose. (The corresponding toxin dilution contained 4 L+/1,000 doses per ml.)

To ascertain a more precise L+/1,000 dose, repeat the test using narrower increments of toxin and 4 to 10 mice per toxin dose. Since tetanus toxin produces very precise and reproducible results in mice, good results may be obtained by using a very narrow range of doses. Increments of 5% over a twofold range can be used successfully.

For serum titrations, test sera should be inactivated at 56°C for 30 min. Constant volumes of 2- to 10-fold dilutions of serum are dispensed into test tubes (13 by 100 mm). To each tube add an equal volume of toxin containing 1 L+/1,000 dose per ml. Each mouse thus receives 1 L+/4,000 dose of toxin per injection volume of 0.5 ml (one-fourth of an L+/1,000 dose). Run a concurrent L+/1,000 titration of the toxin against standard antitoxin as described above, using the same pool of mice. One group of mice should also receive the toxin test dose (1 L+/1,000 dose per ml) mixed with an equal volume of diluent. For serum titrations, groups of two to four mice per serum dilution give satisfactory results. The test is considered satisfactory if the concurrent L+/1,000 dose of toxin is within 25% of the test dose.

The results are interpreted as follows: if all mice are protected by undiluted serum but all die at the 1:10 dilution, then 0.25 ml of the undiluted serum contained >0.00025 AU and 0.25 ml of the 1:10 dilution contained <0.00025 AU. Thus, the serum contained >0.001 but <0.01 AU/ml. For purposes of calculation, such a serum can be assigned a value equal to the logarithmic mean of the values, or 0.003 AU/ml. For more precise titration, narrower increments of test sera can be used or the level of testing can be shifted by using multiples or fractions of the L+/1000 dose of toxin.

REAGENTS

U.S. standard samples of equine tetanus antitoxin are supplied to qualified laboratories by the Center for Biologics Evaluation and Research, Rockville, Md. The quantity of antitoxin is indicated in the label on the vial.

These samples are to be used by the receiving laboratory in preparing and standardizing its own reference stock.

Antitoxin may be purchased from pharmaceutical houses or state laboratories, which prepare tetanus antitoxins for prophylactic or therapeutic use. Such antitoxins must be precisely standardized against the official U.S. standard preparation before they can be used as reference reagents for the mouse neutralization tests. Tetanus immune globulin of human origin can be purchased from several pharmaceutical companies and then standardized against the standard reagent for use in ELISAs.

Immunologic Methods for Diagnosis of Infections Caused by Diarrheagenic *Enterobacteriaceae* and *Vibrionaceae*

MARCELA F. PASETTI, JAMES P. NATARO, AND MYRON M. LEVINE

53

The families *Enterobacteriaceae* and *Vibrionaceae* encompass a heterogeneous group of gram-negative organisms. Many members of these families are normal colonizers of the human intestinal tract (e.g., *Escherichia coli* strains) or may cause transient asymptomatic infections. Alterations of the immune system or breakdown in normal epithelial or mucosal barriers to infection may render these organisms virulent. Under such circumstances, they may cause bacteremia, meningitis, or infections of the urinary tract, skin, and soft tissues. However, certain members of these two families possess virulence factors that render them primary pathogens for the human intestinal tract. The consequences of infection with these agents are predominantly, but not necessarily, limited to diarrhea.

Members of the *Enterobacteriaceae* family associated with acute diarrheal disease include diarrheagenic *E. coli* and *Salmonella* and *Shigella* spp. There are six distinct categories of *E. coli* generally recognized as causative agents of diarrheal disease: enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enteroaggregative *E. coli* (EAEC), and diffusely adherent *E. coli* (23, 40). Pathogenic isolates from each category tend to be clonal groups that fall within distinct somatic O (lipopolysaccharide [LPS]) and H (flagellar) serotypes (23). Within the *Vibrionaceae* family, *Vibrio cholerae* strains of serogroups O1 and O139 are the major agents of watery diarrhea.

The organisms chosen for discussion in this chapter are recognized as major public health concerns because of their significant contribution to morbidity and mortality in both children and adults in less developed and industrialized countries. In developing countries, diarrheagenic *E. coli*, particularly ETEC, isolates are the second most common cause of dehydrating diarrhea (after rotavirus) in infants and toddlers (40), while *V. cholerae* remains a major cause of epidemic diarrhea in South Asia and sub-Saharan Africa (28). In industrialized countries, these organisms are responsible for infections primarily in travelers, although some of them cause disease in institutional settings and among day care attendees (28).

Although acute diagnosis of infections with some of these agents has traditionally been made by microbiological isolation and serotyping of strains, this conventional approach may not be practical or even reliable for the following reasons: (i) the virulent *E. coli* strains are indistinguishable from

normal flora by conventional bacteriology; (ii) some pathogens, such as EHEC, may no longer be retrievable at the time of disease presentation; (iii) optimal bacteriological specimens may be technically difficult to obtain (acute or chronic infection with *Salmonella enterica* serovar Typhi, for example); (iv) a bacteriology laboratory may not be available (or may not be well prepared) during acute outbreak situations, particularly in developing countries; and (v) bacteriological isolation may be too slow to allow timely clinical or public health intervention. Although O-antigen serogrouping may help to presume the category of diarrheagenic *E. coli*, this is not a reliable method of definitve diagnosis. Strains of *E. coli*, for example, that have the same O antigen may have virulence markers that put them into distinct categories. Thus, diarrheagenic O111 isolates may be either EPEC or EHEC. In addition, organisms that do not fall into the traditional EPEC O:H serotypes may possess some virulence characteristics of EPEC strains. For this reason, it is important to characterize and identify organisms based on their genetic virulence determinants and/or phenotypic expression of these virulence determinants. Improved, rapid immunologic and molecular methods for diagnosis of enteric infections can be important tools for clinical care and for public health action.

ENTEROBACTERIACEAE

EHEC

EHEC strains cause diarrhea that may progress to bloody diarrhea (hemorrhagic colitis); 5 to 10% of these cases may progress to hemolytic-uremic syndrome (HUS), a severe complication characterized by the triad of hemolytic anemia, thrombocytopenia, and acute renal failure (40). Up to 40% of patients with HUS develop long-term renal dysfunction, and 3 to 5% die during the acute phase of the disease. It has been suggested that the use of antibiotics for treatment of EHEC diarrheal illness may actually increase the risk for developing HUS (40). Consequently, it is critical to have adequate rapid diagnostic methods to identify disease caused by EHEC strains.

The principal EHEC serotype that causes disease in the United States and much of the industrialized world is O157:H7. Other EHEC serotypes implicated as causes of HUS include O26:H11, O4:NM (nonmotile), O111:H8, O111:NM, and O145:NM. These EHEC strains possess one

or more phage-encoded Shiga toxins (Stx1 and Stx2) (also known as verocytotoxins), an ∼ 60-MDa virulence plasmid, and a chromosomal pathogenicity island (the locus of enterocyte effacement [LEE]), all of which contribute to virulence (23, 40).

Detection of Stx by Cytotoxicity

Demonstration of cytotoxicity for Vero cells remains the "gold standard" method to detect Stx-producing strains in fecal samples (4, 24). HeLa cells can also be used, although they lack the preferred Stx2 cell surface receptor and therefore may be less sensitive than Vero cells (44). In these assays, serial dilutions of filtered stool supernatants are incubated in cell monolayers (in 96-well plates) and examined for cytopathic effect 48 to 72 h later. Cytotoxicity is usually examined under the microscope or can be quantified by colorimetric methods. Positive samples should be retested in the presence of Stx-specific antibodies to confirm the specificity of the cytotoxic effect. The success of the assay is limited by the number of bacteria in the fecal samples (44, 45); it is known that 1 week after the onset of diarrhea, two-thirds of HUS patients no longer excrete *E. coli* O157 or other causative EHEC organisms in their stools (40). Results may also be influenced by the amount and potency of the Stx secreted and the degree to which it is released from the bacterial cells (44). Nonetheless, cytotoxicity tests are extremely sensitive and free fecal toxin can be detected even though stool cultures are negative. This assay, however, is labor-intensive and time-consuming. Although more than 200 serotypes of *E. coli* produce Stx, most of these do not contain the LEE pathogenicity island and are not associated with human disease (23). Thus, for proper diagnosis of EHEC, detection of Stx should be accompanied by the demonstration of EHEC virulence factors.

Detection of Stx Antigen

A number of immunoassays that detect Stx1 and Stx2 in fecal samples have been described (4, 24, 44). Most of them consist of a sandwich enzyme-linked immunosorbent assay (ELISA) that uses monoclonal antibody (MAb) or affinity-purified polyclonal antibodies immobilized to the microplate to capture Stx in the specimens, which is revealed with Stx-specific antibodies labeled with an enzyme or using an appropriate secondary antiserum. There are commercially available ELISA kits (4) to detect Stx (e.g., Premier EHEC from Meridian Biosciences, Inc., Cincinnati, Ohio, and ProSpecT Stx *E. coli* microplate assay from Alexon-Trend, Ramsey, Minn.). Results from these tests are influenced by the amount of bacteria in fecal samples and their capacity to produce toxin; for this reason, specimens should be obtained as early as possible in the course of infection. The Premier EHEC test has a sensitivity of 100% and a specificity of 99.7%, in comparison with fecal EHEC isolation using sorbitol-MacConkey (SMAC) agar, the culture method routinely used in clinical laboratories (4). The ProSpecT assay was also found to be highly sensitive and specific (100%) compared to SMAC agar, and the values are similar to those reported for the Premier EHEC technique (16). A reverse passive latex agglutination test to detect Stx1 and Stx2 (VTEC-RPLA "Seiken" from Denka Seiken, Tokyo, Japan) is commercially available. According to the manufacturer, the VTEC-RPLA has a limit of detection of 1 ng of toxin per ml and is 100% sensitive and 100% specific for Stx detection compared with the Vero cell assay. To reiterate, detection of both Stx and virulence factors is needed to confirm EHEC infection.

Detection of O157 LPS Antigen

Expression of O157 antigen can be assessed by agglutination of sorbitol-negative *E. coli* colonies from SMAC agar cultures (24). However, some O157 strains which ferment sorbitol have emerged as causes of human disease, and these strains are missed by this diagnostic procedure (4). Sandwich ELISAs have been described that detect O157 antigen in fecal samples. These assays have similar or higher sensitivity compared with the culture of organisms on SMAC agar and can detect sorbitol-fermenting strains (24). There are several *E. coli* O157 immunoassay detection kits commercially available (*E. coli* O157 latex test from Denka Seiken; ImmunoCard *E. coli* O157 from Meridian Biosciences, Inc.; *E. coli* O157 antigen detection microwell ELISA from Biotech Trading Partners, Encinitas, Calif.; and *E. coli* antigen detection by Diagnostic Automation, Calabasas, Calif.). The usefulness of these methods is limited by the fact that most patients are no longer excreting O157 EHEC in stools at the time of clinical presentation of HUS. There may also be cross-reactivity between O157 LPS and LPSs of other bacteria. Because nontoxigenic isolates of *E. coli* O157 have been reported (40), these assays must be considered primary screening methods that require confirmation by culture and/or demonstration of Stx production. It must also be emphasized that EHEC of serotypes other than O157:H7 are emerging as agents responsible for HUS, outbreaks and sporadic causes of HUS, and the clinical features of these cases are identical to those caused by Stx+ O157:H7 strains (44).

Molecular Methods To Detect EHEC Strains

In the late 1980s and early 1990s, hybridization using DNA probes to detect virulence determinants, such as the 60-MDa EHEC virulence plasmid and genes encoding Stx1 and Stx2, was a sensitive and specific technique to diagnose EHEC infections. These probes were used to test large numbers of stool *E. coli* isolates by hybridization (4, 24, 40). The sequencing of EHEC virulence genes now permits the design of primers for amplification using PCR (23, 40, 43). For example, Stx + O157 strains have been distinguished from non-EHEC strains by amplifying a variable sequence on the 3′ portion of the *eae* gene (a component of the LEE pathogenicity island that encodes the bacterial adhesin intimin) either alone or combined with Stx genes (40, 43). PCR kits for detection of Stx + *E. coli* are commercially available (e.g., ZipLys Bacto from ZipGen Inc., Solon, Ohio). PCR can also differentiate serogroups O157, O111, and O113 by using primers directed to the genetic loci (*rfb* regions) involved in O-antigen biosynthesis (43). Two other genetic markers associated with O157:H7 Stx + *E. coli* strains, *fliCh7*, which encodes the H7 antigen, and *uidA,* responsible for the β-glucoronidase-negative phenotype of O157:H7 strains, have been used for PCR assays (40, 43). A system that allows identification of *Salmonella*, *Shigella*, and *E. coli* O157:H7 with sensitivity to detect as few as 3 to 50 CFU was recently developed (32). This system combines common PCR, seminested PCR, and random amplification polymorphic DNA (RAPD) analysis, using universal primers of enteric pathogens located in the *uidA* gene, primers for *ipaH* from *Shigella, eae* from *E. coli,* and the most conserved fragment, 16S rRNA, for *Salmonella* (32). PCR techniques are rapid and can be applied to crude lysates or DNA extracts from single colonies, broth cultures, feces, or food. They are extremely sensitive and specific, as the identity of the amplified product can be confirmed by ethidium bromide staining after separation in agarose gel electrophoresis, by restriction analysis, and by DNA probe. PCR analysis has an advantage over the serological methods to detect EHEC Stx,

other virulence factors, or LPS, since it can be combined to identify the toxin type, other specific virulence genes, or genes associated with serogroups. A multiplex PCR assay combining specific primers for the *eae*, *bfp*, *stII*, and *lt* virulence genes that allows detection of EHEC, EPEC, and ETEC in a single reaction was used in an epidemiological study to evaluate the incidence of *E. coli* diarrheal infections in pediatric patients in Chile (56). This multiplex PCR can differentiate *E. coli* strains in cases of HUS, food-borne diarrheal disease outbreaks, and cases of sporadic enterocolitis or diarrhea (56). Despite its high sensitivity, however, even PCR may be unable to detect bacteria in the late course of the disease due to the low number of organisms present. In addition, stools may contain substances that interfere with PCR, thereby decreasing its sensitivity. Sometimes the results may be difficult to interpret, as the genotype profile observed may correspond to more than one organism (43). Whereas molecular techniques were once regarded as sophisticated, labor-intensive, and reserved for research laboratories, they are being increasingly adopted by large clinical laboratories.

Detection of Serum Antibodies to *E. coli* O157 LPS

Detection of immunoglobulin M (IgM), IgG, and IgA antibodies specific for O157 LPS has emerged as a useful, popular, and reliable tool for clinical diagnosis of O157 infection associated with HUS, especially when stool cultures are negative (9, 44). Children with HUS caused by O157 EHEC mount a rapid IgM response to O157 LPS that can be readily measured by ELISA (9). IgG antibodies, which may be detected early in the course of HUS caused by O157, persist for several months after disease onset. LPS antibodies measured by ELISA in serum samples or saliva (described below) may also serve to determine exposure to *E. coli* O157 in epidemiological surveys and to evaluate the extent of outbreaks. Several other techniques have been described to measure serum LPS antibodies, including immunoblotting, agglutination, and indirect hemagglutination, and the results obtained appear to be in close agreement (9, 24, 44). We describe the O157 ELISA, since we consider it one of the most practical and useful techniques.

Reagents

O157 LPS antigen can be extracted from a clinical isolate using the hot water-phenol method (9). Antigen preparations need to be free from protein and nucleic acid contamination. The optimal concentration of antigen should be determined by standard ELISA checkerboard titration, coating plates with different amounts of antigen and testing them with known positive and negative control sera during the standardization of the assay (13). The usual range of LPS coating concentrations is 1 to 10 μg/ml. Coating buffer is sodium bicarbonate, pH 9.6. Washing buffer is phosphate-buffered saline (PBS), pH 7.4, with 0.05% Tween 20 (PBST). Blocking solution is 10% nonfat dry milk in PBS, pH 7.4 (PBSM). Horseradish peroxidase (HRP)-labeled goat anti-human IgG (MP [formerly ICN Biomedicals], Aurora, Ohio) is used as secondary antibody; the appropriate dilution needs to be established in checkerboard titrations (13) (usually around 1:5,000). The diluent for serum and secondary antibody is 10% nonfat dry milk in PBS, pH 7.4, with 0.05% Tween 20 (PBSTM). The substrate solution is (3,5,3′,5′)-tetramethylenebenzidine (TMB) microwell peroxidase (Kirkegaard and Perry Laboratories [KPL], Gaithersburg, Md.).

Procedure

This technique follows a standard indirect ELISA procedure for detection of serum antibodies (13). ELISA plates (Immulon II; ThermoLabsystems) are incubated with 100 μl of antigen solution for 3 h at 37°C, washed, and blocked overnight at 4°C with 250 μl (full wells) of blocking solution (PBSM). Note that milk should be properly dissolved. After each incubation, plates are washed six times with washing buffer (PBST), soaking plates for 2 min between washes; the residual wash fluid is removed from the wells by tapping the inverted plate on absorbent paper. Proper washing is critical to minimize background signals. After plates are washed, serum samples are added at the appropriate dilution and incubated for 1 h at 37°C. When the antibody titer of the sample is unknown, starting dilutions of 1:100 or 1:1,000 are recommended for screening. Further twofold dilutions are made in the plate until row G; the last row (H) is usually reserved for blanks. Additional runs using different dilutions may be needed in order to obtain a linear dose-response curve of absorbance versus serum dilutions. Conjugate is added in a 100-μl volume, and plates are incubated for 1 h at 37°C. Substrate solution is prepared by following instructions from the manufacturer, added to the washed plates in a 100-μl volume, and incubated in an ELISA rotator for 15 min at room temperature in darkness. Color development is stopped by adding 100 μl of 1 M phosphoric acid. Absorbance is read immediately at 405 nm. The following controls should be included in each assay. (i) Blanks consisting of coated wells in which serum samples are replaced by the diluent should be used; the rest of the reagents, such as conjugate, substrate, and stop solution, as well as procedures are maintained. (ii) A calibrated positive control, which can be prepared from a pool of serum samples with a high LPS antibody titer, should be used. The titer of this calibrated control is established during the calibration of the assay; it must be run in each assay to confirm reproducibility. (iii) A calibrated negative control, usually prepared from a pool of negative samples, should be used; this control allows assessment of reproducibility in each assay and confirmation of the cutoff value for positive samples.

Endpoint antibody titers can be calculated as follows. Mean absorbance values for blank wells are subtracted from all individual absorbance values. Mean absorbance values (from duplicate wells) for the different serum dilutions are analyzed by linear regression. An endpoint titer is calculated through regression parameters as the inverse of the serum dilution that produces an absorbance value of 0.2 above the blank.

Results and Interpretation

Each laboratory must determine an appropriate cutoff value for positive samples as the mean absorbance produced by control (e.g., negative) samples + 3 standard deviations. A high proportion of patients infected with O157 strains have elevated acute-phase levels of serum antibody to O157 LPS; healthy controls have a low seropositivity rate.

Remarks

High titers even in a single sample at the time of acute disease is considered a reliable indicator of current or very recent infection (9, 24). O157 LPS serology was shown to be consistently more sensitive than bacterial isolation or Stx serology (24). Serodiagnosis is less valuable when serum is obtained several months after clinical disease, due to the rapid decrease of antibody titers. Another limitation of this method is that healthy people living in areas where EHEC strains are prevalent may have increased baseline O157 LPS titers. Indirect hemagglutination assays detecting O157 LPS antibodies have also been used for serological diagnosis of

E. coli O157 infections (6). Early studies showed that using a cutoff of ≥1:4,096, the indirect hemagglutination assay has a sensitivity of 81 to 91% and a specificity of 94 to 100% (6, 44). These studies examined samples from children with HUS during the acute and postacute phases; samples from children with diarrhea but who did not develop HUS were used as controls (6).

EHEC organisms belonging to serogroups other than O157 may also cause HUS and bloody diarrhea (40). Thus, if possible, clinical samples that are seronegative for O157 LPS should be tested against common non-O157 serogroups (e.g., O26, O55, O111, and O128, available from Sigma Chemical Co., St. Louis, Mo.). It should be noted that *E. coli* O157 shares epitopes with other gram-negative organisms, such as *Yersinia enterocolitica* O9, *V. cholerae* non-O1, *Citrobacter freundii*, *Brucella abortus*, and *Salmonella* spp. This fact limits the specificity of serodiagnosis based on antibodies that bind O157 antigens (9); thus, highly purified LPS antigens must be used to minimize cross-reactions.

Detection of Salivary Antibodies to *E. coli* O157 LPS

A few studies have demonstrated that saliva-based immunoassays offer a reliable, noninvasive method for the diagnosis of *E. coli* O157 infection in patients (including children) with enteropathic HUS (9, 36), particularly small and severely anemic children. In one study, paired serum and saliva samples from 22 children with HUS collected during acute disease and the convalescent phase and 44 age-matched controls were tested for O157 LPS IgM and IgA antibodies by ELISA (36). Increased O157 LPS IgM and IgA titers were found in saliva of all HUS patients with stool cultures positive for Stx$^+$ *E. coli* O157 and from four of five HUS patients for whom stool cultures were negative. The saliva antibody titers showed a strong correlation with titers in serum. In Stx$^+$ *E. coli* O157 culture-confirmed cases, the sensitivity of the ELISA was 92% for saliva IgM and IgA, based on the first available sample, and 100 and 92%, respectively, when subsequent samples were included. The specificities were 98% for IgM and 100% for IgA. Saliva- and oral fluid-based assays are increasingly being used for diagnosis and prediction of disease progression (10). Since oral fluid collection is a simple, noninvasive procedure and oral fluid antibodies accurately reflect serum antibody levels, one may expect the use of such assays to become increasingly popular for diagnosis in children.

Detection of Antibodies to Stx and EHEC Virulence Factors

The presence of serum neutralizing antibodies to the Stxs has been reported for patients with HUS (9, 44). But the specificity of these responses has been questioned, since Stx-neutralizing antibodies (mostly to Stx2) have also been found in sera from healthy individuals (9). Another limitation of this method is that only a minority of patients with proven Stx-producing *E. coli* infection exhibit detectable serum antibodies to the respective toxin type (9). Paton and Paton showed by Western blot analysis that convalescent-phase sera from patients with HUS caused by LEE-positive strains reacted with an important EHEC virulence determinant, Tir, the translocated intimin receptor that is inserted by the bacterium into host cells (45). Another study confirmed the presence of strong antibody responses to Tir in all patients with diarrhea or HUS caused by EHEC as early as 8 days after onset of illness and for at least 2 months following acute disease (33). Brazilian mothers and children had antibodies to Tir in colostrum and serum (50). The clinical specificity of this assay, however, is

not known since Tir is also an important virulence factor of EPEC. Immune responses to other products of the LEE locus, such as intimin and the secreted protein EspB, have also been demonstrated in patients infected with O157 EHEC (33, 40). Although titers of antibodies against these virulence factors may be lower than those against LPS, evidence indicates that they are expressed during acute disease and the host can still recognize them.

ETEC

ETEC strains producing heat-labile toxin (LT) and/or heat-stable toxin (STa and STb) are common agents of dehydrating diarrhea among young children in developing countries and are a major cause of traveler's diarrhea (40). Approximately 50% of clinical ETEC strains produce LT with or without ST. ST, of which STa is most commonly seen in human infections, is not immunogenic. LT is antigenically and functionally similar to cholera toxin (CT) of *V. cholerae* O1 and O139 and is highly immunogenic (40). The expression of these toxins is plasmid mediated, as is the expression of the fimbrial colonization factors (CFAs) that mediate attachment to intestinal mucosa. CFA/I represents a single antigenic type of fimbrial antigen, while CFA/I and CFA/IV constitute families of fimbrial antigens. All CFA/II strains contain the common coli surface antigen 3 (CS3), alone or with CS1 or CS2. CFA/IV-producing ETEC strains express CS6 either alone or in conjunction with CS4 or CS5. These virulence factors are usually associated with a limited number of serotypes of *E. coli*; however, due to the multiple serotypes involved, serotyping of isolates is of only limited value in the diagnosis of ETEC infections and should be limited to epidemiological studies.

Diagnosis of acute ETEC infections requires the detection of LT, ST, or toxin genes in isolated strains. Since ETEC strains may produce either or both toxins, immunologic identification of ETEC strains must detect them both. Simple immunologic assays, such as agglutination and ELISAs, to detect LT and ST have been described.

The STa detection assay described below utilizes STa-specific MAbs (54). STa produced by *E. coli* isolates competes with adsorbed STa for binding to the antibody. A similar ST competitive ELISA using synthetic peptide toxin bound to microtiter plates and toxin-specific MAb is commercially available from Denka Seiken.

The LT detection assay uses GM1 ganglioside, a receptor for LT, adsorbed to microtiter plates that captures free LT in the specimens (49). A latex test to detect LT is available from Denka Seiken; the manufacturer reports a limit of detection of approximately 1 to 2 ng/ml and 100% correlation to the classical Y1 bioassay.

Retrospective analysis can be made for some ETEC infections by measuring antibodies to LT and CFAs. However, the LT antibody assay is limited since about one-third of diarrhea-causing ETEC strains express only ST. In addition, there exists significant antigenic cross-reactivity between LT and CT that needs to be considered. ELISAs to measure antibodies to ETEC CFAs in serum and intestinal fluids have been developed and used to assess the immunogenicity of vaccine candidates (1). However, the many fimbrial antigens prevalent on ETEC strains that cause disease in humans and the lack of availability of reagents limit their usefulness in seroepidemiological studies.

Detection of ETEC LT by GM1 ELISA

The GM1 assay enables the detection of LT produced by *E. coli* clinical isolates. It is useful for diagnosis of clinical cases.

Reagents

E. coli is grown in Casamino Acid-yeast extract medium containing, per liter, 20 g of Casamino Acids (Difco Laboratories, Detroit, Mich.), 6 g of yeast extract (Difco), 2.5 g of NaCl, 8.71 g of K_2HPO_4, 2.5 g of glucose, and 1 ml of trace salts (containing 5% $MgSO_4 \cdot 7H_2O$, 0.5% $MnCl_2 \cdot 4H_2O$, and 0.5% $FeCl_2$), pH adjusted to 8.5. The essential requirements for optimal LT production are glucose and trace salts, which increase LT production by 40 to 90%. In addition, lincomycin (4.5% final concentration) is added to the culture to release LT from the periplasmic space, significantly increasing the amount of LT that can be detected in culture. The coating antigen is GM1 ganglioside (Sigma). Coating buffer is 0.1 M PBS, pH 7.2. Washing buffer is PBS–0.05% Tween 20. Blocking buffer is PBS–5% fetal calf serum (FCS). Hyperimmune rabbit anti-LT (or anti-CT) antibody produced against purified enterotoxin is used as detector antibody, along with alkaline phosphatase or HRP-labeled anti-rabbit IgG (KPL). Substrate is TMB (KPL).

Procedure

Microtiter plates are coated overnight at room temperature with 100 μl of GM1 solution (1 μg/ml) or PBS (control) in different rows and blocked for 1 h at 37°C. Culture medium is added to all wells (200 μl) and test strains are inoculated in duplicate into the GM1-coated and control wells. Plates are incubated for 24 h on a rotary shaking platform at 37°C. *E. coli* LT is used as a positive control in a range of concentrations, and PBS is used as a negative control. After incubation, plates are washed six times with PBST and incubated with anti-LT (or anti-CT) antiserum diluted in PBST containing 1% FCS (100 μl/well). Plates are then washed, incubated with a conjugate secondary antibody (100 μl/well) for 1 h at 37°C, washed again, and incubated with substrate. The reaction is stopped and absorbance values are measured.

Results and Interpretation

The mean absorbance value of the control wells is subtracted from absorbance values of test wells. Each laboratory should establish a cutoff value based on absorbance values from non-LT-producing strains. This assay has been shown to be 97% sensitive and 100% specific compared to the Y1 adrenal cell assay (49). The limit of detection is approximately 1 to 7 ng of purified LT per ml (49).

Remarks

This assay can be read visually, maintaining high levels of accuracy. LT can also be detected using sandwich ELISAs, with LT-specific antibodies attached to microtiter plates.

Detection of STa by Competitive Binding ELISA

Detection of STa from culture supernatants of *E. coli* isolates is valuable for clinical diagnosis, epidemiological studies, and assessing ETEC vaccine candidates.

Reagents

Purified STa is conjugated to bovine serum albumin (BSA) (Sigma) using 1-ethyl-3-(3 dimethylaminopropyl)-carbodiimide (Bio-Rad Laboratories, Richmond, Calif.) at a coupling ratio of 5:1, STa to BSA. The STa to specific MAb (no. 20C1B8; Genetic Diagnostics, Great Neck, N.Y.) is diluted in 0.1% BSA–PBS. HRP-labeled goat anti-mouse IgG (Roche, Indianapolis, Ind.) is used as a secondary antibody at optimal dilution (around 1:1,000). Coating buffer is sodium bicarbonate buffer, pH 9.6. Washing buffer is PBST. Blocking buffer is PBS with 1% BSA. Substrate is TMB (KPL).

Procedure

The optimal coating concentration for STa-BSA antigen and the optimal dilution for MAb and anti-mouse conjugate must be determined using standard checkerboard titrations (13). The recommended STa-BSA coating concentration is 1 μg/ml; MAb concentrations range from 5 to 100 ng/ml. Plates are coated with STa-BSA for 18 h at 4°C, washed, and blocked for 2 h at 37°C. Strains are grown in a Casamino Acid-yeast extract medium as described above. MAb (100 μl) mixed with STa alone (0.5 to 10 ng/ml) or with different dilutions of unknown samples (100 μl) are allowed to equilibrate at room temperature for 5 to 10 min before being added to the plate. Plates are incubated for 1 h at 37°C, washed, and incubated again with 100 μl of secondary antibody at the appropriate dilution. Plates are washed again and substrate is added. Specific absorbance values are determined by subtracting from the absorbance values of the test wells the mean absorbance of control wells. Controls must include (i) coated wells that will have added diluent in lieu of samples (and all other reagents), (ii) samples and only secondary detector antibody (no STa-MAb), and (iii) uncoated wells with all the rest of the reagents.

Results and Interpretation

Absorbance values measured for different concentrations of STa are analyzed by linear regression. Strains are considered positive when a culture supernatant tested yields a ≥65% reduction in absorbance (from that measured in the absence of competing toxin). A quantitative measurement of STa present in a sample is obtained by interpolation of its absorbance value in the standard curve.

Remarks

Changes in temperature and incubation time may affect the kinetics of the reaction, influencing the sensitivity of the assay. The sensitivity of this assay is 3 to 10 pg of toxin (54). There is no cross-reactivity with LT, CT, or staphylococcal enterotoxin B. Similar competitive inhibition ELISAs that use STa chemically linked to other protein carriers, such as the B subunit of LT or CT, have been described to enhance ST binding to the solid phase via GM1.

Molecular Methods To Detect ETEC Strains

Molecular diagnostic techniques became available early on to detect ETEC strains (40). Comparison of LT detection immunoassays with early membrane-based DNA hybridization assays with LT probes has shown more than 95% concordance of results. In these studies, however, as many as 10% of isolates that were positive by hybridization techniques did not produce phenotypically detectable LT. Similar to the DNA probes for LT, oligonucleotide hybridization assays to detect STa plasmid genes show a high rate of concordance with ELISA techniques. In studies comparing competitive ELISA with hybridization for the STa gene, the ELISA detected STa production in 94% of probe-positive strains (54). Hybridization assays to identify ETEC strains with probes that detect ST, LT, and CFA/I, CS1 to CS8, CS12 to CS15, CS17 to CS19, and CS22 have been described (52). Further refinement in molecular methods for the detection of ETEC gave rise to PCR and multiplex PCR that can detect ETEC in stool specimens with enhanced sensitivity over bacteriological culture (40). A real-time PCR assay using primers and hybridization probes for simultaneous detection of LT and ST (STa and STb) genes has been described; this technique is 10^2 to 10^3 times more sensitive

than block-cycle PCR assays, allowing the detection of 10^5 to 10^6 CFU of ETEC per g without enrichment (48).

Measurement of IgG Anti-LT by ELISA

Because of the antigenic cross-reactivity between LT of ETEC and CT of *V. cholerae,* simple measurement of antibody responses against LT alone is not sufficient for the accurate diagnosis of ETEC infection in the absence of bacterial isolation from stool. However, differences in the magnitude of the antibody responses against CT and LT antigens can be used to differentiate between infections caused by CT^+ *V. cholerae* strains and LT^+ ETEC strains (31). This approach can also be used for seroepidemiological studies or to assess immune responses to new vaccine candidates.

Reagents

Purified *E. coli* LT is used as a coating antigen. Detector antibody is HRP-labeled goat anti-human IgG (ICN Biomedicals) diluted in PBSTM. The working dilution is selected during calibration of the assay. Coating buffer is PBS, pH 7.4. The rest of the reagents are the same as described for O157 LPS ELISA.

Procedure

The optimal antigen coating concentration is determined by checkerboard titration using different amounts of LT in the presence of positive and negative calibrated control sera (13). A number of assays report that the optimal LT coating concentration was 1 μg/ml (from a 0.1- to 10-μg/ml range tested) (31). The recommended starting dilution for samples of unknown titer is 1:25. The ELISA procedure is similar to that described above.

Results and Interpretation

For the diagnosis of ETEC infections caused by LT^+ strains, the most reliable way to prove causality is to test both pre- and postinfection serum samples. A fourfold rise in titer of paired sera is considered a positive response. If only a single serum sample is available, high levels of LT IgG antibody can only give evidence of recent exposure to LT. Even though there are antigenic similarities between CT and LT, one can discriminate between infections caused by LT^+ ETEC and CT^+ *V. cholerae* by the magnitude of antibody response between LT and CT. While LT antitoxin levels fall after 3 months of infection, high CT titers persist during the convalescent period (31). Nevertheless, it is possible to establish a cutoff level of LT for diagnosis of recent (within the previous 3 months) ETEC infection (31). Data derived from wild-type challenge studies with nonimmune North American subjects have shown the presence of a significant level of antitoxin as early as day 10 postchallenge, peaking at day 21 postchallenge (31). Using appropriately timed paired specimens, this assay can detect approximately 80% of both clinical and subclinical LT^+ ETEC infections. When only single specimens are available, this assay can accurately detect a recent LT^+ ETEC infection (within the last 6 months) with a sensitivity above 80% and a specificity of 100%, using the CT/LT ratio described above.

Remarks

The need to discriminate between CT- and LT-specific antibody responses makes the immunologic detection of LT^+ ETEC infections difficult for a nonresearch laboratory. These assays are most reliable for diagnosis of an individual case when paired sera are available. Consequently, this assay is mainly used for seroepidemiological studies or to assess immunogenicity of vaccine candidates.

EPEC

EPEC strains are clonal pathogens that harbor both chromosomal and plasmid-mediated virulence determinants (23, 40). Typical EPEC strains carry both a chromosomally encoded LEE, which mediates a complex signal transduction phenotype on the target epithelial cell, and the EPEC adherence factor plasmid (EAF), which encodes the principal EPEC adhesin. The attaching and effacing histopathology (visualized by electron microscopy) that is conferred by the LEE is accompanied by cytoskeletal rearrangement, perturbation of signal transduction cascades, activation of inflammatory and secretory responses, and opening of the epithelial tight junction fence. The essential components of the LEE include a type III secretion apparatus and a series of protein effectors that are thereby injected into the target cell. Among these are Tir, which activates target cell signal transduction and serves as the epithelial receptor for intimin, a ca. 94-kDa bacterial outer membrane protein. Interaction of intimin with Tir mediates adherence and colonization as well as the attaching and effacing phenotype.

Identification of several LEE genes or their products has been used in EPEC diagnosis, particularly the gene encoding intimin (*eae*) (40). It should be recognized, however, that an *eae* homologue is also present in EHEC. Several diarrheal outbreaks have been linked to atypical EPEC carrying the LEE but no other recognizable virulence genes. Thus, the presence of *eae* or other LEE-borne genes or products cannot be considered definite evidence of an organism being an enteric pathogen. Identification of a typical EPEC strain requires identification of both the LEE and the EAF plasmid.

Two diagnostic genetic targets for the EAF have been well substantiated: the original EPEC probe, derived empirically from the plasmid of strain E2348/69, and the gene corresponding to the major pilin subunit of the bundle-forming pilus (*bfpA*). They yield similar sensitivity and specificity in the detection of EPEC strains (40). Both gene probes and PCR have been described for *eae* and EAF plasmid-borne genes, and the performance of these assays is essentially equivalent. Multiplex PCR assays have been described recently which permit simultaneous detection of *eae* and EAF genes, often in combination with other gene targets, such as *bfpA;* this method offers great potential for detection of EPEC in conjunction with other diarrheagenic *E. coli* strains (41).

The HEp-2 adherence assay can be used to identify EPEC, recognized by their specific localized, microcolony adherence pattern (40). However, the test must be performed using rigorous standards and is best interpreted by a trained observer. In addition, cultivation of cells for use in diagnosis is cumbersome and likely to delay timely diagnosis.

EAEC and EIEC

EAEC is an emerging diarrheal pathogen that is important in three epidemiological scenarios: infant diarrhea in both developing and industrialized countries, diarrhea of travelers from industrialized to developing countries, and persistent diarrhea in human immunodeficiency virus-infected patients (23, 40). Though EAEC strains are classically defined by the presence of a characteristic stacked-brick pattern of adherence to HEp-2 cells, this phenotype is nonspecific and can be considered only suggestive of the presence of a true enteric pathogen. Recently, the designation "typical EAEC" has been offered to describe organisms harboring a series of virulence-related genes under the control of the gene activator AggR. Thus, identification of one or more AggR-controlled loci is highly suggestive of pathogenic EAEC strains. Diagnostic tests

for the AggR regulon include detection of the *aggR* plasmid-borne gene itself; both genetic probes and PCR have been shown to offer excellent sensitivity and specificity for *aggR* detection (40). Results generated by *aggR* detection are similar to those produced by the first EAEC probe (variously called the AA or CVD 432 probe), now shown to detect the *aatA* gene under the control of AggR. Several multiplex PCR assays have been described to detect typical EAEC along with other diarrheagenic pathotypes (41). EIEC strains are similar to *Shigella* spp. at the genetic and pathogenetic level. EIEC strains are best detected using DNA probes or PCR for the target genes of *Shigella*, including the *ipaH* locus and the *ial* locus (14).

Shigella

Shigella flexneri and *Shigella dysenteriae* are responsible for about 15% of all deaths attributable to diarrhea in children younger than 5 years of age in developing countries; *Shigella sonnei* is also encountered in industrialized nations, particularly in specialized settings such as day care centers (28). *Shigella* infections occur primarily in children 6 months to approximately 5 years of age; illness peaks in toddlers and preschool children 12 to 47 months of age. However, adults from industrialized countries who travel to areas of high endemicity are also susceptible to diarrheal infection with these agents. Thus, *Shigella* is often the second most important cause of traveler's diarrhea in surveys. Since *Shigella* invades the mucosa of the distal small intestine and colon, the full-blown clinical disease can progress to overt bacillary dysentery, marked by gross blood and mucus in diarrheal stools, systemic toxicity, high fever, abdominal pain, and tenesmus. The diarrhea is watery for about 24 h but then decreases in volume. Acute diagnosis of shigellosis is primarily made by bacteriological isolation. However, because *Shigella* may be difficult to isolate or facilities for culturing may not be available, serological assays may be helpful in retrospective diagnosis. Serum antibody responses are primarily directed against two surface antigens: LPS and invasion plasmid antigens (IpaB, IpaC, and IpaD). Cohen et al. reported a significant correlation between levels of *Shigella* LPS IgG and resistance to shigellosis (11). This group also proposed the use of a single high serum *Shigella* LPS IgA determination as a potentially reliable indicator of recent symptomatic and asymptomatic *Shigella* infection. IgM shows a pattern similar to that of IgA, except that it has a much lower convalescence increase. Following exposure to these strains, serum antibody responses directed against Ipas are not as frequently detected as LPS responses. IpaB and IpaC are the most immunogenic antigens (25), and Ipa-specific secretory IgA antibodies can be detected following dysentery. In cases of *S. dysenteriae* type 1 infection, measurement of antibodies to Stx by ELISA has been found to be unhelpful diagnostically because few infected individuals generate responses (29).

Herein we describe a general format for an indirect ELISA which can be used to measure both LPS IgG and IgA for all *Shigella* groups. Antibody responses can be helpful in diagnosing *Shigella* infection retrospectively, although IgA antibodies are more transient, peaking at 2 weeks after infection and declining to baseline by approximately 2 months.

Molecular Methods To Detect *Shigella* Strains

DNA probes detecting portions of the three *ipa* genes (*ipaB*, *ipaC*, and *ipaD*) were described early as indicators of invasive dysentery bacilli. However, the spontaneous loss of invasion plasmids seen in *Shigella* may produce false-negative results. The same group later developed a probe for the *ipaH* gene, a multiple-copy element found in the large invasion plasmid and the chromosome (55).

PCR techniques have been used to detect *Shigella* in stool samples amplifying target sequences of *ial*, *ipaH* (14), and *rfc* (20). In a study carried out in India, the *ipaH* PCR assay was approximately 100-fold more sensitive than the colony hybridization assay and the conventional culture and could identify a number of nontypeable *Shigella* strains (Sh OUT), which otherwise would have remained undiagnosed (14). Although highly sensitive to detect organisms directly from stool samples, PCR amplifying *ial* and *ipaH* sequences cannot distinguish EIEC from *Shigella* or one *Shigella* species from another. Serotype-specific primers derived from the *rfc* genes allowed for the first time differentiation among *Shigella* serotypes (e.g., *S. sonnei*, *S. flexneri*, and *S. dysenteriae* type 1) (20). Furthermore, a multiplex PCR containing the same *rfc*-specific primers can efficiently identify the most prominent *Shigella* serotypes in raw stool samples from acute diarrheal patients (20).

Measurement of *Shigella* LPS IgG by ELISA

ELISA to measure *Shigella* LPS IgG is most useful for retrospective diagnosis of infection in immunologically naive individuals, especially for *S. sonnei* and *S. dysenteriae*. However, because multiple serotypes exist for *S. flexneri* and *Shigella boydii*, serological diagnosis is useful only if a particular serotype is suspected. The assay is also useful to assess *Shigella* vaccines in clinical trials, since LPS IgG antibodies correlate with protection from homologous wild-type challenge.

Sample Requirements

Although optimum collection times are preinfection (as in the case of serum samples obtained prior to travel) and 21 to 28 days postinfection, access to preinfection serum is unusual in clinical practice. Sera from the acute phase (i.e., at the time of presentation) and convalescent phase (4 weeks after) are more likely to be available but may be less useful to detect a seroconversion, especially for people living in areas where *Shigella* is endemic. For example, approximately 65% of culture-confirmed *S. dysenteriae* type 1 infections could be detected in Thai individuals by evaluating acute- and convalescent-phase serum samples; however, 25% of the subjects had such high titers in their acute-phase sera (obtained 7 to 14 days after disease onset) that seroconversion could not be demonstrated from comparison of the acute- and convalescent-phase sera (29). A single serum sample can be useful for previously nonexposed subjects such as travelers, if that sample is obtained within 3 weeks to 3 months of the onset of diarrhea.

Reagents and Procedure

Shigella LPS is purified using hot water-phenol extraction. The appropriate coating concentration should be determined by checkerboard titration (13). Coating concentrations range between 2 and 10 μg/ml. Reagents and procedures are the same as described for O157 LPS ELISA.

Results and Interpretation

A cutoff for positive response can be established by testing a large number of known negative serum samples. To maximize the specificity of the assay, accounting for cross-reactive antibodies, convalescent-phase sera from individuals with known culture-proven *Shigella* infections should be tested using LPS preparations from heterologous *Shigella* serotypes (*S. sonnei* and *S. flexneri* 2a in the case of *S. dysenteriae* infection, for example) and cutoff values should be adjusted accordingly.

Measurement of anti-LPS antibodies by ELISA using paired acute- and convalescent-phase sera has a sensitivity of 60 to 85% and a specificity between 85 and 100% based on culture-proven cases (29). When a single specimen is available (obtained within 3 weeks to 3 months of onset of diarrhea), the sensitivity and specificity of this assay to determine infection are slightly lower, 60 to 70% and 80 to 90%, respectively. Measurement of serum antibodies to LPS and Ipa antigens is useful to assess immune responses to vaccine candidates (25).

S. enterica Serovar Typhi

Typhoid fever is a systemic infection that results from the ingestion of *S. enterica* serovar Typhi and uptake into the gut-associated lymphoid tissues. In successive steps, the bacilli reach draining lymph nodes, enter the lymph and then the blood circulation, and ultimately attain their intracellular niche in fixed macrophages of the reticuloendothelial system. After an incubation period of 8 to 14 days a secondary bacteremia occurs, accompanied by a stepwise increase in fever, headache, and abdominal pain. The case fatality rate in untreated typhoid fever is 10 to 20%. From 1 to 6% of acutely infected individuals, depending on age and sex, can develop chronic infections of the gallbladder that may persist throughout life. These chronic biliary carriers intermittently excrete organisms in their stool and serve as an epidemiological reservoir of infection. Typhoid fever is endemic in many developing areas of the world and is a risk for travelers to such areas.

Isolating the organism from blood, bone marrow, or duodenal aspirate in cases of acute infection or from bile or stool from chronic carriers provides a definitive diagnosis. However, bacteriological culture has limitations. The yield from blood cultures is 70 to 80% during the first week of fever and steadily decreases thereafter. Bacteriological isolation of *Salmonella* can take several days (it is much more rapid if automated blood culture systems are used), and the sensitivity of cultures can be influenced by previous antibiotic treatment, inadequate sampling, and the low level of bacteremia (1 to 10 organisms per ml of blood). Sensitivity can be increased by culturing bone marrow samples; however, bone marrow collection is an invasive procedure that is not suitable for routine use. Culturing of stools is not practical for large-scale screening to identify chronic carriers.

There is a long history of serodiagnosis of acute typhoid fever, going back to the agglutination tests of the late 19th century. Modern serodiagnosis is based on measurement of specific anti-serovar Typhi LPS and flagellar H antibodies. Commercial kits for the diagnosis of typhoid fever include the Multi-Test Dip-S-Tick (PANBIO INDX, Inc., Baltimore, Md.), TyphiDot (Malaysian Biodiagnostic Research SDN BHD, Singapore, Malaysia), and TUBEX (IDL Biotech, Sollentuna, Sweden). The Multi-Test Dip-S-Tick tests for five pathogens, including serovar Typhi. It consists of a dipstick that detects IgM or IgG against serovar Typhi LPS, H, and capsular polysaccharide Vi antigens. The TyphiDot is a dot enzyme immunoassay that qualitatively detects either IgM or IgG antibodies against a serovar Typhi outer membrane protein. TUBEX is a semiquantitative inhibition latex agglutination test to detect IgM antibodies to the O9 antigen. Olsen et al. evaluated the performance of these three commercial kits in comparison with the Widal test for Vietnamese patients, considering blood culture as the gold standard. They found that overall, TUBEX and TyphiDot exhibited the most promising results, with ~79% sensitivity and 89% specificity (42). ELISAs that measure H and LPS antibodies are commonly used (39, 47) and are described below. Detection of antibodies to the Vi capsular polysaccharide is helpful as a screening test for identification of chronic carriers, since only about 20% of subjects with acute typhoid fever exhibit increased levels of IgG anti-Vi antibodies, whereas over 90% of chronic carriers exhibit high titers of Vi antibodies (34).

Detection of H and O Antibodies by Agglutination (Widal Tests)

The Widal tests, which measure agglutinating antibodies to serovar Typhi H and LPS antigens, are the classic assays for serodiagnosis of acute typhoid fever (27, 47). Although the validity of these tests for the serological diagnosis of typhoid fever in areas where typhoid is endemic has been questioned, they are widely used throughout the world; therefore, it is important to discuss their usefulness and limitations. Only the tube dilution method for H antigen agglutination is described here, since the assay using LPS antigen is very similar (27).

Reagents

For the LPS agglutination assay, a suspension of serovar Typhi adjusted to a standardized concentration is used. The infecting strain is used during outbreaks; otherwise, clinical laboratories use a nonflagellated serovar Typhi O-901 strain containing LPS W (Difco). For the H-agglutination assay, exposed H antigen from formalinized whole-cell *Salmonella enterica* serovar Virginia (10^{10}/ml) is used (27). Serovar Virginia has the identical flagellar antigen as serovar Typhi but has distinct O antigens and does not express Vi. Serum samples and H antigen are diluted in 0.85% NaCl.

Procedure

Serum samples in serial twofold dilutions (starting at 1:20) are incubated with an equal volume of H (diluted 1:10) overnight in a 45°C water bath. Each tube is examined for agglutination against a black background in a well-lighted area. A positive test will exhibit flocculent agglutination, similar in appearance to cotton balls. The amount of agglutination is graded according to clarity of the supernatant and amount and size of flocculence: 4+ agglutination has a clear supernatant and large flocculent clumps, 3+ agglutination is similar to 4+ except that clumps are smaller, 2+ agglutination has a cloudy supernatant with small clumps of cells, 1+ agglutination has a cloudy supernatant with very fine clumps of agglutinated cells, and 0 grading reveals a cloudy supernatant with cells appearing as a smooth button in the bottom of the test tube. The O antigen, being somatic, produces a coarse, compact, and granular agglutination, whereas H antigen, being flagellar, brings about a larger, loose agglutination. Turbid or contaminated sera should not be used for testing. The endpoint titer is the last serum dilution that exhibits a 3+ or 4+ agglutination of cells. Positive and negative calibrated control sera are included in each run. The sera for positive controls used in the assays were obtained from patients with bacteriologically confirmed acute typhoid fever obtained at the time of hospital presentation (27). Negative controls were obtained from age-matched healthy patients from an area of nonendemicity.

Results and Interpretation

The reading of agglutination can be difficult, and the reliability of the results is correlated with the experience of the reader. When acute- and convalescent-phase serum samples are available, a fourfold rise in titer is considered a positive response and believed to be a reliable indicator of infection when the clinical picture is compatible with typhoid fever. This is true for both travelers and people living in areas where infection is endemic. However, the development of

agglutination antibodies in people with bacteriologically proven infection is variable, ranging from 25 to 100%, depending on the degree of illness and the time the second serum sample was collected. As expected, those patients with more severe illness and from whom serum samples were taken within 2 months of onset are more likely to have a serological response (75 to 100%). Since peak titers occur approximately 2 to 3 weeks after onset of illness, samples obtained much earlier may yield negative results. Agglutination results are more variable for LPS than for H antibodies since other *Salmonella* organisms (such as *Salmonella enterica* serover Enteriditis) that cause disease in humans share antigenic LPS determinants with serovar Typhi. Titers considered positive vary depending on geographic area and the laboratory performing the assay but usually are in the range of ≥1:40 to ≥1:400 (27). Using a cutoff of 1:160 as indicative of infection, for example, yields a sensitivity of 46%, with a specificity of 98%; 1:80 gives a sensitivity of 66% but a specificity of 94%; and 1:40 gives a sensitivity of 90% and a specificity of 85% (27).

Although the Widal test requires acute- and convalescent-phase serum samples, usually only one serum sample taken at the time of clinical presentation is available for evaluation. In such cases, however, a single Widal test has no diagnostic value, since even high titers may be due to other *Salmonella* species, rather than serovar Typhi; a high prevalence of antibodies has also been found among healthy individuals in areas of endemicity (27). Results may also be difficult to interpret for people receiving antibiotic treatment.

Remarks

Standardization of this assay is extremely important. It can be performed in large laboratories with experienced personnel used to run samples from areas of endemicity, but it is not recommended to diagnose the infrequent case of acute typhoid fever. Recipients of both oral and parenteral typhoid vaccines can also have a positive Widal result.

Measurement of LPS and H Antibodies by ELISA

Measurement of LPS antibody and H antibody levels by ELISA may have diagnostic potential for acute typhoid fever for patients from areas where the disease is endemic (21, 39, 47).

Reagents

Serovar Typhi LPS is commercially available (Sigma). Flagellar H antigen can be purified by a bulk shearing method from the rough serovar Typhi strain Ty2R or from serovar Virginia. The appropriate coating concentration should be determined by checkerboard titration (13). Usually, coating concentrations range between 2 and 10 µg/ml (39, 53). The rest of the reagents are the same as for above-described ELISAs to measure LPS antibodies.

Procedure

Tacket et al. describe a standard indirect ELISA procedure to measure serum antibodies to serovar Typhi LPS (53); a number of similar techniques have been reported elsewhere (21). The procedure is identical to that used for detection of antibodies to O157 LPS, except that plates are coated with serovar Typhi LPS or H. Serum samples of unknown titer may be added at a 1:25 starting dilution, and further serial twofold dilutions are made in the plate. A higher starting dilution (e.g., 1:1,000 to 1:10,000) is recommended for screening of samples collected in areas of endemicity or from potentially infected individuals.

Results and Interpretation

Nardiello et al. showed that the IgM ELISA test is as specific as the Widal test (using a cutoff of 1:160) in identifying acutely infected individuals; a strong correlation was demonstrated between LPS titers obtained by both methods, yet the ELISA was significantly more sensitive (39). Others have confirmed the higher sensitivity of the LPS IgM ELISA than the Widal test when used with a single acute-phase serum sample and have proposed its use for diagnosis of typhoid fever in patients with suspected infection but whose blood cultures are negative (21). As with the Widal method, this assay is helpful only within the first month of clinical presentation.

Remarks

Detection of LPS IgM (21) or combined LPS IgM and IgG antibodies (47) has been proposed as one of the most sensitive methods to diagnose acute typhoid fever. In areas where typhoid is endemic, however, preexisting high levels of IgG against LPS and H antigens, particularly in adults, preclude an accurate interpretation of the results (27). In such cases, detection of IgM antibodies may be more suitable because they not only arise early in the course of infection but also fall off rapidly, whereas IgG antibodies can persist in the absence of ongoing infection. Measurement of LPS-specific IgG and IgA antibody levels has been helpful to assess immune responses following vaccination (53).

As a noninvasive diagnostic alternative, an ELISA was developed to measure serovar Typhi-specific IgA antibodies in a single salivary sample. This test had a sensitivity of 83% and a specificity of 97% compared with culture-confirmed cases, with maximum efficiency during the first 2 to 3 weeks of fever, enabling detection of acute infection (18).

In Chilean field trials with Ty21a vaccine, vaccine formulations and immunization schedules that produced the highest levels of protection also elicited the strongest rises in LPS antibody (26). Thus, LPS seroconversion was an immunologic correlate of protection. Nevertheless, there is no evidence that LPS antibodies actually mediate protection; they may merely serve as a proxy for other immune responses that do mediate protection.

Measurement of Vi Antibodies by ELISA in Chronic Carriers

Since humans are the only reservoir of serovar Typhi, identification of chronic carriers may be useful to control typhoid fever outbreaks. Most individuals with chronic infection develop high levels of antibodies to the Vi capsule. Chronic carriers of serovar Typhi can be identified by measuring the levels of IgG antibodies against Vi by ELISA (34).

Reagents and Procedure

Purified Vi is used as a coating antigen. The optimal antigen concentration is determined by checkerboard titration (13). The usual range of coating concentrations is 1 to 2 µg/ml (34, 53). The rest of the reagents and procedure are the same as described for ELISAs above.

Results and Interpretation

A similar ELISA that detects Vi antibodies was 86% sensitive and 95% specific in identifying carriers using serum samples from known chronic carriers, noninfected individuals, and people with acute typhoid fever (34).

Remarks

The licensed live attenuated typhoid vaccine Ty21a neither expresses Vi antigen nor elicits Vi antibodies; therefore,

it does not produce false-positive results for vaccinated individuals. The parenteral Vi vaccine, however, has over a 90% rate of Vi seroconversion in vaccinated individuals, and therefore assessment of the chronic state by means of Vi antibody testing in such individuals would not be reliable.

Molecular Methods To Detect Serovar Typhi

Early molecular methods included Vi-specific DNA probe to detect serovar Typhi among freshly isolated bacteria and in clinical specimens followed by enrichment. Highly specific and sensitive PCR and nested techniques have been successfully used to detect serovar Typhi by amplification of the dH flagellin gene in blood samples from patients with acute typhoid fever (38) or by amplification of Vi antigen gene fragments (17). A PCR was developed for diagnosis of typhoid fever by amplification of *hilA*, a regulatory gene found in pathogenicity island 1 of *Salmonella* spp. (51), which is important for the regulation of the type III secretion apparatus, involved in the invasion of enterocytes. The sensitivity, specificity, positive predictive value, and negative predictive value of the *hilA* PCR with blood samples were all 100%, and these values were 97 to 100% for PCR with fecal samples. Hirose and colleagues developed a multiplex PCR with primers for O, H, Vi antigen genes, *tyv* (*rfbE*), *prt* (*rfbS*), *fliC-d*, *fliC-a*, and *viaB* for rapid identification of *S. enterica* serovars Typhi and Paratyphi A; all clinical isolates examined were accurately identified by this assay (19).

VIBRIONACEAE

V. cholerae O1

V. cholerae O1 strains producing CT cause cholera gravis, a disease clinically characterized by voluminous watery diarrhea leading to severe dehydration and death if left untreated. Clinical O1 isolates from cholera patients express CT, the principal virulence factor responsible for intestinal water and electrolyte loss due to the enzymatic activity of the toxin A subunit. The seventh pandemic of cholera, caused by the El Tor biotype, has been spreading across the world since the 1960s; it started in Asia, spread throughout that continent and then Africa, and finally moved to South and Central America in the 1990s. Among individuals infected with *V. cholerae* O1 El Tor, only a small number proceed to develop cholera gravis. Thus, El Tor strains often cause milder diarrhea and asymptomatic infection. Milder illness caused by these strains cannot easily be differentiated from other causes of gastroenteritis in areas where cholera is endemic.

In persons with a clinical presentation suggestive of cholera, rehydration treatment should never be withheld in order to make a diagnosis. Laboratory diagnosis is important primarily for epidemiological and public health control purposes. A definitive clinical diagnosis has traditionally relied on the bacteriological isolation of *V. cholerae* from stool, with isolates screened for agglutination with O1 antiserum.

The O1 serogroup is divided into three serotypes, Inaba, Ogawa, and Hikojima (rare), which are differentiated from each other based on the presence of three antigenic factors, so-called A, B, and C. All three serotypes contain the A factor, Inaba strains contain the A and C antigens, and Ogawa strains contain A, B, and a small amount of C. Poly- and monovalent O1 (Inaba and Ogawa) antisera for serotyping of bacteriological isolates are readily available for clinical laboratories (Oxoid/Denka Seiken Co. Japan). Antibody-based detection systems for O1 antigen offer a rapid diagnostic approach using whole-stool samples without the need for culture. Assays to detect CT from whole-stool and culture isolates have clinical applicability and are also discussed.

Natural cholera infection gives rise to a high level of enduring antibacterial and antitoxin immune responses that protect against illness (30). Antibody detection assays have been very useful in retrospective diagnosis of cholera infections, epidemiological studies, and assessment of vaccine-induced immunity (30). Popular current assays include serum vibriocidal antibody testing and ELISA to measure anti-CT IgG.

Rapid Immunologic Assays for Direct Detection of *V. cholerae* O1

Different rapid agglutination tests were developed to detect *V. cholerae* O1 antigens, including agglutination of latex beads (7) and coagglutination using heat-killed *Staphylococcus aureus* (e.g., Cholera-Screen) (12). In these assays the agglutinating support (latex beads or heat-killed *S. aureus*) is coated with specific antibodies against *V. cholerae* O1 antigen; agglutination occurs when capture antibodies bind cholera antigens. These tests are simple and inexpensive and provide results faster than conventional methods. They have higher sensitivity (100%) than bacterial culture and specificity (100%) with regard to asymptomatic controls (7). A *V. cholerae* O1 latex test is available from Denka Seiken. The latex particles are coated with a MAb to cell wall antigen of O1 serogroups. Additional reagents are included in this kit for subtyping. The manufacturer indicates that this test has a sensitivity of 100% for culture confirmation and 65% for point-of-care screening of stool samples. A commercial colloidal gold-based sandwich immunoassay is commercially available to identify O1 strains (Cholera-SMART Cholera O1 from New Horizons Diagnostics Corp., Columbia, Md.). This assay uses a colloidal gold-labeled MAb specific for the A antigen of O1 LPS; after binding the antigen, the complex diffuses and is captured and concentrated by a detector polyclonal antibody that concentrates the gold, forming a pink to red spot. The level of detection of the Cholera-Screen and Cholera-SMART assays using pure cultures of *V. cholerae* O1 is approximately 10^5 to 10^6 CFU/ml (12). These assays have been found to be highly sensitive (>90%) and 100% specific to detect O1 strains in stool samples from infected individuals. In areas where cholera is endemic, stool specimens have yielded positive O1 results for 20 to 25% of *V. cholerae* O1 culture-negative specimens. This finding suggests that O1 antigen is present in stools of infected individuals either as nonviable organisms or as free antigen. In many instances, positive antigen results in the absence of cultured microorganisms were confirmed by serological evidence of infection (vibriocidal antibodies) (7, 12).

CT Antigen Detection Systems

Since CT and LT are antigenically similar, antigen detection systems for CT using whole stools without culture isolation of the organism, such as the ELISA, also detect some LT-producing ETEC strains and thus are less useful clinically. In addition, in the absence of isolated organisms, CT detection will not differentiate between cholera caused by O1 or O139 strains. However, if *V. cholerae* O1 strains are isolated from the stool, CT production can be confirmed using a latex agglutination assay, a GM1-based antigen capture immunoassay similar to the one described for LT detection, or specific gene probes for the *ctx* genes encoding CT. A latex agglutination kit is commercially available (VET-RPLA; Denka Seiken); this test has a sensitivity of 97% and a specificity of 100% compared with a sandwich ELISA. CT agglutination kit results with clinical *V. cholerae* isolates from areas where

cholera is not endemic should be confirmed by a reference laboratory due to the possibility of false negatives. Immunoassays with increased sensitivity for CT detection using GM1 or antibody capture systems coupled with novel detection systems such as to biosensors have been described.

Serum Vibriocidal Antibodies

The functional capacity of serum antibodies to kill bacteria in the presence of complement can be measured by assay. The assay is most useful for diagnosis of recent cholera infections in outbreak situations in areas where cholera is not endemic or in previously unexposed individuals living in areas where cholera is endemic. It is useful for the diagnosis of cases of symptomatic cholera caused by V. cholerae O1, regardless of age, in areas of endemicity. However, it is less useful for assessing recent V. cholerae O1 exposures and asymptomatic infections in adults from areas where cholera is endemic because continued exposure results in the acquisition of antibodies with age, and secondary vibriocidal responses upon reinfection may not be elicited.

Procedure

Two days before the test, V. cholerae Inaba strain 89 and Ogawa strain 79 are plated on blood agar and incubated overnight at 37°C. Their identities should be confirmed by agglutination with specific antiserum, using PBS as a negative control. Organisms are then transferred onto a brain heart infusion (BHI) agar plate and incubated overnight at 37°C. On the day of assay, a BHI agar plate should be inoculated for confluent growth and incubated for 4 h at 37°C. Organisms should be harvested with 1.5 ml of PBS and the bacterial suspension adjusted to a concentration of 1.5×10^9 CFU/ml using a calibrated curve of absorbance versus CFU. The antigen preparation is diluted 1:20 in cold PBS containing 1:10 guinea pig complement (Sigma) and kept at 4°C to preserve complement activity. The 96-well plate should be turned so that rows A to H are on the top and columns 1 to 12 are on the side. Serum samples diluted 1:10 in sterile PBS are added in 50-µl volumes to the first row and in 25-µl volumes to the last row. PBS is then added to the remaining wells from rows 2 to 11. Note that sera should not be heat inactivated since doing so could alter the functional capacity of antibodies. Twofold dilutions are made from rows 1 to 11. Antigen is added to wells except to row 12, which is used as a serum control. Plates are shaken for 1 to 2 min and incubated for 1 h at 37°C. BHI broth (150 µl) is then added to the entire plate and incubated for 3 to 4 h at 37°C. The final readings are made after overnight refrigeration. There should be a clear distinction between the turbid fluid in the wells in which the vibrios had grown out and the crystal-clear yellowish fluid in those wells in which the organisms had been killed and lysed. Calibrated positive and negative controls are included in each assay.

Results and Interpretation

An endpoint titer of vibriocidal activity is determined as the highest dilution of serum that inhibits bacterial growth. The reproducibility of this assay depends on the activity of the complement and the bacterial suspension used. A decrease of 1 log in bacterial concentration can result in a two- to fourfold titer increase. The use of paired sera is most helpful, with a fourfold rise in titer of acute- to convalescent-phase samples indicative of exposure. However, since the peak response occurs 10 days after infection, reflecting the presence of IgM as the primary isotype responsible for vibriocidal activity in naive individuals, acute-phase serum samples need to be obtained at the time of clinical presentation to be most useful. For those living in areas where cholera is endemic and for cholera-naive individuals, a single serum sample obtained within 2 weeks of clinical presentation is most reliable. In these situations, a titer of ≥1,280 is indicative of recent O1 infection. For people with a single V. cholerae O1 exposure in areas where cholera is not endemic, vibriocidal titers return to baseline in approximately 6 months (30).

Remarks

The majority of the vibriocidal response is directed against the V. cholerae LPS, although it may also include activity against protein antigens of the bacterial surface (30). This causes cross-reactive responses seen as an increase of vibriocidal activity against both Ogawa and Inaba serotypes after exposure to a single serotype. The magnitude of the antibody response, typically higher for the infecting serotype, can be used to differentiate them. Secondary vibriocidal responses are more difficult to elicit on subsequent O1 exposures, especially if no overt clinical disease occurs and active mucosal immunity is present. Seroepidemiological studies in Bangladesh and Pakistan in the early 1960s showed that the best correlation of protective immunity against clinical cholera is the serum vibriocidal antibodies (30). These studies reported a rise in vibriocidal antibody with age, with an impressive inverse relationship between the geometric mean vibriocidal titer and the incidence of disease. It is believed that serum vibriocidal antibodies, rather than being the actual mediator of protection, are surrogate markers for mucosal immunity, such as intestinal secretory IgA, which might protect the gastrointestinal mucosa by preventing colonization by cholera organisms after ingestion (30). Measurement of vibriocidal responses following vaccination has been used to assess vaccine immunogenicity. Unfortunately, individuals from areas where cholera is endemic who already have serum vibriocidal activity may not mount a secondary vibriocidal response after immunization.

Measurement of Anti-CT IgG by ELISA

Measurement of anti-CT IgG by ELISA is most useful for seroepidemiological studies of cholera or to measure CT responses in individuals from areas where cholera is not endemic who are exposed to wild-type cholera (outbreaks) or vaccine strains.

Procedure

The procedure is the same as that described above for the detection of LT antibodies by ELISA, except that purified CT (List Biological Laboratories, Campbell, Calif.) is used as a coating antigen. Another method to measure CT antibodies is GM1 ganglioside ELISA (31). However, when purified reagents are used, results are the same whether the antigens are used to coat the plate directly or used to coat the GM1 receptor attached to the plate (31).

Results and Interpretation

Because individuals with cholera infection may have cross-reactive antibodies to LT, serodiagnosis of recent cholera infection requires the detection of both LT and CT antibodies. Higher CT titers are seen in the majority of individuals with recent cholera infection in areas where cholera is endemic (31).

Remarks

In contrast to LT antibody responses, which are transient, antibodies to CT remain elevated for several years after infection, precluding the use of this assay as a marker for recent

infection in areas of endemicity. However, it is very useful for seroepidemiological purposes. Infection with *V. cholerae* O139 strains in nonimmune individuals elicits antitoxin antibody; therefore, assays to detect anti-CT IgG antibody will not discriminate between infections caused by O1 or O139 strains.

V. cholerae O139 Bengal

In 1993, a new variant of *V. cholerae* that was clinically indistinguishable from toxigenic *V. cholerae* O1 yet had new surface antigens appeared in the Indian subcontinent; this strain has reemerged recently (15). This epidemic pathogen belongs to a new serogroup, O139, and is called O139 Bengal to identify its place of origin. From this initial site, the organism has spread to cause sporadic outbreaks in Pakistan, Nepal, China, Thailand, and other neighboring countries. It contains the principal virulence factors, CT and Tcp, which make it similar to the O1 strains. However, it does not produce the O1 LPS; rather, it produces a single unique O antigen attached to the LPS core surrounded by polymerized O-antigen repeat units forming a capsule. The majority of cases in these areas where *V. cholerae* O1 is endemic are in adults, suggesting that preexisting O1 immunity does not protect against O139 infection.

Detection of *V. cholerae* O139 Antigens

A number of rapid immunoassays that could be useful in remote settings have been proposed as reliable alternatives to bacterial culture to diagnose *V. cholerae* O139 infection. Coagglutination assays have been developed to detect *V. cholerae* O139 in a 4-h enrichment culture and in stool samples (46). In enrichment culture, this test had 100% sensitivity and specificity, with no cross-reaction with *V. cholerae* O1 antigen or coliform enterobacteria. With watery diarrhea samples the coagglutination test had 92% sensitivity (with a limit of detection of 10^7 CFU/ml), 100% specificity, and 100% positive and 95% negative predictive values (46). A dot blot ELISA using O139 LPS MAbs was developed to detect *V. cholerae* O139 in watery stools. This assay showed high sensitivity and specificity (100 and 96.3%, respectively) compared with the conventional bacterial isolation method using a large number of stool samples (8). A one-step immunochromatographic dipstick test for rapid detection of *V. cholerae* O1 and O139 from stool samples was developed. In areas where cholera is endemic the specificity of the O1 and O139 dipsticks ranged between 84 and 100% and the sensitivity ranged from 94.2 to 100%. A subsequent study with hospitalized patients with diarrhea showed that the dipsticks had enhanced sensitivity and specificity (>92 and 91%, respectively) when used with enriched rectal swabs rather than stool samples (5). An assay to detect *V. cholerae* O1 and O139 strains using purified outer membrane proteins and polyclonal antibodies was described (37). This assay can be used with whole stools and is capable of detecting 10^6 and 10^8 CFU/ml in a dot as well as regular ELISA format. A Cholera- and Bengal-SMART direct fluorescence kit to detect *V. cholerae* O1 and O139 strains in stool specimens is available from New Horizons Diagnostics.

Measurement of O139 Vibriocidal Antibodies

Vibriocidal assays developed for *V. cholerae* O1 strains need to be modified for non-O1 strains because the capsule reduces the effectiveness of complement-mediated antibody attachment and bacterial lysis. To solve this problem, Losonsky et al. adapted the vibriocidal assay using capsule-deficient mutants such as Tn*phoA* insertion mutant 2L of fully encapsulated strain AI-1837, which retains the LPS but not the

capsule (35). This assay was used to measure bactericidal antibodies after administration of wild-type or attenuated *V. cholerae* O139. The responses observed, however, were very low and did not correlate with immune status upon rechallenge. Moreover, low-level vibriocidal activity was detected in sera obtained 7 days after experimental wild-type challenges with *V. cholerae* O1, *S. flexneri* 2a, EPEC, and EAEC (35), probably due to cross-reactive antibody. Others have used a spontaneous O139 colony variant of a disease-causing strain with low levels of capsule production in a microplate assay. These assays require a smaller inoculum (1 to 2 $\log_{10}$/ml lower), use of $Mg2^+$ in the sample diluent, and an amount of complement carefully determined to avoid antibody-independent bacterial lysis. To more accurately determine endpoints, plates can be read spectrophotometrically, calculating, for example, 70% inhibition growth (2). Preexposure bactericidal titers measured with a recently described microplate assay showed a significant inverse correlation with bactericidal response subsequent to vaccination with an oral, inactivated, bivalent O1/O139 vaccine, or after O139 disease (2). A quantitative bactericidal assay in tubes that uses fully encapsulated clinical strains at a small bacterial inoculum (2×10^3 cells/ml) and increased complement activity (10%) has been described; this test allowed detection of bactericidal responses in 9 of 11 cases of O139 disease (3).

Molecular Methods To Detect *V. cholerae* O1 and O139

In order to cause diarrhea, *V. cholerae* strains belonging to serogroups O1 and O139 require genes for CT (*ctx*), TcpA, and central regulatory protein ToxR. A number of DNA probes are available to detect the *ctx* genes (22). DNA fragment probes have levels of sensitivity of approximately 10^3 CFU/g of stool. PCR techniques, however, by amplifying the genetic signal, can increase the sensitivity at least 100-fold. PCR and multiplex PCR targeting a number of different genes have been used for epidemiological studies (15). These techniques detect the presence of genes specific for *V. cholerae* biotypes, including *tcpA*, *ctx*, and *rstR*. A multiplex PCR (ezAmp Octaplex Cholera; Centre for Medical Innovations & Technology Development, Kelatan, Malaysia) is commercially available; this assay is designed to amplify genes for all serogroups (O1, O139, non-O1 and non-O139, El Tor, and classical biotype), toxin genes, and O139-specific *rfb*. These genetic techniques are limited to research laboratories but have great potential applicability, particularly in screening environmental sources such as water and food as vectors for transmission of toxigenic *V. cholerae*.

Serologic and Molecular Diagnosis of *Helicobacter pylori* Infection and Eradication

BRUCE E. DUNN AND SUHAS H. PHADNIS

54

CLINICAL PRESENTATION AND OUTCOMES OF INFECTION WITH *HELICOBACTER PYLORI*

Helicobacter pylori is a gram-negative, microaerophilic spiral bacterium which is recognized as the primary cause of chronic gastritis in humans. *H. pylori* infection is an essential contributing factor in the development of duodenal and gastric ulcers except in cases of nonsteroidal anti-inflammatory drug use and Zollinger-Ellison syndrome. The most convincing evidence supporting the role of *H. pylori* as an essential factor in the development of gastric and duodenal ulcers comes from clinical studies which have demonstrated that eradication of *H. pylori* infection eliminates ulcer recurrence (19).

H. pylori is distributed worldwide; the prevalence of infection in adults ranges from 30% in developed countries to more than 90% in developing countries. In developing countries, the infection is acquired primarily in childhood and, unless treated, persists for life (15, 19). In developed countries, the prevalence of infection increases with age. Improvements in hygiene in developed countries have probably resulted in reduction of *H. pylori* infection rates within the younger population. Persistent infection with *H. pylori* is a significant risk factor for the development of gastric carcinoma and gastric mucosa-associated lymphoid tissue lymphoma. The prevalence of *H. pylori* infection, gastritis, and gastric carcinoma increases with age, is inversely related to socioeconomic status, and declines in successive generations in developed countries. In contrast, a definite association between *H. pylori* infection and nonulcer dyspepsia has not been established, although a subset of individuals with dyspepsia may have symptoms related to *H. pylori* infection (15, 19).

A consensus panel convened by the National Institutes of Health in 1994 recommended that all individuals with gastric or duodenal ulcers who are infected with *H. pylori* receive antimicrobial therapy in addition to traditional antiulcer medications as primary therapy for ulcer disease, whether at initial presentation or at the time of recurrence (15, 19). Empiric anti-*H. pylori* therapy is generally considered inappropriate and should not be substituted for diagnostic evaluation and diagnosis-guided therapy. Success or failure of treatment cannot be determined reliably until 4 weeks or more after cessation of antimicrobial therapy (15).

GENETIC HETEROGENEITY OF *H. PYLORI*

Rapid advances in molecular genetic methods have allowed the elucidation of the complete genome sequences of two different *H. pylori* strains. In addition, DNA sequencing of a number of defined regions, along with other genetic techniques, has shown a high degree of heterogeneity among *H. pylori* strains, perhaps due to frequent genetic exchange between strains. With the notable exception of the CagA status of the infecting strain, little is known about the impact of strain heterogeneity on serologic detection methods.

The CagA protein, which is highly immunogenic, is one of the most widely studied virulence factors of *H. pylori*. The *cagA* gene is one of the genes in the *cag* pathogenicity island (26). The severity of *H. pylori*-related disease is correlated with the presence of the *cag* pathogenicity island. The CagA protein is injected into gastric epithelial cells by a type IV secretion mechanism; once in these cells, it becomes tyrosine phosphorylated and mediates changes in the host cell signal transduction pathways and actin skeleton reorganization (26). Another important virulence factor, vacuolating cytotoxin (VacA), is so named because it causes vacuolization of cultured eukaryotic cells (17). The *vacA* gene encodes a 140-kDa toxin precursor and is present in all strains. However, its expression is transcriptionally regulated; therefore, only about 50% of all strains express the toxin. Epidemiological studies have shown an increased risk of developing gastric or peptic ulcers and/or gastric carcinoma in patients infected with *cagA*- and *vacA*-positive strains (28, 29).

METHODS FOR DETECTION OF *H. PYLORI*

A variety of techniques are available for the diagnosis of *H. pylori* infection. In large part, due to the significant potential and actual clinical impact of *H. pylori* infection, the number of commercial tests available to diagnose infection has proliferated significantly over the past several years. In this chapter the tests are discussed generically rather than listed specifically. These methods can be categorized into two broad categories. The first involves invasive assays, which require the availability of gastric tissue obtained by endoscopic biopsy for histological examination, culture, molecular assays such as PCR, and biopsy urease tests. The second involves noninvasive assays, which detect either an

TABLE 1 Diagnostic tests for detection of *H. pylori*

Test	Requirement for endoscopy	Advantages	Disadvantages	Approximate sensitivity and specificity (%)
Histology	Yes	Allows evaluation of the type and degree of inflammation and direct observation of bacteria	Results may be variable, depending on pathologist experience; multiple biopsies recommended	>90, >90
Culture	Yes	Allows identification of antibiotic-resistant isolates	Variable results, depending on laboratory experience; considerable risk of false-negative results	>75, 100
Biopsy urease test (e.g., CLO test)	Yes	Rapid, inexpensive; endoscopic method of choice	May be falsely negative immediately after antibiotic treatment or during treatment with omeprazole	>90, >95
Urea breath tests (^{14}C and ^{13}C UBT[a])	No	Responds rapidly to eradication of *H. pylori*, noninvasive; breath samples can be sent to reference laboratories	^{14}C UBT involves radiation exposure; ^{13}C UBT requires specialized equipment (mass spectrometer) but is preferred when multiple tests are required.	>95, >95
Stool antigen	No	Noninvasive, available commercially; potentially responds rapidly to bacterial eradication	Guidelines required for follow-up after antimicrobial therapy	>90, >95
Serology	No	Noninvasive, inexpensive, available commercially	Prolonged delays before antibody levels decrease	>95, >90
Urine antibody	No	Noninvasive, potentially inexpensive	Methods require further standardization	>80, >80
Molecular tests	Depends on specimen	Allow sensitive detection of *H. pylori* and specific virulence markers	Not well standardized or available in clinical laboratories	Variable

[a] UBT, urea breath test.

immunologic response (e.g., specific antibodies directed against *H. pylori*), metabolic products of *H. pylori* urease activity (urea breath test), bacterial antigens, or nucleic acid present in stool or urine. The most common diagnostic tests for detection of *H. pylori* infection are summarized in Table 1. Molecular methods not only permit highly sensitive detection of *H. pylori* but also allow detailed characterization of the infecting strain by detection and analysis of virulence-associated genes. Local validation of diagnostic tests is important since, in addition to characteristics of the tests themselves, other factors such as local prevalence of *H. pylori* infection influence the predictive value of the tests.

Invasive Tests

Histologic examination allows evaluation of the type and degree of inflammation and direct observation of bacteria, if present. *H. pylori* can be difficult to detect on hematoxylin-and-eosin-stained slides. Thus, special stains such as the Warthin-Starry stain, in which darkly stained spiral bacteria appear prominent on a lightly colored background, are frequently employed, despite the technical demands and higher cost involved.

Microbiological culture of *H. pylori* is the most specific diagnostic method, but the sensitivity of culture is usually significantly lower than that of other methods. There are several reasons for this low sensitivity. The patchy distribution of *H. pylori* in gastric mucosa can lead to endoscopic sampling error, resulting in false-negative cultures. In addition, isolation of *H. pylori* is technically demanding and

requires proper specimen transport, specific medium, and microaerophilic growth conditions. Isolation of the organism is highly recommended, however, when antimicrobial susceptibility testing of *H. pylori* is desired.

An important characteristic of *H. pylori* that forms the basis of several diagnostic tests is the ability of the bacterium to produce large amounts of the enzyme urease. Urease catalyzes the hydrolysis of urea to ammonia and bicarbonate. This reaction causes an increase in the pH of the surrounding medium, which can be detected by a pH indicator dye. Thus, the presence of urease activity, and hence of *H. pylori*, is heralded by a color change in the indicator. Commercial biopsy urease tests are available which provide a medium in which to incubate gastric biopsy specimens to detect the presence of preformed urease and hence of *H. pylori*. Results are available within 2 to 24 h, depending on the test and conditions used. Compared with histologic and culture methods, biopsy urease tests are the endoscopic method of choice for rapid diagnosis of *H. pylori* infection on the basis of low cost and excellent sensitivity and specificity (14).

Once the biopsy specimen is obtained, the bacteria present within the specimen can be used for molecular assays without the need for bacterial culture. PCR-based molecular assays have been developed to detect *H. pylori*-specific DNA from gastric biopsies and from paraffin-embedded tissues. Additionally, *cagA* and *vacA* genotyping of *H. pylori* strains is possible using such specimens. However, DNA-based assays remain relatively time-consuming and expensive for routine clinical laboratory application.

Noninvasive Tests

Urea breath testing involves oral administration of urea which has been labeled with a carbon isotope. In infected individuals, urea is metabolized to ammonia and bicarbonate; the latter is excreted in the breath as labeled carbon dioxide. The amount of labeled carbon dioxide which is excreted can then be quantified. The [^{14}C]urea breath test involves radiation exposure but has the advantage that it can be performed in a relatively large number of laboratories equipped to detect such radioactivity. In contrast, the [^{13}C]urea breath test uses a nonradioactive isotope of urea, which requires a specialized mass spectrometer to detect $^{13}CO_2$ in the breath sample (5). The [^{13}C]urea breath test is preferred when repeated testing is required on an individual. Urea breath testing is an excellent noninvasive method by which to evaluate successful eradication of *H. pylori*, since it reflects active bacterial metabolism and responds rapidly to changes in *H. pylori* infection status. Many referral centers now accept urea breath samples for analysis of $^{13}CO_2$ at moderate expense. In selected circumstances, urea breath testing is well suited as the method of choice for follow-up of antimicrobial therapy (5).

Enzyme immunoassays for detection of *H. pylori* antigens in feces (*H. pylori* stool antigen test) have been developed commercially. As the next-most-common test after urea breath testing, stool antigen tests have been recommended for noninvasive diagnosis of *H. pylori* before and after eradication therapy (10, 15). In general, the sensitivity of the polyclonal antibody-based stool antigen tests varies from 57 to 96% in different studies. Recent improvements appear to have increased the sensitivity (73 to 95%) of a modified stool antigen test by replacing polyclonal antibodies with a specific monoclonal antibody. In a pretreatment setting, a commercial polyclonal antibody-based stool antigen test showed a sensitivity of 84 to 94% and a specificity of 90 to 100% compared to urea breath testing. In a posttreatment setting comparing the results of the polyclonal stool antigen test to those obtained using urea breath testing, nearly 8% of the patients gave discordant or indeterminate results with the two tests. Thus, the polyclonal stool antigen test appears to be less accurate than the urea breath test (23). However, compared with urea breath testing 4 to 6 weeks posttherapy, the monoclonal stool antigen test was more specific (88.6%) than was the polyclonal test (77.1%) but the specificities were similar (95 to 97%) (12). Continued progress in increasing the sensitivity of the stool antigen testing may lead to a robust noninvasive test to monitor eradication of *H. pylori* after antimicrobial therapy. However, the unpleasantness of the stool collection procedure may limit acceptance of this assay by patients.

Enzyme-Linked Immunosorbent Assays

Infection with *H. pylori* results in a systemic immune response characterized by circulating specific immunoglobulins (immunoglobulin G [IgG], IgA, and, acutely, IgM) (2). Spontaneous eradication of *H. pylori* infection rarely occurs. Thus, the presence of *H. pylori*-specific antibodies is indirect evidence of active infection (15).

Enzyme-linked immunosorbent assay (ELISA) methodology is considered the optimal approach to test for *H. pylori* antibodies because such tests are noninvasive, simple to perform, rapid, and cost-effective compared to endoscopic biopsy. Further, serologic testing allows "global" sampling of gastric mucosal infection whereas biopsy-based assays allow only localized sampling of the gastric mucosa. The choice of antigen is critical for the success of ELISA. In general, four types of antigen have been used for detection of *H. pylori*-specific anti-

bodies (23, 24). These preparations include crude antigens such as whole cells and whole-cell sonicates, cell fractions such as glycine extracts and heat-stable antigens, component-enriched antigenic fractions such as urease and the 120-kDa protein associated with vacuolating cytotoxic activity, and specific recombinant antigens such as CagA. The sensitivities and specificities of several of the enriched antigen preparations typically exceed 95%. While analysis of whole-cell preparations of *H. pylori* by sodium dodecyl sulfate-polyacrylamide gel electrophoresis reveals a large number of polypeptides, generally no more than about 25 protein antigens are recognized by immunoblotting using sera from infected individuals. There is significant heterogeneity in the specificity of these antibodies. As shown by a variety of techniques, very few, if any, antigens are recognized by all positive sera. Among the most commonly recognized antigens are the 62- and 30-kDa subunits of urease and the 58-kDa homolog of the Cpn60 family of heat shock proteins (HspB). Considering the genetic heterogeneity of *H. pylori* strains, it is generally thought that use of pooled extracts from multiple and genetically diverse strains as antigen preparations for detection of antibody will improve diagnostic performance. A significant fraction of individuals infected with *H. pylori* also produce serum and local antibodies directed against the 120-kDa CagA protein and the 89-kDa VacA protein. Antibodies directed against CagA and/or VacA protein antigen have a strong association with the severity of gastritis and with gastric cancer (9, 14).

The possibility of false-negative serologic test results for *H. pylori* has to be considered for any individual with an impaired immune response, e.g., the elderly, dialysis patients, immunosuppressed individuals, and organ recipients. In addition, chronic nonsteroidal anti-inflammatory drug treatment may suppress infection and decrease the sensitivity of serologic tests. False-negative results may also occur during the first few weeks of infection if methods are used which detect only IgG or IgA.

Value of Analysis of Specific Immunoglobulin Classes

In general, measurement of *H. pylori*-specific IgM levels has not proven useful in the clinical laboratory. A number of studies have evaluated the relative value of detecting *H. pylori*-specific IgG and IgA. Detection of *H. pylori*-specific IgA alone is generally less sensitive than detection of specific IgG antibodies alone (14). Testing for the presence of *H. pylori*-specific IgA in addition to IgG may increase test sensitivity slightly. However, the specificity of *H. pylori*-specific IgA appears to be at least equal to that of *H. pylori*-specific IgG (24). Individuals who have IgA but not IgG antibodies against *H. pylori* are uncommon.

Stability of *H. pylori*-Specific Antibody Levels in Untreated Individuals

Infection with *H. pylori* is chronic, and the host retains the capacity to respond to infection. As a result, circulating levels of specific IgG and IgA in *H. pylori*-infected individuals typically remain elevated for years, if not an entire lifetime, in the absence of bacterial eradication.

H. pylori-Specific Antibodies in Body Fluids Other than Serum

In an attempt to eliminate the need for venipuncture, diagnostic tests have been developed for the detection of IgG and IgA antibodies in saliva and urine (21,27). Studies using urine-based ELISA for detection of IgG antibodies against *H. pylori* have been conducted (13, 27). Such studies have

shown sensitivity between 82 and 90% and specificity between 68 and 82%. The ease of obtaining specimens is an obvious advantage of using urine as a source of IgG antibodies against *H. pylori* infection, especially in children.

Effect of Eradication of *H. pylori* on Antibody Levels

In untreated individuals with *H. pylori* infection, specific IgG and IgA antibody levels generally remain elevated. After successful bacterial eradication, specific antibody levels may decrease to as little as 50% of the pretreatment value within 6 months (14). However, specific antibodies may persist for years even after eradication of *H. pylori*. Some antigens, in particular the 120-kDa CagA protein, induce very persistent antibodies. Serology is, therefore, a potentially problematic method for the follow-up of treatment response. If *H. pylori* is suppressed but not eradicated, antibody levels may transiently decrease as antigen load falls but eventually rise to pretreatment levels.

Immunoblot Analysis

Immunoblot analysis of whole-cell lysates of *H. pylori* permits a detailed analysis of antibody profiles and is useful for identifying immunologic responses to specific antigens. However, beyond research studies, immunoblot technology is of limited utility for several reasons. First, antibodies in some patients infected by specific strains of *H. pylori* may not recognize antigens if a single strain of *H. pylori* is used in the immunoblot assay. Second, the resolution of the immunoblot is limited, permitting only about 25 distinctive bands to be detected. It may be difficult to distinguish between antigens with similar molecular sizes. Finally, since immunoblot assays are labor-intensive and semiquantitative, this type of assay is not suitable for automation or for screening large collections of sera. One new commercial immunoblot method showed high sensitivity (99%) and specificity (98%) compared with three other methods (18). However, when CagA antibodies were determined by this assay, false-positive reactions were detected in patients infected with CagA-negative strains and in individuals not infected with *H. pylori* (18, 21).

Rapid Serologic Tests

Over the past several years, a number of rapid near-patient tests have been marketed to detect antibodies to *H. pylori* in untreated individuals. These rapid tests are generally based on latex agglutination or flowthrough membrane-based enzyme immunoassays. Serum, plasma, or whole blood can be tested. Most of these tests detect IgG antibodies. While some studies have shown acceptable sensitivity and specificity, many qualitative rapid antibody tests have been clearly inferior to quantitative ELISAs. The use of rapid tests has not been recommended in Europe (15). The present authors recommend that if near-patient testing for *H. pylori* is to be instituted, the results of such tests must be correlated with results of serologic tests from the local reference laboratory, on a select group of well-characterized patients, before the test is accepted for widespread clinical use.

Serologic Tests for Children

Pediatric iron deficiency may be due to otherwise asymptomatic *H. pylori* gastritis (4). While the stool antigen test and [^{13}C]urea breath testing were the methods of choice for diagnosis and "test for cure" of *H. pylori* in Europe in 2003, these tests have not yet become accepted standards of care in the United States (4). Upper endoscopy and biopsy remain the gold standard for diagnosis of pediatric infection in the United States. Variable results have been reported for ELISAs used to detect *H. pylori* infection in children.

Molecular Methods

Over the past several years, a variety of molecular techniques have been developed to detect *H. pylori*, determine susceptibility to clarithromycin, and serve as tools for strain typing. A major limitation of PCR-based detection methods for *H. pylori* is the inability to distinguish between living and dead organisms. Thus, residual DNA may potentially be detected by PCR even after successful eradication of *H. pylori*. While molecular methods have been applied to the detection of *H. pylori*, such methods have not yet been applied systematically to testing the eradication of *H. pylori* after antimicrobial therapy.

PCR is as sensitive as culture in detecting *H. pylori* in gastric biopsy specimens (11). PCR has the advantage of allowing the detection of virulence factors such as *cagA*, *vacA* alleles, and other factors such as *iceA*. Real-time PCR has been used to estimate the gastric mucosal density of *H. pylori* (8). Chisholm et al. developed a multiplex PCR technique to detect *vacA* alleles in a single step (3). The latter authors reported perfect correlation with the genotypes determined directly in gastric biopsy specimens and in the *H. pylori* isolates cultured from the specimens. "Fingerprinting" of *H. pylori* strains can be performed on gastric biopsy specimens directly using PCR-restriction fragment length polymorphism without having to culture bacteria. Real-time PCR using TaqMan technology has been applied to determine the bacterial load of *H. pylori* in the gastric mucosa. A good correlation was obtained with results obtained using the urea breath test (8). PCR has been used to detect the presence of *H. pylori* in tissues other than gastric biopsy specimens as well.

Molecular methods have been developed to detect resistance of *H. pylori* to clarithromycin by using cultured isolates or gastric biopsy specimens directly. Clarithromycin resistance is due to single point mutations in the peptidyltransferase region of the 23S rRNA gene (1, 6, 16, 25); hence, detection of such mutations is well suited to PCR analysis. More recently, real-time PCR protocols have been developed which allow the detection of clarithromycin resistance-associated point mutations on the 23S rRNA (20).

PCR tests have been developed to detect *H. pylori* in human feces (7, 10). There are a number of potential limitations to the PCR method for detection of *H. pylori* in stool specimens. (i) False-negative results may occur due to the presence of PCR inhibitors or to genetic variability. (ii) False-positive results may occur by contamination or nonspecific amplification of human genomic DNA. (iii) PCR detection of *H. pylori* has not yet been standardized and is not generally available. However, when appropriate steps are taken to purify DNA in fecal specimens by using various biochemical, immunological, and physical steps prior to PCR amplification, the sensitivity and specificity of stool-based PCR for detection of *H. pylori* can approach 100% in the appropriate research setting (7). One-step PCR protocols have been developed using radiolabeled primers, an efficient extraction protocol, and 80 cycles of amplification to genotype *vacA* and detect *cagA* in stool specimens of *H. pylori*-infected children (28).

USE OF SEROLOGIC TESTING

Clinical Indications

As noted above, an accurate diagnosis of the presence of *H. pylori* infection should precede antimicrobial therapy. Routine serologic follow-up of patients after treatment for *H. pylori* infection is not recommended, since no clear guidelines have been established to quantify the reduction of

antibody level which is correlated with bacterial eradication, outside of the research setting.

Specimens

Generally, serum can be collected using standard phlebotomy techniques. There are no dietary restrictions prior to collection of the serum sample. Typically, no more than 10 μl of serum is needed to perform a single test.

Procedure

A variety of ELISA kits are available from manufacturers in North America and Europe. A general outline of methods involved in detection of *H. pylori*-specific IgG antibodies by ELISA testing is provided below. All procedures described in the package insert must be followed exactly as described for the particular test kit being used. In typical commercial ELISA kits, antigen is attached to the surface of microtiter plate wells, diluted serum is added to individual wells, and the *H. pylori*-specific IgG antibody, if present, binds to the antigen. All unbound antibody is washed away, and enzyme-conjugated anti-human IgG is added. The enzyme conjugate binds to the antibody complex. Excess enzyme conjugate is then washed away, and substrate is added. Bound enzyme conjugate begins a hydrolytic reaction. After a specified period, the enzyme reaction is stopped. The results are read by a spectrophotometer, which gives an indirect measurement of the amount of *H. pylori*-specific IgG antibody present in the serum.

Results and Interpretation

Typically, ELISA kits have a predetermined cutoff for absorbance values considered to be positive or negative. There is usually a range of absorbance values between which the reading is considered equivocal. It is recommended by many manufacturers that specimens giving equivocal results be retested. If the retest result is also equivocal, the report should be reported as "equivocal" and the sample should be retested by an alternate method or with a new serum specimen drawn after an interval of at least 4 weeks.

Commercial ELISAs are designed for use in the qualitative detection of *H. pylori*-specific IgG antibodies in human serum. Such tests typically assess the serologic status by using a single serum specimen per individual and are intended to be used as an aid in the diagnosis of *H. pylori* infection in individuals with gastrointestinal symptoms. Virtually all individuals infected with *H. pylori* possess IgG antibodies. Because infection with *H. pylori* is so prevalent and because it may be asymptomatic, many individuals apparently free of gastrointestinal symptoms exhibit *H. pylori*-specific antibodies. The prevalence of *H. pylori* antibodies increases with age. *H. pylori* antibodies are found in men and women at approximately equal rates. Blacks, Hispanics, and persons born outside of the United States tend to show higher rates of infection with *H. pylori*.

Technical Limitations

Typically, icteric, lipemic, hemolyzed, or heat-inactivated serum may cause erroneous results; such samples should be avoided if possible.

A positive test result indicates that the individual has antibodies to *H. pylori*.

Such a result does not indicate that any existing symptoms are necessarily due to *H. pylori* infection. In the absence of prior therapy to eradicate *H. pylori* infection, the positive test result very probably indicates active infection with *H. pylori*. However, in the absence of an adequate

patient history, a single positive test result does not differentiate between active and past infection.

A negative serologic test result indicates that the individual does not have detectable levels of antibody to *H. pylori*. If a sample is drawn too early during *H. pylori* infection, IgG antibodies may not be present.

Use of Specific Antigens in ELISA

The most important factor in using immunological methods for identifying VacA-specific antibodies by ELISA is the antigen preparation used to detect circulating antibodies. VacA protein is quite diverse among *H. pylori* strains and is broadly classified as *s1/m1* or *s2/m2* type. While commercial kits are available for detection of VacA antibodies by using immunoblot assays, most ELISA studies have been developed with purified or enriched VacA protein fractions; this is a time-consuming and expensive approach (22). The availability of recombinant VacA protein will help to make the VacA ELISA more widely available.

At least one commercial assay is available which uses recombinant CagA protein to detect CagA-specific IgG. This assay also uses anti-human IgG monoclonal antibody enzyme conjugate to detect the presence of specific IgG. The assay has been automated to operate in a high-speed walk-away analyzer for 96-well ELISAs.

Limitations of Serologic Assays in Monitoring Eradication

There are two basic limitations to the clinical utility of serology in monitoring the eradication of *H. pylori* infection. First, baseline and follow-up sera must be analyzed at the same time to minimize assay variability. Significant variability may result from assaying sera at different times or using different lots of reagent. Therefore, pretreatment sera must be saved to be analyzed along with posttherapy samples. This limitation requires that pretreatment specimens be saved for up to 12 months. The second limitation is that serology must be monitored for at least 3 months (and for 6 to 9 months in many cases) before a significant decrease in antibody concentration is observed. Depending on the clinical circumstances, this may represent an unacceptable delay. The percent decrease in the concentration of *H. pylori*-specific IgG which indicates eradication of infection in an individual patient has not been clearly established.

When using serologic analysis in the evaluation of treatment success under controlled conditions, the absolute concentrations of *H. pylori*-specific IgG antibodies in the serum are less important than are the changes in concentrations from the pretreatment level. For example, over 60% of individuals from whom *H. pylori* was eradicated continued to have seropositive IgG levels (index value, >1.0) at 6, 9, and 12 months despite demonstrating a 20% reduction in antibody concentration. Thus, a single serum specimen from such an individual would appear to reflect active infection with *H. pylori* in the absence of an adequate clinical history.

In summary, ELISAs for detection of *H. pylori*-specific antibodies are sensitive, specific, and cost-effective in untreated individuals. The major limitation of such tests is the lack of a rapid, clear serologic response to eradication of bacterial infection. Molecular tests have been developed which preclude culture and allow direct, sensitive detection of *H. pylori* and specific virulence factors thereof in a variety of biological specimens. Much work remains to be done to standardize molecular assays so that they can be applied generally to the diagnosis of *H. pylori* infection and eradication.

Detection of Antibodies to *Legionella*

PAUL H. EDELSTEIN

55

Legionnaires' disease is a type of bacterial pneumonia caused by the legionellae (15). *Legionella pneumophila* causes more than 90% of cases of Legionnaires' disease, with *L. pneumophila* serogroup 1 (SG1) being responsible for about 85 to 95% of the cases of community-acquired Legionnaires' disease (4, 31). Determination of the levels of antibody to *L. pneumophila* was one of the first methods used to diagnose Legionnaires' disease and was especially valuable when culture diagnosis was at a primitive stage. Serologic testing is now a second-line test because of the length of time required for seroconversion, its relatively low sensitivity, and the low specificity of seroconversion for antigens other than *L. pneumophila* SG1. The major use of this test is for epidemiologic purposes, such as outbreak investigations, research purposes, and to complement other diagnostic tests. Other immunologic tests used to diagnose Legionnaires' disease include detection of bacteria in respiratory tract samples using immunofluorescent microscopy and detection of *L. pneumophila* SG1 antigenuria by enzyme-linked immunosorbent assay (ELISA) or immunochromatographic assay (13–15). Culture of respiratory tract specimens is an excellent but insensitive method to diagnose Legionnaires' disease, while urinary antigen detection is the most useful test for diagnosing *L. pneumophila* SG1 infection. Molecular methods for diagnosis, such as PCR, have been successfully used on a research basis, and a newly introduced commercial DNA amplification and detection test for *L. pneumophila* (BD ProbeTek ET *Legionella pneumophila*) has great promise. This chapter describes antibody testing because it is still very widely used and is of major importance for epidemiologic and research studies.

HISTORY OF AND CONTROVERSIES SURROUNDING ANTIGEN PREPARATION

McDade and Shepard, the test originators, used live yolk sac-grown bacteria; this method was subsequently adopted and modified by Harrison and Taylor, who used Formalin-killed yolk sac-grown bacteria (20, 27). Centers for Disease Control (CDC) workers then switched to heat-killed plate-grown bacteria, which had equivalent sensitivity to that of the original McDade and Shepard antigen (27). Heating is the antigen inactivation method used in the United States, whereas Formalin-inactivated yolk sac-grown bacteria was preferentially used in the European Community. Use of the

Harrison-Taylor preparation gave an exceptionally low background frequency of elevated titers (1 to 3% at a titer of 16), as opposed to the 1 to 20% frequency (titer of 128) with use of the CDC antigen (20, 27). The relative performance of the two antigen preparations was not studied for large numbers of specimens, but if seroconversion was used as a diagnostic criterion, there was probably little difference. Some commercial North American laboratories provide Formalin-fixed plate-grown antigen, which is not equivalent to the yolk sac-grown one. There is currently no public or private supplier of the yolk sac-grown Formalin-fixed antigen.

The CDC method uses antigen suspended in yolk sac, whereas none of the North American commercial laboratories producing Food and Drug Administration (FDA)-cleared kits for antibody detection use yolk sac, nor is yolk sac itself commercially available. The non-FDA-cleared Focus Technologies antigen is Formalin fixed and suspended in yolk sac (Focus Technologies, personal communication, July 2004). Yolk sac helps the antigen to adhere to the slide and prevents bacterial aggregation, and its use may affect antibody titers. Yolk sac is also used in the CDC method for making the first serum dilution, to decrease autofluorescence. Yolk sac omission in commercial kits may therefore affect the interpretive criteria.

A very important point is that validation studies of the CDC and Harrison-Taylor methods utilized only *L. pneumophila* SG1 antigen (20, 27). This antigen is very specific, much more so than that of other serogroups and other *Legionella* spp. The interpretive criteria developed for these antigens cannot be applied to other antigen preparations, regardless of serogroup and species. Elevated titers of antibody to other *L. pneumophila* serogroups and *Legionella* species are more common among healthy blood donors than are those of antibody to *L. pneumophila* SG1 (5, 29). Because of this, neither CDC nor British Public Health Laboratories routinely perform testing for other serogroups and species. Laboratories are strongly advised against routine testing for antibody to other serogroups and species unless an adequate local control population is available to determine the specificity of testing and unless appropriate interpretive criteria are used. An adequate control population should encompass not only healthy blood donors but also patients with bacteriologically confirmed pneumonia not caused by *Legionella*. Unfortunately, many commercially available indirect immunofluorescent-antibody (IFA) kits sold in the

United States contain polyvalent antigen, so the results of positive screening tests must be confirmed by using a monospecific assay kit or home-made reagents.

TEST SENSITIVITY AND SPECIFICITY

When seroconversion to heat-killed *L. pneumophila* SG1 is defined as a fourfold increase in titer from ≤32 to ≥128, the sensitivity is in the range of 70 to 80%, provided that up to 9 weeks is allowed for antibody levels to rise (27). Using different criteria, the Formalin-fixed antigen had similar sensitivity (20). Of note, the test sensitivity is lower for epidemic disease, about 50%, presumably because convalescent-phase sera are not collected at later time points (11, 12). The sensitivity of seroconversion to other antigens in the case of infections caused by other serogroups and species is unknown. Because of cross-reactive antibody formation, a significant but not precisely known proportion (possibly around 50%) of patients with non-*L. pneumophila* SG1 infection will demonstrate seroconversion to *L. pneumophila* SG1 (29). The specificity of seroconversion to *L. pneumophila* SG1 ranges from 99 to 99.9%; for other serogroups and species, it ranges from 90 to 95% (29). This makes seroconversion to *L. pneumophila* SG1 highly predictive of disease even in low-prevalence populations, but it makes seroconversion to other serogroups and species nonspecific when pretest probabilities are below 20%. Once positive due to Legionnaires' disease, antibody levels fall to a background level in 3 to 10 years (10).

RATE OF SEROCONVERSION AND USE OF SINGLE RATHER THAN PAIRED SAMPLES

Up to 9 weeks may be required to develop a significant rise in titer in those who seroconvert (27). About 25% of patients seroconvert in week 1 of illness, 50% seroconvert in week 2, 75% seroconvert in week 3, 90% seroconvert in week 4, and the remaining 10% of patients seroconvert during weeks 6 to 9. Thus, testing of paired sera drawn during the first 2 weeks of illness has only about a 40% (50% of 80%) chance of yielding a positive result in patients with Legionnaires' disease. The Harrison-Taylor antigen apparently has a higher early yield, with 30 to 40% of patients developing elevated titers, but not necessarily seroconversion, after the first week of illness (20). Because of high background antibody levels (1 to 20%) in North America, unpaired serum testing is often of low specificity and should not be done. The low specificity of single antibody titers as high as 1:256 (*L. pneumophila* SG1 heated antigen) has been documented by Plouffe et al. (25). It is exceptionally important that serum specimens be tested in parallel when testing for seroconversion. Otherwise, in the process of testing specimens on different days, the normal 1 two-fold dilution variability of testing that occurs from day to day could either mask a fourfold rise or produce apparent titer changes that are not real.

High single titers are often used in the investigation of known outbreaks of Legionnaires' disease. In this case, the very high pretest probability of disease makes single-serum testing useful. Serum antibody to *L. pneumophila* SG1 heat-killed antigen at a titer of ≥1,024 is often used as "presumptive" evidence of Legionnaires' disease in outbreak settings. Recently, detection of single elevated levels of immunoglobulin M (IgM) to *L. pneumophila* SG1 heat-killed antigen has been used to detect epidemic-disease patients with otherwise negative antibody tests (12, 18). The speci-

ficity of elevated IgM levels in this setting is not known with certainty but may be around 93 to 99%, with a sensitivity of around 70% (12). In an epidemic setting, where pretest probability may be as high as 50%, the positive predictive value of a single elevated IgM or IgGAM test is about 89 to 98%, an epidemiologically helpful level of certainty. However, in the setting of sporadic disease, the positive predictive value of such a positive test is only about 18 to 60%, a dubious level of certainty for clinical purposes.

USE OF POLYVALENT ANTIGENS

More than 60 different *Legionella* serogroups have been described to date. Patients infected with some *Legionella* serogroups may not demonstrate antibody to other serogroups. In one study, about 60% of seroconversions were missed by workers screening sera by using only *L. pneumophila* SG1 antigen; it is unknown how many patients with missed seroconversions actually had Legionnaires' disease and how many had cross-reactive antibody to other bacteria (29).

The failure to detect seroconversions with non-*L. pneumophila* antigens led to the use of polyvalent pools of antigens for screening purposes (16, 27). Very good correlation between monovalent and polyvalent antigen results were observed for *L. pneumophila* SG1 disease, but no negative control sera were tested. A subsequent study examined the specificity of multiple polyvalent pools; overall, the specificity of seroconversion was estimated to be 96% (29). Unfortunately, the control groups did not contain sera from patients with infections caused by organisms known to be cross-reactive. These studies led to the use of multiple polyvalent pools, for which proper studies of correlation of results with monovalent antigens have not been performed and for which specificity is not well established but probably is low. Fallon and Abraham found that the specificity of an *L. pneumophila* SG1 to SG4 polyvalent antigen was quite good when judged against reactivity with monovalent antigens but that it was not perfect, and they recommended that the polyvalent pool be used only for screening purposes and that all high antibody titers be checked with the monovalent components (16). I have found that at least 25% of seroconversions to four different polyvalent antigen pools did not prove to be genuine when the sera were retested with the monovalent components (P. Edelstein, unpublished observations). In most of these cases, patients had nosocomial pneumonia caused by *Pseudomonas* and other gram-negative bacteria, a group of patients not tested by the CDC workers. Because of this, it is mandatory to confirm polyvalent seroconversions by using the monovalent components. A better policy is to avoid the use of such pools completely and to use only *L. pneumophila* SG1 antigen as discussed above. Use of this antigen alone should enable a serologic diagnosis of the majority (65 to 70%) of cases of Legionnaires' disease (26). A case can be made for the use of such pools for screening purposes in epidemiologic investigations, providing that adequate control populations are studied and that monovalent antigen preparations are used once the epidemic strain becomes known.

DETERMINATION OF INFECTING SEROGROUP

It is often not possible to determine the serogroup or species causing infection by using antibody responses (27). For example, in one outbreak caused by *L. pneumophila* SG1,

some patients had marked antibody responses to other *Legionella* species and serogroups (17). Thus, the use of relative antibody titers to determine the infecting type of bacterium can be misleading.

ANTIBODY IMMUNOGLOBULIN TYPE

Antibody to *L. pneumophila* during and after infection may be composed of either IgA, IgG, IgM, or various combinations of the three immunoglobulin classes (1, 3, 20, 28). It has been demonstrated that tests for *L. pneumophila* antibody must examine for all three of the immunoglobulin classes for optimal sensitivity. IgM antibody can persist for considerable lengths of time, making impossible the distinction of new from old disease by determining IgM antibody levels. Unfortunately, some commercial kits for IFA testing do not use a secondary antibody proven to react with IgM or IgA antibodies to *L. pneumophila*.

AGGLUTINATION ASSAYS

A rapid microagglutination assay is used in the European Community to detect early rises in levels of antibody to *L. pneumophila* SG1 (20). The advantage of this over immunofluorescence microscopy is the slightly more rapid appearance of agglutinating antibodies and the ability to test a large number of specimens more easily. The specificity of such testing is estimated to be 97 to 99%, with a sensitivity of about 80% (20). About 40% of people who eventually seroconvert have agglutinating antibodies detected during the first week of infection (20). The Michigan State Department of Community Health Laboratory uses a multivalent hemagglutination assay which has been well validated only for the detection of antibodies to *L. pneumophila* SG1 (21, 30).

ELISAS

Extensive studies of the performance of ELISAs for the measurement of *L. pneumophila* antibody have not been performed. Sonicated whole bacterium and purified lipopolysaccharide appear to be the best antigens for use in this assay (1, 3). Detection of specific IgA antibodies may also increase the sensitivity and specificity of the ELISA (3).

Several enzyme immunoassay (EIA) kits that measure *L. pneumophila* antibodies are commercially available and are manufactured or sold by Wampole Laboratories and Zeus Diagnostics. These kits screen for IgM and IgG antibodies to *L. pneumophila* SG1 to SG6. The sensitivity of the kits for measurement of antibody to *L. pneumophila* SG2 to SG6 is unknown, but they do appear to be reasonably sensitive in comparison to the IFA method (70 to 90%) for the estimation of SG1 antibodies (19). Test specificities are about 98%. These tests are designed to detect relatively high IFA titers, in the range of 1:128 to 1:256. Of note, the IFA technique detects IgA antibody, which is apparently not detected by ELISA; this has the potential to decrease ELISA sensitivity (28). The Serion Classic EIA test A kit is used in Europe but has not been FDA cleared, in contrast to the Zeus and Wampole EIA kits. Detailed published studies of the performance of the Serion EIA test A kit are unavailable, but use of the kit in a large outbreak of Legionnaires' disease caused by *L. pneumophila* SG1 showed the sensitivity to be 62%, about the same as that observed historically for IFA testing in the same setting (11). The specificity of the Serion EIA in patients with pneumonia not caused by *Legionella*

spp. is unknown, but its age-related normative values have been determined (6). Since all the EIA kits use a pool of serogroups, a positive EIA result can be the result of cumulative low-level antibodies to different serogroups, as has been observed for the IFA method using multiple antigens (16). Because of this, the positive predictive accuracy of a positive EIA result may be low. The predictive value of a positive Wampole assay is about 90%; in other words, about 90% of EIA-positive or indeterminate sera will have IFA titers (heat-killed antigen) of ≥64, with most being >64 (Edelstein, unpublished). All positive EIA results should be confirmed by use of the IFA test with an *L. pneumophila* SG1 antigen (19). The best use of the EIA test is as a screening assay of convalescent-phase sera (19). Any such sera yielding positive or indeterminate results can then be tested in parallel with the acute-phase serum by the IFA method. Using this scheme, about 10% of serum pairs so selected are positive for a significant change in IFA titer (Edelstein, unpublished). A recent comparison of the sensitivity of the Wampole and Zeus EIA kits versus a home-made polyvalent IFA test showed the EIAs to be about 24% sensitive, in striking contrast to prior studies and FDA submission data; this may be because of nonspecificity of the IFA results or, less likely, because of poor detection of IgA antibodies by the ELISA kits (22).

CROSS-REACTIVE ANTIBODY

Cross-reactive antibody is occasionally found in patients with non-*Legionella* infections. These infections have included pneumonia and bacteremias caused by *Pseudomonas, Haemophilus, Mycobacterium*, gram-negative enteric rods, *Bordetella, Chlamydia, Rickettsia*, and *Bacteroides* (reviewed in references 2 and 9). Most problematic are pseudomonas infections, especially when antibody to *Legionella* antigens other than *L. pneumophila* SG1 is measured (9, 20). Up to 25% of people with *Campylobacter jejuni* enteritis have cross-reactive antibodies to *L. pneumophila* (7, 8, 23). Bornstein et al. found that cross-reactive antibodies to yolk sac-grown Formalin-fixed *L. pneumophila* SG1 were very rare (ca. 0.4%) in sera collected from patients with tuberculosis or non-*Legionella* pneumonia. However, as many as 10% of patients with tuberculosis had cross-reactive antibodies to other *Legionella* serogroups and species (5). Using similar antigen preparations, McIntyre et al. found that 193 patients with other causes of pneumonia had no appreciable titer (<16) of antibody to *L. pneumophila* SG1 antigen, whereas 21 (11%) had elevated convalescent-phase titers (>16) of antibodies to a number of other *Legionella* antigens (24). Taylor and Harrison found the specificity of their *L. pneumophila* SG1 antigen to be near 100% when testing presumably late-phase sera collected from 317 patients with a variety of bacterial infections not caused by *Legionella*. The only exception involved sera collected from 2 of 26 patients with *Pseudomonas* infections, both of whom had positive but low (titer of 16) antibody titers (20).

BLOCKING ANTIGEN

Because of the cross-reactivity noted above, Wilkinson and colleagues absorbed serum with an *Escherichia coli* "blocking antigen" to remove cross-reactive antibody, somewhat analogous to the absorption step used in syphilis serologic testing (28). It is unclear whether this absorption removes only nonspecific antibodies and what criteria should be used to evaluate the serologic results of testing before and after the

use of this blocking antigen (2). Boswell and colleagues have also proposed using a *C. jejuni* blocking antigen (23). Because of its uncertain utility, the blocking antigen has been little used by most laboratories and probably adds little to this test.

CLINICAL INDICATIONS

Detection of *L. pneumophila* SG1 serum antibody is indicated in suspected cases of Legionnaires' disease or Pontiac fever. Pontiac fever is an acute, nonfatal febrile illness associated with *Legionella* but not proven to be caused by it. In the majority of cases, it is most appropriate to freeze acute-phase serum and to test it in parallel with a convalescent-phase serum sample only if a clinical or laboratory diagnosis has not been made by other means. Antibody testing used to diagnose Pontiac fever often requires testing of sera from matched controls. Investigations of outbreaks of pneumonia or research studies may be indications for testing single serum specimens.

SUMMARY

1. Only paired sera which have been collected at least 2 weeks, and preferably 6 to 9 weeks, apart should be accepted for serologic testing.

2. All specimens from the same patient must be tested together for optimal results.

3. Except for epidemiologic surveys, with well-matched negative control populations, testing should be done with *L. pneumophila* SG1 antigen only.

4. To obtain results that can be related to CDC results, heat-fixed Philadelphia 1 strain antigen should be used and suspended in yolk sac and the first serum dilution should be made in yolk sac diluent.

METHODS

Principles of the IFA Procedure

The IFA test measures the level of antibody to bacteria fixed to multiple wells of a microscope slide. Serially diluted serum ("primary antibody") is added to the slide wells containing the fixed bacteria and incubated to allow adherence of serum to the bacteria. The slide is then washed to remove any unbound serum. Antibody to human globulins that is conjugated with fluorescein isothiocyanate ("secondary antibody") is added to the slide and allowed to react with the bound primary antibody. Excess secondary antibody is then washed off. The presence of secondary antibody is detected by observation of the slide using a microscope equipped with a UV light source and the proper filters. Wells with sufficient bound secondary antibody contain fluorescent bacteria, whereas wells containing little secondary antibody (because of poor binding of primary antibody to the bacteria) contain very few or no fluorescent bacteria. The actual concentration of antibody is determined by ascertaining the serum dilutions at which there is bright staining of the bacterial cells.

Specimen Requirements, Collection, Transport, and Storage

A 4-ml volume of blood collected in a tube without anticoagulants is required for testing. The blood specimen can be transported to the laboratory at ambient temperatures but protected from freezing. On arrival at the laboratory, blood should be allowed to clot at room temperature. The serum is separated by centrifugation at 500 to 1,000 $\times$ g and removed from the clot promptly. Serum separation should be done within a day of specimen collection; this period can be prolonged by storage of the clotted specimen at 5°C. Once the serum has been separated, it should be stored at 5°C until aliquoted for low-temperature storage. *Legionella* antibodies are relatively stable, such that serum can be transported at temperatures above freezing without significant antibody loss. Freeze-thawing may reduce antibody titers, necessitating aliquoting of samples before testing so that more than one comparative test can be performed on the same specimen without loss of antibody.

The serum specimen is aliquoted into at least three glass or plastic freezer vials that will withstand storage at -70°C. The filled vials are stored at -70°C. If low-temperature freezing is not possible, the vials should be stored at the lowest possible temperature and freeze-thaw cycles should be avoided.

Serum samples should be collected at the onset of illness and every 2 to 4 weeks afterward for a total of 8 to 9 weeks. Testing of single specimens should not be performed routinely, regardless of the stage of illness. In epidemic situations, testing of acute-phase specimens may be helpful, but this practice should be confined to such instances. The minimum number of specimens required is two, drawn at least 2 weeks apart. Exceptions to the requirement for two specimens include patients with pneumonia of more than 2 months' duration and spot prevalence epidemiologic surveys when a control population is used.

The most cost-efficient method of testing is to test only the convalescent-phase sera at a dilution of 1:64. If this is positive, then both acute- and convalescent-phase sera can be further tested at the same time. If it is negative, there is no need to test the acute-phase serum. Although unpaired serum specimens should not ordinarily be tested, screening should be done at a dilution of 1:512 if they are tested. An alternative screening approach is to first screen the convalescent-phase sera by using one of the commercial ELISA kits; all specimens giving positive or equivocal results in the assay are then tested in parallel with the acute-phase serum in the IFA test. This second strategy can be cost- and time-effective if a large number of samples must be tested. About 1 to 2 h of hands-on time and about 3 to 4 h of total time is required to screen 90 samples using the ELISA kits, whereas two to four times the amount of time is required to screen the same number of specimens using the IFA method. In addition, usually only about 1 to 10% of convalescent-phase sera from patients suspected of having Legionnaires' disease are positive in the ELISA screening, greatly reducing the number of IFA assays that have to be set up.

Materials

Serum

Serum to be tested (minimum volume, 20 μl)

Positive control serum for antigen to be tested (minimum volume, 20 μl)

Anti-human globulin (IgG, IgA, and IgM) conjugated with fluorescein isothiocyanate, at its working dilution (this is available from a number of commercial sources; the working dilution for each lot has to be determined; for example, the working dilution of Kirkegaard and Perry goat anti-human globulin, catalog no. 02-1-07, lot no. UH065, is 1:25 in my assay; minimum volume is 0.3 to 0.4 ml total for two samples and the controls)

Supplies and Equipment

Multiwell Teflon-coated glass slides, 6 or 12 wells per slide, staggered, 5-mm-diameter wells

Glass coverslips, no. 1 thickness (40 by 60 mm)

Disposable, nonsterile glass tubes (12 by 75 mm), seven per specimen, or nonsterile 96-well microtiter plates

Pasteur pipettes, 5 in. (13 cm) long, disposable and nonsterile

Micropipette tips, nonsterile

Calibrated micropipettes, capable of dispensing 50, 100, and 750 μl

Glass staining dish with stainless steel rack or Coplin jar

Covered plastic or metal box with an interior slide rack, large enough to hold at least three slides (a 150-mm-diameter petri dish with wooden sticks on the bottom can be used) (this is referred to as a moisture chamber in the instructions; during all incubations the chamber should be kept humid inside by covering its bottom with wet paper towels

Air incubator, preferably humidified, set at 35 to 37°C

Microscope equipped with an epi-illumination UV source (HBO 50 to HBO 200) and proper filters for fluorescein isothiocyanate (oculars should be in the range of 10× to 12.5×, and the objective should be 20× to 40× [oil, water, or dry], with a total magnification of about ×250 to ×500

Reagents

Bacterial antigen suspension (minimum volume, 0.2 ml for one specimen and two controls)

3% yolk sac suspension in phosphate-buffered saline (PBS) (minimum volume, 1.5 ml for one specimen and two controls)

PBS, 0.01 M (pH 7.6), 0.5 liter

PBS, 0.01 M (pH 7.6), filter sterilized, 2 ml (for reconstituting lyophilized conjugate, if required)

Wash bottle containing PBS

Distilled or deionized water

Bicarbonate-buffered glycerol mounting fluid (pH 9). Use of antifade mounting media is not required and may decrease intensity and titer.

Controls

A negative and a positive control are used for each run. The positive control uses a serum specimen of known high titer, usually 512. Positive and negative control sera for *L. pneumophila* SG1 are commercially available, although they are of variable quality. It is sometimes better to use aliquoted human serum of known titer than to use commercially available antisera. It is difficult to obtain good control sera for other serogroups and species. Two approaches are possible for a negative control. The best one is to use serum of a known low titer, such as 32. A negative monkey control serum is available for *L. pneumophila* serogroups 1 to 6 but has not been extensively tested for any other antigens. Normal blood donors can often be used as the source of a negative control serum. A non-serum-containing negative control, such as PBS, can be used to help troubleshoot assay problems but is not routinely needed. This nonserum control is used to detect nonspecific binding of the secondary antibody to the antigen (antigen, PBS instead of serum, and conjugate) and autofluorescence of the antigen (antigen, PBS instead of serum, but no conjugate).

Procedure

Preparation of Slides

1. Store the microscope slides at −20°C to prevent the masking from coming loose. Thaw them at room temperature, and then dust them lightly with lint free tissues. **If commercially prepared antigen coated slides are being used, skip this step and the next step.**

2. Make sure that the antigen is evenly suspended by mixing with a vortex mixer. Apply 1 drop of the antigen to each well of the slides with a Pasteur pipette, and then immediately suck back as much solution as possible, leaving only a fine film on the slide. Air dry for 30 minutes. **Do not heat fix, as this will agglutinate the antigen and invalidate the assay.**

Dilution of Sera

1. Label seven test tubes with the specimen identification number and with the final serum dilution (16 to 1,024). Also, label tubes for the positive and negative control sera. Put the tubes in order in a rack, with the lowest dilution on the far left. Add 100 μl of PBS to all of the tubes except for the ones marked 16. These dilutions can also be carried out in a 96-well microtiter tray, using half the volumes specified for the tube method and mixing with a multichannel pipette or plate shaker.

2. Make an initial 1:16 dilution of serum in 3% yolk sac-PBS solution. You can do this by adding 50 μl of serum and 750 μl of the yolk sac diluent to the tube marked 16; for smaller volumes of serum, use 20 μl of serum and 300 μl of diluent. Vortex mix this tube.

3. Add 100 μl of the 1:16 dilution of serum to the test tube marked 32, and vortex mix briefly. Using a new pipette tip, add 100 μl of the 1:32 dilution to the tube marked 64, and vortex mix briefly. Continue this until you have made the 1:1,024 dilution of serum, changing the pipette tip each time.

Addition of Sera and Conjugate to Slides

1. Using a Pasteur pipette, add 1 drop of the 1:32 to 1:1,024 dilutions of the patient sera and the control sera to the wells of their respective slides. The drops should be added to the slides in decreasing order starting with the 1:1,024 dilution. In this way, one pipette can be used per specimen. The entire dilution should be expelled before pipetting the next lower dilution. The drop should cover the entire well of the antigen slide. It is most useful to place both acute- and convalescent-phase sera on the same slide, since this will allow ready comparison.

2. Place the slides flat on racks in the moisture chamber, cover the chamber, and incubate at 35 to 37°C for 30 min.

3. Remove the slides one at a time from the moisture chamber, and rinse each one with a stream of PBS from a squeeze bottle. The slide should be held horizontally and the stream of PBS should be directed gently downward to avoid rinsing different dilutions of the specimen together. Place the slides in the racks in glass rinsing dishes (Coplin jars); avoid touching the slides together. Fill the dishes with PBS, and incubate them for 10 min at room temperature.

4. Empty the PBS out of the dishes, and replace it with distilled water twice for 15 to 30 s each time.

5. Remove the slides from the rinsing dishes, and blot each slide dry with bibulous paper; alternatively, the slides can be left to air dry.

6. If required, reconstitute the anti-human conjugate with the filter-sterilized PBS (pH 7.6), and vortex mix until the solution is clear.

7. Add a drop of conjugated secondary antibody (ca. 8 to 20 μl) to each well of the dry slides, which have been placed on racks in the wet chamber. Since secondary antibody may be expensive, as little as 7 to 8 μl can be used; the pipette tip is then used to break the surface tension and allow the small drop to distribute evenly over the well. Using smaller conjugate volumes is more labor-intensive than use of a larger volume, which can be added as a free-flowing drop. The conjugate should fill the wells completely.

8. Cover the chamber, and incubate at 35 to 37°C for 30 min.

9. Repeat steps 3 to 5 above.

10. Mount coverslips with glycerol mounting medium. Care should be taken to use a minimum amount of glycerol for confluency to avoid leakage around the edges of the slides.

Reading the Slides

The prepared slides should be examined using a fluorescence microscope equipped as stated above. The 10× objective should be used initially to locate the antigen circle in the well. When this is achieved, the circle should be examined using the 20× to 40× objective. A 20× objective can be just as accurate as a 40× objective, especially if a 12.5× or 15× ocular is used; practice is required for correct reading with the smaller objective, but the end result is a shorter reading time, less affected by photobleaching. It is important that the UV light source be changed on a regular schedule (e.g., every 150 h for an HBO 100 bulb) to maintain relatively constant light intensity. Different results will be obtained for each type of light source, magnification, kinds of objective (immersion type, numerical aperture, flatness of field, and color correction), and filters. Also, there is often observer-to-observer variability of ±1 dilution. Reading of the end points with each microscope should be done with reference to the positive control serum used with the antigens and conjugate. The only commercially available positive control serum is of monkey origin and has been highly diluted. The end point of this control serum is not clear-cut, and the fluorescence tends to be very weak at the stated titer. Record the brightness of the staining at each dilution. The degree of staining intensity is based on the overall appearance of the smear. Specifically, a single bright area in an otherwise dimly fluorescent well should be ignored, as should fluorescent bits of yolk sac and filamentous bacterial cells that have a fluorescence intensity different from the majority of other bacteria in the well. Novices to this procedure should pay special attention to the appearance and fluorescence intensity of negative controls, especially wells containing bacteria, PBS, and secondary antibody. Otherwise, wells containing nonfluorescing but visible bacteria may be mistakenly thought to contain dimly fluorescent bacteria.

Scoring Fluorescence Intensity

4+ = maximal fluorescence; brilliant yellow-green staining of bacterial cells

3+ = bright yellow-green staining

2+ = definite but dim yellow-green staining

1+ = barely visible yellow-green staining

Negative = absence of yellow-green specific fluorescence

Serum titration end point (titer): the reciprocal of the highest dilution of serum giving 1+ fluorescence of at least half the number of *Legionella* bacteria in the field

Quality Control Testing

Each day the test is performed, tests of positive and negative controls must be carried out. The control sera should give the expected titers within one twofold dilution. If a negative control serum is not used, the negative control wells of conjugate plus antigen and of antigen alone must have been read as negative. If the control results are not within acceptable limits, the run must be repeated.

Test Interpretation

Providing that the results of quality control tests are acceptable and that sera were tested in parallel, a fourfold rise in titer to ≥128 from the acute to the convalescent phase provides evidence of a recent infection for *L. pneumophila* SG1. A single high titer of ≥256 is compatible with no disease, past disease, or current disease; however, an *L. pneumophila* SG1 antibody titer of ≥1,024 is very unlikely to be found in the normal population and could reasonably be interpreted to be compatible with past or, more likely, current disease. A single negative serum specimen is compatible with current or past disease and failure to produce antibody or with nondisease. The interpretation, or definition, of elevated high titers or seroconversion for antigens other than *L. pneumophila* SG1 is uncertain.

Antigen Preparation for Indirect Fluorescent-Antibody Test

Materials and Equipment

Bent glass rod or Pasteur pipette, sterile
Pasteur pipettes, sterile
16- by 120-mm glass screw-cap test tubes, sterile
10-ml volumetric pipettes, sterile
1-ml volumetric pipettes, sterile
Micropipette tips, sterile
Hot plate
Beaker for boiling-water bath
Bacteriological loop
Microcentrifuge
Micropipettor
Microcentrifuge tubes, sterile
Spectrophotometer cuvettes, 1-cm cell width
Spectrophotometer set at 660-nm wavelength

Reagents

Sterile distilled water
Buffered charcoal yeast extract α (BCYEα) and blood agar plates
Filter-sterilized PBS (pH 7.6), 0.01 M
0.5% yolk sac in PBS containing 0.05% sodium azide
Legionella strain to be used as antigen (Table 1)

Procedure

Monovalent-Antigen Preparation

1. Maintain sterility throughout the procedure to avoid bacterial contamination of the antigen suspension.

TABLE 1 *Legionella* strains used for IFA antigens

Species and serogroup	Strain
L. pneumophila serogroup 1	Philadelphia 1
L. pneumophila serogroup 2	Togus 1
L. pneumophila serogroup 3	Bloomington 2
L. pneumophila serogroup 4	Los Angeles 1
L. pneumophila serogroup 5	Dallas 1E
L. pneumophila serogroup 6	Chicago 2
L. pneumophila serogroup 7	Chicago 8
L. pneumophila serogroup 8	Concord 3
L. pneumophila serogroup 9	IN 23
L. dumoffii	TEX-KL
L. longbeachae serogroup 1	WADS 80-537B
L. longbeachae serogroup 2	Tucker 1
L. micdadei	TATLOCK

Appropriate biosafety precautions must be used, including using a class II biosafety cabinet for preparing the antigen. Once the antigen has been boiled, it may be safely handled outside the safety cabinet. Streak *Legionella* for confluent growth on a single BCYEα plate. Incubate for 48 to 72 h at 35°C in a humidified air incubator. Harvest the growth when it is confluent but not heavy; some strains may require longer periods of incubation than others. Examine a wet mount of the harvested antigen to determine the fraction of filamentous cells present; if these constitute more than 5% of the cells present, the preparation will not be optimal. To reduce the frequency of cellular filaments, harvest younger growth and make certain that the incubator is well humidified (>85% relative humidity) and that the BCYEα medium is fresh. Some strains of non-*L. pneumophila* species (e.g., *L. gormanii* and *L. sainthelensi*) may require a 3 to 5% CO_2 atmosphere for optimal growth without excessive filament formation. It is extremely important to use the specified strains, since aberrant results may occur when other strains are used.

2. Add 1 to 2 ml of sterile distilled water to the culture plate, and gently rub the growth off the plate with a bent Pasteur pipette. Transfer the suspension to a screw-cap sterile test tube. Subculture a loopful of the suspension to a blood agar plate to check for contamination by other bacteria; incubate for 3 days at 35°C in 5% CO_2 before reading. Discard the suspension if contamination is detected.

3. Place the tube containing the bacterial suspension in a boiling-water bath (not a dry heating block) for 15 min.

4. Centrifuge the tube contents for 1 minute in a microcentrifuge tube at ca. $14,000 \times g$.

5. Discard the supernatant fluid, and resuspend the bacterial cell sediment in 2 ml of sterile distilled water.

6. Prepare 1:100, 1:200, 1:400, and 1:800 dilutions of the resuspended organism in filter-sterilized PBS.

7. Check the optical densities (OD) of the antigen dilutions, using a spectrophotometer set at 660 nm, using PBS or distilled water as a blank. The desired OD for the working antigen suspension is 0.09 ± 0.01. Determine approximately which dilution of antigen will give this OD, by graphical means; make this dilution, and recheck the OD. You may have to make several other dilutions near this approximate value to get the OD right.

8. Make a working dilution of antigen in 0.5% yolk sac, from the original washed boiled suspension, that corresponds to the dilution determined in the step above. A 5- to 10-ml volume of suspension is adequate for several hundred assays. Save the undiluted suspension for future use.

9. Check for contamination of the working antigen suspension by streaking a loopful of the suspension on a blood agar plate. Examine the plate after 2 days of incubation at 35°C in 5% CO_2. Discard the suspension if contamination is detected.

Polyvalent-Antigen Preparation

1. Choose the four strains of *Legionella* which are to be used together as polyvalent antigen. Prepare each strain separately as for monovalent antigen. Use the procedure described above, through step 7 (determination of the dilution required to give an optical density of 0.09 ± 0.01).

2. For each strain, using the 0.5% yolk sac as diluent, make a dilution twice as concentrated as that determined to be needed for monovalent antigen.

3. Pool equal-volume aliquots of the double-strength dilutions of the four strains into one test tube. This is the polyvalent antigen. Each of the four strains is now represented by organisms at one-half the concentration that would be provided in a monovalent antigen.

4. Follow step 9 above.

Quality Control

1. Determine that the bacterium from which the prepared antigen is made is of the correct serogroup by staining it with monovalent antibody specific to that serogroup. This need be done only once, providing that the stock bacterial strain is handled correctly.

2. Determine that the new antigen preparation gives results with positive and negative control antisera that agree within one twofold dilution of their stated titer. There should be about 300 to 500 organisms per ×350 magnification field.

Storage and Shelf Life

Store the working dilution and undiluted antigen suspensions at 5°C. The shelf life of the diluted suspension is about 2 to 3 months, while that of the undiluted suspension is highly variable but as long as 6 months to 1 year. New lots of working dilutions can be made from the undiluted suspension until quality control testing with positive and negative control sera gives results that are out of range.

Preparation of 3% Yolk Sac Diluent

Materials and Equipment

    Embryonated hen eggs, 12 to 14 days old, three
    10% povidone iodine
    70% isopropyl alcohol
    Forceps, two pairs, sterile
    Petri dish, 150-mm diameter, sterile
    Egg candling light
    Food blender with sterile glass jar, or sterile tissue grinder
    PBS (pH 7.6), 0.01 M, filter sterilized, containing 0.05% sodium azide, 300 ml
    Cotton gauze, sterile
    Flask, 500 ml, sterile

Procedure

1. Candle the eggs to be certain that the embryos are alive (indicated by movement, with extensive blood vessel formation).

2. Paint the top of the egg with the povidone iodine, and allow it to dry completely. Remove the iodine by

painting the egg with the isopropyl alcohol, and allow it to dry completely.

3. With the closed pointed ends of the forceps, make a small hole in the egg tops. Enlarge the holes with the forceps so that the top 25% of the egg shell has been removed. Invert the eggs over a petri dish bottom so that the egg contents fall into the dish; you may need to use your forceps to effect complete removal.

4. Using blunt dissection, separate the yolk sacs from the rest of the egg contents, and transfer them to the inverted petri dish lid. Make a small tear in the yolk sacs, and allow their contents to drain freely.

5. Transfer the yolk sacs to the tissue grinder or homogenizer, and add an equal volume of PBS. Blend or grind until homogeneous.

6. Filter the yolk sac homogenate through two layers of the sterile gauze into the sterile flask. Add 300 ml of PBS. This will make a roughly 3% solution.

7. Culture a small portion of the 3% suspension on a blood agar plate to check for sterility. Discard the lot if not sterile.

8. To make a 0.5% solution, dilute the 3% solution in PBS containing 0.05% sodium azide.

Quality Control

It is best to perform quality control tests in parallel with an old lot of yolk sac. The titers of negative and positive control sera should be within their specified range. The bacterial antigen suspended in the new lot of yolk sac should be uniformly adherent to slides without large clumps of yolk sac.

Shelf Life and Storage Conditions

Store at 5°C and handle aseptically. The yolk sac suspension is of highly variable stability, from 3 months to over 20 years.

Glycerol Mounting Fluid

A high-pH mounting fluid must be used for fluorescein isothiocyanate, since the fluorescence intensity is pH dependent; the optimal pH for maximal brightness is 9, and the pH used should not be below 8. Mounting medium is commercially available from a number of vendors.

Reagents

Glycerol (glycerin), reagent grade
Sodium bicarbonate ($NaHCO_3$), reagent grade
Sodium carbonate (Na_2CO_3), reagent grade
Deionized or distilled water, 100 ml

Procedure

1. Make stock 0.5 M buffer by adding 0.22 g of Na_2CO_3 and 4.00 g of $NaHCO_3$ to a beaker. Add 100 ml of water, and mix until completely dissolved. Check the pH, which should be 9.0 ± 0.1. If the pH is below 8.9, add a small amount of Na_2CO_3, while stirring, until the pH is correct.

2. Add 5 ml of buffer to 45 ml of glycerol, and stir to dissolve.

Quality Control

Check the pH of the buffered glycerol monthly. Discard if the pH is less than 8. Check clarity daily, and discard if the solution is cloudy.

Storage and Shelf Life

Store the buffered glycerol at room temperature. The shelf life is 2 to 4 months. The stock buffer solution should be stored in a closed high-quality glass (Pyrex type) or plastic container at 5°C for up to 6 months, as long as it remains clear and the pH is acceptable.

Immunologic Methods for Diagnosis of Spirochetal Diseases

VICTORIA POPE, MARY D. ARI, MARTIN E. SCHRIEFER, AND PAUL N. LEVETT

56

BIOLOGIC CHARACTERISTICS OF THE ORDER *SPIROCHAETALES*

The bacteria that comprise the order *Spirochaetales* (Table 1) have in common a helical shape and two or more axial filaments (periplasmic flagella) permanently wound around a cytoplasmic cylinder and enclosed by an outer sheath (3). Although enclosed and not in contact with the environment, as are the flagella of other bacteria, the flagella of the spirochetes still rotate to produce the characteristic corkscrew movement of the organisms, enabling them to move through environments of relatively high viscosity, such as intracellular space, that block the flagellar motion of other bacteria. Nine genera are found within the order (3, 16), but only three contain human pathogens. They differ morphologically in thickness, length, number of spirals, and spiral depth. All seven genera within the family *Spirochaetaceae* lack the hooked end of the family *Leptospiraceae*. The spirochetes differ in their nutritional requirements as well (Table 1). Some species, such as *Borrelia hermsii*, grow in vitro on artificial media with little difficulty (16), whereas others, such as the subspecies of *Treponema pallidum*, are extremely difficult or impossible to culture in vitro. Even though growth requirements vary greatly within the same genera, species differentiation is not usually based on growth characteristics but rather on disease manifestation (treponemes), animal or vector tropism (borreliae), or antigenic and serologic relationships or DNA relatedness (3, 4) (leptospires).

Clinical Characteristics

Three genera, *Treponema*, *Borrelia*, and *Leptospira*, contain pathogenic spirochetes (Table 2) (3, 16). Only named species clearly shown to cause disease in humans are included in Table 2. All spirochetal diseases share remarkable similarities in clinical manifestations, including spirochetemia early in the course of the disease, dissemination of spirochetes to body organs, skin lesions, one or more stages of disease frequently interrupted by periods of latency, and neurologic and cardiac involvement (34). Syphilis is the most common spirochetal disease in the United States, with the most recent estimate being 32,871 newly reported cases in 2002. About 100 cases of leptospirosis and 20 cases of tick-borne relapsing fever are reported in the United States each year.

Etiologic Diagnosis

For the spirochetal diseases, direct dark-field microscopic examination often provides an immediate means of presumptive diagnosis. If a specific fluorescein-, alkaline phosphatase-, or peroxidase-labeled conjugate is used, the identification is definitive. *Borrelia burgdorferi*, the subspecies of *T. pallidum*, and *Treponema carateum* may be detected in skin lesions. *T. pallidum* subspecies *pallidum*, *B. burgdorferi*, and *Leptospira* spp. may be detected in biopsied material from organs or tissues and in some body fluids. The *Borrelia* species causing relapsing fever may be detected by dark-field examination of blood or Giemsa staining of a blood smear. With the exception of the pathogenic *Treponema* spp. and some noncultivatable species of *Borrelia*, culture may also provide a preliminary diagnosis.

Serologic tests (Table 3) play a primary role in the diagnosis of syphilis and provide a presumptive diagnosis for leptospirosis but are only emerging as aids in the diagnosis of relapsing fever. Syphilis, borreliosis, and leptospirosis have many serodiagnostic assay methods in common. However, each of these test procedures has been modified for a specific etiologic agent and may play a different role in the diagnosis of that particular disease. Therefore, the test procedures are described for a specific disease rather than in general terms.

Collection of Specimens for Serologic Tests

In general, serum is the specimen of choice. Plasma or cerebrospinal fluid (CSF) may be an appropriate sample for some of the serologic tests. If serum samples are to be stored, use a mechanical pipetting device to carefully transfer serum to a labeled storage tube. Samples should be stored at 4 to 8°C if they are to be tested within a few days; otherwise, storage at −20°C is preferred. Freeze-thawing should be avoided. Single serum samples are appropriate for syphilis testing, but both acute- and convalescent-phase serum samples should be collected for leptospirosis. Tubes containing specimens should always be stored upright. When shipping a sample to a reference laboratory, secure the top and seal it with tape or Parafilm. Place the tube containing the sample in a container, with absorbent tissue impregnated with germicide. Place specimen documentation around the outside of this sealed container, and place both in a container that cannot be crushed during shipment.

TABLE 1 Characteristics of the order *Spirochaetales*

Organism	Habitat	Distinguishing features
Spirochaetaceae	Worldwide	Utilize carbohydrates or amino acids as carbon and energy sources; do not utilize long-chain fatty acids or alcohols
Spirochaeta	Free-living in aquatic environments	Utilize carbohydrates as carbon and energy sources
Cristispira	Digestive tract of mollusks	Crest or ridge (crista) on protoplasmic cylinder
Treponema	Mouth, intestinal tract, and genital area of humans and animals	Utilize carbohydrates and amino acids as carbon and energy sources
Borrelia	Rodents, reptiles, bats, birds, armadillos, monkeys, humans, horses, and ruminants	Stain with aniline dyes; arthropod vector borne; microaerophilic
Serpulina	Intestinal tract of pigs	Growth on tryptose blood agar
Brachyspira	Intestinal tract of humans	Growth on tryptose blood agar
Anguilina	Intestinal tract of humans, and pigs	
Leptospiraceae	Worldwide	Utilize long-chain fatty acids or long-chain fatty alcohols as carbon and energy sources
Leptospira	Free-living in surface water and moist soil, or animal and human host associated	One or both ends hooked
Leptonema	Worldwide	Intracytoplasmic tubules; growth in Trypticase soy broth without blood

TABLE 2 Spirochetal diseases of humans

Etiologic agent	Disease	Mode of transmission	Geographical distribution
Treponema species			
T. pallidum subsp.			
pallidum	Syphilis	Sexual	Worldwide
pertenue	Yaws	Contact with lesion	Tropical climates
endemicum	Nonvenereal endemic syphilis (bejel)	Contact with lesion or lesion material	Middle East, Africa, Southeast Asia, and former Yugoslavia
T. carateum	Pinta	Contact with lesion	Tropical climates of South America
Borrelia species			
recurrentis	Relapsing fever	Louse	Europe, Asia, Africa, possibly South America
caucasica	Relapsing fever	Tick	Caucasus to Iraq
crocidurae	Relapsing fever	Tick	Africa, Near East, Central Asia
duttoni	Relapsing fever	Tick	Africa
hermsii	Relapsing fever	Tick	Western United States, Canada
hispanica	Relapsing fever	Tick	Spain, Portugal, Morocco, Algeria, Tunisia
latyschewii	Relapsing fever	Tick	Iran, Central Asia
mazzotti	Relapsing fever	Tick	Mexico, Guatemala
parkeri	Relapsing fever	Tick	Western United States
persica	Relapsing fever	Tick	Middle East, Central Asia
turicatae	Relapsing fever	Tick	United States, Mexico
venezuelensis	Relapsing fever	Tick	Central and South American
burgdorferi	Lyme disease	Tick	Northern hemisphere
afzelii	Lyme disease	Tick	Eurasia
garinii	Lyme disease	Tick	Eurasia
Leptospira species			
interrogans	Leptospirosis	Zoonoses	Worldwide
borgpetersenii	Leptospirosis	Zoonoses	Worldwide
santarosai	Leptospirosis	Zoonoses	Worldwide
inadai	Leptospirosis	Zoonoses	Worldwide
noguchi	Leptospirosis	Zoonoses	Worldwide
weilii	Leptospirosis	Zoonoses	Worldwide
kirschneri	Leptospirosis	Zoonoses	Worldwide
meyeri	Leptospirosis	Zoonoses	Worldwide
alexanderi	Leptospirosis	Zoonoses	China

TABLE 3 Tests for diagnosis of spirochetal diseases

Disease	Assay method	Test	Use
Syphilis	Flocculation (cardiolipin, lecithin, cholesterol antigen)	Venereal Disease Research Laboratory (VDRL) slide; unheated serum reagin (USR); RPR 18-mm-circle card test; toluidine red unheated serum test (TRUST)	Serologic screening; treatment monitoring; presumptive diagnosis
	Hemagglutination	T. pallidum hemagglutination assay	Confirmation of screening test results
	Agglutination	TP-PA	Confirmation of reactive screening test results
	Direct microscopic examination	Dark-field microscopy	Visualization of treponemes in lesion exudates
	DFA (monoclonal or absorbed polyclonal antibody-T. pallidum conjugate)	DFA-TP	Definitive diagnosis of T. pallidum in lesion material or tissue sample
	IFA (polyclonal antibody-human conjugate, human gamma chain-specific conjugate, T. pallidum antigen)	FTA-ABS FTA-ABS DS	Confirmation of reactive screening test results
	Immunoassays	ELISA, Western blot	Confirmation of reactive screening test results
	Molecular antigen detection methods	PCR	Detection of T. pallidum in ulcers, CSF, blood
Leptospirosis	Indirect hemagglutination	IHA	Serologic screening in early stages of disease
	Agglutination	Macroscopic slide agglutination test	Serologic screening
	Agglutination lysis	MAT	Serologic screening and confirmation of other screening assays
	Immunohistochemistry (anti-Leptospira conjugate)	Immunochemistry for Leptospira	Detection of leptospires in formalin-fixed tissues
	Immunoassays	ELISA, Dip-S-Ticks, LEPTO dipstick	Serologic screening
Borreliosis	Direct microscopic examination	Dark-field microscopy; Wright- or Giemsa-stained blood smears	Screening blood to visualize borrelia
	Immunoassays	IFA; ELISA; Western blotting	Serologic screening

METHODS

Syphilis

For the laboratory-assisted diagnosis of syphilis, each test method (antigen detection, screening tests, and confirmatory tests) has a role in the diagnosis of syphilis and may be used singly or in combination with other tests, depending on the stage of syphilis or the patient population studied.

DFA-TP Test

Clinical indications

The direct fluorescent-antibody test for T. pallidum (DFA-TP) (19) is a practical alternative to dark-field microscopy and is the most specific means of diagnosing syphilis in most clinical laboratories. The demonstration of T. pallidum in lesion material or tissue in primary, secondary, early congenital, or infectious early latent stages constitutes a positive diagnosis for syphilis. All genital lesions should be examined for T. pallidum, even if the lesion is atypical and the individual does not belong to a population considered at high risk. In persons who are members of a high-risk group, all lesions, including oral, anal, and skin lesions, should be examined, because the lesions of syphilis can resemble lesions related to various conditions from psoriasis to Lyme disease to human

immunodeficiency virus (HIV) infection. The DFA-TP examination of tissue and body fluids is particularly valuable in the diagnosis of congenital syphilis. Specimen sources include (but are not limited to) amniotic fluid, placenta, umbilical cord, mucous patches, nasal discharge, and skin lesions. In the diagnosis of tertiary or late-stage syphilis, DFA-TP plays a lesser role; however, the CSF, brain biopsy tissue, aqueous humor, synovial fluid, and tissue from gummas may serve as specimen sources.

Equipment

Fluorescence microscope assembly

Slide board or holder

Moist chamber

35 to 37°C incubator

Bibulous paper

Adjustable micropipettors able to deliver 30 μl

Rubber bulbs, approximately 2-ml capacity

Disposable capillary pipettes, 5.75 in. (ca. 14.6 cm) long

Microscope slides, 1 by 3 in. (ca. 2.5 by 7.6 cm), frosted end, approximately l mm thick

Coverslips, no. 1, 22 by 22 mm

Reagents

Sterile distilled water

Phosphate-buffered saline (PBS), pH 7.2

PBS, pH 7.2, with 2% Tween 80

Methanol, reagent grade

Mounting medium (one part buffered saline [pH 7.2] plus nine parts reagent grade glycerol)

Fluorescein isothiocyanate (FITC)-labeled anti-*T. pallidum* globulin that has been absorbed with the non-pathogenic *Treponema phagendenis* biotype Reiter treponeme and demonstrated to stain only *T. pallidum* after absorption, or FITC-labeled monoclonal antibody to *T. pallidum*

Sample Preparation

Body fluids, exudates, or macerated tissue.

1. Body fluids, lesion exudates, suspensions of macerated tissue, or other materials should be well mixed with a disposable pipette and rubber bulb to ensure even distribution of material.

2. If quantity allows, organisms in spinal fluids and aqueous humor fluids should be concentrated by centrifugation ($17,300 \times g$ for 30 min). Supernatant fluid is carefully removed, and slides are made from the sediment.

3. Smears prepared in the clinic should be air dried. If they are being shipped to a reference laboratory, they should be mailed without fixation.

Tissue sections.

1. Cut sections from paraffin-embedded tissues at 2 μm, attach to slides with gelatin in a 44°C flotation water bath, and dry in an oven at 60°C for 20 min.

2. Deparaffinize tissue sections in two 3-min changes of xylene.

3. Rehydrate tissue by passage through two changes of absolute alcohol, 95% ethyl alcohol, and 80% ethyl alcohol, respectively, and place in PBS (pH 7.2).

4. Treat deparaffinized slides in one of the following ways.
  (a) NH₄OH treatment
    (i) Flood deparaffinized tissue sections on microscope slides for 3 min with PBS (pH 7.2) containing 1% NH₄OH.
    (ii) Wash the slides for 10 min in 3% Tween 80 in PBS, and rinse in two 5-min changes of PBS.
    (iii) Rinse briefly in distilled water. Blot dry around tissue borders.
  (b) Trypsin treatment
    (i) Flood deparaffinized tissue sections on microscope slides with PBS (pH 7.2) containing 0.25% trypsin (1:250 trypsin; ICN Biochemicals).
    (ii) Place slides in a moist chamber, and incubate at 37°C for 30 min.
    (iii) Rinse slides in three 5-min changes of PBS.
  (c) Microwave treatment
    (i) Place slides in glass slide holder. Place holder in microwavable container that will hold 500 ml. Add 500 ml of PBS (pH 7.2).
    (ii) Place in microwave set on high. Boil for 5 min.
    (iii) Remove from microwave, and allow to cool for 5 min. Remove slides, and briefly rinse them in PBS.

Controls

Positive control. Smears made from FTA-ABS antigen or testicular impression smears made from *T. pallidum*-infected rabbits must be included. If tissue sections are the samples being stained, a section from an infected tissue should be used.

Negative control. Smears made from washed nonpathogenic Reiter treponeme cultures, freshly obtained human mouth treponemes, or washed *T. denticola* biotype microdentium cultures may be included.

Procedure for Staining

Exudates.

1. Spread approximately 10 μl of test material within each circle or l-cm area of clean, grease-free slide, and allow to air dry. If possible, four smears should be prepared for each specimen.

2. Fix the slides in 100% methanol for 10 s. All slides from an individual patient must be handled separately throughout the staining process.

3. Cover each circle with approximately 30 μl of diluted conjugate or with a sufficient amount to cover the smear, and place the slides in a moist chamber at 35 to 37°C for 30 min.

4. Rinse the slides individually with PBS, and cover the slides, placed on a staining rack, with PBS for a total of 10 min. Follow with a brief final rinse in distilled water. Reactive controls and nonreactive controls may be rinsed in the same staining dish.

5. Drain the slides to remove excess water. Blot areas outside of the smears with bibulous paper if necessary. Place a very small drop of mounting medium on each circle, and apply a coverslip. (The mounting medium should be dropped from a disposable capillary pipette. Discard any medium left in the pipette.)

Tissues.

1. Dilute the FITC-labeled anti-treponemal monoclonal conjugate in 2% Tween 80 in PBS containing a 1:20,000 concentration of Evans blue dye.

2. Cover tissue sections with 30 μl of the diluted conjugate.

3. Place slides in a moist chamber for 30 min at 35 to 37°C.

4. Rinse slides in two 5-min changes of PBS, briefly rinse in distilled water, allow to drain, and blot along the edge to remove any residual water.

5. Place a very small drop of mounting medium on each circle, and cover with a no. 1 coverslip. (The mounting medium should be dropped from a disposable capillary pipette. Discard any medium left in the pipette.)

Reading Test Results

1. Use a microscope equipped with UV and tungsten light sources for observations. When an HBO-200 mercury bulb is used, a BG-12 exciter filter or a KP490 filter may be used in combination with an OG-1 barrier filter (K510 or K530).

2. A 45× high-dry objective is used for scanning the area, and a 100×/1.25 oil immersion objective is used for verification. (For fluorescent-antibody [FA] testing with transmitted illumination, the oil immersion objective must be fitted with a funnel stop or equipped with a built-in iris diaphragm.)

3. Scan the complete smear or tissue section. If definite evidence of typical fluorescing treponemes is observed, verify morphology using a 100× oil immersion objective.

Reporting Results

1. If FITC-stained treponemes are observed, report: "Treponemes, immunologically specific for *T. pallidum*, were observed by direct immunofluorescence."

2. If no treponemes were observed, report: "No treponemes were observed by direct immunofluorescence."

Precautions and Potential Problems

During the fixation and rinsing of smears, treponemes may be washed off the slides, particularly the control slides, and can adhere to other smears. Therefore, smears from patients must be handled individually to prevent *T. pallidum* organisms from adhering to nonreactive smears, resulting in a false-positive report. If staining dishes are used for controls, they must be cleaned after each use.

Failure to demonstrate *T. pallidum* from a syphilitic lesion may be caused by the age or condition of the lesion, treatment of the patient before the specimen was taken, or, most commonly, poor technique in collecting the specimen.

If a precipitate occurs in the labeled globulin, the precipitate should be removed, because artifacts about the same size as *T. pallidum* may interfere with the correct reading of the slide. This can occur with staining of both lesion and biopsy material. Poor technique in processing tissues and prior treatment of the patient adversely affect DFA-TP staining in tissues.

Rapid Plasma Reagin (RPR) 18-mm-Circle Card Test

Clinical Indications

Humoral antibodies, both immunoglobulin M (IgM) and IgG, as detected by the nontreponemal test for syphilis, usually do not appear until 1 to 4 weeks after the primary chancre has formed. Thus, the sensitivities of the tests may vary in primary syphilis according to time the blood is drawn after lesion formation. However, within 2 months, as the lesion begins to resolve spontaneously, all nontreponemal tests are 100% reactive. Because the disseminated lesions of the secondary stage take many forms, the nontreponemal tests are used to distinguish the lesions of syphilis from those of other infections or conditions. In addition, serologic tests for syphilis may be the only means of identifying individuals with untreated syphilis during the latent periods of infection.

Reactive nontreponemal test results should be quantitated. The titer of the nontreponemal tests will decrease with adequate treatment. When an individual is treated during the primary or secondary stage of a first infection with *T. pallidum*, the titer should show a 2-dilution decline after treatment, usually within 6 months. Patients who are treated in the latent or late stages of syphilis, have had more than one infection with syphilis, or are infected with HIV frequently show a more gradual decline in titer. Persistent seroreactivity does not necessarily signify treatment failure. However, a 2-dilution or fourfold increase in titer usually indicates a treatment failure or a reinfection.

Kit

Kits for the RPR 18-mm-circle card test (19), the most commonly used nontreponemal test, contain test antigen, disposable 20-gauge needle, antigen-dispensing bottle, plastic-coated test cards, and disposable sampling straws-spreaders or stirrers. Some kits also contain control serum samples with specified reactivities of reactive, minimally reactive, and nonreactive.

Control Serum Samples

The reactive, minimally reactive, and nonreactive control sera are used to test the antigen suspension each day of use to confirm optimal reactivity before routine testing is performed and are not intended to be used as reading standards. Only RPR card antigen suspensions that produce the established reactivity pattern of the control serum samples should be used. The minimal reactive control is the most critical and is the first indicator of problems with the antigen, such as deterioration, which reduces reactivity.

Equipment

Mechanical rotator with fixed speed or adjustable to 100 ± 2 rpm circumscribing a circle 2 cm (3/4 in.) in diameter on a horizontal plane.

Humidity cover. Any convenient cover containing a moistened blotter or sponge can be used to cover cards during rotation.

Safety pipetting device. Must deliver 0.05 ml (50 μl) of reagent for use in the quantitative test and may also be used for the qualitative test.

Light source for reading test results. A high-intensity lamp can be used.

Reagents

0.9% saline. A 900-mg portion of dry sodium chloride (ACS) is used for each 100 ml of distilled water.

Diluent. A 1:50 dilution of serum nonreactive for syphilis prepared in 0.9% saline should be used in the quantitative procedure for making 1:32 and higher dilutions of serum specimens.

Antigen. Antigen suspension is stored in ampules or in the antigen-dispensing bottle at 2 to 8°C. An unopened ampule of antigen is stable until the expiration date. Antigen suspension in the plastic dispensing bottle (stored at 2 to 8°C) is stable for 3 months or until the expiration date, whichever is earlier. The suspension must not be used beyond the expiration date. A new lot of antigen suspension should be tested in parallel with a reference reagent to verify that it is of standard reactivity before it is placed in routine use.

Qualitative Test

Note: All flocculation tests for syphilis are affected by room temperature. For reliable and reproducible results, control serum samples, RPR card test antigen suspension, and test specimens must be at room temperature, 23 to 29°C (73 to 85°F), when tests are performed.

1. With a dispensing or an automatic pipetting device that delivers 0.05 ml (50 μl), place 50 μl of serum onto an 18-mm circle of the RPR test card.

2. With the reverse end of the dispensing device or with a toothpick, spread the specimen to fill the entire circle. Take care not to allow the serum to spread beyond the confines of the circle. Use a clean spreader for each sample.

3. Gently resuspend the RPR antigen suspension. Hold the dispensing bottle in a vertical position, and add exactly 1 free-falling drop (1/60 ml) of suspension to each test area containing serum.

4. Place the card on a mechanical rotator under a humidity cover.

5. Rotate for 8 min at 100 rpm.

6. Read the test reactions in the wet state under a high-intensity light source immediately after removing the card from the rotator. Read the test without magnification. To better differentiate minimally reactive from nonreactive serum, immediately after rotation tilt the card to about 30° from horizontal and briefly rotate the card manually.

7. Report the results as follows.

Reactive: Characteristic clumping of the RPR card antigen from slight but definite (minimally reactive) to marked and intense (reactive).

Nonreactive: No clumping of RPR card antigen or only slight "roughness."

Note: Results are reported as reactive or nonreactive regardless of the degree of reactivity. Slight but definite flocculation should always be reported as reactive.

Specimens giving any degree of reactivity should be quantitated. Rough nonreactive results should also be quantitated to identify possible prozone reactions.

8. On completion of the daily tests, remove the needle, rinse it with distilled or deionized water, and air dry. (Avoid wiping the needle because this removes the silicone coating.) Recap the dispensing bottle, and store it in the refrigerator.

Quantitative Test

1. For each specimen to be tested, place 50 µl of 0.5% saline onto circles 2 through 5. Do not spread the saline.

2. Using a safety pipetting device, place 50 µl of serum specimen onto circles 1 and 2.

3. Mix the saline and the specimen in circle 2 by drawing the mixture up and down in the safety pipettor eight times. Avoid the formation of bubbles. Continue making serial dilutions through circle 5. Discard 50 µl from circle 5.

4. Using a clean stirrer for each specimen, start at the highest dilution (1:16, circle 5), and with the broad end of the stirrer, spread the serum dilution within the confines of the circle. Repeat this action using the same sampling stirrer in circles 4, 3, 2, and 1.

5. Gently resuspend the RPR card antigen suspension in the dispensing bottle. Hold the antigen suspension bottle in a vertical position, dispense 1 or 2 drops to clear the needle of air, and then place exactly 1 free-falling drop (1/60 ml) of antigen suspension onto each test area.

6. Place the card on the rotator under a humidity cover. Rotate for 8 min at 100 rpm.

7. Read the test reactions as described in step 6 of the qualitative test (above).

8. Report results in terms of the highest dilution giving any reactivity, in accordance with the examples in Table 4.

9. If the highest dilution tested (1:16) is reactive, proceed as follows:

(a) Prepare a 1:50 dilution (2.0%) of nonreactive serum in 0.9% saline (this is to be used for making 1:32 and higher dilutions of specimens to be quantitated).

(b) Prepare a 1:16 dilution of the test specimen by adding 100 µl of the specimen to 1.5 ml of 0.9% saline. Mix thoroughly.

(c) Place 50 µl of the 1:50 nonreactive serum in circles 2, 3, 4, and 5 of an RPR card.

TABLE 4 Reporting results of the RPR card test on serum (quantitative test)[a]

Reaction with undiluted serum (1:1)	Reaction at serum dilution of:				Report
	1:2	1:4	1:8	1:16	
Rm	N	N	N	N	Reactive, 1:1 dilution or undiluted only
R	R	N	N	N	Reactive, 1:2 dilution
R	R	Rm	N	N	Reactive, 1:4 dilution
R	R	R	R	N	Reactive, 1:8 dilution

[a]Abbreviations: N, nonreactive; R, reactive; Rm, minimally reactive.

(d) Place 50 µl of the 1:16 dilution of the test specimen onto circles 1 and 2.

(e) Using the same pipettor, make serial twofold dilutions, and complete the test as described under steps 2 through 8 (RPR card quantitative test). Higher dilutions may be prepared, if necessary, in a similar manner.

Note: All dilutions may be made on the card if the 1:50 nonreactive serum is used as the diluent from circle 6 (1:32) on.

Interpretation of Results

Interpretation of the results must be based on the population being tested and the stage of syphilis suspected. When the nontreponemal tests are used as a screening test in a low-risk population, all reactive results should be confirmed with a treponemal test.

In pregnancy, irrespective of reports in the literature of false-positive results in the nontreponemal test in expectant mothers, reactive results should be confirmed with a treponemal test, and if it is reactive, the patient should be treated unless she has documented adequate treatment and declining antibody titers. In congenital syphilis, at birth the nontreponemal tests for syphilis measure passively transferred maternal IgG as well as infant IgM. If the nontreponemal test titer for the infant is higher than that of the mother, some clinicians interpret these results as indicative of congenital syphilis, but infants with congenital syphilis frequently have a titer lower than the mother's titer.

Precautions and Potential Problems

Most of the problems in nontreponemal test performance can be avoided if instructions for test performance, reagent control, and general quality control are carefully followed. Test results with plasma specimens improperly collected, e.g., collection tube only partially filled, or with specimens tested more than 24 h after collection can appear as minimally reactive. Cord blood samples may also react in this manner. Because of these problems, the use of plasma and/or cord serum should be restricted to special testing situations.

Problems which cannot always be avoided result in test misinterpretation by the physician as well as the laboratory. Prozone reactions occur in 1 to 2% of patients with secondary syphilis. These specimens may exhibit a nonreactive pattern which is slightly granular or "rough" or show an atypical appearance. On dilution, the reactivity increases and then decreases as the end-point titer is approached. All tests with a rough appearance should be quantitated to render a dilution that will surpass the prozone.

Another problem is that of false-positive results, which occur in the general population at a rate of between 1 and

2% regardless of the nontreponemal test used. In populations of intravenous drug users, more than 10% of the sera may give false-positive test results. Acute false-positive reactions lasting less than 6 months usually occur after various febrile diseases, shortly after vaccinations, and during pregnancy. Chronic false-positive reactions are more often associated with autoimmune diseases such as arthritis and lupus, the aging process, or chronic infections such as leprosy. False-positive titers are usually less than 1:8, but low titers are also seen in latent and late syphilis and high-titer false-positive results are associated with intravenous drug use and lymphomas. False-positive test results may be excluded through repetition of the test, confirmation with a treponemal test, and subsequent testing of a second specimen.

Test misinterpretation most often results from (i) failure to recognize that a variation of ±1 dilution is inherent in most serologic tests, (ii) failure to establish the true positivity of test results, and (iii) failure to obtain adequate patient history. A particular error which leads to misinterpretation involves using more than one nontreponemal test to monitor treatment. Initially, all serum samples should be tested in a qualitative nontreponemal test. The same nontreponemal test should be used for subsequent quantitative testing, since up to a fourfold difference in end-point titer may result with certain serum samples when they are tested by different nontreponemal tests.

TP-PA Test

Clinical Indications
The need to perform a treponemal test is related to the results of the nontreponemal test. Treponemal tests should be performed when clinical signs or patient history disagree with the nontreponemal test result. In general, only when late syphilis is suspected should the treponemal test be performed when the nontreponemal test is nonreactive. The *T. pallidum* particle agglutination (TP-PA) test (19) is more widely used than the fluorescent treponemal antibody-absorption test for confirmatory testing of nontreponemal test results or clinical impression.

Equipment
Safety pipetting devices capable of delivering 100 and 25 µl
Pipettes, 1.0 ml serologic, for reconstituting reagents
Vibratory shaker
Polystyrene microplates with U-shaped wells
Tray viewer (optional)

Reagents
All reagents are supplied in the kits (Fujirebio America, Inc., Wilmington, Del.).

Controls
A positive control, which is serially diluted, and a negative control are included in each test run. The sensitized and unsensitized particles are monitored for nonspecific agglutination, and each sample is tested with sensitized and unsensitized particles to check for anti-*T. pallidum* antibodies and nonspecific antibodies that may cause false positive reactions.

Procedure
Four wells are required for each patient sample and negative control run in the test (eight wells for reactive control). Wells 1 and 2 are for dilution of the sample, well 3 is for the unsensitized particles, and well 4 (wells 4 to 8 for the reactive control) is for the sensitized particles.

1. Add 100 µl of the sample diluent to well 1 and 25 µl to wells 2 to 4 (2 to 8 for the reactive control).
2. Using a micropipettor, add 25 µl of patient sample or control to well 1.
3. Mix the contents of well 1 by filling and discharging the micropipette five or six times. Using the micropipette, transfer 25 µl of the diluted serum sample from well 1 to well 2. Mix the contents of well 2, and transfer 25 µl to well 3. Mix the contents of well 3, and transfer 25 µl to well 4. Mix the contents of well 4, and discard 25 µl. (For the reactive control, continue the procedure through well 8 and discard 25 µl from well 8.)
4. Add 1 drop (25 µl) of unsensitized particles to well 3 and 1 drop (25 µl) of sensitized particles to well 4 (wells 4 to 8 for the reactive control) using the droppers supplied in the kit.
5. Repeat the process for each patient sample.
6. Mix the contents of the wells thoroughly by placing on a vibratory mixer for 30 s or tap the plate sharply several times with a finger. Cover the plate with a microplate cover or empty microplate. Allow the plate to sit undisturbed at room temperature for 2 h before reading. Alternatively, the plate can incubate overnight and be read the next morning.
7. Place the plate on a flat surface against a white background to observe the agglutination pattern for each well. A plate viewer may be used to aid visualization of the reaction. Observe the agglutination pattern for each patient and control well. Ensure that the well containing the unsensitized particles is nonreactive. Record the agglutination according to the criteria in Table 5.

Interpretation of Results
Treponemal tests vary in their reactivity in early primary syphilis. Reactivity in these tests appears at approximately the same time as reactivity in nontreponemal tests. In secondary and latent stages of syphilis, the treponemal tests are usually 100% reactive. The sensitivity declines somewhat in the late stage of syphilis to about 95%. In approximately 84% of cases of syphilis, once the treponemal tests are reactive they remain reactive for life. Treponemal tests are qualitative and are not recommended for monitoring of reinfection or the efficacy of treatment. In babies with possible congenital syphilis, all treponemal tests that detect IgG antibodies may be reactive. Passively transferred maternal IgG treponemal antibodies should be catabolized and undetectable in uninfected infants by the age of 12 to 18 months.

TABLE 5 Reporting system for TP-PA test

Initial test reading	Repeat test reading	Report
2 to 4 +		Reactive
1+	>1+	Reactive
	1+	Minimally reactive[a]
	<1+	Nonreactive
<1+		Nonreactive
N[b]		Nonreactive

[a] In the absence of historical or clinical evidence of treponemal infection, this test result should be considered equivocal. A second specimen should be obtained 1 to 2 weeks after the initial specimen and submitted to the laboratory for serologic testing.
[b] N, nonreactive.

Precautions and Potential Problems

Inadequate mixing of the microplate after all the regents are added, disturbance of the plate during the incubation step, the presence of dirt or dust in any of the wells of the microplate, or use of V-shaped or flat-bottom wells instead of U-shaped wells may affect the results of the test.

The TP-PA test is not intended for routine use as a screening procedure. The greatest value is to distinguish true-positive nontreponemal results from false-positive results and to establish the diagnosis of late latent or late syphilis. Problems arise when these tests are used as screening procedures, especially in low-prevalence populations, because about 1% of the general population will have false-positive results. False-positive results in the treponemal tests are often transient, and their cause is unknown.

When the treponemal test results and clinical opinion disagree, the treponemal test should be repeated and additional clinical history information should be obtained. If the disagreement persists, the specimen should be sent to a reference laboratory for additional confirmatory tests. The final diagnosis depends on clinical judgment.

EIA

There are at least two types of enzyme immunoassay (EIA) on the market. One uses sonicated treponemes, and the other uses cloned antigens. The procedures for the two tests differ slightly, but in general the antigen is coated on the wells of a microtiter plate. A dilution of serum is added, and the plates are incubated at 37°C for a specific period (usually about 30 min). The plates are washed, and conjugate is added. After a 30-min incubation, the plates are again washed and an enzyme substrate is added. If the serum sample contains antibodies to *T. pallidum*, a color reaction takes place. The reaction is halted by the addition of a stop reagent, and the plates are then read at 450 nm on a microplate reader. The tests offer the advantages of being able to be automated, having an objective interpretation of results, and having a hard copy of the results automatically printed.

The EIAs were originally cleared by the Food and Drug Administration for confirmatory testing, but one test has received clearance as a screening test. A disadvantage of using the EIA as a screening test is that because it is a treponemal test, it will remain reactive for life in approximately 84% of all persons who have ever had syphilis. As with all serologic tests, there is also some nonspecificity, although for treponemal tests it is generally only around 1%. When it is used as a screening test, all reactive results must be followed up with a nontreponemal test. This will help determine whether an active case of syphilis is present and will give a baseline titer for determining treatment efficacy if a new case of syphilis has been detected. Because the test can be automated, large numbers of samples can be tested by fewer technicians than when manual procedures are used. In some populations, such as intravenous drug users or people with autoimmune diseases, there will also be fewer false-positive results when the EIA is used for screening, because antitreponemal antibodies rather than anti-cardiolipin antibodies are being detected. In addition, prozone reactions are eliminated because the detection method is dependent on attachment of antibodies rather than on flocculation.

Molecular Biology-Based Techniques

Molecular biology-based techniques, using unique sequences of *T. pallidum* DNA, are being used to detect the spirochete for definitive diagnosis and for typing of subspecies and strains of *T. pallidum*. None of the procedures being used are currently available commercially, nor is there any universal technique for either detection or subtyping.

PCR

PCR can be used on CSF or blood, lesion exudates, or tissues to detect the presence of *T. pallidum* (25, 29). There is no standardized method or target. The target used at the Centers for Disease Control and Prevention is the polymerase A (*polA*) (25) gene. PCR has advantages over some of the other antigen detection methods such as DFA-TP. PCR does not depend on the organisms being alive or intact, and fewer organisms can be detected than when using DFA-TP or dark-field microscopy (25). Because the methods are not commercially available, PCR is generally restricted to the larger laboratories. The procedure is not cleared by the Food and Drug Administration; therefore, it must be considered an experimental procedure.

Subtyping

Subtyping for *T. pallidum* done at the Centers for Disease Control and Prevention is based on two genes that exhibit intrastrain variability, the genes encoding the acidic repeat protein (*arp*) and the *T. pallidum* repeat (*tpr*) protein (31). The method appears to be useful for epidemiologic purposes. The number of repeats of *arp* varies from 4 to 25 in different strains of *T. pallidum*. The *trp* gene has several unique MseI restriction fragment length polymorphism patterns labeled a to g. Using a combination of the number of *arp* repeats (4 to 25) and *tprJ* restriction fragment length polymorphism patterns (a to g), a workable, discriminating typing scheme has been developed (31). Using this system, the Nichols strain is determined to be subtype 14a. In addition to differentiating among strains of *T. pallidum*, the typing scheme distinguishes the various pathogenic treponemes from each other. This could potentially be useful in areas of the world where the endemic treponematoses exist.

The *tpr* family of genes is composed of three subfamilies of genes: subfamily I (*tprC*, *tprD*, *tprF*, and *tprI*), subfamily II (*tprE*, *tprG*, and *tprJ*), and subfamily III (*tprA*, *tprB*, *tprH*, *tprK*, and *tprL*). *tprK* has also been used to differentiate different strains of *T. pallidum* as well as the various subspecies based on size heterogeneity in the central portions of the hydrophilic domain (6).

Leptospirosis

Most leptospiral infections are subclinical or of mild severity and may go unrecognized. The clinical presentation is difficult to distinguish from dengue, malaria, influenza, and many other diseases characterized by fever, headache, and myalgia. Icteric leptospirosis is a more severe disease characterized by rapid progression and may include liver, pulmonary, cardiac, and ocular involvement. A diagnosis of leptospirosis should also be considered in cases of unexplained jaundice, aseptic meningitis, and fever of unknown origin. Diagnosis is usually made based on the patient's clinical history, exposure history, and laboratory results. Members of some occupations are at a higher risk than the rest of the population, but recreational and hurricane or extensive flooding-related water exposures have recently become significant (18, 28, 35). The disease is fatal in 5 to 30% of all cases.

Leptospirosis can be diagnosed by detection of the organism by microscopy; culture of blood, CSF, or urine; or DNA amplification (from serum, urine, or tissues) (21). Definitive diagnosis of leptospirosis is made by isolation of leptospires from tissue or body fluids, but leptospires grow slowly on initial isolation and culture is therefore often not useful in

patient management. Most cases are therefore diagnosed by serology. However, serology cannot be used to determine the infecting serovar. This can be done only by isolation and serotyping of the organism.

Antibodies are detectable in blood about 5 to 7 days after onset of symptoms. The microscopic agglutination test (MAT) is the reference method for serologic diagnosis (11). However, the MAT is relatively insensitive when acute-phase samples are tested (7). Because of the complexity of the MAT, rapid screening tests for detection of antileptospiral IgM antibodies in acute infection have been developed, and some of these are commercially available. The diagnostic tests discussed in this chapter are the MAT, which is the standard against which all other serologic tests for leptospirosis are evaluated, and two screening tests, the IgM dot enzyme-linked immunosorbent assay (ELISA) (1, 23) and the IgM ELISA (1, 40). These assays have been extensively evaluated for use in the diagnosis of leptospirosis (21).

MAT

Clinical Indications

The MAT detects agglutinating antibodies and is considered the standard reference test for the diagnosis of leptospirosis. Agglutinating antibodies are directed against surface antigens of leptospires and are of both IgM and IgG classes. Antibodies can be detected approximately 1 week after onset of symptoms and reach maximum titers usually within 4 weeks. The use of paired sera, drawn at least 1 week apart, is required to confirm a diagnosis of leptospirosis. A fourfold increase in titer between paired sera indicates recent exposure. Low titers may persist for years after exposure, so a low titer in a single serum sample is insufficient evidence from which to make a diagnosis of leptospirosis, but a single titer of 1:800 is generally considered diagnostic in areas of endemic infection. In regions where leptospirosis is not endemic, the threshold titer for a presumptive diagnosis may be correspondingly lower.

Antibodies in serum may cross-react with several different serovars in the MAT (paradoxical reaction), particularly in acute-phase specimens (20). As the immune response matures, the cross-reactivity lessens and the test becomes relatively serogroup specific; for this reason, a battery of antigens, composed of serovars that each represent a different serogroup, is used. The serovars generally included are listed in the MAT methods section (see below). If the patient has been outside the United States recently, serovars endemic to the places visited should be included since antibodies to these may not be detected by the standard battery of antigens. The test is generally done using live spirochetes, but formalin-killed leptospires may also be used. If the latter are used, titers are lower and the reactivity is somewhat less specific (20). Regardless of which antigens are used, the MAT cannot be used to determine the infecting serovar because the test uses only 12 to 19 of the more than 200 known serovars. The antigens listed below detect antibodies to most serovars.

The MAT may be run with either human or animal sera. It is used in epidemiologic studies or outbreaks to determine the potential source of infection.

Equipment

Multichannel pipettors, 50 and 100 μl, and tips
96-well flat-bottom microtiter plates
Dark-field microscope with 10× long-working-distance objective and standard-working-distance objective
Glass microscope slides (for checking antigens)

Pipettes and pipetting devices (pipettor, rubber bulb)
Test tubes: 16- by 125-mm screw cap and 12- by 100-mm cork stoppered
Monitek model 21 nephelometer or 0.5 McFarland turbidity standard (a spectrophotometer is used in some laboratories to measure transmittance)

Reagents

Antisera. Antiserum is needed for each corresponding serovar (antigen) used in the assay. These antisera are used as homologous controls for each antigen and should have titers of ≥1:3,200 to the corresponding antigen. Antisera are available commercially from Difco Laboratories or the National Veterinary Services Laboratories, Ames, Iowa.

Antigens. A panel of serovars relevant to the testing area should be used. Commonly the panel consists of the following serovars: Alexi, Australis, Autumnalis, Ballum, Bataviae, Borincana, Bratislava, Canicola, Celledoni, Copenhageni or Icterohaemorrhagiae, Cynopteri, Djasiman, Georgia, Grippotyphosa, Javanica, Mankarso, Pomona, Pyrogenes, Tarassovi, and Wolffi.

Maintenance of culture

1. Serovars previously mentioned are grown in PLM-5 broth (Intergen Co., Purchase, N.Y.). Cultures can be grown in milk bottles (250 ml bottles).

2. Maintain cultures by transferring them weekly, using a 10% inoculum, and incubating at 30°C. The frequent transfer helps prevent excessive clumping.

Antigen preparation. Antigens for the MAT are live cell suspensions prepared from 4- to 7-day-old PLM-5 broth cultures.

1. Check cultures for use in the test by dark-field microscopy for clumping and contamination. Do not use contaminated cultures. Clumps can sometimes be dispersed by shaking.

2. With a sterile 10-ml pipette, transfer 10 ml of 4- to 7-day-old culture to a 16- by 125-mm screw-cap tube.

3. Measure the turbidity with a turbidity meter/nephelometer calibrated for the 0.5 McFarland standard. Alternatively, turbidity can be estimated visually against the 0.5 McFarland standard.

4. If necessary, dilute with sterile PBS to adjust the turbidity of each cell suspension to match the turbidity of the 0.5 McFarland standard or to measure in the range of 45 to 79 on the nephelometer.

5. After the cell suspensions have been adjusted to the appropriate turbidity, shake them vigorously to disperse any aggregates. Centrifuge cultures at 1,500 to 2,000 × g for 15 min to sediment any large clumps, and set them aside until ready to use.

Homologous Titer Determination

Test all antigens against their homologous antisera weekly. The titer obtained should be within a twofold dilution of the known titer of the homologous antiserum. If the titer is not within the acceptable range, the antigen should not be used. Three 96-well plates are required for the homologous titer determination.

1. Make an initial 1:50 dilution of antisera. Dispense 100 μl into the first wells (column 1) of each row of a microtiter plate.

2. Using 50-μl volume transfers, make a serial twofold dilution of antisera in PBS starting with a 1:50 dilution. Use

one row for each homologous serum. The last wells (column 12) should contain only PBS.

3. Add 50 µl of homologous antigen to all wells for each corresponding antiserum.

4. Tap plates gently to mix, and incubate at ambient temperature for 1.5 to 2 h. Read reactions by dark-field microscopy at a magnification of ×100, and grade on a scale of 0 to 4+. The end point is the dilution that gives 50% agglutination.

Screening Procedure

Each unknown specimen is screened against all the serovars on the antigen panel. Map out a block of wells to accommodate all specimens to be tested, including controls for each antigen, on 96-well microtiter plates. For example, a 96-well plate can be used to screen 45 specimens plus 3 controls (48 wells) against 2 antigens.

1. Make a 1:50 dilution of the patient's serum by adding 60 µl of serum to 3.0 ml of PBS (pH 7.2). Heat inactivate the diluted serum at 56°C for 30 min. Positive (homologous) and negative control sera are also diluted 1:50 (5 µl of control serum to 250 µl of PBS).

2. Screen serum samples by placing 50 µl of diluted serum into wells of 96-well flat-bottom microtiter plates. To screen eight serum samples (five unknowns and three controls) against 20 antigens, two microtiter plates (eight wells, or a column per antigen) are required.

3. For each antigen, allow wells for the positive control, a negative control, and antigen control. The antigen control well contains PBS instead of serum to check for nonspecific agglutination of the antigen.

  Note: A set of controls (negative, positive, and antigen) is required per antigen for every test run.

4. After all the serum samples have been added to the plate, add 50 µl of antigen, one per column, to all the serum samples and the controls. This is now a 1:100 dilution of serum.

5. Gently mix the contents of the plates, cover, and allow the plates to sit at room temperature for 90 min to 2 h.

6. Read the plates under a dark-field microscope, using a l0× long-working-distance objective and a 10× eyepiece.

7. Any well with at least 50% agglutination (2+), provided that the antigen control has no agglutination or only a roughness, is considered reactive.

Confirmatory Procedure

For confirmation, each serum sample with a positive agglutination reaction in the screening test should be subjected to determination of its titer against the antigens for which it is positive. Careful planning is required to map out test plates. Group all serum samples positive by each antigen to the same block of wells, using a row (12 wells) for each serum sample tested. *Note:* Titer determinations can also be done per column (eight wells) if generally specimens do not have very high titers.

1. Place 50 µl of PBS in wells of columns 2 to 12 on a microtiter plate, and place 100 µl of the serum dilution in the first well.

2. Using 50-µl volume transfers, make twofold dilutions through column 11. Discard the last 50 µl. Wells of column 12 serve as the antigen control.

3. After the serum is diluted, add 50 µl of antigen to each well.

4. Repeat steps 1 to 3 for each antigen with which the patient's serum reacted in the screen.

5. The titer is the last dilution that shows a 2+ (50%) or greater agglutination.

Note: The agglutination pattern differs from one serovar to the next. Sera that were reactive in the screening test may be nonreactive when subjected to titer determination.

Quality Control

Positive controls (homologous antisera) are included to ensure that the right antigens are used. Homologous serum titers should be within a twofold dilution of their established titer. Antigen controls are included in the assay to check for autoagglutination. The antigen control should not have more than a 1+ reaction. The negative control should not have more than a 1+ reaction.

Interpretation of Results

1. Results are reported as the reciprocal of the titer for each antigen that was reactive with that serum.

2. Titers of ≥1:100 are considered positive.

3. Nonspecific reactions may occur due to unknown factors in the patient's serum. If all or most of the sera tested are reactive with a particular antigen at the 1:100 (or screening) dilution, the antigen is too sensitive and should not be included in the run.

Precautions and Potential Problems

As mentioned above, an excessively sensitive antigen can give false-positive results. Nonspecific agglutination in the antigen control may also occur. If agglutination of ≤1+ occurs, then the end-point titer is the highest serum dilution with 3+ agglutination. Prozone reactions occasionally occur with high-titer sera. All serum samples should be treated as potentially infectious and handled using universal precautions.

A serum sample may test falsely nonreactive if the patient has been exposed to a serovar not commonly found in the home geographic area. Therefore, it is important to know the patient's travel history so that serovars representative of those geographic areas may be included in the screening test. Each laboratory must establish its own baseline antibody levels, especially in areas of endemic infection.

Cross-reactions (sometimes with significant seroconversion) have been observed with serum from patients with syphilis, relapsing fever, Lyme disease, legionellosis, viral hepatitis, and Epstein-Barr virus infection (1). Therefore, results should be interpreted with caution.

Dot ELISA Dipstick

Clinical Indications

The IgM dot ELISA is a qualitative screening test; therefore, confirmation of results is recommended. The assay detects antibodies earlier than do the agglutination assays (indirect hemagglutination assay and MAT) (1, 23) and is ideal for use when only a few specimens are tested at a time. The dot ELISA dipstick (INDX Dip-S-Ticks; PANBIO Inc., Columbia, Md.) uses a genus-specific antigen (*Leptospira biflexa* serovar Patoc) dispensed as discrete dots on a solid membrane. The patient sample is added to diluent containing Prosorb-G, which adsorbs the IgG in the test serum. Diluted serum reacts with the antigens on the assay strip, and alkaline phosphatase-conjugated anti-human immunoglobulin reacts with the bound antibodies from the patient's serum, eliminating competitive inhibition of IgM binding by IgG. The test is intended as a screening test for the diagnosis of acute infection. The presence of antibody is considered suggestive of active *Leptospira* infection.

Equipment

Dry-heat bath or water bath with racks, adjustable to 50°C. *Note*: If a water bath is used, caution is required to prevent water from getting into the reaction cuvettes.

Accurate micropipette (10 μl) and serologic pipettes

Cup or beaker to serve as the clarifier vessel

Distilled or deionized water to be used as the clarifier

Timer

Absorbent toweling to blot dry the assay strips

Materials

INDX Dip-S-Ticks kit. The kit contains assay strips, sample diluent, enhancer, anti-human immunoglobulin conjugate, enzyme substrate (5-bromo-4-chloro-3-indolyl phosphate and *p*-nitro blue tetrazolium), reaction cuvettes, positive control serum, and negative control serum.

Test Procedure

1. Bring all reagents and serum samples to room temperature.
2. Label assay strips with corresponding patient identifier.
3. Remove and label (1 to 4) four reaction cuvettes (RC-1 to RC-4) per sample. Place in rack in a 50°C water bath.
4. Place 2 ml of appropriate reagent in the corresponding reaction cuvette:
   (a) To RC-1, add 2 ml of diluent.
   (b) To RC-2, add 2 ml of enhancer.
   (c) To RC-3, add 2 ml of conjugate.
   (d) To RC-4, add 2 ml of developer.
5. Add sufficient distilled or deionized water to the clarifier vessel to adequately cover the window of the assay strip when it is immersed.
6. Allow the reaction cuvettes to sit for 10 min to equilibrate all reagents to 50°C. During this step, specimens may be added (step 7).
7. Add 10 μl of patient serum or heparinized plasma specimen to the corresponding cuvette labeled RC-1.
8. Prewet the assay strip by immersing it in clarifier vessel for 2 to 4 min.
9. Using 10 to 15 quick up-and-down motions with the assay strip, mix the diluent and patient sample thoroughly in RC-1. Let stand for 5 min.
10. Remove assay strip from RC-1, and swish in the clarifier vessel. Use a swift back-and-forth motion for 6 to 10 s, allowing for optimal washing of the assay strip membrane window.
11. Dispose of used distilled water in the clarifier vessel, and replace with fresh distilled water.
12. Place assay strip in RC-2. Mix thoroughly by using 6 to 10 quick up-and-down motions. Let strip stand in RC-2 for 5 min.
13. Remove strip from RC-2 and rinse in clarifier vessel as described in steps 10 and 11.
14. Place strip in RC-3. Mix thoroughly by using 6 to 10 up-and-down motions. Let strip stand in RC-3 for the length of time indicated on the kit master label.
15. Remove assay strip and rinse as in step 10. Allow assay strip to remain in the clarifier vessel for 5 min. Dispose of used distilled water, and replace with fresh distilled water.
16. Place assay strip in RC-4. Mix thoroughly using 6 to 10 quick up-and-down motions. Let strip stand in RC-4 for 5 min.
17. Remove assay strip from RC-4 and swish in clarifier vessel as described in step 10.
18. Blot assay strip, and allow to air dry. Do not use artificial methods, other than a fan, to dry the strips. Borderline specimens cannot be interpreted until the assay strip has been allowed to dry completely.

Quality Control

The top two membrane windows on the assay strip contain reagent controls. The top dot is a positive reagent control and must be positive for the assay to be valid. The second dot is a reagent negative control and must be negative for the assay to be valid. Positive and negative control sera included should also yield the desired results for the assay to be valid.

Interpretation of Results

Reactions are graded from 1 to 4 according to the number of reactive dots that appear. The dots should be easily seen; they have a distinct border, and the outer perimeter of the window must be white to pale gray. Results are interpreted as the number of reactive dots: 0 to 1 for negative, 2 to 2.5 for borderline positive, and 3 to 4 for strongly positive. Specimens showing a borderline positive reaction should be further tested with an additional specimen collected later or confirmed by MAT. A negative reaction does not eliminate the diagnosis of leptospirosis in a symptomatic patient. A convalescent-phase specimen, collected at least 7 days later, should be tested for patients whose acute-phase specimens are negative. A positive result for the second sample implies seroconversion but should be confirmed by MAT.

Precautions and Potential Problems

The dot ELISA dipstick assay is designed as a screening test. Results must be considered in conjunction with epidemiologic factors, clinical findings, exposure in regions of endemic infection, and other laboratory results. Lipemic, hemolyzed, or contaminated sera may interfere with the assay; these specimens should not be used. All sera demonstrating a weakly positive result should be referred to a reference laboratory for confirmation using the MAT. Although this is an IgM assay, positive results do not necessarily reflect recent or acute infection since IgM is known to persist for months or years following recovery (7). Cross-reactions have been observed with sera positive for Epstein-Barr Virus and HIV (1).

IgM ELISA

The IgM ELISA exhibits high sensitivity while maintaining a high specificity (1, 22). The assay is useful as a screening tool for testing few specimens or large numbers of specimens and has been especially valuable in the investigation of outbreaks. This is a solid-phase assay in which IgM present in serum binds to leptospiral antigen attached to the polystyrene surface of the microwell. Peroxidase-conjugated anti-human IgM reacts with the antigen-bound antibody. The detection system is a colorless substrate, tetramethyl benzidine plus hydrogen peroxide, which is hydrolyzed by the enzyme, and the chromogen changes to a blue color. The color intensity is directly related to the concentration of anti-*Leptospira* IgM antibodies in the test sample.

Materials

The *Leptospira* IgM ELISA kit (PANBIO Inc., Columbia, Md.) contains antigen-coated plates (12 8-well strips), wash buffer concentrate, serum diluent, horseradish peroxidase-conjugated anti-human IgM, tetramethyl benzidine substrate (TMB), stop solution, positive control serum, cutoff calibrator serum, and negative control serum.

Equipment

Micropipettes (10-μl single, 100-μl multichannel) and serologic pipettes

Deionized water

Microplate washing system

Microplate reader with 450-nm filter

Test tubes or dilution block for serum dilution

Solution basin

Timer

Graduated cylinder

Test Procedure

All reagents must be equilibrated to ambient temperature before the assay is begun. Microwells should not be removed from their bag until after they have reached ambient temperature.

1. Remove the required number of microwell strips, and insert into the holder. Five microwells are required for controls (one positive, one negative, and calibrator in triplicate).

2. Using appropriate tubes, make a 1:100 dilution of patient and control sera.

3. Mix and pipette 100 μl of diluted test, calibrator, and control sera into their respective wells.

4. Cover and incubate plates for 30 min at 37°C.

5. Wash six times with diluted wash buffer by repeatedly aspirating well contents and filling each well with 350 μl of wash fluid. After the final wash, discard contents of well and tap plate on blotting paper to get rid of any moisture left.

Note: Automated plate washers can be programmed to perform this wash cycle. Ensure all channels on the washer are open for efficient washing.

6. Pipette 100 μl of horseradish peroxidase-conjugated anti-human IgM into each well, cover the plate, and incubate for 30 min at 37°C.

7. Wash six times as described in step 5.

8. Pipette 100 μl of TMB to each well, cover, and incubate for 10 min at ambient temperature, timing from the first addition. A blue color will develop.

9. Pipette 100 μl of stop solution to each well and mix well. The color changes to yellow.

10. Within 30 min of completion of the assay, read the absorbance of each well at a wavelength of 450 nm, using automatic ELISA reader.

Note: If a dual-wavelength spectrometer is being used, set the reference filter between 600 and 650 nm.

Quality Control

Each kit contains a cutoff calibrator, positive control, and negative control sera. Acceptable values for the sera are found on the specification sheet packaged with each kit. The test is invalid if the absorbance readings of the controls and/ or the calibrator do not meet the specifications.

Interpretation of Results

PANBIO units are calculated by dividing the unknown specimen absorbance by the mean absorbance of the cutoff calibrator and multiplying by 10. Results are reported as negative, equivocal, or positive.

Negative: <9 PANBIO units indicates no evidence of IgM antibodies.

Equivocal: 9 to 11 PANBIO units is suggestive of possible infection, and retesting of the specimen and a second specimen taken at a later date is recommended.

Positive: >11 PANBIO units indicates presence of IgM antibodies and is suggestive of recent or past exposure to leptospires.

Note: If a negative or equivocal result is obtained and there is a strong suspicion of leptospirosis clinically, a second specimen taken 7 to 14 days later should be tested.

Potential Problems and Precautions

Results should be interpreted in conjunction with other laboratory and clinical findings. This assay is designed as a screening test; therefore, confirmation of positive and equivocal specimens by the MAT is recommended.

The design of this assay potentially allows competitive inhibition of IgM binding in the presence of high levels of IgG; therefore, false-negative results are possible. Although this is an IgM assay, positive results do not necessarily reflect recent or acute infection since IgM is known to persist for months or years following recovery (7). Cross-reactions in this assay have been observed with sera positive for autoimmune disease, cytomegalovirus, HIV, group C *Neisseria meningitidis*, and viral hepatitis (1).

Molecular Biology-Based Techniques

Diagnosis

Several PCR assays have been described for amplification of leptospiral DNA (20). However, few of these assays have been evaluated in experiments with human (5, 27) or veterinary (14, 39) populations. Real-time assays, which offer greater analytical sensitivity and more rapid diagnosis, have recently been described (24, 36). Primers, probes, and targets for some PCR assays used for human diagnosis are shown in Table 6.

Identification and Subtyping

Because of the difficulty in serologic identification of leptospires (20) many molecular subtyping techniques have been applied to the identification and subtyping of the genus *Leptospira* (37). Pathogenic leptospires are now classified into several species determined by DNA reassociation (4), and strains of some serovars are found in multiple species (21), so it is no longer adequate to know the identity of a serovar in order to understand its pathogenic potential and likely epidemiology. Both species and serovar identity must be determined.

The most widely applicable approach for species determination is 16S rRNA sequencing (17). Of the numerous molecular methods evaluated for subtyping, only pulsed-field gel electrophoresis has sufficient potential for standardization (15).

Borreliosis

Borreliae pathogenic to humans are the agents of louse-borne (epidemic) relapsing fever (LBRF), tick-borne (endemic) relapsing fever (TBRF) and Lyme disease. Human relapsing-fever infections occur throughout tropical and temperate regions with the possible exception of Australia, New Zealand, and the southwestern Pacific. Lyme disease, which has recently emerged as a leading vector-borne disease in the northern hemisphere, is discussed separately in the chapter on *Borrelia burgdorferi*.

Humans are the only known reservoir of the LBRF spirochete, *Borrelia recurrentis*, and outbreaks involving many thousands of people were common in the first half of the 20th century in parts of Europe, Africa, South America, and Asia. The disease is still prevalent in Africa, most notably in Sudan and Ethiopia. Because of the close association of the louse

vector, *Pediculus humanus humanus*, and the human reservoir, epidemic outbreaks are associated with conditions of overcrowding, malnutrition, and poor hygiene. Case fatality rates range from greater than 40% in untreated epidemic outbreaks to less than 5% in treated cases. It is unclear if virulence factors play a role in the higher mortality rates commonly associated with large epidemic outbreaks or whether this outcome is reflective of generally poorer patient management under these circumstances.

TBRF is caused by infection with any one of 11 *Borrelia* species (Table 2). These spirochetes are transmitted by soft ticks of the genus *Ornithodoros*. Species designations of the relapsing-fever spirochetes are often based on their vector tick species (e.g., *Borrelia hermsii* is transmitted by *Ornithodoros hermsi*). In contrast to LBRF, TBRF is usually a zoonotic disease cycling between ticks and their rodent hosts. Because of the extreme dependence of these ticks on their animal hosts, humans are only rarely exposed to the vector ticks. The distribution of endemic foci includes the western United States, British Columbia, Mexico, Central and South America, much of Africa, Europe, and Asia. Cases in the United States are typically sporadic, although common-source clusters of 6 to 62 cases have been reported in Washington, Arizona, California, and Colorado (10). These clusters typically involve rodent-infested cabins left vacant for periods just prior to human occupation and exposure. Vector ticks are also found in caves and burrows of owls and snakes associated with rodent and other animal inhabitants or their nesting materials. The nocturnal, brief (5 to 30 min), and usually painless feeding habits of the vector ticks are responsible for low recall of tick exposure. Thus, unless a history of lodging in rodent-infested dwellings or of wilderness or cave exposure is noted, the disease is rarely suspected during the initial febrile episode. The disease is reportable in 12 western states: Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, Texas, Utah, Washington, and Wyoming. In addition to these states, cases have been reported from Ohio and Oklahoma. Between 1990 and 2000, 247 cases were reported in the United States. However, due to its frequent misdiagnosis and the lack of systematic reporting, the incidence of TBRF is unknown. Case fatality rates range from 2 to 8%.

The clinical presentations of LBRF and TBRF are similar, although LBRF tends to be more severe (9, 10). The incubation periods range from 4 to 18 days (average of 8 days) and

are followed by the sudden onset of fever, headache, shaking chills, and myalgia and arthralgia. Other symptoms include nausea, vomiting, anorexia, dry cough, photophobia, neck pain, eye pain, and confusion. Thrombocytopenia is common to both diseases, although bleeding complications (epistaxis, subconjunctival hemorrhage, and petechial hemorrhage) are much more frequently associated with LBRF. The febrile period lasts for 3 to 7 days. A skin rash with variable appearance, rarely resembling erythema migrans associated with Lyme disease, has been detected in 28% of relapsing-fever patients. After an afebrile period of several days to weeks, a relapse occurs. The number of relapses is variable and is affected by antibiotic therapy. Most untreated LBRF patients suffer one relapse, but the occurrence of three or more relapses is rare. In untreated TBRF, 3 to 5 relapses (range, 0 to 13) are common. The severity and duration of the relapse generally decrease with each subsequent episode, while the afebrile interval is extended. Numbers of circulating spirochetes also diminish with each relapse, and spirochetes are rarely observed or recovered during afebrile periods.

Diagnosis of relapsing fever is largely dependent on obtaining a detailed travel history for the several weeks prior to onset of illness. If a history of risk exposure in an area of endemic infection is given, a blood smear should be examined. Blood samples must be collected during a febrile period, and the presence of spirochetes is considered diagnostic. Spirochetes are observed in approximately 70% of cases. Failure to demonstrate spirochetes does not rule out relapsing fever, and alternative culture or serologic approaches may confirm or support the diagnosis. Both LBRF and TBRF spirochetes are capable of crossing the placenta in pregnant women. Fetal infection, even in the absence of apparent maternal disease or in the face of maternal disease resolution, may result in an overwhelming spirochetemia and abortion.

The sporadic nature of relapsing fever and the spontaneous antigenic variation of the spirochetes have minimized and complicated efforts to develop serodiagnostic assays (33). Nonetheless, substantial progress has been made toward the understanding of regulation of antigen expression, and several specific markers, both genetic and antigenic, have been identified. In experimentally infected mice, each relapse is associated with the expression of a novel surface antigen designated variable major protein (VMP). Twenty-six VMPs and associated serotypes originating from

a mouse infection with a single relapsing-fever spirochete have been described.

Direct Detection and Isolation of Borreliae

Detection in Blood

The most direct and simple approach to laboratory confirmation of relapsing-fever infection is by microscopy. Spirochetemias of greater than 10^8 organisms/ml of blood are common during early febrile periods of TBRF and LBRF and enable microscopic detection. The large size (5 to 25 μm in length and 0.2 to 0.5 μm in width) of spirochetes and their coiling (3 to 10 spirals; average, 5 to 7) facilitate identification with magnifications of ×400 to ×1,000. Additionally, spirochetes may be concentrated up to 100-fold by buffy coat preparations (38).

Spirochetes may be visualized in peripheral blood wet mounts by dark-field microscopy or in fixed and stained preparations by bright-field microscopy. In live wet mounts (anticoagulated blood diluted 1:1 with saline), the corkscrew motility of spirochetes is readily detected under dark-field microscopy. Alternatively, Wright- or Giemsa-stained thick or thin blood smears (Fig. 1) also afford visualization of spirochetes. Thick blood smears should be dehemoglobinized for 10 to 20 s with 6% acetic acid in ethanol before being stained.

For all microscopic detection of spirochetemia, it is crucial that blood be collected during a febrile episode. Analysis of multiple blood smears collected during the febrile period significantly increases the likelihood of spirochete observation. However, as the level of spirochetemia diminishes with each subsequent relapse, attempts to visually confirm spirochete presence become less fruitful. Examination of stained thick smears is recommended during later relapses or whenever thin smears are negative. Phenotypic variations in borreliae (number and size of coils as well as overall spirochete length) are affected by environmental and culture conditions, and species are not readily discriminated on the basis of morphology.

Molecular Biology-Based Detection

Molecular biology-based techniques analyzing amplified signature gene sequences from borreliae have been developed and widely utilized to establish taxonomic relationships, further our understanding of the life cycles of spirochetes, and identify vaccine candidates. Diagnostic application of these analytic approaches has focused largely on the confirmation of Lyme disease infection. Due to the comparatively small numbers of Lyme borreliae in any infected tissue source compared to TBRF and LBRF spirochetes in blood, the molecular biology-based diagnosis of relapsing fever has not received much attention. Nonetheless, there are clinical situations, such as afebrile periods and later relapses, in which circulating spirochete numbers are diminished, where highly sensitive molecular biology-based detection tests may find application and utility. A number of specific gene targets have been identified (30, 32). Standardization of protocols and multicenter evaluation of test performance will greatly facilitate a broader application of molecular biology-based diagnostic approaches to relapsing fever.

Animal Inoculation

Although most laboratories are not equipped to perform animal inoculation for the propagation of relapsing-fever spirochetes, this approach is sensitive and relatively simple. Weanling mice or rats are inoculated intraperitoneally with 0.1 to 0.2 ml of anticoagulated patient blood or a blood clot triturated in an equal volume of saline. Spirochetes may be observed in smears of peripheral blood from test animals as soon as 3 days postinoculation. Since infected animals experience phasic spirochetemias, smears should be examined daily for up to 15 days. Animal inoculation and subsequent analysis of blood smears are often more sensitive for detecting relapsing-fever spirochetes than is direct examination or culturing of patient blood. It is highly recommended during later relapses, when spirochetemias may be very low.
FIGURE 1 *B. hermsii* in a Giemsa-stained human peripheral blood smear. Magnification, ×1,000.

Detection by Culture

In addition to demonstration of spirochetes by animal inoculation, direct culture of relapsing-fever spirochetes is possible. Barbour-Stoenner-Kelly II (BSK-II) medium is most commonly used, and a commercial formulation is available (BSK-H; Sigma Chemical Co., St. Louis, Mo.). Optimal growth is obtained under microaerophilic conditions at temperatures between 30 and 37°C. Generation times of approximately 12 h are common at 35°C. Cultures should be seeded with 0.1 to 0.2 ml of patient blood or a suspension of a triturated blood clot. If culture medium is not on hand, weanling mice may be inoculated with the blood sample or blood may be stored or transported at 4°C for several days until medium is obtained. Borreliae are resistant to rifampin (50 μg/ml), phosphomycin (100 μg/ml), and amphotericin B (10 μg/ml), and these antibiotics may be added to the culture medium to minimize contamination by other bacteria and fungi. Dark-field microscopy of culture wet mounts is utilized to confirm the presence of spirochetes.

Indirect Detection of Borreliae

Although serologic assays detecting antibody responses to spirochetal infection have not been fully standardized or widely practiced, several approaches may be used to support the initial diagnosis. Serologic tests include indirect fluorescent-antibody assay (IFA), ELISA, and Western immunoblotting. It must be noted that seroconversion is rarely demonstrated during the first febrile episode and that prompt antibiotic therapy may abrogate the antibody response. Thus, while positive results in any of these assays may strongly support the clinical diagnosis of relapsing fever, negative results are inconclusive.

Detailed protocols for cell growth, harvest, and antigen preparation have been reported, and stock cultures of *B. hermsii* (serotype C) are available from the American Tissue Type Collection. Additional relapsing-fever spirochete isolates are available from the reference collection of the Centers for Disease Control and Prevention, Division of Vector-Borne Infectious Diseases, in Fort Collins, Colo. For ELISA, whole-cell lysates of *B. hermsii* are used as antigen sources and assay cutoffs are based on patient serum reactivity in relation to a set of negative and positive control samples. Western immunoblot analysis of sera from relapsing-fever patients has also been reported, and patients typically demonstrate increasing IgM and IgG reactivity to an expanding number of antigens during the first few weeks postinfection (12).

In Western blots, IFA, and ELISA, which utilize whole-cell spirochete lysates as antigen sources, antibody cross-reactivity is observed among patients with Lyme disease, syphilis and other treponemal diseases, and leptospiral infections. Absorption of relapsing-fever serum with heterologous antigens indicates that relapsing-fever-specific seroconversion does occur. Antibody responses to one antigen, glycerophosphodiester phosphodiesterase, have been reported to enable the sensitive detection of both TBRF and LBRF infections and are not observed in infections with the closely related Lyme disease spirochete (32). Further evaluation and standardization of assays utilizing this antigen may justify its greater use. Despite the utility of laboratory diagnostic tests, the importance of a detailed case history and clinical presentation in the diagnosis of relapsing-fever borreliosis cannot be overemphasized.

Lyme Disease: Serologic Assays for Antibodies to *Borrelia burgdorferi*

BARBARA J. B. JOHNSON

57

Lyme disease is the most common tick-borne bacterial disease in the northern hemisphere (5, 23). The disease is caused by three genomic groups or genospecies of *Borrelia burgdorferi* sensu lato: *B. burgdorferi* sensu stricto, *Borrelia garinii*, and *Borrelia afzelii*. Only *B. burgdorferi* sensu stricto is known to cause Lyme disease in North America, whereas all three genospecies are responsible for the disease in Europe. *B. garinii* and *B. afzelii* but not *B. burgdorferi* sensu stricto have been isolated from patients in Japan, China, and eastern Russia. Eight other genospecies within the sensu lato complex have been identified. Of these eight, there is some anecdotal evidence that *Borrelia valaisiana*, *Borrelia lusitaniae*, and spirochetes related to *Borrelia bissettii* also are pathogenic to humans (reviewed in reference 20).

In 2003, more than 21,200 new cases of Lyme disease were reported to the Centers for Disease Control and Prevention (CDC) in the United States (5). The risk of exposure to *B. burgdorferi*-infected ticks in the United States depends on geographic area and is highly focal. Most cases of Lyme disease are reported in northeastern, mid-Atlantic, and north central states. Twelve states—Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin—account for 95% of cases reported nationally. Although few European countries have official surveillance systems for Lyme disease, the World Health Organization reports that Lyme disease increases in incidence from west to east, with the highest estimated incidences in central eastern Europe, especially Austria and Slovenia. There also is a gradient of increasing incidence from south to north, with higher rates in Scandinavia. Lyme disease is widespread in the forested areas of the Russian Federation, ranging from the Baltic region to the Far East (20). Since the probability of Lyme disease in a patient depends on the risk of having received a bite from a *B. burgdorferi*-infected tick, knowledge of the geographic distribution of documented human cases and of the circumstances of a patient's tick exposure is diagnostically useful.

Lyme disease spirochetes are transmitted by ticks of the genus *Ixodes* (18, 20). The tick vectors in North America are *Ixodes scapularis* (deer tick) in the northeastern and north central regions and *Ixodes pacificus* (western black-legged tick) in the Pacific northwest. *Ixodes ricinus* and *Ixodes persulcatus* are responsible for the transmission of *Borrelia* in Europe and Asia. The major incidence of early Lyme disease coincides with the seasonal feeding activity of nymphal vector ticks, usually from April to September. Late manifestations of the disease may occur throughout the year. *I. scapularis* ticks are slow feeders, requiring several days for engorgement and more than 24 h of attachment before the spirochetes are effectively transmitted. *Ixodes ricinus* ticks may transmit *B. afzelii* earlier in the course of feeding than *I. scapularis* transmits *B. burgdorferi* sensu stricto. An expanding erythematous skin lesion, erythema migrans, develops at the site of the tick bite 7 to 9 days following tick engorgement in about 80% of patients. Weeks to months later, some untreated individuals develop abnormalities of the nervous system, heart, and joints. Since the hallmark of the disease, erythema migrans, may be absent or atypical in appearance and signs and symptoms of the disease may be nonspecific, laboratory tests play an important role in the diagnosis of Lyme disease.

Serology is the most useful type of laboratory test that is widely available to support a clinical diagnosis of Lyme disease. Positive serologic test results, however, should not be used by themselves to establish this diagnosis. A patient's clinical history, physical signs and symptoms, and risk of exposure to infected ticks are essential components of a clinical diagnosis (3, 18, 19). An American College of Physicians expert panel has defined the conditions of appropriate use of laboratory testing as when the pretest probability of Lyme disease in a patient is estimated to be between 0.20 and 0.80 (19). A patient with erythema migrans exposed to tick bite in an area where Lyme disease is endemic is considered to have a pretest probability of greater than 0.80. Laboratory testing is not recommended, and the patient should be treated with antibiotics. A patient with nonspecific findings such as headache, fatigue, and malaise is considered to have a pretest probability for Lyme disease of less than 0.20. Laboratory testing of samples from such patients also is not recommended, since testing will result in more false-positive results than true positives.

When serologic testing is appropriate, the Association of Public Health Laboratories (APHL, formerly ASTPHLD) and CDC recommend a two-test protocol (1, 4). Serum specimens first should be evaluated by a sensitive enzyme immunoassay (EIA) or immunofluorescent assay (IFA). Specimens found to be positive or indeterminate (also called borderline or equivocal) by this first test should be evaluated further by a standardized Western blot procedure.

Specimens found to be negative by a sensitive EIA or IFA need not be tested further. During the first month of infection, both immunoglobulin M (IgM) and IgG antibody responses should be determined. After 1 month of infection, the antibody responses of most untreated patients with Lyme disease will have switched class from IgM to IgG. Since most patients have an IgG response after 1 month, the finding of only IgM antibodies in a patient with prolonged illness should not be used by itself to establish a diagnosis of Lyme disease. It may be a false-positive result, especially since the specificity of IgM assays is not as high as that of IgG tests (7, 15, 19).

The usefulness of serology depends on the stage of Lyme disease (Table 1). During the first few weeks of infection by *B. burgdorferi*, serum antibody responses are often undetectable, even by the most sensitive tests (2). This is the period when most patients develop erythema migrans, so the false-negative serologic results occur mainly in patients who should be treated but not tested. If early Lyme disease is suspected when erythema migrans is atypical or absent, testing of both acute- and convalescent-phase serum samples may be of value, although negative results will not rule out the diagnosis. After patients with early Lyme disease are treated with antibiotics for 8 to 12 days, the sensitivity of serology with convalescent-phase serum reaches 70 to 80% (2, 7–10). About 20 to 30% of patients treated for early Lyme disease do not develop an antibody response, suggesting that early initiation of antibiotic therapy may abort the immune response (2, 8).

If the signs and symptoms of Lyme disease are not recognized early and appropriately treated, *Borrelia* may disseminate to the major organ systems. Later-stage Lyme disease may develop weeks to months after tick bite and affect the nervous system, the joints and, uncommonly, the heart.

Patients with later-stage disease, particularly those with arthritis, have a strong humoral response with a predominance of IgG antibodies. Most patients with neuroborreliosis also have serum antibodies, and some also have intrathecally produced antibodies in the cerebrospinal fluid (CSF) (17).

After successful antibiotic therapy, most patients have a slowly declining antibody titer. However, antibody titer to whole-cell antigens cannot be used to monitor a patient's response to therapy. Some patients, especially those with a strong IgG response, may remain seropositive for years following successful antibiotic therapy. The IgM response may persist as well; therefore, the presence of IgM antibodies is not definitive proof of recent infection (3, 15, 18).

The false-positive rate for the first test of two-tiered testing of samples from healthy blood donors is about 2 to 5% (4% for the data set in Table 1). Other spirochetes—such as the agents of syphilis, leptospirosis, and tick-borne relapsing fever—elicit antibodies that cross-react with *B. burgdorferi* antigens. Patients infected (or previously infected) with these spirochetes have high rates of false-positive test results. About 6 to 7% of patients with inflammatory disorders within the differential diagnosis of Lyme disease (for example, rheumatoid arthritis) also have false-positive reactions (Table 1). Immunoblotting significantly improves the specificity of serologic testing (Table 1) (1, 3, 6–9, 15, 18, 19).

A strain used as an antigen in a serologic test should express appropriate amounts of the immunoreactive proteins of diagnostic interest. Since *B. burgdorferi* sensu lato is genetically diverse, strain choice may affect test performance (11). Ideally, serum samples from patients should be tested for reactivity with antigens appropriate for the geographic area where patients were exposed to infected ticks, since there are antigenic differences between genospecies of borreliae.

TABLE 1 Performance of serologic tests for detecting antibodies to *B. burgdorferi* sensu stricto in serum[a]

Serum sample classification	No. of samples	ELISA results[b]				Two-tiered results for ELISA plus Western blot[b]			
		No. with results		Se (%)	Sp (%)	No. with results		Se (%)	Sp (%)
		+ or ±	−			+	−		
Lyme disease	280	236	44	84		189	91	68	
Acute (erythema migrans)	80	47	33	60		30	50	38	
Early convalescent	106	96	10	91		71	35	67	
Early neurologic	15	15	0	100		13	2	87	
Early neurologic convalescent	11	11	0	100		9	2	82	
Arthritis	33	32	1	97		32	1	97	
Arthritis convalescent	24	24	0	100		23	1	96	
Late neurologic	11	11	0	100		11	0	100	
Diseases other than Lyme disease	559	52	507		91	5	554		99
Anti-nuclear antibody positive	116	7	109		93	2	114		98
Healthy blood donors	257	11	246		96	0	257		100
Leptospirosis	10	3	7		70	0	10		100
Multiple sclerosis	10	0	10		100	0	10		100
Rheumatoid arthritis and/or rheumatoid factor positive	109	6	103		94	1	108		99

Tick-borne relapsing fever	14	8	6		43	2	12		86

[a]Patients in the United States. Adapted from data in references 2 and 10.
[b]Automated VIDAS immunoassay for IgM and IgG antibody to *B. burgdorferi* whole-cell antigens (BioMérieux Vitek); Se, sensitivity; Sp, specificity; +, positive; −, negative; ±, equivocal.
[c]Includes samples that were positive for anticardiolipin antibodies and/or rapid plasma reagin reaction.

Large differences in the accuracy of EIAs in detecting serum antibodies have not been observed, however, when antigens from various sensu stricto strains have been compared (1, 14). Apparently, immunodominant epitopes are sufficiently widely shared that antigens from numerous strains are appropriate for use in EIAs. With some individual specimens, however, antigen choice may affect the determination of diagnostically significant levels of antibody.

Serologic testing in Europe is complicated by the fact that three genospecies of *B. burgdorferi* may be sympatric. Differences among these three groups of strains may result in diverse immune responses in patients infected in Europe. At present, various testing approaches, including EIAs and immunoblots using whole-cell antigens, indirect and antibody-capture EIAs using morphologically intact flagella, and assays based on purified recombinant proteins, are employed. A framework for immunoblot interpretation has been developed, but there is no single set of criteria that performs equally well in laboratories across Europe (16, 22).

Efforts by APHL and the CDC to standardize immunoblot interpretation in the United States have resulted in the recognition of 10 proteins as particularly useful in the serodiagnosis of *B. burgdorferi* sensu stricto infection (1, 4, 7, 8). Of these 10 proteins, 3 currently are scored in the interpretation of IgM immunoblots: OspC (apparent molecular mass, 21 to 25 kDa, depending on the *B. burgdorferi* strain and gel system used for separation of proteins), BmpA (39 kDa), and FlaB (41 kDa). If bands corresponding to two of the preceding three proteins are present, an IgM blot is considered to be positive (8). Seven additional proteins are scored in IgG immunoblots, which are usually named by their apparent molecular masses: 18, 28, 30, 45, 58, 66, and 93 kDa (the last one is also referred to as 83 kDa or 100 kDa in some laboratories). The 18-kDa antigen is DbpA; the 45-kDa antigen comigrates with Bbk32 and may be identical to it. An IgG immunoblot is considered to be positive if antibody reactivity with 5 of the 10 scored proteins is present (7).

The level of expression of the 10 proteins currently recommended to be scored in immunoblots will affect test sensitivity. Three strains have been demonstrated to be particularly well suited for use as *B. burgdorferi* sensu stricto antigens: 2591, low-passage 297, and low-passage B31. Some strains are deficient in OspC or the 39-kDa protein, for example, particularly after many passages in in vitro culture (1, 7). Adequate production of all 10 diagnostic antigens should be verified by immunoblotting with calibrating monoclonal antibodies and serum samples.

Newer, simpler technologies have been developed and are undergoing evaluation as potential alternatives to two-tiered serologic testing. The most promising tests are based on VlsE antigen or a synthetic peptide that reproduces a 26-amino-acid portion of VlsE (2, 12, 13). At this writing, the U.S. Food and Drug Administration has cleared a test based on the peptide antigen for use as the first test in a two-tiered protocol.

METHODS

EIA

Specimens and Controls
Specimens for serologic tests must be taken aseptically and preferably refrigerated until assayed. When necessary, samples may be frozen, but freeze-thaw stress of serum should be avoided. IgM antibodies are particularly vulnerable to freeze-thaw damage. Gloves should always be worn, and specimens should be handled with the precautions extended to any human body fluid (universal precautions).

An essential part of test development is establishing positive and negative cutoff values. Patient samples are compared with reference ranges established by using panels of controls. To identify negative controls, a large number of serum samples (preferably more than 100) from healthy donors not known to have a history of exposure to *B. burgdorferi* should be tested individually. Once a large number of samples have been evaluated, a small subset of them can be randomly selected for use on a given EIA plate. Statistical methods should be applied first to exclude samples with atypically high or low optical densities (ODs) from the large set of samples from which negative controls are randomly selected (9). In the protocol below, healthy blood donors ($n = 116$) were screened to determine the range of reactivity in the control population. Specimens with ODs that were >1.5 times the interquartile range over the third quartile or ODs that were <1.5 times this range below the first quartile ("outliers") were eliminated from the group of negative controls (~10% of the specimens). Six serum samples were selected randomly from the remaining 90% of healthy donor specimens for use on each EIA plate. A sufficient volume of these controls should be available for long-term use and to determine test reproducibility over time. Negative control samples should not be pooled (physically mixed). The OD of the pool will probably be lower than the ODs of the individual samples.

Positive-control serum samples from patients with well-characterized Lyme disease are required, preferably four samples that possess a range of anti-*B. burgdorferi* antibody levels from low to high. Investigators may obtain reference quantities of positive-control serum samples suitable for assessing antibodies to *B. burgdorferi* sensu stricto from the Diagnostic and Reference Laboratory, CDC, Fort Collins, Colo. (phone 970-221-6400).

Instruments, Equipment, and Labware

Incubator (35°C)

High-speed centrifuge, rotors, centrifuge bottles and tubes

Filter apparatus with filters (pore size, 0.22 μm, and "prefilter")

Sonicator

Spectrophotometer

Polystyrene microtiter plates, 96 wells, flat-bottom (Immulon II [Dynex Technologies] or equivalent)

Micropipettors, single and multichannel, plus appropriate tips

Refrigerator (4°C)

Microtiter plate washer

Microtiter plate reader capable of reading at 405 nm

Reagents

Culture medium for *B. burgdorferi* (BSK supplemented with 6% [vol/vol] trace hemolyzed rabbit serum)

Cell wash solution (10 mM Tris HCl [pH 8.2], 150 mM NaCl, 5 mM $CaCl_2$ or phosphate-buffered saline [PBS] plus 5 mM $MgCl_2$), chilled on ice

Protein assay kit (bicinchoninic acid assay, Pierce; Bio-Rad [Richmond, Calif.] assay, or equivalent)

Tris-buffered saline (TBS = 13 mM Tris HCl, 3 mM Tris base [pH 7.4], 140 mM NaCl, 2.7 mM KCl)

Tween 20

Distilled water

Carbonate plate-coating buffer (90 mM NaHCO$_3$, 60 mM Na$_2$CO$_3$ [pH 9.6])

Carbonate substrate buffer (23 mM NaHCO$_3$, 25 mM Na$_2$CO$_3$, 0.1 M MgCl$_2$ [pH 9.8])

Plate-washing solution (TBS-T = TBS plus 0.05% Tween 20)

Blocking buffer (15 mM NaCl, 10 mM Tris HCl [pH 7.5], 0.05% Tween 20, 3% fetal bovine serum)

Goat anti-human IgM alkaline phosphatase-conjugated antibody (Kirkegaard & Perry Laboratories, Gaithersburg, Md.) or equivalent

Goat anti-human IgG alkaline phosphatase-conjugated antibody (Kirkegaard & Perry) or equivalent

Goat anti-human IgG-IgM alkaline phosphatase-conjugated antibody (Jackson ImmunoResearch Laboratories, West Grove, Pa.) or equivalent

Substrate for alkaline phosphatase (2 mg of *p*-nitrophenyl phosphate per ml)

Cell Growth and Antigen Preparation

1. Grow *B. burgdorferi* cells in BSK culture medium (21) at 35°C under microaerophilic conditions to late log phase (approximately 10^8 cells per ml). To do this, start a 1-liter culture in a sterile glass bottle by inoculation with 1 to 5 ml of a highly motile miniculture started from a frozen, low-passage stock. With serial passage, borreliae lose plasmids encoding proteins of diagnostic importance. It is critical to make and maintain primary frozen stocks for production of antigens. Incubate cells in tightly capped vessels that have minimal air space. Document that *B. burgdorferi* was free of contaminating microorganisms by culture of samples of the seed stock and of the bacterial suspension collected immediately before harvest. Four bacteriologic media should be inoculated to detect possible contamination: brain heart infusion broth, Trypticase soy agar slants, thioglycolate medium, and Sabouraud dextrose agar slants. Hold one of each test specimen at room temperature and another at 37°C, with the exception of the Sabouraud dextrose agar, which can be incubated at room temperature only. Hold quality control test specimens for 2 weeks, then examine them by microscopy to verify the absence of contaminating cell growth.

2. Harvest borreliae while they are in late log phase of growth (after about 7 days; growth rate is strain and passage dependent). To do this, decant cultures into centrifuge bottles, and pellet the cells at 10,000 × *g* for 20 min at 20°C. Discard supernatants as biohazard waste. Immediately place cell pellets on ice to reduce protease activity.

3. Wash cells to remove residual culture medium, particularly bovine serum albumin. To do this, suspend cells in cell wash solution, a cold isotonic buffer supplemented with divalent cations to reduce loss of borrelial lipoproteins from the cell surface. For each wash, disperse the pellet gently. If necessary, allow the pellet to soak in wash buffer on ice (up to ca. 15 min) to facilitate dispersion of the pellet without lysis of the cells. Centrifuge the cells again at 10,000 × *g* for 20 min at 4°C. Wash and collect the cells a second time. Suspend the cells in cold TBS at a concentration of 1 × 10^9 to 2 × 10^9 cells per ml.

4. Sonicate the cell suspension on ice until the cells are completely lysed (typically requires three 20-s intervals at intermediate power). Verify cell lysis by microscopy.

5. Filter sonicate through 0.22-μm-pore-size filter. Aliquots can be frozen and stored at −70°C for at least 1 year.

6. Determine protein concentration of the sonicate by using a protein assay kit.

Procedure

1. Dilute antigen in carbonate coating buffer to a concentration of 1 μg of protein per 100 μl.

2. Add 100 μl of antigen to each well of microtiter plate. Investigators developing an assay with a strain of *Borrelia* other than the B31 described here should perform titrations to determine the concentration of whole-cell proteins that produces the highest ratio of ODs between positive and negative control samples.

3. Incubate covered plates overnight (16 to 18 h) at 4°C.

4. Wash wells five times with about 400 μl of TBS-T each, add 300 μl of blocking buffer, and hold plates for 1 h at room temperature. Wash the wells five times again.

5. Add 100 μl of each serum sample diluted 1:500 in blocking buffer to duplicate wells and blocking buffer alone to background control wells. The appropriate dilution factor for serum is determined by twofold serial dilution of positive and negative control samples. The dilution giving the highest ratio between the ODs of the positive and negative controls is selected. The optimum dilution depends on the class(es) of antibodies to be detected. This protocol is for detecting IgG and IgM together.

6. Incubate plates, covered, for 1 h at room temperature.

7. Wash wells five times with TBS-T.

8. Add 100 μl of anti-human IgG plus IgM conjugated to alkaline phosphatase, appropriately diluted in TBS-T. Optimal working dilutions must be determined previously. *Examples:* IgG-IgM conjugate is diluted 1:10,000, IgG conjugate is diluted 1:20,000, and IgM conjugate is diluted 1:7000.

9. Incubate plates, covered, for 1 h.

10. Wash wells five times with TBS-T.

11. Add 100 μl of substrate solution in carbonate buffer, and develop for 0.5 h. Development time is determined by how long it takes for positive controls to reach expected OD readings (20 to 60 min).

12. Stop color development with 5 N NaOH (100 μl/well).

13. Read OD at 405 nm (minus the OD at 630 nm) with a microplate reader.

Results and Interpretation

The mean of the OD for each patient sample is calculated and compared with reference ranges previously established for healthy blood donors. A serum specimen is considered positive if the OD is 3 standard deviations (SD) above the mean absorbance of the control samples from the six healthy donors. The mean + 1 SD of the six negative controls is the negative cutoff value. Indeterminate values are between 1 and and 3 SD of the mean. All positive and indeterminate samples should be further tested by Western blotting.

IFA

An IFA can be used for testing serum, CSF, and other body fluids for the presence of antibodies to *B. burgdorferi*. IFA was the first test to be used to detect antibodies to *B. burgdorferi*, but it is less commonly used than EIA because it requires a skilled and experienced microscopist and cannot be automated for testing large numbers of samples. Reading and interpretation of IFA results are subjective, so interlaboratory standardization of results is difficult.

Specimens and Controls

The specimens are the same as for the EIA (see above). Positive controls yielding strong and weak fluorescence, as well as a negative control, should be run on each slide.

Instruments, Equipment, and Labware

Fluorescence microscope: microscope, ARC lamp with UV light source (xenon or mercury bulb), filter appropriate for fluorescein, 40× high dry objective for scanning, 63×/1.40 oil immersion objective for titer determinations

Dark-field microscope for determining viability of culture (preferred) or phase-contrast microscope

Microscope slides (fluorescent antibody slides, 25 by 75 mm, with 12 5-mm wells)

Moist slide chamber for incubations

Slide-rinsing jar

Coverslips, 24 by 50 mm

Micropipettor capable of 2-μl delivery and tips

Micropipettor capable of 100-μl delivery and tips

Microtiter plates, polystyrene U-bottomed

Incubator, 37°C

Reagents

Acetone, for antigen fixation

PBS (pH 7.2), sterile, to wash cells and dilute them

Positive control serum sample

Negative control serum sample

Antibody conjugate labeled with fluorescein (goat anti-human IgM, IgG, or IgM-IgG fluorescein isothiocyanate conjugate). Prepare and store master stock as specified by the manufacturer. Prepare working dilution, generally 1:200, in PBS–1% bovine serum albumin before use.

Mounting medium (preferably glycerol-based medium formulated to retard photobleaching of fluorochromes or 9 ml of glycerol plus 1 ml of PBS)

Distilled water

Clear fingernail polish with applicator brush

Cells

Select a genospecies of *B. burgdorferi* known to circulate in the geographic area where patients were potentially exposed to infected ticks. In North America, the type strain of *B. burgdorferi* sensu stricto, B31, is an appropriate choice. To detect antibodies to European *Borrelia* species, strains such as *B. garinii* PBi or 20047, *B. afzelii* strains PKo or PGau, or local isolates are suitable.

Grow cells at 35°C until log phase (approximately 10^8 cells per ml). Harvest cells by centrifugation at $10,000 \times g$, and thoroughly wash them three times with PBS–5 mM $MgCl_2$. Resuspend washed cells in PBS so that a small drop of cell suspension fixed on a slide yields approximately 100 cells per field when viewed under oil immersion. The number of cells per field of view under the microscope should be as consistent as possible from slide to slide. These concerns also apply to antigen slides obtained from commercial suppliers.

Procedure for Analysis of Serum

1. Apply antigen preparation to slides (approximately 10 μl per well), and allow them to air dry at room temperature.

Fix cells on slides in acetone for 15 min, and then air dry again. Slides may be wrapped in aluminum foil and frozen at −20°C for storage of up to 6 months.

2. Make serial twofold dilutions of negative and positive control serum samples and patient serum in PBS in a microtiter plate. Dilute patient serum to 1:512.

3. Place 10 μl of undiluted and diluted patient sera into 9 wells. Place 10 μl of the 1:4 dilution of the negative and positive controls into three other wells.

4. Incubate slides in a moist chamber at 37°C for 60 min.

5. Rinse slides in PBS, and dry them in air.

6. Apply 10 μl of the appropriately diluted goat anti-human immunoglobulin-fluorescein isothiocyanate conjugate to each well.

7. Incubate slides in a moist chamber at 37°C for 60 min.

8. Rinse slides in PBS.

9. Rinse slides in distilled water and air dry them.

10. Place a small drop of mounting fluid on each slide, and apply a coverslip.

11. Seal all edges with nail polish and air dry (optional if slide will be read immediately).

12. Scan slide using high dry objective. Read results using oil immersion objective.

Results and Interpretation

Titer is defined as the reciprocal of the highest dilution of sample at which the fluorescence has decreased by 50%. Negative and weak and strong positive controls should be run on each slide and should always yield their expected results. Established values for positive samples may vary from laboratory to laboratory but are generally 256 or higher.

Since the interpretation of IFA results is subjective, rigorous proficiency and quality control procedures are critical to ensure test reliability. An experienced microscopist can often distinguish false-positive reactions by the beaded fluorescent staining pattern of the cells. Positive results should be confirmed by Western immunoblotting

Western Immunoblotting

The Western blot is used to supplement positive and indeterminate EIA or IFA results. It should not be used for initial testing because it is not quantitative.

Specimens and Controls

The specimens are the same as for the EIA. Three human serum controls should be run with each set of samples: a strongly positive control, a weakly positive control to standardize blot development time, and a negative control. Calibration controls (mouse monoclonal antibodies recognizing diagnostically important antigens) should be run individually when the procedure is first set up. Pooled monoclonal antibodies may be run subsequently to establish a calibration "ladder." Monoclonal antibodies suitable for calibration of diagnostic immunoblots are available from the Diagnostic and Reference Laboratory, Division of Vector-Borne Infectious Diseases, CDC. These reagents include antibodies that recognize the following *B. burgdorferi* sensu stricto antigens: Decorin-binding protein A (P18), OspC (P21-P24, depending on strain), OspA (P31), OspB (P34), P35, FlaA (P37), BmpA (P39), FlaB (P41), VlsE1 (P43), GroEL (P62), P66, and P93.

Instruments, Equipment, and Supplies

Dounce homogenizer

Power supply for electrophoresis, capable of delivering 40 mA at constant current

Power supply for electroblotting capable of delivering 1 A at constant current

Polyacrylamide gel slab electrophoresis apparatus, with wide sample slot and lanes for molecular weight standards

Micropipettor or Hamilton syringe, 50 μl, for loading antigen

Electroblotting apparatus to transfer proteins from gel to membrane

Nitrocellulose sheets, 0.2-μm pore size (Schleicher & Schuell [Keene, N.H.], BA 83)

Membrane cutter (Matrix 1201, Kinematic Automation, Twain Harte, Calif., or equivalent) or scalpel and shallow cutting tray

Immunoblot incubation tray, 40 channel (MarDx Diagnostics, Carlsbad, Calif.), or disposable incubation trays, 8 channel (Schleicher & Schuell)

Glass pans (Pyrex)

Lab markers, permanent alcohol or waterproof

Reagents

TE buffer (10 mM Tris HCl [pH 8], 1 mM EDTA), sterile

Protein assay kit (bicinchoninic acid assay, Pierce; Bio-Rad assay or equivalent)

Sample buffer, 2× concentration (125 mM Tris-HCl [pH 6.8], 4.0% sodium dodecyl sulfate, 20% glycerol, 200 mM dithiothreitol, 0.01% bromophenol blue)

30% acrylamide–0.8% bisacrylamide solution

Sodium dodecyl sulfate, electrophoresis grade

Ammonium persulfate

N,N,N',N'-Tetramethylenediamine (TEMED)

Trizma base

Glycine

Sodium chloride

Glycerol

Dithiothreitol

Bromophenol blue

Molecular weight standards, unstained

Molecular weight standards, prestained (Bio-Rad or equivalent)

Methanol, acetone-free

Gel transfer buffer (3.03 g of Trizma base, 14.4 g of glycine [pH 8.3], 400 ml of methanol, distilled water to 2 liters [final volume])

Amido black ink stain solution (0.1 g of amido black, 45 ml of methanol, 45 ml of distilled H$_2$O, 10 ml of glacial acetic acid)

Goat anti-human IgG conjugated to alkaline phosphatase (Kirkegaard & Perry or equivalent)

Goat anti-human IgM conjugated to alkaline phosphatase (Kirkegaard & Perry or equivalent)

Goat anti-mouse IgG conjugated to alkaline phosphatase (Kirkegaard & Perry or equivalent)

Instant dry milk (Carnation or equivalent)

TBS as in EIA protocol above

BLOTTO (0.5% instant dry milk in TBS)

Tween 20

TBS-T solution

Nitroblue tetrazolium (NBT)

5-Bromo-4-chloro-3-indolylphosphate (BCIP)

N,N-Dimethylformamide (DMF)

NBT solution (1.13 g of NBT in 10.5 ml of DMF and 4.5 ml of distilled water; freeze in 0.8-ml aliquots at −20°C)

BCIP solution (0.75 g of BCIP in 15 ml of DMF; freeze in 0.6-ml aliquots at −20°C)

Magnesium chloride (MgCl$_2$·6H$_2$O)

Developing buffer (12.11 g of Trizma base, 5.84 g of NaCl, 10.17 g of MgCl$_2$·6H$_2$O, 1 liter of distilled water; adjust pH to 9.5 with concentrated HCl).

Developing solution (200 ml of developing buffer, 1 aliquot of BCIP [0.6 ml], plus 1 aliquot of NBT [0.8 ml]); add BCIP and NBT to developing buffer 5 min prior to use.

Cells and Antigen Preparation

1. Grow cells, harvest, and wash as described above for the EIA.

2. Resuspend pellet in TE buffer with a sterile Dounce homogenizer (approximately 3.0 ml of TE buffer/0.1 g [wet weight] of cells).

3. Determine protein concentration, adjust to 2 mg/ml with TE buffer, and add an equal volume of sample buffer. Mix thoroughly, and boil for 2 min in closed tubes. Divide sample stock (1 mg/ml) into convenient portions, and store at −70°C.

Procedure

The procedure for preparing and running polyacrylamide gels and formulas of the solutions used for this are described elsewhere in this volume. Electroblotting of gels and immunoprobing of Western blots are also described. A detailed guideline for Western blot assay for antibodies to *B. burgdorferi* has been developed by the Clinical and Laboratory Standards Institute (formerly NCCLS) through its formal consensus process. A copy of Approved Guideline M34-A may be purchased (www.nccls.org). A brief outline of immunoblotting procedures is given here.

1. Prepare a 12% polyacrylamide resolving gel or a linear gradient gel from 7.5 to 15%. Top the resolving gel with a 4% polyacrylamide stacking gel. A larger size range of antigens is resolved in 7.5 to 15% gradient gels, but the antigens of greatest diagnostic interest can be well separated in a 12% gel. Either a large-gel (16-cm format) or mini-gel apparatus may be used, provided that adequate physical separation of the antigens to be scored is obtained. The conditions below are for a large-format gel, 1.5 mm thick. Antigen loads should be adjusted proportionally for smaller gels.

2. For each gel, use a comb that produces a large trough (111 mm) for the antigen and two small lanes (6 mm) for the molecular weight standards (one unstained, one prestained). With a micropipettor, load 4 μg of the molecular weight standard into the small lane. Load antigen (150 μg of protein per gel) into the large lane, using a 50-μl Hamilton syringe.

3. To each gel, apply 40 mA of current for about 3 h until dye front reaches the bottom of the gel. (This current is appropriate for the large-format gel under discussion; use conditions specified by the manufacturer for the gel rig selected.)

4. Remove the gel(s), and equilibrate it in 300 ml of transfer buffer for 15 min by gentle agitation on a shaker.

5. Transfer the antigens in the gel to nitrocellulose paper by electrotransfer at 100 mA for 1 h for the system described

(use conditions specified by the manufacturer of the electroblotter selected).

6. With a scalpel, cut off sections containing the molecular weight standards and small strips containing antigen from each side of the blot. The remaining center piece may be dried and stored for up to 1 month.

7. Stain the sections described in step 6 (except the prestained markers) with amido black stain for 3 min, rinse with water, destain with methanol-acetic acid solution, and rinse again with water. These stained sections will be used to identify specific protein bands in the immunoblots. The prestained strip is used to monitor protein separation during electrophoresis.

8. To rewet a dried blot (the center piece), incubate it in 200 ml of 0.5% Tween 20–PBS for 30 min.

9. Block the blot by incubation in BLOTTO for 1 h.

10. Incubate the blot in TBS-T solution for 45 min.

11. Draw a line at the top of the blot before cutting it, to assist in alignment of strips later. Cut the blot into strips (3 mm wide) with a membrane cutter or by hand with a scalpel, and number them sequentially.

12. Incubate strips in a multichannel tray with serum samples or calibrating monoclonal antibodies for 1 h in 2 ml of BLOTTO with 20 µl of serum per channel (1:100) or in an incubation tray (allow serum and BLOTTO to mix before adding the strips).

13. Wash each strip twice in 2 ml of TBS-T solution for 5 min each time.

14. Incubate each strip for 1 h in 2 ml of BLOTTO containing the appropriate diluted goat anti-human IgG and/or IgM conjugate. Strips used for calibration by reaction with mouse monoclonal antibodies should be incubated with goat anti-mouse IgG conjugate.

15. Wash each strip twice in 2 ml of TBS-T solution for 5 min each time.

16. Wash each strip twice in 2 ml of TBS for 5 min each time.

17. Wash each strip once in developing buffer for 5 min.

18. Develop each strip in 2 ml of developing solution for 10 to 15 min until the weakly reactive positive control band becomes visible.

19. Rinse each strip twice in distilled water for 10 min. Dry between sheets of filter paper.

20. Align the probed strips with the amido black-stained sections containing antigen and standards, and tape together.

Results and Interpretation

The specificity of Lyme disease serodiagnosis is greatly improved through the use of the Western blot to supplement positive or indeterminate results of a sensitive EIA or IFA. An IgM blot is considered positive if two or more of three bands (OspC, ca. 21 to 24 kDa, depending on strain; BmpA, 39 kDa; FlaB, 41 kDa) are present. An IgG immunoblot is considered positive if 5 of 10 bands (18, 21 to 24 [OspC], 28, 30, 39, 41, 45, 58, 66, and 93 kDa) are present. Monoclonal antibodies should be used to calibrate blots to aid in the correct scoring of blot bands. It is unusual that a patient with active Lyme disease will have only a positive IgM immunoblot after 4 to 6 weeks of infection; the likelihood of a false-positive test result should be considered.

Caution

Western immunoblotting is a labor-intensive, time-consuming, and technically demanding procedure. Care should be exercised in establishing the appropriate dilution of the serum samples and conjugate and in determining the developing
FIGURE 1 Example of immunoblot calibration. Lanes: 1, monoclonal antibodies defining selected antigens of *B. burgdorferi* B31 separated in a linear sodium dodecyl sulfate-polyacrylamide gel (Marblot; MarDx Diagnostics, Carlsbad, Calif.); 2, human serum (IgG) reactive with the 10 antigens scored in the currently recommended criteria for blot interpretation. Arrowheads mark the bands recommended for scoring; lines indicate other calibrating antibodies. Molecular masses are in kilodaltons.

times. Failure to carefully determine these conditions may lead to either false-positive or false-negative results. Immunoblots must be calibrated with monoclonal or polyclonal antibodies reactive with antigens of diagnostic importance, as well as with molecular weight standards (Fig. 1). Calibration is important, since the apparent molecular mass of some proteins of *B. burgdorferi*, such as OspC, vary depending on the *B. burgdorferi* strain and the gel electrophoresis system used. Reading of blots involves judgment that develops with experience. A common source of false-positive blots is scoring of very faint bands. In the United States, the Food and Drug Administration has cleared several commercial immunoblot kits. Monoclonal antibody calibration controls also should be used with commercial immunoblots.

Immunological Tests in Tuberculosis and Leprosy

GRAHAM H. BOTHAMLEY

58

Tuberculosis is one of the most common of the serious bacterial infections. Approximately one-third of the human population has been infected with *Mycobacterium tuberculosis*, and there are 8 million notified cases with about 2.6 million deaths each year. Culture of the tubercle bacillus remains an absolute requirement for the diagnosis of tuberculosis. The identification of mycobacterial genes using PCR has achieved the sensitivity of culture techniques, and the problems of reliability have been largely overcome (20). However, at least one-third of patients with tuberculosis do not have a positive culture. In these patients, the diagnosis rests on an immunologic response, most notably the delayed hypersensitivity reaction to tuberculin, with histological evidence and/or a response to antituberculosis drug treatment. Blood tests based on gamma interferon production are now used routinely in some parts of the world. Serology, also described here, may become complementary to T-cell-based assays.

The association between infection with human immunodeficiency viruses (HIV) and tuberculosis has become increasingly important. Unfortunately, the very nature of this combination implies that immunological tests will be of limited value in the diagnosis of coexistent tuberculosis. The value of tuberculin testing in HIV-positive individuals is discussed.

The diagnosis of leprosy is clinical. The cardinal criteria are anesthetic skin patches and thickened nerves; acid-fast bacilli are found in skin smears in patients with multibacillary (lepromatous) leprosy. Despite a substantial fall in the point prevalence of leprosy from 5.4 million in 1985 to below 1 million in 1998, due to the almost universal implementation of multidrug therapy with rifampin, clofazimine, and dapsone, the annual incidence of leprosy remains unchanged (5). The lepromin test is rarely of diagnostic help but can confirm the polarity of leprosy, whether lepromatous or tuberculoid, and thereby can be of prognostic value. Indeterminate leprosy, perhaps the earliest clinically apparent form of the disease, lacks the distinctive immunological features which indicate polarity. Serological tests have also found no role in the clinical management of leprosy. Preventive treatment for close contacts with subclinical infection, a diagnosis made immunologically on the basis of reaction to antigens of *Mycobacterium leprae*, is not widely used.

The clinical spectrum in tuberculosis and leprosy is broad. Tuberculosis can be divided into primary and postprimary disease depending on the absence or presence, respectively, of preexisting immunity. Primary tuberculosis occurs most frequently in children, affecting mediastinal lymph nodes with or without a primary focus visible on the chest radiograph and occasionally progressing to more significant, disseminated disease such as tuberculous meningitis, renal involvement, and osteomyelitis. Postprimary tuberculosis is characterized in young adults by pulmonary cavitation that leads to infectious tuberculosis and a sputum smear displaying large numbers of tubercle bacilli. Less severe forms of postprimary tuberculosis, such as pleural effusions and smear-negative pulmonary disease, may also occur. The presentation of tuberculosis in elderly patients is frequently atypical. An inverse relationship between cell-mediated and humoral immunity has been described for different forms of tuberculosis and is the essential discriminator between lepromatous and tuberculoid leprosy. This relationship reflects a dichotomy in T-helper-cell function that is characterized by the secretion of different cytokines. This broad spectrum of disease and immunological reactivity in mycobacterial disease is responsible for both the value of immunological tests and the difficulties in their interpretation.

TUBERCULOSIS

Tuberculin Skin Testing

Tuberculin

Measurement of the delayed hypersensitivity reaction to extracts from *M. tuberculosis* has been performed for more than a century. Old tuberculin, the first reagent used in skin testing, was prepared by autoclaving and filtering autolyzed 8-week-old liquid cultures of *M. tuberculosis*. The protein content of this preparation, purified first with trichloroacetic acid and later with ammonium sulfate, was termed purified protein derivative (PPD). A large batch of PPD produced by Florence Seibert in 1939 (PPD-S) has become the international standard. Subsequent preparations have equivalent biological reactivity and contain a detergent (0.05% Tween 80) to prevent adsorption. The concentration of these tuberculin preparations is determined such that 0.1 ml will be biologically equivalent to 0.1 μg of PPD-S (5 tuberculin units). This amount of tuberculin gives maximal sensitivity with minimal adverse reactions.

Clinical Indications and Methods

Tuberculin testing can be used to increase the suspicion of tuberculosis (e.g., in patients with symptoms consistent with tuberculosis or in those with abnormal chest radiographs) or as a screening test (e.g., for contacts of tuberculosis patients or for those with a high risk of tuberculosis through concurrent disease, social circumstances, or country of birth). For each tuberculin test, it is necessary to clearly record the technique, dose and nature of tuberculin, and size of the reaction in millimeters.

Mantoux Test

The Mantoux test is used for diagnostic purposes and in documenting skin test conversion in individuals regularly exposed to tuberculosis. PPD (0.1 ml) is injected just beneath the surface of the skin of the forearm with a 1-ml syringe and a 26- or 27-gauge needle. The skin becomes pale and elevated, with a characteristic "peau d'orange" appearance, if the solution has been injected intradermally (Color Plate 7); a subcutaneous injection will not produce these characteristic features. The test result should be read at 48 to 72 h. The extent of erythema gives greater sensitivity and specificity and was measured in the past, but observer error was significant in reading the results for patients with dark skin. Induration is now the measure of choice. The edge of induration can be determined by using a ballpoint pen, and the diameter should be measured across the long axis of the forearm.

Multiple-Puncture Tests

Multiple-puncture tests are less widely used but are valuable in screening because of their ease of administration. The Heaf test is performed by using a six-prong head through a film of tuberculin solution (20 mg/ml), using a spring release action to penetrate the skin surface with a disposable head. The reaction is read at 48 to 72 h as millimeters of induration, or a grading system is used. The absence of any reaction or minute puncture scars with slight erythema but no induration is termed grade 0, and individual papules indicate grade 1 (Color Plate 8); both of these are considered negative. Positive reactions include grade 2, when the six papules coalesce to form a ring of induration; grade 3, a combined weal 5 to 10 mm in diameter; and grade 4, in which the induration is >10 mm or there is vesiculation of the response. Multiple-puncture test results are frequently read after 7 days. Because

the quantity of tuberculin introduced by multiple-puncture methods is variable, a confirmatory Mantoux test is recommended unless vesiculation is present.

The tine test is similar but uses a disposable plastic holder with a stainless steel disk with four prongs dipped in old tuberculin. The disk is applied to the volar aspect of the forearm for 1 s with sufficient pressure to produce four visible puncture sites and a circular depression of the skin from the plastic base. The reaction is read at 48 to 72 h, and ≥2 mm of palpable induration is considered comparable to a 5-mm induration in the Mantoux technique. A positive reaction of ≥5 mm is thought to be equivalent to a Mantoux reaction of 10 mm, but Mantoux testing is recommended for indurations between 2 and 4 mm.

Interpretation of the Tuberculin Test

Interpretation of the tuberculin response requires the clear separation of reactions due to tuberculosis from those arising for other reasons. Epidemiological evidence from populations with no history of household contact with tuberculosis has established the distribution of tuberculin reactivity in infected and uninfected individuals (9). In the United States, data from naval recruits suggested that no person with tuberculosis would have a Mantoux reaction of <5 mm but that the number of incorrectly classified subjects would be smallest if an induration of ≥10 mm was used in diagnosis. Therefore, a positive Mantoux test was defined as an area of induration of >10 mm 48 to 72 h after the administration of 5 tuberculin units (0.1 μg in 0.1 ml of PPD-S or biological equivalent). The sensitivity of a test is the percentage of people with the condition who have a positive test; the specificity of a test is the percentage of people without the condition who have a negative test. The sensitivity of the tuberculin test is ~89% and the specificity is 85% when these criteria are used in a population which has not received *Mycobacterium bovis* BCG vaccination (9). In areas where tuberculosis is endemic, the sensitivity and specificity of tuberculin testing both fall (e.g., 61 and 64% in Indonesia when a cutoff of 15 mm is used [2]), with a corresponding fall in the positive predictive value. In general, the larger the reaction, the more likely it is that tuberculosis is present. However, clinical considerations determine the importance of failing to make a diagnosis of tuberculosis. As a result, a positive test is defined by both diameter of induration and context of the test (Table 1). There is about 15% variability

TABLE 1 Definition of a positive tuberculin test[a]

Diam of induration (mm)	Clinical situation
>5	Patients in contact with tuberculosis
	Patients with concurrent HIV infection
	Patients with clinical or radiographic evidence of tuberculosis
	Patients with organ transplants or otherwise immunosuppressed
>10	Individuals suspected of having tuberculosis
	Persons from areas where tuberculosis is common
	Intravenous-drug users
	Persons with social reasons for exposure to tuberculosis
	Residents of long-term-care facilities (including prisons)
	Persons with medical conditions which increase the risk of tuberculosis
	Children younger than 4 years exposed to a smear-positive index case
>15	Patients with no known risk factor for tuberculosis
	Patients from areas where false-positive tuberculin reactions are common, e.g., southern United States

[a] Data from reference 1.

with the Mantoux test; that is, a concurrent test would place the subject in a different diagnostic category (7). Readers show an unconscious bias toward 10- and 15-mm measurements (18).

A recent skin test conversion is defined in a person 35 years of age or younger as a ≥10-mm increase in induration and in a person older than 35 years as a ≥15-mm increase over a 2-year period.

Not all individuals who react to tuberculin are infected with tubercle bacilli. Cross-reactivity with environmental mycobacteria causes a significant number of positive reactions and explains the geographical variability of tuberculin testing. Tuberculin reactivity develops after BCG vaccination, but the diameter of induration is usually smaller than in patients with tuberculosis. In BCG-vaccinated subjects, a positive skin test (>10 mm) can be attributed to tuberculosis if there is contact with a patient who has tuberculosis, if there is a family history of tuberculosis or a high incidence of tuberculosis in the person's country of origin, or if the subject was vaccinated a long time before the tuberculin test (6). In BCG-vaccinated patients with tuberculosis, an accelerated reaction to tuberculin can be observed at 6 h (2).

Concurrent infections, immunosuppression due to drugs, nutrition, age, stress, and disease are the most common causes of a false-negative response to tuberculin (1). More importantly, the tuberculin skin test can be negative in patients with active tuberculosis, although tuberculin positivity returns with treatment. Interestingly, erythema and induration can be suppressed in responsive subjects by hypnotic suggestion (2). Histological examination shows substantial numbers of inflammatory cells at the site of the tuberculin test even when there is no visible induration in patients with leprosy or sarcoidosis and in those treated with steroids (2). Tuberculin reactivity declines with age. Repeated testing after a week can be helpful both in patients with suspected tuberculosis and in older persons. This "booster" or "recall" phenomenon occurs most commonly in those older than 55 years but is unusual in individuals older than 75 years. Technical failures due to subcutaneous rather than intradermal injection or to administration of <0.1 ml are common problems. Tuberculin testing itself does not induce delayed hypersensitivity.

Allergic reactions to the diluent (phosphate-buffered saline), preservative (phenol), and detergent (Tween 80) are unknown. Some reactions may ulcerate, and topical hydrocortisone cream or intradermal triamcinolone can reduce these symptoms. Lymphangitis, regional lymphadenitis, and fever are recorded and most often respond to aspirin.

Conclusions

Most individuals infected with the tubercle bacillus will contain the infection and do not develop overt disease. Tuberculin testing reveals existing cellular immunity but can only suggest a probability of active disease. Culture of M. tuberculosis remains essential in the diagnosis of tuberculosis. Tuberculin tests can be interpreted only in the context of the patient and the prevailing epidemiology of mycobacterial exposure. Attempts have been made to improve the specificity of the delayed hypersensitivity reaction by using selected antigens, but none are as yet commercially available.

Cytokines

Cell-mediated immunity acts directly by cytotoxicity toward infected cells and indirectly by secretion of cytokines that permit the proliferation of cells engaged in the immune response (e.g., interleukin-2 [IL-2]) or activation of other effector cells (e.g., gamma interferon and IL-12 toward macrophages). Diagnostic tests for tuberculosis have therefore been designed with specific antigens to stimulate cytokine production by cells from peripheral blood (Table 2).

Gamma Interferon Secretion in Response to Antigenic Stimulation

The QuantiFERON-TB test (Cellestis Inc., Valencia, Calif.) was based on earlier findings in cattle, which showed that M. bovis infection could be detected by measuring gamma interferon in whole blood stimulated with tuberculin (24). Aliquots of blood (1 ml) are stimulated with tuberculin or an equivalent product made from M. avium, with saline as a negative control and phytohemagglutinin (PHA) as a positive control. Samples are incubated for 16 to 24 h at 37°C, and then 200 to 300 µl of plasma is removed without disturbing settled red blood cells. Plate wells are coated with 50 µl of a conjugate (which binds gamma interferon), and then 50 µl of plasma is incubated in each well for 60 min at room temperature. After the plates are washed, a second antibody to gamma interferon with a color detection system (100 µl of substrate) is incubated for 30 min at room temperature, after which the reaction is stopped and absorbance is measured. The kit comes with analytical software, which will determine whether the test is positive by using the criteria

- absorbance from wells stimulated by tuberculin (T) minus absorbance from wells with normal saline control (C), divided by absorbance from wells stimulated by M. avium extract (A) minus C $[(T - C)$ divided by $(A - C)] \geq 0.15$ and
- $(T - C) - (A - C)$ divided by $(T - C) \geq 0.10$, using the same notation.

  Reactivity to M. avium was defined as
- $(A - C)$ divided by (PHA response $- C) \geq 0.20$ and
- $(T - C) - (A - C)$ divided by $(T - C) < -0.1$.

The assay was considered void if there was no response to PHA (i.e., PHA $- C < 0.5$). Comparison with tuberculin testing showed discordance related to prior BCG vaccination and reactivity toward M. avium (18). The test is currently recommended for patients with an increased risk of latent tuberculosis infection and has received Food and Drug Administration approval (19). Patients with active tuberculosis are more likely and those with treated tuberculosis are less likely to have a positive QuantiFERON-TB test than a positive tuberculin reaction (11).

Understanding the molecular biology of M. tuberculosis has advanced the quest for a more specific test for tuberculosis. The genomes of pathogenic strains of M. tuberculosis and M. bovis BCG differ by a deletion of eight open reading frames known as RD1. This region includes the early secreted antigen of tuberculosis of 6 kDa (ESAT-6) and the culture filtrate protein of 10 kDa (CFP-10). There is a member of each of the PE and PPE families (characterized by recurring motifs of proline [P] and glutamine [E] in the N terminus of these proteins) and four other proteins. These proteins have therefore been proposed as specific antigens for distinguishing between infection with M. tuberculosis and BCG vaccination. A new test, based on measuring the gamma interferon response to overlapping peptides derived from the sequences of ESAT-6 and CFP-10 and using colloidal gold to increase the sensitivity of detection of gamma interferon (QuantiFERON-GOLD), has been developed and is currently available for research purposes from the manufacturer of QuantiFERON-TB.

TABLE 2 Summary of diagnostic value of cytokine-based and serological tests

Antigen or assay	Sensitivity and 95% confidence intervals (%) for[a]:			
	Smear-positive pulmonary tuberculosis	Smear-negative pulmonary tuberculosis	Extrapulmonary tuberculosis	Child tuberculosis
Gamma interferon				
ESAT-6 5-day cell culture supernatant	33.3 (17.9–48.7)	47.8 (41.6–54.0)		ND[c]
ESAT-6 ELISPOT	ND	88.7 (83.1–93.2)[b]		0.7 (58.4–79.5)[b]
CFP-10 5-day cell culture supernatant	72.9 (64.2–80.1)[b]	63.0 (55.6–70.4)		ND
CFP-10 ELISPOT	ND	80.0 (69.9–91.1)[b]		ND
T SPOT-TB	96.5 (88.3–98.9)[b,f]		ND	80.7 (68.6–88.8)[b]
QuantiFERON-GOLD	85.4 (77.3–91.0)[g]	76 (56.4–88.4)[g]	92.3 (66.1–98.2)[g]	ND
Antibody to				
38 kDa	62.2 (59.2–65.2)	50.0 (46.7–53.3)	ND	85.7 (70.0–100)
TB72 monoclonal antibody competition	76.7 (72.1–81.3)	59.9 (52.6–67.2)	76.7 (66.0–86.4)	16.7 (0–33.9)[d]
81 kDa	63.5 (53.3–73.7)[b]	51.3 (40.2–62.4)[b]	ND	ND
30 kDa/antigen 6	57.1 (50.5–63.7)	27.0 (18.7–35.3)	ND	ND
16 kDa	51.7 (60.7–42.7)	49.4 (57.0–41.8)	25.6 (16.1–35.1)[e]	33.3 (11.5–55.1)
19 kDa	40.4 (32.9–47.9)	33.6 (25.3–41.9)	32.5 (24.0–41.0)	ND
CFP-10	27.6 (22.0–33.2)	ND	ND	ND
ESAT-6	22.7 (5.2–40.2)	17.3 (7.0–27.6)	ND	ND

[a] The cutoff titer was calculated as the mean +2 standard deviations of control values, i.e., a defined specificity of 95%. Confidence intervals have been calculated from the sensitivity and the number of patients tested, combining studies.

[b] Only a single group has been responsible for the data, but this may include multiple publications.

[c] ND, no data.

[d] Sensitivity using cutoff titers derived from adult control values.

[e] Tuberculous meningitis only.

[f] Sensitivity, 91.7% (64.0 to 98.1%).

[g] Specificity, 88.2% (64.6 to 94.4%) in one study.

Enumeration of Gamma Interferon-Secreting Cells

The ELISPOT (enzyme-linked immunosorbent spot-forming cell) technique was first used in 1983 to identify antibody-secreting cells by using anti-immunoglobulin antibodies linked to peroxidase, and the assay was adapted 5 years later to the enumeration of gamma interferon-secreting cells (10). This technique has been applied to overlapping peptides from ESAT-6 and CFP-10 as a diagnostic test (15). Polyvinylidene difluoride-backed 96-well plates (MAIP S 45; Millipore, Bedford, Mass.) are coated with 15 μg of anti-gamma-interferon monoclonal antibody (1-DIK; Mabtech, Stockholm, Sweden) per ml overnight at 4°C. The plates are washed with RPMI 1640 and blocked for 1 h with RPMI 1640 supplemented with L-glutamine, ampicillin and gentamicin, and 10% heat-inactivated pooled human AB serum. Peripheral blood mononuclear cells are separated from whole blood on a Ficoll-Hypaque gradient and washed three times in supplemented medium, and then 5×10^5 cells are added to each well in 100 μl of supplemented medium containing peptides at 2 μmol/liter in duplicate or triplicate wells. A positive control with PHA and a negative control without peptide are used as standards. Assay mixtures are incubated overnight in 5% CO_2, the contents are shaken off, and the wells are washed six times with phosphate-buffered saline (PBS)–0.05% Tween 20 (PBST). A 100-μl volume of a different monoclonal antibody to gamma interferon (7-B6-1; Mabtech) labeled with biotin at 1 μg/ml is then added to each well, the plates are incubated for 3 h at room temperature, and the wells are washed six times with PBST. Spots are developed using streptavidin-alkaline phosphatase conjugate for 2 h followed, after washing, with 100 μl of chromogenic substrate for 30 min and further washing to halt the reaction. Spots are counted under ×20 magnification, and only large spots with fuzzy borders are scored. A positive score requires at least five more spots than the negative control and a number at least twice that of the negative control. This assay has been developed into a commercial test (SPOT-TB; Immunotec, Oxford, United Kingdom) and is available currently for clinical use in the United Kingdom.

The HIV pandemic has clearly shown the importance of $CD4^+$ T cells in containing tuberculous infection. Studies of mice in which the genes for gamma interferon or IL-12 and their receptors have been deleted have confirmed the importance of these cytokines in resisting the development of tuberculosis after aerosol challenge. Genetic analysis of human families with an increased susceptibility for mycobacterial infections has shown similar defects within the pathways initiated by these cytokines. These data suggest that tests based on gamma interferon might better detect individuals with a protective response to tuberculosis rather than those who will develop or have developed disease, unless exposure to the tubercle bacilli leads inevitably to disease in the setting of propitious circumstances within the human host. The immunological spectrum of tuberculosis suggests that complementary tests based on Th2 responses (i.e., measurement of IL-4 to RD1 antigens or antibody responses) may be important to obtain a high diagnostic sensitivity.

Serology

Clinical Indications

Patients with infectious tuberculosis may have symptoms for 2 or 3 months before diagnosis and may frequently present to hospital services with nonspecific complaints. A serological test, which could make an early diagnosis, perhaps even before a chest radiograph is obtained, would be valuable in restricting the transmission of tuberculosis. Patients who have smear-negative pulmonary tuberculosis, reactivation, or extrapulmonary disease (particularly tuberculous meningitis) and children with tuberculosis would also benefit from a serodiagnostic test which could increase the suspicion of tuberculosis.

From these clinical indications, it is apparent that few serological studies have been performed in a manner relevant to clinical practice. Common errors include the use of healthy subjects rather than patients with suspected tuberculosis in whom an alternative diagnosis is reached as controls, biased selection and enrollment of patients, and failure to analyze test performance by sputum smear status and site of disease. Other problems include the small numbers studied, leading to wide confidence intervals for sensitivity and specificity. Many of the near-patient tests require interpretation by the reader, and repeatability has not been demonstrated.

Purified Antigens

The selection of antigens for serological tests is defined by the need for specificity. Many mycobacterial antigens are cross-reactive. The specificity of the RD1 antigens ESAT-6 and CFP-10 has been noted. Historically, antigens specific for *M. tuberculosis* have been identified by using preabsorbed hyperimmune serum or monoclonal antibodies. Four independent groups identified the same antigen with a relative molecular mass of 38 kDa by these methods. The recombinant antigen is available through the World Health Organization (WHO) and forms the basis of commercial kits (Omega Diagnostics and ICT Diagnostics). The sensitivity of antibody to this antigen in smear-positive pulmonary tuberculosis has been explored by several groups and remains the greatest of the sensitivities of the 25 antigens tested to date (Table 2).

Most researchers agree that a serological test for tuberculosis will require several antigens. Starting with the 38-kDa antigen, patients who are seronegative for this antigen are positive to antigens such as the 16-kDa, CFP-10, Mtb8.4, Mtb48, Mtb81, and MPT32 antigens. These antigens have been combined as a multiepitope polyprotein, which is being currently investigated as a serological agent (14). Antibody to the 14-kDa (16-kDa) and ESAT-6 antigens has been associated with latent tuberculous infection (3, 22).

Monoclonal Antibodies

Monoclonal antibodies are used widely in all aspects of clinical immunology and microbiology. An animal is immunized with an antigen or mixture of antigens, and plasma cells are harvested from the spleen and fused to a malignant cell to produce a potentially immortal hybrid, which secretes antibody of a single specificity. Monoclonal antibodies to *M. tuberculosis* (and *M. leprae*) have been defined in WHO-sponsored workshops by their ability to bind to extracts from other mycobacterial species and/or their specificity for these pathogenic mycobacteria. Several monoclonal antibodies with defined specificity for *M. tuberculosis* are available through WHO. These reagents have been used to prepare purified antigens by affinity chromatography or to select clones expressing the recombinant protein (3). Even highly cross-reactive proteins may have species-restricted epitopes, and a competition assay can measure antibody levels which overlap with the binding site of the monoclonal antibody.

Methods

ELISA with Purified Antigens

The enzyme-linked immunoassay (ELISA) has become an integral part of the methodology of the immunology laboratory (17). Microtiter wells are coated with an antigen at a concentration at which maximal binding occurs (usually within the range of 1 to 10 μg/ml). Nonspecific binding is blocked by incubating the wells with bovine serum albumin or milk, often containing 0.05% Tween 20. A fixed dilution (e.g., 1:100) or a series of dilutions of sera are incubated in duplicate or triplicate microtiter wells, and after being washed, the wells are incubated with anti-human immunoglobulin G (IgG)-peroxidase or IgG-alkaline phosphatase conjugate. After another washing of the wells, antibody titers are determined by color development with chromogens such as tetramethylbenzidine or *o*-phenylenediamine. Antibody titers are recorded as the absorbance (optical density) after the reaction has been halted by a change in pH. Wells not coated with the purified antigen act as a negative control, and wells containing hyperimmune serum which displays maximal binding to the purified antigen act as a positive control. Some serum samples show excessive nonspecific binding despite the blocking step, and for serum dilutions of <1:100, the absorbance of a negative control for each serum dilution must be subtracted from the absorbance of the complete assay. Antibody titers should also be compared to the maximal absorbance of a standard hyperimmune serum in order to correct for any variability in the procedure or reagents.

Competition Assays

The preparation of large quantities of a purified antigen requires an enormous investment. Monoclonal antibodies are more readily obtained and can measure antibody titers by competing with human sera for binding to antigens. There is no need to purify individual mycobacterial antigens. Wells are coated with a soluble extract of *M. tuberculosis*. After nonspecific binding is blocked with bovine serum albumin or milk containing 0.05% Tween 20, human serum is incubated in duplicate or triplicate wells in serial dilutions. A dilution of the monoclonal antibody which will give 90% of the maximal binding in the absence of competing human serum is then added to the wells (the human serum is not removed by washing prior to this step). The monoclonal antibody either can be conjugated directly to peroxidase or can be detected using an antiserum to the class of antibody specific for the animal from which the monoclonal antibody was prepared, e.g., mouse anti-IgG (γ-chain specific)-peroxidase conjugate for a mouse IgG monoclonal antibody (23). The presence of the monoclonal antibody is then detected with a chromogen and hydrogen peroxide as with the ELISA technique. The nature of the competition assay gives a high sensitivity because low dilutions of sera can be employed without raising the problems of background interference.

Immunochromatographic assays. Near-patient tests are based on lateral-flow techniques where the antigen is immobilized on a nitrocellulose membrane. As the serum passes the antigen and forms an immune complex, anti-human IgG labeled with colloidal gold reacts with the

antibody from the serum and creates a visible line. The main problem with these assays is the variable density of the observed reaction and hence the potential for observer error. These assays are available as preformed kits.

Reliability

Serological tests have improved greatly in terms of specificity and reproducibility and compare well with those for other infectious diseases, especially in patients with smear-positive pulmonary tuberculosis (Table 2). False-negative results have been attributed to HLA restriction, when antigens of such restricted specificity are used, and to the presence of circulating immune complexes, which are rapidly removed from the bloodstream. The use of a collection of antigens or epitopes defined by monoclonal antibodies improves the sensitivity of serological tests. Although tuberculosis is characterized by cell-mediated immunity, the development of significant disease is associated with a change in T-helper-cell phenotype to one which encourages antibody production. Different antigens evoke more of an antibody response in patients with early or primary tuberculosis than in those with more extensive disease (3). False-positive serological results occur in patients with lepromatous leprosy and have been attributed to T-cell priming by prior exposure to tuberculosis. False-positive results have not been demonstrated in patients with nontuberculous mycobacterial disease for antigens currently under investigation. The clinical circumstances of false-positive results would probably not cause any difficulty in the interpretation of these tests.

LEPROSY

Delayed Hypersensitivity

Lepromin and Leprosin

M. leprae cannot be cultured in vitro, and therefore there is no material equivalent to tuberculin, which is derived from the culture filtrate of *M. tuberculosis*. In the 1920s, Mitsuda prepared lepromin from heat-sterilized bacilliferous tissue from lepromatous leprosy patients. Attempts to purify this material involved differential centrifugation (National Institute of Medical Research, Mill Hill, London; lepromin-H) and, later, extraction of bacilli with chloroform (Dharmendra lepromin). *M. leprae* can multiply within the nine-banded armadillo, and this material forms the basis of the WHO preparation lepromin-A. Standardization was achieved by bacterial count such that preparations contain 4×10^6 to 16×10^6 bacilli per 0.1 ml of inoculum. Leprosin is a soluble filtered sonicate of leprosy bacilli derived from armadillos which has been sterilized by exposure to 2.5 megarads from a cobalt-60 source; this material is standardized by using a protein concentration of 10 μg/ml.

Clinical Indications and Methods

Lepromin testing is not of value in the diagnosis of leprosy. However, in borderline leprosy and as indeterminate leprosy progresses, the presence of a positive delayed hypersensitivity reaction indicates progression toward the tuberculoid form of the disease. A large response also occurs in the majority of individuals living in areas where leprosy is endemic. Lepromatous leprosy usually occurs in the lepromin-negative population. The test is performed by injecting 0.1 ml of lepromin intradermally into the upper arm over the deltoid muscle.

Interpretation of the Lepromin Test

Two types of delayed hypersensitivity reaction can be elicited by lepromin: the Fernandez reaction and the classical Mitsuda reactions.

Fernandez Reaction

The Fernandez reaction occurs after 48 to 96 h, is essentially similar to the tuberculin reaction, and is thought to be a response to soluble extrabacillary antigens. There is marked variability in the amount of this soluble material in different preparations and a corresponding variability in positive reactions. In general, very few healthy persons, even those who give a positive Mitsuda reaction, will develop an early reaction. The frequency of positive responses is related to the degree of contact with leprosy patients, so that many household contacts of a lepromatous leprosy patient will give an early reaction to lepromin. Only patients with tuberculoid leprosy have a Fernandez reaction. Measurement of the diameter of the reaction has no clinical significance.

Mitsuda Reaction

The Mitsuda reaction is the more classical measurement of delayed hypersensitivity to lepromin. It appears as an indurated nodule 7 to 10 days after intradermal injection and can persist for more than a month. The delay has been attributed to the release of antigens from within the leprosy bacillus; leprosin coupled to liposomes produces a similarly delayed reaction. As many as 70% of healthy individuals living in countries where leprosy is rare will give a small positive reaction, and this figure rises to 90% in areas where leprosy is endemic. Again, in leprosy patients, a positive reaction occurs only in those with tuberculoid rather than lepromatous features. An area of induration with a diameter of ≥5 mm is widely accepted as a positive reaction; the lesion can progress through superficial necrosis, ulceration, and scarring.

Leprosin

Leprosin is a soluble extract of leprosy bacilli and gives the equivalent of a Fernandez reaction, i.e., almost no reaction in healthy individuals and patients with lepromatous leprosy. However, leprosin also fails to evoke a response in at least half of those with tuberculoid leprosy.

Thus, delayed hypersensitivity can indicate the prognosis of patients with leprosy by confirming their polarity, whether lepromatous or tuberculoid. If household contacts of leprosy patients have no reaction to lepromin, they could be considered for preventive therapy.

Serology

Clinical Indications

The ease of clinical diagnosis of leprosy makes a serological test for leprosy superfluous. As with the lepromin test, antibody levels can be used to distinguish between lepromatous and tuberculoid leprosy. Antibody levels correlate well with the bacterial index and might be helpful in judging the duration of chemotherapy (21). Some studies have suggested that seropositivity in contacts of leprosy patients indicates an increased likelihood of developing leprosy at a later stage, but these studies lack confirmation.

Phenolic Glycolipid

Phenolic glycolipid was identified from *M. leprae* sonicates and proved to have a unique trisaccharide component not found in other mycobacterial species. The crude extract is hydrophobic, and so conventional ELISA techniques are

difficult to use. Synthesis of the trisaccharide and conjugation of its inherent terminal disaccharide to bovine serum albumin provided reagents that were more readily incorporated into the standard ELISA. If wells are coated with the phenolic glycolipid and nonspecific binding is blocked with an irrelevant protein plus 0.05% Tween 20, then sera can be added at serial dilutions or at a fixed 1:300 dilution. After the wells are washed, IgM binding is measured using anti-human anti-IgM (μ-chain specific)-peroxidase conjugate and developed with chromogens. Absorbance (optical density) is related to the amount of IgM antibody, and positive titers have an absorbance of >0.2. As before, subtraction of absorbances measured with the same dilutions of serum on uncoated plates improves accuracy, and a standard high control is especially valuable for correcting any plate-to-plate variation.

Monoclonal Antibody-Based Tests

A competition assay using the ML04 monoclonal antibody which binds to an *M. leprae*-specific epitope on a 35-kDa antigen gives a sensitivity similar to, if not greater than, that of phenolic glycolipid in leprosy patients. The method is the same as with serodiagnostic competition assays for tuberculosis, except that the wells are coated with a soluble extract of *M. leprae*. Levels of anti-35-kDa antibody show a strong correlation with bacterial load and can be used to monitor effective chemotherapy (18).

BCG VACCINATION

Bacillus Calmette-Guérin (BCG)

BCG was first derived from *M. bovis* attenuated by serial culture at the Pasteur Institute in Lille, France. The original BCG strain was not derived from a single colony but from a whole culture and was therefore, strictly speaking, not a strain at all. The continuous subculturing of BCG has subsequently given rise to a number of different strains that can be identified by variations in their virulence toward guinea pigs and their ability to induce tuberculin sensitivity. However, widely disparate vaccines have given similar efficacies in the prevention of tuberculosis (e.g., Danish BCG and a vaccine derived from *M. microti*). Two BCG vaccines are licensed for use in the United States, namely, the Glaxo strain (Quad Pharmaceuticals, Inc., Indianapolis, Ind.) and the Tice strain (Bionetics Research, Inc., Chicago, Ill., or Antigen Supply House, Northridge, Calif.) (6). BCG vaccines have been given to more than 3 billion individuals and are the world's most widely used vaccines. The adjuvant properties of BCG vaccines may be exploited by the incorporation of recombinant genes into BCG to provide immunity to a number of different infectious diseases.

Efficacy of Vaccination

BCG vaccines were first used against human tuberculosis in France in 1921. A number of controlled trials of BCG were conducted in the 1930s but gave inconsistent results. Examination of randomized controlled trials and case-control or household contact studies has shown a beneficial effect, albeit with a wide variation in efficacy (12). A meta-analysis of studies, which included random allocation of subjects for BCG vaccination and measured the number of cases and/or deaths due to tuberculosis, also demonstrated significant benefit from BCG vaccination in preventing active tuberculosis (8). The overall relative risks for tuberculosis and for death due to tuberculosis were 0.49 (95% confidence interval, 0.34 to 0.70) and 0.29 (95% confidence interval, 0.16 to

0.53), respectively, in those who received BCG vaccination compared to nonvaccinated subjects. The protective effects were 64% against tuberculous meningitis (i.e., relative risk of 0.36 for BCG-vaccinated individuals) and 78% against disseminated tuberculosis. Much of the variation among the different trials was associated with geographic latitude and study validity score.

Four controlled trials have shown that BCG vaccination is effective against the development of leprosy, and in one trial in which both tuberculosis and leprosy were studied (Chingleput, India), benefit was confined to the prevention of leprosy (12).

Clinical Indications

Most nations (except the United States and The Netherlands) recommend routine BCG vaccination for the prevention of tuberculosis. The WHO recommends a single dose at birth as part of the Extended Program on Immunization. In the United Kingdom, neonatal vaccination is recommended in areas where the incidence of tuberculosis is >40/100,000 (i.e., London) and vaccination at 13 years is recommended elsewhere, whereas in Eastern Europe, multiple doses of BCG vaccine are given throughout childhood. In the United States, BCG vaccination is recommended for groups in which the incidence of tuberculosis is >1% per year, for tuberculin-negative infants and children who are exposed to infectious tuberculosis and cannot take isoniazid, and for tuberculin-negative children exposed to multiple-drug-resistant tuberculosis. BCG vaccination is also given to household contacts of leprosy patients in Cuba and Venezuela, and recent studies recommend a wider use in the prevention of leprosy. BCG should not be given to individuals with immunodeficiency from whatever cause, whether familial, due to concurrent disease (e.g., HIV infection or malignancy), or drug induced.

Procedure

BCG vaccines should be reserved for persons whose tuberculin skin test reaction to 5 TU is negative. Data from countries where tuberculosis is endemic suggest that a tuberculin skin test is not necessary in children younger than 10 years before vaccination. Intradermal injection of BCG is superior to other methods such as multiple puncture, scarification, jet injection, and the use of a bifurcated needle and is recommended for the Glaxo strain. Percutaneous injection (Tice strain) gives adequate results in terms of induced tuberculin sensitivity but may produce an abscess or unsightly scar. A dose-dependent relationship between the amount of BCG and the protective effect can be demonstrated in animals. The human immune response is also dose dependent in terms of induced tuberculin sensitivity, size of local reaction, and incidence of regional lymphadenitis. The dose recommended by WHO is 0.1 ml containing 0.75 mg of BCG per ml (100,000 to 300,000 CFU) or half this dose for children younger than 1 year. BCG is a live vaccine and consequently requires greater care than tuberculin in storage and administration. A 5-min exposure to tropical sunlight reduces the number of culturable particles by 99%. Freeze-dried vaccine has a lower viability than liquid preparations but can be prepared in bulk in a standard form, keeps better after distribution, and is therefore specified as the required form of BCG vaccine. The vaccine should be refrigerated when not in use and then reconstituted, protected from exposure to light, and used within 8 h. The vaccine is drawn up in a 1-ml syringe and injected with a short-bevel 25-gauge needle just beneath the surface of the skin at the level of the insertion

of the deltoid muscle. A weal of about 7 mm should be produced. Normally, a local reaction appears after 2 to 6 weeks. It begins with a small papule that slowly increases in size and may discharge purulent material to leave a shallow ulcer. This lesion heals after 1 to 3 months, with the formation of a small scar. Dry permeable dressings may be used to cover the ulcer, but impermeable dressings delay healing and can be recommended only for short periods. An early reaction to the vaccine suggests the possibility of tuberculosis (see below). Inspection of the vaccination site after 6 weeks is suggested to ensure that the vaccination has been successful and that no severe reactions have occurred.

Complications from BCG vaccination are variously estimated at 1 to 10% (4) and 15 per million vaccinations (16). Lymphadenitis accounts for approximately two-thirds of the reported complications, followed by local ulceration and keloid scarring. Keloid scarring can be minimized by not using the upper deltoid region of the arm and, in susceptible persons, using an alternative site which is more readily concealed. Disseminated BCG may occur with otitis media, osteomyelitis, and cutaneous "tuberculosis." Dissemination is particularly common in persons with a defect in cell-mediated immunity and is responsible for the small number of deaths (3 per billion vaccinations [16]) attributed to BCG vaccination worldwide.

HIV Infection and BCG

Disseminated BCG disease may occur after vaccination in patients with AIDS. The WHO recommends BCG vaccination for children in areas where HIV infection and tuberculosis are common unless the children have symptoms of AIDS (6). HIV infection is difficult to assess in the infant who may be seropositive because of maternal antibodies. If it occurs, BCG dissemination can be effectively treated with antituberculous chemotherapy, but, clearly, the prognosis is poor. In populations in which tuberculosis is rare, BCG vaccination should not be given to persons suspected of being infected with HIV.

Use as a Diagnostic Test

In persons with tuberculosis, the response to BCG vaccine is accelerated (13). Malnutrition and disseminated tuberculosis (as with tuberculous meningitis and miliary disease) reduce the sensitivity of the tuberculin skin test and are common features of child tuberculosis. Following a report by WHO in 1964, BCG as a diagnostic test for childhood tuberculosis was evaluated in India. In children with tuberculosis but without a visible BCG scar, a papule of >5 mm in diameter appeared within 24 to 48 h (compared to the normal 2 to 3 weeks) and a pustule appeared in the next 3 to 5 days. Reactions may begin as early as 6 h. A delayed reaction occurs in malnourished children but is still earlier than expected. BCG vaccination is especially effective in preventing primary tuberculosis (see above), and the use of BCG as a diagnostic test in areas where tuberculosis is endemic has the advantage of vaccinating the unprotected population as well as confirming the clinical suspicion of active disease.

CLINICAL VALUE OF TESTS OTHER THAN IN DIAGNOSIS

Chemoprophylaxis

The tuberculin response remains a key test in deciding who should receive preventive treatment with isoniazid. Despite the potentially toxic effects of this drug, epidemiological evidence promotes the use of preventive therapy in those with recent contact with tuberculosis and in persons with abnormal chest radiographs consistent with previous tuberculosis. The definition of tuberculin positivity in the light of the clinical situation restricts the need for isoniazid treatment in subjects with no known exposure to tuberculosis (Table 1). The incidence of isoniazid-induced hepatitis has been estimated to be 10.3 in 1,000, with a mortality of 0.06%. Immunological markers which could predict the persons who are most likely to develop tuberculosis, perhaps by HLA phenotype (DR15) or the human equivalent of the Bcg^s phenotype, could further restrict the use of isoniazid to those who would gain the greatest benefit from this treatment. Enumerating cells from peripheral blood which secrete gamma interferon in response to peptide epitopes of ESAT-6 may be helpful in indicating the patients infected with M. tuberculosis (15), but its value in comparison with tuberculin skin testing remains uncertain.

Compliance with Treatment

A large number of serological studies have shown that there is an early increase in antibody levels immediately following the start of treatment for tuberculosis (3). Levels of antibody to the 16-kDa antigen rise when the lack of effective treatment has been sufficient to allow tubercle bacilli to multiply again in numbers that can be detected by sputum culture (4). Antibody levels are slow to rise in patients infected with isoniazid-resistant strains of tubercle bacilli (4). Immunological markers might be valuable in assessing significant problems in the treatment of tuberculosis, whether adherence or drug resistance.

Reactivation

In patients with radiographic evidence of self-healed tuberculosis, reactivation may occur. Estimates suggest a breakdown rate of 1 to 5% per year. One study suggested that the development of detectable antimycobacterial antibody coincides with reactivation and that serological assessment of patients with radiographic evidence of healed tuberculosis might define a population which requires treatment for tuberculosis (3).

Nontuberculous Mycobacteria

The epidemiology of infection with nontuberculous mycobacteria has changed radically as infection with HIV progresses. Infection with the M. avium-M. intracellulare complex (MAC) is particularly common, and empirical therapy for both tuberculosis and MAC is often given to immunosuppressed patients while the results of culture are awaited. Detection of species-specific mycobacterial DNA following amplification by PCR will become the preferred means of early distinction between the two species. Tests involving species-restricted monoclonal antibodies were used briefly, but the requirement for culture to obtain material for testing means that the new test has insufficient advantage over the detection of mycobacterial DNA directly in clinical specimens.

Epidemiological studies have shown a high frequency of MAC in the southern United States and have been cited to explain the variation in tuberculin sensitivity. Skin testing with soluble antigens from different mycobacterial species has enjoyed some favor but has no certain clinical application. One group suggested that the observed reduction in responses to other mycobacterial sensitins in patients with tuberculosis compared to healthy controls indicates a lack of immune responsiveness to "common antigens" or perhaps a focusing of the immune response on the invading pathogen.

CONCLUSION

Tuberculin testing remains the most widely employed immunological test for the diagnosis of tuberculous infection. Tests based on cellular immunity and the secretion of gamma interferon have shown significant progress and are used routinely in some parts of the world. Serological tests may have a complementary role and remain the basis for near-patient tests.

APPENDIX

Sources of Materials

Tuberculin PPD solution for the Mantoux test
Parke-Davis, Morris Plains, N.J.

Tuberculin PPD multiple-puncture devices
Lederle Laboratories, Division of American Cyanamid Co., Wayne, N.J.

Mycoplasma: Immunologic and Molecular Diagnostic Methods

KEN B. WAITES, MARY B. BROWN, AND JERRY W. SIMECKA

59

Mycoplasmas and ureaplasmas are members of a unique group of organisms (class *Mollicutes*) that are characterized by their small genomes, lack of cell walls, sterols in cell membranes, and complex nutritional requirements. The role of *Mycoplasma* and *Ureaplasma* species in human diseases was largely underappreciated until recent years, and as a result, most diagnostic laboratories ignored them. Because of their complex nutritional requirements as well as their adaptation to the host during infection, these fastidious organisms can be difficult and time-consuming to culture from patient samples. However, there are improved methods for detection, including PCR detection assays, serologic assays, and commercially available growth media, but these are still limited compared to the products for other organisms.

Several organisms in the class *Mollicutes* are associated with human disease. The best-known mycoplasma disease in humans is *Mycoplasma pneumoniae* respiratory disease, and it remains a leading cause of respiratory illness worldwide. Some members of the *Mollicutes* are also significant causes of urogenital tract disease; these include *Mycoplasma genitalium*, *Ureaplasma* species, and *Mycoplasma hominis*. A number of other mycoplasma infections occur in humans, which in some instances may also contribute to disease. Thus, mycoplasmas are emerging as primary etiologic agents in a number of human diseases. Additional evidence supports their role in exacerbation of other diseases. As diagnostic approaches become better established and more frequently used by clinical laboratories, the impact of this unique group of infectious agents in humans is likely to become better appreciated.

The purpose of this chapter is to discuss the advantages and disadvantages of current molecular and serologic diagnostic techniques for mycoplasmal and ureaplasmal infections. Established approaches to the detection of *M. pneumoniae*, *Ureaplasma*, *M. genitalium*, and *M. hominis* infections are discussed. A majority of the discussion focuses on *M. pneumoniae*, but many of the same principles and limitations of detection also apply to the other members of the *Mollicutes*.

MYCOPLASMA PNEUMONIAE

M. pneumoniae occurs endemically and epidemically in persons of all age groups. The most frequent clinical syndrome is tracheobronchitis, often accompanied by upper respiratory tract symptoms. Typical symptoms can persist for weeks to months and include hoarseness, fever, cough, sore throat, headache, chills, coryza, and general malaise (10). *M. pneumoniae* may occur in up to 20% of adults requiring hospitalization for community-acquired pneumonias in the United States (26) and probably an even greater proportion of those not requiring hospitalization. The incubation period is 1 to 3 weeks, and spread throughout households often occurs. *M. pneumoniae* can persist in the respiratory tract for several months after initial infection and sometimes for years in hypogammaglobulinemic persons (10, 36). Some people may experience extrapulmonary complications including skin rashes, pericarditis, hemolytic anemia, arthritis, meningoencephalitis, and peripheral neuropathy.

Serology

Historically, serology was the most common laboratory means of diagnosis of *M. pneumoniae* respiratory tract infections. It has the advantages of not requiring viable microorganisms, of allowing easy acquisition of small amounts of serum for storage and testing, and of having the availability of many different commercially available assays. *M. pneumoniae* has both lipid and protein antigens which elicit antibody responses in clinical infections that can be detected after about 1 week of illness, peaking at 3 to 6 weeks, followed by a gradual decline, allowing the use of several different serologic assays based on different antigens and technologies. Although serology is a historically common and useful approach to the diagnosis of mycoplasma infection, its use alone has several potential disadvantages.

One disadvantage of serology is that ideally both acute- and convalescent-phase sera need to be tested in order to confirm seroconversion. Measurement of immunoglobulin M (IgM) and IgG levels in paired specimens collected 2 to 3 weeks apart is optimal for the most accurate diagnosis of recent or current *M. pneumoniae* infection, especially in adults older than 40 years, in whom an IgM response may be minimal or absent, presumably because of reinfection (37). A fourfold or greater rise in antibody titer indicates a current or recent infection. The duration of the IgM response can be variable; it usually peaks after about 3 weeks and then gradually declines. However, IgM antibodies can last for several weeks in some cases, further complicating the interpretation of serologic data in diagnosis of acute *M. pneumoniae* infection and making it risky to base a diagnosis on the analysis of

a single serum specimen for IgM. Detection of IgA responses may be a better approach to diagnosis. M. *pneumoniae* is primarily a pathogen of mucosal surfaces, and therefore IgA antibodies are produced early in infection. Serum IgA levels also decrease sooner, since the half-life of IgA in serum is short. Thus, IgA may perhaps be more reliable and useful for diagnosis of acute infection than IgM; however, few commercial tests include reagents for the detection of *Mycoplasma*-specific IgA.

One of the first serologic indicators used in diagnosis of M. *pneumoniae* infection is the presence of cold agglutinins, which does not rely on *Mycoplasma*-specific antibody responses. Cold agglutinins are IgM antibodies that agglutinate human erythrocytes at 4°C. They occur in association with M. *pneumoniae* infection in about 50% of cases within a few days, and their levels remain elevated for about 6 weeks. One hypothesis is that cold agglutinins result from cross-reactive autoantibodies against the I antigen of human erythrocytes. Another is that they develop directly as a result of antigenic alteration of erythrocytes caused by M. *pneumoniae* infection.

Performance of a qualitative "bedside cold-agglutinin test" involves placing 1 ml of anticoagulated blood in a cup of crushed ice for several minutes and then visually examining it for agglutination. On warming, the agglutination will resolve, but repeating the cooling procedure can reproduce it. A positive test for a patient in whom mycoplasmal infection is strongly suspected may have some clinical value. A more precise test is to determine the cold-agglutinin titer by reacting 0.1 ml of doubling dilutions of patient sera with 0.1 ml of a 1% suspension of washed human type O erythrocytes in a microtiter plate and determining the highest dilution at which agglutination occurs after 30 min of incubation at 4°C. Titers of 64 to 128 or a fourfold or greater rise in titer suggest a recent M. *pneumoniae* infection, and the magnitude of the cold-agglutinin response may correlate directly with the severity of pulmonary disease. Detection of cold agglutinins is generally not recommended for the diagnosis of M. *pneumoniae* infection since cold agglutinins are associated with a wide variety of conditions, such as viral infections and collagen vascular diseases, and, more importantly, specific serologic assays are now widely available.

Complement fixation (CF) was the major diagnostic technique used to measure M. *pneumoniae*-specific serum antibodies for many years. Seroconversion, defined as a fourfold change in titer, measured in paired sera collected 2 to 4 weeks apart and assayed simultaneously, provides the greatest diagnostic accuracy. However, CF measures mainly the early IgM response and is unable to differentiate the other antibody classes. In addition, CF has limited sensitivity and specificity because the glycolipid antigen mixture used is not specific for M. *pneumoniae* and may be found in other microorganisms, as well as human tissues and even plants. Cross-reactions with other organisms, most notably M. *genitalium* (21), are well recognized, and false-positive results due to cross-reactive autoantibodies induced by acute inflammation from other unrelated causes may occur. To help overcome the problem with cross-reactivity, confirmation of positive CF results using Western blotting can be done, but this adds to the time and cost. Commercial assays for detection of M. *pneumoniae* antibodies by Western immunoblotting are available in Europe (Virotech, Rüsselheim, Germany) but not yet in the United States.

Most clinical laboratories have replaced CF with techniques of greater sensitivity and specificity. Numerous assay formats have been developed over the past several years and

sold as commercial kits. Commercial kits are often evaluated using CF as the reference method. However, considering its lack of antibody class distinction and its cross-reactivity with other microorganisms, CF is not really suitable as a reference standard. Many of these tests, however, have not been fully evaluated and compared. In addition, the extent to which newer commercial serologic assays for M. *pneumoniae* will cross-react with M. *genitalium* or other mycoplasma was not established with certainty, but this seems less likely to be a problem than with CF.

An in-depth discussion of various types of commercial M. *pneumoniae* antibody assays and a comparative analysis of them based on published studies is available in a recent review (41). Table 1 summarizes the three most popular types of serologic assays used to detect M. *pneumoniae* infection that have been developed commercially. These are indirect immunofluorescence, particle agglutination, and enzyme immunoassays (EIAs).

Experience with EIAs dates back to the 1970s, and these assays are now the most widely used techniques for measuring antibodies against M. *pneumoniae*. A review of Food and Drug Administration-approved diagnostic tests reveals at least a dozen different M. *pneumoniae* EIAs marketed in the United States over the past several years, all of which are described as having either moderate or high complexity according to CLIA (Clinical Laboratory Improvement Act) classification. EIAs are more sensitive for detecting acute infection than is culture and can be comparable in sensitivity to PCR, provided that sufficient time has elapsed since infection for antibody to develop and that the patient has a functional immune system. Although most EIAs are sold as 96-well microtiter plate formats, some can be obtained as breakaway microwell strips, which allow smaller numbers of sera to be tested economically.

There are two EIAs packaged as qualitative membrane-based procedures for the detection of single test specimens. These are truly rapid EIAs (taking 10 min or less) and are simple to perform. The Meridian Immuno*Card* (Meridian Diagnostics, Cincinnati, Ohio) is an IgM-only assay that is simple to read and is especially useful for testing pediatric samples. However, as discussed above, there are limitations in interpreting the results of IgM-only assays. The Remel EIA (Remel Laboratories, Lenexa, Kans.) is a membrane-based assay that detects IgM and IgG simultaneously. Although acute- and convalescent-phase sera should be tested quantitatively for both IgG and IgM for greatest diagnostic accuracy, the practical value of the qualitative single point-of-care tests offered by both kits is lost if paired specimens are required. Thus, these single point-of-care tests can be useful if the potential limitations are considered in the diagnosis.

Molecular Biology-Based Techniques

The attention focused on nucleic acid amplification techniques, such as PCR, has largely eclipsed earlier interest in nonamplified antigen detection or DNA hybridization systems. Numerous studies since the late 1980s using simulated clinical specimens, animal models, and clinical trials have validated the ability of the PCR assay to detect M. *pneumoniae,* often in conjunction with serology and/or culture (for example, see reference 8). The same types of clinical specimens that can undergo culture, such as throat swabs, nasopharyngeal swabs, sputum, and other sterile tissues or body fluids, can also be tested by the PCR assay. Additional advantages of PCR assays are that they can be used to detect mycoplasmas in tissue that has already been processed for

TABLE 1 Major commercial serologic test kits for M. *pneumoniae* in United States

Assay format	Antibodies measured	Equipment required	Comments and limitations
EIA	IgM, IgG, or IgA separately	Spectrophotometer/ EIA reader	EIAs are typically performed using a microtiter plate format in which antigens are adsorbed onto the polystyrene surface. Dilutions of test serum are added to the wells and incubated. Antibodies bound to the solid-phase antigen are visualized by using enzyme-labeled conjugates directed against the primary antibody and substrate read in a spectrophotometer. The amount of conjugate reacting is proportional to the levels of antibody present. EIAs have the adva tages of requiring very small serum volumes (<100 μl), are adaptable to testing larger or small numbers of specimens, and can be made isotype specific.
Membrane EIA	IgM or IgG separately	None	Membrane EIAs are rapid, qualitative, point-of-care procedures designed for testing single serum specimens. A permeable membrane or filter paper is impregnated with antigen to which serum is added. This step is followed by addition of anti-human IgG or IgM enzyme conjugate. Development of color after enzyme substrate is added constitutes a positive test. Lipemic or hemolyzed serum samples will interfere with results.
Particle agglutination (PA)	IgG or IgM separately or simultaneously	None	PA tests utilize latex or gelatin as carrier particles coated with antigen that are incubated with test serum. If specific antibodies are present, the particles agglutinate, resulting in a visible reaction. PA products may provide qualitative results that can be visualized on a card or quantitative data read in a microtiter plate format. PA assays do not offer any advantages over other techniques such as EIAs or IFAs, except possibly their ease and simplicity of performance.
Indirect immunofluo-rescence (IFA)	IgG or IgM separately	Fluorescence microscope	Antigen is fixed to glass slides. Specific antibody is detected in dilutions of test serum after staining with anti-human IgM or IgG fluorochrome conjugate. Results can be affected by the presence of rheumatoid factor and high M. *pneumoniae*-specific IgG antibody levels. Additional procedures to validate IgM results are needed in these settings. IFA provides quantitative data but interpretation is very subjective.

histologic examination or in cultures that are contaminated so that culture is impossible (35, 40). Furthermore, PCR assays generally require only one specimen, can be completed in 1 day, may give positive results earlier in infection than serology does, and do not require viable organisms.

Most PCR-based techniques are somewhat similar and do not differ in principle from PCR assays used for detection of other microorganisms. Although most approaches focus on amplifying sequences of *Mycoplasma* genomic DNA, RNA-based amplification has also been used. Specific advantages of RNA-based amplification techniques are the high sensitivity that can be achieved due to the large number of rRNA copies per mycoplasmal cell and the fact that its detection is more indicative of viable mycoplasmas in a clinical sample (6). Table 2 lists selected original references of M. *pneumoniae* nucleic acid amplification assays that describe different target regions of the genome. However, it is difficult to compare the results of one study utilizing PCR directly with another because of the different specimen types, DNA extraction and amplification techniques, primer selection, and reference

standards used for comparison. Additional technical information, primer sequences, and tabulations of various nucleic acid amplification assays according to respiratory specimen tested or to publication with or without validation data are available in recent publications on this topic (6, 23, 27).

Comparison of the PCR technique with culture has yielded varied results, and large-scale experience with M. *pneumoniae* is still limited. In view of the enhanced analytical sensitivity of the PCR assay over culture, a positive PCR result together with negative culture can be easily

TABLE 2 Gene target used in M. *pneumoniae* nucleic acid amplification assays

Gene target	PCR product size (bp)	Reference(s)
ATPase operon gene	144	3
P1 adhesin gene	153–466	7, 15, 31
16S RNA	277	38
tuf gene	950	24

explained. However, in a situation of a negative PCR assay with a positive culture, the presence of inhibitors or some other technical problem with the PCR assay must be considered. Interestingly, PCR inhibition is much more likely to occur with nasopharyngeal aspirates than with throat swabs, according to one study (32). In support, another study (8) found that sputum was more likely to be PCR positive than were nasopharyngeal specimens, throat swabs, or throat washes. Sometimes dilution of samples overcomes inhibition of PCR due to a reduction in inhibitors during the reaction, but this is at the cost of diminished sensitivity because the nucleic acid is diluted along with any inhibitors. To overcome this problem, there are commercial reagents for nucleic acid purification that are effective in removing most inhibitors of amplification in PCR assays. Thus, the type of sample and its preparation influence the ability to detect mycoplasma infection using the PCR assay.

PCR results may not always correspond with serologic test results. For example, elderly adults with pneumonia might have age-related impairment in immunity, resulting in low serologic responses after *M. pneumoniae* infection (8). A positive PCR test together with a negative serologic test could also mean that the specimen was collected too soon in the course of the illness to allow sufficient time for antibody to develop. PCR results may also be negative as soon as 24 h following antibiotic treatment, whereas serologic results remain positive. Based on the discussion above, there are further reasons for positive serologic data when concomitant PCR testing is negative.

Despite the issues in comparing PCR with serology and culture, there is justifiable concern when PCR is used as the sole means of detection for surveillance purposes without being accompanied by culture, serology, or clinical data. It is not known with certainty whether there is a specific threshold quantity of *M. pneumoniae* in respiratory tract tissues that can differentiate colonization versus infection. Therefore, relying solely on a positive result by PCR may overestimate the clinical importance of *M. pneumoniae* as a pathogen if the population sampled has a high carriage rate and because of the propensity of this organism to cocirculate with other bacterial and viral pathogens.

Further refinements to traditional PCR assays are needed. These improvements could include the development of multiplex PCR tests to detect other atypical pathogens such as *Chlamydophila pneumoniae* simultaneously with *M. pneumoniae*, which may make PCR assays more attractive and practical for routine use in diagnostic laboratories. A number of products are currently in clinical trials, but no diagnostic products are being sold commercially in the United States thus far. Ideally, the development of multiplex assays that also provide quantitative information would be useful. In support, Hardegger et al. (12) found that a real-time PCR assay was equal to a conventional nested PCR in its sensitivity of detection of *M. pneumoniae* in clinical samples, allowing for quantitation of the amplified product during PCR and reduction in hands-on time. Tests of this nature may eventually turn out to be the most valuable for *M. pneumoniae* diagnosis since they might be able to take into account the potential confounding effect of a prolonged low-level carrier state in healthy persons. Thus, until PCR assays can be standardized, made available at a reasonable cost, and sold commercially as complete diagnostic kits suitable for use in hospital-based or other reference laboratories, this method of diagnosis is unlikely to achieve widespread use in the detection of *M. pneumoniae* infection for clinical as opposed to epidemiological purposes in the United States.

Recommended Diagnostic Approach to *M. pneumoniae* Disease

Clinical manifestations, radiographic presentation, and general laboratory tests are not sufficiently specific to allow the differentiation of *M. pneumoniae* infection from infections caused by other common microorganisms, and more specific laboratory methods are needed to confirm the diagnosis. This situation is complicated further by the fact that mycoplasmal respiratory infections often coexist with infections caused by several other respiratory pathogens (39). Mild respiratory infection suspected to be due to *M. pneumoniae* may not require a microbiological diagnosis to guide patient management. Furthermore, most of the diagnostic methods currently available for the detection of *M. pneumoniae* infections are somewhat better suited for use in epidemiological studies, as opposed to direct management of individual patients, due to their prolonged turnaround time, limited availability, and high cost. However, attempts to detect *M. pneumoniae* infection are justified in the event of an outbreak of illness in which *M. pneumoniae* is suspected or any infection that is of sufficient severity as to require hospitalization, especially in patients with an immune deficiency or underlying condition that may contribute to an unfavorable outcome.

The ideal diagnostic strategy will take advantage of both serology and PCR, since culture is laborious, time-consuming, insensitive, and expensive. There are several factors imposing limitations on the use of serology as a sole means of diagnosing *M. pneumoniae* infections. However, the single point-of-care tests, such as those marketed by Remel and Meridian, can be useful, particularly for use with pediatric patients, after considering the potential problems of serology alone. PCR assays are promising due to their analytical sensitivity and specificity, but the results can be confounded by the presence of a carrier state. Therefore, the use of serology combined with PCR can overcome many of the limitations of each approach alone in diagnosis, but the expense has to be considered along with the lack of standardized commercially available PCR assays.

UREAPLASMA UREALYTICUM AND UREAPLASMA PARVUM

Ureaplasma spp. are implicated in a number of human urogenital infections. *Ureaplasma* was proven to cause nongonococcal urethritis in experimental infection studies of humans. Demonstrating their role in disease is complicated by the high carriage rate of the microbe in the lower genital tract of asymptomatic, healthy women. Most recently, colonization of the placenta and/or amniotic fluid with *Ureaplasma* spp. has been associated with histologic chorioamnionitis and premature birth (42). Importantly, colonization of the neonate was linked to the development of chronic lung disease (20).

Originally thought to have two biovars composed of 14 serotypes, *Ureaplasma* is now recognized as two species: *U. parvum* (formerly biovar 1; serovars 1, 3, 6, and 14) and *U. urealyticum* (formerly biovar 2; serovars 2, 4, 5, and 7 to 13). Although some serovars are more fastidious than others, most *Ureaplasma* species are relatively easy to culture and develop classic colonies on A7 or A8 agar (commercially available from Remel Laboratories) within 2 to 3 days.

Serology

Although several EIA protocols have been published, no commercial product is available in the United States. The EIA does not differentiate between *U. parvum* and

U. urealyticum, and other approaches, such as monoclonal antibody capture assays, microimmunofluorescence, growth inhibition, and metabolic inhibition, were used to detect serovar differences. As with *M. pneumoniae*, seroconversion, a fourfold rise in titer, or change in subclass-specific response may be useful. However, serology has never been used to any significant degree for the diagnosis of ureaplasmal infections in a clinical setting.

Molecular Biology-Based Techniques

The same principles, limitations, and considerations that were discussed for *M. pneumoniae* also apply to the detection of *Ureaplasma* species. Furthermore, not all PCR assays differentiate between the two newly recognized species of *Ureaplasma*. The newest molecular biology-based tools permit the identification of species as well as limited determination of serovars (17, 18, 29). However, it is presently unclear if there are differences in the pathogenic potential of the two *Ureaplasma* species or between the different serovars, and therefore, species- and serovar-specific assays are limited to epidemiologic studies and are currently not necessary in clinical diagnosis.

The most commonly tested samples from adults include urine, urethral swabs, vaginal swabs, endocervical swabs, placental or endometrial tissues, amniotic fluid, and, more rarely, synovial fluid. Synovial fluid has a particular problem in that some samples appear to be inhibitory for PCR assays and therefore false-negative results can occur. Due to high carriage rates, vaginal swabs are of limited clinical significance for *Ureaplasma*. Urethral swabs from males are more informative than are those from females. In addition, first-void urine is a frequent sample used for PCR, but again there is the inherent caveat that first-void urine may reflect transient contamination rather than a clinically significant finding. For neonates, both transtracheal aspirates and nasopharyngeal lavages can be informative, but the results from nasopharyngeal lavages can be confounded by transient colonization due to passage through the birth canal.

Ureaplasma-specific primers were developed to target several different genes; the most commonly used are the urease, multiple-band antigen, and 16S rRNA genes (Table 3).

At least one commercial PCR test is based on the urease gene (Maxim Biotech, Inc., San Francisco, Calif.). However, extensive field-testing data and comparisons with other test systems have not been done, and this assay does not appear to differentiate between species or among serovars. Multiplex PCR assays have also been developed for the genital mycoplasmas, including *U. urealyticum* and *U. parvum*. A recent approach incorporated hybridization with specific labeled probes to standard PCR reactants in a microtiter plate format (25, 30, 43). This system has the advantage of using a single primer pair to amplify the 16S rRNA target from the major genital mycoplasmal species as well as the two ureaplasmal species, followed by a probe specific to each of the species. In addition, detailed protocols were developed by using real-time PCR. The advantages to real-time PCR are that the reactions can be completed rapidly and are quantitative, allowing an estimation of microbial load. Thus, PCR tests to detect ureaplasmas need further field evaluation, but ongoing efforts to improve and standardize PCR approaches are likely to lead to more specific and cost-effective diagnostic methods.

Recommended Diagnostic Approach

Since none of the serologic assays are available commercially, most clinical laboratories depend on the use of culture. The recommended 10B broth and A8 agar are available commercially. Although PCR assays need to be fully validated, they may be of great value when combined with culture, particularly in high-risk situations such as cultures of amniotic fluid or neonatal specimens. Research laboratories are strongly encouraged to use PCR assays that permit the differentiation of the two species of *Ureaplasma*.

MYCOPLASMA GENITALIUM

M. genitalium is a very fastidious, slow-growing mycoplasma first identified in 1981 from the urethras of men with urethritis. Its role in human disease is just now becoming apparent, mainly as a result of epidemiological studies that have used PCR to detect infections. Despite the increased awareness of the pathogenic potential of *M. genitalium*, there are

TABLE 3 Examples of PCR-based assays and gene targets for detection of urogenital mycoplasmas

Genital *Mycoplasma* species detected	Assay (references)	Target gene (references)	Clinical samples tested
Ureaplasma species	PCR	Urease (42), 16S rRNA (28)	Amniotic fluid, synovial fluid, endocervical swab, urine, urethral swab, placenta and membranes, endometrium
U. parvum and *U. urealyticum*	PCR (17, 19); PCR and microtiter plate hybridization (25, 30, 43); PCR-single strand conformation polymorphism analysis (29)	16S rRNA (25), urease (30), MBA (17, 29), 16S rRNA-23S rRNA intergenic spacers (19)	Urethral swab, urine, endocervical swab, endotracheal aspirate, nasopharyngeal aspirate, amniotic fluid, synovial fluid
M. genitalium	Real-time PCR (4, 14, 16); PCR (2, 16); PCR + liquid hybridization (9, 43)	16S rRNA (16, 43), *MgPa*/P140, Adhesin (2, 9), *GyrA* (4)	Urine, urethral swab, vaginal swab, endocervical swabs, synovial fluid
M. hominis	RT-PCR (1); PCR (33); PCR microtiter plate hybridization (43)	*gap* (1), 16S rRNA (33, 43)	Urine, blood, wound abscess, vaginal swab, endocervical swab, placenta and membranes, endometrium, amniotic fluid, synovial fluid

very few clinical isolates of the microbe because of the extremely fastidious nature of the microbe. This mycoplasma is believed to play a role in some cases of cervicitis and pelvic inflammatory disease in women and in urinary tract infections in both men and women.

Serology

A microimmunofluorescence assay for *M. genitalium* was developed as a research tool and shown to detect antibody responses in men with nongonococcal urethritis and women with salpingitis (11). This method is rapid, reproducible, and quite sensitive and specific, with less cross-reactivity with *M. pneumoniae* than is seen with other methods. EIA protocols using LAMP antigens were applied to population studies, and the results were confirmed by Western blotting (2). LAMP antigens have limited cross-reactivity with *M. pneumoniae*, and the EIA platform is more amenable to large-scale testing than is Western blot analysis. However, these assays are not available outside of specialized research laboratories and therefore cannot be recommended at this time for diagnostic purposes.

Molecular Biology-Based Techniques

Perhaps more than for any other mycoplasma, molecular biology-based techniques have played the critical and indeed defining role in diagnosis of *M. genitalium* infections. *M. genitalium* is notoriously difficult to culture, perhaps in part because of its ability to persist in the intracellular environment but also because of its fastidious growth requirements. The sites that are sampled, preparation of DNA template material, and conventional PCR approaches are basically identical to those used for *M. pneumoniae*, *U. urealyticum*, and *U. parvum*. The 16S rRNA (13, 16, 43) gene is a common target, as is the *M. pneumoniae* P1 adhesin homolog, *MgPa* (9, 14). Both multiplex PCR and real-time PCR assays were developed for the genital mycoplasmas (14, 16, 25, 43). Although presently unavailable, several commercial kits are currently in the development stage. Because of the extraordinary difficulty in obtaining culture-based confirmation of the presence of *M. genitalium* in clinical samples, it is especially critical that PCR assays be stringently controlled and monitored. Ideally, a positive PCR result should be confirmed by a second PCR assay using an unrelated target gene.

Recommended Diagnostic Approach

The recommended approaches to and considerations for diagnosis of *M. genitalium* infections have been recently reviewed (2). The major consideration is that one single test or combination of tests is not adequate. The difficulty in cultivation, coupled with the recent findings that suggest more variability in both PCR and EIA than was originally believed to occur, strongly suggests that the true incidence of *M. genitalium* infection may be underestimated.

MYCOPLASMA HOMINIS

Like *Ureaplasma* species and *M. genitalium*, *M. hominis* is associated with urogenital infections. However, unlike *Ureaplasma* species, detection of *M. hominis* in the vagina is of clinical significance since this microbe is a component of the suite of bacteria associated with bacterial vaginosis. *M. hominis* is also more closely linked to systemic diseases, including pyelonephritis, postpartum fever and endometritis, meningitis, bacteremia, and wound infections. Like *Ureaplasma* species, *M. hominis*, although slow growing, is relatively easy to cultivate and can be isolated using commercial

SP4 agar and broth or 10B broth and A8 agar (Remel Laboratories). Classic "fried-egg" colonies can be observed within 3 to 7 days.

SEROLOGY

As with the other urogenital mycoplasmas, no commercial serological assays are available in the United States. The most recent EIA is based on LAMP antigens (22) and is more broadly cross-reactive among different *M. hominis* strains than are assays using cell lysates as antigens (5). Confirmation by immunoblot analysis is also appropriate. Seroepidemiology to determine exposure to *M. hominis* within a population can be done with a single serum sample; however, for diagnostic purposes, paired acute- and convalescent-phase sera are likely to be more informative. As is the case for ureaplasmas, clinical experience using serology for diagnosis of *M. hominis* infections is scant.

Molecular Biology-Based Techniques

The molecular biology-based techniques and considerations are essentially the same as for the other mycoplasmal species. The most common target gene is 16S rRNA, and both multiplex PCR and real-time PCR assays have been developed (1, 25, 34, 43). Because of the relative ease of cultivation, standardization and validation of the PCR assays can be more easily achieved. Commercial PCR assays are under development and may be available in the future.

Recommended Diagnostic Approach

Since none of the serologic or molecular assays are available commercially, most clinical laboratories will have to depend on culture using specific procedures designed to recover these organisms. Use of Columbia blood agar or blood culture systems such as BacT/Alert is strongly discouraged because the number of false-negative results would be significant and culture results would therefore be unreliable.

Chlamydial Infections

LEE ANN CAMPBELL, CHO-CHOU KUO, AND CHARLOTTE A. GAYDOS

60

Chlamydiae are obligate intracellular bacteria, which cause many diseases in animals and humans. This chapter will focus on the diagnosis of human infections.

CHLAMYDIA TRACHOMATIS

C. trachomatis is divided into two biovars, namely, biovars trachoma and lymphogranuloma venereum (LGV) (22). The trachoma biovar causes ocular and urogenital infections. Trachoma is the leading cause of preventable blindness (22). Urogenital infections are sexually transmitted and may be transmitted to infants during birth by infected mothers, causing acute neonatal conjunctivitis and infantile pneumonia. *C. trachomatis* infections are among the most common sexually transmitted diseases among young adults and adolescents (7). The LGV biovar causes LGV.

Introduction and Epidemiology

C. trachomatis genital infections are associated with many syndromes, including cervicitis, urethritis, pelvic inflammatory disease, infertility, and ectopic pregnancy in females, and urethritis, proctitis, and epididymitis in males (7). The population prevalence in young adults is 5 to 20% (6). Up to 80 to 90% of infected women and >50% of infected men are asymptomatic (1), which creates a public health problem in disease control. Widespread screening of high-risk individuals has been recommended (7). More than 50 million cases occur worldwide, and 3 to 4 million cases occur in the United States annually (7).

Serovars of *C. trachomatis*

Eighteen serovars are recognized. The trachoma serovars are A, B, Ba, and C, the genital serovars are D to K, and the LGV serovars are L_1 to L_3. Serovars can be distinguished by serology or by genetic typing of the major outer membrane protein (MOMP) gene. Serotyping differentiation is not usually important for treatment, since the antibiotic susceptibility patterns are the same. If LGV is suspected, serovar determination should be done to guide treatment, which needs to be performed for a longer period for cases of LGV.

Diagnosis of *C. trachomatis*

Culture

The cell line most commonly used for the culture of *C. trachomatis* is McCoy cells, but others have also been used (HeLa, HEp-2, and monkey kidney cells). Since cell culture is difficult and not often available in clinical labs, it is rarely used except for sexual abuse cases and medical legal matters. Culture sensitivity compared to molecular techniques can range from 50 to 100% (an average of 85%), while culture specificity is 100% (29, 30). Culture procedures are as described below for *Chlamydia pneumoniae*, except that the preferred cell line for *C. trachomatis* is McCoy cells and the incubation time is 2 days for biovar LGV and 3 days for biovar trachoma. After incubation, the cells are fixed, stained with a fluorescein-conjugated monoclonal antibody, and read for the presence of inclusions using an epifluorescence microscope. Commercial monoclonal antibodies for either the genus-specific lipopolysaccharide or the species-specific epitope on the *C. trachomatis* MOMP are available.

Nonculture Tests

A direct cytological examination of clinical specimens for the detection of elementary bodies (EBs) can be done by direct fluorescent antibody (DFA) staining (1). The specimen swab is rolled onto a glass slide, air dried, and fixed with methanol. A fluorescein-conjugated monoclonal antibody is applied to the slide. After incubation, a coverslip is mounted with mounting medium and the slide is read for the presence of EBs with an epifluorescence microscope at a magnification of ×1,000. This test requires a trained microscopist and has a sensitivity of 80 to 85% with a specificity of 98 to 99% compared to culture (22).

Antigen detection using an enzyme immunoassay (EIA) was used before the advent of molecular tests and is still the most common nonculture detection test for *C. trachomatis* (1). Table 1 shows a comparison of the sensitivities and specificities of diagnostic tests. Methods for improving EIA sensitivity include retesting samples which give values close to the cutoff value (negative gray-zone value) by EIA and confirming the results with DFA staining or amplified testing (http://www.aphl.org/docs/NCCNGZTesting).

Serology

The microimmunofluorescence (micro-IF) test has been the "gold standard" for the detection of antibodies against chlamydiae (5). The assay is useful for population studies but not for the diagnosis of *C. trachomatis* disease in adults. It has been widely used for the diagnosis of *C. pneumoniae* (see below).

TABLE 1 Sensitivity and specificity of diagnostic tests for the detection of *C. trachomatis*

Diagnostic method or sample type	Sensitivity (%)	Specificity (%)
Tissue culture	70–85	100
DFA staining	80–85	>99
EIA	53–76	95
Hybridization (Pace2)	65–83	99
LCR		
Cervical	94.4–96.4	99.5–100
Female urine	93–98	99–100
Male urine	96.4	94–100
PCR (COBAS)		
Cervical	89.7	99.4
Female urine	89.2	99.0
Male urine	90.3	98.4
SDA		
Cervical	92.8	98.1
Female urine	80.5	98.4
Male urine	93.1	93.8
TMA		
Cervical	94.2	97.6
Female urine	94.7	98.9
Male urine	97.0	99.1
Male urethral	95.2	98.2

New Molecular Diagnostic Tests for Detection of *C. trachomatis*

Nonamplification Tests

The first molecular test, the nucleic acid probe hybridization test, which uses DNA-RNA hybridization to detect chlamydial RNA, is commercially available (GenProbe, San Diego, Calif.) and widely used (2). Recently, the Digene hybrid capture II CT-ID test (Digene, Silver Spring, Md.) was introduced. This test amplifies the detection signal, not nucleic acids. It has had limited evaluation, but in one study with cervical specimens, the sensitivity and specificity were 95.4 and 99.0%, respectively (15). It has not yet been evaluated with urine specimens.

NAATs

Nucleic acid amplification tests (NAATs) comprise the standard testing modality with the highest sensitivities. These tests include PCR (Roche Molecular Diagnostics, Indianapolis, Ind.), ligase chain reaction (LCR; Abbott Laboratories, Abbott Park, Ill.), transcription-mediated amplification (TMA; APTIMA; GenProbe), and strand displacement amplification (SDA; ProbeTec; Becton Dickinson, Sparks, Md.). All have >90% sensitivity and high specificities (Table 1) (11, 29, 30) and are approved by the Food and Drug Administration (FDA) for the detection of *C. trachomatis*. All except the LCR test, which has been taken off the market, are commercially available for use with cervical and urethral swabs or urine specimens. The TMA test is no longer produced and has been replaced by the APTIMA Combo2 assay (14). The lower specificities (Table 1) of this assay may be artificial, as this assay may be more sensitive than other NAATs, and the confirmation of uniquely positive samples by another NAAT can be problematic.

Unique positive results can be confirmed by using another primer set with the same assay (11, 14).

Comparisons and Validation of New Tests

Calculations of the sensitivity and specificity of new tests can be problematic when a new test is more sensitive than the older test to which it is being compared. "Discrepant analysis" of samples by performing a third, "tiebreaker," test has been used to confirm unique positive results but has been criticized as slightly biasing upward the sensitivity and specificity of the new test (16). In evaluating a new NAAT, there is probably an inherent underestimate of specificity since the new test may identify more true-positive results (11).

NAATs can be used to define the infected patient gold standard to evaluate chlamydia diagnostic tests. Using data from a large clinical trial comparing results from three different assays, Martin et al. determined that the use of any "two-tests-positive-out-of-three" definition resulted in estimates that were as good as or better than those based on the use of any other definition of the infected patient gold standard and provided the best combinations of sensitivity and specificity estimates (23).

Inhibitors

Specimens may contain inhibitors to amplification. Some inhibitors are labile and disappear upon retesting, diluting, or heating. The prevalence of inhibitors ranges from 1.8 to 2.6% for female and male urine samples to 19% for cervical samples. A failure to amplify the nonspecific amplification control in commercial NAATs indicates the presence of inhibitors in the specimen (http://www.aphl.org/docs/NCCInhibitorsofAmplification).

Contamination Issues

The contamination of laboratories with amplification products (amplicons) from previous PCRs can cause false-positive results. Besides recommendations of using barrier-filter pipette tips and dedicated rooms and equipment for preamplification and postamplification procedures, monitoring on a monthly basis of environmental amplicon contamination in each area where procedures are performed is recommended. The "swipe test" is performed by using a sterile NAAT sampling swab. Twenty to 30 laboratory and equipment surfaces should be sampled. The swab should be moistened with sterile molecular-grade water, used to wipe the desired area, placed into the test's transport buffer or tube, and processed as a NAAT. If an amplicon is found, the area should be cleaned with a 5 to 10% bleach solution, wiped with 70% ethanol, and retested. This should be repeated until the test is negative.

Point-of-Care Tests and Leukocyte Esterase (LE) Test

Several rapid point-of-care tests, which are performed while the patient waits for results, have been introduced. These include an individual, single-use device (optical immunoassay; Biostar Inc., Boulder, Colo.). These tests have low sensitivities (50 to 70% or less) and cannot be recommended for general use. If their sensitivities can be improved, they will be useful in settings, such as homeless shelters and detention centers, where the patient may not return for test results.

The LE test is a rapid dipstick test for use with urine specimens to determine the presence of polymorphonuclear leukocyte esterase. This nonspecific test diagnoses urethritis but cannot determine the specific cause because it only detects polymorphonuclear leukocytes. The sensitivity of the LE test for *C. trachomatis* varies from 31 to 100%, and its

specificity ranges from 83 to 100% (1). This test is used to screen adolescent males and should not be used for testing specimens from women or older men (1). The LE test may be useful for screening asymptomatic men to determine who should be screened with more sensitive and specific tests (1).

New Types of Specimens for Detection of *C. trachomatis*

Because of the improved sensitivities of new NAATs, other specimens, including first-void urines from both men and women and vaginal or vulvar swabs, are useful for diagnosis (20, 26). Because urines are easily obtainable, noninvasive specimens, they offer a great advantage for large public health screening programs, for which cervical or urethral specimens cannot be obtained (13). Additionally, urine specimens are acceptable to asymptomatic individuals and those who are unwilling to have a medical examination. Because a clinician is not required for urine collection, cost savings are also generated (19). Studies have reported the successful use of self-administered vaginal swabs, but this specimen type is not yet FDA approved, except for use in the APTIMA Combo2 assay (25, 31). The usefulness of noninvasive specimens has made nontraditional sites (e.g., schools, prisons, and shopping malls) attractive for screening programs.

Choice of Diagnostic Test, Specimen, and Venue for Testing

Often, only symptomatic persons or contacts of infected patients will seek care. Symptomatic patients should receive a pelvic examination, with a sample taken for a NAAT, as recommended by the Centers for Disease Control and Prevention (CDC) as the test of choice (6). For asymptomatic infections, traditional approaches leave a large population that would not ordinarily get tested. Because physical examinations are not required for urine or vaginal swabs, the use of self-obtained specimens for testing with NAATs has enhanced the use of nontraditional sites for screening programs. For the screening of asymptomatic persons, only a NAAT can be used because none of the older tests have the necessary sensitivity.

Need for Confirmation of Positive Tests

Because of potential lower positive predictive values (i.e., <90%) of NAAT results for low-prevalence populations, where the test specificity is <100%, the CDC has recommended the use of an additional test for persons with positive screening test results (6). Approaches for the additional test include testing a second specimen with a different test that uses a different target, testing the original specimen with a different test that uses a different target or format, repeating the original test on the original specimen with a blocking antibody or competitive probe, or repeating the original test on the original specimen (6). The need for confirmatory testing is controversial and requires more definitive studies.

Tests of Cure versus Rescreening

The CDC does not routinely recommend doing a test of cure (25). Because DNA may persist for about 2 weeks after treatment, retesting by a NAAT should be done after 21 days (12).

Cost Considerations

Even though NAATs are more expensive than older nonculture tests, they are more cost-effective for use with women for preventing sequelae associated with chlamydia infections (19). If a woman does not have a pelvic exam because it is not indicated, the clinician should obtain a urine specimen or self-administered vaginal swab for amplification testing.

Recommendations for Screening and Rescreening

In the United States, the CDC recommends that all sexually active adolescent women be screened for *C. trachomatis* infection at least annually (7). Annual screening of sexually active women 20 to 25 years of age and of older women with new or multiple sex partners is recommended (5). Previously infected women are at a high risk and should be rescreened 3 to 4 months after treatment (7).

Influences of New Diagnostic Tests on Prevalence and Epidemiology

The introduction of the NAATs has resulted in a dramatic increase in estimates of the population prevalence of *C. trachomatis* infection (7). In 2000, 702,093 *C. trachomatis* infections were reported to the CDC, which was an increase from 78.5 cases per 100,000 persons in 1987 to 404.0 per 100,000 (7). Caution must be exercised in interpreting prevalence trends since the use of a more sensitive test can result in an increase in the number of positive tests with no real increase in the true infection prevalence.

Topics on laboratory diagnosis, including specimen rejection criteria, negative-gray-zone supplemental testing, and guidelines for test verification, can be found on the Association of Public Health Laboratories website (http://www.aphl.org/chlamydia_lab.cfm).

C. PNEUMONIAE

Introduction and Epidemiology of *C. pneumoniae*

C. pneumoniae is a human respiratory pathogen. The first isolate, TW183, was obtained from the conjunctiva of a Taiwanese child in 1965 (21). The association of TW183 with respiratory tract infections was discovered by serology during an outbreak of pneumonia in military conscripts in Finland, and the first respiratory isolate was obtained in Seattle from a university student with pharyngitis (21). The species *C. pneumoniae* was established in 1989 based on antibody reactivity, EB ultrastructure, and DNA homology (21). Recently, *C. pneumoniae* and *Chlamydia psittaci* were designated as a separate genus, *Chlamydophila*; however, this designation remains controversial (10, 27).

Approximately 50% of adults have antibodies against *C. pneumoniae* (21). Antibodies against *C. pneumoniae* are rare in children under the age of 5 in the United States, increase sharply from ages 5 through 14, at an increment of 6 to 8%, and continue to increase in adulthood to a prevalence of approximately 75% in the elderly. Most people are infected and reinfected throughout their life.

Transmission occurs via respiratory secretions, and secondary transmission is rare (21). The incubation period is about 3 weeks, which is longer than that for other respiratory pathogens.

Diseases Caused by *C. pneumoniae*

C. pneumoniae causes 10% of pneumonia and 5% of bronchitis and sinusitis cases in adults (21). Asymptomatic infections and mildly symptomatic illnesses are the most common outcomes. *C. pneumoniae* is associated with other diseases, such as asthmatic bronchitis, asthma exacerbation, and chronic obstructive pulmonary disease (21).

The most widely studied association of *C. pneumoniae* with a chronic disease has been that with coronary artery

disease and other atherosclerotic syndromes (4). Evidence of an association includes an increased risk of cardiovascular disease (CVD) for individuals with antibodies against *C. pneumoniae*, detection of the organism in approximately 50% of atherosclerotic lesions, but not in healthy tissue, by immunocytochemistry (ICC) and PCR, and isolation of the organism from atheromatous tissue. Both in vitro and in vivo studies with animal models support a role for *C. pneumoniae* in CVD, although this has not been definitively determined (4).

Classical Methods for Diagnosis of *C. pneumoniae* Infection

Culture

The identification of cell lines that are more susceptible to *C. pneumoniae* infection than those classically used for *C. trachomatis* culture was critical to the successful culturing of *C. pneumoniae*. These include HL (human line) and Hep-2 cells (5).

Handling and Storage of Specimens

C. pneumoniae is sensitive to temperature and to freezing and thawing. Adding sucrose and glutamic acid to potassium phosphate buffer best preserves the organism's viability. Two useful storage media are SPG and 2SP (Table 2). Slow freezing preserves viability better than quick freezing. Infectivity is reduced by 23% when specimens are kept in a refrigerator (4°C) for 0.5 to 4 h and frozen at −75°C (5) but by 61% if specimens are frozen immediately. It is not necessary to freeze the samples if isolation can be done within 24 h. For thawing, organisms should be quickly thawed in lukewarm water (no higher than 37°C).

Specimen Collection

Samples for the diagnosis of a respiratory infection are usually collected from the nasopharynx (infants) or throat (older children and adults) by use of a standard swab. Sputum is difficult to process for cell culture isolation and is not a specimen of choice. Bronchoalveolar lavage fluid can be used.

Rarely, tissue samples from surgery or autopsy may be tested. Tissues should be homogenized by use of a tissue homogenizer or a mortar and pestle in SPG or 2SP medium, coarse tissue debris removed by low-speed centrifugation, and the supernatants used for culture.

Early reports demonstrating *C. pneumoniae* in peripheral blood mononuclear cells (PBMC) at a high frequency for patients undergoing coronary angiography (59%) and for blood donors (46%) by PCR raised the possibility that *C. pneumoniae* DNA in PBMC might serve as a surrogate

marker for *C. pneumoniae* in CVD (3). However, in a review of 18 studies, the overall prevalence of *C. pneumoniae* DNA in patients with CVD was 14.3%, compared to 8.5% for controls (28). Most PBMC preparation methods use 8-ml CPT tubes (BD Vacutainer Systems, Franklin Lakes, N.J.), which are centrifuged to separate the white cell layer out at $3,000 \times g$ for 10 min at room temperature. The cell layer should be removed and frozen at −70°C or placed on dry ice within 10 min. The use of a QIAamp DNA extraction kit (Qiagen, Valencia, Calif.) is common.

Culture Medium

Eagle's minimal essential medium supplemented with 10% fetal calf serum, antibiotics (gentamicin or streptomycin and vancomycin), and a fungicide (amphotericin B or mycostatin) is commonly used. Cycloheximide (0.6 to 1.0 μg/ml) is added to enhance chlamydial growth. Fast-growing cells require more cycloheximide (1.0 μg/ml for HeLa cells) than slow-growing cells (0.6 to 0.8 μg/ml for HL cells).

Isolation Procedure

Cell monolayers are prepared in 24- or 96-well culture plates or 1-dram shell vials. For the identification of inclusions, a round coverslip (12-mm diameter) is placed in the well or vial. Freshly prepared (24-h) monolayers are more susceptible than older ones. Plating 1×10^5 to 2×10^5 cells per well (24-well plate) or vial produces a confluent monolayer overnight.

Inoculation

The culture medium is removed before inoculation, and the cell monolayers are washed once with Hanks balanced salt solution. One- to two-tenths of a milliliter of inoculum is inoculated into each well or vial. A small inoculum volume gives a higher infection efficiency than a large volume. For an enhancement of infectivity, cultures are centrifuged at $900 \times g$ for 60 min at room temperature. The inoculum is removed, and culture medium is added (1 ml per well [24-well plates] or vial or 0.2 ml per well [96-well plates]). At least three wells or vials are inoculated. One is used for the detection of inclusions, and the remaining two are harvested for passage. Cultures are incubated at 35°C in a CO_2 incubator (open vessel culture) or a dry incubator (sealed culture) for 3 days.

Passages

After incubation, one coverslip is stained for the detection of inclusions, and the remaining two wells or vials are harvested for passage. The harvested material is used to inoculate three fresh monolayers. Two passages are recommended to determine whether a sample is positive or negative (9). The keys to successful passaging are "slow expansion" and the use of the minimum inoculum volume. For harvest, minimal essential medium is removed, and the cell monolayer is scraped off the vial with a plastic Pasteur pipette in a small volume (0.5 ml per two vials) of SPG or 2SP medium. Vial cultures can also be harvested by vortexing with glass beads. Although harvested cells can be used for passaging without further processing, sonication (20 s) increases the release of intracellular organisms.

Inclusion Detection

Inclusions are detected by fluorescent-antibody (FA) staining using a genus- or *C. pneumoniae*-specific monoclonal antibody conjugated with fluorescein isothiocyanate. If a genus-specific antibody is first used to detect all chlamydiae, each positive culture is then stained with a *C. pneumoniae*-specific antibody.

TABLE 2 Storage media for *C. pneumoniae*

Medium or component	Formula (component, amt or concn)
SPG	Sucrose, 75 g; KH$_2$PO$_4$, 0.52 g; Na$_2$HPO$_4$, 1.22 g; glutamic acid, 0.72 g; H$_2$O to 1 liter; pH, 7.4–7.6
2SP	Sucrose, 68.47 g; KH$_2$PO$_4$, 0.6 g; K$_2$HPO$_4$, 2.83 g; H$_2$O to 1 liter; pH, 7.4–7.6
Antibiotics	Gentamicin (10 μg/ml), or vancomycin + streptomycin (100 μg/ml each), for antibacterial activity; add amphotericin (25 μg/ml) or mycostatin (25 U/ml) for antifungal activity

Nonculture Methods

Swab Samples

Two direct detection methods, FA staining and EIA using *C. pneumoniae*-specific monoclonal antibodies, have been evaluated. FA staining is not sufficiently sensitive and specific for *C. pneumoniae,* and EIA has not been sufficiently evaluated with clinical specimens to make any recommendation.

Tissue Samples

C. pneumoniae has been detected in formalin-fixed tissues by the standard ICC avidin-biotinylated immune complex method (4). By counterstaining with hematoxylin, histology can be examined. A positive tissue control and a tissue control stained with an irrelevant antibody should be included. To avoid false-positive results from nonspecific background staining or artifacts, the staining pattern should be noted. An intracytoplasmic granular staining pattern of macrophages, endothelial cells, or smooth muscle cells is considered positive, while a homogenous staining pattern is suspect (9).

PCR (see relevant section below) is useful for the diagnosis of chronic *C. pneumoniae* infection because isolation is rare at this stage.

Sensitivity of Detection Methods

The sensitivity of cell culture for the diagnosis of serologically confirmed acute *C. pneumoniae* respiratory infection is about 60% (5). In one study, the sensitivity of PCR for diagnosis from throat swabs taken during acute respiratory infections was 95% for isolation- and serology-positive patients and 46% during the chronic stage for seropositive, isolation-negative patients (5). All isolation-negative and seronegative patients were negative by PCR.

Serology

The serological diagnosis of chlamydial infection was originally done by the complement fixation (CF) test, which uses boiled whole EBs as the antigen and is genus specific. The micro-IF test for serology and typing of *C. trachomatis* isolates was developed by S.-P. Wang in 1970 and subsequently modified for the serodiagnosis of *C. pneumoniae* (5, 21). Although micro-IF has revealed only one *C. pneumoniae* serotype, a peptide-based *C. pneumoniae* enzyme-linked immunosorbent assay (ELISA) specific for serology is difficult because the epitope is conformational.

Antigen Preparation

Cell culture-grown organisms are purified by Hypaque-76 (Nycomed, Inc., Princeton, N.J.) density gradient purification, resuspended in 0.02% formalin, and stored at 4°C ($\sim$10^9 EB particles in stock solution). Formalin-fixed EBs are stable for many years at 4°C. An $\sim$100% infected T155 culture flask yields 1×10^8 to 2×10^8 EBs after purification.

Formalin-Fixed Yolk Sac Membrane Homogenate

A homogenate of yolk sac membranes is used as an adhesin to bind EBs to the microscope slide. Yolk sac membranes are harvested from 13-day-old chick embryos. The yolk is drained, and the membranes are kept in a petri dish in a refrigerator overnight to drain off more yolk. Membranes are homogenized in phosphate-buffered saline (PBS) by use of a blender or mortar and pestle and washed a few times with PBS. Egg yolk adhered to the centrifuge tube is wiped off with cotton swabs after each centrifugation.

Stock suspensions of yolk sac homogenates (40% [wt/vol]) are stored at -20°C. Equal volumes (0.1 ml) of EBs and 2 to 3% yolk sac membrane homogenate in 0.02% formalin are mixed, sonicated, kept at 4°C, and used within a week to avoid aggregation. The optimal EB concentration is determined by micro-IF using a positive serum.

Test Procedure

Dip pen points (e.g., Hunter Fine Pens #104; Hunt Manufacturing, Statesville, N.C.) are used to dot the antigen onto a microscope slide. A template with four by four equidistant dots spaced 5 mm apart is placed under the slide to guide antigen application. To assist in reading, the microscope stage is marked with fluorescent paint to locate the antigen positions when the slide is centered. More than one antigen can be placed over each of 16 spots, e.g., if duplicate readings are desired or if different serovars or species are included. If more than one antigen is placed in the area of the spot, care should be taken that the antigens do not fuse with each other. Slides are air dried and fixed with acetone for 15 min at room temperature.

Twofold serum dilutions starting at 1:8 are prepared in a 96-well microtiter plate. Each dilution is applied to the antigen dot by use of a bacteriology loop and incubated in a moist chamber at 37°C for 30 min. Antibody dilutions are applied from the highest to lowest dilutions. Slides are rinsed by dipping and draining slides in a series of four beakers of 0.01 M PBS followed by three beakers of distilled water and then air dried at room temperature. Fluorescein isothiocyanate-conjugated anti-human immunoglobulin (Ig) and the counterstain rhodamine-conjugated bovine albumin or Evans blue (0.05%) are applied to each dot. Slides are incubated in a moist chamber for 30 min at 37°C, washed with PBS and distilled water, and air dried. A coverslip is mounted with FA mounting fluid.

Reading Slides

Only crisp, bright, apple-green fluorescence associated with distinctive EB particles is considered positive. Dull fluorescence associated with unevenly distributed particles without clear EB morphology is considered negative. The end point or titer is defined as the highest serum dilution with an unequivocal positive reaction. The simultaneous testing of paired sera is recommended. When a large number of sera are tested, it is more practical to screen sera first at a single dilution of 1:8. Positive sera are then titrated to determine the end points.

Interference of Rheumatoid Factor

Sera from patients with IgG autoantibodies against IgM may cross-react with the anti-*C. pneumoniae* IgM antibody. Thus, a positive result for IgM antibodies against *C. pneumoniae* should be retested after rheumatoid factor is removed by use of a commercial kit, such as Gullsorb (Meridian Diagnostic Corp., Cincinnati, Ohio).

Criteria of Serological Diagnosis

The serodiagnosis of acute *C. pneumoniae* respiratory infection has been based on the antibody kinetics of paired sera. Because the appearance of antibody during primary infection is often delayed, the paired sera should be collected 3 weeks instead of 2 weeks apart as with other infectious agents. For the micro-IF test, current or acute infection has been defined as follows: (i) seroconversion, (ii) fourfold titer rise, or (iii) IgM titer of ≥16 or IgG titer of ≥512. The presence of chronic antibodies has been defined as an IgG titer

of 8 to 256. For the genus-reactive CF test, the presence of acute antibodies has been defined as a fourfold titer rise or a titer of ≥64.

ELISA Serology

ELISA serology using *C. pneumoniae* EBs as the antigen has been applied for the measurement of serum antibodies but lacks sensitivity and specificity. Variability among different commercial kits has been reported (18). Other disadvantages are that ELISA results are often based on a single dilution, reported as positive or negative based on an arbitrarily determined optical density cutoff point, and not standardized among different kits.

Development of Molecular Diagnostic Techniques

Although culture remains the gold standard for the diagnosis of acute infection, alternative methods are needed for detecting the organism during chronic disease. Although many in-house PCR methods have been developed, the literature is confounded by reports of methods that have not been standardized or validated by comparison to established methods. Of the few multicenter studies analyzing different PCR tests on the same specimens, all have found interlaboratory variations in diagnosis (e.g., see reference 8). Additional factors contributing to discrepant results are different sample collection, preparation, processing, and DNA extraction methods, a lack of appropriate controls, and no confirmation of results (9). In 2001, the CDC and the Laboratory Centre for Disease Control in Canada convened a workshop to address the standardization of methods. The recommendations are summarized as follows. Only four PCR assays, targeting a *Pst*I fragment, rRNA, and MOMP genes, met the following criteria for a validated assay: (i) validation by more than two outside laboratories for sensitivity and specificity, using "spiked" specimens and clinical specimens; (ii) a sensitivity of <1 inclusion-forming unit (IFU); and (iii) documentation of specificity. Swab specimens should be placed in transport medium and stored as described previously. The aliquot should be centrifuged at ~18,000 × *g* for 15 min and processed for DNA extraction. Positive controls (DNA dilutions to <10 ng of DNA or <10 IFU) should be used. Negative controls consisting of water in place of the clinical specimen should be run on at least every fifth extraction.

A positive step toward PCR standardization has been the development and testing of a commercial kit, the LCx research-use-only PCR developed by Abbot Laboratories. In a multicenter study comparing LCx to validated assays, the results of the LCx test were promising, as (i) a 100% sensitivity was reported for positive samples with more than one copy of DNA per microliter of specimen, in contrast to those of in-house PCRs, which ranged from 54 to 94%; (ii) no false-positive results were observed with negative specimens; and (iii) LCx results were reproducible (8).

Real-time PCR assays have been developed in research laboratories but are not yet standardized for use in the clinical laboratory. The advantages of these assays are their sensitivity, decreased possibility of contamination, and ability to quantify DNA. A recent study tested 355 samples by real-time PCR, nested PCR, and touchdown enzyme time-released PCR and found real-time PCR to be sensitive and specific (17).

Impact of Nonculture Methods

The recurrent theme for *C. pneumoniae* diagnosis is the dire need for commercially available, user-friendly, standardized tests. The multilaboratory studies that have been done have shown variations in both micro-IF serology and PCR results (8, 24). The key impact of these methods has been the association of the organism with clinical syndromes. It is imperative that personnel performing micro-IF, ICC, or culture are trained in correct interpretation by individuals skilled in the art. Investigators should not use in-house tests that have not been compared to validated methods when investigating the disease spectrum of *C. pneumoniae*, as there are examples in the literature where controversial and unsubstantiated associations have been noted.

OTHER *CHLAMYDIA* SPECIES

Introduction and Epidemiology

Originally, *C. psittaci* was a heterogenous group comprised of pathogens of primarily birds and nonhuman mammals. It has now been separated into five species, *C. psittaci*, *C. pecorum*, *C. feli*, *C. abortus*, and *C. caviae* (10). Transmission to humans of species infecting nonhuman mammals is rare, with only a few cases of abortion reported for women who worked with *C. abortus*-infected sheep. Avian strains (*C. psittaci*) are virulent to humans and cause severe pneumonia accompanied by systemic symptoms known as psittacosis (5). Transmission occurs by the airborne route, either by direct contact with birds or by the inhalation of dust contaminated with excreta of infected birds. Cases of psittacosis are still reported from households owning birds. The largest reservoirs of infection in North America and Europe have been turkeys, ducks, and pigeons, which puts poultry breeders and processing workers at risk. Transmission from person to person has been suggested but not proven. The incubation time is usually 7 to 14 days but can range from 4 to 28 days (5).

C. psittaci is resistant to desiccation and remains viable for a month at room temperature but is destroyed within 3.5 to 5 min at 56°C. Proper cooking of poultry eliminates any risk. There have not been any reports of food-borne transmission.

Diagnosis

Culture

The diagnosis of *C. psittaci* infection is commonly done by cell culture isolation and serology, as described for other *Chlamydia* spp. Various cell lines have been used for the isolation of *C. psittaci* because *C. psittaci* grows much better than *C. trachomatis* and *C. pneumoniae*. Specimens for isolation can be throat swabs, bronchoalveolar lavage fluid, or PBMC.

Nonculture Tests

The rapid diagnosis of *C. psittaci* pneumonia has been reported for the use of direct immunofluorescent antibody staining of respiratory secretions. In-house PCR tests have also been developed.

Serology

The group-reactive CF test is often used for the detection of serum antibodies in patients suspected of *C. psittaci* infection because the infecting *C. psittaci* strain is unknown and strain-specific antigens are not available. The micro-IF test has been shown to detect type-specific antibodies to *C. psittaci* in human sera and can be used for typing isolates (5). For micro-IF testing of *C. psittaci*, paired sera should be taken at the onset of symptoms and 2 weeks after the first specimen.

The *Rickettsiaceae, Anaplasmataceae, Bartonellaceae,* and *Coxiellaceae*

KARIM E. HECHEMY, YASUKO RIKIHISA, KEVIN MACALUSO,
ANDREW W. O. BURGESS, BURT E. ANDERSON, AND HERBERT A. THOMPSON

61

During the past two decades, significant changes have occurred in the rickettsial field, including the redefinition of the level of pathogenicity of some rickettsiae, the isolation of new species that have emerged as pathogens of old and new syndromes, and the reemergence of old pathogenic species. In addition, phylogenetic analyses of the rickettsiae by molecular taxonomic techniques have resulted in extensive changes in the taxonomy of the rickettsiae (12).

TAXONOMY

The order *Rickettsiales* (Fig. 1) consists of the family *Rickettsiaceae* and the family *Anaplasmataceae*. The family *Rickettsiaceae* contains the genus *Rickettsia* and the genus *Orientia*. Members of the family *Rickettsiaceae* are short rods or coccobacilli, and members of the family *Anaplasmataceae* are small pleomorphic cocci. All are obligate intracellular gram-negative bacteria.

The rickettsiae that cause diseases in humans belong to the families *Rickettsiaceae* and *Anaplasmataceae* (Fig. 1 and Table 1). All human pathogenic rickettsiae belong to the α1-group proteobacteria and are nonglycolytic. The family *Rickettsiaceae* includes two genera. The genus *Rickettsia* comprises the highly related typhus (TG) and spotted fever (SFG) groups and the genetically heterogeneous species *Orientia tsutsugamushi,* which includes several serovars.

The family *Anaplasmataceae* currently comprises five established genera, namely, *Ehrlichia, Anaplasma, Aegyptianella, Neorickettsia,* and *Wolbachia,* and two "*Candidatus*" genera, namely, "*Candidatus* Neoehrlichia" and "*Candidatus* Xenohaliotis." The genera *Bartonella* and *Coxiella* are now classified out of the order *Rickettsiales* and in the orders *Rhizobiales* (α-proteobacteria) and *Legionellales* (γ-proteobacteria), respectively. However, they are included in this chapter because of historical precedence (Fig. 1).

The family *Bartonellaceae* consists of two genera, one of which, *Bartonella,* includes human pathogens belonging to the α2-group proteobacteria. Nine species of the genus *Bartonella* have now been implicated in human disease. These include *Bartonella bacilliformis* (Oroya fever and verruga peruana), *Bartonella henselae* (cat scratch disease [CSD], bacillary angiomatosis [BA], bacillary peliosis [BP], and endocarditis), *Bartonella quintana* (BA, BP, endocarditis, and trench fever), *Bartonella clarridgeiae* (CSD), *Bartonella elizabethae, Bartonella vinsonii* subsp. *berkhoffii, B. vinsonii* subsp. *arupensis, Bartonella*

koehlerae (all causing endocarditis), and *Bartonella grahamii* (neuroretinitis) (10). The family *Coxiellaceae* includes one species, *Coxiella burnetii,* the agent of Q fever. It belongs to the γ group of proteobacteria and is glycolytic (46).

EPIDEMIOLOGY

The rickettsiae are endemic worldwide (Table 1). Rickettsiae are known or thought to be associated with invertebrates (arthropods and trematodes). Invertebrates are also the vectors that transmit the rickettsiae to humans and other vertebrates. Humans are accidental hosts to the rickettsiae, except for those that cause epidemic typhus and recrudescent typhus or Brill-Zinsser disease, which belong to the species *Rickettsia prowazekii.*

Some species of rickettsiae within a biogroup appear to be confined to certain geographic areas of the world. These species acquire some biologic, pathogenic, and genetic characteristics within their respective areas that make them different enough from each other within a biogroup to be classified as new species; e.g., the SFG member *Rickettsia japonica* is confined to Japan and *Rickettsia rickettsii* appears to be limited to the Western hemisphere. *Rickettsia felis,* a newly isolated rickettsia that causes an endemic typhus-like syndrome, has at present only been isolated in the Western hemisphere. *Rickettsia conorii* is primarily found in the Mediterranean basin and Africa, and *O. tsutsugamushi* is found in Southeast Asia, Japan, Korea, Northern Australia, and some island nations in the southwest Pacific, including the Philippines, New Guinea, and the Palau Archipelago.

In contrast, other species are ubiquitously found in various geographic areas of the world and appear to be biologically, genetically, and pathologically similar or nearly identical. Two examples are *C. burnetii* and *Rickettsia typhi,* which cause Q fever and endemic typhus, respectively. Q fever is found everywhere except New Zealand.

Epidemic typhus caused by *R. prowazekii* was found worldwide in the past. However, at present it appears to be confined to foci in areas of Africa, areas of the former Soviet Union, and South America. Members of the *Bartonella* genus implicated in CSD and in the new syndromes of BA and related extracutaneous manifestations are seen on both sides of the Atlantic. The syndrome of monocytic ehrlichiosis in humans (HME), which is caused by *Neorickettsia sennetsu* and was thought to be limited to Asia and Japan, has now

been reported in other geographic regions. In the United States, the HME syndrome is caused by an ehrlichia species, *Ehrlichia chaffeensis.* In addition, a granulocytic ehrlichiosis which was reported for equines, ruminants, and canines is now diagnosed in humans (HGA). It is caused by *Anaplasma phagocytophilum. Ehrlichia ewingii,* once thought to infect only dogs, has recently been discovered to cause human granulocytic ehrlichiosis (HGE).

In the United States, Rocky Mountain spotted fever (RMSF), both types of endemic typhus caused by *R. typhi* and *R. felis,* HME, HGE, HGA, Q fever, CSD, and other diseases caused by *Bartonella* spp. are the most prevalent of the diseases described in this chapter. Most cases occur between May and September, except for *Bartonella* infections, which can occur year-round. Q fever is regional in occurrence and peaks slightly after the birthing seasons of ruminants (29). Between May and September, environmental conditions are optimal for tick activity, and human outdoor activities peak. However, a few cases have also been diagnosed during the winter months. Therefore, rickettsial diseases cannot be considered strictly seasonal.

In the United States, most RMSF cases occur east of the Rockies, with Oklahoma and the Carolinas leading the states. Ninety percent of endemic typhus cases in the United States are detected in the Southwest, especially in southern Texas, and in the West in southern California. A few endemic typhus cases have been reported from Virginia, North Carolina, Oklahoma, and California. Classic louse-borne epidemic typhus is not known to occur in the United States. However, a rickettsial organism closely resembling *R. prowazekii* was isolated from a flying squirrel.

Cases or outbreaks of Q fever are mainly associated with work-related exposures associated with carrier animals, e.g., sheep, cattle, and goats, especially during parturition. Also, patients with heart valve problems appear to be susceptible to chronic infection with *C. burnetii. C. burnetii* is also known to be resistant to physical and chemical treatment. The importance of Q fever as a public health problem varies tremendously by country. In the United States, the disease was common in some states such as California, Texas, and the upper Midwestern states during the 1950s and 1960s; human infection is not reported at that frequency now. Although the possibilities of underreporting and misdiagnosis are often given as underlying reasons for the low frequency of Q fever in the United States, these are balanced by increased awareness of the disease due to its bioterrorism potential, the better availability of reliable tests and testing reagents, and the fact that the disease was made nationally notifiable in 1999. A relatively low frequency of sheep farming and sharply improved agricultural and mechanized dairy food production practices may have combined to make this disease comparatively less frequent in the United States, in spite of the fact that many, perhaps most, U.S. dairy herds show convincing serologic evidence of present or past infection (30).

It should be noted that *C. burnetii* is considered a biothreat (category B) agent with characteristics that place it high on the list of incapacitating agents (6). The organism's broad host range, ease of dispersal and survival, high environmental stability, and high infectivity rates for humans are major reasons for concern (45). The tendency of this organism to produce serious manifestations of persistent and chronic infections in humans adds further concern. In contrast to acute Q fever disease, the latter infections are difficult to manage and carry a significant fatality rate (29).

PATHOBIOLOGY

The pathobiology of the rickettsiae was reviewed in a monograph (3). The site of growth of all rickettsiae, except the members of the family *Bartonellaceae,* is intracellular in

TABLE 1 Representative types of pathogenic rickettsiae in humans

Species	Disease	Distribution	Agent of transmission	Target cells	Cellular location	LPS	C + G content (%)	Antigenic protein molecular mass(es) (kDa)	Plasmid
R. rickettsii	RMSF	Western hemisphere	Tick bite	Endothrlium	Cytosol	Yes	32–33	190, 135	No
R. conorii	MSF	Middle East, Africa	Tick bite						
R. typhi	Endemic typhus	Worldwide	Infected flea feces

B. henselae	BA	United States, Europe	Cat fleas?						
	Cat scratch fever	United States, Europe							
B. elizabethae	Endocarditis?	United States				Yes			

the eukaryotic cell. However, there are differences in the intracellular sites of growth. Members of the SFG rickettsiae, e.g., *R. rickettsii*, grow in the cytoplasm and sometimes in the nucleus. In contrast, members of the TG, e.g., *R. typhi* and the organism causing scrub typhus, grow in the cytoplasm, while *C. burnetii* grows in the phagolysosomes of mononuclear phagocytes. Members of the family *Anaplasmataceae* replicate in the membrane-bound compartment that does not fuse with lysosomes. Except for members of *Wolbachia* and "*Candidatus* Xenohaliotis," members of the family *Anaplasmataceae* infect cells of hematopoietic and bone marrow origin of mammals or birds. Generally, wild animals are reservoirs of these bacterial infections and humans and domestic mammals or birds are infected by the bites of ticks infected with *Ehrlichia* or *Anaplasma* spp. or by the ingestion of trematodes infected with *Neorickettsia*. *Wolbachia* is so far known to infect only invertebrate cells. However, it can be found in the bloodstream of humans when released from filarial worms infesting the vertebrates. Among *Ehrlichia* species, so far *E. chaffeensis, E. ewingii,* and *Ehrlichia canis* have been isolated and/or detected in blood specimens from humans. For the genus *Anaplasma, A. phagocytophilum* is the only species, and for the genus *Neorickettsia, N. sennetsu* is the only species documented so far in humans.

No exotoxin has been reported to explain the pathogenic properties of the *Rickettsiaceae, Anaplasmataceae, Bartonellaceae,* and *Coxiellaceae*. The diseases caused by the rickettsiae are systemic illnesses exhibiting protean manifestations. The hallmark of the various diseases caused by the SFG and TG rickettsiae is the maculopapular rash; however, it is not found in every case. With SFG rickettsiae, it begins on the wrists and ankles and extends throughout the body. For scrub typhus and Mediterranean spotted fever (MSF), an eschar may develop at the site of the arthropod (mite or tick) bite. With TG rickettsiae, the rash is usually centrally distributed on the trunk and rarely involves the palms and soles. The internal lesions caused by the pathogen are a vasculitis localized in the endothelium and smooth muscles. Vascular permeability is increased, causing various degrees of hemorrhage, tissue edema, and peripheral circulatory failure. The extent of the internal vascular lesions is related to the degree of pathogenicity of a given species, e.g., for scrub typhus, vascular damage is not usually as severe as that seen with RMSF.

C. burnetii induces Q fever (29). Human Q fever manifests as two primary forms, an acute and a chronic from. About one-half of all human chronic infections are either mild or unrecognized. In these cases, only serologic analysis will portray evidence of a recent infection. The acute, recognized disease is often characterized by fever, headache, sweats, shaking chills, myalgia, and sometimes photophobia. In other cases, the presentation can be less constitutional, and the disease may cause pneumonia, hepatitis, and less commonly, neuritis or osteomyelitis. Interstitial pneumonia is often seen in patients with recognizable disease. For some patients, the course of events can lead to debilitating disease requiring a long period of recovery. In most cases, however, the disease is considered self-limiting, and recovery usually occurs in 10 to 20 days. Antibiotic (doxycycline) therapy can shorten the morbidity pattern.

The chronic or latent forms of the disease are of more concern. Endocarditis is the most common of these and is usually suspected only after most other diagnostic patterns and possible etiologic agents for infective endocarditis have been eliminated. The development of Q fever endocarditis usually occurs in those who have had the primary acute disease, either recognized or not, and who additionally have predisposing valvular,

vascular, or hemodynamic imperfections or deficiencies. Infective endocarditis in these patients can thus present years after the acute episode of the disease. Q fever endocarditis may or may not be characterized by nodules or vegetations on the endocardium. Thus, a lack of echocardiographic signals does not indicate a lack of infection or a lack of valvular immunopathology due to *C. burnetii*. A lingering chronic disease syndrome after acute Q fever has also been described and is termed "Q fatigue syndrome." Patients with this syndrome have indications of the organism in their bone marrow cells (presumably promonocytes) and do seem to get well (19). These patients are also characterized by a genetic proclivity to dysregulate normal cytokine shutdown after recovery from acute inflammatory episodes of Q fever (20).

Finally, the infection by *Coxiella* of human parturient tissues during pregnancy raises concerns that the proclivity of the organism to infect sheep and goat placental tissues and cow udder tissues may not be limited to ungulates. Indeed, there is increasing evidence and awareness of the dangers of exposure of pregnant human females to the organism (25). Infection of these tissues, as with defective valves, can occur long after acute disease. Unique among the rickettsiae, *C. burnetii* exhibits antigenic phase variation. It exists in two phases (I and II), which appear to be host influenced. Phase I exists in nature and changes to phase II after continuous sub-culturing in tissue or egg yolk sac cultures. This variation resembles the smooth-rough variation seen in other bacteria. Biochemical studies have suggested that this variation is due to changes in the sugar residue of the lipopolysaccharide (LPS). This phase variation is important in the preparation of diagnostic reagents and the interpretation of test results (29).

Human ehrlichiosis and anaplasmosis also exhibit non-specific protean manifestations (11, 38), which are similar to those observed in patients with RMSF. However, only 20 to 30% of patients have a rash. The onset of illness is abrupt. Symptoms include fever, chills, headache, myalgia, anorexia, nausea or vomiting, and weight loss. Thrombocytopenia, leukopenia, and liver enzyme abnormality are often reported. A meningitis syndrome or an encephalitis or encephalopathy syndrome may occur with HME, and *E. chaffeensis* may be detected in the cerebrospinal fluid. Fatal seronegative infections have been reported for human immunodeficiency virus-infected patients, and secondary infections due to *Anaplasma*-induced immunosuppression may lead to severe disease and death. The patients also lack remarkable lesions such as cell lysis, tissue necrosis, abscess formation, or severe inflammatory reactions. The monocytes and granulocytes are the primary target cells for monocytic ehrlichiosis and granulocytic anaplasmosis, respectively. The replication site for the monocytic ehrlichia agents within the cell is the early endosome, where the bacteria are found.

Bartonellaceae bacteria grow preferentially on the surfaces of eukaryotic cells and sometimes intracellularly (35). The target cells are endothelial cells and erythrocytes. *Bartonella* spp. can be cultivated in cell-free culture on brain heart infusion agar and tryptic soy agar supplemented with 5% rabbit blood in a 5% CO_2 humidified atmosphere at 35°C. Original isolates take 9 to 15 days to grow. The bartonellas have a relatively simple pattern of three major fatty acids: octodecanoic, octodecenoic, and hexadecanoic. The clinical syndromes (35) associated with the *Bartonella* species are cutaneous BA, extracutaneous infection, BP of the liver and spleen, *Bartonella* bacteremic syndrome (fever and bacteremia), cat scratch fever, and trench fever. The histopathology of lymph nodes in CSD is characterized by granuloma, a nonspecific inflammatory infiltrate, and stellate abscesses. The organisms may be stained in sections

with Warthy-Starry stain. In human immunodeficiency virus-infected patients with BA, multiple subcutaneous nodules that contain argyrophilic bacillary forms are present throughout the interstitium.

LABORATORY DIAGNOSIS

Serodiagnosis is presently the method of choice for the laboratory diagnosis of the diseases described in this chapter. However, serodiagnosis is confirmatory and retrospective. New molecular PCR-based and antigen capture techniques that have been developed for research purposes are being formatted for the laboratory diagnosis of these bacteria. In the coming years, it is expected that these molecular biological techniques will greatly enhance the ability of laboratories to identify and speciate rickettsial infections. Isolation of the bacteria causing the diseases described in this chapter from clinical specimens requires expertise and specialized facilities that are not readily available in the routine diagnostic laboratory. In addition, the time required for detection in culture of most of these organisms, as well as the danger associated with their handling, is beyond the capacity of most diagnostic facilities. For example, culturing *Bartonella* from clinical samples still remains difficult, with primary isolates typically appearing after 12 to 14 days, and sometimes up to 45 days, when blood agar is used (26). Therefore, isolation of the bacterium as a diagnostic tool is limited and is also retrospective. Isolation procedures have been described in the eighth edition of *Manual of Clinical Microbiology* (31).

In this chapter, we present some of the new techniques and review the classical serodiagnostic techniques. The details of the latter can be found in the sixth edition of *Manual of Clinical Laboratory Immunology* (39). It is expected that in the coming years, laboratory diagnoses of these bacteria will evolve significantly because of these new molecular techniques.

Serodiagnosis

Currently, the principal techniques used for the serodiagnosis of rickettsial diseases are probe-based immunoassays. Complement fixation using specific bacterial antigens and agglutination-based assays using whole bacteria or bacterial antigen extract-coated latex (latex agglutination [LA]) or red blood cell (indirect hemagglutination [IHA]) particles have been described previously (39). The LA test for the serodiagnosis of RMSF is available commercially by one manufacturer (Panbio). Note that serodiagnostic test results may not indicate the species within the group antigens that cause the infection without further laboratory studies and epidemiologic investigation.

Immunoprobes

Immunoprobe-based tests (39) include the indirect fluorescence assay (IFA) and its micromodification, the micro-IF or MIF test. The micro-IF test is still considered the gold standard. Other immunoprobe tests include immunoperoxidase assays (IPAs); enzyme-linked immunosorbent assays (ELISAs), in which the antigens are adsorbed either onto the well of a microtiter plate or onto nitrocellulose in a dot blot or slot blot configuration; and immunoblot assays (IBAs). IFAs and IPAs require the whole bacterium as the antigen. The remaining immunoprobe assays use either highly purified rickettsiae or an extract.

IFA

The rickettsia IFA and its modification, the micro-IF assay, are at present considered the gold standard. Both tests are

relatively sensitive and specific. Also, the reagents for these tests are available commercially from several manufacturers. For the IFA, a suspension of one antigen is spread onto the slide. For the micro-IF test, several antigens are added as dots to a single well. This test has the added advantage of simultaneously detecting antibodies to up to nine rickettsial antigens with the same drop of serum in a single well containing bacterial antigen dots. Therefore, the micro-IF test economizes both time and reagents. More importantly, however, micro-IF is a more objective test modality when the cross-reactivity levels of the antibodies in a given serum are measured against a panel of antigens. It usually takes 7 to 9 days after the onset of the disease for sera to become significantly reactive, and they remain significantly reactive for years. As a result, IFA-based tests are suited for serodiagnostic purposes and seroepidemiologic studies. For step-by-step procedures and preparations of reagents, consult the references in reference 39. With the emergence of *Ehrlichia* and *Anaplasma* infections, it is suggested that a four-specific-antigen dot test be performed on submitted sera to rule out or rule in RMSF, typhus, ehrlichiosis, or *Anaplasma* infection. For the *Bartonella* spp., two or more antigens, as needed, e.g., *B. quintana* and *B. henselae* antigens, are placed on a slide. Usually, when testing for antibodies to *C. burnetii*, two dots are prepared, one containing *C. burnetii* phase I antigens and the other containing *C. burnetii* phase II antigens. For large numbers of sera, there may be a need to first screen the sera at a 1:64 dilution. Those that score reactive are then serially diluted and titrated to the end point of 2+ immunofluorescence. For the reading of *Bartonella* slides, the bacteria should be present mostly at the periphery and outside the eukaryotic cell, and few should be intracellularly located. For the reading of ehrlichia slides, try to find morulae (characteristic mulberry-like microcolonies of bacteria) (39) in the cytoplasm of cultured cells.

Because of the rising significance of Q fever as a biothreat agent, the IFA is described here with relatively more details. IFA can be done with impure or partially purified antigens. The specific measurement of immunoglobulin M (IgM), IgG, and IgA antibodies directed against either surface protein or LPS entities or both can be accomplished. Wild-type organisms found in human infections are in antigenic phase I, which means that they contain both a full-length (nontruncated) LPS and surface protein targets. The processing and presentation of these epitopes, however, are probably not simultaneous, and thus the IgM antibody response to phase II antigen is the first detectable serologic response to infection. This is followed by an IgM response to phase I antigen and then the IgG responses to both. Phase I and phase II antigens are available commercially from Focus Technologies, Cypress, Calif. (www.focustechnologies.com). Small quantities of reference reagents for IFA for use by public health laboratories are available from the Centers for Disease Control and Prevention. Direct requests to the Q Fever Laboratory, Viral and Rickettsial Zoonoses Branch, DVRD, MS G-13, 1600 Clifton Rd. NE, Atlanta, GA 30333, or telephone (404) 639-1075.

To reduce nonspecific fluorescence, the serum diluent is 1% albumin and 0.1 g of sodium azide in phosphate-buffered saline. The diluent of the secondary antibody probe is made by mixing heat-inactivated normal serum from the same species of animal used to prepare the antiserum to a final concentration of 1% in the dilution buffer. For step-by-step procedures and preparations of reagents, request the protocol from the Viral and Rickettsial Zoonoses Branch, Centers for Disease Control and Prevention. Studies are almost always done with

a fluorescein isothiocyanate-conjugated goat anti-human polyvalent probe. By screening a serum batch at 1:16 and 1:256 dilutions, a group can be sorted into those giving negative results and those giving weak positive results. For individual human specimens of suspected acute or chronic disease, it is desirable to obtain IgG and IgM titers to both antigens. For IgG determinations, a goat anti-human IgG, gamma-chain-specific conjugated antibody is used in assays of unadsorbed antisera. For accurate IgM determinations, it is desirable to remove the IgG from the serum specimen by use of a recombinant protein G suspension available in kit form (Mini-Rapi-Sep-M). The resulting supernatant after centrifugation is a 1/8 dilution of the serum. The analysis for IgM is then performed with goat anti-human IgM (mu chain specific). The testing is done as for other IFAs. Serology remains the best confirmation method for Q fever.

IPA

The IPA was developed as an alternative to the IFA (reviewed in reference 39). The IPA uses an ordinary light microscope instead of a UV microscope. Claims have been made that the sensitivity and specificity of this methodology are similar to those obtained with the IFA. Tests for antibodies to *O. tsutsugamushi* and *Rickettsia israeli* have been the most studied with the IPA technology.

ELISA

The antigens used for ELISA must be purified antigens or extracts from purified antigens. Alternatively, ELISAs based on recombinant or recombinant truncated proteins are now being developed. The whole antigens used are sonicated (all rickettsiae), disrupted in French pressure cells (*Rickettsia*), lysed (*Ehrlichia* or *Anaplasma*) in distilled water, or chemically extracted (*Coxiella*) or are LPS-like material (SFG rickettsiae) or whole rickettsiae (genus *Bartonella*). Recently, attempts to use recombinant rickettsial antigens in the ELISA format were reported to be successful for *A. phagocytophilum* (Fig. 2) (44). In general, the ELISA for rickettsiae is performed along previously described lines (39). The optimum antigen concentration in antigen mixtures used for ELISA is obtained by block titration. However, amounts of >2 μg of material per well should not be used to coat the wells. If the ELISA plates are prepared within the diagnostic laboratory, a buffer background control (no serum) at an optical density (OD) of 0.05 and a background control, a nonreactive serum with an OD of <0.2, should be obtained. Unless a commercial kit is used, each laboratory should establish an in-house standard of operation (39).

ELISA methods for *Coxiella* use yolk sac-grown, centrifugation gradient-purified phase I and II (separately) antigens, either whole or sonicated, or subcellular fractions thereof, at 1 to 2 μg per well. High-quality phase I and phase II (whole-cell-inactivated) antigens are not always available, and when available, are usually expensive. Presently, there is no widely used ELISA employing a recombinant protein.

Dot Blot and Slot Blot

Dot blot and slot blot tests (39) represent two configurations of antigens on membrane matrix supports and depend on how the antigen is applied. The antigens used are the same as those used in the ELISA. The matrices consist of either nitrocellulose or nylon sheets; the antigen can be applied in the dot or slot format, respectively. The steps are similar to those of the standard ELISA. The chromogen used for the last step should precipitate on the matrix upon development. A correlation of the immunodot assay and IFA (51), using *A. phagocytophilum*, is shown in Fig. 3. Such tests, when reactive, do indicate the presence of antibodies but do not differentiate between active or recent and past infections.

IBA

The interpretation of test results obtained with conventional serodiagnostic techniques, e.g., ELISA, IFA, and LA, is usually difficult when the titers of sera in the conventional assay are in the "gray zone" (relatively low positive results or results

FIGURE 3 (A) Dot blot immunoassay of HGE patient sera with different IFA testing titers by use of 0.5 µg of affinity-purified recombinant P44 (rP44) antigen. The sera were diluted 1:1,000. (B) Layout of experiment. (Reprinted with permission from reference 51.)

at the minimum level of significance), when the titration results are irregular from one dilution to the other, or when there is no gradation in ODs when serum dilutions are tested. The IBA has become a necessary qualitative tool (39) for differentiating, for a significant number of events, true-positive from false-positive results. The IBA will allow the direct visualization of the antigen bands and hence help to make a determination from the antigen profile regarding the status of the test serum when whole antigens are used. Alternatively, when recombinant antigens are used (51) (Fig. 4), the direct visualization of the specific band when specific antibodies are present in the serum would confirm the test results observed with the conventional assays. Usually, the significant band(s) is determined by using sera from clinically well-defined cases. Bands for sera from patients with nonrickettsial disease that light up in the IBA for rickettsial antibodies should be noted. This reactivity is probably due to common epitopes among the rickettsial and certain nonrickettsial antigens, e.g., *Proteus* antigens. The "correct" banding pattern(s) would probably include a mixture of specific and nonspecific bands. Patterns of reactivity that include only nonspecific bands should not be considered positive. As with the dot blot and slot blot tests, reactive test results in the IBA do not differentiate between active or recent and past infections.

Molecular Diagnosis

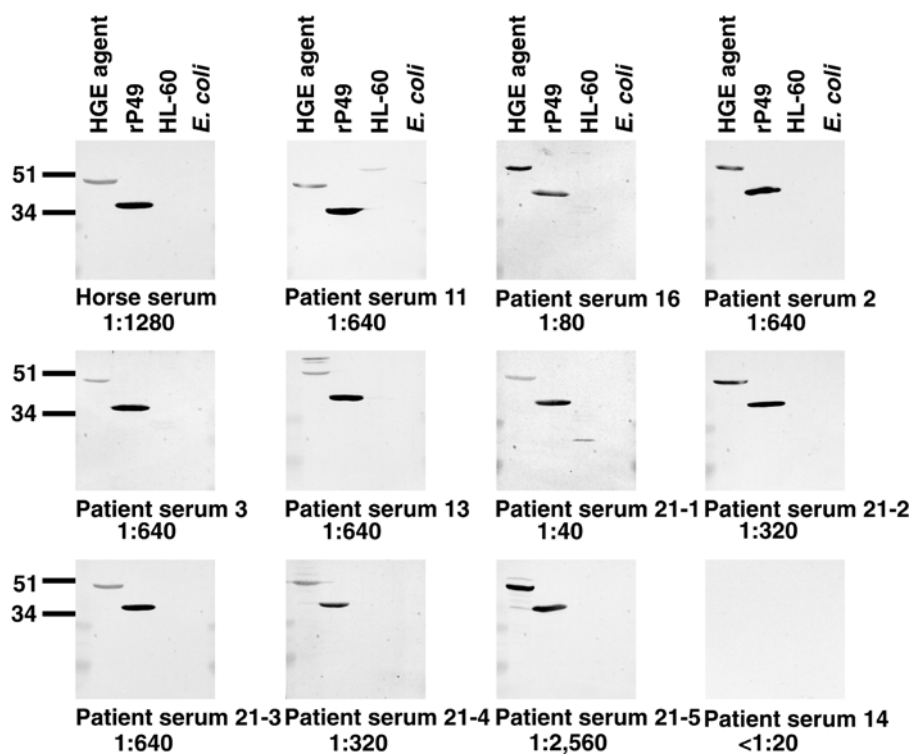
Over the past decade, the development and refinement of PCR-based approaches to identify and differentiate rickettsiae have allowed for faster, more accurate diagnosis of rickettsial infections. Rickettsial DNA has been identified in host blood, serum, biopsy samples, and often, arthropod vectors (16) that have been collected from the patient or within the immediate surroundings of the patient. Through the amplification of portions of rickettsia-specific genes and the


FIGURE 4 Western immunoblot analysis of anti-HGE (presently, anti-HGA) sera using purified HGE (presently, HGA) agent isolate 13 and rP44 antigen. The sera used for this study included a horse anti-HGE-agent serum; five convalescent-phase serum samples, from patients 2, 3, 11, 13, and 16; five serum samples collected at different times of illness over a 2-year period from patient 21, who was suspected of having persistent infection or reinfection; and negative control serum (IFA titer, <1:20). Samples subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis consisted of 10 μg of purified whole-cell preparations of HGE agent strain 13, affinity-purified rP44, HL-60 cells, and *E. coli* BL21(DE30)/pLysS. These proteins were transferred to a nitrocellulose sheet and incubated with a 1:1,000 dilution of antisera. The number at the bottom of each panel represents the IFA test titer of the serum sample. The numbers on the left indicate molecular masses in kilodaltons based on broad-range prestained standards (Bio-Rad) (adapted and reprinted with permission from reference 51).

subsequent enzymatic digestion of amplicons, one is able to identify and determine the specific nature of the rickettsia in a matter of hours.

TG and SFG

Several options are available for the identification of rickettsiae from both the TG and SFG. While PCR sample preparation is of the user's preference, higher success rates for reactions are consistently observed when DNA is first isolated from the sample. The general philosophy and basic mechanics (e.g., sample preparation and salt, polymerase, and buffer concentrations) of PCR have been presented elsewhere in this volume and in reference 31. Therefore, only the details pertinent to rickettsial applications will be presented here.

Commonly used primer sets that amplify portions of genes that are unique to rickettsiae, as well as genes that are limited to SFG rickettsiae, are presented in Table 2. A screen for the presence or absence of rickettsial organisms is achieved by using genus-specific primers designed to amplify portions of genes encoding either citrate synthase or the 17-kDa genus-common antigen. A further analysis of positive samples for hypervariable portions of the genes encoding either the 120- or 190-kDa antigen common to the SFG rickettsiae can delin-

eate TG or SFG infection. Use a matched pair of primers and typical thermocycler conditions, including 35 cycles of denaturation (20 s at 95°C), annealing (30 s at 48°C), and extension (1 to 2 min at 60°C). A final extension period (7 min at 72°C) is typically added to allow for complete extension of the PCR amplicons (36). Appropriate positive and negative controls (genomic DNAs of previously characterized rickettsiae and water, respectively) should be used in place of the sample template with each reaction. PCR products should be resolved by electrophoresis on a 1% agarose gel. Amplicons matching the positive control should be considered positive. Initial reactions should determine rickettsial infection by the use of one of the genus-common primers, and subsequent PCRs should utilize one set of the SFG-specific primers listed in Table 2. A negative result with any of these three sets of primers would indicate the presence of TG rickettsiae. Exceptions exist, including *R. felis*, which will not be amplified by the SFG primers, although it is a member of the SFG rickettsiae. It is possible to separate *R. felis* from TG rickettsiae based on either sequencing or endonuclease digestion of the 17-kDa PCR product, as discussed below.

For a definitive identification of the rickettsial species, nucleotide sequence analysis of the amplicon from the

17-kDa protein- or citrate synthase-encoding gene can be used for the identification of most TG and some SFG rickettsiae. Likewise, nucleotide analysis of the amplicon from the gene encoding the 190-kDa antigen is the standard for the identification of every recognized species of SFG rickettsiae in the research laboratory setting. However, because the time and resources required to move from gel analysis to nucleotide sequence analysis are not feasible for many clinical laboratories, alternative analyses have been and are being developed. One commonly used technique involves enzymatic digestion of the original amplicon, which results in a unique digestion product for several of the TG and SFG rickettsiae. Another method is the use of real-time PCR, in which species-specific primers are used to identify the rickettsiae.

For all of the PCR-amplified products described above (encoding citrate synthase and the 17-, 120-, and 190-kDa antigens), restriction fragment length polymorphism (RFLP) analysis is a simple, cost-effective, and efficient method to aid in the specific identification of the rickettsiae. Currently, by utilizing the primers identified in Table 2 to generate a DNA template, the differentiation of rickettsiae can be achieved by using AluI for citrate synthase (15, 36) and the 17-kDa genus-common antigen (4, 49). For the 120-kDa SFG-specific antigen, digestion with RsaI (15) allows for the differentiation of several SFG rickettsiae. Based on the success of the 190.70n and 190.602p primer set (15, 16, 36), the most effective differentiation of SFG rickettsiae results from using the 190.70n (36) and 190.701 (40) primer set in combination with endonuclease digestion with RsaI, PstI, AluI, XbaI, and AvaII, which will allow for the differentiation of most of the recognized SFG rickettsiae (40).

Following the general PCR protocol described above, PCR products should be purified and an aliquot combined with 10 to 20 U of the endonuclease, the appropriate buffer, and water to a final volume of roughly 30 μl. The volume used for each component is dependent on the products used. The digestion reaction should be done according to the manufacturer's recommendations. Temperature requirements vary from 37 to 50°C, and digestion can be completed in as little as 1 h, or an overnight digestion may be suggested for best results. Due to the nature of the potential fragment sizes (~20 to ~650 bp) resulting from digestion, resolution of the digested products is best achieved by electrophoresis on an 8% polyacrylamide gel. The banding pattern can be compared to those available in the literature or to positive-control TG and/or SFG reactions carried out at the same time.

The development of real-time PCR-based diagnosis and rapid PCR-based diagnostic methods has been the focus of much attention in many research laboratories. The published literature concerning applications for rickettsial diagnosis using real-time PCR is limited. The instrumentation that has been developed for both laboratory and portable field applications was recently reviewed in the literature (24). Much real-time PCR development has focused on ensuring the specificity of the assay, identifying assay detection limits (quantitation), and determining the feasibility of utilizing different samples for template generation. Recent reports have assessed various aspects of real-time PCR for O. tsutsugamushi (22) and TG and SFG rickettsiae (14). Duplex assays for the detection of different species of Rickettsia are being developed. Similar to the PCR techniques described above, these real-time applications have been successful with infected tissue culture samples, animal tissues (blood and biopsies), and arthropod vectors.

Coxiella

The molecular identification of Coxiella species is performed with both conventional and real-time PCR methods, as summarized previously (46), and includes the use of an insertion sequence (IS1111), a superoxide dismutase gene (sod-1), an outer membrane protein gene (com-1), heat shock protein genes (htpAB), and other targets. A quantitative real-time assay has been published (5). Recently, a protein-based method for the detection of the small-cell variant protein A (ScvA) plus other protein markers comprising a Coxiella fingerprint via matrix-assisted laser desorption–time of flight (MALDI-TOF) mass spectrometry has been developed (43). The MALDI-TOF method may prove to be a powerful technique for strain and variant identification for this genus. This method works exceedingly well, with very high reproducibility, among protein samples possessing a highly basic character; with an average pI of 8.25, Coxiella contains more basic proteins than almost any other medically important genus (42).

Ehrlichia, Anaplasma, and Neorickettsia

There are two primary important facts to be aware of for the molecular diagnosis of members of the family Anaplasmataceae. Very few bacteria are generally present in blood or tissue specimens from infected humans or animals, e.g., one A. phagocytophilum genome equivalent per peripheral blood leukocyte of acutely infected horses (48). Also, enrichment or culture isolation of this group of bacteria is not practical, so testing is performed in the high background

of the host cell DNA. For blood specimens from patients who had clinical signs and laboratory manifestation of HGA, 100% of culture isolation-positive specimens were PCR positive (21, 51). Also, in these studies 3 of 15 (20%) and 3 of 8 (38%) culture isolation-negative specimens were PCR positive, suggesting that PCR is more sensitive than culture isolation for the diagnosis of HGA. PCR diagnosis is more sensitive at the acute stage of infection with A. *phagocytophilum* and E. *chaffeensis* than serologic diagnosis (7, 51). However, patients who are negative by culture isolation or PCR at the acute stage seroconvert, or have a fourfold rise in IFA titers, during the convalescent stage (2, 21, 51). Thus, compared with IFA, PCR may give an overall lower clinical sensitivity. For determinations of the analytical sensitivity and specificity of the PCR test, the target specimens (human EDTA-anticoagulated blood) are spiked with serially diluted known amounts of *Anaplasma* or *Ehrlichia* DNA. The task force on consensus approach to *Anasplasmataceae* recommends that each laboratory establish its own assays and validate them with appropriate samples (47).

Single-step PCR, nested PCR, real-time PCR (27), reverse transcription-PCR, and PCR with reverse-line blot hybridization (41) are some methods employed, depending on the target gene and bacterial species being detected, to provide a sensitivity and specificity sufficient for each study purpose. As long as cross-contamination is carefully prevented, nested PCR is the most convenient and frequently used diagnostic method. The most commonly used target is the 16S rRNA gene. The *groEL* gene is another frequently used target gene. Since these genes are universally present in all bacteria, the primer sequence should be selected from bacterial species-specific regions. In the case of the 16S rRNA gene, this is near the 5′-end region. The PCR results should be unequivocal single distinct bands with the expected target size, as determined by alignment with a molecular size marker that is electrophoresed within the same gel. However, occasionally a nontarget band with a similar molecular size may be amplified from clinical specimens. The simplest way to deal with this nonspecific amplification is to sequence the nonspecific PCR product. By aligning the target and this newly obtained sequence, one can tailor new primers that selectively amplify the target sequence, but not the contaminant sequence, from given specimens. Since PCR sensitivity is affected by primer design and the PCR conditions, if a higher sensitivity is desired, these parameters should be experimentally optimized. From our experience, touch-down PCR may improve the sensitivity without requiring a change in the primer sequence for some specimens.

Other PCR targets used are repetitive-motif sequences that vary in the number of repeats among different isolates of E. *chaffeensis*. These are the variable-length PCR target gene, which has three to six 90-bp repeat units, and the 120-kDa antigen gene, which contains two to four 240-bp repeat units (33). A. *phagocytophilum* multigene family *p44* (*msp2*)-based nested PCR is approximately 50-fold more sensitive than 16S rRNA gene-based PCR due to the presence of a large number of *p44* paralogs in the genome (48). The ankyrin-rich genes (*ankA* and *epank1*) of A. *phagocytophilum* and the *omp-1* gene (*p28*) of E. *chaffeensis* are also sensitive species-specific PCR target genes.

For PCR testing, aseptically collected anticoagulated whole blood or buffy coat specimens are generally used; however, when whole blood has not been available, serum and plasma specimens have been used (28). When using serum or plasma specimens, one should keep in mind that negative results are not definitive but that positive results are definitive. In addition to blood specimens, E. *chaffeensis* has been detected in human cerebrospinal fluids (13) and various other biopsy or postmortem human tissue specimens (9) by PCR and/or in situ hybridization. For paraffin-embedded or formalin-fixed specimens, a special precaution should be made to effectively recover and/or unmask the target DNA to reduce false-negative results.

Bartonella

The use of molecular techniques for the diagnosis of *Bartonella* infections is a rapidly expanding field. Presently, there is little consensus regarding the best test to use in the clinical laboratory. Furthermore, there are only a few comparative studies of clinical specimens regarding the sensitivity and specificity of the assays being used. Molecular techniques used for the diagnosis of *Bartonella* infections include PCR, RFLP analysis, and gene sequencing.

A PCR-RFLP method using the RNA polymerase beta-subunit gene, *rpoA*, amplifies an 825-bp region of the rpoA gene (37) from 13 *Bartonella* strains. Restriction enzyme analysis of the PCR fragment with *Apo*I, *Alu*I, and *Afl*III can then differentiate the *Bartonella* strains. The application of this method to 94 lymph node samples or pus aspirates from patients suspected of having CSD resulted in 21 samples being positive for B. *henselae*.

PCR amplification targeting the riboflavin synthase gene (*ribC*) shows promise for use as a molecular diagnostic tool for CSD in the clinical laboratory (23). PCR using a unique primer pair highly homologous to segments of the *ribC* gene conserved among the *Bartonella* spp., but not to the corresponding segments in the genomes of unrelated bacteria, can amplify target DNAs from B. *henselae*, B. *quintana*, B. *bacilliformis*, B. *clarridgeiae*, B. *elizabethae*, and B. *vinsonii* subsp. *berkhoffii*. Species identification performed by restriction enzyme digestion with *Taq*I provides a unique pattern for each species. The primers appear to be specific for *Bartonella* since amplicons are not generated for a number of bacterial species, including *Afipia felis*. When used on 18 lymph node biopsies and 3 lymph node aspirates from patients with possible CSD, the assay detected B. *henselae* in 1 lymph node biopsy and all 3 lymph node aspirates (23).

PCR has also proven useful for the diagnosis of BA and BP. Unlike the localized infection of CSD, BA and BP are the result of disseminated infections caused by B. *henselae* and B. *quintana*. There are numerous case reports and case series showing the ability of PCR to detect *Bartonella* DNA in cutaneous tissues of BA patients and to identify the organism to the species level in other tissues such as bone and the brain (1). PCR can also be used to identify and determine the species of organisms obtained from cultures of tissues and blood from BA and BP patients. The latter would offer a minimally invasive approach to the diagnosis of BA and peliosis.

The molecular biology-based diagnosis of *Bartonella* endocarditis by the PCR-RFLP-based approach may lead to incorrect species identification. Since DNA sequencing is not commonly utilized in most clinical laboratories, the multigene PCR-RFLP approach should be used as a preliminary diagnostic step for patients with suspected *Bartonella* endocarditis. DNA sequencing should then follow for accurate species identification.

Real-time PCR is the most current molecular diagnostic tool for *Bartonella* infection. A real-time one-step nested PCR assay with a LightCycler instrument (LCN-PCR), using specimens of serum sampled early during the disease from 43 patients diagnosed as having *Bartonella* endocarditis, had a specificity of 100% and a sensitivity of 85.7% with serum

stored for less than 1 year (50). The sensitivity gradually decreased as the length of serum storage increased. The sensitivity of this PCR method was higher than that of prolonged blood culturing but lower than that of PCR amplification from valvular biopsy specimens.

Another real-time PCR assay was recently used for the rapid detection and differentiation of *Bartonella* spp. involved in endocarditis and CSD in humans (8). The assay is based on the LightCycler instrument via fluorescence resonance energy transfer and probes hybridizing an internal 379-bp region of the *gltA* fragment amplified from genomic DNA. For the assay, PAC1 and PAC2 probes were selected to target the *gltA* gene, resulting in zero, two, or three mismatches for the different *Bartonella* species, which enabled species differentiation by melting point analysis. The assay appears to be reproducible and sensitive in that it was able to reproducibly detect up to 10 DNA copies at a concentration of one copy per reaction, on average. Species specificity was demonstrated by showing the lack of hybridization when purified DNAs from *R. prowazekii*, *R. rickettsii*, *Borrelia burgdorferi*, *C. burnetii*, and *Escherichia coli* were used in the LightCycler fluorescence resonance energy transfer assay. These organisms have the potential to result in a 379-bp PCR product from the *gltA* region as a consequence of the low-stringency annealing temperature (32). Due to its speed, sensitivity, specificity, and reproducibility, real-time PCR may be the molecular method of choice for diagnostic application to clinical samples. A summary of recent molecular methods used for the molecular diagnosis of bartonella diseases is presented in Table 3.

Interpretation of Test Results

Several aspects should be considered in the interpretation of test results for the rickettsial and other diseases described in this chapter. First, cross-reactivity within a biogroup will vary, depending on the technique used and on the host animal from which the antiserum is obtained. Human sera show extensive cross-reactivity within a biogroup. For example, cross-reactivity among the SFG or TG rickettsiae is so extensive that in most instances identification of the species within the biogroup cannot be accomplished by standard diagnostic techniques. Human antisera to the SFG rickettsiae *R. rickettsii* and *R. conorii* cannot be differentiated serologically (39). However, the geographic origin of the infection may indicate the infecting species. A reactive test result for either RMSF or MSF may be reported as reactive for SFG rickettsiae. It should be noted that for serodiagnostic purposes, identifying the species and determining the extent of cross-reactivity are not as important as they are for seroepidemiologic purposes. This is because the cure is the same, regardless of the specific rickettsial etiologic agent. In contrast to within-group cross-reactivity, cross-reactivity among groups (39) within a genus, e.g., among SFG and TG rickettsiae, may be present, but with the extent of the homologous titers being different enough from that of the heterologous titers to indicate the etiology of the rickettsial biogroup.

For scrub typhus rickettsiae, the various strains share cross-reacting epitopes that are observed in all of the various serologic procedures except the complement fixation test. The complement fixation test appears to be strain specific and therefore is contraindicated for use as a diagnostic screening procedure. For the *Ehrlichia* spp., there is apparently cross-reactivity within each of the three species, e.g., between *E. canis* and *E. chaffeensis*. In contrast, cross-reactivity among the genera of the *Anaplasmataceae*, e.g., between *E. chaffeensis* and *A. phagocytophilum*, appears at present to be minimal. Recently, a consensus statement was published for the diagnosis of human ehrlichioses (47). For

[a] Sequence of probe hybridizing an internal region of the *gltA* fragment during a real-time PCR assay.

Bartonella spp., cross-reactivity with human sera is relatively extensive. However, the homologous reactivity with a given serum is sometimes of a high enough amplitude that it can be differentiated from the heterologous reaction.

Next, for serodiagnosis, the definitive evidence of recent rickettsial infection is a minimum fourfold rise in titer between two or more serum specimens obtained at time intervals of between 7 and 21 days. Test results obtained with single serum specimens should be interpreted with caution. A negative or weakly reactive specimen taken within 2 weeks of the onset of disease may not necessarily indicate that the patient is negative for a given rickettsial disease. A second blood specimen drawn 1 or 2 weeks after the previous specimen should be requested. A positive serodiagnostic test result for one specimen usually establishes the presence of antibodies to the test antigen. It does not, however, indicate the presence of a disease state.

With the probe test, specific IgG to rickettsiae can remain positive and at a diagnostic level for years. Accordingly, a correlation of positive serologic results and an active disease condition is usually made if there is a significant increase in the antibody titer in sera between two paired serum specimens collected at ≥7-day intervals. Guidelines for the interpretation of test results are shown in reference 39. The titers stated are for reference purposes only. Laboratorians should be wary of serum samples in test runs that do not exhibit gradations in the intensity of the visual reaction (fluorescence, OD, or agglutination) as the serum dilutions reacting with the test antigen are close to the end point. Sera that exhibit gradations are probably true-positive samples. In contrast, test results for sera showing no gradation should be repeated or confirmed by a different methodology, e.g., the IBA. Such reactions might be due to nonspecific reactions, the explanation of which is at present unknown.

Agglutination-based assays (39) are best suited to detecting antibodies during active infection and are less suitable for past infections and serosurveys. This is because of the greater efficiency of specific IgM as an agglutinator than that of specific IgG. Therefore, a sample that scores reactive in such tests probably indicates an active infection or the presence of residual specific IgM. When comparing acute- and convalescent-phase sera, the paired sera should be run in the same assay to avoid interassay variation. For acute Q fever, phase II antibody titers are usually, but not always, higher than or equal to those from phase I determinations. The ratio is very dependent on when the specimens are drawn relative to the onset of symptoms. For chronic Q fever, the phase I titer for IgG is usually markedly higher than the phase II titer. An IFA titer of 1:16 or higher (class-specific or polyvalent immunoglobulins) plus signs and symptoms consistent with the disease comprises presumptive evidence of Q fever. A fourfold rise in titer is confirmatory. With only a single value, an IFA titer should be at least 1:64 to be considered positive. For surveillance studies, a value of 1:128 is considered a minimum value for a positive result.

PCR-based techniques are specific and efficient and have the potential to yield results from specimens obtained at the early stage of the disease and prior to antibiotic treatment. Subsequent analysis of infection after the clearance of rickettsiae associated with antibiotic treatment will result in negative PCR results. It should also be noted that conventional PCR may not be sensitive enough because of the relatively low number ($<10^4$ organisms/ml) (14) of these bacteria circulating in the blood of patients. Some of the more recent applications should be used to detect low levels of bacteria.

The usage of a broad-range PCR methodology can sometimes generate false-positive results due to the amplification of environmental contaminants or previously amplified products (amplicon carryover) that may be present in the clinical laboratory where PCR is routinely performed. These concerns regarding the validity of a positive result may hinder the wider usage of broad-range PCR for molecular diagnosis in the clinical laboratory. The substitution of dUTP for dTTP and the addition of uracil-*N*-glycosylase, both of which are compatible with direct sequencing, can be used to prevent carryover contamination (18). Simply dividing samples into multiple aliquots upon specimen arrival can serve as an important contamination control checkpoint for the subsequent procedures carried out in the laboratory (34). Confirmation of the results obtained with broad-range primers to amplify part of the 16S rRNA gene, followed by sequencing and a database search, can also be achieved by amplifying and sequencing a second genetic target, the heat shock protein gene *htrA*, specific for the identified organism (34). It should also be noted that PCR results may not be determinative in confirming the initial diagnosis for acute infections. This is because the time window for finding organisms in the blood for a successful PCR or culture test result is often narrow, probably the first 24 to 48 h after the onset of symptoms and prior to the administration of antibiotics.

Finally, the protean clinical manifestation of rickettsial diseases makes a definitive clinical diagnosis difficult without laboratory input. However, the correlation of test results with a clinical diagnosis may not always be possible because of the highly variable clinical presentation. It is recommended that diagnosticians consider the diagnosis of infection with one of the bacteria presented in this chapter if a patient presents with a high fever of unknown origin and without apparent clinical manifestations. In addition, it could be helpful to a clinician to obtain patient information pertaining to their travel to regions in which these diseases are endemic, outdoor activities, work environment (e.g., abattoirs for suspected Q fever), and other pertinent epidemiologic data. This could help diagnosticians in the clinical diagnosis of patients presenting with such protean manifestations. Because serodiagnosis is retrospective and until more molecular techniques are formatted for diagnostic use and are more accepted within the diagnostic community, it is suggested that physicians treat patients that they suspect of having one of the diseases described in this chapter before test results are available.

Serologic and Molecular Tools for Diagnosing *Bordetella pertussis* Infection

SCOTT A. HALPERIN

62

CLINICAL PRESENTATION AND EPIDEMIOLOGY OF INFECTIONS CAUSED BY *BORDETELLA PERTUSSIS*

B. pertussis is a gram-negative, pleomorphic coccobacillus for which humans are the only natural host. Infection by *B. pertussis* causes a prolonged coughing illness called pertussis or whooping cough. The spread of infection occurs person-to-person through the inhalation of infected respiratory droplets. After an incubation period of 7 to 10 days, symptoms of an upper respiratory infection develop, with rhinorrhea, lacrimation, malaise, low-grade fever, and a mild cough; this period is called the catarrhal stage and lasts from 1 to 2 weeks. With time, the cough becomes more frequent and severe, often occurring in bursts or fits (paroxysms), with multiple (5 to 10) coughs during a single expiration. During a cough, the infected individual may turn red in the face with bulging eyes, protruding tongue, and distended neck veins, all of which may progress to cyanosis. The coughing episode may terminate with a rapid in-drawing of air against a closed glottis, causing a "whooping" sound. Vomiting may also occur at the end of a paroxysmal cough, frequently associated with expulsion of a mucous plug. Paroxysms may be precipitated by eating, noise, or physical contact. Between episodes, the individual may look and feel healthy. Sleep disturbance and weight loss are common during the paroxysmal phase. Complications of pertussis typically appear during the paroxysmal phase and include pneumonia, pneumothorax, subconjunctival hemorrhage and other petechiae, inguinal and umbilical hernias, rib fractures, urinary incontinence, seizures, encephalopathy, and occasionally death (7). With time (2 to 4 weeks), the cough becomes less frequent and severe as the patient enters the convalescent stage. For up to a year, recurrent paroxysms can occur with any intercurrent upper respiratory infection.

Pertussis occurs at all ages, although most of the morbidity and virtually all of the mortality occur in young infants (27). As a result of universal childhood immunization, the incidence of pertussis has fallen by >95% in industrialized nations. However, the disease continues to occur in infants too young to have completed their three-dose primary immunization series. In the last decade, there has been a dramatic resurgence of pertussis, particularly in adolescents and adults, likely as the result of a waning of vaccine-induced immunity (23). In an effort to control adolescent pertussis and perhaps decrease the transmission of infection from adolescents to young infants, several countries have recently introduced a booster dose of pertussis vaccine in mid-adolescence (19).

DIAGNOSTIC METHODS TO DETECT *B. PERTUSSIS*

If all of the classical clinical symptoms of pertussis are present, clinical diagnosis is not difficult. However, symptoms may be atypical in young infants, adolescents, and adults, and the full classical clinical syndrome of pertussis may take weeks to develop. Laboratory confirmation of pertussis is therefore recommended. Detection of the etiologic agent is the optimal method of making a laboratory diagnosis; however, with *B. pertussis* infections, the nature of the infection and the natural history of the infection make this difficult. Table 1 and Fig. 1 summarize the diagnostic methods for the detection of *B. pertussis*.

Culture

The cornerstone of laboratory diagnosis of pertussis has been the culture of the causative organism from the nasopharynx. *B. pertussis* is most consistently found in the nasopharynx early in the clinical course, when the diagnosis is least likely to be considered. *B. pertussis* is present in the nasopharynx throughout the catarrhal stage and in the early paroxysmal stage; after a week or two of the paroxysmal stage, the organism can no longer be isolated from the nasopharynx, despite this being the period of maximal and classical symptomatology. The optimal specimen for culture is an aspirate of nasopharyngeal secretions (5), obtained by passing a fine, flexible plastic catheter attached to a 10-ml syringe through the nares into the nasopharynx and then withdrawing it while exerting gentle suction. A nasopharyngeal culture with a calcium alginate swab is also adequate (Dacron swabs are acceptable, but cotton swabs inhibit the growth of the organism and should not be used) and may be more acceptable to adults. Throat cultures are poor specimens for the recovery of *B. pertussis*, likely because the organism attaches to ciliated mucosal cells which are not present in the throat. Culture diagnosis has a high specificity; however, despite being the "gold standard," cell culture has a low sensitivity. *B. pertussis* is a fastidious, slow-growing organism that

TABLE 1 Characteristics of diagnostic tests for detection of *B. pertussis*[b]

Diagnostic test	Optimal use	Advantages	Disadvantages	Sensitivity	Specificity	Rapidity
Organism detection						
Culture	Diagnosis early in course of illness, particularly for young infants	No false-positive results, inexpensive, organism available for molecular epidemiology and antibiotic sensitivity (in rare cases, where indicated)	Moderately low sensitivity, requires special media and laboratory capability, specimen transport control is important	++	++++	++
PCR	Diagnosis early in course of illness	More sensitive than culture, less affected by prior treatment with antibiotics, positive for longer in clinical course than culture	Specificity affected by laboratory and environmental contamination, more expensive than culture, sophisticated equipment required	+++	+++	+++
DFA assay	Diagnosis early in course of illness	Rapid, inexpensive	Poor sensitivity and specificity, dependent on skill of operator and quality of reagents	+	+	++++
Serology						
Agglutinins	Population seroepi-demiology studies	Easy to perform, correlates with population exposure to pertussis, long history of use	Poor correlation of titers with individual protection, no longer widely available	++	+++	+++, +[a]
CHO cell neutralization	Antibody to PT after immunization	Measures functional antibody	Labor-intensive, requires cell culture facilities, not widely available	+++	++++	+++, +[a]
IgG EIA						
PT	Diagnosis of infection or response to immunization	Specific for *B. pertussis*, most consistently immunogenic antigen, diagnosis late in clinical course, diagnosis of adolescents and adults	Cannot differentiate infection from immunization, young infants may have suboptimal immune response	+++	++++	+++, +[a]
FHA	Diagnosis of infection or response to immunization	Consistently immunogenic antigen, diagnosis late in clinical course, diagnosis of adolescents and adults	Cannot differentiate infection from immunization, cross-reacts with other *Bordetella* species and some other microorganisms	+++	+++	+++, +[a]
PRN	Diagnosis of infection or response to immunization	Diagnosis late in clinical course, diagnosis of adolescents and adults	Less consistently immunogenic antigen, cross-reacts with other *Bordetella* species, less standardized assay	++	+++	+++, +[a]
FIM	Diagnosis of infection or response to immunization (one vaccine)	Diagnosis late in clinical course, diagnosis of adolescents and adults	Less consistently immunogenic antigen, cross-reacts with other *Bordetella* species, less standardized assay	++	+++	+++, +[a]
IgA assays	Diagnosis of infection	Less likely to be positive after immunization	Less consistently positive	+	Depends on antigen	+++, +[a]

[a]+++ for single-serum diagnosis and + for paired serology.

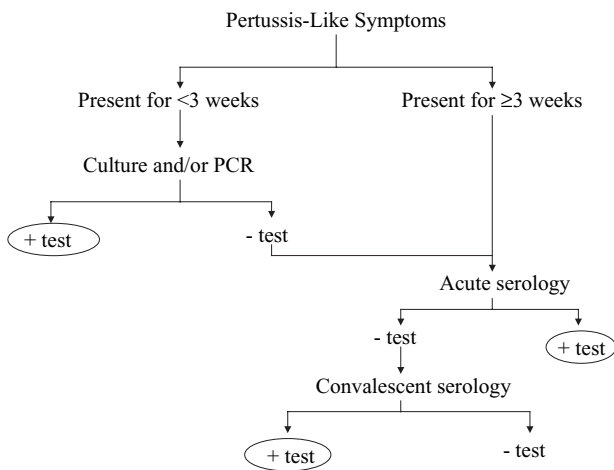
62. Serologic and Molecular Tools ■ 541


FIGURE 1   Algorithm for the laboratory diagnosis of pertussis.

requires special media (Bordet-Gengou or Regan-Lowe charcoal agar) and careful specimen handling (the organism is extremely sensitive to drying, so it must immediately be put on appropriate agar plates or into appropriate transport medium). The requirement for specialized and selective media means that the organism will not be isolated unless it is specifically sought. To further complicate matters, cultures are less likely to be positive from older individuals, previously immunized individuals, or those who have received an antimicrobial agent to which the organism is sensitive (18). *B. pertussis* is also slow growing, typically requiring 5 days of incubation before being identifiable, further decreasing the sensitivity of culture as a result of overgrowth of other, faster-growing organisms present in the nasopharynx. The incorporation of cephalexin into the growth medium is useful for the suppression of other organisms but may also inhibit the growth of some *B. pertussis* strains; therefore, culture is recommended to include both cephalexin-containing and cephalexin-free media. Despite these numerous methodological reasons for the decreased sensitivity of cell culture, the collection of specimens late in the clinical course, at a time when the microorganism is no longer present in the nasopharynx, is the major contributor to negative cultures from pertussis infections.

Once suspicious colonies with the appropriate morphology are detected on culture plates, the identification of *B. pertussis* is confirmed by biochemical tests, direct fluorescent antibody (DFA) staining, bacterial agglutination, or PCR (11).

DFA Staining

A more rapid method for the diagnosis of pertussis is to identify the organism directly in nasopharyngeal secretions, although the issue of the timing of specimen collection that limits the usefulness of culture also applies to DFA staining. Using fluorescein-labeled antibodies, one can directly observe *B. pertussis* in nasopharyngeal secretions, thereby providing almost immediate laboratory confirmation of the diagnosis. Although DFA reagents have been available commercially for decades, the test is fraught with problems of poor sensitivity and poor specificity and is highly dependent on the expertise of the technician performing the test (6). More specific reagents (monoclonal antibodies) have improved the specificity of the test but are not widely available (14). Because of the difficulties with the test, DFA staining should only be used in conjunction with culture;

some national surveillance systems do not accept DFA results as laboratory confirmation of pertussis infection.

PCR

More recently, molecular diagnostic techniques have been applied to the laboratory diagnosis of pertussis. The detection of *B. pertussis* by amplifying sections of the bacterial genome found in nasopharyngeal secretions has dramatically increased the sensitivity of bacterial detection methods. Various methods using different genomic sequences have been described; however, universally accepted target genes, amplification primers, and detection systems and a standardized methodology do not exist, and commercial kits are not widely available. PCR can be performed on nasopharygneal aspirate specimens, although the secretions should be treated with a mucolytic agent and centrifuged to remove PCR-inhibiting substances and to concentrate the bacteria. Nasopharyngeal swabs can also be used; however, a DNA extraction method is required for specimens collected with calcium alginate swabs which is not required if Dacron swabs are employed (18, 26). Multiple target genes have been proposed, including repeated insertion sequences (3), the pertussis toxin (PT) promoter region (8), a DNA region upstream of the porin gene (10), and the adenylate cyclase toxin gene (1). Although the repeated insertion sequence intrinsically has greater sensitivity and is the most frequent target used, similar results can be obtained with all of the target genes by adjusting the number of amplification cycles. Most detection systems use ethidium bromide staining, although other methods (immunoblotting, Southern blotting, and dot blotting) have been described. With most reported methods, a sensitivity sufficient to detect <10 bacteria per reaction has been achieved. Recently, the most sensitive detection was achieved by using the insertion sequence in a real-time PCR format.

The ability to detect fewer organisms and the lesser importance of specimen handling because of the growth characteristics of the bacteria result in a far greater sensitivity of PCR. Also, the ability to detect nonviable organisms means that PCR likely remains positive for a longer time during the paroxysmal phase, when the organism is no longer cultivatable (although this increased duration has not been quantified). PCR is also less affected by antimicrobial effects than is cell culture, permitting laboratory diagnosis even after effective antibiotics have been initiated (2). With this increased sensitivity, however, there are more possibilities of cross-contamination leading to false-positive tests and decreased specificity. False-positive results can occur from contamination with other bacteria with similar genetic sequences, contamination with laboratory strains of *B. pertussis* or with other positive clinical specimens, or carryover from other specimens in the assay. Extreme care must be taken to avoid environmental contamination of specimens in the diagnostic laboratory with genomic DNA from previous specimens or bacterial cultures. Indeed, PCR is so sensitive that cross-contamination can occur from the presence of *B. pertussis* on surfaces and in the air of the specimen collection units (24). A strict separation of specimen processing areas and amplification and detection areas in the laboratory, the incorporation of known positive and negative controls into each assay, and the inclusion of blinded negative specimens improve the performance of PCR diagnosis. Real-time PCR methodology (9), which requires less specimen handling during the assay, and nested PCR techniques (21) have also decreased the risk of specimen contamination within the laboratory but do not affect the problems associated with specimen

collection that are often outside the purview of laboratory quality control efforts. False-negative results may occur for many of the same reasons that affect the sensitivity of bacterial culture (collection of specimens late in the clinical course, prior antimicrobial use, inadequate specimen collection, or improper specimen handling or storage) as well as for reasons specific to PCR (presence of inhibitors such as blood in the specimen, insensitivity of the detection system, or presence of strain variants of *B. pertussis* with alterations in the target genetic sequence). Despite these limitations, PCR has consistently proven to have a superior sensitivity in the laboratory diagnosis of pertussis compared to that of bacterial culture.

SEROLOGIC METHODS FOR THE DIAGNOSIS OF *B. PERTUSSIS* INFECTIONS

Serologic methods for the diagnosis of pertussis have both advantages and disadvantages relative to organism detection methodologies. Since serology detects the host immune response to the infection, early acquisition of the specimen during the time when the organism is present in the nasopharynx is not required. In contrast to many infections for which one may have a falsely negative serologic test if specimens are obtained too early in the clinical course, with pertussis, by the time typical symptoms are present, the antibody response is usually well established. With pertussis, the difficulty with serology is demonstrating seroconversion because the timing of paired serology can more aptly be described as convalescent-late convalescent phase rather than the desired acute-phase–convalescent-phase pair. However, serologic assays have been the primary method of demonstrating the frequency of pertussis infections in adolescents and adults, for whom culture methods are less sensitive than for younger children. Indeed, in the United States, most cases of pertussis in adolescents and adults are reported from Massachusetts, one of the few jurisdictions that routinely performs serologic diagnostic testing for pertussis (28).

Pertussis Agglutinins

The measurement of pertussis agglutinins is one of the oldest assays used for determining antibody titers against *B. pertussis*. Widely used in the early and mid-20th century, particularly in the Medical Research Council clinical trials that demonstrated the efficacy of whole-cell pertussis vaccines, pertussis agglutinins correlated well with population immunity to pertussis but did not predict individual protection (16). The assay is currently performed as a microagglutination assay by vigorously mixing serial dilutions of patient sera with a standard concentration of whole phase I *B. pertussis* organisms in microtiter plates, incubating the mixtures overnight at 35°C, and observing them for bacterial agglutination. A negative agglutinin test appears as a thick button of cells at the bottom of the well, whereas complete (4+) agglutination appears as a sheet of cells covering the entire bottom of the well (13). Recently, agglutinin antibodies have been demonstrated to correlate best with antibodies against fimbriae (FIM), pertactin (PRN), and lipooligosaccharide (15). Agglutinins are no longer widely used and have no useful role in clinical diagnostic laboratories.

EIA

Enzyme-linked immunosorbent assays (EIAs) are the most widely used methodology for measuring antibodies against *B. pertussis*. A variety of solid-phase antigens have been used for EIA antibody detection, and assays have been described for immunoglobulin G (IgG), IgA, and IgM antibodies. The antigen(s) and antibody class(es) used affect both the sensitivity and specificity of the diagnostic test, so they must be selected carefully.

B. pertussis Antigens

EIAs have been developed with whole bacterial cells, PT, filamentous hemagglutinin (FHA), PRN (also referred to as the 69-kDa protein), FIM, lipooligosaccharide, and adenylate cyclase toxin. Commercially produced EIA kits have had limited availability; most have used sonicates of whole bacterial cells. Whole bacterial EIAs have the advantage of ease of antigen production (although a standardization of growth conditions is required to ensure consistent antigen expression by the bacteria) but are limited by cross-reactivity with related *Bordetella* species (most commonly *B. parapertussis*) and other unrelated bacteria (such as nonencapsulated *Haemophilus influenzae*).

PT is the most important pertussis antigen and is responsible for many of the biological activities of *B. pertussis*. PT is an A-B-type toxin with six subunits (S1 to S5). The B pentamer (made up of the S2, S3, two S4, and S5 subunits) is responsible for binding of the toxin to mammalian cells. The S1 protomer is the enzymatically active A subunit, which catalyzes the ADP-ribosylation of the membrane-bound regulatory protein G_i that normally inhibits adenylate cyclase, resulting in increased intracellular cyclic AMP. This results in the disruption of intracellular function, including decreased phagocytic activity and lymphocyte homing (resulting in lymphocytosis). PT is only produced by *B. pertussis*, making it a highly specific antigen (while *B. parapertussis* has the gene encoding PT, it is not expressed). PT is also included in all acellular pertussis vaccines currently manufactured worldwide and is an important protective antigen in the immune response to infection and immunization. Demonstration of an antibody rise to PT is diagnostic of pertussis (or of recent immunization), and the presence of antibodies against PT implies prior exposure to the organism or vaccine. Unfortunately, an antibody response to PT does not occur in all individuals after pertussis infection (young infants may not have an adequate response to PT) and may be diminished in previously immunized individuals. Thus, PT antibody assays are specific but by themselves are not of sufficient sensitivity for the reliable diagnosis of pertussis.

FHA is a component of the bacterial cell wall and plays an important role in binding to mucosal surfaces. FHA is a large, 220-kDa protein that forms filamentous structures on the bacterial cell surface. FHA has three distinct binding domains, including one that binds to sulfated sugars in the mucus of epithelial cells, an RGD domain that binds to integrins of macrophages and neutrophils, and a lactosylceramide binding site for attachment to macrophages and ciliated cells. EIAs with FHA are also widely used, typically in combination with PT assays. FHA is also a component of most acellular pertussis vaccines (with the exception being a monovalent PT vaccine), although whether or not FHA is a protective antigen is still controversial. Animal studies have been inconclusive; FHA has been demonstrated to induce protective antibodies in mice by some investigators, whereas others maintain that the protection induced was a result of trace contamination with PT. The presence of FHA antibody has not been correlated with protection in human studies. The antibody response to FHA is more consistent after infection, which increases the sensitivity of the test; however, all *Bordetella* species have FHA, so specificity is an issue. Indeed, anti-FHA antibodies have been demonstrated after infections caused by *H. influenzae* and *Mycoplasma pneumoniae*, suggesting that antibodies to unrelated antigens may cross-react with FHA.

PRN is another outer membrane adhesin protein that, like FHA, is mediated through an RGD sequence that promotes binding to the integrins of macrophages. PRN has a higher specificity for *B. pertussis* (although other *Bordetella* species produce related proteins). PRN is included in several widely used acellular pertussis vaccines and has been demonstrated to increase the efficacy of PT-FHA vaccines. PRN has also been correlated with protection after pertussis immunization. A PRN antibody response after infection may not occur as consistently as a response to PT (4). PRN-specific EIAs are not widely available and were shown to be associated with a greater degree of interlaboratory variability than either PT or FHA assays (12).

FIM are important hair-like surface antigens of *B. pertussis* that play a role in adherence to ciliated epithelial cells. Fimbrial antigens correlate best with agglutinogens, the components classically used to type *B. pertussis* isolates. Like the case for PRN, antibodies against FIM may occur less consistently than those against PT (4). FIM (types 2 and 3) are components of only one commercially available acellular pertussis vaccine, which limits access to supplies of the purified antigen for use in EIA (many of the purified antigens used in EIA are provided by the vaccine manufacturers). Thus, there is less information available on their use in diagnosis. Antibodies to FIM may cross-react with other bacterial species.

EIAs specific for other *B. pertussis* antigens, including the lipooligosaccharide and adenylate cyclase, have been described but are only available in a few research laboratories.

Antibody Class Assays

Although EIAs have been described for the detection of IgG, IgA, and IgM antibodies against *B. pertussis* antigens, IgG assays are the most frequently used as a diagnostic test, the best standardized, and the most widely available. IgG antibodies appear most consistently after infection or immunization; an antibody rise can typically be detected within 2 to 3 weeks after infection or primary immunization and as early as 1 week after a booster immunization. The antibody rise may be substantially slower in young infants. The rapidity of the antibody response may vary by antigen. PT and FHA antibodies are elicited most consistently, while PRN, FIM, and lipooligosaccharide antibodies are less predictable. PT antibodies appear somewhat later than antibodies against the surface antigens. IgG antibodies can be detected long after infection or immunization (decreasing over a 1- to 3-year period), so an elevated antibody titer may be the result of recent or remote infection or immunization (25). Although measurements of IgM might be useful for differentiating recent from remote infections, IgM assays have only occasionally been reported and are not well standardized. Little is known about the natural history of the IgM response after infection. To date, IgM assays have not provided any diagnostic utility.

Measuring the IgA response after pertussis infection has been proposed as a means of differentiating infection from immunization. IgA responses after infection occur less commonly (20 to 50%) than IgG responses (>90%) but are more frequent after infection than after immunization (18). IgA antibodies usually persist for up to a year after infection. The IgA response is even less predictable for young infants, and some IgA responses have been demonstrated after immunization with acellular pertussis vaccines, limiting the diagnostic specificity of the test (17). IgA serological diagnosis has not gained widespread acceptance to date but may be increasingly useful, particularly for interpreting equivocal anti-PT antibody responses.

Combinations of assays (antigens or antibodies) have been used to increase the diagnostic sensitivity and specificity of tests (6). Using assays against two or more antigens and two or more antibody classes does increase the sensitivity of serological diagnosis but, depending on the antigen, may decrease the specificity if the antigen cross-reacts with antigens from other *Bordetella* species or other unrelated bacteria. Some investigators have used serological algorithms to minimize the loss of specificity, requiring a positive antibody response to two or more antigens that have cross-reactions (e.g., FHA and FIM) or a single antibody response to a unique *B. pertussis* antigen (e.g., PT), although the use of multiple antigens or antibody isotypes increases the cost of the diagnostic test (22). For all of these reasons, most clinical diagnostic laboratories offering serological diagnosis only use a PT or a PT-FHA IgG assay and limit the use of multiple antigens and antibody isotypes to seroepidemiological studies.

EIA Methodology

There is no universally accepted methodology for the performance of EIA for the detection of pertussis antibodies; however, most published assays are similar and follow basic EIA methodology. Purified pertussis antigen (PT, FHA, PRN, or FIM at 0.5 to 2 μg/ml) or whole bacterial cells are diluted in a neutral to alkaline coating buffer and bound to polystyrene EIA plates. After incubations of various durations (ranging from 1 to 2 h at 28 to 37°C to overnight at 4 to 28°C) and blocking of remaining binding sites with a blocking solution (typically containing a detergent such as Tween 20 and/or a high-protein solution such as bovine serum albumin or fetal calf serum), serum dilutions are added (typically starting at a dilution of 1:60 to 1:100 in phosphate-buffered saline at physiological pH) and incubated for a 1- to 3-h period at 28 to 37°C. After another series of washes with the blocking solution, a 1- to 16-h incubation is performed at 28 to 37°C with an enzyme-conjugated anti-human IgG (or IgA or IgM) antibody (e.g., alkaline phosphatase-conjugated goat anti-human IgG), after which a substrate is added; the enzyme-substrate combination results in a colorimetric change, which is read by a spectrophotometer at the substrate's optimal wavelength.

Antibody levels are typically quantified by assigning the test serum an EIA unitage by comparison to a simultaneously assayed standard serum that has been assigned an arbitrary antibody value. Standard sera for each of the pertussis antigens have been made available to diagnostic laboratories from the Pertussis Laboratory of the Center for Biologics Evaluation and Research of the U.S. Food and Drug Administration (FDA). Because of the limited supply of these standard sera, most pertussis serology laboratories have produced their own internal serum standards that are correlated with the FDA standard and then used with each assay. Various methods have been described to calculate the EIA unitage relative to the standard serum, but the reference-line method has been shown to be the most reproducible (20). With this method, the line generated by serial dilution of the test sample is assumed to have the same slope as the line generated by the reference serum, and the titer of the sample is calculated from the distance in dilution between the two lines (20).

The reproducibility of antibody titers measured by EIA is dependent on several factors. Variability can be attributed both to materials and to the operator. Intra-assay variability has been attributed to differences in binding characteristics

of the EIA plates, to variability in binding related to the specimen's position on the plate (internal versus external wells), and to pipetting inaccuracies. Day-to-day (interassay) variability may be related to dilution differences and to variability in the reagents. Because of these variabilities, paired sera from an individual should be assayed together, preferably on the same EIA plate. To control for the inherent variability in EIA assays, pertussis serology laboratories should implement a quality control program to ensure that intra- and interassay variability is kept within acceptable limits. A positive control serum can be assayed on each plate, and the variability between assays can be expressed as the coefficient of variation (standard deviation divided by the mean and then multiplied by 100). Assays for which the control serum result falls outside a defined bound (such as ±2 standard deviations) should be rejected and repeated (20).

Antibody measurement by EIA is least accurate at low and high antibody concentrations, for which the antibody dilution curves are nonlinear. Low antibody levels are most difficult to measure accurately because the variability of the assay may be greater than the antibody level present. For each EIA, the coefficient of variation for the assay should be determined and should be <15%. A level of quantification should be determined which can then be used to determine the minimum level of detection (MLD) of the assay. Any antibody units with values lower than the MLD should be reported as less than the MLD.

Although EIA methodologies vary among laboratories providing serological diagnoses of pertussis, there have been efforts to explore whether results from various reference laboratories are comparable. Led by investigators at the FDA, 13 laboratories participated in an assessment of pertussis serological diagnosis by assaying a bank of test sera and comparing results. This study demonstrated that there was a good correlation for anti-PT IgG assays amongst the laboratories, a fair correlation for anti-FHA antibodies, and a relatively poor correlation for PRN and FIM antibodies (although the number of laboratories performing the last two assays was limited).

Other Serological Assays

Several other serological tests have been used to detect antibodies against B. pertussis, but none have gained wide acceptance or application. The most important of these is the measurement of neutralizing antibodies using the Chinese hamster ovary (CHO) cell neutralizing assay. CHO cells undergo a characteristic morphological change in the presence of PT that can be neutralized by anti-PT antibodies. The CHO assay quantifies these antibodies by assessing the ability of a serum to prevent the morphological change of a given, standardized quantity of PT. The CHO cell neutralizing titer is defined as the reciprocal of the last dilution that completely prevents the PT-induced morphological change. Proponents of the CHO cell neutralizing assay argue that the assay measures biologically active antibodies and thus might correlate better with protective antibodies. However, CHO titers have been shown to correlate well with the technically simpler to perform and easier to standardize anti-PT IgG EIA.

Use and Interpretation of Serological Tests for Pertussis

Serological tests for pertussis have important uses but also have several limitations. Measurements of antibodies have been used to evaluate the response to immunization (in clinical trials or after routine immunization) and for the diagnosis of natural infection. For the latter purpose, serology is most useful later in the course of illness, when bacterial or DNA detection assays may no longer be positive. Serology is also useful for older children, adolescents, and adults, for whom culture and PCR may be less consistently positive. Paired sera are the gold standard for serological diagnosis, demonstrating an antibody response after infection with B. pertussis. Fourfold increases in antibody levels have typically been used for pertussis agglutinins (and other assays that use serial dilutions), where a two-tube or -well change in titer is certain to be beyond the variability of the assay and to indicate a true increase in antibody. Fourfold dilutions are less defensible as a minimum indicator of an antibody increase in EIAs, for which test-to-test variability is measured by the coefficient of variation. With most well-performed EIAs, the coefficient of variation is sufficiently low (<15%) to allow a reliable differentiation of increases in antibodies of 50% or more; thus, a twofold increase in antibody level conservatively ensures that one is measuring a change in antibody level rather than assay variability. Despite this fact, however, fourfold responses are most often reported, most likely due to tradition.

Demonstrating a rise in antibody level is hindered by the late collection of the first specimen, by which time the antibody levels may have achieved the maximal levels after infection. In immunized individuals, the rapidity of the anamnestic antibody response may preclude the demonstration of an antibody rise. Single-serum criteria for the diagnosis of pertussis have been proposed, typically requiring an antibody level in excess of 3 standard deviations or the 99.99th percentile of a healthy age-matched population. These criteria have greatly increased the sensitivity of serological diagnosis, although, to retain a high specificity, requiring positive antibody titers against two or more antigens (except if against PT) is recommended. Single-serum diagnosis is becoming increasingly accepted as more age-specific reference values for IgG anti-PT antibodies become available. The interpretation of serological results for infants and young children must take into account any recent pertussis immunization, since acellular pertussis vaccines in current use contain two or more of these same antigens, therefore making differentiation between immunization and infection impossible. Serology testing is particularly useful for adolescents and adults, for whom culture is less sensitive and immunization is more remote. The recent implementation of adolescent booster doses of pertussis vaccine in a number of countries will further limit the use of serological diagnosis for these age groups unless assays are developed with consistently immunogenic and specific antigens that are not contained in the vaccines.

SUMMARY AND CONCLUSIONS

The laboratory diagnosis of pertussis continues to present challenges due to the fastidious nature of the organism, the natural history of the infection, whereby the organism is least likely to be present in the nasopharynx and thus detectable by culture or PCR when the clinical suspicion of pertussis is likely to be highest, the difficulty with demonstrating seroconversion because of the late collection of an acute-phase serum specimen, and the lack of a standardized, widely available assay specific for an antigen not included in acellular pertussis vaccines. Although molecular diagnosis (PCR) has revolutionized pertussis diagnosis by increasing the sensitivity of bacterial detection, the methodology is

likely reaching its limits of improvement and is limited by the fact that the organism is no longer present in the host well before the clinical symptoms begin to resolve. Improvements in serological diagnosis have the greatest potential for improving the laboratory diagnosis of pertussis, particularly as the epidemiology shifts from young infants and children to adolescents and adults. The identification of a *B. pertussis*-specific antigen which consistently elicits an immune response but is not a vaccine candidate is a prerequisite for better serological diagnosis. The ability to differentiate recent from remote infections, perhaps through IgG and IgA assays, would make the test more interpretable. Standardization of the assay so that results from various laboratories can be compared is essential for the dissemination of such a diagnostic test.

Bacillus anthracis Detection and Anthrax Diagnosis

ALEX R. HOFFMASTER AND TANJA POPOVIC

63

Anthrax is primarily a disease of herbivores, which acquire the disease by ingesting *Bacillus anthracis* spores from contaminated soil. Although anthrax is more common in parts of Central Asia and Africa, it still occurs sporadically in animals in parts of the United States, including the West, Midwest, and Southwest. There are three clinical forms of human anthrax, depending on the route of infection: cutaneous (acquired via skin abrasion), gastrointestinal (acquired via ingestion), and inhalation anthrax. While naturally acquired anthrax is rare in the United States, the fear of inhalation anthrax continues in this era of bioterrorism that became reality in 2001 when 22 people in the United States acquired anthrax from spores sent through the mail (16).

The genus *Bacillus* contains a wide range of endospore-forming species, of which very few are pathogens. *B. anthracis* and other members of the *B. cereus* group are exceptions to this general rule. *B. anthracis* is the etiologic agent of anthrax, *B. cereus* is most frequently associated with food poisoning but can cause a variety of serious infections, and *B. thuringiensis* is an insect pathogen but has also been implicated in some cases of gastroenteritis (20). These species have been shown to be phylogenetically very closely related by several methods (17, 29), resulting in some researchers suggesting that they be considered a single species (12). At least some of the differences in virulence between *B. anthracis* and most of its close relatives can be attributed to the presence of two virulence plasmids, pXO1 and pXO2. The pXO1 and pXO2 plasmids carry the genes which encode the anthrax toxins (lethal toxin and edema toxin) and the antiphagocytic poly-γ-D-glutamic acid capsule, respectively (23, 26). However, whether they are considered a single species or not, the need to rapidly differentiate them remains due to the different diseases they cause, potential bioterrorism use, and the implications for treatment.

Just a few years ago, anthrax was rarely encountered and few laboratories had the capacity to identify *B. anthracis* in the United States. Since the threat of bioterrorism and the development of the Laboratory Response Network (LRN), that situation has changed dramatically (22). Currently, there are LRN laboratories in every state that have the capacity to rapidly detect and identify *B. anthracis*. The number of methods, assays, and new instrumentation that are currently being used and described in the literature to detect *B. anthracis* is too exhaustive to be included in this review. This chapter will primarily focus on methods that are currently in use within LRN laboratories and on commercially available tests that have been approved by the U.S. Food and Drug Administration (FDA) and thus are widely available. This chapter includes four sections, covering culture, molecular, antigen, and antibody detection methods for the diagnosis of anthrax. Throughout the chapter, the methods are discussed relative to the Centers for Disease Control and Prevention (CDC) definitions of suspected and confirmed cases used during the 2001 anthrax outbreak. A confirmed case of anthrax was defined as a clinically compatible case that was laboratory confirmed by the isolation of *B. anthracis* from an affected tissue or by laboratory evidence based on at least two other supportive tests. A suspected case was defined as a clinically compatible illness without isolation of *B. anthracis* and with only a single supportive laboratory test or a clinically compatible case epidemiologically linked to a confirmed environmental exposure but without corroborative laboratory evidence (5). Supportive laboratory tests included the LRN PCR assay, immunohistochemical (IHC) staining of tissues, and anti-protective antigen (anti-PA) immunoglobulin G (IgG) detection by an enzyme-linked immunosorbent assay (ELISA) and are discussed later in the chapter.

CULTURE

Culturing *B. anthracis* from clinical specimens remains the standard for diagnosing anthrax. Biosafety level 2 practices are adequate for work with clinical materials and diagnostic quantities of infectious cultures. Biosafety level 3 practices and facilities are recommended for work involving larger quantities or concentrations of cultures and for activities with a high potential for aerosol production (1). *B. anthracis* may be present in blood, skin lesion exudates, cerebrospinal fluid, pleural fluid, sputum, and feces. If the *B. anthracis* infection has become systemic, it is generally easy to culture the organism from blood, with organisms reaching concentrations of 10^8 CFU/ml. Culturing *B. anthracis* from cutaneous lesions is more difficult, and growing the organism is not likely, regardless of the form of disease, once antimicrobial therapy has been initiated. The most common laboratory medium used for culturing and identification of *B. anthracis* is sheep blood agar. *B. anthracis* produces a characteristic ground-glass appearance and is nonhemolytic on this medium. Laboratories have also used polymyxin lysozyme

EDTA thallium acetate (PLET) semiselective medium when high levels of background contamination are expected (e.g., with environmental samples) (8, 18).

Despite the phylogenetic data suggesting that members of the *B. cereus* group may be considered a single species, *B. anthracis* can be readily distinguished from its close relatives by several phenotypic differences (20). *B. anthracis*, unlike *B. cereus* and *B. thuringiensis*, is not motile, is susceptible to penicillin, and is not hemolytic. Although exceptions to these phenotypes can occur, it is generally very easy to distinguish *B. anthracis* from *B. cereus* and *B. thuringiensis* based on these differences. In addition, susceptibility to lysis by a bacteriophage (gamma phage) has been used very successfully since the 1950s to help identify *B. anthracis* and is still in use today (3). *B. anthracis* is lysed (susceptible) by the gamma phage, while its close relatives are not. Resistant isolates of *B. anthracis* and susceptible isolates of *B. cereus* have been reported but are not common (10, 30). In addition, isolates can be tested by PCR and several of the antigen-based methods discussed later in this chapter. It is important that no single test can be used to rule out or identify *B. anthracis*.

Advantages and Disadvantages

All of these tests require an isolate of *B. anthracis* and require about 24 h to complete. However, they can easily be performed by most laboratories, with the possible exception of the gamma phage test, which is available at LRN reference laboratories. Once antimicrobial therapy has been initiated, it is very difficult to culture *B. anthracis* from patient specimens.

Specimen Collection and Transport

Isolates of *B. anthracis* or other *Bacillus* spp. can be transported on most common, nonselective laboratory media at room temperature. Clinical specimens such as swabs, stools, sputa, pleural fluid, and blood should be transported at 2 to 8°C. For cutaneous lesions in the vesicular stage, collect the vesicular fluid on a dry, sterile swab. For lesions in the eschar stage, lift an edge of the eschar and insert and rotate the swab without removing the eschar. Fresh tissue samples (e.g., not formalin fixed) should be sent frozen.

MOLECULAR DETECTION

PCR is another commonly used laboratory method for the detection of pathogens. In recent years, several different chemistries, assays, and instruments have become available for the performance of real-time PCR. These methods utilize fluorescent probes (primers labeled with fluorescent dyes) that allow the detection of amplicons by measuring fluorescence. Some of the common types of probes used include TaqMan (5′ exonuclease assay) probes, dual-hybridization probes, and molecular beacons (6, 21). The use of fluorescent primers as probes not only allows for real-time detection of the PCR products but also increases the specificity of the reaction since both the amplification primers and the fluorescent probes need to hybridize to the target in order to produce a signal.

Great efforts have been made to develop specific PCR assays for the detection of *B. anthracis*. The plasmids have generally proven to be reliable targets, particularly the toxin genes (*pagA*, *lef*, and *cya*) on pXO1 and the capsule operon (*capBCA*) on pXO2. However, false-positive amplification using primers specific for the *capB* gene has been reported previously (27), and recently pXO1 was identified in a *B. cereus* isolate (15). A commercial real-time PCR kit is available (Roche, Mannheim, Germany) that targets the toxin gene (*pagA*) and a capsule gene (*capB*) (2). However, this

section will focus on the LRN PCR assay used in the U.S. public health system.

LRN PCR

The LRN real-time PCR assay for the detection of *B. anthracis* is a 5′ exonuclease assay that includes three separate targets: one on the chromosome, one on pXO1, and one on pXO2 (14). This greatly reduces the risk of false-positive and false-negative results by not relying on a single target. This assay demonstrated 100% sensitivity and specificity when tested on a diverse set of 81 *B. anthracis* isolates and an extensive set of its close relatives ($n = 56$) (14). The limit of detection for this assay is approximately 5 to 10 spores based on PCRs performed directly on diluted spores. DNA extraction from the spores is not necessary since the spore surface is covered in DNA as a result of the sporulation process.

This assay was also used during the 2001 bioterrorism-associated anthrax outbreak to detect *B. anthracis* in environmental samples and clinical specimens to confirm anthrax diagnosis when the isolation of *B. anthracis* failed due to the initiation of antimicrobial drug treatment. The LRN PCR assay was particularly useful for detecting *B. anthracis* in pleural fluids of patients with inhalation anthrax but was also successfully used to detect *B. anthracis* in blood, serum, cerebrospinal fluid, lymph node tissue, lung tissue, sputum, pericardial fluid, and tissue from cutaneous lesions. Pleural fluid specimens were positive for all five inhalation anthrax patients from whom samples were received, despite the specimens having been taken after the initiation of antimicrobial therapy and consequently being culture negative (14).

Advantages and Disadvantages

The LRN real-time PCR assay is specific, sensitive, and rapid. Once the DNA has been extracted, the assays can be set up and results obtained in about 1 to 2 h. However, since PCR detects DNA from viable or nonviable cells, it is not useful for detecting *B. anthracis* contamination in the environment after decontamination since dead cells and spores will still be detected. In addition, the sensitivity greatly decreases if specimens are taken after the initiation of antimicrobial therapy.

Specimen Collection and Transport

As stated previously, isolates of *Bacillus* spp. for testing can be sent on most common, nonselective laboratory media at room temperature. Specimens such as swabs, stools, sputa, pleural fluid, and blood should be transported at 2 to 8°C and fresh tissue should be sent frozen.

ANTIGEN DETECTION

Several antibodies and antigen-based detection methods are in use for the detection and identification of *B. anthracis*. Regardless of the methodology, an antigen detection assay is limited by the affinity and specificity of the antibodies used, and in the case of clinical or environmental samples, the concentration of the antigen in the sample. Antibodies have been used successfully to detect the vegetative and spore forms of *B. anthracis*. This section will cover the following four methods: a direct fluorescent-antibody assay (DFA), time-resolved fluorescence (TRF) assays, an immunochromatographic assay, and IHC assays.

DFA

A two-component DFA using two different monoclonal IgM antibodies specific for a *B. anthracis* cell wall antigen (galactose–*N*-acetylglucosamine) and the *B. anthracis* capsule

(poly-γ-D-glutamic acid) has been used successfully to identify vegetative cells of *B. anthracis* (7, 9, 10). Both antibodies are conjugated to fluorescein isothiocyanate, which when bound to *B. anthracis* allows for visualization of the fluorescent cells by using a UV microscope with a 40× or 100× objective. Although neither antibody is 100% specific for *B. anthracis*, when they are used in combination the assay is 100% specific to date (i.e., no isolates other than *B. anthracis* have been positive for both antigens) (7). In addition to being used directly on isolates, this assay successfully detected *B. anthracis* in pleural fluid, blood, lung tissue, and lymph node tissue collected during the 2001 bioterrorism-associated anthrax outbreak (7).

TRF Assays

In addition to the real-time PCR assay, some LRN laboratories have the capacity to detect spores or vegetative cells in samples by using a spore or vegetative cell-specific antibody in a dissociation-enhanced lanthanide fluoroimmunoassay (DELFIA; Perkin-Elmer). This type of assay is essentially comprised of noncompetitive sandwich ELISAs that utilize biotinylated capture antibodies and detector (secondary) antibodies labeled with a lanthanide chelate (europium) (24). Once the secondary antibody has been washed away, a low-pH (2 to 3) enhancement solution containing a β-diketone and Triton X-100 is added to the sample. The buffer interacts with the europium label to produce a highly fluorescent chelate suspended within a micelle, allowing for increased sensitivity and length of signal (24).

These assays can be used on various environmental and clinical specimens. Clinical specimens may include sera, nasopharyngeal swabs, bronchial or tracheal washings, or lesion exudates, but not whole blood. The *B. anthracis* TRF cell assay is specific for *B. anthracis* at concentrations of ≤10^6 CFU/ml. The TRF spore assay utilizes an antibody that is specific for *B. anthracis* spores but also cross-reacts with *B. anthracis* vegetative cells. Both assays have a limit of detection of approximately 100 total spores or vegetative cells per reaction (LRN, unpublished data).

Immunochromatographic Methods

The development of lateral-flow immunochromatographic devices similar to many home pregnancy tests has remained an attractive concept due to their small size, speed, possible field use, and ease of operation. There are several varieties of tests, but typically a suspension of the sample (antigen) is added to a strip which rehydrates a monoclonal antibody labeled with colored beads or colloidal gold. The solution migrates via capillary action along the membrane, and if antigen is present, the labeled monoclonal antibody-antigen complex will be captured by a second antibody at the test line, resulting in a colored band that is easily visualized (24). Most attempts to utilize this type of technology for the detection of *B. anthracis* have suffered from low sensitivity, low specificity, or both.

The RedLine Alert test from Tetracore, Inc., is an immunochromatographic test utilizing an antibody specific for one of the *B. anthracis* S-layer proteins and has been approved by the FDA for use on nonhemolytic *Bacillus* colonies cultured on sheep blood agar plates. Restricting the test to nonhemolytic isolates reduces the risk of false-positive results that may be caused by hemolytic species such as *B. cereus* and *B. thuringiensis*. The test is easy to use, and results can be read within 15 min. The test was positive for a diverse set of *B. anthracis* isolates (143 of 145; 98.6% sensitive) and negative for all 49 nonhemolytic, non-*B. anthracis* isolates tested (manufacturer data); however, the identification of

B. anthracis with this test is considered presumptive, and the test should not be used as a stand-alone method.

IHC Assays

During the 2001 bioterrorism-associated anthrax outbreak, *B. anthracis*-specific IHC assays were among the supportive laboratory tests used to establish the diagnosis of anthrax when the culture of *B. anthracis* failed (11, 28). These assays were performed on 3-μm-thick sections of formalin-fixed, paraffin-embedded tissues and utilized antibodies specific for the *B. anthracis* cell wall and capsule as described for the DFA. A biotinylated anti-mouse IgM antibody, streptavidin-alkaline phosphatase complex, and naphthol-fast red substrate were used for the colorimetric detection of antigens within tissues. Analyses of specimens from inhalation anthrax patients revealed bacilli, bacillary fragments, and some granular antigen staining by use of the cell wall IHC assay, while the capsule IHC assay mostly detected bacterial granular antigens (11). IHC staining was attempted on tissues from the lymph nodes, lung, heart, liver, spleen, kidneys, conjunctiva, gastrointestinal tract, bronchial biopsies, pleural biopsies and pleural fluid cell blocks. Significantly, IHC staining of skin biopsies from 8 of 10 cutaneous cases tested was positive for both the capsule and cell wall antigens, making IHC staining particularly useful for establishing a diagnosis in these cases (28).

Advantages and Disadvantages

The DFA is 100% specific for *B. anthracis* when used on isolates, but this method will not detect strains cured of pXO2 since this plasmid is required for capsule production, and the cell wall-specific antibody has produced rare false-negative results (99% sensitive) (7). IHC assays have limitations similar to those of the DFA since the same antibodies are used. The LRN TRF assays are rapid and require minimal sample preparation; however, false-positive results can occur if a high level of innate europium is present in the samples. The RedLine Alert test is fast and easy to use but is intended for use on isolates only.

Specimen Collection and Transport

For IHC analysis of cutaneous lesions, a full-thickness punch biopsy fixed in 10% buffered formalin from a papule or vesicle lesion and including adjacent skin should be taken. Biopsies should also be taken from both the vesicle and eschar, if present (4, 28). Unlike fresh tissues (frozen), formalin-fixed samples can be sent at room temperature, while other specimens should be transported at 2 to 8°C.

SEROLOGY

Serology was the third approach, in addition to the LRN PCR and IHC assays, that was used to diagnose anthrax when the isolation of *B. anthracis* from patients failed. A quantitative anti-PA IgG ELISA was used during the 2001 outbreak to measure antibodies to the anthrax toxin protein, PA. Serology was only negative for a single patient with confirmed or suspected anthrax during the outbreak and was particularly useful for the diagnosis of cutaneous anthrax. In addition, quantitative ELISAs and the toxin neutralization assay (TNA) have also been used in vaccine-animal challenge studies to show that levels of anti-PA antibodies are a significant predictor of survival (19). Recently, a commercially available test was FDA approved to qualitatively measure anti-PA antibodies in human serum (QuickELISA Anthrax-PA kit).

Human Anti-PA IgG ELISA

The CDC has developed a quantitative ELISA for the detection of human IgG antibodies to PA, with a lower limit of quantification of 3.0 μg of anti-PA IgG/ml of serum (25). The assay has a 97.6% diagnostic sensitivity and 94.2% diagnostic specificity based on the analysis of specimens from confirmed anthrax cases and from anthrax vaccine adsorbed (AVA) vaccinees. A fourfold or higher rise from the baseline in the concentration of anti-PA IgG (acute- versus convalescent-phase serum sample) is considered reactive. Anti-PA IgG was detectable in 16 of 17 bioterrorism-associated patients with confirmed or suspected anthrax by 11 days after the onset of symptoms. Only a single patient with cutaneous anthrax failed to mount a detectable antibody response. In addition, serology was the only positive test for 3 of the 11 suspected or confirmed cutaneous anthrax cases.

A competitive inhibition anti-PA IgG ELISA can be used to enhance the diagnostic specificity to 100% (25). Briefly, one of two duplicate serum samples is treated with excess, purified recombinant PA (rPA). The sera are centrifuged to remove antibody-antigen complexes, and the supernatants are retested in the standard ELISA. A ≥85% suppression of reactivity in the competitive ELISA is used to discriminate between true-positive and false-positive results. For the analysis of the 2001 bioterrorism-related cases, the competitive ELISA was only used on serum samples that had an anti-PA IgG reactivity of ≥10 μg/ml and when paired sera were reactive but the anti-PA IgG concentration did not change over time.

TNA

Unlike the ELISA, the TNA is a measure of functional antibodies. This colorimetric assay measures the ability of antibodies to protect mouse macrophage cells (J774A.1) from anthrax lethal toxin cytotoxicity (13). Neutralization occurs when antibodies bind functional epitopes on PA, lethal factor (LF), or the PA receptor which inhibit toxin function. The ability of antibodies to neutralize lethal toxin activity and protect the cells is measured colorimetrically by use of a tetrazolium salt, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT). The degree of neutralization is reported as the serum dilution that effectively neutralizes 50% of the toxin-mediated cytotoxicity.

QuickELISA Anthrax-PA Kit

The FDA-approved QuickELISA Anthrax-PA kit from Immunetics (Boston, Mass.) has recently become available for the presumptive detection of anti-PA IgG and IgM antibodies in human serum. This assay is a qualitative detection assay for total antibodies against the PA protein. In principle, anti-PA antibodies present in serum bind strepavidin-rPA and horseradish peroxidase-rPA conjugates. The complex binds to biotin immobilized in the wells of a microtiter plate. The horseradish peroxidase-rPA-containing complex converts a chromogenic substrate containing tetramethylbenzidine, and the absorbance is measured. The assay exhibited >99% specificity and 100% sensitivity when validated on sera from 19 individuals with anthrax, 49 individuals vaccinated with AVA, 583 healthy individuals, 205 sera from individuals with other infections, and 20 influenza vaccine recipients (manufacturer's data).

Advantages and Disadvantages

The major disadvantage of serology is the time required for seroconversion to occur after infection. Despite this, however, serology may be particularly useful for diagnosing cutaneous anthrax and for cases when the use of antimicrobial therapy results in negative cultures and PCR.

Specimen Collection and Transport

Sera should be transported frozen on dry ice.

SUMMARY

Numerous molecular and antigen-based methods are available for identifying B. anthracis and diagnosing anthrax. The advantages, disadvantages, and general availability of these tests are summarized in Table 1. Culturing of B. anthracis remains the definitive method for diagnosing anthrax, and

TABLE 1 Diagnostic tests for detection of *B. anthracis*

Test	Target	Availability	Advantages	Disadvantages
Culture	Spores or vegetative cells	LRN	Definitive identification of isolate and diagnosis	Isolation not likely after initiation of antimicrobial therapy
LRN PCR	Spores or vegetative cells	LRN	Rapid and 100% specific for use on isolates	Sensitivity decreases rapidly after initiation of antimicrobial therapy
DFA	Vegetative cells	LRN	100% specific for use on isolates	pXO2-cured strains will not be positively identified
TRF spore assay	Spores	LRN	Rapid, detects plasmid-cured strains	Samples with high innate europium levels can cause false-positive results
TRF cell assay	Vegetative cells	LRN	Rapid, detects plasmid-cured strains	Samples with high innate europium levels can cause false-positive results
IHC staining	Vegetative cells	CDC	Diagnosis of cutaneous anthrax cases	Not widely available
Immunochromatographic RedLine Alert test	Vegetative cells	Commercially available	Speed and ease of use	For use on isolates only
Serology ELISA TNA QuickELISA Anthrax-PA Kit	Immune response against toxin (PA)	CDC and commercially available	Diagnosis of cutaneous anthrax cases	Time to seroconversion

phenotypic, molecular, and antigen-based tests are available for the identification of isolates. It should be reiterated that no single phenotype or test should be used to rule out or positively identify *B. anthracis*. While culture is the standard, it is not always possible to isolate *B. anthracis*, particularly when specimens have been collected after the initiation of antimicrobial treatment. In these instances, the use of molecular, antigen-based, and antibody-based (serology) detection methods becomes even more important. If *B. anthracis* cannot be isolated, the CDC recommends that the diagnosis of anthrax be based on at least two supportive tests (5, 16). In recent years, there has been a rapid development and dissemination of assays for the detection of *B. anthracis* throughout the U.S. public health laboratory system. Current research interests and funding in this area will continue to yield novel technologies and new methods for the detection of *B. anthracis* and the diagnosis of anthrax in the future.

Introduction

THOMAS B. NUTMAN

64

Combining the sections on clinical immunology of parasitic and fungal infections into one unit stems not so much from the similarity between parasites and fungi but rather from their not being part of either the infectious diseases or immunological mainstream. From a phylogenetic perspective, parasites (even the single-cell protozoa) differ from the fungi by a considerable evolutionary distance; interestingly, based on phylogenetic analyses, the differences between protozoan parasites and fungi are less significant than the differences between unicellular and multicellular parasites (Fig. 1).

Parasitic diseases are historically defined as infectious illnesses caused by unicellular protozoa or multicellular helminths distinct from viral, bacterial, or fungal etiologic agents. They are the special health care problem of tropical and subtropical countries, where their marked prevalence imposes a major medical and economic burden (5, 6). These infections afflict billions of people worldwide and are responsible for millions of deaths every year. The importance of parasitic illness has received recent additional emphasis as a result of the emergence of *Toxoplasma,* microsporidia, and *Cryptosporidium* as opportunistic pathogens in patients who are immunosuppressed.

Parasites encompass a heterogeneous group of organisms with extremely diverse biologies. Protozoa are usually a few micrometers in size, whereas worms are typically centimeters to meters in length. Tissue-dwelling protozoa are often intracellular parasites at some stage of infection, whereas helminths, being larger than most tissue cells, are almost always extracellular pathogens—the significant exception being *Trichinella spiralis,* which encysts within mammalian muscle cells. Protozoa usually replicate during infection of a single host; helminths do not reproduce without the assistance of intermediate hosts or passage through soil or water.

Both protozoan and helminth pathogens have complex life cycles, often with two or more developmental stages present in the host during infection (3). Because each stage of parasite development may be antigenically distinct, protozoan or helminth infections are often characterized by a series of discrete immune responses that develop at different times during the course of disease. Immune responses directed against a single stage may be circumvented by parasite differentiation. Each stage of parasite development may also entail a change in tissue tropism, introducing a compartmental feature to the immune responses. This temporal evolution of antigenic complexity and tissue tropism is unique to parasite immunology and further distinguishes this field from viral, fungal, and bacterial immunology.

Nevertheless, the immunology of fungal and parasitic infections converges at several levels. First, despite the enormous progress made in the biochemical purification and/or recombinant production of immunologically relevant antigens—some now based on parasite or yeast genomics—many of the diagnostic antigens used for either parasitic or fungal infections are crude (unfractionated) antigens that often contain epitopes (or whole antigens) that cross-react not only with organisms of different genera but also with those from unrelated species. Moreover, the diagnosis of mycotic infections cannot always be definitively addressed by culture or histology. Since the diagnosis of most parasitic infections has relied most commonly on the identification of the organism in appropriately collected specimens, those involved in the diagnosis of mycotic or parasitic infections have turned their attention to immunologic and molecular methods of diagnosis.

Traditionally, antibody-based diagnostic assays have suffered from a variety of difficulties that include: (i) the inability to distinguish between past infection and an active, current infection; (ii) poor specificity; (iii) reliance on changes in antibody isotypes or titers over the weeks or months following infection (retrospective diagnosis); and (iv) difficulty in their use in immunocompromised individuals. For many mycotic and parasitic infections, the limitations of standard serological assessments have been overcome by the use of antigen detection systems (see chapters 65 and 66) or methods of detecting microbial DNA (1, 2, 4) usually PCR.

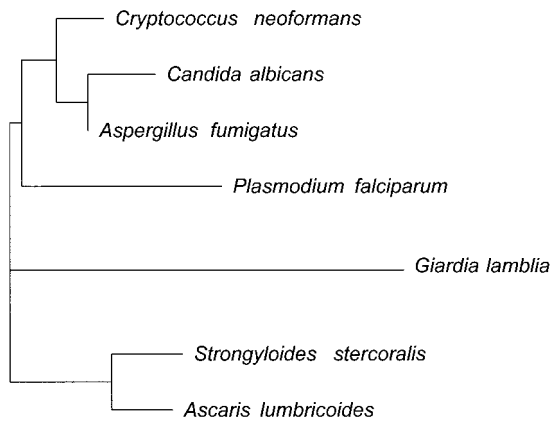
Indeed, antigen detection methods have been extraordinarily useful in the diagnosis of fungal infections caused by *Aspergillus, Candida, Cryptococcus, Histoplasma,* and *Paracoccidioides* spp. and parasitic infections caused by *Entoamoeba, Giardia, Cryptosporidium*, *Wuchereria*, and *Trichomonas* spp. Many of these antigen detection systems have moved into the commercial arena and are available for clinical use. In contrast, PCR-based assays, although definitive in many instances, are not in widespread use. Nevertheless, PCR assays for the relatively rapid diagnosis of invasive *Candida* and *Aspergillus* spp. (see chapter 66) infections and for filarial and malarial organisms have moved beyond the laboratory bench and are offered in some clinical laboratories. Impediments to the widespread use of molecular diagnostics remain the lack of standardized methods for


FIGURE 1 Phylogenetic dendrogram of selected pathogenic fungi and parasites based on 16S/18S ribosomal sequences.

sample preparation and difficulties extracting DNA from certain organisms and/or tissues.

Another area of progress in diagnostic mycology and parasitology is the use of immunohistochemistry to demonstrate particular organisms in tissue or body fluids. For example, the availability of fluorescently labeled antibodies for the detection of *Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum, Pneumocystis carinii, Paracoccidioides basiliensis, Trichomonas vaginalis, Giardia lamblia,* and *Cryptosporidium parvum* among others has provided often rapid detection of organisms in appropriately collected specimens.

Continued efforts to improve the positive and negative predictive value of immunologic- and molecular-based assays remain the major goal of those interested in the accurate diagnosis of mycotic and parasitic infections. Although heralded as the new diagnostic gold standard, PCR-based assays are not yet in mainstream use. Notwithstanding the cost and issues related to quality control, the time required for sample preparation, PCR itself, and detection of the product suggests that other methods for clinical diagnosis of fungal and parasitic infections are needed, particularly rapid antigen detection systems.

Molecular and Immunological Approaches to the Diagnosis of Parasitic Infections

MARIANNA WILSON, PETER M. SCHANTZ, AND THOMAS NUTMAN

65

The diagnosis of parasitic infections is definitively made by the identification of parasites in host tissue or excreta. Such identification is not generally possible for diseases such as toxoplasmosis or toxocariasis, in which parasites are located in deep tissue sites, and is not initially recommended for diseases such as cysticercosis or echinococcosis, for which invasive techniques with some risk to the patient are necessary to obtain material. The detection of antibodies can be very useful as an indicator that an individual has been infected with a specific parasite. A positive result for a person with no exposure to the parasite prior to recent travel in an area where disease is endemic may be interpreted as indicating recent infection. However, the detection of specific antibodies in a person who is native to an area where the parasite is endemic may reflect only a past infection unrelated to the current clinical status. In general, the detection of antibodies to parasitic diseases indicates only infection at some indeterminate time and not necessarily an acute or current infection. Levels of antibodies to parasites slowly decline after the patient is cured of the infection but generally last for at least 6 months to many years, depending on the infecting parasite, and thus are not generally reliable indicators of a successful cure.

The detection of specific immunoglobulin M (IgM) and IgA antibodies may be of value in determining the approximate time of initial infection with *Toxoplasma gondii*, but it is not recommended for any other parasitic disease. If infection with a parasite is suspected and blood film, stool, or urine examinations are either not indicated or negative, then the appropriate serology test for parasite-specific Ig or IgG antibodies should be requested. Tests for parasite-specific IgM, IgA, or IgE are generally not useful for diagnosis and should not be requested. If the parasite-specific Ig or IgG test is negative, then a positive IgM, IgA, or IgE result is generally a false-positive reaction and should not be considered when determining patient management.

The majority of parasitic immunodiagnostic procedures (Table 1) are performed in a few commercial laboratories, with reference testing available at the CDC. Although commercial kits for in vitro diagnostic use for some parasitic diseases are now available in the United States (Tables 2 to 4), the quality of these reagents is variable. Reagents for most parasitic diseases are classified as exempt from the U.S. FDA approval process; kits may be marketed in the United States without

review, with the exceptions of *Toxoplasma* and *Trypanosoma* sp. serological reagents.

For most parasitic diseases, the antigen is generally the assay component which has the most influence on test sensitivity and specificity. Parasites generally have more than one life cycle stage, which may have both mutually shared antigens and stage-specific antigens. The matrix to which antigens are bound for use in a specific procedure also physically selects which antigen subset will be available for antibody binding. The decision of which parasite stage and antigen preparation will be used in a specific assay should not be made without an extensive review of the published literature. A determination of the sensitivity of a procedure should be made with specimens from patients in whom the specific parasite has been observed. Unfortunately, this is not possible for diseases such as toxoplasmosis, toxocariasis, or trichinosis because the parasites are sequestered in muscle or organ tissues and are generally not detectable. Specimens from well-defined clinical cases are acceptable for assay evaluations of these diseases, but they are usually difficult to obtain. The patient specimens should be characterized to suit the particular disease. The sensitivity of a procedure may be affected by the stage and type of the patient's disease. For example, patients who have undergone surgery for an echinococcal cyst in the liver almost always will have detectable antibodies, but they may be negative prior to surgery. A test evaluated with only postsurgery case specimens will have close to 100% sensitivity, but a test evaluated with presurgery case specimens will have a lower sensitivity which is more indicative of how efficient the assay is as an aid to establishing a diagnosis prior to surgery. Duplication of a published procedure does not necessarily mean that the results of several laboratories are identical without a comparable evaluation and, ideally, an exchange of reagents and sera. An organized, impartial proficiency program for parasitic serology assays other than those for *Babesia microti* and *Toxoplasma* does not exist to aid in determining comparability between tests and laboratories.

The diagnosis of human intestinal protozoa depends on microscopic detection of the various parasite stages in feces, duodenal fluid, or small intestine biopsy specimens. Since fecal examination is very labor-intensive and requires a skilled microscopist, both antibody tests and antigen detection tests have been investigated as alternatives. Antibody tests are of limited value except for invasive amebiasis due to

Entamoeba histolytica. The detection of parasite antigens is more indicative of a current infection and can be quickly performed by less skilled laboratory personnel than an experienced morphologist. Much work has been accomplished on the development of antigen detection systems, resulting in commercially available reagents for the intestinal parasites *Cryptosporidium parvum*, *E. histolytica*, *Giardia lamblia*, and *Trichomonas vaginalis.* In addition, rapid tests (dipstick-like) for antigen detection are available outside the United States for malaria and *Wuchereria bancrofti.*

Although molecular biology techniques show promise for improving the diagnosis of a variety of parasitic infections, they are generally research tools, with the exceptions of *B. microti* PCR, *Plasmodium* PCR, and *Toxoplasma* PCR, and probably will not be available for routine use in clinical diagnostic laboratories in the foreseeable future.

For detailed information on parasites and diagnostic procedures, go to DPDx (www.dpd.cdc.gov/dpdx), the Division of Parasitic Diseases, CDC, website for the laboratory diagnosis of parasitic diseases. For questions not addressed at the website, inquiries may be sent by e-mail through the website. For information and references regarding specific test procedures and protocols, the reader should contact the testing laboratories and the manufacturers of commercial kits.

Abbreviations. The following abbreviations are used in this chapter: **CDC,** Centers for Disease Control and Prevention; **CDC-EITB,** CDC enzyme-linked immunoelectrotransfer blot (immunoblot); **CSF,** cerebrospinal fluid; **DFA,** direct fluorescent antibody; **EIA,** enzyme immunoassay; **ES,** excretory-secretory; **FAST-ELISA,** Falcon Assay Screening Test (F.A.S.T.)–enzyme-linked immunosorbent assay; **FDA,** Food and Drug Administration; **IFA,** indirect fluorescent antibody; **IHA,** indirect hemagglutination assay; and **OLM,** ocular larva migrans.

SPECIMEN REQUIREMENTS
Specimens for Antibody Detection
For all antibody detection tests for parasitic diseases, sera or plasmas are acceptable specimens. For toxocariasis and toxoplasmosis, aqueous and vitreous eye fluids may be tested when accompanied by a serum specimen. For central nervous system infections such as cysticercosis or toxoplasmosis, CSF accompanied by a serum specimen may be tested. All specimens may be shipped at room temperature. In general, acute- and convalescent-phase specimens are not required; valid results generally can be obtained by testing only one specimen because many parasitic diseases are past the acute stage when initially considered.

Specimens for Antigen Detection
Fresh or preserved stool samples are acceptable for antigen detection testing with most kits, but please refer to the recommended collection procedure for each specific kit.

AFRICAN TRYPANOSOMIASIS
Immunodiagnostic tests for the detection of African sleeping sickness caused by infections with *Trypanosoma brucei rhodesiense* or *T. brucei gambiense* are not available without prior consultation with the CDC. If African trypanosomiasis is suspected, please call the Division of Parasitic Diseases, CDC, at (770) 488-7775 for information on diagnosis and clinical management.

AMEBIASIS

EIA kits for *E. histolytica* antibody detection as well as for antigen detection are commercially available in the United States (Tables 2 and 3). Antibody detection is most useful for patients with extraintestinal disease, i.e., amebic liver abscess, for which organisms are not generally found upon stool examination. Antigen detection may be useful as an adjunct to microscopic diagnosis for detecting parasites and can distinguish between pathogenic and nonpathogenic *Entamoeba* infections (32).

Commercial EIA kits are available for routine serodiagnosis of amebiasis. The antigen consists of a crude soluble extract of axenically cultured organisms. The EIA detects antibodies specific for *E. histolytica* in approximately 95% of patients with extraintestinal amebiasis, 70% of patients with

active intestinal infections, and 10% of asymptomatic persons who are passing cysts of *E. histolytica*. If antibodies are not detectable in patients with an acute presentation of suspected amebic liver abscess, a second specimen should be drawn 7 to 10 days later. If the second specimen does not show seroconversion, other agents should be considered. Detectable *E. histolytica*-specific antibodies may persist for years after successful treatment, so the presence of antibodies does not necessarily indicate acute or current infection. The specificity of the test is 95% or higher, and false-positive reactions rarely occur. Although the detection of IgM antibodies specific for *E. histolytica* has been reported, the test sensitivity is only about 64% for patients with current invasive disease. Several commercial EIA kits for antibody detection are available in the United States (Table 2).

Immunodetection of *E. histolytica* antigens in fecal specimens may be used to distinguish the morphologically identical pathogenic *E. histolytica* and nonpathogenic *Entamoeba dispar*. Fecal antigen assays employing monoclonal antibodies have improved sensitivities and specificities, resulting in the commercial availability of several EIA kits (Table 3). Organisms of both the pathogenic *E. histolytica* and the nonpathogenic *E. dispar* strains are morphologically identical. Detection of the galactose-inhibitable adherence protein, which appears to be necessary for pathogenesis, by tests for fecal antigen allows for the differentiation of pathogenic and nonpathogenic *Entamoeba* infections, thus avoiding unnecessary chemotherapy. A major drawback to this assay is that the test requires fresh stool samples instead of samples containing any fixative. Several EIA kits for antigen detection of the *E. histolytica/E. dispar* group are available in the United States, but only a TechLab kit is specific for *E. histolytica*.

[b] ACCESS, Advia, AxSYM, Immulite, IMx, and VIDAS are automated assays.

The detection of *E. histolytica* and *E. dispar* DNA by PCR also allows for determinations of pathogenic versus non-pathogenic species. This assay is available in some state public health labs and the CDC. Contact information for each state lab is available at the Association of Public Health Laboratories website (www.aphl.org).

ANGIOSTRONGYLIASIS

Immunodiagnostic tests for the detection of antibodies to *Angiostrongylus* (*Angiostrongylus cantonensis*, which may cause eosinophilic meningitis, or *Angiostrongylus costaricensis*, the causative agent of abdominal angiostrongyliasis) are not currently available in the United States. If angiostrongylosis is suspected, please call the Division of Parasitic Diseases, CDC, at (770) 488-7775 for information on the availability of diagnostic testing and clinical management.

BABESIOSIS

Natural transmission of *B. microti* occurs primarily in the coastal areas of the northeastern United States and occasionally in Minnesota and Wisconsin. Rare human infections in California, Washington, Missouri, and Kentucky have occurred with *Babesia* sp. strains CA and WA1 and with *Babesia divergens*-like organisms which are antigenically and genotypically distinct from *B. microti* (8). Because the tick vector of *Babesia microti* also transmits the causative agents of Lyme disease and ehrlichiosis, dual and triple infections of *B. microti*, *Borrelia burgdorferi*, and *Ehrlichia* may occur.

The diagnosis of *Babesia* infection should be made by the observation of parasites in patients' blood films. However, antibody detection tests are useful for detecting infected individuals with very low levels of parasitemia, such as asymptomatic blood donors in transfusion-associated cases, for posttherapy diagnosis after parasitemia is no longer detectable, and for discrimination between *Plasmodium falciparum* and *B. microti* infection for patients whose blood film examinations are inconclusive and whose travel histories cannot exclude either parasite.

The IFA test using *B. microti* parasites as the antigen detects antibodies in 88 to 96% of patients with *B. microti* infections (15). IFA antigen slides are prepared by using washed, parasitized erythrocytes produced in hamsters. Patients' antibody levels generally rise to ≥1:1,024 during the first weeks of illness and decline gradually over 6 months to levels of 1:16 to 1:256, but antibodies may remain detectable at low levels for a year or more. The test specificity is 100% for patients with other tick-borne diseases or persons not exposed to the parasite. Cross-reactions may occur in serum specimens from patients with malaria infections, but generally, antibody levels are highest with the homologous antigen. The extent of antibody cross-reactivity between *Babesia* species appears variable. A negative antibody result with *B. microti* antigen for a patient exposed on the West Coast may be a false-negative reaction for a *Babesia* species other than *B. microti*. In those cases in which serology is negative but *Babesia* organisms are observed, identification to the species level may be accomplished by DNA sequence analysis of the organism (8). IFA tests for *Babesia* sp. strain WA1 and *B. divergens* are available from the CDC. IFA test kits are not available commercially, but one company offers *B. microti* IFA antigen slides for sale.

B. microti PCR assays are available in several commercial laboratories and at the CDC. PCR is at least as sensitive as microscopy, but the persistence of *Babesia* DNA is variable, ranging from 3 weeks posttherapy to 3 or more months in untreated patients. For the detection of *B. microti* infection in chronic carriers, such as asymptomatic infected blood donors, or in patients after therapy for *Babesia*, antibody detection by IFA is the initial test of choice because it is more sensitive than microscopy or nucleic acid detection in these situations.

BAYLISASCARIASIS

Immunodiagnostic tests for the detection of antibodies to *Baylisascaris* are available only at Purdue University. If infection with *Baylisascaris* is suspected, please call the Division of Parasitic Diseases, CDC, at (770) 488-7775 for information on the availability of diagnostic testing and clinical management.

CHAGAS' DISEASE

Infections with *Trypanosoma cruzi* are common in Central and South America. Many immigrants from areas where Chagas' disease is endemic currently reside in the United States and are potential sources of parasite transmission via infected blood. During the acute stage of illness, blood film examination generally reveals the presence of trypomastigotes. During the chronic stage of infection, parasites are rare or absent from the circulation. Immunodiagnosis is the method of choice for determining whether the patient is infected. Although differentiating between acute and chronic infections is very important in determining the necessity of therapy, serology cannot be used to do so. A positive antibody response indicates only infection at some unknown time, and not acute infection.

The IFA test and EIA are employed at the CDC. IFA antigen slides are prepared from a suspension of epimastigotes; crude soluble antigens of epimastigotes are used for EIA. Although the IFA test is sensitive, cross-reactivity occurs with sera from patients with leishmaniasis, a protozoan disease that occurs in the same geographical areas as *T. cruzi* infection. The sensitivity (93 to 98%) and specificity (99%, excluding leishmania patients) of EIAs that use crude antigens are similar to those of the IFA test. In the United States, the radioimmunoprecipitation assay has been used as a confirmatory test (17), but generally the results of a combination of tests are employed. A variety of cloned antigens have been investigated for use in diagnosis, but they are not yet available in the United States (34). Four EIA kits for antibody detection are available in the United States (Table 2).

CRYPTOSPORIDIOSIS

Tests for the detection of human antibodies specific for *C. parvum* are not currently recommended due to a lack of sensitivity and specificity. Both a plate EIA and an immunoblot assay for antibody detection have been reported, but their usefulness will probably be greatest for epidemiological studies and not as clinical diagnostic tools. Organism or antigen detection in stools is the current immunodiagnostic test of choice and provides equal or increased sensitivity over that of microscopy. Molecular tools are not recommended for clinical diagnosis but may be useful for isolate or strain identification for epidemiological purposes.

Table 3 lists 12 commercial products (3 DFA, 4 EIA, and 5 rapid tests) available in the United States for the immunodiagnosis of cryptosporidial infections. Several kits are combined tests for *Cryptosporidium*, *Giardia*, and *E. histolytica*. Factors such as ease of use, technical skill, and the time

necessary to complete the test, single versus batch testing, and test cost must be considered when deciding on the test of choice for individual laboratories. The most sensitive (99%) and specific (100%) method is reported to be the DFA test, which identifies oocysts in concentrated or unconcentrated fecal samples by using a fluorescein isothiocyanate-labeled monoclonal antibody. A combined DFA test for the simultaneous detection of cryptosporidial oocysts and *Giardia* cysts is available.

Four commercial EIAs are available in the microplate format for the detection of cryptosporidial antigens in fresh or frozen stool samples and also in stool specimens preserved in formalin, merthiolate-iodine-formalin, or sodium acetate-acetic acid-formalin fixative. Concentrated or polyvinyl alcohol-treated samples are unsuitable for testing with antigen detection EIA kits. The kits are reportedly superior to microscopy (especially acid-fast staining) and show a high correlation with the monoclonal antibody-based DFA test. Kit sensitivities and specificities ranged from 93 to 100% when used in a clinical setting. Laboratories which use these EIA kits need to be aware of potential problems with false-positive results and take steps to monitor each kit's performance (3).

Five rapid immunochromatographic assays are available for the combined antigen detection of either *Cryptosporidium* and *Giardia* or *Cryptosporidium*, *Giardia*, and *E. histolytica*. These offer the advantages of a short test time and multiple results from one reaction device. Initial evaluations indicate a comparable sensitivity and specificity to those of previously available tests.

CYSTICERCOSIS (LARVAL *TAENIA SOLIUM*)

The CDC-EITB assay with purified *T. solium* antigens is the immunodiagnostic test of choice for confirming a clinical and radiologic presumptive diagnosis of neurocysticercosis (36). The CDC-EITB assay is based on the detection of antibodies to one or more of seven lentil lectin purified structural glycoprotein antigens from the larval cysts of *T. solium* in an immunoblot format. It is 99.9% specific and has a sensitivity superior to that of any other test yet evaluated. Serum specimens for 97% of 108 parasitologically confirmed cases of cysticercosis had detectable antibodies. No serum samples from 376 patients with other microbial infections contained antibodies that reacted with any of the *T. solium*-specific antigens. The most important factors identified as determining positive immunoblot reactions are the numbers and stage of development of cysticerci. Cumulative clinical experience has confirmed that for patients with multiple (more than two) lesions, the test has >95% sensitivity. Seropositivity for biopsy-confirmed patients with single, enhancing parenchymal cysts was <50%; for clinically defined patients with a single cyst but who were not biopsied, the sensitivity was 70%. Seropositivity in the sera and CSF of patients with multiple but only calcified cysts was 82 and 77%, respectively. Seropositivity in the sera and CSF of patients with intraventricular neurocysticercosis was 93% (single cyst) or 95% (two or more cysts). For all patients, regardless of clinical presentation, the immunoblot assay is 10% more sensitive for serum than for CSF specimens: consequently, there is no need to obtain CSF solely for use in the immunoblot assay.

The CDC-EITB assay is both more specific and more sensitive than the EIA systems with which it has been compared. Nonspecificity has been a major problem with most EIAs because of cross-reacting components in crude antigens derived from cysticerci; these components react with antibodies specific for other helminth infections, especially echinococcosis and filariasis. Most partially purified fractions evaluated in an EIA appear to have lower sensitivities than do crude antigens and do not necessarily achieve higher specificities. Assays employing crude antigens for the detection of antibody are not reliable for the identification of this disease; all positive results and any negative results strongly suspected of cysticercosis should be confirmed by immunoblot. Currently available antibody detection tests for cysticercosis do not distinguish between active and inactive infections and thus have not been useful for evaluating the outcomes and prognoses of medically treated patients. Both the CDC-EITB assay and an EIA are commercially available in the United States (Table 2).

ECHINOCOCCOSIS

Strategies for the diagnosis of echinococcosis were presented in a recent review (26). Immunodiagnostic tests can be very helpful for the diagnosis of echinococcal disease, and they should be used before invasive methods (19). However, the clinician must have some knowledge of the characteristics of the available tests and the patient and parasite factors associated with false results. False-positive reactions may occur in persons with other helminthic infections, cancer, and chronic immune disorders. Negative test results do not rule out echinococcosis because some cyst carriers do not have detectable antibodies. Whether the patient has detectable antibodies is dependent on the physical location, structural integrity, and vitality of the larval cyst. Cysts in the liver are more likely to elicit an antibody response than cysts in the lungs, and regardless of localization, antibody detection tests are least sensitive for patients with intact hyaline cysts. Cysts in the lungs, brain, and spleen are associated with decreased or nondetectable antibody levels, whereas those in bone appear to elicit a more detectable immune response. Fissuration or rupture of a cyst is followed by an abrupt stimulation of antibody production. A patient with senescent, calcified, or dead cysts is generally found to be seronegative.

Molecular tools are used primarily for isolate or strain identification for epidemiological purposes but not for clinical diagnosis.

Cystic Echinococcal Disease (*Echinococcus granulosus*)

IHA, IFA, and EIA are sensitive tests for detecting antibodies in sera of patients with cystic disease; sensitivity rates vary from 60 to 90%, depending on the characteristics of the cases. Crude hydatid cyst fluid is generally employed as the antigen. At present, the best available serologic diagnosis is obtained by using a combination of tests. EIA or IHA is used to screen all specimens; a positive reaction is confirmed by an immunoblot assay or any gel diffusion assay that demonstrates the presence of the echinococcal "Arc 5." Although these confirmatory assays give false-positive reactions with sera from 5 to 25% of persons with neurocysticercosis, the clinical and epidemiological presentation of neurocysticercosis patients should rarely be confused with that of cystic echinococcosis. One commercial EIA kit and one immunoblot kit for antibody detection are available in the United States (Table 2).

Circulating antigens have been detected in the sera of only about half of patients with cystic echinococcosis; however, these antigens may be detectable in the sera of many patients with negative or borderline antibody levels. Antigen assays might be useful as additional tests for those patients

with no detectable *Echinococcus* antibodies, but such assays are not available in the United States.

Antibody responses have also been monitored as a way of evaluating the results of treatment, but with mixed results. Following successful radical surgery, antibody levels decline and sometimes disappear; antibodies rise again if secondary hydatid cysts develop. Tests for Arc 5 or IgE antibodies appear to reflect an antibody decline during the first 24 months post-surgery, whereas the IHA and other tests remain positive for at least 4 years. Chemotherapy has not been followed by consistent declines in antibody levels. Consequently, the usefulness of serology to monitor the course of disease is limited; imaging techniques provide a more accurate assessment of the patient's condition.

Alveolar Echinococcal Disease (*Echinococcus multilocularis*)

Most patients with alveolar echinococcal disease have detectable antibodies in tests using heterologous *E. granulosus* or homologous *Echinococcus multilocularis* antigens. With crude *Echinococcus* antigens, nonspecific reactions occur as described above. However, the affinity-purified *E. multilocularis* antigen (Em2) used for EIA allows the detection of positive antibody reactions in >95% of alveolar cases. Comparing the serologic reactivity to the Em2 antigen with that to antigens containing components of both *E. multilocularis* and *E. granulosus* permits the discrimination of patients with alveolar disease from those with cystic disease. The combined use of two purified *E. multilocularis* antigens (Em2 and the recombinant antigen II/3-10) in a single antibody detection assay allows for optimized sensitivity and specificity. These antigens are sold in a commercial EIA antibody detection kit in Europe, but not in the United States (Table 2). An *E. multilocularis* antigen prepared by isoelectric focusing and used for immunoblot and EIA was also sensitive for detecting alveolar disease and differentiating between cystic and alveolar disease (11). As with cystic echinococcosis, antibody detection tests are more useful for postoperative follow-up than for monitoring the effectiveness of chemotherapy.

FASCIOLIASIS

The acute manifestations of human fascioliasis may precede the appearance of eggs in the stool by several weeks; immunodiagnostic tests may be useful for an early indication of *Fasciola* infection as well as for confirmation of chronic fascioliasis when egg production is low or sporadic and for ruling out pseudofascioliasis associated with the ingestion of parasite eggs in sheep or calves' liver.

The current tests of choice for immunodiagnosis of human *Fasciola hepatica* infection are an IFA or EIA for antibody that uses ES antigens combined with the confirmation of positive results by immunoblot (9). Specific antibodies to *Fasciola* may be detectable within 2 to 4 weeks after infection, which is 5 to 7 weeks before eggs appear in the stool. The sensitivity of the FAST-ELISA was reported to be 95%, while the sensitivity of immunoblot using 12-, 17-, and 63-kDa antigens appeared to be 100%. However, cross-reactivity may occur in the FAST-ELISA with serum specimens from patients with schistosomiasis. Antibody levels decrease to normal 6 to 12 months after chemotherapeutic cure and can be used to predict the success of therapy. The IFA test with parasite sections as the antigen is still used extensively in Europe, but its sensitivity and specificity may not be optimal.

FILARIASIS

Among the eight filarial species that commonly infect humans, the four most likely to be pathogenic are three bloodborne filariae, *Brugia malayi*, *W. bancrofti*, and *Loa loa*, and the skin-dwelling organism *Onchocerca volvulus*. For each of these infections and for infections by other filariae (*Mansonella perstans*, *Mansonella ozzardi*, *Mansonella streptocerca*, and *Brugia timori*), demonstration of the parasite (microfilariae in the blood or skin or adult parasites in tissue samples) or of parasite DNA by PCR remains the "gold standard" for definitive diagnosis. Nevertheless, diagnosis can be elusive, not only because occult infections (low parasite burdens) occur but also because microfilariae (for most *Brugia* and *Wuchereria* organisms, at least) are nocturnally periodic.

Lymphatic Filariasis (*W. bancrofti* and *Brugia* spp.)

A definitive diagnosis of lymphatic filariasis can be made only by detection of the parasites and hence can be difficult. Adult worms localized in lymphatic vessels or nodes are largely inaccessible. Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly or—for greater sensitivity—after concentration of the parasites by the passage of fluid through a polycarbonate cylindrical pore filter (pore size, 3 μm) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the region of endemicity involved. Many infected individuals do not have microfilaremia, and a definitive diagnosis in such cases can be difficult. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infections. Two tests are commercially available: one is an ELISA and the other is a rapid-format immunochromatographic card test (Table 3). Both assays have sensitivities that range from 96 to 100% and specificities that approach 100% (4, 35). There are currently no tests for circulating antigens in brugian filariasis.

PCR-based assays for DNAs of *W. bancrofti* and *B. malayi* in blood have been developed (38). Several studies indicate that this diagnostic method is of equivalent or greater sensitivity than parasitology-based methods, detecting patent infection in almost all infected subjects.

Immunologically based diagnostics which measure IgG responses against crude extracts of *Brugia* or *Dirofilaria* worms have traditionally suffered from poor specificities. Extensive cross-reactivity is found in the sera of individuals infected with closely related helminth parasites and even certain protozoal parasites. Furthermore, it is difficult to differentiate a previous infection or exposure to the parasite (aborted infection) from a current active infection; most residents of regions where filariasis is endemic are antibody positive. Nevertheless, such serologic assays for IgG antibodies have a definite place in diagnosis, as a negative assay result effectively excludes past or present infection. The prominent role of antifilarial antibodies of the IgG4 subclass in active filarial infection has led to the development of diagnostic serological assays based on antibodies of this subclass. Antifilarial IgG4-specific tests have an improved specificity (16), but positive results may still be seen for uninfected individuals living in areas of endemicity and for those infected with other filarial species (e.g., *O. volvulus*, *L. loa*, and *Mansonella* spp.).

In cases of suspected lymphatic filariasis, an examination of the scrotum or the female breast by the use of high-frequency

ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics. Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men.

Onchocerciasis

A definitive diagnosis of onchocerciasis depends on the detection of an adult worm in an excised nodule or, more commonly, of microfilariae in a skin snip or in the anterior chamber of the eye by use of a slit lamp. Skin snips are obtained with a corneal-scleral punch, which collects a blood-free skin biopsy sample extending to just below the epidermis, or by lifting of the skin with the tip of a needle and excision of a small (1 to 3 mm) piece with a sterile scalpel blade. The biopsy tissue is incubated in tissue culture medium or saline on a glass slide or flat-bottomed microtiter plate. After incubation for 2 to 4 h (or occasionally overnight for light infections), microfilariae emergent from the skin can be visualized by low-power microscopy.

Because the detection of parasites in the skin or eye is invasive and insensitive, immunodiagnostic assays have been sought. Antifilarial IgG antibody assays, while positive for individuals with onchocerciasis, suffer from the same lack of specificity and positive predictive value seen in the case of bloodborne filarial infections. The combined use of three groups of recombinant antigens provides sensitivities and specificities that approach 100% for the diagnosis of onchocerciasis (23). Although no recombinant antigen test is available commercially, an experimental rapid card test that detects IgG4 antibodies to the Ov-16 recombinant in serum or whole blood has been shown to have >90% sensitivity and specificity.

Antigen detection methods for use on serum or plasma samples or on urine are theoretically feasible, but prototypes have lacked both specificity and sensitivity. Assays using PCR to detect onchocercal DNA in skin snips are now in use in filariasis research laboratories and are highly sensitive and specific.

Loiasis

A definitive diagnosis of loiasis requires the detection of microfilariae in the peripheral blood or the isolation of the adult worm from the eye or from a subcutaneous biopsy specimen from a site of swelling developing after treatment. PCR-based assays for the detection of *L. loa* DNA in blood are now available in filariasis research laboratories and are highly sensitive and specific.

Antifilarial IgG and IgG4 may be useful for confirming the diagnosis of loiasis in visitors to areas of endemicity who have suggestive clinical symptoms or unexplained eosinophilia; however, currently available methods using crude antigen extracts from *Brugia* or *Dirofilaria* species do not differentiate between *L. loa* and other filarial pathogens. The utility of such testing in endemic populations is limited by the presence of antifilarial antibodies in up to 95% of individuals in some regions. Recently, a *Loa*-specific recombinant (L1-SXP-1) has been tested; IgG4 antibody-based assays have been found to be 98% specific but have a limited (56%) sensitivity (14).

GIARDIASIS

G. lamblia is the most common human intestinal protozoan pathogen in the United States and is an important cause of diarrhea in children and adults. Outbreaks of disease are common within day care centers as a result of person-to-person contact and may also occur in communities as a result of drinking water contaminated by infected human or animal feces. Infected persons often excrete cysts intermittently, so multiple stools collected over at least several days must sometimes be examined to detect the parasite. Tests for antibody detection in human *Giardia* infection are not currently recommended due to a lack of sensitivity and specificity. Molecular tools are most useful for isolate or strain identification and not for clinical diagnosis.

Table 3 lists 11 commercial products (3 DFA, 4 EIA, and 4 rapid tests) available in the United States for the immunodiagnosis of giardiasis. DFA assays may be purchased that employ a fluorescein isothiocyanate-labeled monoclonal antibody for the detection of *Giardia* cysts alone or in a combined kit for the simultaneous detection of *Giardia* cysts and *Cryptosporidium* oocysts. The sensitivity and specificity of these kits are both 100% compared to those of microscopy. They may be used for the quantitation of cysts and oocysts and thus may be useful for epidemiologic and control studies.

Four commercial EIAs are available in the microplate format for the detection of *Giardia* antigens in fresh or frozen stool samples and also in stool specimens preserved in formalin, merthiopate-iodine-formalin, or sodium acetate-acetic acid-formalin fixative. Concentrated or polyvinyl alcohol-treated samples are not suitable for testing with EIA kits. EIA kit sensitivity rates were recently reported as ranging from 94 to 100%, while specificity rates are all 100% (1, 7).

Four rapid immunochromatographic assays are available for the combined detection of either *Cryptosporidium* and *Giardia* or *Cryptosporidium*, *Giardia*, and *E. histolytica*. These offer the advantages of a short test time and multiple results from one reaction device. Initial evaluations indicate a comparable sensitivity and specificity to those of previously available tests.

GNATHOSTOMIASIS

Immunodiagnostic tests for the detection of antibodies to *Gnathostoma* are not currently available in the United States. If gnathostomiasis is suspected, please call the Division of Parasitic Diseases, CDC, at (770) 488-7775 for information on the availability of diagnostic testing and clinical management.

LEISHMANIASIS

IFA and EIA tests are used for the detection of antibodies to *Leishmania* (31). IFA slide antigens consist of cultured epimastigotes of various species, while EIA antigens are usually crude solubilized epimastigotes. These procedures can differentiate leishmaniasis from other clinically similar conditions but cannot determine the infecting species of *Leishmania*. Cross-reactions occur for patients with antibodies to *T. cruzi* (Chagas' disease), which is also endemic to some Central and South American countries where leishmaniasis occurs. If visceral leishmaniasis is suspected, antibody detection tests can be a useful adjunct to clinical findings because test sensitivities are >95%. However, the sensitivities of antibody tests for cutaneous leishmaniasis are poor: most patients do not develop a detectable circulating antibody response to the parasite, so diagnostic testing should include aspirate and tissue impression smears and parasite culture.

Although biochemical, immunologic, and molecular biology techniques have been used extensively in *Leishmania* research, molecular probes for the detection and identification of parasites are currently available only in research labs (24). If leishmaniasis is suspected, a consultation on diagnosis and therapy may be obtained by calling the Division of Parasitic Diseases, CDC, at (770) 488-7775.

MALARIA

The serodiagnosis of malaria is not recommended except for (i) screening blood donors involved in cases of transfusion-induced malaria when the donor's parasitemia may be below the detectable level of blood film examination and (ii) testing a patient with a febrile illness who is suspected of having malaria and from whom repeated blood smears are negative. IFA tests with organisms of the four human *Plasmodium* species for malarial antibody detection are 97% sensitive and 99% specific, but the presence of antibodies indicates that infection occurred at some time in the past and does not necessarily indicate a current infection (30). Determination of the infecting species by serology is usually not possible. One commercial EIA kit for antibody detection is available in Great Britain and has been evaluated for use in blood bank screening (13).

There are many rapid tests for the detection of *Plasmodium* antigens in blood or serum available outside the United States. A list of rapid tests may be found at the website of the World Health Organization at www.wpro.who.int/rdt/. Although these assays have been extensively evaluated and found useful in field trials, their use for individual patient diagnosis is not sufficiently sensitive or specific to warrant the replacement of conventional microscopic diagnosis in clinical laboratories in nonmalarious areas (20).

PCR is sometimes a more sensitive method than microscopy for the detection of acute *Plasmodium* infection (29) and is available in some state public health laboratories and at the CDC. If infection is suspected, submit blood smears for morphological examination and EDTA-anticoagulated blood for PCR. The blood smears should be examined first for the presence of parasites. If malarial parasites are observed and the species is determined, then the diagnosis is complete. However, if parasites are not observed or if parasites are observed but the infecting species cannot be determined morphologically, PCR can then be performed. *Plasmodium* DNA generally becomes nondetectable within a week of antimalarial chemotherapy. If a chronic infection is suspected or if the patient has been treated for malaria, serology is the most sensitive assay compared to PCR and blood film exam.

For more information about malaria and its diagnosis, please visit the CDC website (www.cdc.gov/malaria).

MICROSPORIDIA

Microsporidia are obligate intracellular parasites that have a variety of animal hosts. Gastrointestinal as well as systemic disease has been reported for humans, principally for patients with AIDS. Eight genera of microsporidia have been recognized in humans: *Enterocytozoon*, *Encephalitozoon*, *Vittaforma*, *Nosema*, *Pleistophora*, *Trachipleistophora*, *Brachiola*, and *Microsporidium*, a genus comprising all those organisms that are not yet classified. Polyclonal sera and monoclonal antibodies raised against the most frequently identified microsporidial pathogens in clinical specimens (*Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*, *Encephalitozoon hellen*, and *Encephalitozoon cuniculi*) have been tested, and their use as diagnostic reagents has been proposed in several reports (6). Additionally, specific antibodies to microsporidia have been detected in humans, but the serologic diagnosis of microsporidial infections is of limited use. Molecular techniques used in assays for the detection of parasite DNA in patient specimens, including fecal samples, have been reported by several research groups. However, no reagents for the immunodetection of microsporidial parasites or soluble antigens are available commercially.

PARAGONIMIASIS

Pulmonary paragonimiasis is the most common presentation of patients infected with *Paragonimus* spp., although extrapulmonary (cerebral or abdominal) paragonimiasis may occur. The detection of eggs in sputa or feces of patients with paragonimiasis is often difficult; therefore, serodiagnosis may be helpful for confirming infections and for monitoring the results of individual chemotherapy. In the United States, the detection of antibodies to *Paragonimus westermani* has helped physicians differentiate paragonimiasis from tuberculosis in Indochinese immigrants.

EIA tests, in both plate and blot formats, have replaced the complement fixation test. The immunoblot assay for antibody detection performed with a crude antigen extract of *P. westermani* has been in use at the CDC since 1988 (27). Positive antibody reactions, based on a demonstration of reactivity with an 8-kDa antigen, were obtained with serum samples from 96% of patients with parasitologically confirmed *P. westermani* infection. The test specificity was ≥99%; of 210 serum specimens from patients with other parasitic and nonparasitic infections, only 1 serum sample from a patient with *Schistosoma haematobium* reacted. Antibody levels detected by EIA and immunoblot do decline after chemotheraputic cure, but not as rapidly as those detected by the complement fixation test. Most published literature deals with pulmonary paragonimiasis due to *P. westermani,* although in some geographic areas other *Paragonimus* species cause similar or distinct clinical manifestations of human infections. Cross-reactivity between species does occur, but at varying levels for different species.

SCHISTOSOMIASIS

Antibody detection can be useful to indicate schistosome infection in patients who have traveled in areas where schistosomiasis is endemic and for whom eggs cannot be demonstrated in fecal or urine specimens. Test sensitivity and specificity vary widely among the many tests reported for the serologic diagnosis of schistosomiasis and are dependent on both the type of antigen preparation used (crude, purified, adult worm, egg, or cercarial antigen) and the test procedure.

At the CDC, a combination of tests with purified adult worm antigens are used for antibody detection (2, 33). All serum specimens are initially tested by FAST-ELISA using *Schistosoma mansoni* adult microsomal antigen. A positive reaction indicates infection with a *Schistosoma* species. The sensitivity of the test for *S. mansoni* infection is 99%, that for *S. haematobium* infection is 95%, and that for *Schistosoma japonicum* infection is >50%. The specificity of this assay for detecting schistosome infection is 99%. Because test sensitivity with the *S. mansoni* adult microsomal antigen is reduced for species other than *S. mansoni*, immunoblots of the species appropriate to the patient's travel history are also tested to ensure antibody detection of *S. haematobium* and *S. japonicum* infections. Immunoblots with adult worm microsomal antigens are species specific, so a positive antibody reaction indicates the infecting species. The presence of antibody is indicative only of schistosome infection at some time and cannot be correlated with the clinical status, worm burden, egg production, or prognosis.

The detection of schistosome antigens in serum and urine, in addition to quantitative stool or urine exams, has been suggested as an indicator of cure after chemotherapy. Although these techniques may be useful for populations in areas of *Schistosoma* endemicity, test sensitivities for patients with low worm burdens and low egg output (<50 eggs/ml)

are not adequate. Antigen detection tests are not available in the United States.

STRONGYLOIDIASIS

Immunodiagnostic tests for strongyloidiasis are indicated when the infection is suspected and the organism cannot be demonstrated by duodenal aspiration, string tests, or repeated examinations of stool. Antibody detection tests should use antigens derived from *Strongyloides stercoralis* filariform larvae for the highest sensitivity and specificity. Although IFA and IHA tests have been used, EIA is currently recommended because of its greater (95%) sensitivity. Immunocompromised persons with disseminated strongyloidiasis usually have detectable IgG antibodies despite their immunodepression (12). Cross-reactions in patients with filariasis and some other nematode infections may occur. Important test limitations are that (i) 5% of individuals infected with *Strongyloides* are seronegative and (ii) antibody test results cannot be used to differentiate between past and current infections. A positive test warrants continuing efforts to establish a parasitological diagnosis followed by antihelminthic treatment. Serologic monitoring may be useful for the follow-up of immunocompetent treated patients: antibody levels decrease markedly within 6 months after successful chemotherapy (18). The potential use of immunoblots for the immunodiagnosis of strongyloidiasis has been reported.

TOXOCARIASIS (LARVA MIGRANS)

Antibody detection tests are the only means of confirmation of a clinical diagnosis of visceral larva migrans, OLM, and covert toxocariasis, the most common clinical syndromes associated with *Toxocara* infections (5, 28). The currently recommended serologic test for toxocariasis is an EIA with larval-stage antigens extracted from embryonated eggs or released in vitro by cultured infective larvae. The latter, *Toxocara* ES antigens, are preferable to larval extracts because they are convenient to produce and because an absorption-purification step is not required to obtain maximum specificity.

Evaluation of the true sensitivities and specificities of serologic tests for toxocariasis in human populations is not possible because of the lack of parasitologic methods to detect *Toxocara* parasites. These inherent problems result in underestimations of sensitivity and specificity. Evaluation of the *Toxocara* EIA with groups of patients with presumptive diagnoses of visceral larva migrans or OLM indicated sensitivities of 78 and 73%, respectively, at antibody levels of ≥1:32. When the cutoff titer for OLM cases was lowered to 1:8, the sensitivity was increased to 90%. Further confirmation of the specificity of the serologic diagnosis of OLM can be obtained by testing aqueous or vitreous humor samples for antibodies. The specificity has been reported to be >90% at antibody levels of ≥1:32.

When interpreting serologic findings, clinicians must be aware that a detectable antibody level does not necessarily indicate a current clinical *Toxocara canis* infection. In most human populations, a small number of those tested have positive EIA antibody levels that apparently reflect the prevalence of asymptomatic toxocariasis. In the United States, 2.8% of nearly 9,000 persons tested showed such positive reactions, but the percentage varied significantly according to age, race, and socioeconomic status. A commercial EIA kit is available in the United States (Table 2).

TOXOPLASMOSIS

A Clinical and Laboratory Standards Institute (formerly NCCLS) guideline entitled *Clinical Use and Interpretation of Serologic Tests for Toxoplasma gondii* has been published as an aid for laboratorians and physicians in determining the status of patients potentially infected with *T. gondii* (22). *Toxoplasma* antibody detection tests are performed by a large number of laboratories with commercially available kits (Table 4). Comparisons of kits indicated that most perform comparably for detecting *Toxoplasma*-specific IgG antibodies but vary markedly for detecting *Toxoplasma*-specific IgM antibodies (37). Quantitative results obtained with kits from different companies must be compared as just positive or negative because of the lack of standardization of expression of results. The College of American Pathologists offers *Toxoplasma* antibody proficiency testing as part of the Virology Antibody Detection Survey. The participation of all laboratories that perform *Toxoplasma* antibody testing should be encouraged. The summary of data obtained by this program is not only an indication of individual laboratory performance but also an indication of kit performance. Laboratories with aberrant results should question the accuracy of the kit they use in addition to their technical performance.

An algorithm for the immunodiagnosis of toxoplasmosis is shown in Fig. 1. EIA or IFA tests for IgG and IgM antibodies are the tests most commonly used today. Persons should be initially tested for the presence of *Toxoplasma*-specific IgG antibodies to determine their immune status. A positive IgG titer indicates infection with the organism at some time. If more precise knowledge of the time of infection is necessary, then a person with a positive IgG titer should have an IgM test performed by an IgM-capture EIA. A negative IgM test essentially rules out infection in recent months. A positive IgM titer combined with a positive IgG titer may be suggestive of a recent infection. However, *Toxoplasma*-specific IgM antibodies may be detected by EIA for as long as 18 months after an acute acquired infection. If the patient is pregnant, an IgG avidity test should then be performed. A high-avidity result in the first 12 to 16 weeks of pregnancy (the time is dependent on the commercial test kit) essentially rules out an infection acquired during gestation. A low IgG avidity should not be interpreted as indicating recent infection, because some individuals have persistent low IgG avidity for many months after infection. A suspected recent infection in a pregnant woman should be confirmed prior to intervention by having samples tested at a toxoplasmosis reference laboratory such as the Toxoplasmosis Serology Lab, Palo Alto Medical Foundation, Palo Alto, Calif.

If a patient is tested initially for both *Toxoplasma*-specific IgM and IgG antibodies, the result will sometimes be a positive IgM titer but a negative IgG result. A positive IgM result with a negative IgG result in the same specimen should be viewed with great suspicion; the patient's blood should be redrawn 2 weeks after the first blood draw and tested together with the first specimen. If the first specimen was drawn very early after infection, the patient should have highly positive IgG and IgM antibodies in the second sample. If the IgG test is negative and the IgM test is positive for both specimens, the IgM result should be considered to be a false positive and the patient should be considered not infected.

Newborn infants suspected of congenital toxoplasmosis should be tested by both an IgM- and an IgA-capture EIA. The detection of *Toxoplasma*-specific IgA antibodies is more sensitive than IgM detection for congenitally infected babies. Although commercial kits for IgA detection are available in Europe, none are available yet in the United States.

FIGURE 1 Algorithm for the serodiagnosis of toxoplasmosis in people older than 1 year of age.

The serological determination of active central nervous system toxoplasmosis in immunocompromised patients is not possible at this time. *Toxoplasma*-specific IgG antibody levels in AIDS patients are often low to moderate, but occasionally no specific IgG antibodies can be detected. Tests for IgM antibodies are generally negative. The detection of circulating antigen in AIDS patients has been evaluated, but the procedure lacks sensitivity.

TRICHINELLOSIS

Immunodiagnostic tests for trichinellosis currently available in the United States include EIAs for antibody detection. Antigen preparations may be crude antigens prepared from homogenates of *Trichinella spiralis* muscle larvae or ES products produced by cultured larvae (21). The TSL-1 group of larval secretory antigens is conserved in all species and isolates of *Trichinella* and thus can be used to detect infection in animals or people infected with any of the currently recognized types of *Trichinella*. Positive antibody reactions are detectable at some time during infection in serum samples from 80 to 100% of patients with clinically symptomatic trichinellosis. Antibody levels are often not detectable until 3 to 5 weeks postinfection, well after the onset of acute-stage illness. Antibody development is also affected by the infecting dose of larvae: the higher the infecting dose, the faster the patient's antibody response will develop. Multiple serum specimens should be drawn several weeks apart to demonstrate seroconversion in patients whose initial specimen was negative. IgG, IgM, and IgE antibodies are detectable in many patients; however, tests based on IgG antibodies are the most sensitive. Antibody levels peak in the second or third month postinfection and then decline slowly for several years.

In our experience at the CDC, the EIA with ES antigens detects antibodies earlier than the bentonite flocculation test in 25% of serum specimens from patients with acute

infection, but the EIA also remains positive for longer periods after infection than the bentonite flocculation test and is reactive for a larger proportion of persons with no clinical evidence of trichinellosis. One commercial EIA kit for antibody detection is available in the United States (Table 2).

TRICHOMONIASIS

Trichomoniasis, an infection caused by *T. vaginalis*, is a common sexually transmitted disease. Diagnosis is made by the detection of trophozoites in vaginal secretions or urethral specimens by wet mount microscopic examination, culture, or the detection of parasite antigens or nucleic acids. The sensitivities of assays compared to that of culture were reported to be 60% for wet mounts, 86% for the DFA test, 80% for the Affirm VP test, 78.5% for the OSOM rapid test, and 78% for the XenoStrip rapid test (10, 25). A DFA test, a nucleic acid probe test, and two rapid antigen detection tests are available commercially (Table 3).

Serological and Molecular Diagnosis of Fungal Infections

MARK D. LINDSLEY, DAVID W. WARNOCK, AND CHRISTINE J. MORRISON

66

Analysis of the signs and symptoms of disease, in conjunction with an evaluation of available epidemiologic information and the results of modern imaging procedures, can often provide a presumptive clinical diagnosis of a fungal infection. However, the clinical presentation of many mycotic diseases is nonspecific and a presumptive diagnosis must therefore be confirmed by appropriate laboratory tests. A definitive diagnosis of fungal disease is usually based upon the isolation of the etiologic agent in culture and/or microscopic demonstration of the organism in histopathologic or other clinical specimens. Unfortunately, these laboratory methods are insensitive and often unsuccessful, despite repeated sampling efforts. In the absence of positive microscopy or culture, immunologic and molecular tests offer alternative laboratory procedures to aid in the diagnosis of a mycotic disease. Advances in molecular diagnostic methods, and the commercial introduction of new antigen and antibody detection tests, hold promise for an earlier and more specific diagnosis than previously possible. Molecular and antigen detection tests are particularly valuable in the diagnosis of fungal infections in immunocompromised patients because such individuals often exhibit poor or variable antibody responses. In contrast, antibody detection tests are often helpful for the diagnosis of fungal infections in immunocompetent hosts. For example, when acute- and convalescent-phase serum specimens are tested, a fourfold rise in antibody titer can be diagnostic or prognostic for several fungal diseases in immunocompetent patients. Monitoring the results of serologic tests at regular intervals during infection can also reveal trends in disease progression or remission and may serve to guide antifungal therapy. In many cases, positive serologic test results lead to increased efforts to isolate and identify the suspected etiologic agent.

Despite recent advances in the production of purified antigens by biochemical and recombinant techniques, many antigens used in antibody detection tests possess cross-reactive epitopes that are shared among different fungal genera or which cross-react with entirely different classes of microorganisms. Other limitations of antibody detection tests include a requirement for the appropriate timing of serum collection so as to coincide with the occurrence of the antibody response. Negative antibody results do not exclude the presence of a mycotic infection, and sera that display low titers or demonstrate cross-reactivity among fungal antigens require the performance of additional laboratory tests to rule out infection. In such cases, an accurate serologic diagnosis relies on (i) the results of several serologic tests performed with a battery of antigens (including those from antigenically related genera), (ii) an examination of serial serum specimens to detect temporal changes in titer, and (iii) an analysis of the results of antigen detection tests, if such tests are available. In addition, knowledge of the clinical history of the patient and the therapy received is necessary for the correct interpretation of serologic test results.

Molecular biological tests, on the other hand, offer the promise of increased sensitivity compared to conventional diagnostic tests; i.e., nucleic acids, once extracted from clinical materials, can be amplified 10^6-fold or more using PCR or other DNA or RNA amplification technologies. In addition, in contrast to antibody detection, detection of fungal DNA is not dependent on a functioning immune system and may therefore allow a diagnosis early in the infectious episode, before an antibody response occurs. Another advantage of molecular diagnostic tests is the capacity to identify the infecting organism to the species level and to detect mixed as well as single-organism infections. However, whereas amplification technologies may provide greater test sensitivity and specificity for the above reasons, these advantages are counterbalanced by the concomitant increased risk of sample contamination resulting in false positivity and a loss of specificity. Moreover, the extraction of fungal DNA or RNA from clinical materials is not a straightforward or standardized process at present. The procedures used to remove inhibitors of the PCR assay may cause loss of target DNA, thereby reducing test sensitivity. Finally, although many DNA-based tests have been developed in single laboratories and are quite successful, confirmation of the usefulness of these technologies awaits multicenter clinical evaluation.

This chapter reviews the most extensively evaluated or routinely used tests for the serodiagnosis of mycotic infections. Commercially available antibody and antigen detection tests are listed in Tables 1 and 2. Specific details regarding the clinical indications for test application and the mechanics of test performance are presented in the body of the text. Experimental antigen and antibody detection tests and molecular biological tests are reviewed briefly in the text.

TABLE 1 Commercially available antibody detection tests for fungal diseases

Disease and test[a]	Specimen	Antigen	Interpretation	Sensitivity	Specificity	Source(s)[b] (reference[s])
Aspergillosis						
CF	Serum	Culture filtrate from A. fumigatus	Titer of ≥1:8 is strong evidence for Aspergillus infection; seroconversion or ≥4-fold increase in titer between acute- and convalescent-phase sera confirms diagnosis	Aspergilloma: 79% ABPA: 46% Invasive pulmonary or disseminated: 20%	95–100%	IMMY (6)
CIE	Serum	Cell homogenate from A. fumigatus Culture filtrate from Aspergillus spp.[c]	≥1 line of identity indicates aspergilloma, ABPA or IA; 5–10 lines of identity are usually observed in cases of aspergilloma	ABPA: 70–90% Aspergilloma: 50%	100%	Bio-Rad (23, 158)
ID	Serum	Culture filtrate from Aspergillus spp.[c]	≥1 line of identity indicates aspergilloma, ABPA, or IA; ≥3 lines of identity is strong evidence for aspergilloma	ABPA: 50–61% Aspergilloma: 80–93%	97–100%	Gibson, IMMY, Meridian, Microgen (6, 19)
Blastomycosis						
CF	Serum	Purified A antigen	Titer of ≥1:8 is presumptive evidence of infection; titer of ≥1:32 is strongly presumptive evidence of recent infection Seroconversion or ≥4-fold increase in titer between acute- and convalescent-phase sera confirms diagnosis	Disseminated: 50% Localized: 33%	97–100%	IMMY (147)
ID	Serum	Purified A antigen	Presence of A band suggests recent infection	Disseminated: 85% Localized: 33%	100%	Gibson, IMMY, Meridian (147)
Candidiasis						
CIE	Serum	Culture filtrate from C. albicans	≥1 line of identity is positive for the presence of antibody; increase in line number correlates with progression of infection in immunocompetent patients	—[d]	—	Bio-Rad (24, 111)
		Cell homogenate from C. albicans		78–87%	75–97%	
EIA	Serum	Purified mannan from C. albicans	<5 AU[e] = negative; 5–<10 AU = intermediate; ≥10 AU = positive; >20 AU, dilute serum 1:4 and retest	C. albicans: 71–88% Other Candida spp.: 25–77%	63–94%	Bio-Rad (115)
ID	Serum	Culture filtrate and cell lysate of yeast-phase C. albicans	≥1 line of identity is positive for the presence of antibody; seroconversion or increase in number of lines suggests systemic infection; the greater the number of lines, the more severe the infection in immunocompetent patients	58–94%	94–98%	IMMY, Gibson (95)
IFA	Serum	Germ tubes of C. albicans	Titer of ≥1:640 suggests invasive candidiasis	76–96%	95–100%	Vircell (85, 98)
Coccidioidomycosis						
CF	Serum, CSF	Culture filtrate (coccidioidin)	Titer of ≥1:2, positive for acute pulmonary disease; titer of ≥1:16 suggests disseminated disease	75% (acute pulmonary), 98% (disseminated)	80–95%	IMMY, Meridian (107)

EIA	Serum, CSF	Mixture of purified TP and CF antigens to detect IgM or IgG, respectively	Absorbance values: < 0.150 = negative; 0.150– < 0.200 = indeterminate; ≥ 0.200 = positive	IgM only: 74% IgG only: 92% IgM and IgG: 97%	IgM only: 96% IgG only: 97% IgM and IgG: 94%	Meridian (92, 170)
IDCF	Serum, CSF	Culture filtrate (coccidioidin)	Band of identity with reference serum indicates active infection	77%	100%	IMMY, Meridian; Gibson (68)
IDTP	Serum	Heat-treated culture filtrate (coccidioidin 60°C for 30 min)	Band of identity with reference serum indicates active infection	75–91%	—	IMMY, Meridian (107)
LA	Serum	Heat-treated coccidioidin-coated latex particles	≥ 2+ agglutination is positive for the presence of antibody; must confirm with ID and/or CF	65–70%	93%	IMMY, Meridian (53)
Cryptococcosis						
TA	Serum	Suspension of weakly encapsulated C. neoformans yeast cells	Titer of ≥1:2 suggests recent or past infection; cross-reacts with blastomycosis and histoplasmosis	38–50%	89–95%	IMMY (105)
Histoplasmosis						
CF	Serum, CSF	Mycelial culture filtrate (histoplasmin)	Titer of ≥1:8 is presumptive evidence for infection; titer of ≥1:32 is strongly presumptive for infection	21%	81–99%	IMMY, Meridian (159)
	Serum, CSF	Yeast cell suspension	Titer of ≥1:8 is presumptive evidence for infection; titer of ≥1:32 is strongly presumptive for infection	82%	81– 88%	
ID	Serum, CSF	Mycelial culture filtrate (histoplasmin)	M band alone indicates acute or chronic histoplasmosis (observed in 75% of patients); presence of both the H and M bands indicates acute histoplasmosis (observed in 20% of patients); positivity for H and/or M band using CSF indicates *Histoplasma* meningitis	65–100%	89–100%	IMMY, Meridian, Gibson (159)
LA	Serum	Mycelial culture filtrate (histoplasmin)	Titer of ≥1:16 is presumptive evidence of active or very recent infection	Acute: 97–100% Chronic: 46–96%	97% 97%	IMMY (36)
Paracoccidioidomycosis						
ID	Serum, CSF	Mycelial culture filtrate (contains gp43 and other antigens)	Band of identity with reference serum indicates active infection	94%	95–99%	IMMY (11, 22)
		Ag7		84%	99%	
Sporotrichosis						
LA	Serum	*Sporothrix* antigen	Titer of ≥1:8, presumptive evidence of sporotrichosis	Disseminated: 100%, Articular: 86–100% Pulmonary: 73–87%, Cutaneous: 56–93%	100%	IMMY (10)

[a]For abbreviations, see beginning of chapter.
[b]Detailed vendor contact information is given at the end of the chapter. IMMY, Immunomycologics, Inc.
[c]Antigens from *A. fumigatus, A. flavus, A. nidulans, A. niger,* or *A. terreus* are tested separately.
[d]Insufficient data.
[e]Arbitrary units compared to a standard curve.

TABLE 2 Commercially available antigen detection tests for fungal diseases

Disease and/or test[a]	Specimen	Antigen detected	Interpretation	Sensitivity	Specificity	Source(s)[b]
Aspergillosis						
EIA MAb (EB-A2)	Serum (boiled)	Galactomannan	EIA index: ≥0.5 units = positive; detection limit = 1 ng/ml	60–100%	78–99%	Bio-Rad (83, 91)
LA MAb (EB-A2)[c]	Serum (boiled)	Galactomannan	Any agglutination = positive; titrate positive sera; detection limit = 15 ng/ml	27–95%	86–100%	Bio-Rad (83, 149, 166)
Candidiasis						
EIA MAb (EB-CA1)	Serum (boiled)	α-(1,2)-Oligomannosides	<0.25 ng/ml = negative; ≥0.25 to <0.5 ng/ml = intermediate; ≥0.5 ng/ml = positive	Overall, 52%; C. albicans, 53–60%; other Candida spp., 20–70%	85–100%	Bio-Rad (129, 166)
LA MAb (EB-CA1)	Serum (boiled)	α-(1,2)-Oligomannosides	Any agglutination = positive; titrate positive sera Detection limit = 2.5 ng/ml	25–77%	99–100%	Bio-Rad (47, 129, 166)
LA PAb	Serum (not boiled)	Uncharacterized heat-labile C. albicans antigen	Titer of ≥1:4 suggests invasive candidiasis	Titer of 1:4, 48–81%; titer of 1:8, 2–59%; titer of 1:16, 59%	Titer of 1:4, 80–97%; titer of 1:8, 93–95%; titer of 1:16, 98%	Ramco (5, 96, 97)
Cryptococcosis						
EIA	Serum, CSF	Capsular polysaccharide antigen	Visual Definite yellow color = positive Spectrophotometric <0.100 OD = negative; ≥0.100–<0.150 = indeterminate; ≥0.150 = positive Detection limit = 0.63 ng/ml	96–100%	93–99%	Meridian (34)
LA PAb	Pronase-treated serum, CSF (boiled)	Capsular polysaccharide antigen	≥2+ agglutination = positive; titrate positive sera; titer of ≥1:8 strongly suggestive evidence for infection	93–100%	93–98%	IMMY, Wampole, Meridian (140)
LA MAb (E1)	Urine Pronase treated Serum, CSF, BAL fluid	Glucuronoxylomannan	Any agglutination = positive; titrate positive sera; detection limit = 50 ng/ml	Overall, 92%; urine, 93%; serum, 85%; CSF, 100%; BAL fluid, 100%	Overall, 98%; urine, 97%; serum, 100%; CSF, 100%; BAL fluid, 100%	Bio-Rad (142)
Panfungal[d]						
Modified Limulus amebocyte assay	Serum, BAL fluid	(1,3)-β-D-Glucan	≥60 pg/ml = positive (Associates of Cape Cod)	100%	90%	Associates of Cape Cod (108); Seikagaku Corp. (76)
	Plasma		≥20 pg/ml = positive (Seikagaku Corp.)	76–97%	100%	

[a]For abbreviations, see beginning of chapter and Table 1.
[b]Detailed vendor contact information at the end of the chapter.
[c]Clone name in parentheses.
[d]Detects species of Candida, Aspergillus, Pneumocystis, Fusarium, and Trichosporon asahii but not Zygomycetes or Cryptococcus spp.

Stock barbital buffer (above) . . . . . . 25 ml
Distilled water . . . . to 100 ml

Heat to boiling until the agar is completely dissolved.

Equipment

Plexiglas matrix (3-mm-diameter wells) with 17 patterns of seven wells each (Quality House, Cartersville, Ga.)
Plastic petri dish, 15 by 100 mm
Spatula, 1-mm tip (flattened)
Light box with indirect backlighting

Procedure

The micro-ID test is recommended to conserve test serum and reagents. In addition to the reference *Aspergillus* antigens and antisera, buffered phenolized agar is required. Care should be exercised when pipetting liquefied phenol.

1. Pipette 6.5 ml of agar into a petri dish (15 by 100 mm) and allow to harden.
2. Overlay the first agar layer with 3.5 ml of hot molten agar and immediately place the Plexiglas matrix on top of the liquid agar.
3. Plates may be used 30 min after the agar has solidified or may be stored in a humidified chamber at 4°C for up to 1 week.
4. Number each seven-well pattern on the bottom of the dish (not on the template).
5. Remove the excess agar from the wells down to the first agar layer with the pointed end of the spatula.
6. Place the reference serum in the top and bottom wells of each pattern and place patient's test sera in the four lateral wells (Fig. 1). Place the reference antigen in the center well of each pattern. All wells must be examined for air bubbles. If bubbles are observed, they should be broken by being gently pierced with toothpicks. Separate toothpicks should be employed for each different antigen and antibody solution. Incubate the reactants in a humidified chamber for 48 h at 25°C.
7. Remove the Plexiglas matrix by gently pressing the sides of the petri dish, and remove the agar overlay by gently sweeping the surface with a cotton swab. Wash the agar with distilled water to remove excess reactants. Cover the agar with distilled water, and examine the plate for lines of identity between test and reference wells.

QA/QC

Positive control sera must be included each time the test is performed. Three or more distinct precipitin lines ("bands") should be formed when *A. fumigatus* reference antiserum is allowed to react with *A. fumigatus* antigen. One or more distinct precipitin lines should be formed when *A. flavus, A. niger,* or *A. terreus* reference antiserum is allowed to react with the homologous antigen. The greatest number of aspergillosis cases may be detected by the use of *A. fumigatus, A. flavus, A. niger,* and *A. terreus* precipitinogens in separate ID tests performed at the same time. Some *Aspergillus* antigenic extracts contain C substance, and this can react with C-reactive protein in the serum of some patients with inflammatory disease. The resulting complex forms a precipitate, which may be erroneously interpreted as the presence of anti-*Aspergillus* antibodies. This false-positive reaction is easily eliminated if the test plates are soaked in 5% sodium citrate for 45 min before being read. In addition, C substance may produce lines of nonidentity with reference antisera.

Interpretation

Precipitins can be found in over 90% of patients with aspergillomas and in 70% of patients with ABPA or CNPA. Only serum samples that produce a line or lines of identity with reference serum from a patient with a proven case of human aspergillosis are considered positive in the ID test. Although one or two precipitins may occur when serum from patients with any clinical form of aspergillosis is used, the presence of three or more bands is usually associated with either aspergilloma or CNPA. Pulmonary fungus balls can also be produced by *Scedosporium apiospermum* (*Pseudallescheria boydii*) and by other fungi; noninfectious conditions or other abnormalities may also be misinterpreted as aspergillomas on chest radiographs. In such cases, the *Aspergillus* ID test is negative. However, the ID test may also be negative in some patients with aspergillosis who are receiving long-term antifungal or corticosteroid therapy.

A   **B**   **C**
FIGURE 1 Examples of immunodiffusion results observed when a seven-well agar gel pattern is used. (A) Band of identity (patient 2); (B) band of partial identity (patient 1); (C) band of nonidentity (patient 3). Ag, reference antigen; Ab, reference antiserum; 1 to 4, patient test sera. A standard reference band is shown midway between the lower antiserum-containing wells and the central antigen-containing wells in all three panels.

Test 2. EIA To Detect *Aspergillus* Cell Wall GM

A commercial antigenemia detection test, the Platelia *Aspergillus* EIA, is a microtitration plate-based double antibody sandwich EIA (91) (Table 2). This assay uses a rat MAb, EB-A2, as both the capture and detector antibody for the $(1,5)$-β-D-galactofuranose residues of GM, an outer cell wall component found in the most clinically important species of *Aspergillus*.

Sample Requirements

Serum specimens should be collected serially during the infectious episode and may be collected at regular intervals before suspicion of infection if the test is to be used as a screening tool in high-risk patient populations such as in allogeneic HSCT recipients. Positive test results for two consecutively drawn serum samples is strong presumptive evidence of IA in the absence of factors that may contribute to false-positive results (see Interpretation, below); hence, multiple serum specimens, collected at least twice per week, are preferred. A 300-µl volume of patient serum is consumed each time the test is performed. Because the test may need to be repeated more than once and because some sample loss occurs during immune complex removal (precipitation of serum proteins during boiling in the presence of neutral disodium EDTA), at least 1 ml of patient serum is required for testing.

Materials and Reagents

Reagents provided in the kit include freeze-dried negative, positive, and cutoff (low-positive) control sera, EDTA solution, peroxidase-conjugated detector MAbs, wash solutions and buffers, H_2O_2, chromogen (TMB), stopping solution (1.5 N sulfuric acid), plate sealers, and microtiter plates precoated with capture anti-GM MAbs. Microtiter plates are composed of 12 eight-well strips so that the entire plate does not have to be used at one time. Strips are supplied in resealable pouches and should be used within 5 weeks of opening. Kits are stored at 2 to 8°C and should be brought to room temperature (18 to 25°C) before use.

Equipment

> Pipettes or multichannel pipettes, adjustable or fixed, to measure and dispense 50, 100, 300, and 1,000 µl
>
> 1.5-ml Eppendorf or similar polypropylene tubes with airtight stoppers, able to withstand boiling
>
> Centrifuge (for 1.5-ml polypropylene tubes) that can attain $10,000 \times g$
>
> Round, floating microcentrifuge rack for a 1-liter beaker
>
> Vortex agitator
>
> Boiling-water bath
>
> Incubator at 37 ± 1°C
>
> Manual or semiautomatic plate washer
>
> Microplate reader equipped with 450- and 620/630-nm filters

Procedure

A detailed stepwise procedure can be found in the package insert included with each kit. Briefly, GM is heat stable and is present in the circulation as soluble immune complexes. These complexes must be dissociated by boiling for 3 min in an EDTA solution provided in the kit. Samples are then centrifuged at $10,000 \times g$ for 10 min to remove precipitated serum proteins that could interfere with the test, and GM is recovered from the fluid phase. Peroxidase-conjugated detector antibodies are added to each test well of the microtiter plate that has been previously coated with EB-A2 capture MAbs by the manufacturer. Treated serum supernatants are then added, and plates are incubated for 90 min at 37°C before being washed five times. H_2O_2-TMB solution is added to each well, and the plates are incubated for 30 min in the dark at ambient temperature (18 to 25°C). Stopping solution is added, and the OD at 450 nm is determined within 30 min.

QA/QC

A negative control serum, a cutoff control serum (serving as a borderline-positive reaction), and a positive control serum containing 1 ng of GM per ml are included in each kit. A set of proficiency specimens can also be obtained from the manufacturer, and test values obtained in-house can be compared to those produced by the manufacturer. Results are expressed as an index (i.e., the ratio of the OD of the test sample to the OD of the mean cutoff control serum provided in the kit). OD values for the cutoff control serum must be ≥ 0.3 and ≤ 0.8; the index of the positive control serum must be greater than 2; and the index of the negative control serum must be less than 0.4.

Interpretation

As defined above, an index of ≥ 0.5 is considered a positive result and an index of <0.5 is considered a negative result. Positive results obtained with the Platelia *Aspergillus* EIA should be interpreted in conjunction with other diagnostic procedures including culture, histopathologic examination of biopsied tissues, and radiologic evidence of infection. For all positive patients, it is recommended that a second aliquot of the same sample be retested and a new sample, collected from the same patient, be tested in a follow-up procedure. In the absence of positive culture or histopathology, if tests for serum GM are repeatedly positive in patients at risk for IA, such results may be interpreted as a probable *Aspergillus* infection. On the other hand, negative test results do not rule out a diagnosis of IA. Even in cases of culture-proven or histopathologically proven IA, not every serum sample from each patient is expected to be positive.

Neonatal or pediatric serum samples have been reported to give a higher rate of false-positive results, and this may be related to the finding that the EB-A2 MAb used in the test reacts with components found in infant milk formulas and with the lipoteichoic acid of a common neonatal gut commensal, *Bifidobacterium bifidum*. False-positive test results may also occur in patients receiving piperacillin-tazobactam and amoxicillin-clavulanic acid antibiotics since these agents also react with the EB-A2 MAb in vitro. Positive test results in such individuals should be interpreted with caution and confirmed by other diagnostic means. Other fungal genera, including species of *Penicillium, Alternaria,* and *Paecilomyces,* have demonstrated reactivity with the EB-A2 MAb used in the Platelia *Aspergillus* test and could cause false-positive test results; however, these genera rarely cause invasive fungal disease. Other possible reasons for false-positive results have been suggested, including reactions with cyclophosphamide and/or adsorption of dietary GM through a damaged intestinal wall.

Reduced detection of GM may occur in patients with chronic granulomatous disease or Job's syndrome or in those with IA who are receiving antifungal therapy (150). Sera from such patients giving negative results should be retested. False-negative results have also been attributed to limited invasion of blood vessels by the organism or to especially high antibody titers in the host.

Experimental and Molecular Biological Approaches

Immunoblot analyses for the diagnosis of IA have been conducted to identify patient antibodies to a number of somatic or cell wall-derived proteins from *Aspergillus* species that range in molecular mass from 33 to 88 kDa (93). On the other hand, tests to detect immunoreactive protein antigens in patient serum and urine have also been described, including those to detect an 18-kDa ribonucleotoxin (3, 44) and one to detect an 88-kDa antigen, hypothesized to be analogous to the HSP90 heat shock protein of *Candida albicans* (14). In general, these antigen detection tests have not achieved the desired test sensitivity for an optimal diagnosis.

All nucleic acid detection tests for aspergillosis are experimental and limited to individual research laboratories. The most beneficial use of nucleic acid detection tests is for the early diagnosis of IA because this disease progresses rapidly and is associated with a high mortality rate (50 to 100%) in immunocompromised patients. Earlier detection of fungal DNA by PCR than by radiographic or culture methods was reported for a large series of patients (31). Fungal DNA extracted from whole blood was detected by PCR a median of 4 days before radiological signs were evident for 12 of 17 patients with hepatosplenic candidiasis or pulmonary aspergillosis. This method could also be used to monitor the response to antifungal therapy in patients with IA, since the number of PCR-positive samples declined in patients responding to therapy, in contrast to those who did not respond (31). This method was reported to have a sensitivity of 100% for patients with documented invasive infections when two or more blood samples were tested (31). Efficient sample preparation included a hot dilute alkali extraction step (0.05 M NaOH at 95°C for 10 min followed by neutralization with 1 M Tris-HCl [pH 7.0]) and the use of Zymolyase to digest fungal cells walls and release *Aspergillus* DNA (31).

BLASTOMYCOSIS

Background

Substantial improvement in the diagnosis of blastomycosis can be attributed to the use of a purified surface antigen of *Blastomyces dermatitidis* called the "A antigen" by one group of investigators (54) and WI-1 by another group (72); both are released from the yeast form of *B. dermatitidis* by autolysis and are recovered from culture filtrates. Immunologically, the A antigen and WI-1 are related in that antibodies directed against the WI-1 antigen recognize the A antigen and vice versa. The A antigen has a molecular mass of 135 kDa and is glycosylated, whereas the WI-1 antigen is a 120-kDa protein that is not glycosylated.

ID test kits and reagents to conduct the ID and CF tests are commercially available (Immuno-Mycologics, Inc.; Gibson Laboratories) for the detection of anti-*B. dermatitidis* antibodies. The A antigen is now incorporated into most commercially available kits and is also supplied as a reagent for in-house ID and CF testing. A positive reaction in an ID test using the purified A antigen is specific and diagnostic for blastomycosis. However, a negative ID test does not rule out a diagnosis of blastomycosis since this test has been reported to be negative in 10% of patients with disseminated infection and over 60% of patients with localized disease.

Initial CF assays for the diagnosis of blastomycosis used a crude yeast antigen which resulted in unsatisfactory sensitivity and specificity. With the incorporation of purified A antigen into the CF assay, the specificity improved markedly

from initial reports of 30 to 87% (73, 80, 148) to 97 to 100% (73, 148). However, the sensitivity still remains unsatisfactory for the diagnosis of disseminated infection (50%) or localized infection (33%) (73). Although the CF test is still in use, its sensitivity is poor and much reduced compared to the ID test, and it is therefore not discussed in further detail here. However, procedures for performing the CF test for the diagnosis of blastomycosis are the same as those for the diagnosis of histoplasmosis but *B. dermatitidis* A antigen is used instead of *H. capsulatum* antigens (see "Test 1. CF Test To Detect Antibodies to *H. capsulatum*" below).

Clinical Indications and Diagnostic Rationale

Antibody detection tests for blastomycosis should be performed with sera from patients showing signs of suspected acute pulmonary blastomycosis, especially if they reside in or have recently traveled to geographic areas where blastomycosis is endemic. Signs of acute pulmonary blastomycosis include a nonspecific respiratory infection characterized by fever, chills, productive cough, myalgia, arthralgia, pleuritic chest pain, and weight loss. Antibody detection tests should also be performed with sera from patients presenting with symptoms of chronic pulmonary blastomycosis, which are similar to those of tuberculosis and include productive cough, hemoptysis, night sweats, malaise, weight loss, and low-grade fever. Antibody detection can be helpful when lesions are present on the skin, a common site of dissemination, and for monitoring CSF specimens from patients with suspected blastomycotic meningitis.

Immunocompromised patients are predisposed to severe forms of the disease, which can relapse and are often associated with a high mortality rate. Up to 40% of AIDS patients with blastomycosis have central nervous system disease which manifests as either meningitis or brain lesions. Others have presented with a septic shock-like syndrome. Experimental antigen detection tests, should they prove to be sensitive and specific, would be helpful for the diagnosis of disseminated blastomycosis in immunocompromised patient populations whose antibody responses may be limited or variable.

Test 1. ID Test To Detect Antibodies to *B. dermatitidis*

Commercial kits for the ID test contain precast agar gels, antigens, and reference antisera. Vendors are listed in Table 1, and more detailed contact information is provided at the end of the chapter. Commercial kits use a precast, macro-ID gel template, whereas the CDC Mycotic Diseases Branch prefers using a micro-ID procedure and phenolized agar as described below.

Sample Requirements

A positive ID test result, giving a line of identity with the reference A precipitin band, is strong presumptive evidence of active or recent infection. Therefore, only a single serum sample is required if positive test results are obtained. However, because the reported sensitivity of the ID test is low, patients with negative serum reactions should have additional sera drawn 3 to 4 weeks after initial sampling to detect the development of an A precipitin band indicating seroconversion and recent infection.

Materials and Reagents

Antigens may be obtained from commercial sources (Table 1) or prepared from 1-week-old brain heart infusion broth (Difco Laboratories, Detroit, Mich.) cultures of yeast-form *B. dermatitidis* cells shaken at 150 rpm and 37°C. Culture

filtrates are precipitated with acetone, and the precipitate is dissolved in a volume of phosphate-buffered saline (0.01 M PBS [pH 7.2]) equal to 1/10 the original filtrate volume.

Phenolized Medium

Sodium chloride	0.9 g
Noble agar (or equivalent)	1.0 g
Sodium citrate ($Na_3C_6H_5O_7 \cdot 2H_2O$) ..	0.4 g
Phenol, liquefied	0.25 ml
Glycine	7.5 g
Distilled water .... to 100 ml

Autoclave the mixture at a pressure of 15 lb/in² for 10 min. The final pH of the medium should be 6.3 to 6.4.

Equipment
The same equipment is used for the blastomycosis ID test as for the aspergillosis ID test.

Procedure
The same procedure is used as described for the aspergillosis ID test, except that serum samples are preincubated for 45 min at 25°C before antigen is added to wells of the ID plate. Reactants are incubated for 48 h at 25°C in a humidified chamber.

QA/QC
Positive control sera must be included each time the test is performed. The *B. dermatitidis* antiserum must react with the homologous reference antigen to form the specific A precipitin band. Only serum samples that produce lines of identity with the reference A precipitin band are considered positive for blastomycosis. Commercial kits most often provide reference antisera and antigens prediluted for optimal test performance. If in-house-produced reagents are being evaluated, it is important to cross-titrate reagents to determine the optimal working dilution. Optimal dilutions of serum and antigen are those that place the precipitin band midway between the serum and antigen wells.

Interpretation
The ID test performed using a *B. dermatitidis* yeast-form culture filtrate, containing the A antigen, is highly specific for blastomycosis. A positive reaction denotes a recent or current infection by *B. dermatitidis*. Positive reactions can therefore be the basis for immediate treatment of the patient without parallel testing for coccidioidomycosis or histoplasmosis. Negative test results, however, do not exclude a diagnosis of blastomycosis because the sensitivity of the ID test has been reported to range from 33% for localized infection to 88% for disseminated disease. In the absence of a positive A precipitin band or in cases where the CF test is positive for blastomycosis but the ID test is negative, patients should be examined extensively for culture or histologic evidence of infection by other endemic fungi as well as by *B. dermatitidis* (especially because the areas of endemicity for blastomycosis and histoplasmosis overlap and cross-reactivity can occur). In addition, sera should be drawn at 3-week intervals and examined by CF and ID tests with *B. dermatitidis*, *C. immitis*, and *H. capsulatum* antigens. Such testing will detect increases in CF titers to the causative organism, indicating infection by that organism, or the development of precipitin bands diagnostic for blastomycosis, histoplasmosis, or coccidioidomycosis. In established cases of blastomycosis, a decline in the number or the disappearance of precipitin lines is evidence for a favorable prognosis. The serologic response, however, is often not as rapid as the clinical response.

Experimental and Molecular Biological Approaches
More recently, a double-antibody sandwich EIA, employing rabbit polyclonal antibodies to detect an uncharacterized antigen from *B. dermatitidis* in urine, serum, CSF, BAL fluid, and other body fluids, has been developed. Test sensitivity was reported to be 89 and 100%, respectively, for the detection of urinary antigen in the disseminated and pulmonary forms of blastomycosis (28). Little or no cross-reactivity was observed when specimens obtained from healthy volunteers or from patients with aspergillosis, candidiasis, coccidioidomycosis, or cryptococcosis were used, but significant cross-reactivity occurred when specimens from patients with disseminated histoplasmosis (96%), paracoccidioidomycosis (100%), or penicilliosis marneffei (70%) were used (28). Because the areas of endemicity for blastomycosis and histoplasmosis overlap, additional tests are required to obtain a specific diagnosis. This test has not yet undergone adequate clinical evaluation and is available only as a fee-for-service test at a single reference laboratory.

A relatively small number of nucleic acid detection tests for blastomycosis have been published and are currently limited to individual research laboratories. Most studies have examined the use of molecular probes to detect *B. dermatitidis* DNA in paraffin-embedded tissues (7) or from pure cultures (86, 124). Using a gene encoding the WI-1 adhesin of *B. dermatitidis* as a target for nested PCR, Bialek et al. (7) detected *B. dermatitidis* DNA in 8 (62%) of 13 tissue samples from microscopically confirmed cases of canine blastomycosis but detected no PCR amplicons from microscopically negative biopsy specimens from dogs with blastomycosis or lymphosarcoma (negative controls). The deleterious effect of formalin on the target DNA during fixation of the tissues was hypothesized to be responsible for the low sensitivity of PCR detection (7).

CANDIDIASIS

Background
Tests for *Candida* antibodies have been extensively evaluated but remain of uncertain usefulness in the diagnosis of invasive forms of candidiasis. The clinical utility of these tests has been hampered by false-positive results in patients who are colonized with *Candida* species or who have superficial infections, as well as by false-negative results in immunocompromised patients who produce small or variable quantities of antibodies. On the other hand, in immunocompetent patients, a fourfold rise in the LA titer or seroconversion from no ID band to an ID band or an increase in the number of ID bands may be diagnostically helpful. Conversely, a fourfold decrease in LA titer may denote successful therapy. No LA test to detect anti-*Candida* antibodies is commercially available. ID kits are available from two commercial sources (Immuno-Mycologics, Inc.; Gibson Laboratories), and a CIE test is available from another (Bio-Rad Laboratories) (Table 1). CIE does not improve test sensitivity significantly compared to ID but can be completed in 90 min rather than in the several days required for the ID test. An EIA to detect antibodies to circulating mannoprotein, a major cell wall component of *Candida* species, is commercially available in some countries but not in the United States (Platelia *Candida* Antibody;

Bio-Rad Laboratories, Inc.). Clinical evaluations of the test in patients with invasive candidiasis demonstrated that the test specificity ranged from 63 to 94% but the test sensitivity ranged from 25 to 88%, depending on the identity of the infecting *Candida* species (the lowest sensitivity occurred for detecting *C. parapsilosis* infections, and the highest occurred for detecting *C. albicans* infections) (Table 1). An IFA test to detect antibodies directed to germ tube forms of *C. albicans* cells is also available commercially (Vircell Laboratories); the sensitivity and specificity ranged from 76 to 94% and 95 to 100%, respectively (98) (Table 1).

Because antibody detection tests have limited sensitivity for the diagnosis of invasive candidiasis in immunocompromised patients and because these patients may be in antigen excess, a variety of antigen detection assays have been developed. Among these are tests to detect heat-labile antigens by reverse passive LA (Cand-Tec test; Ramco Laboratories, Inc., Stafford, Tex.) and heat-stable *Candida* cell wall mannan by LA and EIA (the Pastorex *Candida* LA test and the Platelia *Candida* Ag EIA, respectively; Bio-Rad Laboratories, Inc.). The Cand-Tec test has been commercially available for many years. The nature of the antigen is unknown, but its susceptibility to heat (56°C), pronase, 2-mercaptoethanol, and sodium periodate treatment suggests that it may be a glycoprotein. Test sensitivity varied widely among studies (2 to 59%) whereas test specificity ranged from 93 to 95%, using a threshold titer of ≥1:8. A threshold titer of ≥1:4 resulted in a somewhat increased sensitivity (41 to 81%) and a specificity of 80 to 97% (5, 95, 96) (Table 2).

Both the Pastorex *Candida* LA test and the Platelia *Candida* Ag EIA use a rat EB-CA1 MAb directed against the α-1,2-oligomannosides of *Candida* mannan. The Pastorex *Candida* LA test employs agglutination of latex particles coated with this MAb to detect circulating *Candida* antigen, whereas the Platelia *Candida* Ag EIA uses the same MAb but employs it in a double-antibody sandwich EIA format (Table 2); neither of these tests is FDA approved at present. The range in reported sensitivity for the Pastorex *Candida* LA test is quite large (25 to 77%), although test specificity has been good (99 to 100%); in contrast, the Platelia *Candida* Ag EIA has an overall sensitivity of 52% and a specificity of 85 to 95%. Because the Platelia *Candida* Ag EIA gives superior test results compared to the Pastorex *Candida* LA test, only the EIA is described below.

Clinical Indications and Diagnostic Rationale

The LA and ID tests to detect antibodies to *Candida* species have been applied using sera from patients with acute disseminated candidiasis, chronic hepatosplenic candidiasis, or localized deep-organ candidiasis (e.g., endocarditis). Those most at risk for these infections include neutropenic cancer patients, HSCT and SOT recipients receiving immunosuppressive agents, and patients receiving critical care, particularly those in adult surgical and neonatal intensive care units. Patient serum containing antibodies that react with homogenate antigens of *C. albicans* in the ID test may produce one or several lines of identity. Systemic candidiasis should be suspected if serial serum specimens show an increase in titer or an increase in the number of reactive bands detected over time.

Serologic tests may also be employed to determine the potential clinical significance of *Candida* species recovered from various body sites. The detection of precipitins or the occurrence of fourfold changes in antibody titer in the LA test may be evidence of systemic candidiasis; however, such

titers may also indicate colonization. The ID and LA tests for antibodies have a sensitivity of approximately 80% for confirmed cases of invasive candidiasis in immunocompetent hosts. The ID test is more specific than the LA test. In cases where candidiasis is suspected and ID reactions are negative for *C. albicans* antigens, the ID test should be performed with other *Candida* species antigens to rule out infections with those species. A decision to treat a patient with antifungal drugs must not be based on serologic data alone, however, but rather should be made after consideration of all available clinical and laboratory data.

Test 1. ID Test To Detect Antibodies to *C. albicans*

Commercial kits for the ID test contain precast agar gels, antigens, and reference antisera. Vendors are listed in Table 1, and more detailed contact information is provided at the end of the chapter. Commercial antigens and antibodies should be used with the agar medium provided by the vendor.

Sample Requirements

Results obtained with a single serum sample are difficult to interpret because a positive result may represent colonization rather than true systemic infection. Therefore, multiple sequential serum specimens, taken weekly or at least every 2 weeks, should be collected to detect seroconversion or an increase in the number of precipitin lines. The *Candida* ID test can also be performed in a semiquantitative manner by testing twofold serial dilutions of sera in normal saline or PBS in the same manner as undiluted sera (below) and recording the highest titer at which bands appear.

Materials and Reagents

Antigens for use in commercial *Candida* ID kits are crude or partially purified, uncharacterized components derived from culture filtrates and/or cell lysates of yeast-phase *C. albicans*. Reference antibodies are directed against the A serotype of *C. albicans* and form at least two precipitin lines against the reference *Candida* antigen.

Equipment

Humidified chamber
Light box with indirect backlighting

Procedure

1. Label ID plates with an identifying number and date.
2. Place plates on a dark background to facilitate well filling.
3. Place the reference serum in the top and bottom wells of the ID pattern, and place each patient's test serum in one of the four lateral wells. The closed plate may then be incubated at 25°C for 30 min to help intensify precipitin lines.
4. Place the reference antigen in the center well of each ID pattern.
5. Place closed plates on a level surface in a humidified chamber, and incubate at 25°C for 24 h.

QA/QC

A positive control serum, preferably containing three precipitin bands, should be included each time the ID test is performed. If bubbles occur during well-filling procedures, they must be broken by being gently pierced with toothpicks. Separate toothpicks should be used for each antigen and antibody solution.

Interpretation

Sera from candidiasis patients which react with homogenate antigens of *C. albicans* in the ID test may produce between one and seven precipitin bands. Systemic candidiasis should be suspected when serial serum specimens demonstrate seroconversion (i.e., when negative antibody test results become positive) or show temporal increases in the number of precipitins.

Test 2. EIA To Detect *Candida* Cell Wall Mannan

A commercial antigenemia detection test, the Platelia *Candida* Ag (Bio-Rad Laboratories), is a microtitration plate-based double-antibody sandwich EIA that can be conducted as either a quantitative (results are compared to a standard curve) or a semiquantitative (results are expressed as an index relative to the calibrator serum) test. This assay uses a rat MAb, EB-CA1, as both the capture and detector antibody for α-(1,2)-linked oligomannosides, outer cell wall components of most clinically important species of *Candida* (129).

Sample Requirements

The test can only be performed with serum samples collected into dry blood collection tubes (no additives or clot activators). Separated serum can be stored in a tightly closed tube at 2 to 8°C if the test is performed within 24 h or should be frozen at −20°C or colder for transport or if the test is not performed within 24 h. Serum can be submitted to a maximum of three freezing and thawing cycles, and frozen samples should be thoroughly mixed before being tested.

Serum specimens should be collected serially during the infectious episode. Sera may also be collected at regular intervals before suspicion of infection if the test is to be used as a screening tool in high-risk patient populations such as SOT recipients and critical-care patients. Mannan occurs in the serum in low nanogram-per-milliliter concentrations and is rapidly cleared from the circulation, necessitating frequent sampling of patients during periods of high risk. Therefore, the use of multiple serum specimens, collected at least twice per week, increases test sensitivity. A total of 300 μl of patient serum is consumed each time the test is performed. Because the test may need to be repeated more than once and because some sample loss occurs during immune complex removal (precipitation of serum proteins during boiling in the presence of neutral disodium EDTA), at least 1 ml of patient serum is required.

Materials and Reagents

Reagents provided in the kit include negative, positive, and calibrator sera, EDTA solution, peroxidase-conjugated detector MAbs, wash solutions and buffers, H_2O_2, chromogen (TMB), stopping solution (1.5 N sulfuric acid), plate sealers, and microtiter plates precoated with capture antimannan MAbs. Microtiter plates are composed of 12 eight-well strips so that the entire plate does not have to be used at one time. Strips are supplied in resealable pouches and should be used within 5 weeks of opening. Kits are stored at 2 to 8°C and should be brought to room temperature (18 to 25°C) before use.

Equipment and Procedure

The equipment and procedure for the Platelia *Candida* Ag EIA are the same as those for the Platelia *Aspergillus* Ag EIA (see "Test 2. EIA To Detect *Aspergillus* Cell Wall Galactomannan" above), except that a MAb directed against *Candida* mannan (EB-CA1) is used as the capture and detector antibody.

QA/QC

Strict compliance with the prescribed 100°C temperature for the boiling water bath is essential for success of the test. A negative control serum (no mannan), a calibrator serum (containing 2.0 ng of mannan per ml and the concentration from which to prepare a standard curve for the quantitative assay or from which to dilute to 0.5 ng for the qualitative assay), and positive control serum (containing between 0.5 and 1.5 ng of mannan) are included in each kit. Results are expressed in nanograms per milliliter extrapolated from the standard curve (quantitative assay) or as an index (semi-quantitative assay; i.e., the ratio of the OD of the test sample to the OD of the mean calibrator serum provided in the kit). In both test modes, OD values for the calibrator, for the four points comprising the standard curve (quantitative mode), and for the positive and negative controls must be within their designated ranges.

Interpretation

Serum samples with a mannan concentration of less than 0.25 ng/ml are considered to be negative, serum samples with a mannan concentration of between 0.25 and 0.5 ng/ml are considered to be intermediate, and serum samples with a mannan concentration greater than or equal to 0.5 ng/ml are considered to be positive. Range points used to plot the standard curve do not allow precise determination of mannan concentrations above 2.5 ng/ml, and strongly positive sera should be diluted 1:5 (vol/vol) with negative serum and retested. Positive results obtained with the Platelia *Candida* Ag test should be interpreted in conjunction with other diagnostic procedures including culture, histopathology of biopsied tissues, and radiographic evidence of infection. Negative test results do not rule out a diagnosis of invasive candidiasis. Even in cases of culture or histopathologically proven candidiasis, not every serum sample from each patient is expected to be positive.

The EB-CA1 MAb is specific for an α-linked mannopentaose common to all *Candida* species (135), but test sensitivity varies depending upon the *Candida* species being detected. For example, in a retrospective study conducted on 106 patients (366 sera) residing in various hospital wards (surgery, hematology, intensive care, burns, and others) and from whom *Candida* species were isolated from the blood or other sterile body sites, the overall sensitivity of the EIA was 52%. For infections by specific *Candida* species, however, sensitivities were 70% for *C. tropicalis*, 50 to 58% for *C. kefyr*, *C. albicans*, and *C. glabrata*, 38% for *C. parapsilosis*, and only 20% for *C. krusei*. The moderate sensitivity exhibited by the test does not provide an optimum negative predictive value for diagnosing invasive candidiasis. However, because the overall specificity of the EIA is so high (98%), a positive result obtained with samples from patients at risk suggests infection.

Experimental and Molecular Biological Approaches

Enolase, a 48-kDa cytoplasmic antigen of *C. albicans*, is a potentially useful diagnostic marker of invasive candidiasis. A clinical trial evaluating a commercial double-antibody liposomal immunoassay to detect enolase in cancer patients reported an overall sensitivity of 75% and a specificity of 96% (157). Unfortunately, this test is no longer available commercially.

An inducible, extracellularly secreted aspartyl proteinase (Sap), originally studied extensively as a virulence factor in the invasion and dissemination of *C. albicans* in animal models of infection (52, 79), has more recently been examined as

a useful diagnostic marker of invasive candidiasis. An antibody detection assay and two antigen detection assays, employing a MAb specific for Sap, were compared in a retrospective analysis. The sensitivities and specificities, respectively, were 70 and 76% for the antibody detection assay and 94 and 92% for the antigen capture ELISA. The sensitivity and specificity of the inhibition ELISA to detect Sap antigen were greater than those of either the antibody detection test or the antigen capture test: 94 and 96%, respectively.

D-Arabinitol, a five-carbon polyol, is produced by the most medically important *Candida* spp. except for *C. krusei* and perhaps *C. glabrata* (18). Its production has been detected in serum or urine by gas-liquid chromatography, gas chromatography-mass spectrometry, and enzymatic fluorometric or enzymatic chromogenic assays (166). Serum creatinine levels, required to normalize results for the increased serum arabinitol concentrations observed during renal dysfunction, can be measured simultaneously with D-arabinitol by use of a centrifugal autoanalyzer (Roche). Patients with persistent candidemia had the highest D-arabinitol/creatinine levels (83% positive) compared to patients with transient candidemia (74%) or negative controls (14%) (166).

Commercial products are currently under development for the rapid extraction and recovery of *C. albicans* DNA from whole blood (MagNa Pure; Roche Molecular Biochemicals, Inc., Indianapolis, Ind.) (87) and for the identification of amplicons by real-time, quantitative PCR (Light Cycler *Candida* kit; Roche). Application of a commercial DNA extraction kit (MagNa Pure LC total nucleic acid Isolation kit; Roche) in conjunction with an automated DNA extraction system (MagNa Pure LC system; Roche) and a "real-time" PCR amplification and detection system (LightCycler) has been reported to detect as few as 1 CFU of *C. albicans* per ml of whole blood (87). This process could be completed in just 3 h. However, it was required that whole blood be treated to lyse and remove erythrocytes and that *C. albicans* cells in the specimen be disrupted by vortex mixing in the presence of glass beads before samples were added to the automated DNA extraction system (87). These additional steps make the application of this method for the extraction of *Candida* DNA too cumbersome for use in a clinical laboratory. However, amplicon detection by the real-time quantitative PCR system obviates the need for postamplification manipulation steps, making the LightCycler system more rapid than conventional PCR detection methods. This system has been adapted for use with species-specific primers, directed to target sequences from the 18S and 28S regions of rDNA, to detect and identify *C. albicans*, *C. glabrata*, *C. krusei*, *C. parapsilosis*, *C. tropicalis*, and *C. guilliermondii* (49) and to target sequences from the ITS regions and 18S rDNA region in *C. albicans, C. tropicalis,* and *C. krusei* (12). Multiplex real-time PCR and melting-curve analysis demonstrated the limit of test sensitivity to be 0.1 pg of fungal genomic DNA (12).

Other quantitative PCR methods have been described for the detection of *Candida* species, and one of these (*Taq*Man System; Perkin-Elmer Applied Biosystems, Inc.) takes advantage of the 5′-3′ exonuclease activity of the *Taq* DNA polymerase to separate a quencher probe from a reporter probe, thereby producing a fluorescent signal proportional to the amount of target DNA amplified. Application of this system to sera obtained from pediatric hematology and oncology patients with culture-confirmed candidemia and clinically proven or suspected systemic candidiasis demonstrated a sensitivity of 100% for the detection of *C. albicans, C. glabrata, C. tropicalis,* and *C. parapsilosis* DNA (88).

Given the low sensitivity of antigen detection and the low specificity of antibody detection for the diagnosis of candidiasis, PCR-based diagnostic methods offer the promise of improved sensitivity and specificity. However, universally standardized methods for the extraction, purification, amplification, and detection of *Candida* species DNA require further development and evaluation.

COCCIDIOIDOMYCOSIS

Background

Tests to detect anti-*C. immitis* antibodies are of proven usefulness for the diagnosis and management of coccidioidomycosis. One of the original serologic methods for the diagnosis of this disease was the TP test which detects IgM antibodies reactive against a heat-stable, carbohydrate-containing component in coccidioidin (a filtrate of autolyzed *Coccidioides immitis* mycelial cultures). These antibodies can usually be detected within the first month of infection. Currently, the diagnosis of early acute disease can be established with similar results by using the same antigen but in an immunodiffusion test format (IDTP). An LA test, using particles adsorbed with heated coccidioidin, is a simple and rapid method to measure early antibody production corresponding to that detected by the TP or IDTP tests. The LA test is more sensitive than the TP or IDTP tests and can therefore be used as a rapid screening tool. However, the LA test is also associated with a false-positivity rate of greater than 5% (27, 53). This false-positivity rate is greater if sera have been diluted before testing. Therefore, the LA test can not be used as a quantitative test and results which are positive by this method must be confirmed by the IDTP test.

In contrast to the IDTP and LA tests, which detect early IgM antibody responses to coccidioidal infection, the CF test detects primarily IgG antibodies produced during the convalescent phase of disease or during chronic infections. The CF test measures the concentration of antibodies against a heat-labile protein antigen, found in coccidioidin, called the F antigen. This same antigen can be used to detect IgG antibodies in an immunodiffusion test format (IDCF). The CF procedure is the most widely used serologic test for the diagnosis of coccidioidomycosis, and reactive antibodies persist for longer periods than do those detected in the IDTP test. The CF test is diagnostic and prognostic: antibody titers rise in proportion to disease severity and subside in response to therapy. The IDCF test can also be conducted in a quantitative manner, using serially diluted serum. Whereas a single test by any of the above methods may provide an accurate diagnosis, performing both the IDCF and CF tests in parallel provides the highest sensitivity and specificity.

A commercial enzyme immunoassay, the Premier *Coccidioides* EIA (Meridian Diagnostics, Inc., Cincinnati, Ohio), is useful for the detection of anti-*Coccidioides* IgG and IgM antibodies in sera from patients with coccidioidomycosis (68). Microwells of an EIA plate are precoated by the manufacturer with a proprietary mixture of purified TP and CF antigens so that the detector antibodies employed can be used to differentiate between reactive IgM (early) and IgG (late) antibodies. Detection of both types of antibodies by the EIA gives the greatest sensitivity (97%) and specificity (94%), although confirmation of positive results by ID is recommended.

Clinical Indications and Diagnostic Rationale

Serologic tests should be considered whenever patients display signs and symptoms of coccidioidomycosis and have

lived in or traveled to areas where *C. immitis* (California) or *C. posadasii* (Arizona, New Mexico, Utah, Texas, Mexico, and Central and South America) is endemic. Serum antibodies may be detected within 1 to 3 weeks after the onset of primary infection in a large percentage of cases. Detection of antibodies by the IDTP or LA tests is diagnostic but not prognostic since antibodies reactive in these tests are rarely detected 6 months after acute pulmonary infection. Reactive antibodies may reappear if the infection spreads or relapses or they may persist in disseminated cases. The CF test becomes positive later than the IDTP or LA tests and is most effective in monitoring disseminated disease. The CF titer rises in parallel with the severity of the infection (20, 107) and declines as the patient improves.

Test 1. IDTP and IDCF Tests To Detect Early and Late Antibodies to *Coccidioides* Species

The ID test format can be used to simultaneously detect IgM (IDTP) and IgG (IDCF) antibodies on a single plate. Both the IDTP and the IDCF tests are performed using a seven-well ID pattern formed in a gel or agar substrate. Positive control IDTP and IDCF sera are placed in independent wells and are tested against patient sera as well as against optimally diluted heated (for IDTP) or unheated (for IDCF) coccidioidin. Lines of identity between patient sera and positive reference sera, corresponding to reactive IgM (for IDTP) and IgG (for IDCF) antibodies, can then be observed for positive cases of early or late disease, respectively (107). Commercial sources for ID kits and reagents for use in ID tests are listed in Table 1.

Sample Requirements

Serum from symptomatic patients may give negative or indeterminate test results early in infection. Additional serum from such patients should be obtained 3 to 4 weeks later, and the tests should be repeated. CSF should be obtained and tested in parallel with serum specimens from patients presenting with signs and symptoms of meningitis. The sensitivity of the IDTP and IDCF tests can be increased by eightfold concentration of serum prior to testing. Serum can be concentrated by evaporation in vacuo (Speed-Vac; Savant Instruments, Inc., Holbrook, N.Y.) or by the use of centrifugal ultrafiltration devices (Centricon; Millipore, Billerica, Mass.). Concentration of test serum may be especially helpful to improve IDTP detection of low levels of IgM antibodies present early in infection and to improve IDCF detection of IgG antibodies in specimens from patients with chronic disease. Serum may demonstrate anticomplementary activity, making CF test results difficult to interpret; however, such sera can be successfully used in the ID test. In addition, the ID test is more specific than CF and may help resolve CF cross-reactivity issues often encountered among the endemic mycoses during CF testing.

Materials and Reagents

The antigens for both the IDTP and IDCF tests are filtrates of mycelial cultures of multiple or single isolates of *C. immitis*. Coccidioidin is prepared by a variety of procedures. In the most widely known procedure, filtrates are produced from cultures grown in synthetic asparagine-glycerol-salts medium originally devised for tuberculin production. The preparation of coccidioidin in this medium usually requires incubation for several weeks at room temperature. Coccidioidin antigens can also be prepared within 1 week by a toluene lysis technique (67). Heating coccidioidin at 60°C for 30 min destroys the F antigen responsible for the IDCF

activity, but the heat-stable antigen responsible for the IDTP reactivity is retained (67).

Phenolized Medium

The same medium as that used for the blastomycosis ID test is used for the IDTP and IDCF tests (see "Test 1. ID Test To Detect Antibodies to *B. dermatitidis*" above). The final pH of the medium should be 6.3 to 6.4. The mixture is autoclaved at a pressure of 15 lb/in^2 for 10 min.

Equipment

The same equipment is used for the coccidioidomycosis ID test as for the aspergillosis ID test (see "Test 1. ID Test To Detect Antibodies to *Aspergillus* Species" above).

Procedure

The same procedure as that described for the aspergillosis ID test is used, except that the patient test sera and the corresponding reference sera must be incubated in test wells for 30 min at ambient temperature before the addition of the IDTP antigen to the center well of the ID test pattern. This preincubation interval provides time for the relatively large IgM antibody molecules (compared to IgG molecules) to adequately diffuse into the agar gel matrix. Antigen-antibody precipitin bands will then be located centrally between the antigen-containing and antibody-containing wells of the ID pattern.

QA/QC

Positive control sera must be included each time the test is performed. Patient serum must react with the homologous reference antigen to form a line of identity with the reference band in order to be considered positive for coccidioidomycosis. Occasionally, interference with test results occurs as a result of formation of a precipitation band resembling that of the IDTP reaction by sera from patients without coccidioidomycosis. The origin of this band is unknown but may be the result of reactions between coccidioidal antigens and C-reactive protein (or a related substance) in serum. Such bands can be dissolved by the addition of an aqueous solution of 1.5% EDTA, which leaves authentic IDTP bands unaffected.

Interpretation

IDTP

Observation of a band of identity in the IDTP assay indicates that the patient from whom the test serum was obtained is in the early stages of coccidioidomycosis. Of patients with coccidioidomycosis, 75% develop a detectable IDTP antibody response as early as 1 week after onset of symptoms; 91% are positive within 3 weeks. Negative test results, however, do not exclude a diagnosis of coccidioidomycosis. In the absence of a positive precipitin band, or in cases where the CF test is positive but the IDTP test is negative, patients should be examined extensively for culture or histopathologic evidence of infection by another endemic fungus as well as by *C. immitis*. In addition, sera should be drawn at 3-week intervals and examined by CF and ID tests with *B. dermatitidis*, *C. immitis*, and *H. capsulatum* antigens to detect increases in CF titer specific for infection by one of the endemic fungi or to detect the development of precipitin bands diagnostic for blastomycosis, histoplasmosis, or coccidioidomycosis. IDTP antibodies may not be detected in immunosuppressed patients with disseminated coccidioidomycosis (1). False-positive IDTP reactions

have been reported to occur in 15% of sera obtained from cystic fibrosis patients in the absence of a positive culture for *C. immitis* (26). A positive IDTP test can also rarely indicate the presence of chronic pulmonary cavities. Although infrequent, a positive result using CSF in the IDTP test indicates the presence of acute meningitis. IDTP reactive antibodies may also occur in cases of disseminated coccidioidomycosis; 347 (48%) of 722 patients with disseminated infections demonstrated reactivity to this antigen, and in some cases, patient sera were reactive for up to several years (131). Persistence of IDTP reactive antibodies (along with positive CF titers) may therefore be an indication of disease severity.

IDCF

Observation of a band of identity in the IDCF assay is presumptive evidence that the patient from whom the test serum was obtained had recent or chronic coccidioidomycosis. IDCF reactive antibodies can usually be detected within 2 to 6 weeks after onset of symptoms. Cross-reactivity has been reported to occur when serum from patients infected with other fungi is used but not when serum from patients with cystic fibrosis is used. Occasionally, a band of nonidentity may be observed very close to the ID well containing the patient's serum. This band may represent the presence of reactive IgM antibodies; in such cases, the IDTP test should be performed. Serum or other body fluids may be tested unconcentrated and without prediffusion in ID wells, but the sensitivity of the qualitative test is improved and becomes greater than that of the CF test by concentration and prediffusion; concentration of CSF may result in the detection of IgG in CSF in the absence of meningitis. Although the IDCF test is generally not performed as a quantitative test, it can be used in this manner after serial dilution of patient serum to obtain an endpoint titer. Titers obtained by using the quantitative IDCF test are not identical to titers obtained from the CF test, but the observed trends are comparable (titers of each will rise or fall in parallel). Results using specimens collected longitudinally may show differences in the intensity of bands or in banding patterns which have prognostic value. On the other hand, IDCF reactive antibodies may not be detected in immunosuppressed patients with disseminated coccidioidomycosis (1).

Test 2. LA Test To Detect Antibodies to *Coccidioides* Species

The LA test is a qualitative slide agglutination assay using *C. immitis* TP antigen-coated latex particles to detect antibodies to *C. immitis*. Antibodies to *C. immitis* present in patient specimens bind to the antigen-coated latex particles, resulting in visible clumping (1+ to 4+ agglutination). Results are graded according to the level of agglutination observed for a particular dilution of serum. The assay measures predominantly IgM antibodies and therefore is used to diagnose early coccidioidomycosis. The assay is rapid and simple to perform, and no special equipment is needed. However, false-positive results can occur (>5%), making it necessary to confirm any positive results with the IDTP and/or CF tests (107). Commercial sources are listed in Table 1 and at the end of the chapter.

Sample Requirements

Blood should be collected into tubes that contain no anticoagulant since anticoagulant can interfere with test performance. Serum must be heat inactivated at 56°C for 30 min before being tested. The LA test should not be applied to CSF or to diluted sera, because false-positive reactions have been reported. Test performance using pleural, joint, or ascitic fluid is unknown. Specimens can be held at 2 to 8°C for up to 72 h before being tested but must be placed at −20°C or colder for long-term storage. Specimens should not be stored in frost-free freezers because repeated freezing and thawing can affect test results.

Materials and Reagents

This test uses latex particles sensitized with coccidioidin that has been heated at 60°C for 30 min (TP antigen). All reagents including sensitized latex particles, positive control serum (from goats or rabbits immunized with *C. immitis*), and negative control serum (normal goat or human serum) can be obtained commercially from Immuno-Mycologics, Inc., or Meridian Diagnostics, Inc. Disposable glass slides with raised rings for the performance of the test are also supplied with the kits from Immuno-Mycologics, Inc.

Equipment

100- and 20-μl pipettes
Clinical rotator (optional)
Timer
Applicator sticks
Fluorescent or natural light source

Procedure

1. Add 25 μl of latex-positive control, negative control, and each undiluted specimen into separate rings on the glass slide.
2. Add 1 drop of optimally diluted sensitized latex particles into each ring.
3. Using separate applicator sticks, thoroughly mix the contents of each ring.
4. Rotate the slide by hand or place on a rotary shaker and rotate at 100 ± 25 rpm for 10 min at room temperature.
5. Immediately examine the slide, macroscopically, over a dark background, for signs of agglutination.

QA/QC

A positive and negative control must be run in parallel with test samples during the initial screening phase but are optional for the titration phase of the test. The LA test can not be used as a quantitative test because false-positive results have been reported with diluted sera. Additional QA/QC practices for the LA test include the following: (i) the latex-positive control must demonstrate 2+ or greater agglutination; (ii) the negative control must demonstrate less than 1+ agglutination; and (iii) periodically, the sensitivity of the latex reagent should be tested by titration of the positive control (i.e., the positive control should give an agglutination result of 1+ at a 1:4 dilution ± one dilution to be satisfactory for use). Agglutination is graded as follows: negative, a homogeneous suspension of particles with no visible clumping; 1+, fine granulation against a milky background; 2+, small but definite clumps against a slightly cloudy background; 3+, large and small clumps against a clear background; and 4+, large clumps against a clear or very clear background. Freezing of the latex particle suspension should be avoided since this can result in granularity leading to false-positive results. Materials should not be allowed to dry on the slide.

Interpretation

Agglutination of 2+ or greater is considered to be a positive test result indicating early or primary coccidioidomycosis,

and agglutination of less than 2+ is defined as a negative result. The LA test is more sensitive than the IDTP test but is less specific; 5 to 10% false-positive rates have been reported. Therefore, a positive LA result with undiluted serum or CSF must be confirmed by ID and/or CF testing. The LA test, however, may yield a positive result earlier than the IDTP test. False-negative LA results may occur in specimens from immunocompromised patients. Also, 10 to 30% of individuals with culturally or serologically (CF or ID) positive results may demonstrate a negative or 1+ reaction in the LA test, limiting the test's negative predictive value. Such test negativity is thought to be related to the rapid rise and fall of IgM levels early in infection.

Test 3. CF Test To Detect Antibodies to *Coccidioides* Species

The CF assay, using unheated coccidioidin antigen, detects antibodies predominantly of the IgG subtype. Sera from approximately 98% of patients with disseminated infection are positive in the CF test within 2 to 6 weeks after onset of illness. The CF reactive antibodies typically disappear within 6 months after onset but can persist in disseminated or chronic infection. An advantage to the use of the CF test for the diagnosis of coccidioidomycosis is that it is a sensitive assay which provides quantitative results. Testing serial specimens to detect rising or falling antibody titers can reveal the progression or regression of illness and the response to antifungal therapy. The major disadvantage of the CF assay is that it is a laborious and time-consuming test that requires experienced personnel for optimum performance. No commercial CF test kit is available, but reagents for in-house use can be obtained from the vendors listed in Table 1.

Sample Requirements

The CF test may be performed with serum and CSF. Pleural, peritoneal, and joint fluids (in conjunction with serum) may also be tested when the corresponding anatomical sites are thought to be involved. Concentration of sera before performance of the CF test can be useful in the detection of chronic cases of coccidioidomycosis which might otherwise be missed.

Materials and Reagents

The antigen is prepared as described above for the IDCF test from cultures grown in synthetic asparagine-glycerol-salts medium (67). Because the CF antigen is destroyed by heating at 60°C for 30 min, this antigen should not be heated.

Equipment and Procedures

A microtitration version of the CF test is recommended when serum samples are tested for antibodies. Equipment and procedures for the CF test for the diagnosis of coccidioidomycosis are the same as those for histoplasmosis except that coccidioidin, prepared as described above for the IDCF test, is used instead of *H. capsulatum* antigens (see "Test 1. CF Test To Detect Antibodies to *H. capsulatum*" below). Also, unlike the *H. capsulatum* CF test, CF titers of <1:8 can be significant. Therefore, testing may begin using specimens diluted 1:2, or undiluted, if necessary.

QA/QC

Negative control serum and positive control serum from a human case of coccidioidomycosis (showing a *Coccidioides* CF titer of ≥1:32) should be included each time the CF test is performed. Anti-complementary activity in serum samples can occur (i.e., those showing <75% hemolysis in the serum

control without antigen), and results may be resolved by subsequent ID testing. However, the ID test may not be as sensitive as the CF test, particularly early in infection. Additional QA/QC measures are listed under "Test 1. CF Test To Detect Antibodies to *H. capsulatum*" below.

Interpretation

Sera demonstrating 30% or less hemolysis at a given dilution are considered to be positive at that titer. A CF titer to coccidioidin at any dilution should be considered presumptive evidence for *C. immitis* infection. Sera giving titers of 1:2 to 1:8 in the CF test that are also positive in the IDCF test reflect currently active or recent infection. CF titers of >1:16 generally indicate extrapulmonary dissemination, whereas titers of 1:2 or 1:4 usually indicate early, residual, or meningeal coccidioidomycosis. However, titers of 1:2 and 1:4 have also been obtained when sera from patients without coccidioidomycosis were used. The parallel use of the IDCF test and the CF test can therefore help confirm or refute the significance of low titers. Negative serologic test results do not exclude a diagnosis of coccidioidomycosis. Patients with clinical presentations consistent with coccidioidomycosis, whose sera give negative or low CF titers, should be retested at 3- to 4-week intervals; all sera collected from a given patient at all time points should then be tested in parallel to detect any increases in titer or to detect seroconversion. Approximately 5% of all CSF specimens from patients with coccidioidal meningitis are negative in the CF test. Sera from patients with chronic cavitary coccidioidomycosis may also frequently be negative.

Test 4. EIA To Detect Antibodies to *Coccidioides* Species

The Premier *Coccidioides* EIA (Meridian Diagnostics, Inc.) is a qualitative test to determine the presence of anti-*Coccidioides* IgG and IgM antibodies by using microtiter plates coated with a mixture of purified CF and TP antigens. Antibodies in serum or CSF are detected colorimetrically after addition of peroxidase-labeled, class-specific, anti-human IgM or IgG. The assay detects IgG and IgM antibodies separately, but maximum test sensitivity is achieved by using results from the detection of both IgG and IgM antibodies (Table 1). It is recommended that any positive result in the EIA be confirmed by the ID assay.

Sample Requirements

Serum and CSF are acceptable specimens for use in the Premier *Coccidioides* EIA, but this assay is not recommended for use with other clinical specimens. Heat-inactivated (56°C for 30 min) specimens may be used, but CSF containing blood is not acceptable. Specimens should be tested as soon as possible but may be stored at 2 to 8°C for up to 5 days and frozen at −20°C or colder for longer storage. It is recommended that specimens be divided into single-use aliquots before being frozen in order to avoid repeated freezing and thawing and that samples not be stored in a frost-free freezer.

Materials and Reagents

Reagents provided in the kit include positive control serum (prediluted positive human serum), sample diluent (buffered protein solution which also serves as the negative control), concentrated wash buffer, two enzyme conjugates (peroxidase-conjugated goat anti-human IgM and IgG), urea peroxide, chromogen (TMB), stopping solution (2 N sulfuric acid), and microtiter plates precoated with a mixture of CF

and TP antigens. Microtiter plates are composed of 12 eight-well strips so that the entire plate does not have to be used at one time. Kits are stored at 2 to 8°C and should be brought to room temperature (22 to 25°C) before use.

Equipment

Pipettes or multichannel pipettes, adjustable or fixed, to measure and dispense 10, 20, 100, and 200 µl

12- by 75-mm test tubes for the dilution of samples

Timer

Manual or semiautomatic plate washer

Microplate reader equipped with a 450-nm filter

Procedure

A detailed stepwise procedure can be found in the package insert included with each kit. Briefly, specimens are diluted (serum, 1:441 [vol/vol]; CSF, 1:21 [vol/vol]) with the diluent provided in the kit before being added to the antigen-coated microtiter plate wells. Plates are incubated for 30 min at 22 to 25°C before being washed three times with buffer. Each of two peroxidase-conjugated detector antibodies is then added, in parallel, to separate wells of the microtiter plate (one conjugate detects IgM, and one detects IgG). Plates are incubated for an additional 30 min at 22 to 25°C and washed as above, and substrate solution is added to each well. Plates are then incubated for 5 min before addition of the stopping solution. Plates are read spectrophotometrically at 450 nm or at 450/630 nm, if a dual-wavelength plate reader is available.

QA/QC

Positive and negative controls must be included each time the test is performed and are included in the kit. Positive control samples should have a definite yellow color and absorbance values between ≥0.500 and ≤2.500 for each of the IgM and IgG conjugates. Negative control (sample diluent) values should be below 0.100 for both conjugates when samples are blanked on air (A_{450}) or below 0.050 when read on a dual-wavelength plate reader. If control sample results are outside of the required ranges, the assay should be repeated.

Interpretation

Absorbance values of ≥0.200 are considered positive, and values of <0.150 are considered negative. Specimens with absorbance values between 0.150 and 0.199 are defined as indeterminate, and testing must be repeated. A new specimen should be obtained from any patient whose original specimen gives repeatedly indeterminate results. Because the test uses a mixture of TP and CF antigens to coat microtiter plate wells, it does not distinguish between antibodies reactive to one antigen or the other. The kit may be used to detect reactive antibodies of a single class (IgG or IgM); however, optimum test sensitivity is obtained by using results for both Ig classes. Attempts to operate the Premier *Coccidioides* EIA as a quantitative test have not given results that correlate precisely with titers obtained by the conventional CF test. Nonetheless, the EIA has been used as a qualitative test in a series of evaluations and has been demonstrated to have an estimated sensitivity of 95 to 100%, a specificity of 96 to 99%, and positive and negative predictive values of >95% (68, 92, 170). The EIA, however, is not absolutely specific, since some sera from patients with blastomycosis or from patients with noncoccidioidal disease gave false-positive results. Therefore, positive EIA test results should be confirmed by IDTP and IDCF assays. The standard CF test should be employed in cases where there is concern about possible extrapulmonary dissemination (61).

Experimental and Molecular Biological Approaches

The component of coccidioidin to which CF antibodies react is a 110-kDa protein that has been further identified as a chitinase (60, 171). Incorporating a recombinant form of the chitinase into an EIA format resulted in a test that was shown to be 96% sensitive and 100% specific for the detection of coccidioidal antibodies (61). A recombinant 190-amino-acid peptide was also examined in an EIA format and found to detect 95% of patients with coccidioidomycosis, with no cross-reactivity with serum from histoplasmosis or blastomycosis patients or from healthy subjects.

Galgiani et al. (35) isolated a 33-kDa immunoreactive protein from the walls of mature spherules which appeared to be different from the CF antigen. CSF from patients having suspected coccidioidal meningitis was tested for this antigen in an EIA test format. Of patients with meningitis, 72% yielded a positive result; in contrast, only 1.4% of patients without meningitis reacted positively.

Only a few studies describe the application of molecular methods to clinical materials for the diagnosis of coccidioidomycosis. Sandhu et al. (124) described the use of primers directed to the large (28S) rRNA subunit gene of *C. immitis* to produce PCR amplicons that could then be detected by a slot blot assay. All specimens had been demonstrated by smear or culture results to contain at least one species of fungus. An oligonucleotide probe was designed from *C. immitis* sequences within the 28S rRNA region. In a limited number of clinical specimens, this probe correctly identified *C. immitis* DNA that had been extracted and amplified from sputum or induced sputum but did not cross-react with amplicons derived from specimens containing other fungi (124).

Recently, based on single-nucleotide polymorphisms and differences in the size of microsatellites, the genus *Coccidioides* has been divided into two species: *C. immitis*, representing isolates found in California, and *C. posadasii*, representing isolates found outside of California (32). Accordingly, a nested PCR assay has since been developed to identify *C. posadasii* in paraffin-embedded tissues. The gene encoding Ag2/PRA, an immunoreactive proline-rich antigen specific for *Coccidioides* (9), was employed as the amplification target. All tissue specimens tested were microscopically positive for *Coccidioides* spherules, and all were also demonstrated to be PCR positive. In contrast, no PCR product was obtained from 20 human tissue samples shown to be positive by microscopy or by specific PCR assays for *H. capsulatum*, *P. brasiliensis*, or *B. dermatitidis*.

CRYPTOCOCCOSIS

Background

The *Cryptococcus* LA test to detect capsular polysaccharide in CSF and serum of patients infected with *C. neoformans* is one of the most reliable diagnostic tests in immunomycology. If more objective end points with equivalent sensitivity are desired, an EIA to detect serum and CSF antigen is also commercially available (see "Test 2. EIA To Detect *C. neoformans* Capsular Polysaccharide Antigen" below and Table 2). The EIA requires at least 1 h to perform, in contrast to the few minutes needed to complete the simpler LA test. Both the LA test and the EIA can be used to screen single test

samples so that only positive specimens need to be subsequently subjected to titer determination. Unlike the LA test, for optimum sensitivity and specificity the EIA does not require serum to be heat inactivated or pretreated with pronase to remove immune complexes, nor does it require that CSF be boiled before testing (140, 142). Nonetheless, the LA test remains the most widely used procedure for detecting cryptococcal antigen because it is rapid, very specific, diagnostic, prognostic, and simple to perform. There are multiple commercial sources for LA tests to detect cryptococcal antigen, including those which adsorb latex particles with PAbs (Immuno-Mycologics, Inc., Meridian Diagnostics, and Wampole Laboratories, Inc., Cranbury, N.J.) or MAb (Bio-Rad Laboratories) (Table 2). Results and end-point titers vary among LA tests from different manufacturers, and reagents are not interchangeable. Similar sensitivities were reported for the MAb-based LA test (Pastorex Crypto Plus; Bio-Rad) compared to two PAb-based LA tests (CALAS, Meridian Biosciences, Inc.; Crypto-LA, Wampole Laboratories, Inc.) using sera obtained from patients with culture-confirmed cryptococcosis (142). Unlike the PAb-based tests, the MAb-based LA test is recommended for use with BAL fluid and urine specimens as well as with serum and CSF (142). A murine polyclonal antibody (DakoCytomation, Inc.), directed against the capsular glucuronoxylomannan of *C. neoformans*, is commercially available for the immunohistochemical staining of *C. neoformans* in tissues by IFA.

In addition to antigen detection tests, a TA test to detect antibodies to *C. neoformans* is commercially available (Immuno-Mycologics, Inc.; Table 1). Antibody detection is of value for the diagnosis of cryptococcosis during the early stages of the disease, before antibodies are neutralized by the large amount of capsular antigen released during evolution of infection. Antibodies may subsequently reappear after successful treatment, and it has been suggested that their detection is a favorable prognostic sign. However, cryptococcal antibody detection tests are generally less useful than those for antigen detection.

Clinical Indications and Diagnostic Rationale

Serologic tests to detect *C. neoformans* antigens are an indispensable tool for the rapid diagnosis of pulmonary, meningeal, or disseminated forms of cryptococcosis. The disease may be primary, but many cases are associated with HIV infection or other immunocompromising disorders. Serologic diagnosis for cryptococcosis should be considered for immunosuppressed patients with signs and symptoms of a subacute meningitis or meningoencephalitis. In HIV-infected persons, headache and fever are common but overt neurological symptoms and signs are unusual. In HIV-negative persons, headache is common but fever is often minimal or absent until late in the course of the infection.

Test 1. LA Test To Detect *C. neoformans* Capsular Polysaccharide Antigen

The LA test is a noncompetitive direct-binding slide agglutination test to detect *C. neoformans* antigens in clinical samples by employing latex particles adsorbed with rabbit polyclonal anti-*C. neoformans* antibodies (CALAS; Latex-Cryptococcus antigen test, Immuno-Mycologics; and Crypto-LA) or with mouse anti-glucuronoxylomannan MAb (Pastorex Crypto Plus; Bio-Rad Laboratories). These tests can be used to screen specimens for positivity, and

positive samples can subsequently be diluted serially to obtain an end-point titer (34, 140, 142).

Sample Requirements

Serum and CSF may be used in all commercial tests; serum, CSF, BAL fluid, and urine may be used in the Pastorex Crypto Plus test. Plasma may not be used. A minimum of 0.2 ml of serum or CSF is generally required to perform the test in a qualitative manner, and an additional 0.25 ml may be required to determine serum or CSF titers in a semiquantitative manner. Most kits recommend that sera be pretreated with pronase before being tested since this procedure has been demonstrated to increase the LA titer by 3 to 9 dilutions for 46 (81%) of 57 sera examined (41). Pronase is then inactivated with pronase inhibitor or by boiling. If no pronase pretreatment is recommended by the manufacturer (Wampole Laboratories), test sera should, at a minimum, be heat inactivated at 56°C for 30 min. Negative control sera (normal goat, rabbit, or human serum) should be heat inactivated each time the assay is performed. In contrast, antibody control serum (goat anti-rabbit serum, pronase control) should never be heated.

CSF should be heated in a boiling-water bath for 5 to 10 min as directed by the manufacturer. Pronase treatment of CSF is generally not recommended but was reported to increase LA titers by 2 to 3 dilutions in 14 (20%) of 70 CSF specimens tested (41). BAL fluids should be treated with pronase prior to assay. No anticoagulants should be used in the collection of blood or added to patient test samples prior to use or in preparation for storage. Specimens can be held at 2 to 8°C for up to 48 h before testing but must be placed at −20°C or colder for long-term storage. Specimens should not be stored in frost-free freezers because repeated freezing and thawing can affect test results.

Materials and Reagents

All reagents including sensitized latex particles, sample diluent, positive control serum, negative control serum, pronase reagents (pronase, pronase control, and, in some kits, pronase inhibitor), control latex particles, and glass slides with raised rings (or disposable reaction cards) are supplied with the test kits.

Equipment

Pipettes or multichannel pipettes to dispense 25, 100, and 200 μl

Clinical rotator capable of 140 rpm

Timer

Applicator sticks

12- by 75-mm borosilicate glass test tubes (nonsiliconized)

Water bath or heat block (56 and 100°C)

Fluorescent or natural light source

Procedure

The procedure for the cryptococcal LA test is essentially the same as that described for the *Coccidioides* LA test (see "Test 2. LA Test To Detect Antibodies to *Coccidioides* Species" above), except that (i) specimens are heat inactivated and/or pronase treated to remove immune complexes prior to use; (ii) end-point titer determinations for samples positive in the initial screening are conducted using serial twofold dilutions up to and including 1:1,024 (or higher, if testing determines that the specimen is still positive at the 1:1,024 dilution); and (iii) control latex particles, adsorbed with normal globulin, may be included in the kit.

QA/QC

QA/QC procedures are similar to those for the *Coccidioides* LA test. Latex particles should not be frozen since this can result in granularity, leading to false-positive results; excessive hand rotation during observation may also lead to misinterpretation of results. Different manufacturers' products can give different titers for the same clinical specimen. The reported range in end-point titers among different LA test kits varied from 6 dilutions above to 8 dilutions below those of the most sensitive kit examined, although high-titer results (≥1:256) were in better agreement than were low-titer results (140). Reagents must not be interchanged between kits from different companies or between different lots of kits from the same company.

False-negative reactions may occur as the result of immune complex formation or the presence of rheumatoid factor. Both of these interfering substances can be removed by performing a pronase treatment step or by boiling the specimen for 5 to 10 min before assay. Also, specimens containing a high concentration of cryptococcal antigen may display weak or no agglutination (prozone effect) and should be retested after dilution (1:10 and 1:100) in glycine-buffered saline. Rarely, false-negative results occur when sera from patients infected with acapsular or poorly encapsulated strains of *C. neoformans* are used. Such strains produce insufficient amounts of polysaccharide antigen to be detected and give false-negative results.

False-positive reactions have been reported to occur as the result of inadequate removal of detergent from the surface of the glass ring slides used for the LA test. Detergent can be removed by soaking slides in 10% bleach followed by thorough washing with distilled water. Rare false-positive results may be caused by the presence of contaminating hydroxyethyl starch, by nonspecific reactivity found in the serum of HIV-infected patients, and by cross-reactions with serum from patients infected with *Capnocytophaga animorsus* or *Trichosporon asahii*.

Periodically, the sensitivity of the latex particles coated with anti-cryptococcal globulin should be tested by titration against purified capsular polysaccharide antigen included in the kit. Pronase provided in the kit must be stored frozen in aliquots after initial reconstitution to eliminate exposure to repeated freezing and thawing and subsequent loss of enzyme activity. Also, at least once per month, an aliquot of frozen pronase should be examined for proteolytic activity by testing, in parallel, goat anti-rabbit globulin (PAb-based systems) or goat anti-mouse globulin (MAb-based systems) that have and have not been pronase treated before use. The untreated pronase control must demonstrate agglutination of 2+ or greater and the pronase-treated control must demonstrate agglutination of less than 1+ in the reaction.

Interpretation

The LA test to detect *C. neoformans* antigen has both diagnostic and prognostic value. A positive LA reaction at a titer of 1:4 or less using CSF, serum, or urine from an untreated patient is suggestive of cryptococcal infection, whereas titers of 1:8 or greater usually indicate active cryptococcosis (strong presumptive evidence). Antigen is detected in the CSF of over 90% of patients with untreated meningeal cryptococcosis. On the other hand, a negative serum antigen test result does not exclude a diagnosis of cryptococcosis, particularly if only a single specimen has been tested and the patient continues to have symptoms consistent with cryptococcal infection.

In HIV-negative patients, the antigen titer is usually proportional to the extent of infection, and increasing titers reflect progressive infection and a poor prognosis. Declining titers, on the other hand, generally indicate a favorable response to chemotherapy and progressive recovery; failure of the titer to fall during therapy suggests inadequate treatment. High initial titers of antigen (1:1,024 or greater) in the serum or CSF prior to treatment indicate a poor prognosis, and high titers at the end of treatment often predict later relapse. In contrast, HIV-positive patients may manifest elevated titers that decline very slowly even in the face of clinical improvement, whereas an unchanged or increased titer in the CSF of these patients is often associated with clinical and mycological failure to respond to treatment. Positive CSF antigen tests, despite no recovery of viable *C. neoformans* from the CSF, may indicate persistent release of capsular antigen from dead as well as from living cells or may indicate slow elimination of capsular antigen from the CSF rather than ongoing infection.

Test 2. EIA To Detect *C. neoformans* Capsular Polysaccharide Antigen

The Premier Cryptococcal Antigen test (Meridian Diagnostics, Inc.) is a double-antibody sandwich EIA for the detection of cryptococcal polysaccharide antigen in patient serum and CSF. Rabbit polyclonal anti-*C. neoformans* antibodies, adsorbed onto the surface of microtiter plate wells, are used to capture cryptococcal polysaccharide antigen found in the serum and CSF of patients with cryptococcosis. Peroxidase-labeled detector MAbs are applied, and plates are read visually or spectrophotometrically after the addition of peroxide and a colorimetric substrate. The EIA can be used as a screening test or as a semiquantitative test after titration of test samples to monitor the disease course and response to drug therapy. Its sensitivity has been reported to be equivalent to or somewhat better than that of the LA test produced by the same manufacturer, and it requires no pretreatment of specimens to remove complement, immune complexes, or rheumatoid factor (34, 140) (Table 2). The EIA is not subject to prozone effects and has also been reported to detect cryptococcal antigen earlier, and at lower concentrations, than does the LA test (34). LA titers and EIA titers are not equivalent but generally follow the same trend (i.e., both titers increase and decrease in parallel).

Sample Requirements

Serum and CSF samples may be tested, but urine may not be tested. Sample preparation of CSF and serum for the EIA consists only of centrifugation to remove any cells or other particulate matter. Pretreatment of specimens is not recommended by the manufacturer. However, samples that have previously been pronase or heat treated (56°C for 15 min) do not appear to be adversely affected and may be used in the screening assay. In contrast, pronase- or heat-treated samples should not be tested in the semiquantitative test mode since such treatment may alter EIA titration results. Therefore, it is recommended that all serial specimens from a given patient be pronase or heat treated in the same manner and that all samples be assayed in parallel when monitoring patients for disease changes or response to drug therapy; earlier specimens collected as part of these series should be aliquotted and frozen if stored for longer than 72 h at 2 to 8°C.

Materials and Reagents

All reagents are provided in the kit, including cryptococcal antigen (positive control), sample diluent (buffered protein solution which also serves as the negative control), concentrated wash buffer, enzyme conjugate (peroxidase-conjugated

mouse anti-cryptococcal antigen-specific MAb), urea peroxide, chromogen (TMB), stopping solution (2 N sulfuric acid), and microtiter plates precoated with rabbit polyclonal antibodies specific for cryptococcal antigen. Microtiter plates are composed of 12 eight-well strips so that the entire plate does not have to be used at one time. Kits are stored at 2 to 8°C and should be brought to room temperature (20 to 30°C) before use.

Equipment

The equipment required to perform the EIA is the same as that for the Premier *Coccidioides* EIA (see "Test 4. EIA To Detect Antibodies to *Coccidioides* Species" above).

Procedure

The EIA can be performed in one of two modes: (i) as a screening assay, designed solely for the differentiation of positive from negative specimens, and (ii) as a semiquantitative assay to monitor relative changes in antigen levels in serum and CSF for the evaluation of patient progress and to monitor the efficacy of drug therapy. Whereas the screening assay examines a patient specimen at a single concentration (undiluted) at a single time point, the semiquantitative assay requires analysis of a series of specimens collected longitudinally, serially diluted to obtain an end-point titer for each. Values obtained using the screening assay may not be used to calculate an EIA titer. A detailed stepwise protocol can be found in the package insert included with each kit for both the screening assay and the semiquantitative assay.

Screening assay. Briefly, the screening assay is performed by placing the test specimen and positive and negative control samples into the bottom of separate microtiter plate wells, which are then incubated at ambient temperature for 10 min. The plates are washed between each step. Enzyme conjugate is added, and the plates are incubated again at ambient temperature for 10 min. Substrate is added, and the plates are incubated as above before addition of the stop solution and performance of visual or spectrophotometric reading at 450 nm (or 450/630 nm for dual-wavelength plate readers). Results are interpreted as follows. (i) For visual reading: negative, colorless well; positive, definite yellow color in well; (ii) for spectrophotometric reading with a single wavelength (OD_{450}): negative, <0.100; indeterminate, ≥0.100 and <0.150; positive, ≥0.150; and (iii) for spectrophotometric reading with a dual wavelength ($OD_{450/630}$): negative, <0.070; indeterminate, ≥0.070 and <0.100; positive, ≥0.100. Tests giving indeterminate results should be repeated; if the results are still indeterminate, a second specimen should be obtained and tested. Extremely strong reactions may produce a purple precipitate, but these samples are considered to be positive.

Semiquantitative assay. Five serial 1:5 dilutions of patient serum or CSF, beginning with a 1:2 dilution, are produced as follows: 1:2, 1:10, 1:50, 1:250, and 1:1,250 (further 1:5 dilutions may be carried out, if needed, to reach an end point). A positive antigen control and a negative control (reagent blank) are included on each test plate. Incubations with patient specimens and, after aspiration and washing, with conjugate are carried out for 10 min each at ambient temperature. Results are read spectrophotometrically at OD_{450} or $OD_{450/630}$. In instances where samples are read with a single-wavelength plate reader at OD_{450}, values for the negative control (sample diluent) must be subtracted from all OD_{450} values before calculation of the EIA titer. The results are analyzed as follows: (i) the highest OD_{450} value for a given sample that falls within the acceptable range (between 0.1 and 1.5) is identified, (ii) that serum dilution is multiplied by 10, and then (iii) the resulting number is multiplied by the OD value (e.g., if the test specimen gave an OD_{450} of 1.20 at the 1:50 dilution, the EIA titer would be $1.2 \times 50 \times 10 = 600$ or 1:600). These titers are not numerically equivalent to LA titers.

QA/QC

All reagents must be mixed gently and be at ambient temperature before use. Unused microwells must be placed back inside the foil ziplock pouch provided and sealed immediately to protect it from moisture. Inadequate plate washing may cause elevated background OD readings.

Interpretation

If the 1:2 dilution of the specimen yields an OD of <0.100, the assay should be repeated using undiluted samples. A positive test for undiluted serum is defined as one giving an OD_{450} of ≥0.15, provided that normal human serum gives a negative result when tested in parallel (undiluted). A negative result does not preclude a diagnosis of cryptococcosis, especially if only a single specimen has been tested and if the patient shows symptoms consistent with the disease. The sensitivity of the EIA was reported to be 93% for serum and 100% for CSF (140), whereas the specificity of the EIA was reported to be 97% (127).

Test 3. TA Test To Detect Antibodies to *C. neoformans*

A semiquantitative TA test is available commercially (YA-*Cryptococcus* antibody tube agglutination system; Immuno-Mycologics, Inc.) to detect anti-*C. neoformans* antibodies in the serum of patients with cryptococcosis. A standardized suspension of formalin-killed, small-capsule *C. neoformans* cells is mixed with an equal volume of serially diluted patient serum. The end-point titer is the highest serum dilution at which any agglutination is observed.

Sample Requirements

The test is performed only with serum. The specimen must not contain anticoagulants since these can interfere with the agglutination reaction. Sera should be heat inactivated at 56°C for 30 min before being tested. Specimens and reagents should not contain any particulate matter (except for the cryptococcal yeast antigen, which contains a suspension of *C. neoformans* yeast cells) and should show no signs of contamination. Specimens may be processed immediately, stored at 2 to 8°C for up to 48 h before being tested, or stored frozen at −20°C or below for longer periods.

Materials and Reagents

All reagents for the TA test are supplied by the manufacturer, including a standardized ($OD_{550} = 0.02$) suspension of formalin-killed *C. neoformans* yeast cells, specimen diluent (10× glycine buffer, pH 8.6, containing albumin), positive antibody control (lyophilized rabbit anti-*C. neoformans* antibodies), and a negative control (normal goat serum).

Equipment

Water bath (37 and 56°C)
Concave reading mirror

Procedure

1. Make twofold serial dilutions of the test serum (from 1:2 to 1:64) in 12- by 75-mm test tubes.

2. Place the mixture on a rotary shaker for 2 min.

3. Incubate mixtures at 37°C for 2 h, and then place in the refrigerator at 4°C for an additional 72 h, during which time readings are taken at 24-h intervals.

4. Examine tubes individually for agglutination by gentle tilting to allow the fluid to swirl the sedimented antigen (do not shake tubes).

5. Examine tubes for agglutination while tilting them over a concave mirror.

Reactions are graded as follows: negative, smooth suspension with no clumping; 1+, slight clumping; 2+, moderate clumping; 3+, moderate and large clumps; and 4+, large clumps.

QA/QC

Positive and negative controls must be included each time the test is performed and should be read first. The positive antibody control must give a 2+ reaction at a dilution of 1:4, and the negative control must not demonstrate any agglutination. If the control reagents do not perform properly, the test must be repeated. It is recommended that clean, disposable, borosilicate glass tubes be used for the test.

Interpretation

If no agglutination occurs at any serum dilution from 1:2 to 1:64, the result is negative. However, if agglutination occurs at any serum dilution, the test is reported as positive and the titer is reported as the highest specimen dilution with any degree of agglutination. A positive result (agglutination titers of 1:2 or greater) is presumptive evidence for recent or past infection with *C. neoformans* but may also indicate the presence of cross-reacting antibodies to *H. capsulatum* or *B. dermatitidis*. Titers of ≥1:16 are rarely observed. The presence of antibody in a single serum specimen is not diagnostic since most individuals are exposed to *C. neoformans* and become seropositive at an early age. In most instances, diagnosis using an antibody assay requires obtaining a second convalescent-phase serum sample 3 to 4 weeks after the first specimen in order to observe seroconversion or a fourfold or greater increase in serum titer. Antibodies may be detected early in disease or in localized infections. As disease progresses, capsular polysaccharide antigen is produced and released into body fluids, with concurrent complex formation or neutralization of antibody. Antibodies may reappear after successful treatment, and it has been suggested that their detection is a favorable prognostic sign. In immunocompetent patients, effective chemotherapy results in a decline in the antigen titer and antibodies may be detected. Therefore, concomitant use of antigen detection tests in addition to antibody detection tests is recommended for optimal detection of cryptococcal infection. Sera from approximately 50% of patients with active extrameningeal cryptococcosis are positive in the TA test, and the test has been reported to have a specificity of about 89%.

Experimental and Molecular Biological Approaches

A limited number of molecular biology-based tests to detect cryptococcal DNA in clinical specimens have been developed in an attempt to increase the sensitivity of diagnosis and to provide a tool for monitoring disease progression and therapeutic response. Initial studies conducted by Sandhu et al.

used the same methods as those described for the detection of *C. immitis* DNA (124). In this instance, *C. neoformans* DNA was extracted from tissue or CSF of patients with smear- or culture-confirmed cryptococcosis. A probe designed to detect the A serotype was found to correctly identify *C. neoformans* DNA in clinical specimens and did not cross-react with DNA extracted from specimens positive for *A. fumigatus, C. albicans,* or *C. immitis* (124).

Rappelli et al. (117) used primers directed to the ITS rRNA gene region to amplify *C. neoformans* DNA from the CSF of AIDS patients with acute cryptococcal meningitis. All 21 culture-confirmed cryptococcal meningitis cases (100%) were correctly identified by this test, and no PCR amplicons were obtained when CSF from 19 of 19 patients with viral or bacterial meningitis or cultures of other fungi known to cause meningitis was used. In addition, six specimens each of serum and CSF were collected from a single patient over a 5-month period to monitor the results of the PCR assay during anticryptococcal therapy. The nested PCR assay became negative at the time that India ink and culture results became negative (suggesting that the PCR assay may be useful for monitoring patient response to therapy.

A PCR method for the diagnosis of pulmonary cryptococcosis in HIV-negative patients was reported to detect four of five culture-positive specimens by using nested PCR primers (139). The sensitivity may have been reduced in this assay because PCR primers were directed to a single-copy gene target (*URA5*) rather than to a multicopy gene target. The specificity of the test, however, was 100% (10 of 10 culture-negative specimens were also PCR negative).

HISTOPLASMOSIS

Background

In the absence of culture or microscopic evidence of infection, the primary methods used to diagnose histoplasmosis are the CF, ID, and LA antibody detection tests and an EIA to detect *H. capsulatum* antigen. The CF microtitration procedure (105) yields information of both diagnostic and prognostic value. Over 90% of patients with culture-proven histoplasmosis are positive by the CF test if serum is collected and tested at 2- to 3-week intervals during infection. Therefore, the major advantage of the CF test is that it provides a quantitative measurement of the amount of antibody present in the test specimen. The titer for a given specimen can then be compared to the titer obtained by using a subsequent specimen to assess disease progression, or the efficacy of treatment, as measured by the respective increase or decrease in antibody titer. The major disadvantages of the CF test are as follows: (i) it is a relatively complex, labor-intensive assay that should be performed by only highly trained technical staff; (ii) accuracy depends on constant, complex quality control standardization or titration of test reagents (hemolysin, complement, sheep erythrocytes) each time a new lot of reagent is obtained; and (iii) specimens may possess anticomplementary activity (i.e., patient serum fixes or destroys complement in the absence of any added antigen), making test results indeterminate.

The CF assay for the diagnosis of histoplasmosis uses two different target preparations for the detection of anti-*H. capsulatum* antibodies: "histoplasmin," a soluble filtrate of mycelial-phase broth cultures (containing the H and M antigens), and *Histoplasma* yeast antigen, a suspension of merthiolate-killed, whole yeast-form cells. The CF assay is more sensitive (82% versus 21%) but less specific (88% versus

99%) when yeast cells rather than mycelial antigens are used. Antibodies to the yeast cells are usually the first to appear after infection and the last to disappear after the resolution of infection. However, antibodies produced during infection by other fungi, including those produced during infection by *C. immitis* or *B. dermatitidis*, as well as during some bacterial infections, such as tuberculosis, may react with the yeast antigen and give false-positive results (159). Antibodies to the yeast antigen usually appear within 4 weeks after exposure, whereas antibodies to the mycelial antigen occur later and have titers which are considerably lower.

The immunodominant antigens detected in the histoplasmosis ID test are referred to as the H and M antigens of *H. capsulatum* (45, 163). Precipitins against M antigen are the first to appear in acute pulmonary histoplasmosis and form the basis of an early presumptive diagnosis. H precipitins occur later and less frequently, and their presence is stronger evidence for recent infection. H bands rarely occur without the presence of an M band. Conversion from no bands to the presence of an M or H band is strong evidence for recent infection (seroconversion). Patients with extrapulmonary disseminated disease frequently exhibit H precipitins together with M precipitins. The ID test is generally less sensitive than the CF test, particularly early in infection, but is generally more specific. Because of this enhanced specificity, the ID test provides a more accurate diagnosis than the CF test, particularly in cases where sera display CF cross-reactivity to other fungal diseases. The ID test may also help to resolve the diagnosis in cases where the CF results are made uninterpretable by anti-complementary activity in the test sample.

The histoplasmosis LA test is a rapid, semiquantitative test that uses latex particles sensitized with histoplasmin for the detection of agglutinating antibodies against *H. capsulatum*. This assay measures predominantly the IgM subclass of antibodies and therefore is most useful in the early diagnosis of acute histoplasmosis. A positive LA test can be obtained as early as 2 to 3 weeks after exposure and has been reported to have an overall sensitivity (including both acute and chronic forms of the disease) of 62% and a specificity of 97% (48).

The HPA test is a colorimetric double-sandwich enzyme immunoassay that uses polyclonal rabbit antisera as both the capture and detector antibody (162). The antigen detected is poorly defined but is thought to be a polysaccharide based on its stability to heat (100°C for 30 min) and its reduced reactivity after passage through a concanavalin A affinity column (43, 119). Antigen can be detected very early in disease (during the first 2 weeks after the onset of symptoms), and then its level rapidly declines in self-limited disease. It can be detected for longer periods in cases of disseminated disease. The EIA has a reported sensitivity of 14, 75, and 92% for the detection of chronic pulmonary, acute pulmonary, and disseminated disease, respectively. Significant EIA cross-reactivity has been reported for the other endemic mycoses, particularly blastomycosis, paracoccidioidomycosis, and penicilliosis marneffei.

Clinical Indications and Diagnostic Rationale

Serologic tests for histoplasmosis should be applied to clinical specimens (serum, plasma, peritoneal fluid, CSF, or urine) from patients with respiratory illness, hepatosplenomegaly, signs of extrapulmonary systemic infection, or meningeal involvement. The patient's residence, travel, and occupation history is useful as a guide to the application of these tests. The CF test is very sensitive, but the current incorporation of unpurified antigens reduces test specificity. Cross-reactions may occur with sera from patients with blastomycosis,

coccidioidomycosis, and other mycoses. Sera from patients with leishmaniasis may cross-react in the CF test with *H. capsulatum* yeast-form antigens. It is generally recommended that both the ID as well as the CF test be applied to obtain maximum sensitivity and specificity. Use of the histoplasmosis ID and CF tests in parallel, with histoplasmin as the antigen, results in an overall sensitivity of approximately 85%. The CF and ID tests are also useful in diagnosing meningitis caused by *H. capsulatum* (99).

The histoplasmosis LA test is satisfactory for the detection of acute primary infections but may yield negative results for sera from persons with chronic histoplasmosis (48). It is particularly valuable in the detection of early disease. Because of the transitory nature of the agglutinins, the LA test cannot be considered a replacement for the CF test.

The EIA to detect HPA in urine and serum is useful for diagnosing disseminated histoplasmosis, particularly in AIDS patients (161). Antigen detection is less effective in diagnosing histoplasmosis in immunocompetent patients with self-limited disease or in cases of chronic pulmonary disease (162). Although less sensitive for the diagnosis of primary disease than disseminated disease, the test can be useful in the early stages of acute pulmonary disease (first 3 to 4 weeks after onset), permitting appropriate therapy to be initiated sooner. The use of urine as the test specimen has increased sensitivity (95%) compared to serum (85%) for the diagnosis of disseminated histoplasmosis. Recently, new procedures have been implemented which are reported by the manufacturer to give increased test sensitivity and specificity compared to the original test, primarily by the removal of human anti-rabbit IgG reactivity (www.miravistalabs.com). However, clinical evaluations to determine the overall test sensitivity and specificity after treatment to remove the antiglobulin activity have not yet been published.

Test 1. CF Test To Detect Antibodies to *H. capsulatum*

The standardized microadaptation of the CDC Laboratory Branch CF test with both *H. capsulatum* yeast-form and histoplasmin antigens is recommended for the determination of titer in sera from persons with suspected histoplasmosis. Because of the complexity of the procedure, only an abbreviated description of the CF test is outlined below. Readers are directed to a more detailed protocol (105) or a modified version, available from Immuno-Mycologics (www.immy.com), for use with their reagents. No commercial kits are available for the CF test, but antigens, antisera, and other reagents can be purchased individually from the commercial sources listed below and in Table 1. Detailed vendor information can be found at the end of this chapter.

Sample Requirements

Serum, peritoneal fluid, or CSF may be used in the CF test. Serum is most often tested in suspected cases of acute pulmonary histoplasmosis. CSF may be used to detect localized antibody production during *H. capsulatum* meningitis. Other body fluids are examined in cases of suspected disseminated disease. Acute-phase sera should be obtained after the onset of symptoms, and convalescent-phase sera should be collected 4 to 6 weeks later to identify changes in titer compared to the titer obtained for the acute-phase sera. Serum should be obtained from clotted blood collected into tubes without anticoagulants. Whereas excessively pigmented specimens must not be used, slightly pigmented specimens may be used because the color will be diluted out during the titer determination process and will therefore not interfere

with test interpretation. Lipids should be removed with a 0.45- to 0.8-μm filter attached to a syringe (Millipore Corp.). CSF should be centrifuged before being tested, to remove any red or white blood cells. Sera and CSF are heated at 56°C for 30 min immediately prior to use to inactivate endogenous complement activity. Serum and CSF can be stored at 4°C for 72 h or stored for longer periods in frozen aliquots at −20°C or colder in a nondefrosting freezer. Repeated freezing and thawing of the samples, which can reduce reactivity, should be avoided.

Materials and Reagents

Two antigens are used in the CDC Laboratory Branch CF test: one is a suspension of merthiolate-killed, intact, yeast-form cells of *H. capsulatum*, and the second is a soluble, mycelial culture filtrate antigen, histoplasmin. Histoplasmin is produced by harvesting and filtering the supernatant from *H. capsulatum* cultures grown at 25°C for approximately 4 to 5 weeks in Smith's synthetic asparagine broth on a gyratory shaker at 150 rpm (78). The optimal dilution for each antigen is determined by a block titration against low- and high-titer positive human sera. These antigens may be purchased from Immuno-Mycologics, Inc., or from Meridian Diagnostics, Inc., in either prediluted or concentrated form. Other key materials, listed below, may be purchased from vendors that sell biological products (e.g., Cambrex Bio-Science,Walkersville, Md.; Rockland Immunochemicals, Inc., Gilbertsville, Pa.; TCS Biosciences Ltd., Buckingham, United Kingdom; and Colorado Serum Company, Denver, Colo.).

Equipment

pH meter
Centrifuge with microtiter plate carriers
Incubator (37°C)
Glass serologic tubes (15 by 125 and 12 by 75 mm)
Pipettes (1, 5, and 10 ml)
Water bath or heat block (37 and 56°C)
Refrigerator
Microtiter equipment
• 25- to 50-μl multichannel pipetter
• U-bottom polystyrene microtiter plates
• Reading mirror (concave, ×1.5 magnification)

Procedure

Reagent preparation and standardization

1. VBD. Dilute a 5× stock solution of VBD to 1× with 0.05% gelatin solution (see item 2 below) and use this throughout the test procedure as a reagent diluent. The pH of the 1× solution must be between 7.3 and 7.4; if it is not, prepare new 1× buffer from the 5× stock. Do not adjust the pH of the 1× buffer. If the pH of the 1× buffer is continually out of range, obtain new 5× buffer. Keep the VBD on ice during the assay. The shelf life of 1× VBD is 24 h at 4°C.

2. Gelatin solution. Make a 0.05% (wt/vol) solution of gelatin in deionized H$_2$O, and heat to 100°C; allow it to cool to room temperature, and use it to dilute 5× VBD to 1×.The shelf life of the solution is 7 days at 4°C.

3. SRBC, supplied in Alsever's solution. SRBCs must be washed three times with 1× VBD by gentle centrifugation on the day the CF test is to be performed (final working concentration, 2.8% [vol/vol] in 1× VBD). If after three consecutive washes red pigment remains, the SRBC are too old and too fragile for use. A fresh lot of SRBCs should be

obtained (SRBCs should be between 5 and 28 days old at the time of use). The shelf life of the stock SRBCs in Alsever's solution is 1 month, whereas the shelf life of washed and diluted SRBCs in 1× VBD is 24 h.

4. Hemolysin. Hemolysin (complement-fixing, anti-SRBC antibody) is used to "sensitize" (i.e., coat with antibody) the SRBCs, allowing them to be lysed in the presence of complement. To determine the optimal concentration of hemolysin for the sensitization of the SRBCs, serially dilute hemolysin in 1× VBD in 15- by 125-mm glass tubes (1:1,500, 1:2,000, 1:2,500, 1:3,000, 1:4,000, and 1:8,000) and titrate it against multiple dilutions of guinea pig complement (1:300, 1:350, 1:400 [see item 5 below]). After adding SRBCs and incubating them in a water bath at 37°C for 1 h, centrifuge tubes and determine the percent hemolysis in each tube by comparison to a standard curve (color standards) constructed from differing proportions of hemoglobin and 0.28% SRBCs (percent lysis = 0, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 100). Plot the percent hemolysis against the hemolysin dilution, and identify the second dilution on the plateau of the graph. This hemolysin dilution is optimum to sensitize SRBCs for complement titration, antigen titration, and serum tests. Hemolysin must be titrated each time a new lot of SRBCs or hemolysin is obtained. The shelf life of the stock hemolysin (a 1:100 dilution of hemolysin in VBD containing 0.2% phenol) at 2 to 8°C is up to 1 year.

5. Guinea pig complement. Reconstitute guinea pig complement into single-use glass vials, and freeze at −70°C until ready to use. Storage in plastic vials will cause a reduction of complement activity over time. The complement must be subjected to titer determination before each use. Once determined, the optimal dilution must then sit on ice for 20 min and be used within 2 h. Titer determination must be done using sensitized, standardized SRBCs prepared as described in item 6 below. Serially dilute complement in 12- by 75-mm glass test tubes with VBD (1:200, 1:250, 1:300, 1:350, and 1:400) and add 0.20, 0.25, 0.30, and 0.40 ml of each complement dilution to 0.60, 0.55, 0.50, and 0.40 ml of VBD, respectively. Then add 0.20 ml of sensitized SRBCs to the tubes, shake the mixture, and incubate the tubes in a 37°C water bath for 30 min (shake again after 15 min and return the tubes to water bath). Remove the tubes, and centrifuge the cells. Determine the percent hemolysis compared to the color standards, and calculate the ratio of lysed to unlysed cells (lysis ratio = lysed/[100 − lysed], i.e., 10/[100 − 10] = 0.111). Using log-log graph paper, plot the volume of complement added to the tubes (0.20, 0.25, 0.30, and 0.40) against the lysis ratio. Two of the lysis ratio values must be less than 1, and two must be greater than 1. With a ruler, join the two points plotted for the two lowest volumes of complement and do the same for the two highest volumes. Draw a line connecting the midpoint of one line to the midpoint of the other line. From the point where this line intersects the vertical 1 line on the *x* axis, draw a horizontal line to the *y* axis on the left. This is the volume, in milliliters, that contains one 50% hemolytic unit of complement (1 CH$_{50}$ unit). Multiply this value by 5 to obtain the equivalent of 5 CH$_{50}$ units.

6. Sensitized SRBCs. Once the optimum concentration of hemolysin has been determined (see item 4 above), slowly add an equal volume of SRBCs with swirling. Incubate the mixture for 15 min in a 37°C water bath before use.

CF test

1. All reagents (hemolysin, complement, SRBCs, and VBD) must be optimally standardized as described above

before the test is used with patient samples or the positive control.

2. Using cold VBD, prepare a 1:8 dilution of the following samples in 12- by 75-mm glass test tubes: patient sample, positive control, and negative control. Samples may also be diluted 1:2 instead of 1:8 or may be diluted more than 1:8 during repeat testing to detect lower or higher antibody titers, respectively.

3. Heat the diluted sera for 30 min in a 56°C water bath, and cool to room temperature.

4. Label the microtiter plates as shown in Fig. 2.

5. Pipette 25 µl of cold VBD into the wells of rows B to H of columns 1 to 12 of the patient plate(s) (Fig. 2A) and columns 1 to 9 of the control plate (Fig. 2B).

6. Add 50 µl of heat-inactivated patient sera to wells 1 to 6 of row A for patient 1 and wells 7 to 12 of row A for patient 2. Add 50 µl of control sera to the appropriate wells in row A of the central plate that correspond to the appropriate antigen.

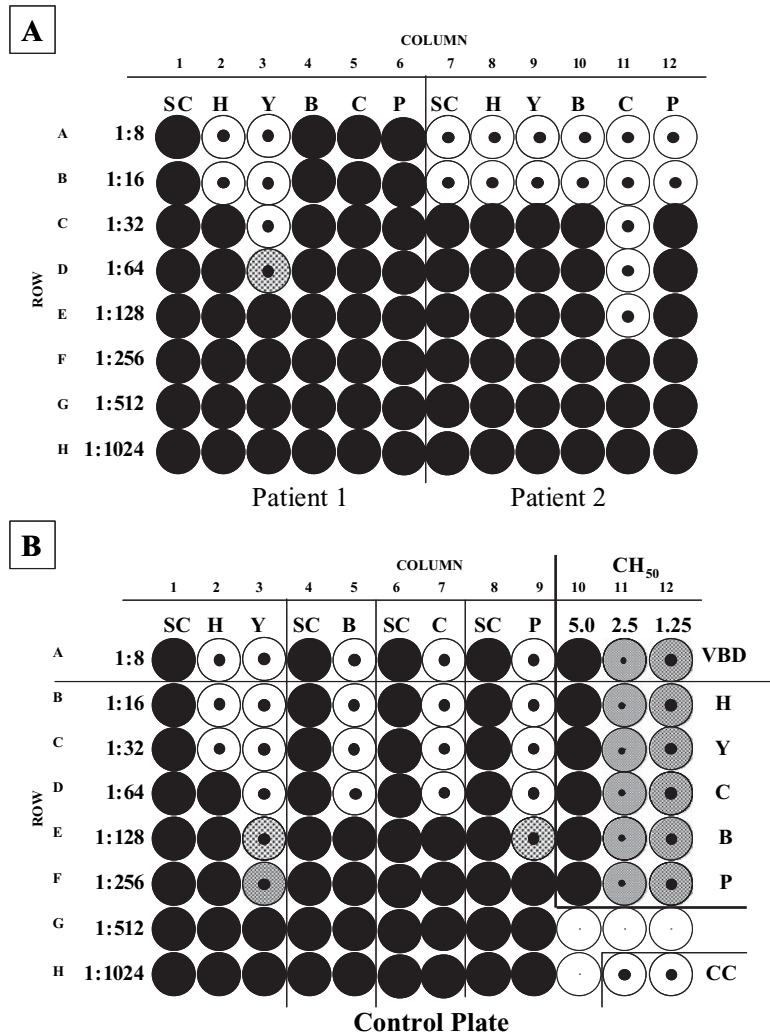
7. Using a multichannel pipette, serially pass 25 µl of serum sequentially from row A through row H, and mix. Remove 25 µl from the wells in row H, and discard (25 µl of serially diluted sera should remain in all wells).


FIGURE 2 Diagram displaying organization of the microtiter plates and results for the complement fixation assay. Percent lysis: solid circles, 100% lysis; shaded circles, 30 to 90%; open circles, 0% lysis. SC, serum control wells receiving buffer in place of antigen; H, column receiving *Histoplasma* mycelial histoplasmin antigen; Y, column receiving *Histoplasma* yeast antigen; B, column receiving *Blastomyces* antigen; C, column receiving *Coccidioides* coccidioidin antigen; P, column receiving *Paracoccidioides* yeast antigen; CC, cell control. CH_{50}, amount of complement required for 50% lysis of SRBC. (A) Patient plate. Patient 1 demonstrates serum that is positive for *Histoplasma* antibodies with a 1:16 titer against mycelial histoplasmin antigen and a 1:64 titer against *Histoplasma* yeast antigen. Patient 2 displays serum that contains an anticomplementary titer of 1:16. However, because antibodies to coccidioidin are present at a titer that is >2 dilutions beyond the anticomplementary titer, the patient CF result is AC 1:16, *Coccidioides* 1:128. (B) Control plate. Percent lysis symbols as above. Columns 1 to 9 depict the reactivity of the control sera to specific fungal antigens. Columns 10 to 12, rows A to F, depict the results of the back titration of complement in CH_{50} units (5 through 1.25) in the presence of fungal antigens or the VBD buffer control. Columns 11 and 12, row H, depict the cell control wells that receive SRBC only.

8. Dilute fungal antigens to the appropriate concentration as determined by the antigen titration assay performed for that lot of antigen. Add 25 µl of diluted antigen to wells A through H of the appropriate columns as follows:

    a. *Histoplasma* mycelial antigen (histoplasmin) to columns 2 and 8 on patient plate(s) and column 2 of the control plate.

    b. *Histoplasma* yeast antigen to columns 3 and 9 on patient plate(s) and column 3 of the control plate.

    c. *Blastomyces* A antigen to columns 4 and 10 on patient plate(s) and column 5 on the control plate.

    d. *Coccidioides* culture filtrate antigen (coccidioidin) to columns 5 and 11 on the patient plate(s) and column 7 on the control plate.

    e. *Paracoccidioides* antigen in columns 6 and 12 on the patient plate(s) and column 9 on the control plate.

9. Add 25 µl of cold VBD to columns 1 and 7 on the patient plate(s) and columns 1, 4, 6, and 8 on the control plate to control for serum activity in the CF test.

10. Thaw guinea pig complement on ice, and dilute with cold VBD in a glass container to the concentration determined by the complement titration assay. Allow to stand on ice for at least 20 min, but use within 2 h.

11. Add 50 µl of diluted complement to all patient specimen wells and columns 1 to 9 of the control plate.

12. A complement "back titration" is performed with each assay to determine the accuracy of the complement titration/dilution. On the control plate, add 50 µl of cold VBD to rows A to F in columns 11 and 12.

13. Add 100 µl of diluted complement to wells A to F of column 10. Serially pass 50 µl of diluted complement from column 10 to column 11 and then to column 12. After gently mixing the content of the wells of column 12, remove 50 µl of diluted complement and discard.

14. Add 50 µl of cold VBD to wells 10 to 12 in row A. In wells 10 to 12 of rows B to F, add 25 µl of cold VBD.

15. Add 25 µl of diluted antigen from step 8 to the appropriate wells in rows B to F of columns 10 to 12.

16. Finally, add 100 µl of cold VBD to wells 11 and 12 of row H. All wells should now contain a total of 100 µl.

17. Mix the contents of the wells for 5 to 10 s on a vibrating microtiter plate shaker.

18. Place plates at 2 to 8°C for 15 to 18 h. Cover the plates to prevent evaporation (an unused plate can serve this function; plates can be placed in stacks of five to eight plates).

19. Add 25 µl of sensitized SRBCs (as described earlier) to all wells of the patient and control plates.

20. Mix the contents of the wells for 5 to 10 s on a vibrating microtiter plate shaker.

21. Cover the plates, and incubate them at 37°C for 30 min. Stack the plates no more than two high.

22. Centrifuge the plates for 5 min at 400 to 450 × *g*.

23. Read the plates for percent hemolysis compared to the color standard.

24. Wells that display ≤30% lysis are considered to be positive. The dilution at which the last well of serially diluted serum displays ≤30% lysis is the antibody titer for that sample. Serum control wells should display >70% lysis. Serum that displays ≤70% lysis in a serum control well is considered to be anticomplementary, and results cannot be interpreted for that dilution of the serum. (See Fig. 2A, patient 2.)

25. For a valid assay, control sera must display the titer recommended by the manufacturer (or the typical titer for laboratory-derived control sera) ± 1 dilution. Also, the complement back titration controls should display 95 to 100% lysis in column 10, 90 to 100% lysis in column 11, 30 to 50% lysis in the VBD control well (A of column 12), and 0 to 50% lysis in the antigen control wells (B to F of column 12). The cell control wells (H 11 to 12) should display no lysis (0%).

QA/QC

Negative control serum and positive control serum from human histoplasmosis patients demonstrating a CF titer of ≥1:32 with the homologous antigen should be tested each time the CF test is performed. Human positive-case serum is preferred for use as the positive control because the use of hyperimmune rabbit serum has, on occasion, given positive results with its homologous antigen in the absence of good reactivity to the same antigen by positive human case serum (84). Anticomplementary activity in serum samples can occur (i.e., those showing ≤70% hemolysis in the serum control wells without antigen) and may be resolved by subsequent ID testing. However, ID tests may not be as sensitive as the CF test. Also, all of the QC measures described in the text under the heading "Reagent preparation and standardization" above must be followed for optimal operation of the test.

Interpretation

CF tests can be valuable in the diagnosis of acute, chronic, disseminated, and meningeal histoplasmosis. Antibodies in primary pulmonary infections are generally demonstrable within 4 weeks after exposure to the fungus or, frequently, when symptoms appear. Antibodies to the yeast-form antigen are usually the first to appear (about 4 weeks after exposure) and the last to disappear after resolution of the infection. Antibodies to histoplasmin usually develop later in primary pulmonary cases, but titers are considerably lower than those obtained with the yeast-form antigen. In contrast, histoplasmin titers are usually higher when serum from patients with chronic histoplasmosis is used.

CF test results can be difficult to interpret because cross-reactions or nonspecific reactions with the yeast or histoplasmin antigens are often encountered. In such instances, titers usually range between 1:8 and 1:32 and occur mainly against the yeast-form antigen. Many serum samples from culture-proven cases of histoplasmosis, however, give titers in the same range. Consequently, titers of 1:8 and greater with either antigen are generally considered presumptive evidence of histoplasmosis. Titers above 1:32 or rising titers offer strong presumptive evidence of infection. The probability of infection increases in proportion to the CF titer.

On the other hand, one cannot rely solely on CF titers above 1:32 as a means of diagnosis because false-positive reactions of similar magnitude may occur in patients with other endemic mycoses. For example, in some situations, the first serologic response noted in a patient with histoplasmosis may be obtained only with *B. dermatitidis* antigen. Some patients with histoplasmosis may demonstrate antibodies against the antigens of *H. capsulatum, B. dermatitidis,* and *C. immitis* or may demonstrate antibodies to only some of these antigens or to none. Furthermore, a lack of immunologic response does not exclude histoplasmosis, particularly when only one specimen has been tested and when the clinical picture strongly suggests a pulmonary mycosis. For example, in cases of disseminated or terminal histoplasmosis, humoral antibody responses may or may not be positive. In contrast, the CF test is usually positive when CSF specimens obtained from patients with chronic meningitis are used; titers in such cases may range from 1:8 to 1:128.

Fourfold or greater increases or decreases in titer are significant indicators of disease progression or remission, respectively. However, culture, clinical, and other laboratory data should also be considered in assessing the patient's prognosis or making treatment decisions. Occasionally, in some patients, positive titers decline slowly and persist long after the patient has been cured. The significance of persistently elevated or fluctuating CF titers is unclear, as is the effect of antifungal treatment on antibody clearance.

Test 2. ID Test To Detect Antibodies to *H. capsulatum*

The ID procedure is recommended for the detection of *H. capsulatum* precipitins directed against the H and M glycoprotein antigens present in histoplasmin. Commercial kits use a macro-ID precast gel template, whereas the CDC Mycotic Diseases Branch prefers the use of a micro-ID procedure and phenolized agar as described under "Test 1. ID Test To Detect Antibodies to *B. dermatitidis*" earlier in this chapter. CIE for histoplasmosis can also be conducted, and its major advantages over ID are that test results are available within 2 h and the frequency to detect the H precipitin is somewhat increased.

Sample Requirements

Serum or CSF may be used in the ID test. Because the reported sensitivity of the ID test is low early in infection, patients with negative serum reactions during the acute phase of infection should have additional sera drawn 3 to 4 weeks later to detect the development of precipitin bands that would indicate seroconversion and recent infection. Concomitant evaluation of patient specimens by using the CF test is also recommended.

Materials and Reagents

Histoplasmosis ID reagents or kits may be purchased from Gibson Laboratories, Immuno-Mycologics, or Meridian Diagnostics. Commercial kits include mycelium-phase culture filtrates containing *H. capsulatum* H and M antigens, positive control sera containing antibodies directed against both the H and M antigens, and ID plates. For those who wish to make ID plates in-house, the recipe is as described earlier in this chapter (see "Test 1. ID Test To Detect Antibodies to *B. dermatitidis*" above). Histoplasmin may be produced in-house as described above for the CF test. However, the mycelium-phase filtrate antigen is concentrated 5- to 10-fold and titrated to determine the optimal dilution that demonstrates well-defined H and M bands on the ID plate when tested against serum from a patient with proven histoplasmosis. Control antisera containing H and M precipitins may also be prepared in animals by using precipitin arcs as immunogens.

Equipment and Procedure

The equipment and procedure for the histoplasmosis ID test are the same as those described for the blastomycosis ID test, except that histoplasmin, unknown sera, and control sera containing H and M precipitins are added to the ID plates simultaneously and no reagent requires preincubation in the agar gel. The ID plates are then incubated in a humidified chamber for 24 h at 25°C.

QA/QC

Positive control sera must be included each time the test is performed and must react with both the H and M antigens. If the reference bands are not visible in the agar, the assay must be repeated. Commercial kits most often provide reference antisera and antigens prediluted for optimal test performance.

If in-house-produced reagents are being evaluated, it is important to cross-titrate reagents to determine the optimal working dilutions. Optimal dilutions of serum and antigen are those that place the precipitin bands midway between the serum and antigen wells; the M precipitin band is closest to the antigen-containing well, and the H band is closest to the reference serum well.

Interpretation

The ID test is a useful screening procedure or adjunct to the CF test for the serologic diagnosis of histoplasmosis. In contrast to the CF test, the ID test is generally performed as a qualitative rather than a quantitative test. The ID assay is generally more specific but less sensitive than the CF test, so that when both assays are employed, the overall sensitivity and specificity to detect histoplasmosis is quite good (85%).

The M band is produced in the ID test by serum from patients with acute or chronic pulmonary histoplasmosis and is frequently the first to appear in patients with acute disease (4 to 8 weeks after exposure). The H band is produced in the ID test by serum from patients with active histoplasmosis and occurs less frequently later in infection. Antibodies to the H antigen are specific for active disease but occur in fewer than 20% of cases; they usually disappear within the first 6 months of infection and are seldom, if ever, found in the absence of M precipitins. The production of an M band in the ID test is considered presumptive evidence of *H. capsulatum* infection and may be attributed to active or previous disease. The demonstration of both the M and H precipitins in serum is highly suggestive of active histoplasmosis. The serum from about 70% of patients with proven histoplasmosis contains M precipitins, whereas sera from only 10% of patients with proven histoplasmosis demonstrate both the M and H precipitins. The detection of M and H precipitins in CSF specimens indicates meningeal histoplasmosis (99). Precipitins can frequently be detected in the CSF of patients with meningeal histoplasmosis at a time before *H. capsulatum* is detected by culture and when attempts to culture the microorganism fail.

Test 3. LA Test To Detect Antibodies to *H. capsulatum*

The LA test is useful for presumptive early detection of acute histoplasmosis. Commercially prepared histoplasmin-sensitized latex particles are available from Immuno-Mycologics, Inc. The LA test is a semiquantitative slide agglutination assay in which *H. capsulatum* antigen-coated latex particles are used to detect antibody to *H. capsulatum*. Antibody to *H. capsulatum* present in the patient's specimen binds to the antigen-coated latex particles, resulting in visible clumping. Results are graded according to the level of agglutination observed for a particular dilution of serum. The assay measures predominantly IgM antibodies and therefore is used to diagnose early stages of acute histoplasmosis. The assay is rapid and simple to perform, and no special equipment is needed.

Sample Requirements

Serum and CSF should be stored at 2 to 8°C if tested within 72 h after collection or at −20°C or colder in a nondefrosting freezer for longer periods. Repeated freezing and thawing of specimens must be avoided. Specimens should be heat inactivated at 56°C for 30 min and allowed to cool before use.

Materials and Reagents

The histoplasmosis LA test uses latex particles sensitized with histoplasmin antigen in a slide agglutination format to

detect anti-*H. capsulatum* antibodies. All reagents including specimen diluent (concentrated glycine-buffered saline [pH 8.6] containing albumin), sensitized latex particles, positive control serum (from goats immunized with *H. capsulatum*), negative control serum (normal goat serum), and disposable glass slides with raised rings for the performance of the test can be obtained from Immuno-Mycologics, Inc.

Equipment and Procedure

The equipment and procedure for the histoplasmosis LA test are the same as those described for the *Coccidioides* LA test (see "Test 2. LA Test To Detect Antibodies to *Coccidioides*" above), except that the histoplasmosis LA test may be performed as a semiquantitative test. Specimens giving a 2+ or greater reaction during the initial screening phase of the test may be serially diluted twofold beginning with a 1:2 dilution to obtain an end-point titer.

QA/QC

Positive and negative control samples must be included each time the test is performed. The positive control must give a ≥2+ agglutination reaction, and the negative control must give a <1+ agglutination reaction. Unexpected reactions invalidate the test run, and all test runs with those specimens must be repeated. The sensitivity of the latex reagent should be tested periodically by titration against the positive control reagent. The sensitivity of the latex reagent is adequate if the positive control yields a result of 1+ at 1:4 ± 1 dilution. Agglutination is graded as follows: negative, a homogeneous suspension of particles with no visible clumping; 1+, fine granulation against a milky background; 2+, small but definite clumps against a slightly cloudy background; 3+, large and small clumps against a clear background; and 4+, large clumps against a clear or very clear background.

Interpretation

The LA test yields results in a matter of minutes and may be used with sera giving anticomplementary activity in the CF test. Although the LA test may be negative with sera from persons with chronic histoplasmosis or from immunosuppressed individuals, it is an excellent presumptive test aiding in the early diagnosis of acute histoplasmosis. A titer of 1:16 or greater is presumptive evidence of infection, and a titer of 1:32 or greater is considered strong presumptive evidence for active or very recent infection. Although a positive LA test result can be demonstrated as early as 2 to 3 weeks after infection by *H. capsulatum*, false-positive results can occur with other systemic mycoses. It is therefore recommended that results be confirmed by using the ID or other laboratory tests. Low-titer results from single specimens should especially be interpreted with caution. In such cases, the test should be performed with another specimen collected 4 to 6 weeks later.

Test 4. EIA To Detect *H. capsulatum* Polysaccharide Antigen

The *Histoplasma* polysaccharide antigen EIA (HPA test) is a microtitration plate-based double-antibody sandwich enzyme immunoassay to detect antigenuria and antigenemia in disseminated histoplasmosis. This test may also be useful in the diagnosis of early stages of acute pulmonary histoplasmosis. The major advantages of this test are that it is simple to perform, it does not require any major equipment, it can be very sensitive in cases of disseminated histoplasmosis where antibody responsiveness may be suboptimal, and it is quantitative without having to perform serial dilutions of the

specimen. No kit or reagents are commercially available for purchase, but this test is performed as a fee-for-service reference test (MiraVista Diagnostics, Indianapolis, Ind.; www.miravistalabs.com).

Sample Requirements

Preferred volumes for testing of urine, BAL fluid, serum, and CSF are 10, 10, 5, and 1 ml, respectively. Refrigeration, freezing, or specimen preservation is not required when shipped within the continental United States (see reference 120 for shipping information). To obtain maximum test sensitivity, it is recommended that both serum and urine specimens be tested in parallel. Treatment success or failure may be assessed by collecting specimens at least 14 days after initiation of treatment and testing the newly acquired sample in parallel with the last specimen that was positive before initiation of therapy. Serum samples are heated at 56°C for 1 h before being tested (to inactivate possible HIV), and urine is boiled for 5 min before use. Newly instituted procedures to remove test interference by human anti-rabbit immunoglobulins have been reported, but no details of the exact procedures employed have been described.

Materials and Reagents

The capture and detector antibodies are raised in rabbits against formalin-killed yeast forms of *H. capsulatum* in incomplete Freund adjuvant followed by multiple intravenous injections of live yeast forms. The percentage of high-responder rabbits producing antibody of suitable affinity for use in the EIA is low (i.e., < 5%), and the use of various immunization routes and schedules has not improved immune responsiveness.

Equipment

The equipment required to perform the HPA test is the same as that for the Premier *Coccidioides* EIA (see "Test 4. EIA To Detect Antibodies to *Coccidioides* Species" above), except that a boiling-water bath is also required.

Procedure

The EIA is conducted as described by Durkin et al. (29). Briefly, heat-treated samples are placed into wells of a microtiter plate coated with the polyclonal capture antibody. Biotinylated detector antibodies are then added, followed by peroxidase-labeled streptavidin. Each well is read after addition of and incubation with H_2O_2 and the colorimetric substrate (TMB) after the reaction is stopped using 1 M H_2SO_4. The substrate color change can then be read visually as a qualitative test result or on a spectrophotometer at OD_{450} as a quantitative test result. Because the exact nature of the antigen is not precisely known, there is no quantification of test results relative to a standard curve. Instead, EIA units (EU) are defined as the OD_{450} obtained for the patient sample divided by 1.5 times the mean of the OD_{450} of the negative control sample. Negative control samples (usually serum and urine) are obtained from normal subjects.

Interpretation

Specimens giving test results between 1 and 2 EU indicate a weak positive result corresponding to a diagnosis of probable histoplasmosis. In such cases, repeat testing is recommended. A test result of >2 to <10 EU corresponds to a moderate positive result, and a repeat test is necessary only if test results are inconsistent with clinical findings. Values of >10 EU reflect strongly positive results. The antigen concentration has been

reported to subside in response to therapy and increase during relapses, but an increase of 0 to 1.9 EU indicates a stable condition. On the other hand, increases of 2 to 4 EU suggest possible treatment failures. In such cases, antigen testing should be repeated and cultures should be obtained. An increase of >4 EU corresponds to probable treatment failure, and more intense therapy is recommended (161).

The HPA test detected measurable antigen concentrations in urine from 50 (89%) of 56 patients with disseminated disease and 11 (37%) of 30 patients with self-limiting disease in a large outbreak in Indianapolis (29). In cases of disseminated or acute pulmonary histoplasmosis, the concentration of antigen is usually higher in urine than in serum when paired samples are tested. The HPA test has been reported to be positive in 21% of patients with chronic pulmonary histoplasmosis (164). Antigen has also been reported to be detected in the CSF of 25 to 50% of patients with *H. capsulatum* meningitis and in the BAL fluid of 70% of patients with diffuse pulmonary histoplasmosis. The test cross-reacts with antibodies from patients with blastomycosis, paracoccidioidomycosis, and penicilliosis marneffei but not from those with coccidioidomycosis; therefore, test results must be interpreted in light of the clinical presentation and the patient's history of travel to or residence in areas where these diseases are endemic and in conjunction with other laboratory results, including those for antibody detection and for culture.

It has been reported that false-positive results can occur when sera from SOT recipients who were treated with rabbit anti-thymocyte globulin are tested in the HPA assay (160). As a result, the HPA test was revised, in an unspecified manner, to reduce such false-positive results (www.miravistalabs.com).

Experimental and Molecular Biological Approaches

Attempts to replace the CF test with an EIA format have been frustrated because of cross-reactive carbohydrate moieties found on the immunodominant H and M antigens (65, 169). Periodate treatment of the M antigen before use in an immunoblot format, however, was reported to remove most of the cross-reactivity and increase the test specificity to 91% (43, 169). Recently, an ELISA for the early diagnosis of histoplasmosis was described in which purified native histoplasmin was compared to its deglycosylated counterpart (42). Deglycosylation resulted in an increase in test specificity from 93 to 96%; more surprisingly, the test sensitivity also increased from 57 to 92% (42). Other studies have employed monoclonal antibodies directed to an *H. capsulatum*-specific 70-kDa antigen in an attempt to improve test specificity (40). An inhibition EIA employing this antibody had 89 and 57% sensitivity for the detection of the acute and chronic forms of histoplasmosis, respectively, and a test specificity of 85% with serum from patients with chronic fungal or bacterial infections.

Aside from a few case reports in humans, a limited number of studies describe the application of molecular biological methods to clinical materials for the diagnosis of histoplasmosis. The most extensive study examined two nested PCR assays for the detection of *H. capsulatum* DNA in formalin-fixed, paraffin-embedded human tissue (8). Of the 29 samples that were described as positive for *H. capsulatum* by periodic acid-Schiff staining, 20 (69%) were PCR positive when a 100-kDa-like protein gene was used as the amplification target and 26 (90%) were positive when primers directed to the 18S rRNA gene were used. However, comparative DNA sequence analysis confirmed that only 20 of the latter 26 samples contained *H. capsulatum* DNA; the

remaining 6 samples were found to contain DNA from other fungi. Whereas the use of primers directed to the 100-kDa-like protein gene was 100% specific (33 samples negative by periodic acid-Schiff staining were also PCR negative), DNA sequence analysis demonstrated that 18 of the 33 histopathologically negative samples tested were falsely positive when primers directed to the 18S rRNA region were used. Although these data suggest that the application of primers directed to a single-copy *H. capsulatum* gene was more specific for the diagnosis of histoplasmosis than were broad-range fungal primers, another study successfully used similar broad-range fungal primers, also directed to the 18S rRNA gene (albeit to a different region of the gene), to amplify and detect *H. capsulatum* DNA from microscopically positive and culture-positive bone marrow (55). These researchers employed a LightCycler, real-time fluorescence PCR assay and melting-curve analysis along with DNA sequencing of the PCR products to confirm that the amplicons produced were derived from *H. capsulatum* DNA.

PARACOCCIDIOIDOMYCOSIS

Background
Serologic tests are useful for the rapid presumptive diagnosis of paracoccidioidomycosis, particularly for diagnosing cases of disseminated disease and for monitoring the response to treatment. The ID and CIE tests are simple to perform and are among the most specific procedures available (reported sensitivities, 84 to 94%; reported specificity, 99%). CF tests that use unpurified antigens have a similar sensitivity to the ID and CIE tests (87%) but are less specific (68%). Therefore, the CF test should be performed in conjunction with the ID test.

Clinical Indications and Diagnostic Rationale
Serologic tests for paracoccidioidomycosis should be performed on specimens from patients with symptoms of chronic disease or who present with ulcerative lesions of the mucosae (oral, nasal, or intestinal) or the skin. A history of travel to or residence in Latin America in conjunction with typical clinical signs should raise suspicion for paracoccidioidomycosis. The CF test detects antibodies in 80 to 96% of patients with paracoccidioidomycosis. CF antibodies are diagnostic, but the CF test results with *P. brasiliensis* yeast-form culture filtrate antigens are not always specific, and cross-reactions may occur when sera from patients with other endemic mycoses, particularly histoplasmosis, are used. These cross-reactions are infrequent and occur mainly at titers of 1:8 or below. Nonetheless, concomitant use of the CF and ID tests allows a correct serodiagnosis of paracoccidioidomycosis in over 98% of cases.

The ID test employing concentrated yeast-form culture filtrate antigens and reference sera is entirely specific and has a sensitivity of 94% when sera from patients with paracoccidioidomycosis are tested. The major diagnostic precipitin is a 43-kDa glycoprotein referred to as gp43 (also known as E$_2$ or A) and is found in 95 to 98% of patients with paracoccidioidomycosis (11, 113).

Test 1. CF Test To Detect Antibodies to *P. brasiliensis*
The standard microtitration CF test with *P. brasiliensis* yeast-form filtrate antigens is recommended for the determination of titers in sera from patients with suspected paracoccidioidomycosis. A detailed protocol for the CF test is available (105). No commercial kits are available for the paracoccidioidomycosis CF test.

Sample Requirements

The sample requirements are the same as those for the histoplasmosis CF test (see "Test 1. CF Test To Detect Antibodies to *H. capsulatum*" above).

Materials and Reagents

Culture filtrate antigens of *P. brasiliensis* are referred to as paracoccidioidin, an antigenic preparation that is suitable for use in the CF and ID tests. Paracoccidioidin is prepared by growing *P. brasiliensis* in a tryptic soy broth-dialyzate medium supplemented with glucose, ammonium sulfate, and vitamins (118). Yeast-form shake cultures of three stock isolates of *P. brasiliensis* are grown singly at 35°C in this medium for up to 4 weeks. References 13 and 21 give details about isolate selection. The culture filtrate from each isolate is dialyzed, concentrated 10-fold, and mixed in equal volumes with those from the other isolates. The optimal dilution for each antigen pool is determined by titration with low- and high-titer CF-positive sera from human paracoccidioidomycosis cases or by the use of ID tests with precipitin-positive sera. References 15 and 21 give details of the kinetics of *P. brasiliensis* antigen production during growth and discuss alternative growth media.

Equipment, Procedure, and QA/QC

The equipment, procedure, and QA/QC measures for the paracoccidioidomycosis CF test are the same as those described earlier in this chapter for the histoplasmosis CF test (see "Test 1. CF Test To Detect Antibodies to *H. capsulatum*").

Interpretation

CF titers of ≥1:8 are considered presumptive evidence of paracoccidioidomycosis. However, 85 to 95% of patients with active disease have titers of ≥1:32. Low CF titers are usually associated with localized disease or involvement of the mononuclear phagocyte system, whereas high titers are found in patients with pulmonary lesions or multifocal disease. Sera from young children with disseminated paracoccidioidomycosis are an exception and ordinarily show low or negative CF reactivity. The CF test has a sensitivity of 87% and a specificity of 68% (13). Serial CF determinations are prognostic in that a decreasing titer generally indicates effective therapy, whereas relapses are accompanied by increasing titers. High and fluctuating titers suggest a poor prognosis. Low levels of CF antibodies may persist long after the patient is cured.

Test 2. ID Test To Detect Antibodies to *P. brasiliensis*

The ID test for *P. brasiliensis* precipitins can be performed on a fee-for-service basis by Cerodex Laboratories, Inc., Washington, Okla., and commercial reagents are available from Immuno-Mycologics, Inc. No commercial kits are available for the performance of the paracoccidioidomycosis ID test.

Sample Requirements

The sample requirements for the paracoccidioidomycosis ID test are the same as those for the histoplasmosis ID test (see "Test 2. ID Test To Detect Antibodies to *H. capsulatum*" above).

Materials and Reagents

See the section on materials and reagents under the heading "Test 1. CF Test To Detect Antibodies to *P. brasiliensis*" (above) for a description of the antigen preparation used for the ID test. Commercial mycelium-phase *P. brasiliensis* culture filtrate antigens, containing gp43 and other antigens, are available from Immuno-Mycologics, Inc.

Interpretation

The ID test is valuable for the diagnosis of acute or chronic pulmonary infection and disseminated paracoccidioidomycosis. The CIE test gives similar results (13) and is not discussed further. The greatest number of precipitin bands has occurred when sera from patients with lung involvement or disseminated disease have been used; up to three precipitin bands have been observed (15). A major diagnostic precipitin is consistently found in the sera of patients with paracoccidioidomycosis, which reacts with a soluble, specific *P. brasiliensis* antigen. Band 1, which appears closest to the antigen-containing well, is thought to contain gp43 on the basis of immunochemical analysis. The precipitin that reacts with the gp43 antigen has been observed to occur in 95 to 99% of sera from patients with active paracoccidioidomycosis and can be found in patient serum for longer periods following infection than are the other two major serum precipitins; the latter disappear during a favorable response to treatment. The positive predictive value of a positive ID test result is 100%.

Experimental and Molecular Biological Approaches

An indirect EIA, measuring anti-gp43 IgG, has been described that provides a simpler test format than the CF test and, like the CF test, provides a quantitative measurement of antibody titer for therapeutic monitoring. The EIA was shown to be more sensitive than the CF test if the gp43 antigen was deglycosylated or if test sera were preadsorbed with mycelium-phase cells from *H. capsulatum* (13, 114). Variously purified and characterized antigens have been described in recent years in an attempt to discover antigens that would be without cross-reactivity, including 22- to 25-, 43-, 58-, and 87-kDa antigens. A 27-kDa antigen that appears to be free of cross-reacting epitopes has been described, and a 60-kDa heat shock protein has been cloned and characterized (57, 104).

Tests to detect antigens in serum, urine, CSF, and BAL fluid have also been described and may be particularly useful for the diagnosis of paracoccidioidomycosis in immunosuppressed patients and to monitor disease progression (39, 90, 94, 123). Paracoccidioidomycosis, in addition to its acute and chronic forms, has also been known to reactivate from quiescent endogenous foci. In such situations, the detection of antigenuria by immunoblotting may provide information not available by performing antibody tests alone. The occurrence of antigenuria in 11 (91.7%) of 12 patients tested in one study indicated that detection of antigenuria may be a promising diagnostic approach (123).

One study examined the detection of *P. brasiliensis* DNA from human clinical materials (38). In this study, a nested PCR assay was described in which primers directed to the gene encoding the gp43 antigen of *P. brasiliensis* were used. Sputa from 11 (100%) of 11 patients with proven chronic pulmonary paracoccidioidomycosis were positive in the PCR assay. Although no amplicons were produced when DNA from pure cultures of *C. albicans*, *H. capsulatum*, or *C. neoformans* was used as an amplification template, no clinical specimens from patients with other fungal diseases were tested and the clinical specificity of this test was not determined.

PENICILLIOSIS MARNEFFEI

Background

Disseminated infection with *Penicillium marneffei* is observed almost exclusively in immunocompromised patients who either live in or have traveled through southeast Asia.

Diagnosis of *P. marneffei* infections relies mainly on culture and/or histopathologic identification. Serologic procedures, which are still being evaluated, detect antibodies by ID and by IFA. More recently, antigen detection tests were developed to detect a 90-kDa cell wall mannoprotein (16). No commercial tests for the diagnosis of penicilliosis marneffei are currently available in the United States.

Clinical Indications and Diagnostic Rationale

Serologic tests for the diagnosis of *P. marneffei* infections should be considered for use with patients who have lived in or traveled to southeast Asia and who display symptoms of intermittent fever, marked weight loss, nonproductive cough, and debilitation. About 60 to 70% of patients present with multiple papular lesions, some of which show a central necrotic umbilication resembling molluscum contagiosum. Other presenting signs include hepatosplenomegaly, generalized lymphadenopathy, anemia, and thrombocytopenia. These symptoms may be confused with those of other fungal infections such as histoplasmosis or cryptococcosis as well as with those of tuberculosis.

Experimental and Molecular Biological Approaches

Detection of antibodies in suspected cases has relied on the ID test (128, 151) and on an IFA test (168). The ID test (69) detected antibody in only 2 of 17 HIV-positive patients with *P. marneffei* infection. More recently, an IFA test was developed that used germinating conidia and yeast-like forms as test antigens (168). Sera from 8 patients with confirmed *P. marneffei* cases had IgG titers of ≥1:160, whereas sera from 95 patients with other diseases and 78 healthy controls had titers of ≤1:40. A recombinant 90-kDa cell wall mannoprotein has been incorporated into an ELISA format to detect anti-*P. marneffei* antibodies. The ELISA was reported to detect 14 (82%) of 17 HIV-positive patients with penicilliosis marneffei with a test specificity of 100% when sera from patients with typhoid fever, tuberculosis, and normal healthy donors were used (16).

Antigenemia was detected using ID and LA tests (69), whereas antigenuria was detected in an EIA (25). The LA test was more sensitive (13 of 17 [77%]) than the ID assay (10 of 17 [59%]), whereas the antigenuria EIA was reported to have a sensitivity of 97% and a specificity of 98% (25). A sandwich EIA in which MAbs were used to detect *P. marneffei* soluble yeast exoantigen in sera had a reported test sensitivity of 72% and a specificity of 100% (106, 145).

One study described the application of a PCR method to the detection of *P. marneffei* DNA in clinical specimens (112). DNA was extracted from the blood of 19 AIDS patients, and amplicons of 331 and 251 bp, characteristic for *P. marneffei*, were detected by agarose gel electrophoresis and ethidium bromide staining. Of 19 blood cultures, 2 grew *P. marneffei*; both were PCR positive.

PNEUMOCYSTOSIS

Background

Until recently, the organisms responsible for pneumocystosis were referred to as *Pneumocystis carinii*. However, recent comparative DNA sequence analysis demonstrated that *Pneumocystis* organisms from different mammalian hosts were genetically quite dissimilar from one another. This finding resulted in a name change from *P. carinii* (which infects rats) to *P. jiroveci* for the organisms infecting humans (133). Until 1988 these organisms were widely thought to be protozoa, but comparative DNA sequence analysis demonstrated that

Pneumocystis strains were phylogenetically more closely related to the fungi (30).

The laboratory diagnosis of pneumocystosis depends largely on the use of Gomori methenamine silver, Calcofluor white, Gram-Weigert, or toluidine blue-O staining of lung biopsy specimens, induced sputum, or BAL fluid specimens to detect the cyst form of the organism and the use of Giemsa stain to detect the trophozoite form or clusters of cysts containing intracystic bodies. Specific antipneumocystis MAbs have been developed that can detect not only the cyst form of the organism but also the significantly more abundant trophozoite form (37, 77). The sensitivity of the MAbs with either induced sputum or BAL fluid specimens has been reported to be similar to or somewhat greater than that of conventional staining methods.

Indirect and direct immunofluorescent assays employing MAbs have most commonly been used for the detection of *P. jiroveci* in induced sputum and in BAL fluid samples; however, less frequently, these reagents have also been used for tissue diagnosis (2, 74, 116). MAbs directed against *Pneumocystis* for use in direct or indirect staining procedures are available commercially from Axis-Shield Diagnostics (Dundee, United Kingdom), Bio-Rad Laboratories, Inc., Chemicon International, Inc. (Temecula, Calif.), and Meridian Diagnostics. Other immunologic methods including CIE, ELISA, Western blotting, and LA tests have also been developed experimentally and are discussed in more detail below. Finally, the increased sensitivity of molecular biology-based diagnostic methods may allow a minimally invasive procedure, such as oral washing (46), to be sufficient for diagnostic purposes.

Clinical Indications and Diagnostic Rationale

PCP is rare in immunocompetent adults but is a leading cause of illness and death in individuals with impaired immunity including malnourished or premature children, persons with AIDS, SOT recipients, and patients receiving long-term corticosteroid therapy. It is often described as interstitial plasma cell pneumonia; histopathologic studies of patients' lungs typically show alveolar interstitial thickening and the presence of a frothy eosinophilic exudate in the lumina. The clinical presentation in children is characterized by cyanosis, mild cough without fever, and, in severe disease, intercostal retractions. In contrast, adults with PCP frequently present with dyspnea, nonproductive cough, chest tightness, night sweats, and an inability to breathe deeply. Tachypnea and low-grade fever often occur, but hemoptysis is rarely present. Adults with CD4 counts below 200 per μl are at increased risk for PCP, and persons with AIDS have a more insidious progression than those who are immunosuppressed but HIV negative. Extrapulmonary pneumocystosis has been found in 1 to 3% of postmortem examinations of patients known to have pulmonary infections (100, 141) and most often involves the lymph nodes (44%) and the spleen, bone marrow, and liver (33%). Infection at multiple extrapulmonary sites is associated with a rapidly fatal outcome (100, 141).

The route of transmission of *P. jiroveci* is not understood, but seroprevalence studies have suggested that exposure occurs in early childhood. It was hypothesized that the strains acquired during first exposure persisted in the lungs in a dormant state throughout life and became active on subsequent immunosuppression of the host (133, 134). However, this hypothesis has recently been challenged, and it has been suggested that *P. jiroveci* organisms are frequently acquired and cleared by the immune system in immunocompetent hosts and do not persist (153).

Experimental and Molecular Biological Approaches

The serologic diagnosis of pneumocystosis has proven to be difficult because most humans become seropositive for *Pneumocystis* antibodies at an early age and are exposed to the organism multiple times throughout life. Therefore, the detection of serum antibodies may not correlate with true infection. In addition, conflicting results have been obtained primarily because different test methods have been used (CIE, LA, Western blotting, ELISA, indirect immunofluorescence), a variety of antigen sources have been employed (rat versus human), and the antigens used have been purified to different degrees (column purified or recombinant).

Other tests include the detection of antigens ranging from 35 to 45 kDa, as well as a 95-kDa major surface glycoprotein antigen, in BAL fluids (132). Western blot analysis demonstrated that the 35- to 45-kDa antigen was found in 88% of the BAL fluids tested whereas the 95-kDa antigen was detected in only 49% of the specimens. Yet another study demonstrated that levels of a panfungal antigen, (1,3)-β-D-glucan [see the section below on (1,3)-β-D-glucan], in plasma were found to parallel the clinical and radiographic improvement of a patient with PCP in a case report (143). Further evaluations of this test in larger studies are warranted.

Molecular diagnosis of pneumocystosis has primarily employed PCR primers directed to the multicopy gene family of the major surface glycoprotein of *P. jiroveci* (81) or to the mitochondrial rRNA gene (155). Both of these gene targets have been demonstrated to be sensitive and specific for the detection of *P. jiroveci* in BAL fluids (51, 154) and have been applied in single or nested PCR formats. Other target genes have included those for thymidylate synthase, heat shock protein 70, β-tubulin, dihydrofolate reductase, and the 5S, 18S, 28S, and ITS regions of rRNA. Most studies have indicated that PCR assays are more sensitive than conventional stains and are equal to or better than DFA or IFA tests for the diagnosis of pneumocystosis (110, 146). However, because 2 to 21% of individuals may be asymptomatic carriers of *P. jiroveci* (130), a positive PCR result in conjunction with a negative staining result may not represent active disease. To resolve this dilemma, researchers have investigated imposing cutoff values for PCR positivity (144) or the application of real-time quantitative PCR methods (33, 82) in an attempt to numerically differentiate the results for colonized patients from those of true cases.

The increased sensitivity of nucleic acid-based tests allows specimens that contain smaller numbers of organisms, and that are more easily obtained than BAL fluid or tissue, to be used for diagnostic purposes. For example, the use of oral wash fluids from patients suspected to have pneumocystosis has demonstrated test sensitivities and specificities of 89 and 94%, respectively; this compares to sensitivities and specificities of 100 and 91% that were obtained using BAL fluid during parallel testing (46). A diagnostic strategy may be to use less invasive procedures, such as oral washings, to obtain screening samples from patients presenting clinical signs consistent with the disease. The diagnostician would proceed to more invasive procedures only if the specimens obtained by less invasive means were negative.

Although respiratory samples such as induced sputum, BAL fluid, and oral and nasopharyngeal aspirates have most commonly been used to recover *P. jiroveci* DNA, other clinical specimens such as blood, serum, and peripheral blood mononuclear and polymorphonuclear cells have been tested with various degrees of success (4, 125, 137). In general,

PCR tests using blood-related specimens have given sensitivities of 41 to 86% and specificities of 100%. Tissues have also been used successfully in both PCR and in situ hybridization test formats (64, 75) but require invasive collection procedures. No commercial kits are currently available for PCR diagnosis of PCP in the clinical laboratory.

SPOROTRICHOSIS

Background

Serologic tests are sometimes helpful for the diagnosis of the extracutaneous or systemic forms of sporotrichosis. A slide agglutination test to detect anti-*Sporothrix schenckii* antibodies has been demonstrated to be the most useful method. This test has been reported to have sensitivities of 100, 86, 73, and 56% for disseminated, articular, pulmonary, and cutaneous disease, respectively, and a specificity of 100% (121). Antibodies are most probably directed toward a peptido-L-rhamno-D-mannan, localized in the outer layer of the *S. schenckii* cell wall. Comparable sensitivity for the detection of *S. schenckii* antibodies has not been reported for an ID test format.

Clinical Indications and Diagnostic Rationale

Serologic tests for sporotrichosis may be applied to sera from patients with skin lesions, subcutaneous nodules, bone and joint lesions, lymphadenopathy, or pulmonary disease and to CSF from patients with undiagnosed chronic meningitis. The disease should be suspected in individuals whose work brings them into contact with soil, plants, timber, plant materials, or sphagnum moss. Cutaneous sporotrichosis is more common in adults than in children, and extracutaneous disease is found more often in men older than 30 years. Although not common, disseminated infection is more likely to occur in immunosuppressed than immunocompetent individuals.

Test 1. LA Test To Detect Antibodies to *S. schenckii*

The LA test is a semiquantitative slide agglutination assay in which *S. schenckii* antigen-coated latex particles are used to detect antibody to *S. schenckii*. The assay is rapid and simple to perform and requires no special equipment. A commercial kit is available from Immuno-Mycologics, Inc.

Sample Requirements

Serum and CSF should be free of any particulates, and lipids should be removed using a 0.45- or 0.8-μm syringe filter. Specimens may be stored at 2 to 8°C if tested within 72 h after collection or at −20°C or colder in a nondefrosting freezer for longer periods. Repeated freezing and thawing of specimens should be avoided.

Materials and Reagents

All reagents including specimen diluent (concentrated glycine-buffered saline [pH 8.6] containing albumin), sensitized latex particles (sensitized with *S. schenckii* culture filtrate antigens), positive control serum (from rabbits immunized with *S. schenckii*), negative control serum (normal goat serum), and disposable glass slides with raised rings for the performance of the test can be obtained from Immuno-Mycologics, Inc. A properly standardized suspension of latex particles, which has an absorbance of 0.30 ± 0.02 after a 1:100 dilution, can be sensitized in-house with an equal volume of an optimal dilution of yeast-form *S. schenckii* culture filtrate antigens. The optimal quantity of

culture filtrate antigen is the highest dilution that produces a clear 2+ agglutination reaction with the highest reactive dilution of rabbit anti-*S. schenckii* reference serum or serum from a human with sporotrichosis.

Equipment and Procedure

The equipment and procedure for the sporotrichosis LA test are the same as those for the coccidioidomycosis LA test (see "Test 2. LA Test To Detect Antibodies to *Coccidioides*" above), except that the sporotrichosis LA test may be performed as a semiquantitative test. Specimens giving a 2+ or greater reaction during the initial screening phase of the test may be serially diluted twofold, beginning with a 1:2 dilution to obtain an end-point titer.

QA/QC

QA/QC procedures for the sporotrichosis LA test are the same as those for the histoplasmosis LA test (see "Test 3. LA Test To Detect Antibodies to *H. capsulatum*" above).

Interpretation

LA titers of 1:8 or greater are considered presumptive evidence of sporotrichosis. False-positive reactions have, however, been noted at titers of 1:8 when sera from patients with nonfungal infections were used. Sera from patients with localized cutaneous, lymphocutaneous, or extracutaneous sporotrichosis may display titers ranging from 1:8 to 1:512. An increasing titer or a sustained high titer indicates pulmonary sporotrichosis. The test has limited prognostic value, since antibody levels may show little change during and after convalescence. Slide latex agglutinin titers of >1:8 with CSF are considered presumptive evidence of meningeal sporotrichosis.

Experimental and Molecular Biological Approaches

A CF test using culture supernatant antigen has been examined for the diagnosis of sporotrichosis, but whereas the specificity of the assay was good, and no cross-reactions with sera from patients infected with other fungi was observed, the assay lacked sensitivity (63). An enzyme immunoassay has also been described and used in a study of *S. schenckii* meningitis (126). A comparison between the LA test and EIA was performed with both serum and CSF from meningitis patients. Antibody titers were typically higher in the EIA (~100- to 1,000-fold higher) than in the LA test, and for a few cases, the EIA was more sensitive. Neither test became positive earlier in the course of disease than the other, although CSF specimens tested by the EIA remained positive for a longer period after disease onset than did those tested by the LA test (126).

S. schenckii DNA was detected in 11 of 12 tissues from various anatomical sites (including arm, hand, nose, foot, face, and neck) of patients with culture- or histopathology-proven sporotrichosis when a nested PCR assay and primers directed to the 18S rRNA gene were used. Negative PCR results were obtained with DNA extracts from common bacteria and fungi or from *S. schenckii*-negative skin specimens. The one culture-positive, PCR-negative specimen was shown to contain inhibitors of the PCR because purified *S. schenckii* DNA, artificially spiked into this sample, was not amplified (50).

ZYGOMYCOSIS

Background

The primary agents of zygomycosis in the order Mucorales include species of *Absidia, Apophysomyces, Cunninghamella, Mucor, Rhizopus, Rhizomucor*, and *Saksenaea*, and those in the order Entomophthorales include *Conidiobolus* and *Basidiobolus* (119, 156). In tissue, these organisms are difficult to differentiate and appear as sparsely septate, irregularly branched, broad, ribbon-like hyphae (17, 156). A murine MAb, WSSA-RA-1, directed against somatic antigens of *Rhizopus arrhizus,* has been reported to react specifically with *Absidia corymbifera, R. arrhizus,* and *Rhizomucor pusillus* when applied as an indirect immunofluorescent histopathology stain; this reagent is commercially available from DakoCytomation, Inc. (58). Although ID tests have been successfully used to detect antibodies in patients with active zygomycosis (65, 70), these methods have not been extensively evaluated.

Clinical Indications and Diagnostic Rationale

The major risk factors for zygomycosis are neutropenia, uncontrolled diabetes mellitus, other forms of metabolic acidosis, and burns. Other contributing factors include corticosteroid use and treatment with deferoxamine. Sera or CSF specimens from patients with diabetic ketoacidosis or evidence of rhinocerebral disease, those who are immunocompromised with renal disease, those with acute leukemia, or those who are debilitated and have signs of pulmonary or systemic infection should be tested for zygomycosis.

Experimental and Molecular Biological Approaches

Antibodies to *Rhizopus arrhizus* have been detected in the sera of patients with brain infections caused by this organism (62, 109). In addition, antibodies to *Absidia corymbifera* were found in the CSF and serum of a patient with culture-proven *Absidia* meningitis (89) and in the serum of a patient with histologically proven *A. corymbifera* brain abscess (109). There appears to be significant cross-reactivity among the major antigens of the genera *Rhizomucor, Absidia,* and *Rhizopus* as a result of the common peptido-L-fuco-D-mannan on their cell surfaces, confounding immunological differentiation of infections by these organisms (65, 165). Preliminary work using homogenized antigens from *Absidia corymbifera, Rhizomucor pusillus,* and *Rhizopus arrhizus* demonstrated a sensitivity of 70% and a specificity of 90% for these zygomycotic agents in an ID test format (65, 66). An EIA format was also evaluated and, using a 1:400 antigen titer as positive, was found to be 81% sensitive and 94% specific for zygomycosis (65, 70). This compared to an ID test for *Rhizopus arrhizus* that had a sensitivity of 66% and a specificity of 91% (70).

Experimental ID tests to detect antibodies to *Conidiobolus coronatus* and *Basidiobolus ranarum* in patients with subcutaneous or gastrointestinal infections have been developed using culture filtrate antigens from these organisms. The tests appear to be specific (66), but their sensitivity has not been determined. Studies of the molecular phylogeny of clinically important Zygomycetes have been conducted (152), but no molecular diagnostic tests using clinical materials have been developed to date.

PANFUNGAL DETECTION USING (1,3)-β-D-GLUCAN

The Fungitell test (Associates of Cape Cod, Inc., East Falmouth, Mass.) is a recently FDA-approved microtiter plate-based EIA for the detection of BDG in serum. BDG is a component of the cell wall of all fungi except the Zygomycetes, and only low levels of BDG are released from *C. neoformans* (101). BDG activates factor G, a coagulation enzyme found in *Limulus polyphemus* (horseshoe crab)

amebocyte lysates. Although there are two *Limulus* amebocyte lysate coagulation pathways, one containing factors B and C and sensitive to activation by endotoxin and the other containing factor G and sensitive to BDG activation, the Fungitell test detects only the second, BDG-specific pathway. Once activated by BDG, the activated enzyme cleaves a chromogenic substrate (*t*-butyloxycarbonyl-Leu-Gly-Arg-*p*-nitroanilide) included in the test, releasing *p*-nitroanilide. The free *p*-nitroanilide can then be quantitated by its absorbance at 405 nm with respect to a glucan standard.

The test has been reported to detect low picogram quantities of BDG, and a serum BDG level of $\geq$60 pg/ml was chosen as the cutoff for positivity in a recent clinical evaluation of the test. Serial serum samples from 283 subjects with acute myeloid leukemia or myelodysplastic syndrome who were receiving antifungal prophylaxis were examined for the presence of BDG (103). For 100% of subjects with proven or probable invasive fungal infection, at least one serum sample was positive for BDG a median of 10 days before the clinical diagnosis of invasive fungal infection was established. Absence of a positive BDG result had a negative predictive value of 100%. Invasive fungal infections studied included aspergillosis, candidiasis, fusariosis, and trichosporonosis. The test specificity was reported to be 90% if a single test result was positive and greater than 96% if two or more sequential serum samples were positive.

Caveats in interpreting the results of BDG determinations are that plasma glucan activity increased in 36 of 45 patients with hematologic malignancies who were undergoing chemotherapy and who had no signs of invasive fungal disease (71). False-positive reactions have also been observed in patients after surgery or hemodialysis, possibly owing to extrinsic BDG present in surgical gauze or to the use of cellulosic membranes, such as cuprammonium rayon, which contain polysaccharides that are shed into the bloodstream during dialysis (102). Also, patients receiving parenteral infusions of plasma components, such as gamma globulin, which is filtered through cellulose membranes during manufacture, can give false-positive results (102). Recently, it was noted that the intramuscular administration of antitumor preparations containing BDG (lentinan and schizophyllan) can also produce false-positive results in the BDG test (56).

Although the BDG test cannot specifically identify the fungus responsible for infection, results can be obtained within 2 h. Such rapidity makes this test a very attractive screening tool to detect invasive infection by common as well as less common fungi, including those for which no other serologic test is available (167). Automation of this assay may make it more attractive for evaluation in prospective studies and for use in the clinical laboratory (138). Alternative colorimetric (Fungitec G Test MK; Seikagaku Kogyo Co., Ltd., Tokyo, Japan) (136) and turbidometric (Wako-WB003; Wako Pure Chemical Industries, Ltd., Tokyo, Japan) (71) forms of amebocyte lysate assays are available in Japan.

Introduction

STEVEN C. SPECTER

67

Viral diagnostics has continued to evolve significantly over the past 4 years since the publication of the 6th edition of the *Manual for Clinical Laboratory Immunology*. It is noteworthy that in the Introduction to the 6th edition Virology section there was an indication that increasing dependence would be placed on molecular diagnostic techniques in place of serologic detection of viruses. This is now reflected in the change of the title of the present 7th edition of this volume to *Manual of Molecular and Clinical Laboratory Immunology*.

The reliance on molecular techniques has expanded significantly; they have come into common usage for numerous virus infections. In addition, the number of viral agents recognized to have an etiologic role in human infections continues to expand. However, with all of this change taking place, protection of the blood supply, epidemiology, identification of the etiology of infectious diseases, and the monitoring of the progression of viral diseases in chronic infections continue to be the major reasons for performing laboratory diagnostic studies of viruses.

As we continue to develop new vaccines, antiviral drugs, more sophisticated technologies to detect viruses more rapidly, and better reagents, we have increased our reliance on the diagnostic laboratory. In addition, we have developed methods to combine cell culture diagnostics with direct detection systems, including antibodies, enzyme expression, and molecular methods, to combine viral isolation with identification. As a result we have succeeded in increasing sensitivity, specificity, and rapidity of diagnosis. More than any other advance, molecular diagnostic techniques have been increasingly applied in diagnostic virology and in several cases have become the "gold standard" for viral diagnosis. Furthermore, these molecular techniques can be applied quantitatively as well as qualitatively. As a result, they can be used to determine if there is a significant amount of virus in bodily fluids, determine whether there is a response to therapy, or use viral load as a prognostic indicator of disease progression.

The major pathogenic virus chapters have all been updated and there is considerable useful information on the latest developments in direct detection methods for viruses. This 7th edition has new chapters covering (i) rotavirus and noroviruses; (ii) Marburg, Ebola, and arenaviruses; (iii) coronaviruses including that causing severe acute respiratory distress syndrome, or SARS; (iv) poxviruses; and (v) prions and the transmissible spongiform encephalopathies they induce. In addition, the chapter on respiratory syncytial virus and parainfluenzaviruses has been expanded to include human metapneumovirus, which was not recognized as a human pathogen at last writing.

Rapid viral diagnosis, using a combination of direct detection, serology, cell culture, and molecular diagnostics, is now a reality for most virus diseases. This section provides an overview of the standards for viral diagnostics as well as the latest developments in the discipline.

Rapid Viral Diagnosis

MARIE LOUISE LANDRY

68

Over the past 3 decades, the populations at risk for serious or life-threatening viral infections have increased due to aggressive cancer chemotherapy, transplantation, the AIDS epidemic, and the survival of patients with chronic diseases. Antiviral therapies have become available but must be administered early in disease to be effective. Hence, a rapid diagnosis is essential. Viruses have also been recognized as serious pathogens in normal hosts. A rapid diagnosis can reduce costs of antibiotics, avert unnecessary and costly tests, prevent nosocomial transmission, and lead to shorter hospitalizations. The emergence of new viruses, such as severe acute respiratory syndrome (SARS) coronavirus and avian influenza virus, as well as threats of bioterrorism further underscores the importance of a rapid viral diagnosis.

In response to these needs, there has been an explosion in rapid viral diagnostic test development. Rapid diagnostic tests are now available that can provide results within 15 min of sample collection for some viruses and within hours for others, thus significantly shortening the time to diagnosis over conventional culture methods. Immunoassays provide the most rapid results, with some newer methods consisting of only one step and no reagent additions. Molecular amplification techniques have been significantly shortened by real-time detection and more rapid thermocycling. In addition, culture techniques using two cell cultures combined in one vial followed by pooled monoclonal antibody (MAb) staining facilitate rapid and efficient detection of multiple viruses.

Both the diagnostic techniques and the diagnostic approaches to specific viruses are described in detail in other parts of this manual. Therefore, this chapter will present an overview of rapid viral diagnosis, focusing on the advantages and limitations of common methods used, the factors involved in test selection, the validation and monitoring of test performance, and the critical importance of sample collection.

RAPID DIAGNOSTIC METHODS

The methods used for rapid viral diagnosis can be generally grouped according to the following strategies: (i) direct detection of viral proteins, nucleic acid, or particles in clinical specimens; (ii) biologic amplification of infectious virus in cell culture followed by detection of viral antigens in cultured cells; and (iii) detection of an immunoglobulin M (IgM) antibody response to viral infection. Advantages and limitations of these methods are listed in Table 1. With the exception of electron microscopy (EM), rapid tests detect only the specific agent(s) sought.

Direct Detection of Virus in Clinical Specimens

In general, the most rapid approach is to detect virus directly in clinical samples, rather than wait either for virus to grow in culture or for an antibody response to occur. The continuing improvements in sensitivity, specificity, reproducibility, and ease of use of direct methods have resulted in replacement of culture methods in many situations where only a specific virus is sought.

Viral Antigen

Rapid antigen tests remain the most commonly used of the rapid viral diagnostic methods, because of speed and cost. A number of simpler and more rapid tests have been developed in recent years, especially for influenza virus (13).

EIAs

Enzyme immunoassays (EIAs) detect both viral antigens expressed in infected cells and viral antigens in cell-free clinical samples. Therefore, EIAs can be used on respiratory samples and on samples such as serum and stool. Convenient commercial kits are available in a variety of formats. The methodology is well suited to automated, high-volume, batched-sample testing, with results determined by spectrophotometers and analyzed by computer. Alternatively, rapid membrane EIAs in single-sample cassettes with 15- to 30-min assay times can be used even in small laboratories or doctors' offices, and testing can be performed multiple times a day as needed.

However, with EIAs one cannot assess the quality of the sample and cannot distinguish nonspecific reactions unless a neutralization or blocking antibody test is done, which can greatly increase turnaround times. In serum, antibody present in the sample can bind antigen, rendering it undetectable; immune complex dissociation can improve sensitivity.

EIAs have been most successful in detecting viral antigens when high titers are present in clinical samples and have been especially useful for viruses that do not grow in routine cell cultures, such as rotavirus, hepatitis B virus (HBV), and enteric adenovirus. EIAs can provide same-day diagnosis and thus allow earlier intervention than culture methods for respiratory syncytial virus (RSV) and influenza

TABLE 1 Advantages and limitations of rapid viral diagnostic methods[a]

Rapid method	Common clinical applications	Time required	Advantages	Limitations[b]
Direct detection				
EIA Membrane	RSV, influenza virus, rotavirus	0.25–0.5 h	Simple format, minimal training required; can test single or multiple samples and run test multiple times a day; no major equipment	Relatively expensive per-test reagent; nonspecific reactions difficult to detect; single agent detected
Microwell, tube, or bead	RSV, rotavirus, HBV, HIV-1, influenza virus, HSV, adenovirus	2–4 h	Suitable for large test volumes, batching of samples; breakaway strips for smaller sample size; cheaper per-test reagent costs; objective endpoints, computerized data analysis, automated format	Sensitivity varies with virus and kit used; neutralization test needed to detect nonspecific reactions; multiple controls processed with each run; EIA reader and washer, multichannel pipette required
Latex agglutination	Rotavirus, enteric adenovirus	0.5 h	Simple format, no major equipment; suitable for single-sample testing	Subjective; weak positives difficult to read; nonspecific reactions; not as sensitive as EIA
Other rapid formats (IC, LFA, IGA, OIA, EVEA)[c]	Influenza virus, RSV, rotavirus	0.25–0.5 h	Simple format, some only one step; no major equipment; suitable for single-sample testing	Subjective; weak positives difficult to read; may have more false positives than EIA
Immunostaining: IF or IP	RSV, influenza virus, parainfluenza virus and adenovirus in respiratory cells; VZV and HSV in skin lesion smears; CMV in leukocytes	0.5–2 h	Can evaluate quality of sample, characteristic staining pattern and morphology; can detect a single positive cell, multiple pathogens in single sample, or quantitate CMV load in leukocytes; can test single or multiple samples; can run test multiple times a day	Requires significant expertise and training; endpoints subjective; needs good sample with adequate cells; requires fluorescence microscope with good-quality objectives for IF; cytocentrifuge desirable
Amplification techniques: PCR, NASBA, bDNA, hybrid capture	HIV-1 RNA and DNA, HBV, HCV, HTLV-1/2; herpes-, entero-, parvo-, adeno-, papilloma-, and polyomaviruses; respiratory viruses	3–9 h	Sensitivity generally exceeds that of culture; replaces hazardous, insensitive, and/or slow methods; potentially quantitative; high-quality, standardized commercial kits with EIA or real-time detection formats; multiplex formats can detect multiple agents, though sensitivity may decrease	Cross-contamination a problem, especially with PCR; amplification inhibitors may be present; reagents expensive; molecular expertise, meticulous technique, and quality control essential; in-house methods not standardized; extensive space (3 rooms) needed; expensive equipment requirements
EM (negative staining)	Gastroenteritis viruses	0.5–1 h	Open minded; can directly visualize virus and discover unsuspected or new viruses; can rapidly differentiate smallpox virus from VZV	Expensive equipment, extensive expertise needed; high viral titers required
Rapid culture[d]				
SVCC	CMV, VZV, HSV, respiratory viruses, adenoviruses, enteroviruses, HHV-6, and polyomavirus BK	16–48 h	Centrifugation enhances infectivity; characteristic staining pattern enhances specificity; can detect a single positive cell; can detect multiple viruses in one culture by combining two cell cultures in one shell vial and staining with pool of antibodies; detects replicating and not latent virus	Cell culture toxicity and contamination can reduce sensitivity; requires infectious virus; labor-intensive; need expertise in cell culture and IF; tissue culture facilities, centrifuge, and fluorescence microscope required
Immune response IgM antibody: capture EIA, IF	Parvovirus, EBV, arboviruses including West Nile virus, HBV, HAV, rubella, measles, CMV	2–4 h	Valuable when culture or antigen methods are not available or molecular methods are less sensitive; for parvovirus (fifth disease), HAV, HBV, and primary EBV, IgM antibodies detectable in almost all patients at clinical presentation	Compromised hosts and neonates may not have detectable antibodies; heterologous antibody rises can occur; appearance of IgM can be delayed until second week of illness; RF and IgG may interfere

[a]HIV-1, HIV type 1; HTLV-1/2, human T-cell leukemia virus type 1 or 2; HHV-6, human herpesvirus 6; bDNA, branched DNA.
[b]All rapid methods except EM are limited to the detection of suspected viruses; an unexpected or new virus will not be discovered.
[c]IC, immunochromatography; LFA, lateral flow assay; IGA, immunogold assay; OIA, optical immunoassay; EVEA, endogenous viral enzyme assay.
[d]Limited to viruses that grow in commonly available cell cultures.

viruses. Microtiter EIAs may be batched and not performed daily if sample numbers are insufficient. In contrast, membrane EIAs can be performed 24 h a day, whenever a rapid diagnosis is needed. Although readily implemented in laboratories without virology experience, EIAs may not be commercially available for the desired pathogen.

Agglutination

The advantages of agglutination assays include simplicity, speed, and lack of expensive equipment. However, the sensitivities are not as high as that of EIA (17). When the specimens contain large amounts of viral antigen, agglutination can be used with acceptable results. This would include rotavirus and enteric adenovirus in stools of infants with gastroenteritis. When antigen is present in great excess, however, a prozone reaction can occur, leading to a false-negative result. This can be detected by repeating the test at a higher sample dilution. The visual reading of agglutination is subjective, and reading borderline samples requires considerable expertise. In addition, some stools can agglutinate control beads. Nevertheless, this test can be used in smaller outpatient laboratories and in doctors' offices.

Other Rapid Antigen Formats

In recent years, a variety of other rapid test formats have become commercially available, especially for influenza A and B viruses and RSV (13). Whereas membrane EIAs usually involve a series of steps, including reagent additions, washes, and addition of stop reagent, newer rapid formats such as lateral flow immunochromatography require addition of one or no reagent and thus are very simple to perform. Optical immunoassays allow visualization of a physical change in molecular thin films, caused by antigen-antibody binding. One rapid influenza virus test utilizes an endogenous virus-encoded enzyme, influenza virus neuraminidase, to cleave a substrate and produce a colored product. Disadvantages include subjective interpretation, lack of automation, and lower sensitivity than immunofluorescence (IF) or culture methods.

IF

IF is a demanding technique that requires careful attention to detail throughout. Personnel training is significantly more rigorous for IF than for EIA. Since viral proteins are visualized in infected cells, IF is limited to samples that contain sufficient numbers of target cells. IF is commonly performed on cell smears from skin lesions, nasopharyngeal (NP) aspirates, tissue touch preparations, and peripheral blood leukocytes (PBLs). Advantages of IF include the opportunity to assess the quality of the sample, to discern specific from nonspecific staining patterns, to detect a single infected cell, and to test one sample for multiple viral pathogens. It can be applied to single or multiple samples, and per-test reagent costs are generally less than for other methods.

Recent improvements include shortening staining incubation time to as little as 20 min, using cytocentrifugation to enhance slide quality, and combining antibodies with different fluorochrome labels, such as fluorescein isothiocyanate and rhodamine B, to simultaneously detect and differentiate multiple viruses on the same slide. This approach has been used successfully to test for herpes simplex virus (HSV) and varicella-zoster virus (VZV) simultaneously in cell smears from skin lesions (1). In addition, a pool of MAbs to seven respiratory viruses can be used for detection of RSV, influenza viruses A and B, parainfluenza viruses 1, 2, and 3, and adenovirus in a single cell smear within 1 to 2 h of receipt of the sample, without compromising test sensitivity

(Color Plate 9) (7). Immunoperoxidase (IP) staining can be used in place of IF. IP slides are permanent and can be read with a light microscope; however, IP staining requires an extra step, the addition of a substrate.

The essential prerequisites for accurate IF testing are an experienced and well-trained microscopist, high-quality antibodies, a fluorescence microscope, and a sufficient and steady flow of samples to develop and maintain expertise. IF also works best in settings that allow education in sample collection and the ability to re-collect inadequate specimens. Established criteria for interpretation must be strictly followed, and results should be validated initially and intermittently thereafter by culture or other methods. MAbs have replaced polyclonal antibodies in most assays. However, low affinity and too narrow specificity of MAbs can be problems for clinical diagnosis, and a pool of two or more MAbs may be required. Antibodies should be selected specifically for the assay and sample type for which they will be used. For example, when cytomegalovirus (CMV) antigen is being detected in PBLs, a pool of MAbs to CMV matrix protein pp65 gives the best results (4). In contrast, early detection of CMV in shell vial centrifugation cultures requires an antibody to an immediate-early CMV protein. MAbs are now commercially available for most common viruses, allowing wide application of IF to clinical diagnosis.

IF staining is more sensitive than culture for detection of RSV in NP aspirates, VZV in skin lesions, and CMV in blood leukocytes. In addition, detection of CMV pp65 antigen in PBLs (Color Plate 10) allows direct quantitation of viral load in the blood, which correlates with clinical disease and can be used to monitor response to treatment. CMV antigenemia on PBLs can be as sensitive as CMV PCR on plasma and can be completed within 2 h (6). The sensitivity for other viruses or sample types is variable, ranging from 60 to 95% of that achieved by culture (7).

Viral Nucleic Acid

Amplification Methods

New developments in amplification methods continue to generate great interest in clinical laboratories due to their sensitivity and speed. In an age of SARS, avian influenza, and bioterrorism, the ability to inactivate virus prior to laboratory analysis is also very appealing. Nucleic acid amplification techniques biochemically amplify either a nucleic acid sequence or a detector molecule, resulting in a sensitivity that equals or exceeds those of culture methods. These methods have found their greatest initial application in the detection of viruses for which other methods are either too expensive, slow, or insensitive or simply unavailable, such as the detection of viruses in cerebrospinal fluid of patients with infections of the nervous system (e.g., enterovirus, HSV, and CMV); detection of human immunodeficiency virus (HIV), HBV, and hepatitis C virus (HCV) in blood; and detection of parvovirus B19 in immunocompromised hosts. In addition, amplification methods are amenable to quantification and thus have been extremely useful in monitoring viral load and response to therapy (e.g., HIV, HBV, HCV, and CMV). Furthermore, DNA is generally more stable than antigen or infectious virus, an important consideration when processing is delayed or samples are shipped to a distant reference laboratory.

To date, the most widely applied method is PCR. Initial PCR formats involved amplification of DNA in a thermal cycler followed by detection of the amplified product (amplicon) by gel electrophoresis, Southern blotting, or spot hybridization. Nested PCR methods provide increased sensitivity but

are at high risk for cross-contamination. The development of commercial kits, enzyme-linked amplicon hybridization detection in microtiter plates, strict quality control guidelines, and strategies to prevent cross-contamination have all been important advances.

Recent emphasis has been on real-time detection methods that eliminate the need for a separate step to detect amplified products. Instead, an indicator or reporter is generated as amplification is occurring, and can be monitored in real time. Real-time assays are especially suitable for quantification of target. A high viral load may correlate with clinical disease, prognosis, and response to treatment, especially in compromised hosts. In addition, thermal cyclers with more rapid temperature cycling have been devised, such as LightCycler and Smartcycler, to shorten amplification time. Automated nucleic acid extraction instruments, commonly used in high-volume laboratories, result in both labor and time savings.

It is critical to note that in-house methods, including those used by reference laboratories, are not standardized. Sensitivity varies tremendously, due to different primers and probes, extraction methods, amplification protocols, detection methods, and platforms used, and cross-contamination remains a concern. Blind interlaboratory comparisons of PCR methods have found significant variation in both sensitivity and specificity among laboratories (10, 12). Thus, PCR results should be carefully monitored and performance characteristics should be clearly defined.

Signal amplification methods are also available in commercial kits and are widely used for genome detection and quantification. While slightly less sensitive than PCR, these methods do not suffer from amplicon carryover, are highly reproducible, and have a large dynamic range which facilitates quantification. Nucleic acid sequence-based amplification (NASBA) is very sensitive for RNA targets, and a basic kit that can be used in many applications is available (8). Since amplified product consists of single-stranded RNA transcripts, contamination of the environment is less of a problem than with DNA amplicons of PCR.

It should be kept in mind, however, that these highly sensitive methods are capable of detecting nonreplicating as well as replicating virus. Many of the viruses sought cause almost universal infection and persist in the host for life (e.g., herpesviruses and polyomaviruses). Thus, the clinical significance of a qualitative positive result, as well as the predictive value of a quantitative result, may be unclear and may vary among laboratories due to different methods employed.

Clinical use continues to increase, and in some large reference laboratories, amplification methods have essentially replaced cell culture (2). For the smaller laboratory, limitations include the need for molecular expertise and expensive equipment, extensive in-house validation required for all non-Food and Drug Administration-approved assays, and sufficient test volumes to make testing cost-effective. The costs of doing separate PCR assays for each virus in the differential can also be prohibitive. Development of multiplex assays, which detect multiple pathogens in a single assay, will help to reduce costs while broadening clinical utility (14).

Nucleic Acid Hybridization

Nucleic acid hybridization techniques without amplification are not widely used in diagnostic laboratories due to lack of sensitivity. However, in situ hybridization, which can provide cellular localization, remains a useful tool in pathology laboratories. Examples include the detection of the Epstein-Barr virus (EBV) genome in tumor tissue, human

polyomavirus (JC) in brain tissue, or human papillomavirus in anogenital samples.

Viral Particles

EM

By use of EM, viral particles can be directly visualized. EM has received renewed attention recently due to concerns about the reintroduction of smallpox as a weapon of bioterrorism and due to the role of EM in the discovery of SARS coronavirus. Samples for EM can be processed within minutes by the negative staining technique. The limit of detection for negative staining is 10^7 to 10^8 virus particles/ml, but the sensitivity can be increased 100- to 1,000-fold by sample concentration with an airfuge. Addition of specific antibody aggregates virus particles, and the immune complexes thus formed can be directly visualized (immunoelectron microscopy). Antibody labeling with colloidal gold also enhances detection of virus. EM is a very labor-intensive and highly skilled procedure, and the basic equipment is very expensive to purchase and maintain. Nevertheless, it remains useful for the discovery and detection of a myriad of noncultivable gastroenteritis viruses and continues to be extremely useful for the detection and identification of unusual, unexpected, or new viruses.

Detection of Virus after Cell Culture Amplification

By this approach, the sensitivity of cell culture is combined with the speed of antigen detection. Isolation of virus by conventional methods involves infection of susceptible cell cultures followed by periodic examination of the cell monolayers for characteristic cytopathic effects (CPE). Depending upon the virus, the inoculum dose, and the cell system used, CPE may appear in less than 24 h to more than 3 weeks after infection. Early detection of viral proteins or nucleic acid, before CPE appears, shortens the time to reportable results. The greatest time savings are obtained for viruses with long replication cycles, and when antibodies to early replication proteins are available. A centrifugation step can be substituted for the standard stationary virus adsorption step to enhance virus infectivity and shorten time to detection.

Several formats for culture amplified rapid diagnosis have been used. Currently, the most common formats are: (i) inoculation of centrifugation cultures in shell vials or multiwell plates, followed by IP or IF staining at 1 to 2 days and microscopic examination; and (ii) inoculation of mixed cell cultures, either stationary or with centrifugation, followed by staining with pooled antibodies (Color Plate 11) (3, 9). The latter method reduces the number of cultures inoculated, read, and stained, while not sacrificing sensitivity for the spectrum of viruses detected. Mixed cell cultures, with corresponding pooled antibodies, are available for respiratory viruses, enteroviruses, and herpesviruses (i.e., HSV, VZV, and CMV).

Another approach to culture-amplified rapid diagnostic testing uses genetically altered cells. In one virus-inducible system, HSV infection activates a viral promoter which then triggers the production of beta-galactosidase (16). The addition of the substrate X-Gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) results in a blue precipitate on infected cells. No antibodies, conjugates, or probes are needed.

Methods using microscopy and IF or IP have the ability to detect a single infected cell and to assess the morphology of the stained cell. Furthermore, nonspecific staining is less of a problem with cell culture monolayers than with clinical samples and training is more readily obtained. Both formats are helpful to laboratories lacking experience in discerning

viral CPE. Multiple viruses can be detected by using a combined antibody pool to screen cultures, followed by separate antibodies to identify specific pathogens, or by using antibodies with different fluorochrome labels.

The optimal staining time after infection varies with the antibody, the virus, the inoculum dose (an unknown for clinical samples), and the susceptibility of the cell culture. One or 2 days' incubation will give a rapid turnaround but may miss low-titered samples. A longer incubation of 3 to 5 days may be necessary for maximum sensitivity, especially for adenovirus and VZV. In addition, samples may be toxic to the cell monolayers, reducing their ability to support viral replication.

Antibody Response

Rapid diagnostic techniques relying on the immune response have some basic limitations. Antibody develops in response to viral replication and therefore appears later. Thus, IgM is useful primarily when viral detection methods are not readily available or are too slow to give clinically useful results. Examples include arboviruses, rubella virus, and measles virus. IgM antibodies can usually be detected within 5 to 7 days of clinical symptoms but may require up to 2 weeks. For some virus infections, the clinical symptoms prompting medical attention are immune mediated; therefore, IgM is usually detectable at presentation (e.g., fifth disease due to parvovirus B19, EBV, hepatitis A virus [HAV], and HBV).

Limitations of IgM testing include weak or undetectable antibody responses in immunocompromised patients or neonates, heterologous IgM responses, interference by IgM class rheumatoid factor (RF), competition between IgG and IgM antibodies leading to false positives and false negatives, variability in test methods, failure to detect IgM due to timing of sample collection, persistence of IgM in some chronic or persistent viral infections, and frequent absence of IgM in reinfections or reactivations. For CMV, IgM antibody increases with age in seropositive individuals, presumably due to subclinical reactivation. Cross-reactions between anti-parvovirus, -rubella, and -measles IgM is a particular problem if a rash in pregnancy is being investigated. Hopefully, the use of synthetic peptides to replace virion antigen-based immunoassays will reduce interference by RF, nonspecific reactions, and cross-reactivity (15).

TEST SELECTION

Since each diagnostic method has advantages and limitations, test selection is ultimately a compromise that should be made with careful consideration of numerous factors. The sensitivity and specificity of a particular method will vary, depending upon the virus, the patient population, the sample type, and the laboratory setting. Nevertheless, the test selection process itself should be similar among laboratories and can be envisioned as a series of steps (Table 2).

The process should begin with a clear assessment and understanding of clinical needs. Therefore, the first step is to communicate with clinicians. Priorities should be established on the basis of knowledge of the patient populations served, the major viral pathogens in those populations, and in what settings intervention, either therapeutic or preventive, would be benefited by a laboratory diagnosis. In specific clinical situations, what test characteristics are most critical—sensitivity, specificity, or rapidity of results? Unfortunately, the most rapid method may not be the most sensitive.

The next step is to evaluate the methods available. For some viruses, the choices are currently limited. For others, there are several acceptable methods and numerous

TABLE 2 Guidelines for test selection

Step
Communicate and establish priorities together with clinicians according to:
Patient populations served
Major viral pathogens
Treatment and prevention strategies
Evaluate characteristics of available tests:
Commercial products vs in-house methods
Product literature, publications, experience of other laboratories
Personnel expertise and training requirements
Sensitivity, specificity, and turnaround time
Fit with laboratory workflow and hours of operation
Reagent cost, personnel time, reimbursement
Equipment and space required
Make test selection
Evaluate and validate test in-house
Educate clinicians in sample collection and test performance characteristics
Monitor test performance and periodically reevaluate
Communicate with clinicians for feedback

commercial products to choose from. Turnaround time, anticipated test volume, personnel expertise, fit with laboratory workflow, cost, equipment needed, etc., should be carefully considered.

In smaller hospital laboratories, testing may be limited to membrane EIAs or other rapid test formats suitable to small test volumes, and with less demanding training requirements. In laboratories serving large tertiary care hospitals, multiple methodologies are commonly available, including IF and nucleic acid amplification tests, and algorithms for test use should be in place. However, during hours when the virology laboratory is closed or has minimal staffing, EIA can be used in lieu of more technically demanding assays.

DIAGNOSTIC ALGORITHMS

While there is no consensus on the details of diagnostic algorithms for specific viruses, they must be developed in every laboratory, keeping in mind the limitations of each method and, most importantly, how results will be utilized clinically. A choice of tests accompanied by recommendations can be provided to the physician, or the diagnostic algorithm can be internal to the laboratory. The tests used will vary with the season, the clinical disease, age, risk factors, immune competence, and severity of illness. Diagnosis of RSV is given as an example in Fig. 1. In the normal child, if the rapid RSV antigen test is positive, detection of additional viruses does not appear to affect patient outcome and thus may not be justified. If the rapid test is negative but the purpose of the test is to cohort patients on admission to the hospital, a multiplex IF test could be done. Culture results available even 1 to 2 days later may be too late for infection control purposes, since many children will be ready for discharge by then. However, for a hospitalized patient, determining an accurate etiology may be important even if results are delayed.

Methods able to detect a spectrum of pathogens include IF, shell vial centrifugation culture (SVCC), conventional culture, and multiplex PCR. Laboratories capable of doing IF can screen for multiple respiratory pathogens in a single cell spot by using pooled MAbs and have results within 2 h of sample receipt (7). Alternatively, SVCC with pooled antibodies has

                          Multiplex RT-PCR

FIGURE 1 Example of a diagnostic algorithm for RSV. (a) Coinfection with multiple viral pathogens does not appear to affect the outcome of RSV infection in the healthy child. (b) For the outpatient, no additional tests or a rapid influenza test may be indicated. (c) For the hospitalized child, either one or several tests can be done, depending upon the severity of illness, the resources available, and the need to cohort patients infected with other viral pathogens. (d) In compromised hosts, a comprehensive workup, including detection of mixed infections, is often indicated.

yielded acceptable results at 1 to 2 days for most common viruses (3, 9). Reports of multiplex PCRs have been published, but these PCRs are not widely available for clinical use. Since all methods miss a proportion of true positives, laboratories may employ multiple methods. To properly design a diagnostic algorithm, data on outcomes should be collected and analyzed to assess the benefits and the cost of each approach. It is apparent that appropriate testing requires clinical information. If this information is lacking, inadequate or superfluous laboratory testing can occur.

VALIDATION AND MONITORING OF TEST PERFORMANCE
Once a test is selected, it must be evaluated in the laboratory. It is important to establish how the test functions in the unique setting into which it will be introduced and to not rely on the manufacturer's claims in the package insert or publications from other institutions. If on initial evaluation the test does not function as anticipated, the reasons should be investigated (e.g., poor sample collection, improper test procedure, different patient population, lack of technical expertise, etc.) and corrective action should be taken or a more suitable method employed. Furthermore, each test offered by the laboratory should be monitored and periodically reevaluated to assess its performance and to determine whether it continues to serve the needs of patients and physicians. Test validation and monitoring are facilitated when more than one technique for a specific virus is in use in the laboratory. Use of two tests, such as IF and culture, in at least a proportion of patients facilitates training, serves as a cross-check, and increases expertise. For direct IF and in-house amplification methods in particular, the

pitfalls are many and careful monitoring of results is critical. Active seeking of both clinical correlation and feedback from clinicians is essential and should be ongoing.

THE IMPORTANCE OF SAMPLE COLLECTION
Poor specimens yield poor results, yet most physicians are unaware of the importance of or the factors involved in proper sample collection. The best samples contain high viral titers and/or numbers of infected target cells. Taking respiratory disease as an example, NP washes and NP aspirates give the highest yield of positive test results. NP swabs give variable results in inexperienced hands (5). Throat swabs (TS) have the lowest yield and are unacceptable for IF since they contain predominantly squamous and not ciliated epithelial cells. If TS are collected for culture or EIA, a combination of TS and NP swab in a single vial is recommended to improve results.

Samples should be collected early in illness, when virus titers are highest, using correct technique and swabs or tissues placed in transport medium appropriate for the tests to be performed. Body fluids should be submitted in sufficient volume for adequate testing. Transportation to the laboratory should be prompt, and samples for culture or IF should be kept on ice if a delay is anticipated. Alternatively, cells from lesions or NP swabs can be applied to slides and fixed in acetone immediately after collection. For CMV antigenemia, blood samples must be processed and leukocytes must be fixed within 6 h of collection for accurate quantitation; a decline in antigen-positive cells can be minimized by storage at 4°C. Nucleic acid amplification tests are also adversely affected by poor sample collection and handling, and requirements for samples for quantitative tests especially should be strictly followed.

Note that in published reports, individuals may have been trained in sample collection for the purpose of the study. The samples routinely submitted to clinical laboratories are collected by untrained persons and often yield inferior results. Since a significant percentage of samples submitted for IF can be inadequate or uninterpretable, IF may not be suitable for large reference laboratories where there is little control over sample collection or opportunity for re-collection.

For nucleic acid detection and quantitation methods, the sample types tested significantly impact the test sensitivity and viral load measurements. It has been shown that higher virus titers are found in plasma than in serum. For cell-associated viruses such as HIV and CMV, PBLs and whole blood contain more virus than does plasma alone.

Lastly, it has been shown that when physicians call the laboratory for advice prior to sample collection, the isolation rate doubles (11). Thus, unless clinicians are educated in sample collection procedures, the substantial effort expended on selecting the most sensitive test method will not yield the desired results.

SUMMARY AND CONCLUSIONS

The choices for rapid viral diagnosis continue to increase. A variety of test formats are available, from walk-away automated systems with computer-generated printouts to single-specimen membrane immunoassays read visually. Nucleic acid hybridization and amplification methods continue to evolve at a dazzling rate, with increasing automation in nucleic acid extraction, amplification, and detection, real-time reporting of amplification results, and faster time to result. Thus, viral diagnosis is no longer an esoteric discipline confined to a small number of university laboratories and state health departments but is becoming increasingly commonplace in community hospitals and even doctors' offices.

Since no method is 100% sensitive and specific and all rapid tests are limited in scope, test selection is ultimately a compromise that should be made with careful consideration of numerous factors. The number and types of techniques chosen will vary with the individual viruses, laboratory expertise, and clinical needs and will continue to change as both test methods and antiviral therapy evolve and improve. Laboratories must know the limitations of the tests offered—specifically, the performance of each test in their hands, with their transport system and their patient population—and communicate this information to clinicians. Once introduced, tests should be routinely monitored and periodically reevaluated.

To provide clinically relevant, cost-effective, and accurate information for patient management, it is important to go beyond the confines of the laboratory, to work with clinicians in establishing priorities, improving sample collection, and seeking clinical correlation and feedback.

Enhanced Detection of Viruses in Cell Cultures

THOMAS F. SMITH

69

Prior to the mid-1980s, practical diagnosis of viral infections was based on the development of cytopathic effects (CPE) and the recognition of those changes in cell cultures. Several viruses such as herpes simplex virus (HSV), respiratory syncytial virus (RSV), influenza virus, and cytomegalovirus (CMV) were able to infect cells cultured in vitro, but the time for recognition of the CPE produced by these agents ranged from a few days to several weeks. With conventional tube cell culture techniques, diagnostic results of a CMV infection causing systemic disease in an organ transplant recipient or an AIDS patient may not have been available to the clinical service for several days.

The most significant step in the implementation of rapid cell culture techniques in the diagnostic virology laboratory has been the ability to develop epitope-specific monoclonal antibodies directed to select early antigens of viruses in the replication cycle (28, 59). Thus, rather than observing the development of CPE during a lengthy incubation period, monoclonal antibodies reacted with regulatory or structural components of viruses that were synthesized during the first few hours of infection in cell cultures; presence of these early antigens could be recognized by using immunofluorescence or immunoperoxidase. Interestingly, cell culture (conventional tube and shell vial cell culture assays) has been the traditional "gold standard" for detection of virus infections in the clinical laboratory. These culture methods have been the benchmarks for comparison of automated commercially available platforms for performing nucleic acid amplification by PCR and other methods. In particular, real-time amplification of target nucleic acids provides more sensitive and rapid detection of viruses for support of clinical medical practices for the routine detection and quantitation of viruses from clinical specimens. Procedures previously implemented for the laboratory diagnosis of *Chlamydia trachomatis* infections by using shell vial cell cultures and low-speed centrifugation to enhance the efficiency of infection of this intracellular organism have been widely implemented for the detection of viruses by using specific monoclonal antibodies. More recently, the shell vial assay has been used for the rapid detection of rickettsiae and several other bacterial species (6, 23, 36, 37). The standard procedure, application for the detection of several viruses, and the technical variables that may affect the ability of the laboratory to provide sensitive and specific results with the shell vial assay are described in this chapter. Certainly, since the previous edition of this manual (57a) there has been

significant incorporation of molecular methods into diagnostic virology laboratories. The transition of cell culture to routine nucleic acid-based methods is presented for consideration of future application in diagnostic virology laboratories.

GENERAL PRINCIPLES

Shell vials (1 dram [3.697 ml]) containing a circular coverslip are seeded with susceptible cells that develop into a monolayer. After removal of growth medium, specimen extracts are inoculated into 1-dram shell vials, which are then centrifuged at $700 \times g$ (2,000 rpm) for 45 min. After addition of medium to the vials and overnight incubation (16 h at 36°C), cell monolayers on the coverslip are stained with a monoclonal antibody by the indirect immunofluorescence (preferably) or immunoperoxidase serologic technique (28, 59). The stained coverslips are then examined microscopically for specific stained foci. Detailed procedural steps, reagents, and equipment are provided in another American Society for Microbiology publication (76).

CELL CULTURES

Preparation of Shell Vial Cell Cultures

Monolayers on the surface of a 32-oz culture vial are removed and dispersed with a solution of trypsin-EDTA. The cells are resuspended in growth medium (~100 ml); 0.5 ml is dispensed into each shell vial to produce a monolayer in 1 to 3 days. Inoculation of preformed monolayers is preferable to simultaneous seeding and infecting of shell vials for the rapid detection of CMV infection (20).

Types

The choice of host cells used in the shell vial assay is based on the viruses to be isolated in a particular clinical setting, cost, and practicality. In the diagnostic laboratory, cell culture systems that provide the broadest range are usually chosen. Embryonic human diploid fibroblast (MRC-5) cells are optimal for the detection of CMV, HSV, varicella-zoster virus (VZV), and adenoviruses in shell vials, whereas mink lung, astrocytoma (U-373MG), and human lung carcinoma (A-549) cells have more restricted susceptibilities to infection by a wide range of viruses (8, 11, 39). MDCK cells can be used for primary detection of influenza virus type A (3). Generally,

cells that are diploid and are nearly confluent monolayers are optimal; neoplastic cell lines tend to produce multiple layers of cells, which makes a single virus-infected focus difficult to detect.

Age

Shell vial cell cultures ranging in age between 3 and 8 days should be used for inoculation of viral specimens. Monolayers exceeding this range are significantly less sensitive to CMV and are more fragile to toxic effects of certain specimens, particularly urine. Importantly, some commercially prepared shell vial cell cultures may be at least a week old when received at the clinical laboratory.

Specimens

Specimens from several sites are appropriate for inoculation into shell vial cell cultures for the diagnosis of herpesvirus (CMV, HSV, and VZV) and adenovirus. Detection of these viruses is optimal in MRC-5 human diploid fibroblast cells; however, HEp-2 cells (RSV), A-549 cells (RSV, influenza B virus, parainfluenza virus, and adenovirus), and primary rhesus monkey kidney or MDCK cells (influenza virus A and B and parainfluenza virus) should be used to detect these viruses in respiratory tract specimens (47, 61).

Urine

Urine is the best specimen for indication of CMV infection but does not provide definitive information about etiology because the virus is excreted commonly by asymptomatic patients, especially those who are immunosuppressed. Nevertheless, the predictive value for invasive disease with this specimen source is 40%. Because urine specimens do not have a high predictability for disease, continuous longitudinal monitoring of this source for CMV is not recommended. It is not necessary to adjust the pH of urine specimens to neutrality prior to inoculation to achieve maximal infection of shell vial cell cultures with CMV. The cellular fraction of urine (sediment after centrifugation) is the most productive specimen for detection of CMV from this specimen source (5).

BAL Fluid

Bronchoalveolar lavage (BAL) is an adaptation of routine bronchoscopic washing that involves wedging a fiberoptic bronchoscope into a subsegmented bronchus to sample cells in the lower respiratory tract. The technique is simple and obviates open lung biopsy, but it is invasive and patients are given atropine (subcutaneously), lidocaine is applied topically to the pharynx and upper airway, and supplemental oxygen is provided during the procedure (46). Most infectious CMV is associated with the cellular components of BAL specimens; however, there may be substantial amounts of virus in the cell-free fraction, particularly in specimens obtained from AIDS patients (14).

BAL specimens from bone marrow transplant patients yielded more positive results for CMV in the shell vial assay than did immunofluorescent antibody staining or cytologic identification of lung biopsy tissue. Nevertheless, CMV has been recovered from BAL specimens in the absence of disease and from patients simultaneously infected with other pathogenic organisms. Importantly, the specificity of BAL culture for CMV results varies greatly with the population being studied. A positive culture has greater clinical significance for solid-organ recipients than most other immunosuppressed patient groups.

Blood

Many viral infections have a viremic phase prior to the onset of clinical manifestations. In contrast, CMV viremia may persist for several days after a febrile episode in an immunocompromised patient. CMV infects leukocytes (lymphocytes, monocytes, and polymorphonuclear leukocytes [PMNs]); therefore, efficient recovery of this cellular fraction from anticoagulated blood specimens is necessary for maximum detection of this virus. For this purpose, HISTOPAQUE-1119 (Sigma Co., St. Louis, Mo.) separates these leukocytes from either EDTA-treated or heparinized blood specimens into a single diffuse band after centrifugation for approximately 20 min preparatory to inoculation into cell cultures. Generally, the greater the number of PMNs inoculated into shell vial cell cultures, the more likely that CMV viremia will be detected. For example, 96% of CMV strains were detected with an inoculum of 800,000 cells, compared to only 63% with an inoculum of 200,000 cells (58).

Detection of CMV in blood is considered a marker of systemic infection and correlates better with clinical disease and organ involvement than does the presence of the virus in urine or respiratory tract specimens (2). CMV accounts for over 90% of the viral isolates from blood cultures. Of 96 CMV strains recovered from blood specimens, 31 (32%) and 24 (25%) were detected exclusively in shell vial and conventional tube cell cultures, respectively (55). On the other hand, viremia with CMV may be transient or at least may not persist for more than a few hours even in immunocompromised patients (53). For example, of 46 CMV-viremic organ transplant patients who had repeat blood cultures performed after 1 to 3 days, only 40% were culture positive for the virus (53).

Although detection of CMV by PCR is more sensitive than the shell vial assay for early detection of the virus and preemptive therapy, the specificity of the shell vial technique (86%) is clearly superior to that of nucleic acid amplification (35%) for association with symptomatic infection (54).

Tissue

Lung tissue has been the single most productive source of viruses from these specimen types; however, BAL generally has replaced open lung biopsy as a technique for evaluation of lower respiratory tract disease due to CMV and other microorganisms (63).

Monoclonal Antibodies

Ideally, a monoclonal antibody directed to an immediate-early antigen product of replication is used for the immunologic detection of a virus infection. Indirect immunofluorescence assays are more sensitive but more labor-intensive than the use of direct labeled monoclonal antibodies to viral antigens. The ability of monoclonal antibodies to react with defined viral epitopes is extremely important for maximum sensitivity of the shell vial assay by immunologic techniques. For example, the 2H2.4 reagent is directed to a specific 72-kDa product of CMV synthesized in the first 3 h in the nucleus of the infected cell. In contrast, a monoclonal antibody reactive with a late product (2F3.0, 68 kDa; 48 to 72 h postinfection) detects structural antigens present in mature CMV particles rather than the regulatory and enzymatic products initially synthesized by the virus-infected cells.

Overall, characterization of the reactivity of monoclonal antibodies is most detailed for the herpesvirus group; however, specific reagents are commercially available for use in the shell vial assay for viruses causing respiratory tract disease.

Variables

Several technical steps of the shell vial assay must be followed to achieve maximum sensitivity for this cell culture detection system. In addition to the age of cells, condition of cell monolayers, and specificity of monoclonal antibodies for immediate-early or early viral antigens, other important variables include incubation temperature, number of shell vial cell cultures used per specimen, centrifugation, type of specimen (urine, blood, BAL fluid, tissue), quality of fluorescence equipment, chemical pretreatment of cell monolayers, and technical experience with the assay to subjectively evaluate specific results (Table 1).

Criteria for Diagnostic Results

Patterns of fluorescence after staining of infected cells are distinct and specific. Sometimes even a single focus (CMV), characterized by a dense immunofluorescence with prominent lobular staining in the nucleus, is sufficient to recognize a virus-infected cell. Both the smooth regularity of the nuclear membrane and the characteristic shape of the CMV-infected cell nuclei allow the specific recognition and distinction of this viral infection from background nonspecific debris that may fluoresce (Fig. 1).

Importantly, laboratory diagnosis can be achieved within 16 to 24 h postinoculation rather than several days after submission of the specimen to the laboratory. Even in laboratories that are not able to achieve maximum detection of virus by the shell vial assay, a significant number of results can be reported rapidly to the clinical service when the shell vial assay is used. Indeed, in 11 separate reports, the sensitivity of the shell vial assay ranged from 55 to 100% compared to eventual isolation of CMV in cell cultures (62). The shell vial assay is 90 to 100% sensitive for detecting VZV infections, whereas for viruses obtained from respiratory tract specimens (RSV, influenza A and B viruses, parainfluenza virus types 1, 2, and 3, adenovirus, and enterovirus), the sensitivity ranges from 60 to 94% compared with conventional tube cell culture (3, 25, 34, 35, 57, 75). Rapid detection of viral infections of the respiratory tract can reduce the time of hospitalization and patient care costs (4).

Mixed infections due to viruses can occur at frequencies that range from 7.6%, for mixed infections with RSV and CMV, rhinovirus, adenovirus, influenza and parainfluenza virus, echovirus, or HSV, to 35% for a simultaneous epidemic of parainfluenza virus and influenza virus (45). Each of these viruses can be specifically isolated and identified by CPE in tube cell cultures provided that susceptible cells are inoculated; eventual identification of each virus requires several days' time with this conventional technology. Generally, only infection with a single virus is recognized by rapid techniques like the shell vial assay, direct immunofluorescence of virus-infected cells, or enzyme immunoassay procedures, unless a mixture of monoclonal antibodies can be used as a single reagent (45). On the other hand, a monolayer stained with antibodies to CMV, for example, may be restained with antibodies to another virus. This procedure may be used in situations in which a rapid shell vial assay result is needed but inoculated, unstained cultures are not available.

QUALITY CONTROL

Cell Cultures

Cell cultures, especially from several commercial sources, may differ significantly in their susceptibility to virus infection. The laboratory should follow an appropriate quality control program extensively outlined in another American Society for Microbiology publication (73).

Positive Controls

Reference strains of viruses are used to inoculate shell vial cell cultures at a concentration designed to produce a countable number of fluorescent foci. The control cell cultures are processed (incubated and stained) in the same manner as specimens from patients.

Negative Controls

Uninoculated shell vial cell cultures are incubated and stained, using the same lot of cells used for the positive control and specimens from patients. No specific fluorescence patterns should be detectable in these controls.

COMPARISONS OF SHELL VIAL ASSAY WITH OTHER METHODS

Conventional Tube Cell Cultures

Performance characteristics of the shell vial assay compared with conventional tube cell cultures have generally been directly related to the effort expended by the laboratory to control the variables of the immunologic detection system used. Several comparisons have demonstrated that the shell vial assay is as sensitive as (for HSV and respiratory tract viruses [adenoviruses, parainfluenza virus types 1, 2, and 3, enterovirus, influenza A and B virus, measles virus, mumps virus, and RSV]) or even more sensitive than (for CMV) the recovery of these viruses in conventional tube cell cultures, which may require several days to weeks for recognition by CPE (25, 34, 35, 75). For some viruses (adenovirus and enterovirus), detection was more sensitive by the shell vial assay within 3 days after inoculation but conventional tube cell cultures ultimately yielded more viral isolates.

Acute respiratory tract infections caused by viruses are a significant cause of morbidity and mortality in all age groups but especially in immunocompromised patients and in individuals at increased risk for influenza virus-related complications (32). Importantly, influenza virus infections have been responsible for an average of approximately 36,000 deaths per year in the United States from 1990 to 1999 (68). Influenza virus vaccination is the primary method for preventing influenza and its severe complications as recommended by the Advisory Committee on Immunization Practices (32). However, antiviral drugs are an adjunct to influenza vaccine for controlling and preventing influenza; nevertheless, these agents are not a substitute for vaccination. Four licensed influenza antiviral agents are available in the United States: amantadine, rimantadine, zanamivir, and oseltamivir. Importantly, active influenza virus infections can now be treated in the early acute stage of disease. For example, oral administration of oseltamivir (Tamiflu) can be effective in patients identified with influenza virus infection within the initial 2 days of infection.

Rapid laboratory diagnosis of influenza virus infections by shell vial cell cultures will not be facilitative to guide specific therapy since recent publications indicate that the majority of isolates were identified only after 48 or 120 h postinoculation of R-mix (a mixed monolayer of human lung-derived cells [A-549] and mink lung-derived cells [Mv1Lu]) shell vial cell cultures (74). In another report, nearly all of the influenza virus infections were detected after 18 to 24 h postinoculation (17). These differences, including the lability of these viruses in transit to the laboratory, may be intrinsic to the variables inherent in cell culture methods (38, 64).

TABLE 1 Technical variables in the shell vial assay

Procedure step	Standard recommendations	Comments
Incubation temperature of virus-inoculated shell vial cultures	36°C	Incubation of inoculated cultures at 39 and 42°C does not increase the sensitivity compared with the standard 36°C
Time between inoculation and staining of shell vial cell cultures	Stain with monoclonal antibody to immediate-early antigen at 16–24 h	Time interval may be increased to 40 h to compensate for a suboptimal shell vial assay procedure, e.g., use of cell monolayers older than 8 days from time of preparation, use of one rather than two shell vial cell cultures, and staining with monoclonal antibodies with reactivity to late viral antigens
No. of cultures inoculated per specimen	Three shell vials should be inoculated with blood specimen; two shell vials are adequate for specimens from other sources	Inoculation of three shell vials versus two increases the rate of detection of CMV by 20%
Centrifugation	700 × g for 40 min	Both the rate and the efficiency of infection of host cells by viruses are significantly enhanced (10–20-fold) compared to shell vials not centrifuged after addition of the virus inoculum; the actual sensitivity of the shell vial assay for the detection of CMV infections increases from 40 to 100% with centrifugation; gravitational forces higher than recommended can cause cell damage and reduced sensitivity of the assay
Volume of inoculation and type of specimen	Urine, BAL fluid, and supernatant fraction of specimen (respiratory, dermal, tissue) extracts are inoculated into two shell vials (0.2 ml/vial); shell vial cell cultures must be used between 3 and 8 days after preparation to ensure maximum sensitivity to viruses	Higher volumes of inocula may produce more fluorescent foci than detected by using recommended amounts of specimen material; however, toxicity of cell monolayers can result from extra debris in larger specimen volumes
Peripheral blood leukocytes	Leukocytes are separated from anticoagulated blood specimens (10 ml) by HISTOPAQUE-1119 and suspended in 2 ml of medium; each of three shell vials receives 0.3 ml of inoculum	Shell vial coverslip cell cultures must be stained 16 h after inoculation with peripheral blood leukocytes to avoid toxicity of monolayers
Examination of infected cells	Fluorescence equipment with appropriate filters should be used to maximize detection of fluorescence with fluorescein isothiocyanate; the fluorescence pattern produced by a virus after immunostaining should be intracellular and produce consistent patterns compared to virus-infected controls	Xenon or mercury light sources are superior to halogen for the immunological detection of virus-infected cells
Detection label for monoclonal antibody (fluorescence, enzyme)	Commercial reagents are readily available for fluorescence detection of virus-infected cells	Sensitivity for detecting virus-specific antigens in infected cells is generally comparable to that of fluorescence or enzyme-labeled antibodies
Technical expertise	Shell vial assay should be standardized according to conditions demonstrated to be optimal; expertise with the assay is built by familiarization with the variables of the test; adequate time is needed to implement the test procedure according to specified procedures	Procedural changes in the laboratory should be implemented only after the results are compared to those of the standard shell vial assay
Chemical treatment of shell vial cell cultures	The role of routine use of 1% solutions of dimethyl sulfoxide and 10^{-5} M dexamethasone has not been consistently established	Effects of chemical treatment and shell vial cell cultures to enhance viral infection appear to be extremely variable in several reported publications; chemicals such as dimethyl sulfoxide and dexamethasone may be toxic to cell culture monolayers
FIGURE 1   Detection of early antigens in the shell vial assay by immunofluorescence (left) and immunoperoxidase (right) stains. Magnification, ×400.

In addition, it was noted recently that R-mix cells can also be infected by severe acute respiratory syndrome coronavirus (SARS-CoV) in specimens from the respiratory tract which may be submitted to the laboratory from patients infected with this highly pathogenic and virulent virus. These findings indicate that further work is needed to enhance appropriate biosafety precautions for use of R-mix cells in diagnostic laboratories likely to process specimens containing SARS-CoV (27).

Antigenemia

The antigenemia test is a rapid (4- to 6-h) quantitative method for detecting CMV antigens in PMNs by using immunoperoxidase or immunofluorescence staining procedures. Importantly, pools of monoclonal antibodies must be directed to a 65-kDa lower matrix protein of the virus. Studies reporting the diagnostic utility of the antigenemia assay have been expanded to include solid-organ and bone marrow transplant patients and individuals with AIDS. In general, the performance characteristics of antigenemia parallel those reported for nucleic acid amplification techniques (PCR) (7, 56) (Table 2). Nevertheless, in most studies, real-time PCR assays detect the presence of CMV infection earlier and with greater sensitivity than do shell vial cell cultures (48) (Table 2). Note, however, that antigenemia and PCR are highly specific for CMV

infection, but these tests must be used in a quantitative fashion to predict and diagnose disease and to yield information for antiviral drug efficacy (10, 13, 41). Antigenemia assays are limited to blood specimens and have been restricted for general use by the cumbersome and nonstandardized technical aspects of sample processing (43). In contrast to nucleic acid amplification technology, automated instruments are not available for antigenemia testing. Lastly, quantification of CMV viremia is more accurate, precise, and measurable over a much wider dynamic range (29, 50). Typically, antigenemia values are reported in increments of 0, 1 to 10, 11 to 100, 101 to 1,000, and over 1,000 positive cells per 2×10^5 leukocytes. These values corresponded to median loads of 125, 1,593, 5,713, 16,825, and 5,425,000 copies/ml, respectively (40).

The test for antigenemia can be obtained in kit form, but the reagents and procedures are not generic. Similar to the shell vial assay, the results of the antigenemia test are influenced by technical variables, including the age of the blood specimen (optimal less than 4 h before processing), formalin fixation followed by permeabilization rather than methanol-acetone, avidity and specificity of monoclonal antibodies to the target pp65 antigen, number of PMNs stained, storage conditions of fixed slides, number of cells examined per slide (especially samples from neutropenic patients) and processing by cytospin preparation (neutropenic patients), quality of microscopic equipment, and technical experience of personnel in interpretation of specific results (9, 16, 26, 41, 42, 65, 77). The wide variability and the lack of standardization among laboratories restrict interpretation of the results of the antigenemia test to local use. The clinical role of this test is still evolving and is predicated on controlling important variables in the test. One of the biggest challenges for the laboratory processing the specimens for the antigenemia test is to stabilize the loss of antigen or viral (CMV) load during periods of specimen transport (12, 51). Importantly, specimens from patients with low-level antigenemia (fewer than five pp65-positive cells) may yield false-negative results if the blood samples are not processed within 4 h of collection.

PCR

Several advances in the performance of PCR and other nucleic acid amplification techniques have occurred in recent years. For example, in the past, conventional automated thermocycling instruments were programmed to perform 40 to 45 cycles of nucleic acid amplification that required 3 to 4 h; this was followed by gel electrophoresis of the PCR-amplified

products and Southern blotting with probe hybridization techniques. More recently, commercially available primers labeled with biotin or a fluorescent label have been incorporated into amplified products, which may be detected by colorimetric, fluorescent, or chemiluminescence methods (67). In addition, these detection methods have been incorporated into several automated platforms that yield quantitative CMV DNA, hepatitis C virus RNA, and human immunodeficiency virus type 1 RNA copy levels which may have application for disease prognosis and evaluation of antiviral efficacy (1, 7, 15, 18). For example, for eight liver transplant patients who developed relapsing CMV infection, the median levels of viral DNA were higher in pretreatment samples (leukocytes) than those in samples from individuals with resolved infection. Importantly, the relapsing group also had persistent detectable CMV DNA (median, 5,810 copies/10^6 leukocytes) after ganciclovir treatment, whereas CMV DNA was undetectable in the nonrelapsing group ($P < 0.0001$) (60).

The most significant innovations in PCR technology have been the availability of automated PCR instruments involving rapid thermocycling formats combined with the capability of quantitation and strain differentiation (e.g., HSV type 1 [HSV-1] and HSV-2) (22). The first system developed (LightCycler; Roche Molecular Biochemicals, Indianapolis, Ind.) combines rapid PCR thermocycling (45 cycles/30 to 40 min) with real-time (i.e., analysis of product after each cycle) specific probe detection and quantification of signal. Continuous monitoring of amplicon development by hybridization probes is based on the principle of fluorescence resonance energy transfer (FRET). Two hybridization probes, designed to anneal next to each other on the PCR amplicon, are used. A hybridization probe with a donor fluorophore, fluorescein, on the 3′ end is excited by an external light source and emits light. If the second probe, with an acceptor fluorophore, LC-Red 640, at the 5′ end, anneals next to the donor probe, the light from the fluorescein is absorbed. The acceptor fluorophore then emits light of a different wavelength which provides a signal that is proportional to the amount of specific PCR product, allowing specific detection and quantitation of the product.

In a prospective study of 200 genital and dermal specimens, we detected and confirmed 88 HSV strains by LightCycler, compared to only 69 by the shell vial cell culture assay. We found the LightCycler to be 100% specific and extremely sensitive in that 19 specimens (22%) were detected exclusively by LightCycler PCR (22).

Similarly, VZV was detected in only 23 (9.1%) of 253 dermal specimens by the shell vial cell culture assay, compared with 44 (17.4%) by LightCycler PCR (21). Collectively, these results (HSV and VZV) suggest that automated PCR such as the LightCycler system could replace cell culture for the detection of these viruses from genital and dermal sources because of the higher sensitivity, rapid results, and closed FRET detection system, which virtually eliminates the risk of crossover amplicon contamination for the routine laboratory.

Of seven studies that compared the detection of HSV DNA and VZV DNA by real-time PCR with shell vial cell culture (38,793 specimens), all demonstrated the superiority of the molecular amplification technology (Table 3). Similarly, real-time PCR was more sensitive for the detection

TABLE 3 Laboratory diagnosis of HSV and VZV infections by cell cultures and by real-time PCR

Virus	Specimens		Cells	Assay and sensitivity (%)		Reference
	Source	No.		Cell culture antibody-enhanced detection (shell vial)	Real-time PCR	
HSV	Genital	335	Human diploid fibroblasts	48.4	74.0	58
HSV	Genital, dermal, ocular	200	MRC-5	34.5	44	22
HSV	Genital, dermal, ocular	500	MRC-5	31.6	45	19
HSV	Genital, dermal, ocular, oral, BAL	668	Human embryonic fibroblasts	29.8	34.9	69
HSV	Various mucosal and dermal sites	36,471	Human diploid fibroblasts	2.98	12.1	71
VZV	Dermal	253	MRC-5	9.1	17.4	21
VZV	Dermal	366	Human embryonic fibroblasts	4.6	7.4	69
Influenza virus	Throat	233	MDCK (canine kidney cells)	24	60	72
Influenza virus types A and B	Combined nose and throat swabs or nasal washes	98	Tertiary monkey kidney cells (shell vial)	22.4	40.8	70
Influenza virus	Throat swabs, nasal washes, BAL, sputum, nasal swabs	557	R-mix (mink lung and A-549 cells)	9.2	16.5	Espy et al. [a]
RSV	Combined nose and throat swabs	168	Tertiary rhesus monkey kidney (shell vial)	2.4	4.9	70

[a]M. J. Espy, S. K. Schneider, P. A. Wright, S. Kidiyala, M. F. Jones, and T. F. Smith, Program Abstr. 20th Annual Clinical Virology Symposium, abstr. no. M51, 2004.

of influenza virus RNA than detection of this important pathogen by shell vial cell culture (Table 3).

The diagnostic laboratory may always find a use for cell cultures; however, the next level of test performance in the clinical laboratory will be formatted for the automated extraction and quantitation detection of target nucleic acids. Amplified nucleic acids will be monitored in real time by thermocycling instruments designed to be used in routine biosafety level 2 laboratories.

Herpes Simplex Virus

D. SCOTT SCHMID

70

Human infections with herpes simplex virus (HSV) type 1 (HSV-1) and HSV-2 are ubiquitous throughout the world. The clinical course of HSV infections is highly variable. Primary infection is subclinical or mild enough to be unrecognized in a majority of cases, whereas clinically apparent infection (1, 4, 35) may range from mild pharyngitis to severe generalized disease and sometimes death. The most frequent manifestation of primary HSV-1 infection is gingovostomatitis in young children, with pharyngitis occurring more commonly in adolescents. Conjunctivitis, keratitis, vesicular eruptions of the skin, herpes whitlow, and encephalitis occur much less frequently. HSV-2 is the most common cause of genital ulcer disease in the Western world, and in some demographic groups genital herpes is the most common sexually transmitted disease. The seroprevalence of HSV-2 has increased more than 30% in recent decades, and the majority of seropositive persons are unaware that they are infected (16). Other presentations of HSV-2 infection are aseptic meningitis and neonatal herpes. Infection in the newborn, which can also be caused by HSV-1, may be localized to the skin or may be generalized and may involve the central nervous system, eyes, skin, and other organs. Persons at risk for serious or prolonged active HSV infection are those with eczema, severe burns, or defective cell-mediated immunity, such as patients after organ transplantation or with AIDS.

Latent infection with both HSV-1 and HSV-2 is typically established after primary infection by viral colonization of the sensory neurons of either the trigeminal or the lumbosacrial ganglia (4, 35). Reactivation from either site may result in subclinical or clinical disease, both with viral shedding. Recurrent infection in the form of fever blisters or, rarely, ocular herpes occurs in up to 40% of the HSV-1-seropositive group (4, 35). Genital eruptions may recur in one-third to two-thirds of individuals infected with HSV-2 (4, 35). Because recurrent infections are frequently subclinical, they may result in unexpected virus spread and may be the source of neonatal infection (10, 24). It is important to understand that the initial clinically recognizable oral or genital HSV disease is not synonymous with primary infection. The term "primary infection" should be reserved for an HSV infection in a person who has not previously been infected with either HSV-1 or HSV-2. A previous oral HSV-1 infection does not protect a person against a genital HSV-2 infection; however, persons with prior HSV-1 infection who

are subsequently infected with HSV-2 normally have a less severe clinical course (1, 35).

Infection with either type of HSV gives rise to humoral and cell-mediated immune responses that, while capable of neutralizing HSV and destroying virus-infected cells, do not eliminate latent infection or prevent recurrent disease. Humans produce antibody to the structural components of the virus, the envelope, capsid, and internal proteins, as well as soluble nonvirion antigens specified by the virus. A majority of persons in most population groups are HSV-1 seropositive by 20 years of age (1, 35). Consequently, evidence of antibody against HSV-1 or HSV-2 in a single serum sample by any serologic test, with the exceptions of an immunoglobulin M (IgM)-specific antibody assay (20, 22) and the avidity assay described below (19), provides no information about the time of onset of infection. Serologic diagnosis of active infection with either virus type depends on demonstration of a significant increase in antibody titer. The two HSV types share many epitopes that give rise to strongly cross-reacting antigens (4, 10), and a major portion of the antibody produced in response to a primary infection is to these shared antigens. Virus culture or type-specific serologic tests, some of which are now commercially available (6, 15, 17), must be performed to determine that an individual has been infected with HSV-1 or HSV-2 or both.

Primary infection with either HSV type is documented by testing for seroconversion in paired serum samples (consisting of an acute-phase serum sample collected as close as possible to the onset of illness and a convalescent-phase serum sample collected 10 days to 3 weeks later) by any of the common serologic tests. Detection of IgM in the absence of other evidence is proof of recent exposure (primary exposure, reactivation, or reexposure) but does not demonstrate a primary infection (20). One diagnostic method that can be used with a single serum sample is an IgG antibody avidity assay. The avidity assay (with 6 M urea) was found to distinguish primary HSV infections from nonprimary HSV infections for as long as 100 days after the onset of infection (19).

The immune response to recurrent infection or reinfection with either HSV type is much more complicated and depends on the number, frequency, and type of previous infections as well as the severity of the subsequent infection. After primary HSV infection, antibody levels may decline and then be boosted by subsequent recurrences or infection

with the heterologous type. Patients who experience severe recurrences, particularly those associated with systemic or neurologic symptoms, may have a significant rise in antibody levels. On the other hand, most adults with recurrent localized HSV-1 or HSV-2 lesions show stable titers (1, 4) in the neutralization (NT) test, complement fixation (CF) test, and many enzyme immunoassays (EIAs) (20). Initial infection with HSV-2 in persons previously infected with HSV-1 (or vice versa) usually causes a significant rise in the level of antibodies to both the shared HSV antigens and the specific antigens of the infecting type.

The only human herpesvirus that shows significant cross-reactivity with HSV-1 and HSV-2 is varicella-zoster virus (VZV). Paired serum samples from patients with recent VZV infection who have preexisting HSV antibody may sometimes show a rise in the level of antibodies to HSV-1 and HSV-2 in nonspecific tests (1). A similar rise in the level of antibody to VZV may occur in patients with recent HSV infection who have prior antibody to VZV. This heterotypic anamnestic response has been observed by use of the CF test, the NT test, the indirect hemagglutination assay, and the immunofluorescence assay (IFA). Patients with atypical skin vesicles from whom a virus isolate was not obtained should have paired serum samples tested for antibodies against both HSV and VZV. Should a rise in the levels of antibodies to both viruses be found, cross-adsorption tests should be done to identify the cause of the current infection.

CLINICAL INDICATIONS

A presumptive clinical diagnosis of HSV infection can frequently be made from the appearance of cutaneous or mucosal lesions alone. The serologic results obtained after waiting to collect and test an appropriately timed convalescent-phase serum sample offer little guidance for therapy in the clinical management of most patients. The definitive diagnostic methods are virus isolation in cell culture (1) and direct detection in material from lesions (direct fluorescence assay and others, Tzanck smear, PCR). The direct detection methods are more rapid and, generally, considerably more sensitive than culture. Direct detection methods include (i) cytology for intranuclear inclusions and multinucleated giant cells (Giemsa; Tzanck smear); (ii) direct examination of specimens for viral antigens by either IFA, immunoperoxidase staining, or EIA; and (iii) detection of viral DNA in material from lesions, cerebrospinal fluid (CSF), and other tissues and fluids by PCR (12, 27, 30, 32). If possible, PCR results should be confirmed by virus isolation or by detection of antibodies in the CSF (11, 28, 35). Some patients with suspected viral encephalitis or other unusual clinical manifestations may have inconclusive initial diagnostic results, and serology could indicate recent HSV infection. When the etiology of encephalitis remains undiagnosed for 7 or more days after onset, CSF and serum should be tested in parallel for HSV antibody (13, 28). A CSF HSV antibody index of ≥ 2 (28) or an antibody titer in CSF that exceeds 6% of the titer in serum strongly suggests local production of antibody and recent central nervous system infection. Tests for HSV antibody may also be helpful in the diagnosis of HSV infection in immunosuppressed patients with prolonged fever of unknown etiology and infants with undiagnosed congenital disease. A recent case study revealed that HSV-1 and HSV-2 PCR testing should be considered as part of the rule-out diagnosis for suspected cases of bioterrorism-related smallpox (14, 18).

Procedures for determination of type-specific antibody to HSV are most useful in epidemiologic, clinicopathologic, and natural history studies (5, 16, 26, 32). They may also alert the physician to the need for prophylactic treatment of severely immunosuppressed patients. In addition, serologic confirmation of genital infection with HSV-2 permits the physician to discuss acyclovir therapy, the risk of recurrence, and ways to decrease the risk of HSV transmission to contacts. Moreover, an accurate diagnosis for persons with mild or unrecognized clinical manifestations also aids in infection control and in issues associated with pregnancy (11, 24). The prenatal detection of specific HSV-2 antibody indicates which women may be at risk of transmitting HSV to their infants at delivery, although the presence of IgG antibody does not indicate the time when active infection is present in the genital tract. Conversely, a negative result indicates that a woman may be at risk of acquiring HSV-2 during pregnancy, particularly if her partner is positive (11, 24).

Specimen Collection

Clinical specimens for HSV-1 or HSV-2 culture can be obtained by swabbing skin lesions that have been unroofed. Cotton or polyester swabs should be used. Culture may also be successfully performed with specimens of aspirated vesicular fluid or CSF. Direct detection methods require swabbing of the base of the lesion to ensure that infected epithelial cells are collected. In patients with disseminated HSV, peripheral blood mononuclear cells may be useful as specimens for either culture or PCR. For PCR or electron microscopy (EM) detection, scabs from crusted-over lesions are excellent specimens, but they are not useful for virus culture or direct detection methods. Specimens for PCR may be stored in a dry condition for extended periods at ambient temperature without substantial loss in specimen quality. In contrast, swabs collected for direct detection methods should be immersed in a small volume of isotonic transport medium and, ideally, tested within 24 h of collection. Virus isolation in cell culture is far more likely to succeed if specimens are inoculated immediately after collection.

VIRUS ISOLATION

Collected specimens are quite labile and must be transported to the laboratory and processed without delay. It is advisable to use several different HSV-susceptible cell lines, such as HEp-2, Vero-E6, and RD, to maximize the chance for successful culture. Inoculated cells should be checked daily for 7 days (incubated at 37°C, 5% CO_2) for the appearance of cytopathic effect. Positive wells should be used to reinoculate conventional tissue culture for additional confirmational testing.

EM

Suitable specimens for EM include dried smears of material from lesions (which can be resolubilized and placed on a copper grid), vesicular fluid, and scabs that have been ground in water. The chief limitations of this method are its relative insensitivity (the sensitivity is quite low compared with that of methods other than virus isolation) and the nonspecific result produced. EM is capable of identifying an agent as a member of the herpesvirus family on the basis of its distinctive morphology, but individual species cannot be discriminated on the basis of morphology. The method can be rendered specific by using type-specific monoclonal antibodies coupled to electron-dense particles.

DIRECT DETECTION METHODS

Tzanck (Giemsa) Smear

Smears of material from mucocutaneous lesions can be dried onto glass microscopic slides, stained with Giemsa reagent, and examined for the presence of cellular anomalies (syncytia, cytoplasmic ballooning, intranuclear inclusions). These anomalies are observed in all alphaherpesvirus infections and as such do not provide a specific diagnosis.

Direct Fluorescent-Antibody Assay

For the direct fluorescent-antibody assay, the same type of clinical specimen as for Tzanck smear is used, except the material is instead suspended in transport medium. Cellular matter is then pelleted by centrifugation, and the pellet is washed and resuspended in a small volume. Cell suspension is spotted onto glass slides, thoroughly air dried, fixed in ice-cold isopropyl alcohol, and stained with fluorescent antibodies specific for HSV-1 or HSV-2. If monoclonal antibody reagents are used in the protocol, it is preferable to use more than one type-specific antibody for each agent, since an individual epitope may be missing due to mutation in some circulating strains.

Variations on this method include the use of shell vial monolayers that are first inoculated with specimen and then examined with HSV-specific fluorescent antibody reagents. There is also a commercially available enzyme-linked virus-inducible system (ELVIS) that takes advantage of a genetically engineered reporter cell line. The cell line includes a hybrid gene that is induced by the HSV UL39 gene product to express bacterial β-galactosidase. Cells infected with HSV undergo a colorimetric change with the addition of substrate. Type specificity is determined by use of fluorescent antibodies.

SERODIAGNOSTIC TESTS

EIA, indirect hemagglutination assay, immunoblotting, IFA, and the NT test have had the widest application for serodiagnosis and serosurveys. Radioimmunoassays (4) are infrequently used because current EIA and immunoblotting procedures fulfill the same purpose and avoid the problem of using and disposing of radioisotopes. A latex agglutination assay is commercially available, but its use has not been widely reported.

Type-Specific Antibody Tests

The extensive cross-reactivity between HSV-1 and HSV-2 prevents accurate delineation of type-specific antibody with standard antigen preparations (1, 9, 10). Early efforts to devise type-specific serologic assays met with limited success, and none of these formats is currently regarded as reliable. The discovery of a type-specific protein, glycoprotein G (gG), and the crafting of assays using gG1 and gG2 have largely resolved the problem of discriminating antibodies to HSV-1 and HSV-2 (2, 9). A variety of protocols based on the use of gG have been developed over the years, including Western blotting (7, 25), monoclonal antibody blocking EIA (33), indirect IgG enzyme-linked immunosorbent assay (ELISA) (22), and capture ELISA (21), but until recently their use has been restricted to the research laboratory. Several commercial gG type-specific assays are now available; commercial methods using older technology, such as cross-absorption, are still marketed but do not adequately discriminate HSV-1 and HSV-2 antibodies.

Excellent reviews of the history of the development of type-specific and gG-based assays have been published by

Bergström and Trybala (9) and Ashley (3). gC of HSV-1 was initially believed to be type specific but was later found to have epitopes that cross-react with HSV-2 antibodies (4, 26). Subsequently, gG1 and gG2 were discovered and shown to be type-specific targets for the human immune response by an immunodot EIA (26), immunoblot assays (4, 5, 32), and EIAs (22, 24). HSV-2-specific monoclonal antibodies have also been used to directly bind gG2 to microtitration plates and detect HSV-2 antibodies by EIA (1). Although the immune response to gG1 and gG2 is not immunodominant, sufficient antibodies to these proteins are made within a month postinfection (6) that gG assays can usually determine the type of HSV infection present.

Nonspecific Antibody Tests

A number of EIAs in which HSV antigen is noncovalently bound to a solid-phase support such as beads, disks, or microtitration plates have been described and are commercially available (4, 13, 22). These assays remain useful as a means for determining recent HSV infection (nonspecific) or recrudescence, by comparing paired acute-phase and convalescent-phase sera. The major advantages of the general EIA are its ability to objectively measure small concentrations of antibody, its use of reagents with long shelf lives, its ability to quickly screen large numbers of serum samples, and the availability of relatively simple instrumentation suitable for automation. However, since type-specific assays accomplish the same objectives, the role of nonspecific serologic methods in clinical practice is likely to diminish.

Immunoblotting

The immune response to HSV can be finely dissected by the immunoblot assay, which is thoroughly described by Ashley and colleagues (4, 5). Briefly, the antigenic proteins of HSV-1 and HSV-2 from infected cells are separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), transferred to nitrocellulose, and reacted with human sera. Bound antibody is detected with a peroxidase-conjugated anti-human IgG and a substrate with an insoluble colored product. In each test, one HSV-2 nitrocellulose strip is incubated with a monoclonal antibody that identifies the 92-kDa band of gG2 as a positive control. Sera with predominant reactivity on the HSV-1 strip and no reaction with the gG2 band on the HSV-2 strip have only HSV-1 antibodies. Sera with predominant reactivity on the HSV-2 strip, including the gG2 band, have HSV-2 antibodies. Sera with both profiles have antibodies to both viruses. Sera with atypical or equivocal results, without a clear 92-kDa gG2 band on the HSV-2 strip, are adsorbed separately with HSV-1 and HSV-2 antigens, and each aliquot is retested with both HSV strips.

The immunoblot assay described by Ashley et al. (5) is a highly sensitive and specific assay for HSV type-specific antibodies. Control sera with known reactivity for HSV-1 and HSV-2 are required. Since immunoblot assays include multiple HSV proteins that detect a range of both type-specific and type-common antibodies, they remain the standard by which other type-specific assays are evaluated (2, 9).

A modification of this approach using baculovirus-expressed gG1 and gG2 has also been described (22, 23). Abundant quantities of HSV gG1 and gG2 have been produced in insect cells by use of a baculovirus expression system (31). Insect cells infected with recombinant baculovirus expressing gG1 or gG2 are harvested and disrupted under conditions that release the proteins. The partially purified proteins are separated by SDS-PAGE, transferred to nitrocellulose, and incubated with test and control sera. This

method has been extensively compared with other HSV antigen-specific methods and has high specificity and sensitivity (10, 31, 32). The availability of these type-specific recombinant or purified proteins from commercial sources (6, 15, 17) has now made possible large-scale testing of human sera in a variety of type-specific formats.

Immunodot EIA

Lee et al. (26) purified gG1 and gG2 antigens with immuno-affinity columns prepared with HSV type-specific murine monoclonal antibodies for an immunodot EIA performed on nitrocellulose disks in 96-well microtitration plates that required very little antigen. The assays are developed using an enzyme immunoaffinity colorimetric reaction. This is a high-throughput technique that has been instrumental in determining population-based seroprevalence rates for HSV-2 in the United States (16).

Monoclonal Antibody Blocking Assays

The monoclonal antibody blocking method was developed in the United Kingdom by the Central Public Health Laboratory, initially using a radioimmunoassay format. The protocol uses monoclonal type-specific antibody reagents directed against gG epitopes of HSV-1 and HSV-2. The method has been extensively validated against a number of alternative gG-based methods and performs with high sensitivity and specificity.

Several other gG-based methods that have performance standards comparable to those of the methods described above have been developed. With the advent of commercially available gG-based serological methods, these methods have rapidly become the standard of choice for performing HSV serology in both research laboratories and clinics. The assays are simple to perform and highly specific and have essentially the same sensitivities as procedures already in use.

Commercially Available Type-Specific Assays

An evaluation of three new commercial gG2-based EIAs has been made by testing serum samples from 25 persons with culture-confirmed infection with HSV-2 (13). The assays were based on recombinant gG2 produced by the baculovirus system or purified HSV-2 gG prepared from infected cell culture. The sensitivities and specificities and the level of concordance between the assays were high. However, caution was advised in the interpretation of low-positive results (possible false-positive results), and such samples might need another confirmatory test. Another report compared a rapid commercial assay, the POCkit-HSV-2 test (Diagnology, Belfast, United Kingdom), with the authors' immunoblot procedure and a gG2 type-specific EIA (Focus Technologies, Cincinnati, Ohio) (6). The sensitivity and specificity of the tests in comparison with the immunoblot results were in the 90 to 95% range. Timing in the collection of sera is important because it was shown that the median time for the POCkit-HSV-2 test and the immunoblot assay to become positive after the onset of symptoms was 13 days, and only 80% of the samples were positive at the end of 4 weeks.

Almost all of these methods that use HSV gG have shown good agreement when evaluated with specimens from cross-sectional studies (2). A current study with samples collected serially over a 2-year period from Thai military recruits found that the serologic status of some individuals determined by gG assays changed from positive to negative over time (32). The inaccuracy was found in four separate assays, and the variation was not confined to the same specimens with each assay. In some cases, the loss of positivity could be associated with weakly positive specimens. It is suggested that testing of cohort specimens from population-based studies in addition to clinical ones should be part of any assay evaluation scheme (32).

PCR Methods

Serological methods are not useful for detecting current HSV infection or viral shedding, and culture is relatively insensitive even when performed under optimal conditions. In the past decade, PCR has emerged as the method of choice for the direct detection of currently active HSV infection (30). HSV PCR on CSF has now supplanted brain biopsy as the method of choice for diagnosis of herpes encephalitis (34). The assays have been determined to be sufficiently specific and sensitive that a carefully performed test with a negative result excludes HSV as a diagnosis in encephalitis. A variety of different methods have been described, including single-agent methods (8, 30), multiplex methods (23, 27, 29), and real-time PCR (12). In studies directly contrasting the performance of PCR with culture, direct fluorescent-antibody assay, and other techniques, PCR is invariably more sensitive and at least comparably specific.

The most frequently used target genes for type-specific PCR are gD and gB, although reported methods have also targeted the thymidine kinase, gG, UL42, DNA polymerase, and ICP27 genes. The highly conserved DNA polymerase gene has been used most frequently for consensus PCR methods that amplify all recognized human herpesviruses.

As commercial PCR formats for clinical diagnosis have become more widely available, the use of PCR in clinical settings for routine diagnosis has become increasingly common. It is the most sensitive and specific method available for the detection of HSV in a wide variety of specimens. Since atypical HSV-1 and HSV-2 disease was, like varicella, historically misdiagnosed as smallpox prior to eradication, HSV PCR is also recommended as part of a testing panel to exclude smallpox used as a bioterrorist weapon.

It must also be kept in mind, however, that not all PCR methods are created equal. Direct comparisons of various formats have sometimes revealed substantial differences in the performance standards. In addition, care should be taken to ensure that substances potentially inhibitory to PCRs are eliminated during DNA purification.

Varicella-Zoster Virus

D. SCOTT SCHMID AND VLADIMIR LOPAREV

71

Varicella-zoster virus (VZV) is a highly contagious alphaherpesvirus that commonly causes two distinct clinical illnesses. Primary infection with VZV causes varicella, known more commonly as chickenpox, which is characterized by a generalized vesicular rash typically accompanied by fever and other nonspecific symptoms. VZV may reactivate decades after the primary infection to cause zoster, also called shingles, a dermatomally distributed vesicular rash. A number of zoster patients present with postherpetic neuralgia, characterized by severe pain that may persist for long periods after the rash has resolved. Some rare complications of zoster include encephalitis, conjunctivitis, keratitis and other eye disorders, Ramsey-Hunt syndrome, neurogenic bladder, and transverse myelitis. The majority of varicella cases are mild in nature and resolve without serious sequelae. On rare occasion, varicella may be complicated by bacterial infections, pneumonia, encephalitis, cerebellar ataxia, hepatitis, thrombocytopenia, and nephritis. Studies have shown that patients with recent varicella have a 40-fold greater risk of developing severe group A streptococcal disease. Populations at increased risk for serious VZV disease include immunocompromised adults and children, VZV-seronegative adults, pregnant women, and newborn infants. Prior to the introduction of varicella vaccine, complications of VZV infections resulted in approximately 100 deaths and 10,000 hospitalizations each year in the United States (1).

A live, attenuated varicella vaccine was approved for use in the United States in 1995 and is recommended for routine immunization of children and for susceptible adolescents and adults. Coverage for the vaccine in the United States is now estimated to be close to 90% for children, and a proportionate reduction in varicella incidence has been observed with evidence of herd immunity (9; J. Seward, personal communication). Vaccination occasionally produces a mild rash, and breakthrough infections by wild-type VZV strains sometimes occur in vaccinated patients, usually causing less severe disease than a typical primary infection.

When varicella was commonplace in the United States, laboratory testing to verify varicella was generally unnecessary, since both varicella and zoster could be readily diagnosed by a clinician. The dramatically reduced incidence of varicella, together with the increasingly common occurrence of modified disease, has made laboratory confirmation of VZV infection and discrimination of the vaccine strain from wild-type virus increasingly important.

The 90% reduction of varicella means physicians will be less likely to encounter cases of varicella and have an increased likelihood of encountering disease that does not meet the conventional case definition for varicella or zoster. Effective monitoring of the changing epidemiology of this virus will therefore hinge critically on the use of laboratory testing. In addition, laboratory services are essential for the identification of susceptible adults for the purposes of immunization of health care workers or individuals in other settings that carry high risk for exposure to varicella or zoster. The varicella vaccine is now recommended for the postexposure immunization of susceptible adults (3).

METHODS

Specimen Collection

Laboratory diagnosis of VZV infection requires the identification of the virus or one of its products in skin lesions, tissues, or fluids from the patient. Techniques include isolation of the virus in tissue culture, direct immunofluorescent staining of cells obtained from lesions, and detection of the virus genome by techniques based on PCR. Among these techniques, PCR-based detection methods are the most sensitive.

Specimens that are most commonly tested for VZV include smears or swabs of vesicular fluid, skin scrapings, crusts, cerebrospinal fluid, and various tissues obtained at autopsy. Vesicular lesions may be sampled by unroofing a vesicle with a sterile needle and then vigorously swabbing the base of the lesion with a sterile swab, applying enough pressure to collect epithelial cells without causing bleeding. Collection of infected epithelial cells from the base of the lesion is important because the majority of VZV virions are cell associated. It is best to use swabs made from synthetic materials, as it may be difficult to elute virus from cotton swabs, porous wooden sticks may absorb the extraction buffer, and substances in the wood may inhibit PCR. To avoid contamination, each swab must be placed directly into a separate tube and labeled. Vesicular fluid can also be collected onto a glass slide and air dried (again, taking care that specimens are placed in separate containers to avoid contamination). For virus isolation, vesicular fluid may be collected in sealed capillary tubes; however, VZV is extremely sensitive to heat and desiccation, making isolation difficult under the best circumstances. Ideally, vesicular fluid should

be inoculated into cell culture immediately upon harvesting. Samples may be frozen at −80°C for several days prior to culture, but this procedure results in a significant loss of infectivity. Crusts are also outstanding specimens for PCR detection of VZV DNA; they may be collected in sterile tubes or plastic bags. Refrigeration is preferred for smears to be examined for viral antigen, but air-dried specimens for PCR can be kept at ambient temperature indefinitely.

Virus Isolation

VZV can be isolated from vesicular fluids of patients with zoster or varicella for a short period (1 to 3 days) following the onset of rash, but culture of VZV from respiratory secretions or biopsy specimens is rarely successful. Crusts do not contain infectious virus. Various cell cultures can be used to culture VZV from vesicular fluid, including human fetal diploid lung (HFDL) or kidney (HFDK) cells, human embryonic lung fibroblasts (MRC5 or WI 38), human melanoma (MeWo) cells, and human lung fibroblasts (HLFs). Our laboratory prefers the HLF and MeWo cell lines. Primary embryonic guinea pig cells will support VZV propagation but are generally less productive than human cells. Sufficient cell culture medium must be used to maintain the culture for 10 to 14 days without change. Several studies have shown that virus isolation, even under optimal conditions, is significantly less sensitive than direct immunodetection or PCR for the detection of VZV. VZV produces a distinctive specific cytopathic effect (CPE) in cell monolayers. Initially, in HLFs the CPE is characterized by discrete crescent-shaped foci of different sizes and consists of rounded and swollen cells. This may appear as early as day 3 or as late as day 14 after inoculation, but most appears between 4 and 7 days. If VZV-specific CPE has not appeared after a week to 14 days, it may be useful to passage the inoculated cultures. CPE may develop even if the amount of vesicular fluid in the capillary tube is barely discernible to the naked eye, if the specimens are obtained within the first 2 days of rash. Confirmation of VZV-specific CPE may be obtained if necessary by staining with fluorescein-labeled specific antibody.

The tendency of VZV to remain cell associated, together with its susceptibility to inactivation, renders virus isolation less sensitive than direct immunofluorescence or PCR. Preliminary identification of VZV can be made on the basis of characteristic CPE, which is usually more focal and progresses significantly more slowly than CPE from herpes simplex virus (HSV). However, the definitive identification of VZV requires additional testing with immunological assays or PCR. Specific identification of a VZV isolate can be made by demonstrating its ability to interact with reference serum from patients who have had a clinically diagnosed case of varicella or with VZV-specific monoclonal antibody. Human sera used for identification of VZV should be free of antibody against other human herpesviruses that may cross-react with VZV proteins due to structural homology (e.g., HSV type 1 [HSV-1] and HSV-2). VZV-specific monoclonal antibodies are commercially available and are the preferred reagent, since they significantly increase sensitivity and specificity of detection compared with human serum or polyclonal serum produced in animals. Specific VZV identification can be accomplished with direct or indirect immunofluorescent staining of infected cells.

Direct Examination of Material from Skin Lesions

Scrapings of vesicular lesions obtained with a scalpel blade can be examined for giant cells or intranuclear inclusions by staining with Giemsa reagent (Tzsank smear). Similar changes are seen with HSV; thus, the method is limited to identifying the presence of an alphaherpesvirus and is not species specific. Staining for examination for inclusions must be performed properly, using specific methods for this purpose, or specimens may yield false-negative results. It should be recognized that the presence of intranuclear inclusions or multinucleated giant cells is not specific for VZV. In contrast, direct fluorescence antibody (DFA) staining appears to have excellent sensitivity and specificity, although its performance is inferior to that of PCR. Staining of the scrapings with conjugated anti-VZV monoclonal antibodies can enable specific identification. A number of monoclonal antibodies are available for this purpose. Specimens must be collected with care; scraping of unroofed lesions must be sufficiently vigorous to ensure the collection of infected cells, but the specimen should contain as little blood as possible, since this can produce false-negative results. Crusts cannot be used for direct detection methods.

EM

Vesicular fluids, crusts that have been ground in water, or skin lesion sections can be examined by electron microscopy (EM). Good results can be obtained with air-dried smears of fluids prepared on glass microscope slides, which can be resolubilized and transferred to a grid. This method is useful only as an identification for herpesviruses; it does not facilitate the identification of VZV. The finding of virus with morphology characteristic of herpesviruses identifies the etiological agent as a member of this genus and serves to distinguish it from orthopoxviruses. However, this method does not provide a specific differentiation for VZV. In addition, this technique is relatively insensitive, capable of reliably detecting virions only at very high concentrations. It has been estimated that as much as 27% of DFA-positive specimens may give negative results by EM. VZV specificity can be conferred on EM by using VZV-specific immunoglobulin tagged with electron-dense materials.

Genetic Stability of VZV

A variety of techniques, including complete genomic sequencing, have been used to show the low degree of genetic variability among VZV isolates. However, at least three distinct VZV genotypes (European, Japanese, and Mosaic [M]) have been identified. Interestingly, the Japanese and European genotypes are dominant in countries with a temperate climate, although the Japanese strains are found almost exclusively in that country, whereas European strains are common to Europe, the United States, Canada, and other countries north or south of the 30th parallels (temperate/polar zones) (5). VZV strains of the M genotype are most common in countries with a tropical climate. Only about 0.1% of the nucleotides vary among individual strains of VZV, and the sequence diversity is distributed randomly throughout the genome. The attenuated vaccine strain (Oka) is derived from a Japanese genotype strain that has only about 40 base-pair differences from the parental strain. Vaccine preparations are now known to contain a number of subvariant strains, and only four of the vaccine markers (all in open reading frame 62 [ORF62]) are consistently maintained in all vaccine subvariants (unpublished observation). The mutations responsible for vaccine attenuation have not yet been determined, however. Genetic variability can have an effect on the performance of serological assays, particularly those involving the use of VZV-specific monoclonal antibodies.

PCR

PCR is the most accurate and sensitive method for VZV detection and differentiation. Taking into account that virus isolation is time-consuming and that viral DNA is much more stable than infectious virus, PCR is the preferred method for confirming the presence of VZV in a specimen. PCR is particularly useful to confirm mild VZV disease in vaccinees or in late stages of varicella when lesions contain no viable virus. Amplification and analysis of targeted VZV DNA regions is the method of choice for discriminating vaccine from wild-type VZV isolates. For routine laboratory diagnostic purposes, the best materials to use are vesicular fluids collected with capillaries or swabs, scrapings dried onto glass slides; or crusts from lesions. By this method, VZV DNA can be detected in various tissues, including lung, liver, kidney, skin and adrenal glands, trigeminal ganglia, and dorsal root ganglia. The viral genome can also be detected in peripheral mononuclear cells and, rarely, in cerebrospinal fluids, bronchoalveolar lavage, breast milk, oropharyngeal swabs, throat swabs, peripheral blood mononuclear cells, and nasal secretions. In some specific situations, VZV DNA can be found in the synovial fluid of patients with arthritis; intraocular fluids, corneal scrapings, and tear films of patients with retinal necrosis; temporal bone sections from patients who had herpes zoster oticus; and amniotic fluid, fetal tissues, and the placenta during neonatal varicella. We had experience of successful identification and typing of VZV strains from environmental swabs. A variety of PCR protocols have been used to detect VZV DNA. However, the current diagnostic convention combines specific VZV detection and wild-type and vaccine strain discrimination. Recently, it was documented that VZV vaccine preparations are heterogeneous, and more than 100 variant viruses carrying different arrays of vaccine-associated mutations exist. Identification of vaccine-specific single-nucleotide polymorphisms can be accomplished either by direct sequencing of a PCR product, by restriction fragment length polymorphism (RFLP), or by Förster resonance energy transfer (FRET)-based real-time PCR (4, 6). Recent studies indicate that while multiple polymorphisms were identified between vaccine and wild-type strains, detection of the sequence polymorphism at genome position 106262 is the most reliable method for discriminating the vaccine strain from wild-type VZV (4, 6). Perhaps the most important concern in the use of PCR is the quality of the template to be amplified. Care must be taken to optimize the purification of DNA from samples that may contain substances that inhibit PCRs. Most modern commercial kits designed for DNA purification from cells and tissues, used in accordance with the manufacturers' instructions, will provide good-quality DNA for immediate PCR amplification. Proper use of controls is an essential element of PCR protocols. Positive, negative, and blank (no virus DNA) controls allow inspection of the extraction, amplification, and product detection steps. In addition, as a universal control for the quality of sample processing, the amplification of human cellular genes (actin or globin) must be performed. This procedure is necessary in the case of negative PCR amplification with specific VZV primers to reduce the possibility of a false-negative result. Several primer sets that, when coupled with the step of restriction endonuclease digestion (RFLP), reliably discriminate between the vaccine strain and wild-type VZV have been identified. We have recently developed a number of PCR assays targeting single-nucleotide polymorphisms in ORF62 that more definitively discriminate vaccine strain than do markers described previously, such as those in ORF38 and ORF54 (4, 6). Recent advances in PCR technology, such as FRET-based approaches, have greatly shortened PCR cycling intervals and have made it possible to bypass the time-consuming endonuclease digestion step, greatly reducing the time required to obtain a strain discrimination result (as little as 3 h) and reducing the risk of contamination (6). We have now expanded the capability of PCR for use in the identification of wild-type VZV genotypes as well as multiple subvariants of VZV Oka, a tool that should prove invaluable to the monitoring of varicella vaccine impact (5).

Serologic Testing

Serologic testing is most often requested for determining susceptibility to VZV in outbreak settings, but on occasion it is needed for diagnosis. We have also used immunoglobulin G (IgG) enzyme-linked immunosorbent assay (ELISA) testing of acute- and convalescent-phase sera to support PCR evidence for breakthrough infection. Acute-phase serum should be obtained as soon as possible after the onset of illness, and the convalescent-phase serum should be obtained 4 to 6 weeks after onset. A variety of methods are available to determine whether there are significant rises in the level of VZV-specific serum immunoglobulin; however, all must be performed in an endpoint dilution format. Assay formats used for simple determination of VZV serostatus include ELISA, membrane fluorescence, and latex bead agglutination. Each of these test formats has limitations, which are discussed in greater detail below.

Rapid Serologic Tests

Rapid point-of-care assays for the detection of VZV antibodies have become commercially available in recent years. These include latex bead agglutination or flowthrough membrane-based enzyme immunoassay (EIA) methods. Serum, plasma, or whole blood can be tested. In general, these assays are designed to detect IgG antibodies; they have been reported to have good sensitivity and specificity, although none is as reliable as either glycoprotein-based ELISA (gpELISA) or fluorescent antibody to membrane antigen (FAMA) tests, particularly for detecting seroconversion in VZV-vaccinated persons. One recent study revealed that the latex bead agglutination test can be prone to false-positive results (2). Since one of the principal uses of these tests is to identify health care workers and other persons at high risk for susceptibility to VZV, a more specific commercial method is probably preferable for that purpose.

Western blotting

Western blotting of whole-cell lysates of VZV-infected cells permits a detailed analysis of antibody profiles and can be useful for the characterization of the antibody response to specific antigens. Western blotting is more cumbersome than most other approaches to antibody detection; in our hands, it has also been considerably less sensitive. In addition, Western blotting is limited to the detection of linear epitopes since the three-dimensional structure of antigens is destroyed by the sodium dodecyl sulfate used for high-performance gel electrophoresis. The resolving capacity of Western blotting is limited to the discrimination of only about 25 distinctive bands; as such, it may be difficult to distinguish between antigens of similar molecular sizes.

FAMA

FAMA is one of the most sensitive assays for the detection of VZV antibodies, when performed in an experienced laboratory.

It has been recognized for some time as one of the few tests sufficiently sensitive and specific to detect VZV antibodies in vaccinated individuals. In part, the enhanced sensitivity of this assay may be attributable to the fact that live, infected cells are used, thus preserving the conformational structure of the surface glycoprotein antigens. If cells are fixed, the antigenic structure is likely modified, and fixation generally results in decreased sensitivity. A modified FAMA assay in which cells are briefly fixed in 0.075% glutaraldehyde for 60 s at 0°C and stored at −70°C has been described (10). The FAMA assay can be used in various formats to detect any of the major classes of specific immunoglobulin. While this method can be quite powerful, optimal performance requires a long learning curve; the protocol requires live, virus-infected cells; and the method cannot be automated for large-scale screening.

gpELISA

Merck and Company developed a highly sensitive and specific ELISA method predicated on the use of a highly purified, high-concentration solution of VZV glycoproteins. It is the only method other than the FAMA test with performance standards adequate to reliably detect seroconversion to VZV vaccination. The method is not currently available commercially, although in recent years our laboratory has secured a supply of the antigen from the manufacturer. Direct comparison between the FAMA assay and gpELISA reveals that they have comparable levels of performance, and the ELISA method has the advantage of being easily performed. It is likely that this assay will become commercially available in the near future.

NT Tests

The presence of neutralizing antibodies in serum can be detected by using a neutralization (NT) assay based on reduction of plaque formation by titered VZV preparations pretreated with serum. Cell-free VZV is preferable for use in such assays and may be obtained from infected HLFs or MeWo cells after the development of visible CPE. The cells generally can be destroyed by sonication. Freeze-thawing procedures are not recommended because they inactivate the virus. Extracellular virus should be used immediately after preparation since it is susceptible to rapid inactivation, or preparations may be frozen at −70°C in calf serum or glycerol. VZV NT assays are rarely used in diagnostic laboratories today, and accompany early stages of vaccine licensing and vaccination efforts. NT methodology for VZV requires some improvement but will likely prove helpful for evaluating the duration of protective immunity among vaccinees. It will also be useful to identify the primary NT targets for VZV. There are no clear recommendations or standardized data for the evaluation of neutralizing antibody. Since it proved difficult to detect neutralizing antibody titers in vaccinated individuals, highly sensitive gpELISA and FAMA tests (both of which likely detect the principal neutralizing targets for VZV) were performed in parallel with, and in some instances completely supplanted the use of, NT tests during Oka vaccine efficacy trials.

Antibody Avidity

Measurement of IgM antibody in individuals with known recent exposure to VZV is inconsistent, and the detection of IgM may reflect either primary infection or reactivation. Evaluations of antibody avidity are straightforward to perform and can provide useful insights into the relative maturity of immunoglobulin responses to VZV. As such, they provide a useful adjunct tool for determining whether a person has a well-established, high-avidity antibody population specific for VZV. This parameter generally has not been investigated for VZV and could be particularly important for VZV vaccinees. It is conceivable that, as vaccination becomes nearly universal and natural reexposure to VZV becomes rare, fully mature immunoglobulin responses might not develop over time. Determination of antibody avidity is usually based on the separation of low- and high-avidity antibodies by using denaturing agents in immunoassays (EIA) or immunofluorescent assays. Several agents, such as guanidine hydrochloride, diethyleneamine, isothiocyanate, and urea, have been used for this purpose. Calculations of the avidity results have been approached in several ways. In general, avidity is expressed as percent ratio of antibody titers or EIA absorbance values with and without denaturation. Avidity results based on endpoint titration with and without denaturant are considered to be the "gold standard" for avidity determination.

INTERPRETATION

If results are required quickly, the preferred method is direct staining of cellular material from lesions, since it is sensitive, specific, and rapid. If, however, rapid turnaround is not an issue, PCR-based methods are more sensitive and informative, since they are agent specific and also can be designed to discriminate vaccine strain from wild-type isolates. That said, real-time FRET-based PCR and more rapid DNA extraction have made these methods comparable to DFA staining in the time required to obtain a result. Serologic testing is not a preferred method for confirming an acute infection. Significant rises in titer between acute-phase and convalent-phase sera are not always observed, and the determination of whether a titer found in such sera is consistent with an acute infection would depend on the test used.

For determination of susceptibility, a properly standardized and sensitive method is essential. As mentioned above, assay specificity trumps sensitivity as a consideration if the goal is to determine susceptibility to varicella in high-risk persons. Passively acquired antibody may also yield false-positive test results, and immunocompromised patients may have lower levels of antibody that may be difficult to detect in some immune patients if the test used is too insensitive.

ANALYTICAL SENSITIVITY AND SPECIFICITY, QUALITY CONTROL AND ASSURANCE, DATA ANALYSIS, PITFALLS, AND TROUBLESHOOTING

Serologic Testing

There have been several reports of inappropriate management of patients due to false-positive reactions (2, 7). While this is the greatest concern in settings where susceptible adults are at high risk of VZV exposure, it is also clear that the majority of VZV assays currently available fail to detect seroconversion in response to vaccination. In some public health organizations, this has led to unnecessary multiple vaccinations of the same individual. Suitable normal tissue control antigens in an ELISA are essential to reduce the risk of false-positive test results, although such controls are generally absent from commercially available assays. New methods are commonly validated by comparing performance with that of an established method that may itself be inaccurate. It is difficult to choose with certainty a set of negative sera that are ideal for this purpose. Sera from seronegative susceptible individuals who are known to have developed varicella can be used to standardize an assay, although, increasingly, vaccinees who fail to develop

detectable antibody titers as determined by some methods and who might subsequently develop breakthrough disease might inadvertently be selected. Cord serum depleted of IgG can be used, but the elimination of IgG from these sera might also obscure nonspecific reactivity that could be present in normal serum specimens. A strategy that we adopted was to identify a set of sera that tested negative by a large panel of techniques, including FAMA tests, latex bead agglutination, immunoblotting, and several commercial and laboratory-based ELISAs. We developed a whole VZV-infected cell lysate-based ELISA that has become our preferred method. It should be emphasized that ELISAs vary considerably in their level of performance, and one should not assume that this method is generically better or worse than other methods. The means by which cutoff values for seropositivity (assessment of assay performance variability, selection of standardization sera, etc.) are established is crucial. More recently, we have been using lentil lectin-purified VZV glycoprotein preparations in the gpELISA format (8); this assay clearly has specificity and sensitivity comparable to those of the FAMA test, reliably detects vaccine seroconversion, and is far simpler and less subjective. Our current strategy is to first test with a whole-virus ELISA and then retest negative and equivocal specimens with the gpELISA.

None of the currently available serologic assays for VZV can reliably detect specific antibody in persons who have been vaccinated. This problem is most pronounced for measuring varicella vaccine seroconversion in adults. Among methods that are available only in selected laboratories, only the FAMA test and gpELISA are sufficiently sensitive and specific to reliably document VZV seroconversion in vaccinees. Unfortunately, FAMA testing cannot be recommended for routine use due to the technical difficulties in performance and interpretation. gpELISA is simple to perform but is not currently available commercially. Latex bead agglutination, which has been reported to perform similarly to the FAMA test, does not perform better than the whole VZV-infected cell ELISA in our hands. Efforts to develop more sensitive VZV serologic assay formats are currently being explored in our laboratory.

A number of studies have documented cases of individuals who develop detectable VZV-specific antibodies after immunization with varicella vaccine who subsequently developed varicella following exposure. This phenomenon should be borne in mind when serologic tests are used to identify adults who are protected from VZV infection in high-risk exposure environments. We recently documented cases of varicella in health care workers who were incorrectly identified as VZV seropositive by the latex bead agglutination method (2). It also should be recognized that immunocompromised patients may have received blood products that can result in transitory false-positive results.

IgM test results are difficult to interpret. IgM antibody capture assays are preferred, because they avoid the obfuscating effect of rheumatoid factor and because they are the most effective means for eliminating all of the IgG in serum specimens. IgM kits that rely on absorbants to remove IgG are commercially available, but they frequently do not remove all of the IgG from a specimen. In addition, extensive studies of sera from persons with documented recent exposures to VZV indicate that VZV IgM antibodies are inconsistently detectable in such persons.

Immunotherapy, Postexposure Prophylaxis in Pregnancy, and the Neonate

The fetuses of susceptible, pregnant women are at risk for severe, lifelong disabilities or death; fetuses of women infected during weeks 8 to 20 of gestation carry approximately a 2%

risk of developing congenital varicella. Neonatal varicella contracted from the mother is often severe. VZV vaccination is contraindicated for women during pregnancy; however, administration of passive VZV immunoglobulin (VZIG) is recommended for seronegative pregnant women with possible VZV exposure, and administration to the infant is advisable if the mother develops varicella 5 days before to 2 days after delivery. A consensus reached at the 3rd Annual Meeting of the International Herpes Management Forum suggested that VZIG could reasonably be given as postexposure prophylaxis to neonates born to mothers who have varicella within 7 days before or after delivery. Despite VZIG prophylaxis, approximately two-thirds of infants exposed to maternal varicella around the time of delivery will become infected. Although in most cases the infection is mild, fatal outcomes have been reported for VZIG-treated infants whose mothers developed varicella rash in the period 4 days before to 2 days after delivery.

REMARKS AND CONCLUSIONS

Test selection must be made appropriate to the clinical circumstances for the individual patient; when appropriate and suitably reliable methods are limited and beyond the capacity of a laboratory, consideration should be given to providing specimens to a facility that is capable of performing the required method. The immunocompetence and history of a receipt of blood products need to be taken into account in the selection of serologic approaches to testing. The particular test selected may depend upon the interval between disease onset and the time required to obtain a test result. For example, the use of acute- and convalescent-phase serum testing is inappropriate in situations where evidence of recent exposure is needed quickly. If the circumstances require documentation of a vaccine adverse event, the use of conventional VZV PCR is not acceptable; RFLP or FRET PCR that specifically identifies the vaccine strain is required.

Immune status testing may be urgent if the patient is a candidate for postexposure varicella vaccination, as it must be administered within 72 h of exposure to be effective. The limitations of each method should be reflected in how the results are reported. Reporting of indeterminate results is of little use to the clinician attempting to use the results to manage a patient, but it is important to distinguish potentially false-negative results from those that are indeterminate. Seropositivity, whenever possible, should be equivalent to immunity. The specific methods selected will depend upon the experience of a particular laboratory.

Epstein-Barr Virus

HAL B. JENSON

72

Epstein-Barr virus (EBV), a member of the *Herpesviridae* family, is a ubiquitous, worldwide infectious agent that is the cause of classic cases of infectious mononucleosis (13). Approximately 10% of cases of infectious mononucleosis-like illness are not caused by EBV. An important relationship between age, socioeconomic status, and disease exists with EBV infection. In developing countries and socioeconomically deprived areas of developed countries, most persons are infected with EBV during early childhood. Infection with EBV in socioeconomically advantaged areas of developed countries is delayed, with infection more frequently occurring during adolescence and young adulthood. Infection is symptomatic in one-half or more of older children and adults and is classically manifest as the syndrome of infectious mononucleosis that consists of the principal symptoms of fever, malaise, pharyngitis, and cervical lymphadenopathy. Primary EBV infection in infants and young children is usually asymptomatic, although the syndrome of infectious mononucleosis may be seen in these age groups.

EBV is generally acquired by oral transmission of virus in saliva. Following lytic replication in oropharyngeal epithelial cells with replication release of infectious virions from the cells, the virus selectively infects B lymphocytes in the peripheral blood and other reticuloendothelial tissues and establishes a lifelong latent, or quiescent, polyclonal infection of resting $CD23^-$ $B7^-$ B lymphocytes. EBV undergoes episodic reactivation of lytic replication with production of mature, infectious virions and intermittent shedding from the oropharynx even from asymptomatic persons. Reactivation is not typically accompanied by distinctive clinical symptoms. Virus is recoverable by culture at any given time from 12 to 33% of asymptomatic healthy seropositive adults and at significantly higher rates (49 to 82%) from immunocompromised persons, indicating greater levels of viral replication. Virus is detectable by PCR in oral secretions in up to 90% of healthy adults.

EBV has been linked with several human tumors including Hodgkin's disease, non-Hodgkin's lymphoma, nasopharyngeal carcinoma, some T-cell lymphomas, and leiomyosarcomas and B-cell lymphomas, especially in the central nervous system, in immunocompromised persons and organ transplant recipients (posttransplant lymphoproliferative disease) (2). Uncontrolled EBV replication in patients with human immunodeficiency virus (HIV) infection and AIDS in oral epithelium may develop into the lesion of oral hairy leukoplakia, and replication in the lungs appears to be the cause of lymphocytic interstitial pneumonitis that is observed in children. Fatal or severe systemic lymphoproliferative disease has occurred rarely in individuals who appear to be immunologically incapable of limiting the replication and dissemination of EBV-infected B cells. The X-linked lymphoproliferative (XLP) syndrome results from deletion or mutation of the *SH2D1A* gene (also known as DSHP or SAP), located in the chromosomal Xq25 region, which permits overwhelming and usually fatal infection upon primary EBV infection. The XLP protein may act as a blocker (inhibitor) or as a regulator (adaptor) of the critical events in T and NK cell signal transduction. Another, rare group of patients demonstrates chronic, progressive, and systemic involvement associated with an impaired immune response to EBV nuclear antigen 1 (EBNA-1).

Several laboratory methods have been applied to identify EBV infection by testing of clinical specimens, and many have developed into important diagnostic and research tools (Table 1). Serologic assays and viral culture have been used historically for diagnosis of EBV infection, but newer molecular methods provide greater insight into the presence and quantitation of lytic viral replication. The genomic origins of the targets used in molecular and serologic tests for the diagnosis of EBV infection have been well characterized (Table 2).

For serologic diagnosis, several distinct EBV-associated antigen systems and their corresponding antibodies have been characterized (5, 8, 18). These EBV antigen systems were initially described phenomenologically and can now be classified by the phase of the viral replicative cycle during which the target genes are expressed (Table 2). Only 10 viral genes are transcribed during latent infection, including the following: six EBV nuclear antigens, or proteins (EBNA-1, -2, -3A, -3B, -3C, and –LP [leader protein]), of which EBNA-1 is the principal constituent; three latent membrane proteins (LMP-1, -2A, and -2B); and two short EBV-encoded RNAs (EBER-1 and –2), which are not translated. LMP-1 and EBNA-2, in combination with the major histocompatibility complex antigens, constitute the lymphocyte-detected membrane antigen (MA), a cell surface antigen recognized by cytotoxic T cells. The early antigens (EAs) are produced during the initial stages of viral lytic replication prior to viral DNA synthesis. The EAs include two morphological components, diffuse (EA-D) and restricted (EA-R), which are distinguished on the basis of their distribution within the

TABLE 1 Tests used in the clinical diagnosis of EBV infection

Assay	Application (and comment)
Serologic tests	Identify acute infection (typically by positive heterophile antibody or positive anti-IgM-VCA)
	Identify remote infection ($\geq$3 months previously; typically by positive anti-EBNA)
	Identify relatively high levels of lytic replication (suggested by high VCA-IgG and high EA)
	Monitor disease status (especially EA-D and IgA antibody responses to VCA for nasopharyngeal carcinoma; serologic monitoring is less precise than monitoring quantitative EBV viral load by PCR and is also unreliable for immunocompromised persons)
Viral culture	Detect EBV in blood, body fluids, and tissues (requires 6–8 weeks and fresh human umbilical cord lymphocytes; much less sensitive than DNA PCR)
Virocyte assay	Semiquantitative EBV culture of infected circulating B lymphocytes
Electron microscopy	Detect whole virions in tissues (impractical for clinical diagnosis)
DNA PCR	
Qualitative	Detect EBV in blood, body fluids, and tissues (confounded by EBV in circulating lymphocytes in tissues)
Quantitative	Monitor viral load, implying lytic replication in blood or body fluids to follow disease status (by PCR amplification of EBER RNA or, alternatively, a DNA target)
Immunohistochemistry	Identify EBV protein expression in specific cell types in tissue samples (typically by identifying LMP-1 or, less frequently, EBNA-2)
	Identify lytic replication (by identifying BZLF1)
In situ hybridization	Identify EBV in specific cell types in tissue samples (using EBER probes)
Clonality assay	Distinguish monoclonal from oligoclonal and polyclonal cell infections
	Identify the presence of lytic replication (by the presence of a smaller ladder of terminal digestion fragments)

cells and by their differential denaturation by fixation procedures and proteolytic enzymes. EA-D and EA-R each comprise two different EBV proteins. The late antigens are produced after viral DNA synthesis and include the viral capsid antigens (VCAs), the structural proteins of the capsid. MAs are structural polypeptides of the virus expressed before and after viral DNA synthesis on the cell surface and also form part of the viral envelope.

HETEROPHILE ANTIBODY

The Paul-Bunnell heterophile antibody associated with acute infectious mononucleosis agglutinates sheep and horse erythrocytes, among others, and is adsorbed by beef erythrocytes but not guinea pig kidney cells (5). The latter adsorption property differentiates this response from other heterophile antibodies found in patients with serum sickness and rheumatic diseases and in some healthy individuals. The heterophile antibody response usually peaks during the second and third weeks of illness and is frequently detectable for several months after resolution of clinical symptoms (Fig. 1). The origin of the antigen is unknown, but it is not an EBV-encoded antigen. Heterophile antibody is primarily immunoglobulin M (IgM). There is no anamnestic response.

The most widely used method to detect Paul-Bunnell heterophile antibody is the qualitative, rapid slide test. The slide tests that use bovine or horse erythrocytes are more sensitive and detect heterophile antibody in 90% of cases of EBV-associated infectious mononucleosis in adults, with a false-positive rate of <10%. This method detects a heterophile response in about one-third of cases in children <4 years of age, although a greater proportion may have heterophile antibody detectable by the immune adherence hemagglutination procedure (18). Erroneous interpretations by the operator account for most of the false-positive results and some of the false-negative results. To improve accuracy, the package directions must be followed very closely, positive and negative controls should be used with each test, and laboratory personnel need to gain experience with the test reactions. Heterophile antibody test kits utilizing sheep erythrocytes or those that lack a guinea pig kidney or beef absorption step (unless the method incorporates native and enzyme-treated erythrocytes for agglutination) should not be used.

Quantitative testing by the more cumbersome Paul-Bunnell-Davidsohn technique, or the simplified ox cell hemolysin technique, is performed rarely and usually for research purposes only. Other recently developed tests utilizing a variety of techniques, such as enzyme-linked immunosorbent assay (ELISA), immune adherence hemagglutination, and latex agglutination with purified forms of heterophile antigen, do not offer any significant or practical improvement over the rapid slide test (with the possible exception of the immune adherence method for testing of children <4 years of age).

Approximately 10% of cases of infectious mononucleosis-like illness are not caused by EBV and are uniformly not associated with a heterophile antibody response. Cytomegalovirus, *Toxoplasma gondii*, HIV, adenovirus, and possibly rubella virus have been identified as causative agents in some cases, although the majority of cases of heterophile-negative infectious mononucleosis remain of undetermined etiology. If the heterophile antibody test is negative and an EBV-associated disease is suspected, EBV-specific serologic testing is indicated to confirm the etiology. EBV-specific serologic testing is also useful in evaluating a positive heterophile antibody test associated with clinical or laboratory findings uncharacteristic of infectious mononucleosis.

EBV-SPECIFIC SEROLOGIC TESTS

The serologic profile of EBV-specific antibodies following infectious mononucleosis has been well documented (Fig. 1). The acute phase of infectious mononucleosis is characterized

TABLE 2 Genomic origins of EBV targets commonly used for diagnosis of EBV infection

Assay and antigen	EBV target		Use and interpretation
	Gene (protein mass)	Function	
Serology			
Latent antigens			
EBNA-1	BKRF1 (60–85 kDa)	DNA-binding protein to *ori*P, permitting episomal replication	Positive serology confirms EBV infection ≥3 months previously; remains positive for life
EBNA-2	BYRF1 (two alleles, EBNA-2A [85 kDa] and EBNA-2B [75 kDa], with 64% homology; EBNA-2B has a major internal deletion that removes a large portion of the polyproline stretch)	Transactivator; component of lymphocyte-derived membrane antigen	Positive serology with acute infection; may decline over time
Early antigens			
EA-D	BMRF1 (50 kDa)	DNA polymerase-associated processivity factor	Positive serology with acute infection; usually declines over time
	BSLF2/BMLF1 (60 kDa)	Transactivator/repressor	
EA-R	BORF2 (85 kDa)	Ribonucleotide reductase (large subunit)	Positive serology with acute infection; usually declines over time
	BHRF1 (17 kDa)	*bcl*-2 homolog (B-cell lymphoma/leukemia 2 proto-oncogene)	
Late antigens			
VCAs	BcLF1 (150 kDa, glycosylated; 135 kDa, unglycosylated)	Major capsid protein	Positive serology with acute infection; remains positive for life
Membrane antigens	BLLF1a/b (350/221 kDa, glycosylated; 135/100 kDa, unglycosylated)	Envelope glycoprotein and plasma membrane protein; ligand for cell attachment to CD21 (CR2)	
	BALF4 (125 kDa, glycosylated)	Membrane protein (gB); virus assembly	
Immunohistochemistry			
Latent antigens			
LMP-1	BNLF1 (58–63 kDa)	Morphological transformation	
EBNA-2	See EBNA-2 above		
Immediate early antigen			
BZLF1	BZLF1 (38 kDa)	Zta or ZEBRA; transcriptional activation of EBV early genes by binding to upstream Z-responsive elements	Positive result indicates viral replication
PCR and in situ hybridization	EBER-1 and EBER-2 (approximately 170 nucleotides)	Unknown	Best in situ hybridization target because of >10⁶ copies/cell; not present in oral hairy leukoplakia
Clonality	Terminal repeats (not a gene)	Required for replication	Identifies monoclonal, oligoclonal, or polyclonal infection. Identifies lytic replication, if present

by rapid IgM and IgG antibody responses to VCA and, in most cases, a lower IgG response to the EA complex. The IgM response to VCA is transient, lasting about 1 to 3 months. The IgG response to this antigen usually peaks during the acute illness, declines slightly over the next few weeks to months, and then persists at a relatively stable level for life. Anti-EA antibodies are usually present for several months but may persist for several years following resolution of the acute infection. Anti-EBNA antibodies typically appear much later, gradually emerging after 2 to 4 months, and

occasionally longer, following the onset of illness and lasting for life. Some immunocompromised patients demonstrate diminishing or undetectable levels of anti-EBNA antibodies.

EBV-specific antibody testing is useful in determining (i) susceptibility or immunity to primary EBV infection on an individual basis or as part of an epidemiologic study in a general population, (ii) the potential etiologic role of EBV in a heterophile antibody-negative infectious mononucleosis-like illness, (iii) the possible etiologic role of EBV in a variety of clinical syndromes that have occasionally been associated
FIGURE 1 Schematic representation of the typical development of antibodies to various EBV antigens in patients with infectious mononucleosis, the prototype symptomatic primary EBV infection. The titers are geometric mean values expressed as reciprocals of the serum dilution. The minimum titers tested are 1:10 for VCA-IgG and EA, 1:8 for VCA-IgM, and 1:2.5 for EBNA. The IgM response to VCA is subdivided because of the significant differences noted according to age of the patient. (Adapted from references 8 and 18.)

with EBV infection, and (iv) the presence of EBV antigens in cells and tissues. In addition, serologic testing for IgA antibody responses to VCA and EA-D may be useful in the initial evaluation as well as the response to therapy for nasopharyngeal carcinoma.

The range of antibody responses can occasionally make it difficult to interpret an individual antibody profile (Table 3). The determination of IgM antibody to VCA (IgM-VCA) is the most valuable serologic procedure to diagnose acute EBV infection; antibody panels that do not include IgM-VCA are not as dependable for detection of acute EBV infection. Properly performed, the IgM-VCA antibody test is quite reliable and specific. Very high titers of IgG-VCA alone do not necessarily indicate an acute infection. The vast majority of patients with infectious mononucleosis develop a transient antibody response to the EA-D component, although in some adult patients and especially in young children this response may be directed mainly against the EA-R component.

TABLE 3 Correlation of clinical status and characteristic serologic responses to EBV infection[a]

Clinical status	Heterophile antibody (qualitative only)	Characteristic antibody profile for:				
		EBV-specific antibody (negative reaction)				
		IgM-VCA (<1:8[b])	IgG-VCA (<1:10)	EA-D (<1:10)	EA-R (<1:10)	EBNA (<1:2.5)
Susceptible	−	−	−	−	−	−
Acute primary infection (infectious mononucleosis)	+	1:32 to 1:256	1:160 to 1:640	1:40 to 1:160	−[c]	− to 1:2.5
Recent primary infection (infectious mononucleosis)	±	− to 1:32	1:320 to 1:1,280	1:40 to 1:160	−[c]	1:5 to 1:10
Remote (past) infection	−	−	1:40 to 1:160	−[d]	− to 1:40	1:10 to 1:40
Reactivation in an immunosuppressed or immunocompromised individual	−	−	1:320 to 1:1,280	−[d]	1:80 to 1:320	− to 1:160
Burkitt's lymphoma	−	−	1:320 to 1:1,280	−[d]	1:80 to 1:320	1:10 to 1:80
Nasopharyngeal carcinoma	−	−	1:320 to 1:1,280	1:40 to 1:160	−[e]	1:20 to 1:160

[a]Adapted from numerous studies. Individual responses outside the characteristic range may occur. −, negative; +, positive; ±, positive or negative.
[b]Some laboratories report <1:10 as the lowest dilution tested.
[c]In young children and adults with asymptomatic infection and seroconversion, the anti-EA response may be mainly to the EA-R component.
[d]A minority of individuals will have the anti-EA response mainly to the EA-D component.
[e]A minority of individuals will have the anti-EA response mainly to the EA-R component.

The testing of a second, or convalescent-phase, serum sample 4 to 6 weeks after clinical onset is of limited assistance for diagnosing a preceding acute EBV infection, since <10% of cases have a significant antibody titer rise over this interval. A past, currently quiescent, EBV infection is characterized by the concurrent presence of moderate but stable titers of antibody to IgG-VCA and EBNA and absence of IgM-VCA. Antibodies to EA are often absent but, if present, are usually at a low level and are directed predominantly to the EA-R component. High titers of IgG-VCA and EA, considered to indicate enhanced EBV replication or reactivation, have been noted in individuals with Burkitt's lymphoma, nasopharyngeal carcinoma, or immunosuppressed or immunodeficient

states. The antibody response to EA is directed principally to the EA-R component in patients with Burkitt's lymphoma and immunosuppressed or immunodeficient individuals and to EA-D in patients with nasopharyngeal carcinoma. High levels of IgA-VCA and IgA-EA are also found in persons with nasopharyngeal carcinoma, including the early asymptomatic stages. In these patients, tumor activity and response to cancer therapy may be monitored by serial IgA-VCA and IgA-EA determinations.

The EBNA, EA, and VCA antigen systems are the most useful for clinical diagnostic purposes and are determined principally by indirect immunofluorescence assay (IFA) and ELISA (Table 4). ELISA-based tests using viral lysate proteins,

TABLE 4 Summary of methodologies of EBV antigen systems classically used for detecting EBV-specific antibodies

Antigen system	Type of test	Source of antigen[a]	Antigen-negative control	Result indicating positive test for antibody
Latent antigens				
EBNA	Anticomplement immunofluorescence	Acetone-methanol (1:1)-fixed cell smears of Raji cells	EBV genome-negative cell line (e.g., MOLT-4)	Indirect immunofluorescence of complement fixation (incubation with complement followed by FITC-conjugated anti-C3)
Early antigens				
EA-R, EA-D	Immunofluorescence	Acetone- or methanol-fixed cell smears of nonproducer cells (e.g., Raji) treated with halogenated pyrimidines (induction) or with virus concentrates of the HR_1K (P3-HR1) line (superinfection)	Nonproducer cell line (e.g. Raji), not induced or superinfected	Indirect immunofluorescence with FITC-conjugated anti-human IgG or IgA
Late antigens				
VCA	Immunofluorescence	Acetone-fixed cell smears of producer cell line (e.g, HR_1K [P3-HR1], B95-8) treated with TPA	EBV genome-negative cell line	Indirect immunofluorescence with FITC-conjugated antihuman IgM, IgG, or IgA
MA	Immunofluorescence	Living cells from Burkitt's lymphoma biopsies and some producer lymphoblastoid cell lines (shows MA on the cell membrane), or acetone-fixed cell smears of producer cell lines (e.g., HR_1K [P3-HR1], B95-8) treated with TPA (shows MA peripherally inside the cell due to fixation as well as on cell membrane)	EBV genome-negative cell line; autologous bone marrow	Blocking of immunofluorescence with FITC-conjugated reference human serum
VCA and MA	Serum neutralization assay	Concentrated extracellular fluid from the HR_1K (P3-HR1) cell line	Concentrated extracellular fluid from an EBV-negative cell line	Neutralization of EA production following superinfection of nonproducer cells or inhibition of colony formation by nonproducer cells (e.g., Raji)
	Serum neutralization assay of EBV transformation	Concentrated extracellular fluid from the B95-8 or Kaplan cell line	Concentrated extracellular fluid from a nonproducer cell line or from the HR_1K (P3-HR1) line (nontransforming)	Neutralization of transformation of primary human leukocytes into continuous cell lines

[a]Antigen is demonstrated by using either commercially available monoclonal antibodies to the antigen or reference human antisera empirically determined to contain antibodies against the specific antigen system.

recombinant proteins, or synthetic peptides are used in clinical laboratories most often. IFA methods are more specific but also more time-consuming and difficult to interpret, requiring experienced personnel. These methods are important for resolution of inconsistent results by other methodologies (e.g., ELISA) and testing for research purposes, and they remain the "gold standard" for evaluation of new tests. Neutralizing antibodies can be detected by the interference of biologic activity (e.g., neutralization of EBV transformation of primary human lymphocytes, or neutralization of induction of EA production in Raji cells following superinfection with the HR$_1$K EBV strain), although these are tedious assays to perform. Neutralizing antibodies correlate well with anti-VCA and anti-MA titers. Determination of complement-fixing antibodies against antigens extracted from EBV-positive lymphoblastoid cell lines is rarely performed.

Several antibody test kits utilizing immunofluorescence and ELISA kits to detect EBV-specific antibodies are commercially available. Many clinical laboratories prefer to use ELISA methods, although sufficient standardization of techniques and correlation of results among these kits have not been adequately performed. There is high concordance between commercial ELISA kits for intertest sensitivity (95 to 100%) and slightly less for intertest specificity (86 to 100%) (3). However, comparative testing of ELISA and IFA shows a sensitivity of ELISA of only approximately 71% for VCA-IgG, 95% for VCA-IgM, and 99% for anti-EBNA, with an overall specificity of 99%. Considerable investigation is ongoing with tests using purified or recombinant proteins.

IFA Testing for Antibodies to VCA

IgM-VCA

The detection of IgM-VCA alone is generally sufficient to diagnose acute EBV infection. This antibody response in almost all cases can be detected for 4 to 12 weeks after clinical onset of infectious mononucleosis. It is prudent to augment the IgM-VCA test with at least one other antibody determination, such as IgG-VCA or EBNA. IgM antibody to cytomegalovirus may be detected in sera of patients with EBV-associated infectious mononucleosis, but IgM-VCA antibody does not appear to be detectable with infectious mononucleosis-like illness caused by cytomegalovirus.

Because rheumatoid factor may produce a false-positive IgM reaction, it is essential to routinely utilize a method that removes or circumvents this factor, such as one involving an IgG-inactivating reagent (GullSORB; Meridian Diagnostics, Cincinnati, Ohio). An adsorption step to remove serum IgG and thus eliminate the false-positive reaction associated with rheumatoid factor also reduces the incubation time needed for a satisfactory reaction between VCA and the test serum. A less acceptable alternative is to test each IgM-VCA-positive serum undiluted for the presence of rheumatoid factor.

Protocol

1. Vigorously growing HR$_1$K cells at a concentration of 6 × 10^5 per ml are incubated with the phorbol ester 12-O-tetradecanoyl-phorbol-13-acetate (TPA) (20 ng/ml) for 5 days at 32°C. This increases the number of cells expressing VCA to approximately 30 to 50%.
2. Antigen smears are prepared using whole cells. Cells are washed twice for 5 min in filtered phosphate-buffered saline (PBS) and resuspended in PBS at a cell density adjusted to produce a confluent layer on a 5-mm-diameter spot (using 8- or 14-well slides) with 10 μl of cell suspension.

3. The cell smears are air dried and then fixed with cold acetone for 10 min. After fixation, the smears may be stored at −20°C for up to 6 months.
4. A 50-μl aliquot of GullSORB is pipetted into a microcentrifuge tube, and 5 μl of patient serum is added. Inactivation of IgG is instantaneous. A quick spin (30 s) removes the flocculent material. The supernatant is a 1:10 dilution of the serum.
5. Serial fourfold dilutions, from 1:10 to 1:160, of the IgG-free serum diluted with PBS are prepared in a microtiter plate.
6. Aliquots (20 μl) of serum dilutions are transferred onto the smears, which are then incubated in chambers humidified with moist gauze or paper for 90 min at 37°C. Cell smears must not be allowed to dry during or between incubations.
7. The smears are washed twice for 5 min in PBS, and liquid around the wells is removed by suction. The smears are then incubated for 30 min at 37°C with 20 μl of fluorescein isothiocyanate (FITC)-conjugated goat F(ab')$_2$ anti-human IgM (mu chain specific; BioSource International, Camarillo, Calif.) containing 0.004% Evans blue counterstain. The FITC-conjugated anti-human IgM is generally diluted 1:100 to 1:150 in PBS, predetermined by testing antiserum dilutions with each lot of slides and control sera.
8. The smears are washed twice for 5 min in PBS, rinsed in distilled water, and air dried; glycerol-PBS (9:1 [vol/vol], pH 8.5 to 9.0) is added; and a coverslip is placed for immunofluorescence reading. The highest dilution of serum showing immunofluorescence is the end point.

Controls

Known negative and low-titer and high-titer IgM-VCA-positive control sera should be employed with each assay. Satisfactory smears of induced HR$_1$K cells should contain at least 30 to 50% VCA-positive cells, which should be confirmed before serum testing by incubation with a monoclonal antibody to VCA (Advanced Biotechnologies, Columbia, Md.) and FITC-conjugated anti-mouse Ig (BioSource International).

IgG-VCA

IgG-VCA antibodies are determined as described for IgM-VCA antibodies, except that the serum absorption step to remove IgG is not performed, TPA stimulation to increase antigen production is not routinely used, and an FITC-conjugated anti-human IgG antibody is used. Acetone-fixed smears of HR$_1$K cells (after maintenance of cells at 32°C for 10 to 14 days without refeeding) are incubated with serial fourfold dilutions of test serum (from 1:10 to 1:2,560) at 37°C for 45 min. After being air dried, the smears are incubated with 20 μl of FITC-conjugated goat F(ab')$_2$ anti-human IgG (BioSource International), usually diluted 1:800, at 37°C for 45 min. Other washes and rinses are performed as in the IgM determination. Adequate cell smears should contain at least 10% fluorescing cells, which can be confirmed by reaction using commercial monoclonal antibody to VCA. Known negative and low-titer and high-titer IgG-VCA-positive control sera should be tested in parallel with each assay.

IgA-VCA

The IgA-VCA procedure is as described for IgG-VCA, except that IgG in the patient serum is removed by using GullSORB as for IgM-VCA, and an FITC-conjugated anti-IgA antibody (BioSource International) is used.

IFA Testing for Antibodies to EA

IgG-EA

Antigen for determination of EA antibodies is derived from normally nonproductive lymphoblastoid cell lines, usually Raji, induced either by the addition of halogenated pyrimidines such as 5-iododeoxyuridine (14) or by superinfection with the HR_1K EBV strain (10). The EA-R antigen shows staining restricted to the cytoplasm and is denatured by methanol or ethanol. The EA-D antigen is found in both the nucleus and the cytoplasm and is stable in methanol. Cells demonstrating EA-R antigen usually demonstrate EA-D antigen also, although the converse is not necessarily true. In cells demonstrating both antigens, the brilliant reactions to EA-D often obscure those to EA-R.

While some laboratories report separate titrations for antibodies to EA-D and EA-R components, many laboratories prefer the traditional reporting of a single interpretation that denotes the predominant reaction observed (anti-EA-D, anti-EA-R, or anti-EA-DR if a predominant reaction cannot be differentiated). A differential EA antibody response directed mainly against EA-D is characteristic of infectious mononucleosis and nasopharyngeal carcinoma, and a response directed against EA-R is characteristic of Burkitt's lymphoma and selected immunocompromised states. The basis for this is unclear. A significant antibody response to EA is found in current or recent infections or in diseases intimately associated with an enhanced replication or putative reactivation of EBV. Low levels of antibodies to EA-R may be found in a minority of the healthy general population with remote past EBV infection.

Protocol

1. Vigorously growing Raji cells at a concentration of 3×10^5 to 4×10^5 per ml are treated with 5-iododeoxyuridine (20 μg/ml; add 4 μl/ml of a stock solution of 5 mg/ml in 0.1 N NaOH) and hypoxanthine-aminopterin solution (14 and 0.4 μg/ml, respectively; 4 μl/ml of a stock solution of hypoxanthine [3.5 mg/ml] and aminopterin [0.1 mg/ml] in 0.1 N NaOH) for 24 h at 37°C. The cells are pelleted, washed with RPMI 1640 medium, and then incubated with hypoxanthine-thymidine solution (14 and 20 μg/ml, respectively; 4 μl/ml of a stock solution of hypoxanthine [3.5 mg/ml] and thymidine [5 mg/ml] in 0.1 N NaOH) for 24 h at 37°C to reverse the inhibitory effects of aminopterin. An alternative method for preparation of cells for EA is superinfection of Raji cells with the HR_1K EBV strain and incubation for 2 to 3 days (10).

2. Antigen smears are prepared with whole cells. The cells are washed twice for 5 min in PBS and resuspended in PBS at a cell density adjusted to produce a confluent layer on a 5-mm-diameter spot (using 8- or 14-well slides) with 10 μl of cell suspension.

3. The smears are air dried and then fixed with either prechilled acetone (4 min) or prechilled methanol (10 min). After fixation, the smears may be stored at −20°C for up to 6 months.

4. Serial fourfold dilutions from 1:10 to 1:160 of sera diluted with PBS are prepared in a microtiter plate.

5. Each dilution of test serum is reacted separately with an acetone- and a methanol-fixed cell smear according to the steps described for determination of IgG-VCA. Cells fixed with acetone contain both EA-D and EA-R; cells fixed with methanol contain only EA-D. There is no method to prepare cell antigen smears for EA-R alone.

6. The smears are washed twice for 5 min in PBS and then rinsed in distilled water. The smears are air dried, glycerol-PBS is added, and a coverslip is placed for immunofluorescence reading. The highest dilution of serum showing immunofluorescence is the end point.

Controls

Known negative and low-titer and high-titer IgG-EA-positive control sera should be tested in parallel with each assay. Satisfactory smears of Raji cells should contain at least 8 to 10% EA-positive cells, which should be confirmed by reaction with a monoclonal antibody to EA-D (Advanced Biotechnologies).

IgA-EA

The IgA-EA procedure is as described for IgG-EA, except that IgG in the patient serum is removed by using GullSORB as for IgM-VCA, and an FITC-conjugated anti-IgA antibody is used.

Anticomplement IFA Testing for Antibodies to EBNA

The EBNA antigen complex is composed of at least six EBV proteins (EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, and leader protein), although EBNA-1 is the chief constituent. EBNA is found in all EBV-positive lymphoblastoid cell lines and biopsy tissues of various EBV-related malignancies. Modification of the anticomplement immunofluorescence method initially described by Reedman and Klein (16) is commonly used to detect antibodies to EBNA.

Protocol

1. Vigorously growing Raji cells are propagated for 48 h after splitting. Aliquots of 10 ml are pelleted and then fixed by adding 1 ml of cold acetone-methanol mixture (1:1), 1 drop at a time. The cells are pelleted and resuspended in cold acetone-methanol at a density to produce a thin, confluent layer on a 5-mm-diameter spot (using 8- or 14-well slides) with 10 μl of cell suspension. The cell suspension may be stored at 4°C for at least 8 weeks.

2. Stored, fixed Raji cells are mixed and then spotted on the wells of an 8- or 14-well slide. (Cell smears on slides cannot be stored.) The cell smears are air dried for at least 30 min.

3. Serum for anti-EBNA determinations must be heat inactivated (30 min at 56°C) to inactivate native complement. Serial fourfold dilutions from 1:2.5 to 1:160 of the serum with EBNA buffer (containing, per liter, 8 g of NaCl, 0.4 g of KCl, 0.2 g of $MgSO_4·7H_2O$, 0.185 g of $CaCl_2·2H_2O$, 1.8 g of Na_2HPO_4, and 0.6 g of KH_2PO_4) are prepared in a microtiter plate.

4. Aliquots (20 μl) of serum dilutions are transferred onto the smears, which are then incubated in chambers humidified with moist gauze or paper for 45 min at 37°C. Cell smears must not be allowed to dry during or between incubations.

5. The smears are rinsed in EBNA buffer and then incubated with 20 μl of diluted (usually 1:10 in EBNA buffer) guinea pig complement (GIBCO Laboratories, Grand Island, N.Y.) for 45 min at 37°C.

6. The smears are rinsed in EBNA buffer and then incubated for 45 min at 37°C with 20 μl of diluted (usually 1:100 to 1:150 in EBNA buffer) FITC-conjugated IgG fraction goat anti-guinea pig C3 (Cooper Biomedical, Malvern, Pa.) containing 0.002% Evans blue counterstain. Testing antiserum dilutions with each lot of slides and known sera

predetermines optimal dilutions of complement and FITC-conjugated anti-C3.

7. The smears are rinsed in EBNA buffer and then in distilled water. The smears are air dried, glycerol-PBS is added, and a coverslip is placed for immunofluorescence reading. The highest dilution of serum showing immunofluorescence is the end point.

Controls

False-positive anti-EBNA reactions are usually due to nonspecific antinuclear antibodies. To ascertain and eliminate this possibility, test serum is also reacted with cell smears of MOLT-4, an EBV-negative T-lymphoma cell line. Known negative and low-titer and high-titer EBNA-positive control sera should be tested in parallel with each assay.

NEUTRALIZING ANTIBODY

The presence of neutralizing antibodies in serum can be detected by using a neutralization assay based on interference of lymphocyte transformation (6). Cell-free B95-8 EBV is obtained from vigorously growing B95-8 cells after treatment with TPA (20 ng/ml) for 7 days at 32°C. The cells are pelleted, the supernatant is filtered through a 0.22-μm-pore-size filter, and the virus is concentrated by centrifugation at $40,000 \times g$ for 2 h. Concentrated virus can be aliquoted and frozen at $-70°C$ for at least 2 years. The titer (50% transforming dose [TD_{50}]/ml) is calculated according to the Reed and Muench method by transformation of human umbilical cord lymphocytes in 10-fold dilutions with at least three wells per dilution. Human umbilical cord lymphocytes are isolated by centrifugation of heparinized cord blood on Histopaque-1077 (Sigma, St. Louis, Mo.).

For the neutralization assay, concentrated B95-8 virus is diluted to $10^{2.3}$ to $10^{2.5}$ TD_{50}/0.1 ml, and aliquots (0.1 ml) of diluted virus are mixed with 0.1 ml of filtered, inactivated (56°C for 30 min) and diluted (1:5 through 1:3645) human serum and incubated at 37°C for 1 h. Fresh human umbilical cord lymphocytes are aliquoted at 1.5×10^5 cells in 0.15 ml of growth medium per well of a 96-well sterile tissue culture plate, and 0.02 ml of virus-serum mixture is added to each of triplicate wells at each serum dilution. The assay plate is incubated at 37°C and 5% CO_2 for 4 weeks with frequent changes (every 4 or 5 days) of one-half of the growth medium. Uninoculated cells, and virus without human serum, are included as controls with each assay. At the end of 4 weeks, the wells are scored as transformed or nontransformed and the 50% neutralizing endpoint titer is calculated by the Kärber method.

VIRUS ISOLATION

The transformation assay, used primarily for research purposes, can semiquantitatively assess the level of infectious EBV by measuring induction of lymphoproliferation or activation of B cells to Ig production. The number of virus-containing cells (virocytes) in a clinical specimen can be determined by the virocyte assay. Transforming EBV can generally be isolated from peripheral lymphocytes during acute infectious mononucleosis. Following acute infection, EBV is shed asymptomatically and intermittently in oropharyngeal secretions for life and occasionally can be isolated. Transforming virus is infrequently isolated from EBV-associated tumors or other pathologic lesions. Electron microscopy can be used to identify whole virions and confirm replicative viral infection but is impractical for clinical diagnosis.

Transformation Assay

Transforming virus may be found in either oral secretions or peripheral blood. For detection of transforming virus from the oral cavity, either saliva or a throat gargle with RPMI 1640 medium should be filtered through a 0.45-μm-pore-size filter (4). Samples are incubated in triplicate with aliquots of fresh human umbilical cord mononuclear cells (2×10^6 cells in 2 ml of RPMI 1640 medium supplemented with 20% fetal bovine serum). The cultures are observed for 6 weeks, with weekly changes of medium, for signs of cell transformation: proliferation and rapid growth, mitotic figures, large vacuoles and granular morphology, and cell aggregation. Transforming virus in peripheral blood is detected by isolating peripheral blood mononuclear cells from 10 to 30 ml of heparinized blood with Histopaque-1077, which are propagated in a medium containing cyclosporine (0.1 μg/ml), either alone or cocultivated with human umbilical cord leukocytes, and observing for signs of transformation. Cyclosporine is added to peripheral blood cultures to inhibit cytotoxic T cells that may cause regression of EBV-transformed B cells. The presence of EBV in transformed cultures can be confirmed by testing for the presence of EBNA, using an anticomplement IFA with a reference serum.

Virocyte Assay

An endpoint dilution assay is used to estimate the number of virus-containing cells (virocytes) in peripheral blood (17). Peripheral blood mononuclear cells, obtained as for the transformation assay, are serially diluted with RPMI-20 containing cyclosporine (0.1 μg/ml) to yield 2-ml volumes of 5×10^6, 5×10^5, 5×10^4, and 5×10^3/ml. Each dilution is dispensed in 0.1-ml volumes into a 96-well tissue culture plate (20 wells per dilution) containing 6×10^5 human umbilical cord lymphocytes per well. The plates are incubated for 8 weeks at 37°C with weekly changes of medium. The number of virocytes per 10^7 cells is calculated on the basis of the dilutions of cells showing signs of transformation.

IMMUNOHISTOCHEMICAL METHODS FOR ANTIGEN DETECTION

Detection of EBV antigens directly in body tissues by immunohistochemical procedures is widely done, but variability in assay interpretation justifies some caution in comparing results across studies. Tissue or tumor specimens or smears or touch preparations of specimens fixed in acetone may be tested by IFA. Monoclonal antibodies directed against components of EBNA-1, EBNA-2, LMP-1, EA, VCA, and BZLF1 are commercially available, although the commercial EBNA-1 monoclonal antibody has not proved satisfactory for direct antigen detection. Alternatively, characterized human reference serum may be used. LMP-1 immunostaining is most commonly used, primarily for evaluation of posttransplant lymphoproliferative disease, but is generally less sensitive than EBER in situ hybridization, especially for non-Hodgkin's lymphoma and carcinomas.

In contrast to latent antigens, it is unusual to detect replicative antigens (e.g., EA and VCA) in tissues with the exception of lesions of oral hairy leukoplakia, which is a purely lytic infection of oral epithelial cells that contain dense concentrations of VCA and EA. Some monoclonal antibodies are to minor EBV antigens, such as viral regulatory proteins (e.g., BLZF1) or minor structural components of the virus capsid. Testing for antibody responses against these

minor EBV antigens is not necessary for the diagnostic evaluation of EBV infection but may be useful in defining the presence of lytic replication, or reactivation, of latent EBV.

Direct Detection of EBNA-2, LMP-1, and the BZLF1 Protein

Touch preparations of soft tissues (e.g., lymph node biopsies), cryostat sections of firm tissues, and smears of suspension cells (cultured cells or peripheral blood cells) are air dried on glass slides and fixed with cold acetone for 5 min or cold, freshly prepared acetone-methanol (1:1) for 2.5 min. The slides are air dried and stored at $-20°C$ until stained. Because the signal from these latent antigens is less intense than that from the replicative cycle antigens, signal amplification of the antigen-antibody reaction by use of streptavidin-biotin is necessary. Monoclonal antibodies to EBNA-2 or LMP-1 (Vector Laboratories, Burlingame, Calif.) or the BZLF1 protein (DakoCytomation, Carpinteria, Calif.) and mouse isotype control antibodies (Sigma) are diluted either 1:5 or 1:10 with PBS, and 10 to 20 µl of diluted monoclonal antibody is incubated with the smears in chambers humidified with moist gauze or paper for 1 h at 37°C. Cell smears must not be allowed to dry during or between incubations. After incubation, the slides are washed, the liquid around the smears is suctioned or blotted, and biotinylated anti-mouse IgG (Vector Laboratories) diluted 1:20 to 1:50 in PBS is added. The slides are incubated for 30 min at 37°C and washed in PBS, and 10 to 20 µl of streptavidin-fluorescein (Vector Laboratories) diluted 1:50 in PBS containing 0.001% Evans blue counterstain is added. The slides are mounted and viewed as described above. B95-8 cells (without TPA treatment) serve as positive control cells for EBNA-2 and LMP-1, and TPA-treated B95-8 cells serve as positive control cells for LMP-1 and BZLF1. Ramos cells are negative control cells for both assays.

Direct Detection of VCA and EA

Cryostat sections from biopsies, cultured cells from tumors, and smears of suspension cells (cultured cells or peripheral blood cells) are air dried on glass slides, fixed with cold acetone for 5 min, air dried, and stored at $-20°C$ until stained. The slides are thawed and air dried before staining. Monoclonal antibodies to gp350/220, VCA p160 and gp125, EA p50, and EA p85 and EA p17 (Advanced Biotechnologies) and mouse isotypes (Sigma) are diluted 1:100 (if the protein concentration of antibody is 1 mg/ml) or 1:200 (if the protein concentration of antibody is 2 mg/ml) with PBS, and 10 to 20 µl of diluted monoclonal antibody is incubated with the smears in chambers humidified with moist gauze or paper for 1 h at 37°C. Cell smears must not be allowed to dry during or between incubations. After incubation, the slides are washed and FITC-conjugated anti-mouse Ig (gamma and light chain specific; BioSource International) diluted 1:50 in PBS containing 0.001% Evans blue counterstain is added. The slides are incubated for 30 min, washed in PBS, mounted, and viewed as described above. Acetone-fixed smears of B95-8 or HR₁K cells treated with TPA serve as positive control cells for both VCA and EA assays. Acetone-fixed Ramos cells serve as negative control cells for each assay.

NUCLEIC ACID DETECTION

Nucleic acid hybridization is a very sensitive and specific method for detection of EBV DNA in clinical specimens and in certain circumstances has advantages over serologic methods. Direct detection of virus is more reliable than serologic

testing in immunosuppressed or immunocompromised patients who may not demonstrate a complete humoral response and in patients who have received immune globulin products, thereby precluding serologic diagnosis. The complete genome sequence of the B95-8 strain of EBV is known, although significant genomic diversity exists among EBV clinical isolates. Unlike culture of EBV by the transformation assay, nucleic acid hybridization will detect noninfectious (defective) as well as infectious virions, including nontransforming variants.

Southern blotting, dot blotting (also known as spot or slot blotting), PCR, and in situ hybridization for EBV DNA have been applied to peripheral blood cells, oropharyngeal secretions, cervical secretions, and fresh or frozen biopsy specimens, principally from lymphoproliferative lesions. Total intracellular DNA is prepared by standard methods. These techniques vary in sensitivity and specificity for identification of EBV DNA, and therefore the results of these tests for the establishment of the causal role of EBV for different syndromes and lesions must be interpreted within the limitations of each test. Approximations of the limits of sensitivity of these techniques for EBV detection are that Southern blotting can detect 10^5 EBV genomes, dot blotting can detect 10^4 genomes, conventional PCR can detect 10^1 to 10^3 EBV genomes, and real-time PCR can quantitate over a range between 10^2 and 10^7 genomes (11, 12). The specificity of dot hybridization, Southern blotting, and especially PCR for identifying EBV within selected cells of tissue specimens is diminished because of simultaneous detection of EBV genomes present in circulating lymphocytes. In situ hybridization is the most specific of these four molecular biological methods because it permits direct evaluation of individual cells (1, 9). Because of their complexity and lack of standardization, these tests currently are not used routinely or generally available for diagnostic testing for EBV infection, nor are they necessary in routine clinical situations.

Dot Blotting and Southern Blotting

Numerous radionucleotide probes derived from regions throughout the EBV genome have been successfully used in dot blotting and Southern blotting to demonstrate EBV in clinical specimens. Certain sequences, such as the large internal repeat (IR_1), have theoretical advantages for increased sensitivity because of multiple copies in each EBV genome. The sensitivity and specificity may vary for each nucleic acid probe, and therefore the limits must be established experimentally, using appropriate controls.

Dot blotting has been performed with either whole-cell lysates or purified intracellular DNA, although the former is less specific and is not recommended. Dot blotting may be more sensitive than Southern blotting but is very susceptible to false-positive results because of concentration of nonspecific hybridization within the area of the dot (7). Dot blotting uses total intracellular DNA and may be semiquantitated by using serial dilutions. Southern blotting uses total intracellular DNA digested with one or more restriction endonucleases followed by separation of restriction fragments by gel electrophoresis. Southern blotting is very specific, as restriction fragments can be distinguished from nonspecific hybridization. The precise pattern of hybridization is dependent upon the restriction endonuclease used to digest the sample DNA and the EBV probe used in the Southern blotting. Genomic variation, including large deletions, among different EBV isolates frequently results in restriction fragment length polymorphisms that may confound interpretation and lead to false-negative test results.

PCR

Similar to in situ hybridization, PCR is among the most sensitive methods available for detection of genomic EBV DNA (11, 12). Semiquantitative PCR assays, including quantitative competitive PCR, can be used to determine the EBV load in plasma, peripheral blood lymphocytes, or tissues. Demonstrating the presence of expected restriction endonuclease sites within the amplified fragment may increase the specificity. Real-time measurement of PCR products, using fluorescent TaqMan-based assays, provides better quantitation with excellent sensitivity, specificity, and reproducibility across a large dynamic range (11). The BamHI W internal repeat, which is present in approximately six copies in various EBV strains, is often used as a target for DNA PCR (19), but is still less sensitive than targeting of EBER RNA, for which a commercial PCR amplification kit is available (BioSource International).

EBV viral load assays are more precise than monitoring serologic assays and are more reliable for immunocompromised persons. With acute infectious mononucleosis, mean EBV viral loads are 6×10^4 copies per ml (19). With posttransplant lymphoproliferative disease, EBV viral loads often exceed 10^6 copies per ml and may rise weeks to months before clinical manifestations, which suggests the need to monitor EBV viral loads routinely. EBV viral loads fall as immunosuppressive therapy is reduced to permit natural immunity to destroy EBV-infected cells. EBV viral load testing also shows promise for monitoring tumor burden and relapse in cases of nasopharyngeal carcinoma and Hodgkin's disease.

PCR has been used to characterize two different genotypes (EBNA-2A and EBNA-2B) of EBV based on EBNA-2 differences (ebnotypes). Diversity among EBV isolates has been utilized as a tool for studying the molecular epidemiology of EBV infection. Genomic variation is not randomly spread throughout the EBV genome; certain regions are highly conserved and may be preferable regions for Southern blot and PCR analysis. The occasional absence of a certain restriction endonuclease site in a clinical EBV isolate as determined by Southern blot or PCR analysis must be interpreted in the context of expected EBV genomic diversity. The sensitivity and specificity may vary for each set of PCR primers, so the limits must be established experimentally, using appropriate controls.

In Situ Hybridization

The EBER transcripts, EBER-1 and -2, are expressed in excess of 10^6 copies per cell in latently infected lymphocytes. They are separate but homologous genes that remain untranslated and are believed to function in controlling translation. They are the best target for EBV in situ hybridization because of their abundance (1, 9). These RNA polymerase III transcripts are approximately 170 nucleotides in length and have minimal homology with mammalian RNAs. Commercially available EBER oligonucleotide DNA probes, RNA probes (riboprobes), or peptide nucleic acid probes are labeled with biotin, digoxigenin, or fluorescein for detection (Fig. 2). In situ hybridization using nonisotopic EBER probes is more sensitive for detection of EBV than PCR is for detection of EBV DNA, provides cellular localization of EBV that demonstrates infected cells even when they are only a minor subpopulation, and can be applied to routinely processed paraffin-embedded tissue sections or cytology preparations. EBER transcripts are present in every EBV-associated infection with the exception of oral hairy leukoplakia, which is a purely lytic infection of oral epithelial cells. A hybridization control, often using a ubiquitous cellular transcript such as U6 RNA, must be performed to document that the RNA in the specimen is intact.

Clonality Assay

The EBV genome exists in two forms, circular (episomal) and linear. In latently infected cells, EBV is maintained only as
FIGURE 2   EBV in situ hybridization with a digoxigenin-labeled EBER-1 riboprobe in a lymphoproliferative tumor in a patient with an immunodeficiency. EBV is detected in the majority of lymphocytes. A blood vessel is present in the upper left portion. The slide is counterstained with methyl green. Magnification, ×400. Photograph courtesy of Margaret L. Gulley.

multiple episomal copies in the cell nucleus and replicates in a coordinated manner with cellular DNA synthesis. During lytic replication, which leads to cell death, EBV replicates with the formation of linear intermediates formed by the random cleavage between the variable number of terminal repeats of the EBV genome. The random cleavage produces linear EBV genomes containing different numbers of terminal repeats at the ends of the linear genomes. Upon malignant transformation, the same fused terminal repeat pattern is inherited by all progeny of the initial malignant cell.

The clonality assay is performed by digestion of EBV DNA with a restriction endonuclease (e.g., BamHI) that does not cut the genome within the terminal repeats (15). The fragments containing the terminal repeats are detected in a Southern blot assay using specific probes (e.g., EcoRI I and XhoI a) for the two ends of the EBV genome. With monoclonal EBV infection, the fused termini of the episomes are present as a single size (usually 8 to 23 kbp) and appear as a single band. Multiple bands indicate oligoclonality or polyclonality, which suggests multiple EBV infection events in the cell population being assayed. In addition to confirming EBV infection and showing the clonality, a ladder of smaller terminal digestion fragments, if present, from linear genomes indicates active EBV replication.

Cytomegalovirus

KIRSTEN ST. GEORGE, AKI HOJI, AND CHARLES R. RINALDO, JR.

73

Human cytomegalovirus (CMV) was first isolated independently in three laboratories in the mid-1950s (51). Initial infection with this ubiquitous *Betaherpesvirus* usually occurs early in life and is asymptomatic, after which the virus establishes a lifelong, latent infection. Transmission occurs during direct contact with body fluids such as occurs with breastfeeding, sexual contact, and the care of young children. Preschool-age children in close contact, either at home or in day care facilities, commonly acquire CMV from one another. Latent infections are periodically reactivated and usually result in asymptomatic shedding from various anatomical sites. CMV infection can, however, cause a spectrum of diseases, including congenital cytomegalic inclusion disease in the neonate, a serious but self-limiting mononucleosis syndrome in immunologically competent adults, and a broad range of potentially life-threatening illnesses in persons with impaired immune function. Congenital CMV infection is the major infectious cause of birth defects and a major cause of sensorineural hearing loss and mental retardation in developed countries. The most clinically significant diseases of the retina, gastrointestinal tract, liver, lungs, and central nervous system occur in immunosuppressed organ and tissue transplant recipients and in persons with severe immunodysfunction due to human immunodeficiency virus (HIV) infection. While the incidence of CMV disease in HIV-positive patients has decreased with the advent of combination antiretroviral therapy, CMV continues to be a major opportunistic pathogen in patients on antiretroviral therapy whose CD4$^+$-T-cell counts remain low (49). In addition to its direct causation of disease, CMV infection in transplant recipients is also associated with an increased incidence of bacterial and fungal infections, organ rejection, and graft-versus-host disease (GVHD); accelerated cardiac allograft vasculopathy; increased hospital length of stay and cost of medical care; and decreased survival. Furthermore, people coinfected with CMV and either HIV or hepatitis C virus have more rapid progression of HIV disease or more severe cirrhosis, respectively (8).

CMV has a linear, double-stranded DNA genome of approximately 245 kb. It is surrounded by an icosahedral nucleocapsid, which in turn is bound by an amorphous tegument and a loose, host-derived lipid envelope. The genome is divided into unique short (US) and unique long (UL) regions, both of which are bounded by repeat sequences. These regions can be inverted, resulting in four isomers of CMV DNA found in equimolar amounts. There are more than 200 open reading frames, including virally encoded envelope glycoproteins; some of these have homology with prototype herpes simplex virus proteins, such as glycoproteins B and H (gB and gH). CMV viral particles have recently been shown to contain 71 virus-encoded proteins and more than 70 host cellular proteins, including cellular structural proteins, enzymes, and chaperones (54).

Replication of CMV begins with attachment to the host cell, followed by fusion of the viral envelope with the cell membrane and entry of the nucleocapsid into the cell cytoplasm. The viral DNA then moves from the nucleocapsid into the host nucleus, and a typical alpha-beta-gamma sequence of herpesvirus gene expression follows. The immediate-early (or alpha) gene proteins (primarily transactivators) appear in the infected cell first, followed by the early (or beta) gene proteins (primarily nonstructural) and, finally, the late (or gamma) gene proteins (primarily structural components of the progeny virions). The capsid is assembled, and CMV DNA is packaged into the capsids in the nucleus. The tegument is acquired in both the nucleus and the cytoplasm, and particles are enveloped by budding into the trans-Golgi network. Although CMV is considered to be a relatively slowly replicating virus, evidence suggests that the virus has an average doubling time of 1 day in peripheral blood.

CMV infection in vivo occurs in epithelial cells of the kidney, liver, bile ducts, salivary gland, gut, lung, and pancreas, as well as in endothelial cells. Furthermore, abortive CMV replication has been described to occur in polymorphonuclear leukocytes, monocytes, and T and B lymphocytes. Infected monocytes/macrophages and endothelial cells are important in latent and acute CMV infections, possibly providing transport of the agent to different organs. In contrast to its broad cellular tropism, CMV replication is highly species specific, both in vivo and in vitro.

The major immediate-early (MIE) promoter of CMV controls production of the immediate-early gene products. Activation of this promoter is essential for initiation of the replication cycle and for reactivation of CMV from the latent state. Interestingly, prostaglandins, tumor necrosis factor alpha, interleukin-1β (IL-1β), IL-6, and IL-10 all upregulate the MIE promoter (29). Since these are all products of activated macrophages, acute inflammation has been proposed as one potential trigger for CMV reactivation. Furthermore, MIE gene products have been shown to

enhance IL-6 production, suggesting a role for CMV in the production of inflammatory states.

Monocytes, dendritic-like cells, and granulocyte-macrophage progenitor cells in the bone marrow and peripheral blood may be important sites of CMV latency. CMV reactivation can be induced in these cells by cocultivation with permissive cells, allogeneic stimulation, and cytokine treatment. Studies suggest that the percentage of cells latently infected is very low (0.004 to 0.01%) following natural infection (44).

Infection with one strain of CMV produces cross-reactive immunity to others, because of strong homology among all strains of CMV. However, immunity to one CMV strain does not always provide protection from superinfection by another strain, particularly in immunosuppressed hosts. Moreover, cell tropism and organ tropism may vary across different gB and other subtypes of the virus. This may relate to intragenic differences of gB types within a given isolate of CMV that result in variable immune specificity.

Cell-mediated immune responses play a major role in the control of CMV disease in an infected host. The presence of CMV-specific, major histocompatibility complex (MHC) class I-restricted CD8$^+$ cytotoxic T-lymphocyte (CTL) responses correlates with recovery from acute CMV infection and avoidance of disease in bone marrow transplant recipients (38). Furthermore, CMV disease can be prevented in bone marrow transplant recipients by the transfusion of autologous, CMV-specific, CD8$^+$ T-cell clones (56). CTL and MHC class II-restricted CD4$^+$ helper T-cell responses have been reported for several nonstructural and structural proteins of CMV (26). The most prominent CD8$^+$ T-cell responses are to the lower matrix tegument protein pp65, which is also the predominant protein in the virus particle. In contrast, there is no dominant viral protein specificity for CD4$^+$ T-cell reactivity.

CMV may suppress immune function in numerous ways. Lymphocytes from patients with CMV mononucleosis show reduced responses to mitogens and viral antigens (39). Data suggest that CMV-infected monocytes produce both tumor necrosis factor alpha, which in turn induces release of arachidonic acid, and prostaglandin E$_2$, which suppresses T-cell function (35). Even more intriguing is the fact that several CMV proteins encoded in the US region of CMV down-regulate MHC class I and class II expression (19). US2 and US11 dislocate MHC class I heavy chains from the endoplasmic reticulum to the cytosol, US3 facilitates their retention in the endoplasmic reticulum, and US6 inhibits the transporter for antigen processing translocation of the peptides. CMV also inhibits MHC class II expression, with US2 causing degradation of two essential proteins in the MHC class II pathway. This inhibition reduces the presentation of CMV antigens and, by extension, recognition by CD8$^+$ and CD4$^+$ T cells in vitro, and it may be involved in virus escape from the cell-mediated immune responses in vivo.

Numerous interactions occur between CMV-encoded proteins and cell chemokines. At least three CMV genes, US27, US28, and UL33, encode proteins that have CC chemokine receptor homology. The US28 gene product, for example, can bind beta chemokines, an event that is followed by cell sequestration of the chemokines.

Thus, CMV infection has an intimate interrelationship with host immunity. Assessments of humoral and cellular immune responses to CMV are therefore central to our understanding of the pathogenesis of the virus, and to the development of suitable therapeutic and vaccine controls for CMV infection.

DIAGNOSIS AND TREATMENT

CMV can be cultured in vitro in diploid human fibroblasts through the use of both conventional and rapid centrifugation-enhanced (shell vial) methods. Classically, congenital CMV infection is diagnosed by the isolation of virus from urine or saliva within 3 weeks of birth. Direct antigen detection by immunostaining has been applied to tissue biopsy sections and to cell smears from bronchoalveolar lavage fluid, cerebrospinal fluid, and peripheral blood. The optimal reagents for staining of tissues and bronchoalveolar lavage cells target both early and late viral antigens. For the staining of leukocytes in cerebrospinal fluid, the pp65 antigen must be targeted; the assay is only useful for the diagnosis of polyradiculomyelopathy and not encephalitis. Optimal staining of peripheral blood leukocytes in the CMV antigenemia assay targets the pp65 protein, and this method has greatly increased the sensitivity of detection of infection (50). Additionally, the assay is quantitative and can be used to assess the likelihood of progression to disease and the response to antiviral therapy.

Molecular methods for the detection of viral nucleic acids have increasingly replaced many of the above-mentioned methods. The most frequently used diagnostic approach for CMV infection is currently molecular amplification and detection of either viral RNA or DNA in peripheral blood. For the detection of CMV DNA in tissues, hybridization reactions have been applied to biopsy sections and amplification reactions have been applied to tissue homogenates. The latter, however, have sometimes been found to be too sensitive for clinical utility. DNA detection by PCR or similar DNA amplification assays has proven to be the method of choice for determining virtually all CMV-related central nervous system diseases, whereas the detection of virus in throat and urine specimens by any method has generally been found to have little clinical utility, due to asymptomatic viral shedding and the consequent lack of disease association.

There is an extensive published literature on countless PCR and other DNA amplification methods for the detection of CMV nucleic acid in blood. These include qualitative and quantitative methods; commercial and in-house methods; and manual, semiautomated, and fully automated methods. Additionally, there has been extensive discussion as to the optimal blood compartment for disease specificity, whether serum or plasma, whole blood, or purified leukocytes. Furthermore, there have been some successful studies showing the clinical utility of the detection of viral RNA in blood; one such method is commercially available (12). Most workers in the field, however, consider quantitative assays for viral DNA in peripheral blood to be optimal for the diagnosis and prognosis of CMV infection. These provide the combination of high sensitivity of detection and of quantitation, factors which are valuable in the determination of likelihood of progression to symptomatic disease, and in the monitoring of response to antiviral therapy. In recent years, the use of real-time PCR assays has become increasingly popular, due to their advantages of rapid quantitative detection, long linear ranges, ease of automation, and sealed systems that minimize the risk of amplicon contamination. There are a variety of real-time chemistries and automated equipment available, as well as ever-increasing numbers of commercial reagents and kits.

Only three drugs are currently approved for the treatment of systemic CMV infection: ganciclovir, foscarnet, and cidofovir (17). Ganciclovir and cidofovir are nucleotide analogs, while foscarnet is a pyrophosphate analog. All are optimally administered intravenously and have considerable

toxicity profiles. Oral ganciclovir, however, has a low bioavailability and is associated with an increased incidence of drug resistance. Fortunately, the valyl ester, valganciclovir, has much higher oral bioavailability, and its successful use is now widespread. Ganciclovir and valganciclovir remain the first drugs of choice and are usually administered prophylactically or preemptively to patients at high risk of disease. The antisense oligonucleotide fomivirsen is only approved for use as an intravitreal injection for CMV retinitis that is not responsive to ganciclovir or foscarnet. With the use of these drugs has come the emergence of resistant strains of CMV, particularly in HIV-positive patients under long prophylactic treatment regimens and in transplant recipients at high risk of severe CMV disease. Resistant strains are commonly virulent, and while some exhibit a decreased replication efficiency in vitro, their emergence in a patient is often associated with serious disease consequences (24).

ANTIBODY RESPONSES

The humoral response to CMV infection includes the production of immunoglobulin A (IgA), IgM, and IgG antibodies. IgM antibodies are the first to appear following a primary CMV infection and may be detectable for a prolonged period. Furthermore, their production can recur following reactivation of latent virus or reinfection with additional strains of CMV. Thus, detection of CMV IgM is not diagnostic of a primary or even a recent infection. IgG antibodies appear 6 to 8 weeks after primary infection and persist indefinitely, with fluctuations in titer believed to be due to reactivations of latent virus. More than 95% of the anti-CMV IgG in normal human serum is of subclass IgG1, and approximately 3% is IgG3. Most sera also have low levels of CMV-specific IgG2 and IgG4.

The CMV genome encodes approximately 65 glycoproteins with a wide variety of functions. gB (also known as UL55) was believed to be the most abundant protein in the CMV envelope; however, recent studies with the laboratory strain AD169 have found that gM (UL100) is in fact more abundant, with gH (UL75) being the next after gB (54). All clinical isolates of the virus express gB, and serological responses to gB can be detected in infected individuals. During primary CMV infection, the production of glycoprotein-specific antibodies is delayed relative to that of immunoglobulins directed against other CMV antigens. During reactivation or reinfection, however, antibody production is more synchronized, and most of the virus-neutralizing activity in the serum of naturally infected individuals is from antibodies against gB (10).

Antigenic domain 1 was the first antibody-binding site to be identified on gB (53). More than 50% of the gB-specific antibody response in serum is directed against antigenic domain 1, and studies with monoclonal antibodies (MAbs) and point mutations indicate various antigenic substructures within the domain (42). This is one of the most highly conserved regions of gB, suggesting a critical role in the structure or function of the protein. Antibodies to gH can also be detected following natural infection. Assays using full-length protein detect these CMV antibodies in 95% of seropositive persons, and in some individuals anti-gH comprises the majority of the virus-neutralizing activity of serum. Latency-associated transcripts have been identified, and antibodies to proteins encoded by them have been detected in the serum of blood donors.

CMV infections have been associated with autoimmune manifestations, including the production of autoantibodies.

For example, CD13-specific antibodies have been found in bone marrow transplant recipients following CMV disease or CMV viremia, presumably stemming from altered presentation to the immune system as part of the CMV virion. These CD13-specific autoantibodies are believed to play a role in chronic GVHD reactions (47). Likewise, the detection of antibodies to ganglioside GM2 in patients developing Guillain-Barré syndrome following CMV infection has suggested a role for these antibodies in the development of this condition.

Serological Assays

While the detection of IgG antibodies provides confirmation of previous exposure to CMV and implies the presence of latent virus, the presence of antibodies does not protect the individual from reactivation of the latent virus or superinfection with a different strain. The clinical utility of CMV IgG assays is therefore somewhat limited. There are instances in which the demonstration of seroconversion is appropriate, particularly in pregnant women. However, even here, additional data from tests of antibody avidity may help to clarify the prognosis (25). Serology is not generally recommended as a diagnostic methodology for immunocompromised patients, as they may be unable to mount a detectable humoral antibody response or may have circulating IgG antibodies resulting from transfusions or immunotherapy. The use of these antibody assays on intraocular eye fluids has been found to be unreliable for the diagnosis of CMV retinitis. Serological assays for CMV IgG are used extensively in blood banking to generate stocks of CMV-seronegative blood. These are important for reducing the risk of severe posttransfusion primary CMV infection in CMV-seronegative immunocompromised patients.

Transmission of CMV to the fetus in utero cannot be predicted by the presence of IgM antibodies in maternal serum, since not all primary infections result in a detectable IgM response and since IgM responses are often seen during reactivations. In fact, fewer than 10% of IgM-positive pregnant women subsequently deliver a congenitally infected infant (31). Likewise, IgM detection is not recommended for immunosuppressed patients and, since CMV IgM responses can be raised even in response to reactivations, the general utility is limited.

IgG Assays

The majority of commercially available assays for CMV IgG antibodies use either viral lysate preparations or semipurified viral proteins as antibody binding targets; the sensitivities of these assays do not vary widely. The most commonly used methods for the detection of IgG antibodies are indirect enzyme immunoassays (EIAs) with either a semiautomated or automated format. Semiautomated formats are generally microtiter-based systems with manual pipetting of reagents and plate-reading spectrophotometers. More highly automated robotic systems for microtiter plate assays are generally only found in very large laboratories. Microparticle systems have also become popular, as they lend themselves readily to smaller-scale automation. Antigen is bound to microparticles, which are suspended in liquid and flow through tubing systems on automated equipment. Antibody-antigen reactions take place on the surface of the microparticles, and the detecting antibody may be tagged with any one of a number of different compounds, to facilitate detection and quantitation. Care must be taken with these systems, however, to ensure homogeneous particle suspension prior to operation.

Another method for IgG detection, although now rarely used, is immunofluorescence. Antigen-containing cells are

bound to the wells of a slide and are incubated with dilutions of patient serum. A second antibody tagged with a fluorescent label, usually fluorescein isothiocyanate, is then added, and the cell spot is viewed under fluorescence microscopy. A few laboratories still use complement fixation tests. The assay, which detects antibody via its ability to fix complement and thereby interfere with cell lysis, does not distinguish IgG from IgM, is time-consuming to perform, and does not lend itself readily to automation. Latex agglutination assays are also used in some laboratories as a rapid screening test for the presence of CMV antibodies, but they are less sensitive than EIAs.

IgM Assays
Assays for the detection of IgM antibodies show more variation in sensitivity than do those for IgG, depending on the antigen preparation used. In general, the necessity for detection of structural and nonstructural viral proteins, in order to achieve optimal sensitivity, renders those IgM assays that use viral lysates more sensitive than those that use semipurified viral protein preparations. However, certain pooled recombinant antigen preparations specifically designed for the purpose also have been found to be good and to avoid problems, such as patient antibody reactivity with cellular antigens, that may produce false-positive results.

As with IgG assays, the most common format for IgM detection is semiautomated EIA-based systems in microtiter plates, with microparticle-based systems also increasing in popularity. In contrast to the almost universal use of antigen coating on solid support to initially bind IgG antibodies, many IgM assays use IgM capture methods. In these systems, an anti-IgM antibody is bound to the solid support, either microtiter well or microparticle, to which any IgM antibody present in the serum will bind. CMV-specific IgM is then distinguished by the binding of CMV antigen to the immobilized IgM, with detection via a conjugated enzyme or other detector molecule. False-positive IgM results can occur with sera that contain high titers of IgG antibody, when an assay is used that relies on the absorption of IgG prior to the detection of IgM. IgM capture methods are not prone to the false-positivity problems caused by rheumatoid factor. The commercially available IgM assays are virtually universally qualitative, whereas many of the IgG assays are quantitative or semiquantitative.

Antibody Avidity
In organ transplant recipients, the delayed development of high-avidity antibody has been correlated with delayed viral clearance and a poor prognosis (32). Additionally, the measurement of antibody avidity has been found to be a powerful tool for distinguishing primary from nonprimary infections in pregnant women and for predicting CMV transmission to the fetus.

Antibody avidity assays are performed by the simple insertion of a chemical elution step in the EIA procedure. Following the incubation of serum with antigen, and prior to incubation with the conjugate, the strength of antibody binding, or avidity, is challenged by the addition of urea. The higher the antibody avidity, the greater the amount of IgG antibody that will remain bound to the antigen. Thus, by comparison of the test results with and without the urea incubation step, the percentage of antibody avidity is calculated.

Neutralization Assays
While antibody neutralization assays are now rarely used in diagnostic laboratories, they have been shown to assist in distinguishing primary from nonprimary infections.

A microneutralization format has been shown to be helpful in predicting outcome in suspected maternal CMV infections during pregnancy (18).

T-LYMPHOCYTE RESPONSES

Blastogenesis (Proliferation)
CD4$^+$ memory T helper cells from CMV-seropositive persons react to CMV antigens in vitro, when the antigens are presented as peptides in the context of MHC class II molecules by antigen-presenting cells (APCs). This clonal response is not evident in T cells from CMV-seronegative persons, although the distinction has become blurred, with reports of CMV DNA and virus in some CMV-seronegative persons. Recently, bacterial polysaccharides have been shown to be presented to CD4$^+$ T cells by MHC class II molecules (15). This suggests that viral sugar moieties can be presented to T cells. Antigen-specific, activated CD4$^+$ T cells provide "help" in the form of cytokines, such as IL-2 and gamma interferon (IFN-γ), that are produced after their antigen-specific interaction with APCs. These cytokines enhance activation and expansion of antiviral effector CD8$^+$ CTLs. Activated CD4$^+$ T cells also augment CD8$^+$-T-cell activation by inducing maturation of APCs, in particular dendritic cells (DCs), through engagement of their CD40 ligand to CD40 on the surface of the APCs. The mature APCs express greater levels of T-cell ligands (MHC and costimulatory molecules) and cytokines (such as IL-12) that mediate activation and expansion of antigen-specific CD8$^+$ T cells.

The conventional assay for CD4$^+$-T-cell immunity is measurement of the turnover of cellular DNA, or blastogenesis. This is more commonly termed lymphocyte proliferation, since most (but not necessarily all) of the blasting cells undergo mitosis. Incorporation of [^{3}H]thymidine into DNA is measured after 5 or 6 days of culture. The method is not commercially available in a kit format. We recommend a consensus lymphoproliferation assay protocol established in 2000 by the Immunology Research Agenda Committee of the Adult AIDS Clinical Trials Group (2). The assay requires in vitro stimulation and culture of the CD4$^+$ T cells with viral antigen, so it is actually an assessment of the ability of precursor CD4$^+$ T cells to replicate DNA and proliferate. Usually, nonreplicating CMV antigen is added to peripheral blood mononuclear cells (PBMCs) that contain the CD4$^+$ T cells and the appropriate APCs (B cells, monocytes, and DCs) for processing of the CMV antigen. Laboratory strains of CMV are typically used as antigen (e.g., AD169, Davis, and Towne), since there is strong cross-antigenicity with clinical, wild-type isolates. Alternatively, recombinant CMV proteins (e.g., immediate-early protein, gB, and pp65) or predetermined MHC class II synthetic CMV peptides can be used to delineate CMV-specific CD4$^+$-T-cell reactivity. Incorporation of [^{3}H]thymidine into DNA is measured after 5 or 6 days of culture.

The results are reported as the difference in radioactivity between the antigen-stimulated cultures and the background control, or as a stimulation index (SI), which is the radioactivity in the antigen-treated cultures divided by that in the control culture. A positive result can be determined using as a lower limit the mean plus 3 standard deviations of the results for CMV-seronegative donors. A significant drawback to this test is that very low radioactive counts in the controls can result in artificially high SIs for biological responses that are relatively nonrobust. Moreover, the assay

is only semiquantitative; i.e., it does not reveal the number of cells that duplicate their DNA or that proliferate in response to the antigens. Limiting-dilution assays have been developed to quantitate the number of proliferating, antigen-specific CD4$^+$ T cells, but these methods have not been widely adopted, due to their labor-intensive nature and technical difficulty.

The activation process described above does not distinguish T helper 1 (Th1) from T helper 2 (Th2) subpopulations of human CD4$^+$ T cells. These subtypes are primarily responsible for activation of antigen-specific CD8$^+$ CTLs and for B-cell antibody production, respectively. Another significant point concerning this assay is that the cells finally incorporating the thymidine label may include bystander, non-CMV antigen-specific T cells that have been activated by the secondary effects of cytokines that were initially produced by the CMV-specific CD4$^+$ T cells, such as IL-2. Finally, this assay is rarely used to assess blastogenesis of CD8$^+$ T cells; for such an application it would require CMV antigen processed by APCs through the MHC class I pathway.

In recent years, the intracellular fluorescent dye 5(6)-carboxyfluorescein diacetate succinimidyl-ester has been used to measure T-cell proliferation (5). As T cells labeled with this dye divide, the dye is successively diluted by half in each daughter cell. This therefore allows determination of the number of cells that have gone through cell divisions, by flow cytometry. The technique measures proliferation of CMV-specific CD4, as well as CD8, T cells. It is typically done in cell culture systems where fresh or frozen PBMCs are stimulated by the addition of either recombinant CMV proteins (e.g., pp65 produced by baculovirus), inactivated whole-virus preparations, or synthetic immunodominant CMV peptides (if the HLA type of the individual is known and if the peptide is available for the particular HLA type). The CMV proteins and virus will be processed through the exogenous MHC class II pathway by APCs in the PBMC cultures, and they will stimulate CMV-specific CD4$^+$ T cells. Stimulation of CMV-specific CD8$^+$ T cells can be done by the use of 8- to 10-mer MHC class I-restricted peptides. Moreover, this method, in combination with staining with CMV-specific MHC class I tetramers (see below), allows simultaneous detection of surface markers (immunophenotyping; see below) and of intracellular molecules that are either up- or down-regulated after antigen-specific stimulation. Thus, from a clinical standpoint, this method has a clear advantage over thymidine incorporation methods, in that it provides additional data for assessing whether CMV-specific T cells are functional or dysfunctional.

Healthy persons with latent CMV infection will have CD4$^+$ T-cell responses to whole CMV antigens and to some, but not always all, recombinant CMV proteins. In contrast, patients subject to immunosuppression, such as in HIV type 1 infection and during organ or tissue transplantation, will usually have low CD4$^+$ T-cell blastogenic responses to CMV antigens, depending on the duration and severity of their immunosuppression. This CMV-specific cellular immune dysfunction is in turn a determinant of their enhanced susceptibility to severe CMV-related disease.

Notably, there are no uniform standards that are widely available for these T-cell assays, leaving each laboratory to adopt internal, self-developed standards and controls. Also, because there are no proficiency testing services like those from the College of American Pathologists, laboratories are limited to proficiency panels provided to members of National Institutes of Health-sponsored programs, such as the AIDS Clinical Trials Group.

Cytokine Production

DCs and CD4$^+$ and CD8$^+$ T cells produce a group of cytokines before and after antigen-specific activation. These glycoproteins are a major factor in augmentation of effector T-cell responses to the virus and in helper function of the CD4$^+$ T cells. Cytokines predominantly produced by myeloid DCs are IL-12 and IL-15, which help to drive Th1 cell reactivity. Plasmacytoid DCs predominantly produce IFN-α, which can also enhance Th1 cell activity. Virus-specific T-cell-modulating activity by both types of DCs can be regulated through binding of natural ligands, such as lipopolysaccharides and CpG oligodeoxynucleotides, to toll-like receptors on the DCs (33).

Cytokines produced by Th1 cells, i.e., IFN-γ and IL-2, activate and expand the populations of antigen-specific effector CD8$^+$ CTLs. These cytokines also activate cells involved in innate immune responses, such as natural killer cells and macrophages. Lack of IL-12 production by DCs can lead to polarization of the T-cell response to Th2 cells instead of Th1 cells. Cytokines primarily produced by Th2 cells, such as IL-4 and IL-5, enhance B-cell antibody production. Thus, cytokine assays can, at least to some degree, distinguish Th1 from Th2 cells. A third set of CD4$^+$ T cells is T-regulatory (or Treg) cells, which are involved in maintaining tolerance by down-regulating effector T-cell responses. For CD8$^+$ T cells, there is a less well-documented division of CD8$^+$ type 1 and type 2 (Tc1 and Tc2) cells that produce cytokines similar to their T helper cell counterparts.

There exist a great number of commercially available EIAs for these cytokines. The test can be done on supernatants from cultures that have been stimulated as in the blastogenesis assay. The peak time for production of these cytokines is usually earlier than the peak blastogenic, or proliferative, response. For CD8$^+$ T cells, the major difference is the use of MHC class I-associated antigens by APCs. Since professional APCs do not support the CMV replication necessary for activation of CD8$^+$ T cells, stimulation of cytokines in CD8$^+$ T cells is done with APCs such as Epstein-Barr virus-immortalized B-lymphocyte cell lines (BLCLs) that have been infected with vectors such as vaccinia viruses expressing CMV proteins. Alternatively, PBMCs can be stimulated directly with synthetic CMV peptides representing predetermined MHC class I epitopes.

These assays have an advantage over the more quantitative tests in that they require relatively few PBMCs and are technically noncomplex. A significant drawback of these EIAs done on "bulk" culture supernatants, however, is that they are semiquantitative. That is, they do not distinguish whether differences in cytokine production are due to alterations in the amount of cytokine produced per cell or due to differing numbers of T cells. Moreover, they measure, to some extent, the levels of cytokines that have been induced through autocrine and paracrine loops by the CMV-specific CD4$^+$ or CD8$^+$ T cells that initially responded to the CMV MHC class II- or I-associated peptides, respectively, that are presented by the APCs. Thus, these assays do not unambiguously determine the numbers of CMV antigen-specific CD4$^+$ and CD8$^+$ T cells.

Single-cell EIA (ELISPOT) and intracellular flow cytometry assays of CMV-specific cytokine production by CD4$^+$ and CD8$^+$ T cells have steadily increased in usage in immunological research. These two assays are quantitative in that they delineate the number of CMV antigen-specific T cells that are producing the cytokines. Furthermore, if done within the first day of antigen stimulation, they essentially capture the CMV-specific memory T cells that are directly responding to MHC class I- or II-bound CMV peptides on the APCs.

For the ELISPOT assay, PBMCs, or enriched CD4$^+$ or CD8$^+$ T cells obtained by negative selection with magnetic beads coated with anti-HLA MAbs, are treated with HLA class I- or II-associated CMV antigens and seeded into commercially prepared microwells containing nitrocellulose membranes that have been impregnated with anticytokine MAb (27). Recently, large libraries of synthetic 15- to 20-mer peptides representing overlapping sequences of major immunogenic CMV proteins, e.g., pp65, have been used to generate anti-CMV CTLs for immunotherapy and for delineation of immunodominant epitopes (52). The 15- to 20-mer CMV peptides can be used in single or batched (up to 50 peptides each) formats. These libraries are a powerful approach in revealing new epitopes and changes in T-cell response to different viral epitopes. Such information is invaluable to the development of CMV vaccines, where it can be used to assess antigenic breadth. It is also notable that the once-strict definition of a specific HLA restriction for a single CMV epitope is now known to be much less rigid. This "degeneracy" is related to promiscuous binding of the peptide epitopes to several HLA class I molecules, which are termed supertype alleles (11).

The optimal time of incubation in the ELISPOT assay may vary according to the antigen preparation, ranging from 6 to 20 h. The dark spots are visible on the membranes for manual counting under a dissecting microscope, although computerized microscope readers are available (e.g., from Cell Technology, Columbia, Md.). Each spot theoretically represents cytokine produced from a single CD4$^+$ or CD8$^+$ T cell. The results are reported as the number of spot-forming cells. It should be noted that non-T cells can produce these cytokines, a fact which can complicate the results. However, if the CMV antigen is highly specific for activation of CD4$^+$ or CD8$^+$ T cells, there is less likelihood of cytokine production by the opposite T-cell subset or by the non-T cells in the preparation.

An alternative to the ELISPOT assay is intracellular staining of cells for cytokines and assessment by flow cytometry (55). The advantages of this method include relative ease and rapidity, less subjectivity in determining the results, and simultaneous determination of multiple cell surface and intracellular parameters of T-cell subpopulations. Thus, the numbers of CD4$^+$ and CD8$^+$ T cells producing cytokines can be directly assessed, without the need for laborious and expensive preenrichment of the cell subsets, as in the ELISPOT assay. However, intracellular staining is more costly, in that it requires flow cytometry for reading the assay, and it may require more PBMCs in cases where the number of positive cell "events" is relatively low.

Whole, anticoagulated blood or PBMCs are stimulated with either MHC class I or II CMV antigens. An inhibitor of protein secretion, such as brefeldin A or monensin, is added during the incubation to enhance the intracellular levels of the cytokines. The T cells are then labeled with anti-CD4 or anti-CD8 MAb and with anti-CD69 MAb (a type II membrane glycoprotein that is expressed on activated, but not resting, lymphocytes); these are each conjugated to different fluorescent dyes. Anti-CD28 MAb, which activates the CD28 molecule, which costimulates the T cells, can be added to enhance the CMV antigen-specific response. The PBMCs are permeabilized to allow intracellular entry of the fluorescence-conjugated anticytokine MAbs. The results, derived by flow cytometry, are expressed as the number of CD4$^+$ or CD8$^+$ T cells that are positive for the cytokine and CD69. Typical levels of T cells producing cytokines like IFN-γ or IL-2 in response to CMV antigens in healthy CMV-seropositive persons are 0.1 to 2.0%, so at least 50,000 cell events have to be read to obtain reliable results.

Cytotoxicity

CD8$^+$ CTLs are the major effectors of host resistance to CMV infection. They are activated by engagement of their T-cell receptors and coreceptors by MHC class I-bound peptides and costimulatory receptors on APCs. Limited endogenous replication of CMV within APCs directly leads to processing of viral proteins through this pathway. DCs, however, may also engulf virus-infected apoptotic cells (e.g., CMV-infected endothelial cells) and may process viral proteins through the HLA class I pathway (termed "cross-priming") for activation of antiviral CD8$^+$ CTLs. These CD8$^+$-T-cell activation processes are enhanced by T helper cells, as described above. Lower numbers of CD4$^+$ CTLs also are induced during CMV infection and are restricted by MHC class II molecules.

Once activated and expanded into effector cells, the CTLs make direct contact with the virus-infected target cells by the same T-cell receptor–MHC class I-restricted mechanism. The CTLs then mediate lysis, mainly by exocytosis of their granules, followed by perforin-dependent redistribution of CTL granzymes that activate the infected cell's apoptotic pathway. A second pathway of lysis that is not as prevalent in antiviral CTLs is engagement and oligomerization of Fas on the infected target cells by Fas ligand on the CTLs, with subsequent activation of the apoptotic pathway.

Anti-CMV CTL function cannot be reliably assayed directly from blood or tissues. Instead, CTLs are measured either by a bulk lysis procedure that is semiquantitative or by a quantitative limiting-dilution assay (40). These both require suitable stimulator cells expressing CMV peptides with the appropriate MHC class I molecules. For this, autologous fibroblasts previously grown from skin or tissue biopsy samples are infected with a laboratory strain of CMV. Alternatively, autologous BLCLs can be infected with viral vectors expressing CMV genes, such as vaccinia virus encoding CMV pp65. Such vectors are necessary, because BLCLs and other hematopoietic APCs are nonpermissive for full-cycle CMV replication. The vectors also allow differentiation of CMV protein-specific CTL responses. This system may stimulate CTLs specific for the Epstein-Barr virus that is used to transform the BLCLs, a response which must be differentiated from the CMV-specific T-cell response.

For the bulk lysis assay, PBMCs or enriched CD8$^+$ T cells are stimulated with APCs loaded with either viral vectors expressing CMV proteins or synthetic CMV peptides representing known CD8$^+$ T-cell epitopes and with IL-2. The IL-2 can instead be added after 2 to 3 days, so as to minimize nonspecific cell activation. Autologous or allogeneic, irradiated, uninfected cells are added as feeder cells to enhance cell viability and growth. Instead of feeder cells, which may introduce complicating factors such as alloreactivity, IL-7 can be added; this helps to maintain the viability of activated T cells. The cells are cultured for 10 days and then added to ^{51}Cr-labeled target cells at several effector/target cell ratios. Thus, the assay is, to a large degree, a measurement that is dependent on the in vitro proliferative capacity of the antigen-specific T cells.

The most convenient target cell systems are autologous cells that express CMV antigens in the context of HLA class I, such as the BLCLs loaded with synthetic peptides or infected with the CMV-vaccinia virus vectors. The percentage of lysis is calculated as follows: [(experimental cpm − spontaneous cpm)/(maximum cpm − spontaneous cpm)] × 100, where cpm is counts per minute. CMV-specific lysis is calculated as the lysis of the CMV antigen-expressing targets minus the lysis of the control targets. Data also can be calculated as lytic units per 10^7 cells; these units are derived

from an exponential-regression analysis of the multiple effector/target cell ratios.

The limiting-dilution assay for anti-CMV CTLs is superior to the bulk lysis assay in that it quantitates the actual number of CD8$^+$ CTL precursors. This precursor frequency assay, however, is much more labor-intensive, and its use in the field has been declining in recent years. PBMCs are plated in two- or fourfold dilutions in 24 replicates. To each well are added irradiated allogeneic PBMCs as feeder cells, IL-2, and cells expressing HLA class I-associated CMV antigens. The cells are cultured as in the bulk lysis assay and on day 10 are split into replicate wells; cytotoxicity is then measured by the ^{51}Cr release assay. The fraction of nonresponding wells is the number of wells in which the ^{51}Cr release does not exceed the mean spontaneous release plus 10% of the incorporated ^{51}Cr, divided by the number of wells assayed. The precursor frequency is estimated by the maximum-likelihood method, using statistical programs that are described in the literature.

Flow cytometry-based assays for CTL function have slowly been accepted as replacements for the chromium release assay. These involve effector-to-target setups similar to those in the chromium release assays, but the target cells are stained with dyes such as 3,3'-dioctadecyloxacarocyanine, which labels green the cell membranes of viable cells. Target cells lysed by CTLs become permeable to counterstain dyes such as propidium iodide, which labels the accessible nuclei red (14). The assay is safer in that it does not use radioactive chromium, and it has been reported to be more sensitive and to have lower background than the chromium release assay. It is commercially available in a kit format from Molecular Probes (Eugene, Oreg.). Several other fluorescence-based assays of CTL function include measurements of apoptosis through assessment of caspase activity in the target cells (13). These proteases can be measured by caspase substrates having covalently bound and quenched dyes that fluoresce upon cleavage by the caspase. The reagents are commercially available from OncoImmunin (Gaithersburg, Md.). Prestaining of the targets with a nonspecific dye such as CellTracker Orange (Molecular Probes) can differentiate them from effector cells. Finally, the phenotype of the T cells mediating the lysis can be determined through costaining with MAbs to CD4 and CD8. The stained cells are assayed by multiparameter flow cytometry. This assay is thought to be more sensitive than other dye staining methods, because it measures early events in cell death, events that precede membrane disruption. Finally, new flow cytometric measures of CTL function include staining for CD107, a lysosomal-associated membrane glycoprotein that is exposed on the CTL surface during degranulation.

HLA Class I Tetramer Staining

In 1996, Altman and coworkers (4) reported that antiviral CD8$^+$ T cells could be directly labeled by staining with a soluble MHC class I tetramer with bound viral peptides. This tetramer staining method has several advantages over other assays for determination of antiviral CD8$^+$-T-cell numbers. First, it directly identifies virus-specific T cells without culturing them in vitro. To culture is to disturb: culture methods are fraught with pitfalls related to differential outgrowth of subpopulations of CD8$^+$ T cells, such as occurs due to apoptosis of activated T cells upon antigen-specific stimulation. Second, tetramer positivity correlates well with antiviral CTL and cytokine effector functions of CD8$^+$ T cells. Third, this method is a relatively objective and non-labor-intensive assay that is read on a flow cytometer. Drawbacks to the tetramer staining assay include, in some virus infections, a lack of correlation of tetramer-positive cells with functional activity, the

occurrence of nonspecific binding of the tetramers to other CD8$^+$ T cells, difficulty in preparing tetramers for certain CTL peptides, and restriction of the technique to known MHC class I epitopes. CMV-specific tetramers use immunodominant peptides such as pp65$_{495-503}$ (NLVPMVATV) (28). The method therefore potentially offers a powerful approach to assessment of numerous aspects of anti-CMV T-cell responses. In addition, HLA class II tetramers are in development and should be available in the near future for the measurement of anti-CMV CD4$^+$ T-cell responses (30).

T-Cell Phenotyping

Expression of certain molecules on the surface of T cells has been associated with their functional capacity. Sallusto and colleagues (41) first proposed two major subsets, termed central memory (CCR7$^+$ CD45RA$^+$) and effector memory (CCR7$^-$ CD45RA$^+$) T cells. This system was further refined by Appay and coworkers (6), who showed that expression of CD27 in combination with CD28 was related to distinct maturational stages. Naive T cells express both CD27 and CD28 (i.e., CD8$^+$ CD27$^+$ CD28$^+$). Conventional, early memory CD8$^+$ T cells maintain expression of CD27 and CD28 (i.e., CD8$^+$ CD27$^+$ CD28$^+$); they are poorly differentiated and weakly cytotoxic, but they can proliferate. As these memory CD8$^+$ T cells proliferate in response to antigen, they differentiate and lose expression of CD27 and CD28 (i.e., they become CD8$^+$ CD27$^-$ CD28$^-$), reflective of their more differentiated state. These cells have strong cytolytic function, due to high expression of the effector molecules perforin and granzymes, and they have been termed effector memory T cells. CD8$^+$ T cells specific for distinct antigens appear to be enriched in particular phenotypic subsets.

Such subsets can further be defined by expression of CD27 and CD28 or of CD27 and CD45RA. CMV-specific CD8$^+$ T cells are typically enriched in a CD27$^-$ CD28$^-$ (6) or CD27$^-$ CD45RA$^+$ (21) phenotypic compartment. This phenotypic subset is functionally equivalent to effector CD8$^+$ T cells, which have the capacity to lyse CMV-infected cells by releasing effector molecules such as granzymes and perforin. Interestingly, CMV-specific CD8$^+$ T cells from immunosuppressed individuals show a greater frequency and higher proportion of the CD27$^-$ CD45RA$^+$ effector subset than do latently infected healthy controls (21). A major factor that controls the size and phenotype of CMV-specific CD8$^+$ T cells appears to be up-regulation of CD70 upon antigenic stimulation (22). During CMV antigenic stimulation of the T cells, CD70 interacts with CD27 and leads to its down-regulation. Thus, development of the CMV-specific CD8$^+$ T-cell phenotypes is highly complex and is influenced by multiple factors present in the microenvironment in which they interact with virus-infected cells.

IMMUNOTHERAPY

Active Humoral Immunotherapy

Since primary CMV infection in pregnant women poses the greatest risk of congenital CMV in the infant, maternal immunization prior to pregnancy may protect newborns from this disease. In an effort to decrease the incidence of congenital CMV infection, it is suggested that recipients of a CMV vaccine include toddlers, preteen children, and young mothers. It should be noted that while preexisting immunity reduces the incidence of congenital CMV infection by 69% (20), such immunity does not significantly reduce the severity of outcome (23). However, the average

incidence of congenital CMV infections in developed countries ranges from 0.5 to 2.0%, with approximately 10% of infected individuals being symptomatic at birth. Of those born without symptoms, 10 to 15% will progress to hearing loss or mental retardation (7, 16). CMV has been recognized as the leading infectious cause of fetal damage in the United States, Europe, and other developed areas of the world. For this reason, the Institute of Medicine in 1999 ranked the development of a CMV vaccine at the highest priority, based on the potential savings in economic costs, in years of life and disability, and in the human suffering that would be alleviated. Likewise, primary CMV infections in solid-organ transplant recipients carry the greatest risk of serious manifestations, and vaccination prior to transplantation may moderate the disease severity of subsequent infections.

Higher anti-CMV cell-mediated and humoral immune responses have been associated with a reduced risk of transmission to the fetus; however, the role of mucosal antibodies in protection is unknown. Circulating levels of anti-gB antibody have been shown to be inversely proportional to systemic viral load in HIV-infected patients (3), and high titers of glycoprotein-specific antibodies correlate with the absence of viral DNA in the blood of bone marrow transplant recipients (43). This suggests a role for antiglycoprotein antibodies in the prevention of CMV disease and in the modulation of its progression. However, for a vaccine, the relatively poor immunogenicity of CMV glycoproteins requires the addition of powerful adjuvants to purified gB proteins. Preliminary trials with one such mixture have shown promising results, but as many as four doses may be required to generate persistent neutralizing antibody responses.

Five types of candidate CMV vaccines have undergone preliminary trials in human subjects: (i) a classically attenuated CMV, (ii) a chimera between an attenuated CMV and wild-type virus, (iii) a nonreplicating canarypox vector with either a gB or pp65 antigen, (iv) recombinant envelope glycoprotein, and (v) a mixture of synthetic peptides including a T helper epitope and CD8+ T-cell epitopes (7). Other proposed vaccines include a DNA vaccine. Studies with live attenuated CMV Towne vaccine show that the majority of adult male, adult female, and pediatric recipients develop cell-mediated immune responses that persist for 6 months, as well as dose-dependent antibody titers comparable to those seen following natural infections. Importantly, seronegative recipients of seropositive kidneys who received this vaccine not only developed humoral and cellular immunity but also were protected from severe CMV disease. Combined-vaccine strategies have also been suggested, with recombinant canarypox live vaccine expressing CMV gB used to prime antibody responses prior to vaccination with the attenuated Towne vaccine (1). However, efficacy trials are still needed for those vaccines that have shown promise in phase I and II trials, and preliminary trials are still needed for the newer candidate vaccines.

Passive Humoral Immunotherapy

CMV immune globulin preparations have also been used in the prevention and treatment of CMV disease. Although results of clinical trials are variable, prophylactic CMV immune globulin appears overall to reduce the incidence of CMV disease and death in both bone marrow and solid-organ transplant recipients (46) and the incidence of acute GVHD in bone marrow transplant recipients (48). There have also been a number of encouraging studies with transplant recipients, using combinations of antiviral drugs and CMV immune globulin (34). In addition to reducing the incidence of CMV

disease, these combination therapies have also been shown to reduce the incidence or severity of CMV-exacerbated conditions, such as intimal thickening and coronary artery disease after cardiac transplantation (57), and fungal and parasitic superinfections following renal and liver transplantation (45). Unfortunately, however, the passive administration of anti-CMV antibodies postnatally is unlikely to modify the development or severity of congenital CMV sequelae (9).

Passive Cellular Immunotherapy

Adoptive immunotherapy has been proposed as an alternative to prophylactic treatments with antiviral drugs for the prevention of CMV disease in transplant recipients. Infusions of ex vivo-expanded CMV-specific, donor-derived CD8+ CTL clones and cell lines have been well tolerated, and they result in the in vivo expansion of CMV-specific CTLs. This immunotherapy is effective in reducing the incidence of CMV disease in high-risk bone marrow transplant recipients, although cytotoxic activity declines in patients who are deficient in CD4+ T helper cells (37, 56). An additional concern in this model is the choice of APCs. Autologous DCs are optimal in this regard, but they are difficult to obtain in large numbers. Nonhuman cell lines expressing a single HLA allele can also be effective APCs for generation of anti-CMV CTLs, but they are limited by single-allele specificity in the resulting effector T cells (36).

Human Herpesviruses 6, 7, and 8

RICHARD L. HODINKA

74

Herpesviruses 6, 7, and 8 are the most recently described members of the human herpesvirus family (Table 1). Like other herpesviruses, they have the ability to establish a latent or persistent infection following primary infection, and reactivation may occur in healthy and immunocompromised people in response to different stimuli. A variety of methods are available or under development for the laboratory diagnosis of each virus, including viral isolation in cell culture, demonstration of viral antigens or nucleic acids in body fluids or tissues, and serology for detection of virus-specific antibodies. This chapter focuses on the immunologic and molecular diagnosis and monitoring of infections with human herpesvirus 6 (HHV-6), HHV-7, and HHV-8 and provides information on the unique features of the epidemiology and biological and clinical characteristics of these viruses.

HHV-6

Introduction

HHV-6 is a lymphotropic virus which was discovered in 1986 in cultures of lymphocytes from patients with lymphoproliferative disorders and AIDS. Since that time, much has been learned about the biology, epidemiology, clinical features, and diagnosis of HHV-6, and a number of comprehensive reviews have been published (see references 4, 9, and 14 for examples of reviews).

HHV-6 is similar in morphology to other known human herpesviruses but is genetically and serologically distinct. The completed virion has a diameter of 160 to 200 nm and consists of an internal core containing double-stranded DNA of approximately 160 to 170 kb and an icosahedral nucleocapsid surrounded by a tegument and a protein-spiked envelope. The virus has a primary cell tropism for mature CD4$^+$ T lymphocytes but also infects CD8$^+$ T cells, natural killer (NK) cells, monocytes, macrophages, megakaryocytes, epithelial cells, endothelial cells, fibroblasts, and neural cells. CD46 has been identified as part of the cellular receptor for infection; this marker is expressed on the surfaces of many human cell types, leading to the broad cellular tropism of HHV-6. Viral replication occurs in the nucleus of the host cell, and the viral envelope is acquired during maturation within cytoplasmic vacuoles before budding of the completed virus from the host cell membrane.

The DNA genome of HHV-6 differs from that of other human herpesviruses by both restriction mapping and nucleic acid hybridization and is unique in that it has a significantly lower guanine-plus-cystosine content, 43 to 44%. Regions of sequence homology between HHV-6 and cytomegalovirus (CMV) have been identified, and HHV-6 is now classified with CMV among the betaherpesviruses. Genetic polymorphism among different isolates of HHV-6 exists, and evidence suggests that HHV-6 isolates form two distinct but very closely related groups (variants A and B) that differ in molecular, biological, and clinical properties. Most isolates of HHV-6 from patients with symptomatic primary infections have been of variant B. Variant A has been isolated or detected only rarely in children with primary HHV-6 infection, with the exception of African children with febrile illnesses. Both variants have been isolated from immunocompromised individuals, including AIDS patients, transplant recipients, and patients with leukemia; dual infections with both variants also have been described. Variant A is seen more frequently in patients with human immunodeficiency virus (HIV) infection, and it may be more neurotropic than variant B. Otherwise, an etiologic role for variant A in causing disease has not been clearly identified.

The HHV-6 genome has a coding capacity of approximately 80 to 100 proteins, although there has been little agreement about the actual number, size, and abundance of virus-specific proteins. More than 30 polypeptides ranging in size from 30 to 220 kDa, including six or seven glycoproteins, have been identified. A 101-kDa nucleocapsid protein was found to be highly reactive with human sera by Western immunoblotting and appears to be a specific marker for HHV-6 infection. A set of five monoclonal antibodies has been developed and used to identify nine proteins designated gp105 and gp82; gp116, gp64, and gp54; gp102; p41 and p110; and p135.

Similar to cases of CMV and Epstein-Barr virus (EBV) infection, infections with HHV-6 are common and often mild or inapparent; however, HHV-6 is now recognized as the causative agent of roseola (roseola infantum, exanthem subitum, sixth disease) in children aged 6 months to 3 years. The disease presents with an abrupt onset of fever (39 to 40°C) for 3 to 5 days, followed by the appearance of an erythematous, blanching, maculopapular, nonpruritic rash beginning on the face or trunk and spreading to other areas. The rash usually lasts for 1 to 3 days, and there is no subsequent

TABLE 1 Characteristics of HHV-6, HHV-7, and HHV-8

Characteristic	HHV-6	HHV-7	HHV-8
Family *Herpesviridae*			
Subfamily	Beta	Beta	Gamma
Genus	*Roseolovirus*	*Roseolovirus*	*Rhadinovirus*
Biological properties			
Genome (linear double-stranded DNA)	~159 kb; encodes 80–100 proteins	~145 kb; encodes at least 70 proteins	~165 kb; 97 genes identified
DNA relatedness (% homology)	CMV (66%)	HHV-6 (50–60%)	Herpesvirus saimiri (51%), EBV (39%)
Variants	HHV-6A, HHV-6B	Unknown	HHV-8 strains A, B, and C
Cell tropism in vitro	CD4$^+$ T lymphocytes, NK cells, macrophages, CD8$^+$T cells, megakaryocytes, neural and epithelial cells	CD4$^+$ T lymphocytes	CD19$^+$ B lymphocytes, spindle cells, endothelial cells
Virus interactions	EBV, CMV, HIV, parvovirus B19, human papillomaviruses	HHV-6, CMV, HIV	EBV, HIV
Epidemiology			
Distribution	Worldwide	Worldwide	Worldwide
Natural host	Human	Human	Human
Transmission	Oral secretions (HHV-6B only); possibly blood and urine; intrauterine and perinatal transmission suggested	Oral secretions; possibly blood and urine	Predominantly sexual contact; possibly oral secretions and blood; transplanted allograft
Seroprevalence	90% or greater	80–90%	0–25% in healthy American and European blood donors; higher in some African and Mediterranean populations; 75–95% of KS patients
Populations affected	Infants (0–3 yr), organ transplant recipients	Infants (1–5 yr)	Homosexual or bisexual HIV$^+$ males or their sexual partners; Mediterranean males; Africans; organ transplant recipients
Incubation period	9–10 days	Unknown	Unknown
Attributable clinical illnesses	Exanthem subitum, infantile febrile illnesses, infectious mononucleosis-like illness in adults, malignancies, posttransplantation and central nervous system diseases, disseminated infections in AIDS	Exanthem subitum, infantile febrile illnesses, pityriasis rosea (?)	KS, primary effusion lymphomas, Castleman disease

desquamation or pigment changes. Recovery is usually rapid and without complications. Interestingly, most cases of acute primary HHV-6 infection in young children do not result in an illness recognizable as roseola. Studies have revealed that acute viremic HHV-6 infection accounts for 14% of febrile children younger than 2 years seen in an emergency room, most of whom have a nonspecific febrile illness without a rash. Other clinical manifestations of primary infection include rash without fever, intussusception, bulging of the anterior fontanelle, lymphadenopathy, hepatitis, an infectious mononucleosis-like syndrome, inflamed tympanic membranes, aseptic meningitis, meningoencephalitis, and encephalitis. Febrile seizures are a common complication of roseola; approximately one-third of all febrile seizures in childhood have been attributed to HHV-6 infection. Primary infection in adults is rare but may result in prolonged lymphadenopathy, hepatitis, or an illness resembling infectious

mononucleosis. Reactivated infection in healthy persons is asymptomatic. It remains to be established whether HHV-6 causes or contributes to disease in immunocompromised hosts, although reactivation in organ recipients following kidney, liver, bone marrow, or heart transplantation has been associated with isolated fever, hepatitis, leukopenia, delayed engraftment, neurologic dysfunction, skin rashes resembling graft-versus-host disease, bone marrow suppression, and interstitial pneumonitis (see references 7 and 10 for reviews). Evidence suggests that HHV-6 infection may contribute to disease progression with HIV type 1 (HIV-1) and may interact with other viruses, such as CMV, EBV, parvovirus B19, and human papillomaviruses, to affect their behavior and exacerbate disease. HHV-6 has also been associated with a number of other diseases in patients in whom elevated titers of HHV-6 antibody have been detected and from whom replicating virus was isolated and/or viral antigens or DNA

was found. The role of the virus in most of these clinical settings, however, remains unproven and controversial.

HHV-6 is a ubiquitous virus, and humans are the only known natural host. The mode of transmission of the virus is poorly understood but presumably requires direct, personal contact. Virus has been identified in saliva, peripheral blood mononuclear cells (PBMC), cervical and vaginal secretions, urine, and various tissues, including skin, lymph nodes, liver, spleen, heart, lungs, kidneys, and brain. HHV-6B, but not HHV-6A, actively replicates in the salivary glands of children and adults, making oral secretions the most likely source of transmission for this variant. Intrauterine or perinatal transmission has been suggested. Congenital infections with HHV-6 have been described to occur in 1% of births; infected infants are asymptomatic at birth, in contrast to the acute febrile illnesses observed with primary postnatal infection (14). In this study, variant A was responsible for one-third of the congenital infections, whereas variant B was observed in all postnatal infections. The incidence of antibody to HHV-6 is high throughout the world, although variation in seroprevalence based on age and the serologic method employed has been reported. Newborn infants have titers of antibody to HHV-6 that are comparable to those in adults, suggesting passive transfer of transplacental maternal antibodies. With the loss of maternal antibody, the seroprevalence to HHV-6 decreases significantly by 4 to 6 months of age but subsequently rises to 90% at the end of the first year of life. By 3 years of age, almost 100% of individuals have antibody to HHV-6; immunity is maintained throughout childhood, adolescence, and early adulthood but may decline after 40 years of age and then rise to high titers following increased rates of reactivation in elderly persons. With the exception of HHV-7, no significant serologic cross-reactivity between different herpesviruses and HHV-6 has been detected.

Immunology of HHV-6 Infection

The host response to HHV-6 infection is thought to involve both humoral and cell-mediated immunity. Children with exanthem subitum develop an immunoglobulin M (IgM) response on day 4 of illness, and the response peaks between 7 and 14 days and declines over a period of 1 to 2 months. In addition, IgM antibodies to HHV-6 can persist for extended periods after a primary infection and can reappear in reactivated infections. IgG appears on day 7 of illness, peaks at approximately 4 weeks, and persists for long periods.

The role of cell-mediated immunity in HHV-6 infections is less well defined. However, the virus appears to have the ability to modulate or alter the expression of a number of cytokines and immune activation molecules. Increased levels of alpha interferon (IFN-α) have been found during the febrile phase of exanthem subitum, while an increase in NK cell activity has been observed during the exanthem period. In vitro infection of PBMC with HHV-6 decreases the expression of interleukin 2 (IL-2) and cell proliferation, upregulates NK cell cytotoxicity, and induces the synthesis of the soluble cytokines IFN-γ, IL-1β, tumor necrosis factor alpha, and IL-15. The virus can downregulate CD3, CD46, and CXCR4 expression and upregulate the chemokine receptor CCR7 in infected T cells and can stimulate IL-10 and IL-12 expression in monocytes and macrophages. Also, HHV-6 infection of transformed T-cell lines in vitro results in an enhanced susceptibility to apoptosis. The significance of these immunomodulating properties to the interaction of infected T cells with other components of the immune system and to the pathogenesis of the virus is unclear. Macrophages are infected with HHV-6 following primary infection and may serve as a reservoir for reactivation of the virus.

Clinical Indications

Although a diagnosis of exanthem subitum in a child can be made on the basis of clinical presentation alone, laboratory confirmation is needed to detect atypical and more severe manifestations of HHV-6 infection and to more clearly define the role of HHV-6 in other childhood illnesses and in diseases of adults and immunocompromised persons.

Immunologic Diagnosis

Antigen Detection

Immunohistochemistry

Monoclonal antibodies suitable for the direct detection of HHV-6 antigens by immunofluorescence have been developed and employed with tissue samples (4). HHV-6 antigen has been demonstrated in biopsy material from allografts of kidney transplant patients, lung tissue from bone marrow transplant recipients with interstitial pneumonitis, cervical lymph nodes of patients with histiocytic necrotizing lymphadenitis and lymphoma, oligodendrocytes from patients with multiple sclerosis, abortive villous tissues from spontaneous abortions, patients with AIDS, and the salivary and bronchial glands of latently infected individuals. Productive infection of tissues with HHV-6 can be detecting by using monoclonal antibodies reactive against the structural protein p101 of variant B and the structural protein gp82 of variant A. Recently, an HHV-6 antigenemia assay similar to that described for detecting CMV has been developed to monitor active HHV-6 infection in liver and allogeneic stem cell transplant recipients (19, 34). This immunohistochemical method involves the cytocentrifugation of purified PBMC onto microscope slides followed by the detection of HHV-6-specific early and structural antigens by monoclonal antibodies and indirect immunoperoxidase staining. The significance of the results from immunohistochemical testing is still unclear, and the results must be further validated and correlated with clinical findings and data obtained from other laboratory tests.

EIA

A commercial antigen capture enzyme immunoassay (EIA) has been developed for the detection of HHV-6 antigens directly from clinical specimens (21). The assay is based on the gp116-gp64-gp54 antigen and is specific for HHV-6 variants A and B. The EIA has a sensitivity similar to that of viral culture from plasma obtained from children with exanthem subitum. Additional studies are needed to determine the utility of this EIA for rapid diagnosis of HHV-6 infection and for monitoring of HHV-6 activity in the immunocompromised host. The EIA has the advantages of being relatively simple and inexpensive to perform relative to culture or nucleic acid detection methods.

Viral Identification in Conventional Cell Culture

HHV-6 can be isolated from PBMC grown in primary culture or by cocultivation of these cells with stimulated cord blood cells (CBC) or donor PBMC (17). Saliva and other body fluids and tissues can be cocultured with activated donor cells for isolation of the virus as well. The optimal time for collection of specimens from children with roseola is during the febrile phase, before the development of rash. Infected PBMC show a specific cytopathic effect, with intracytoplasmic and intranuclear inclusion bodies appearing within 7 to 10 days. The cytopathic effect on primary isolation can be subtle and

difficult to recognize, and virus production from infected cells should be confirmed by detection of viral antigens, in situ hybridization, or electron microscopy. Viral antigens can be detected by indirect immunofluorescence assay (IFA), anticomplement immunofluorescence (ACIF), or EIA with commercially available reagents or kits. IFA staining reveals a characteristic granular nuclear and cytoplasmic fluorescence in infected cells. The sensitivity and specificity of immunologic reagents for confirmation of viral growth have not been extensively studied, and it is recommended that appropriate antigen and antibody controls be used when attempting to identify infected cells. HHV-6 infects a number of established continuous T-cell lines, most notably HSB-2, MOLT-3, Sup-T1, J-Jhan, MT-4, and ET62, which are used mainly to grow virus following primary isolation. The two variants can be differentiated in culture by their growth in different cell lines; variant B strains of HHV-6 do not replicate in HSB-2 cells, and variant A strains do not replicate in MOLT-3 cells. The described culture methods are slow and labor-intensive and require a high level of technical expertise. Their routine use in clinical laboratories is limited.

Spin Amplification Shell Vial Assay

The human diploid lung fibroblast line MRC-5 has been reported to support primary virus isolation and has been used in a centrifugation-assisted shell vial amplification assay for the detection of the immediate-early antigen of HHV-6 from PBMC of patients (29). Panspecific polyclonal and monoclonal antibodies to the immediate-early antigen of variants A and B of HHV-6 and monoclonal antibodies specific to either variant A or B are commercially available; they stain the nucleus of infected MRC-5 cells as early as 12 h after infection and give maximum staining within 48 to 72 h of infection. In the assay, PBMC are obtained from heparinized whole blood by Ficoll-Hypaque density gradient centrifugation, washed once with Hanks' balanced salt solution, and resuspended in 1 ml of RPMI 1640 medium supplemented with 10% fetal bovine serum, 20 mM HEPES, and 2 μg of Polybrene per ml. MRC-5 cells are grown to confluency on 12-mm-diameter round coverslips in 1-dram (3.7-ml) vials and inoculated with 0.5 ml of specimen to each of two vials. After inoculation, the vials are centrifuged at $800 \times g$ for 45 min at 25°C, and then 1.5 ml of RPMI 1640 medium is added as described above. The cultures are incubated at 37°C for 48 to 72 h, fixed in cold (−20°C) acetone for 10 min, and stained by IFA. Uninfected and HHV-6-infected monolayers are included as negative and positive controls, respectively. The monolayers are counterstained with Evans blue. Coverslips are scanned at magnifications of ×200 to ×250 with a fluorescence microscope, and specific staining is confirmed at ×400 to ×630. Staining of immediate-early antigen occurs in the nucleus of an infected fibroblast and appears as a speckled or an even matte green fluorescence. The spin amplification shell vial assay has the important features of being more rapid and less labor-intensive than conventional culture, but the sensitivity and specificity of this assay remain to be defined. This test is currently not offered as a routine service in most clinical virology laboratories.

In general, positive culture results are most useful to diagnose primary infection but can be difficult to interpret for immunocompromised hosts and during reactivation of the virus, when the presence of the virus may be unrelated to the clinical presentation.

Antibody Detection

A number of tests have been developed for the serodiagnosis of HHV-6 infection, of which IFA, ACIF, EIA, and the neutralization (NT) test have been most commonly employed (see references 4 and 17 for reviews). The method that is chosen depends on the volume of specimens, turnaround time, cost, equipment needs, ease of performance, reagent availability, and levels of assay sensitivity and specificity. Overall, variation in the rates of seropositivity for HHV-6 appears to be related to the assay systems and the need for standardization of methods and reagents. The use of different cutoff values and serum dilutions and the method of preparing antigen substrates for individual assays can have a marked effect on the percentage of serum specimens that are determined to be positive for antibody to HHV-6. Overall, higher rates of seropositivity are observed when either NT or EIA is used than when the less sensitive method of IFA is used.

Collection and Storage of Specimens

Serum is the specimen of choice for most serologic assays, although plasma can normally be used as well. A total of 1 to 2 ml of serum should be collected from clotted blood. The serum should be refrigerated at 4°C shortly after collection and during transport to the laboratory. If an extended delay in transport or testing of a specimen is anticipated, the specimen should be frozen to at least −20°C. Freeze-thawing of specimens that have been frozen should be avoided. A single serum specimen is required to determine the immune status of an individual or to detect IgM-specific antibody. Paired serum specimens, collected 2 to 3 weeks apart, are required for the diagnosis of a current or recent HHV-6 infection when specimens for IgG antibody are examined. The acute-phase serum should be obtained as soon as possible after the onset of illness. The most useful results are obtained by submitting acute- and convalescent-phase sera together to be tested simultaneously.

Methods

IFA

The IFA is the most widely used method for detecting antibodies to HHV-6. Initially, IFAs were found to be both insensitive and nonspecific, in part because of the use of infected CBC as a source of antigen but also because of variations in the criteria used for positive results. With the preparation of HHV-6 antigen in continuous T-cell lines, such as HSB-2, MOLT-4, and J-Jhan, and following improvements in the definition of seropositivity, IFAs have become increasingly more sensitive and reliable.

In the IFA, HHV-6-infected cells are spotted onto wells of Teflon-coated slides, allowed to air dry completely, and then fixed in cold (−20°C) acetone for 10 min. Fixed slides can be used immediately or stored at 4°C for short periods or at −20 to −70°C for extended times. Serial dilutions of patient and positive and negative control sera are added to individual wells, and the slides are incubated at 37°C for 30 min in a humidified chamber. The slides are then washed two or three times in phosphate-buffered saline (PBS), and an appropriate dilution of fluorescein-labeled anti-human IgG or IgM is added to each well. The slides are again incubated at 37°C for 30 min in a humidified chamber, washed two or three times in PBS, counterstained with Evans blue, and air dried. Coverslips are mounted in buffered glycerol (pH 8.0), and the slides are examined at magnifications of ×200 to ×400 under a fluorescence microscope. The presence of HHV-6 antibodies in the serum is determined by the observation of positive fluorescence within infected cells. Antigen substrate slides can be purchased commercially, and some manufacturers provide kits that contain all

the necessary reagents for staining, including diluted conjugated antibody, wash buffer, mounting fluid, control sera, and substrate slides. When testing for HHV-6-specific IgM antibodies, serum samples should be appropriately treated before the test, to decrease the incidence of false-positive results due to interfering rheumatoid factor or false-negative results caused by high levels of specific IgG antibodies blocking the binding of IgM to HHV-6 antigen.

ACIF

The ACIF test is an immunofluorescence assay that has been developed to reduce the nonspecific fluorescence observed when CBC are used in the IFA. It also has the added advantage of enhancing the fluorescent signal from positive cells. As with IFA, HHV-6-infected cells are spotted onto wells of Teflon-coated slides, allowed to air dry completely, and then fixed in cold (−20°C) acetone for 10 min. Sera are heat inactivated at 56°C for 30 min, and serial dilutions are added to individual wells. The slides are incubated at 37°C for 30 min in a humidified chamber and then washed two or three times in PBS. HHV-6-specific antibody bound to the infected cells is detected by incubating the slides with a source of complement at 37°C for 30 min in a humidified chamber, washing the slides in PBS, and then incubating the slides with fluorescein-conjugated anticomplement antibodies for a final 30 min at 37°C. The slides are washed, counterstained, air dried, mounted in buffered glycerol (pH 8.0), and examined at magnifications of ×200 to ×400 under a fluorescence microscope. The presence of nuclear and cytoplasmic fluorescence within infected cells indicates positivity for antibodies to HHV-6.

EIA

EIAs for the determination of HHV-6 antibodies have been developed. HHV-6-infected and uninfected HSB-2 cells are harvested by centrifugation and disrupted by one of several methods, such as sonication in glycine buffer (pH 9.5) for 30 s, solubilization in Tris-Triton X-100 buffer, or cycles of freezing and thawing. Polystyrene 96-well microtiter plates are then coated with optimal dilutions of antigen by overnight adsorption of the antigen at 4°C. Coated plates can be stored at −20°C for extended periods. Prior to use, the plates are washed three times in PBS–0.05% Tween 20 and the wells are blocked for 30 min with PBS containing 1% bovine serum albumin. Diluted patient serum and controls are added to antigen wells of infected and uninfected cells, and the plates are incubated for 1 h at 37°C. The plates are then washed three times with PBS-Tween 20, and bound antibody is detected by reaction with an enzyme-conjugated anti-human IgG or IgM antibody at 37°C for 1 h. After washing is performed as described above, a substrate is added, and the plates are incubated for 30 to 45 min at room temperature. Following color development, the reaction is stopped and the absorbance of each well is read with a spectrophotometer. The results are calculated by subtracting the absorbance in wells containing uninfected cell antigen from the absorbance in wells containing infected cell antigen. The main advantages of the EIA are that it is rapid and more sensitive than the IFA and the results can be evaluated in an objective manner. In addition, the EIA is applicable to large numbers of specimens, and the potential for automation is excellent. Kits that detect HHV-6 IgG and IgM antibodies are now commercially available, although the performance of these reagents has not been fully examined. A μ-capture EIA has recently been developed to enhance the specificity for the detection of HHV-6-specific IgM antibody in human sera (22).

NT Assay

Neutralizing antibodies to HHV-6 are determined in the NT assay by mixing serial twofold dilutions of patient sera in microtiter plates with an equal volume of cell-free virus containing $10^{2.5}$ 50% tissue culture infective doses per 0.1 ml. After 1 h of incubation at 37°C, 2×10^5 HSB-2 or MOLT-4 cells or CBC are added to each well, and the cultures are maintained for 7 days at 37°C. The antibody titer is determined as the reciprocal of the highest dilution of serum that completely prohibits the observation of viral cytopathic effect or the detection of antigen by IFA. The NT assay has a sensitivity and a specificity that are comparable to those of EIA, but the method is cumbersome, labor-intensive, and less suited to a routine diagnostic laboratory.

Antibody Avidity Assay

An indirect immunofluorescence antibody avidity test has been used to distinguish primary from past infections with HHV-6 (35). Since the binding of an antibody increases with time after exposure to an antigen, a primary antibody response to HHV-6 infection would be of much lower avidity than an antibody response that had occurred in the more distant past or following viral reactivation. By using urea to denature proteins in serum samples treated prior to performing the immunofluorescence assay, low-avidity antibody-antigen reactions are preferentially disrupted and differentiated from high-avidity antibody-antigen reactions. This test has been successfully used to diagnose primary HHV-6 infection in children with rashes and to distinguish primary from secondary antibody responses in solid-organ transplant recipients.

Other Serologic Tests

Western immunoblots and radioimmunoprecipitation are other serologic assays that are used to measure antibody to HHV-6. These assays have been used mainly to identify and analyze the role of specific proteins in the immune response to HHV-6.

Molecular Diagnosis

The diagnosis of HHV-6 infection is increasingly being made by the amplification of viral DNA by PCR. Many in-house and some commercial qualitative assays have been developed, and the sensitivity and specificity of PCR for diagnosis of active HHV-6 infection are being evaluated. Multiplex conventional and real-time PCR assays for the simultaneous detection and differentiation of HHV-6 variants A and B and HHV-7 also have been described (16, 25). Amplification has been performed with a number of different primer pairs, including those from the immediate-early antigen 1 and 2, large tegument protein (U31), DNA polymerase, U22, U65-U66, and U67 regions of the HHV-6 genome. PCR has been used successfully to detect HHV-6 DNA in a variety of clinical specimens from solid-organ and bone marrow transplant recipients; children with roseola, acute febrile illnesses, encephalitis, and other clinical manifestations of primary HHV-6 infection; AIDS patients; and individuals with less common forms of HHV-6 infection. However, qualitative PCR for HHV-6 diagnosis cannot reliably distinguish between active disease and asymptomatic infection or latency, and HHV-6 DNA can often be detected in saliva and, to a lesser extent, in blood of healthy individuals. Measuring the level of HHV-6 DNA appears to be necessary to predict and diagnose HHV-6 disease, particularly in immunocompromised individuals such as transplant recipients with illnesses that may be associated with reactivation

of the virus or that are possibly caused by another pathogen. Consequently, conventional (28) and real-time (13) quantitative PCR assays have been developed and used to monitor the levels of HHV-6 DNA in a variety of different body fluids and tissues of both healthy subjects and selected patient populations. Similar to the diagnostic paradigm for CMV, these assays may be useful to associate HHV-6 infection with disease, to predict and monitor disease progression, to assess the efficacy of antiviral drugs, and to facilitate our understanding of the natural history and pathogenesis of this virus. As with CMV, viremia is considered to be the best predictor of disease, and quantitative measures of HHV-6 DNA in PBMC, plasma, or serum have proven useful for the continued surveillance and management of transplant recipients. When testing transplant recipients, it is more important to monitor the relative changes in DNA levels from serial blood specimens collected over time, since absolute HHV-6 DNA levels or breakpoints for symptomatic disease have not been determined. It may also be important to monitor both plasma and PBMC fractions of blood, since it has been reported that both HHV-6 variants A and B are detected in plasma but only variant B can be found in PBMC of patients after bone marrow transplantation (23).

Reverse transcriptase PCR assays that qualitatively amplify specific HHV-6 mRNA transcripts that are expressed only during active infection have been used as a substitute for quantitative assays to assist in identifying patients at greatest risk for developing symptomatic infection (33). Alternatively, qualitative detection of HHV-6 in cell-free specimens such as serum or plasma can be diagnostically useful in supporting a causal relationship between active HHV-6 infection and disease (27).

Qualitative and Quantitative Real-Time TaqMan PCR

For the detection and quantitation of HHV-6 DNA by real-time TaqMan PCR in my laboratory, a total of 4 to 7 ml of EDTA-anticoagulated whole blood is collected. Leukocytes are isolated from 2.0 ml of whole blood using 6.0 ml of Puregene red blood cell lysis solution (Gentra Systems, Minneapolis, Minn.). The white blood cells are then pelleted by centrifugation for 2 min at $2,000 \times g$, washed once in 15 ml of PBS without Ca^{2+} or Mg^{2+}, and resuspended in 2.0 ml of PBS. The cells are counted using a hemocytometer, and the concentration of cells is adjusted to 2.0×10^6 cells/ml by dilution in PBS. The remainder of the whole blood is centrifuged at $500 \times g$ for 10 min to obtain plasma. Single-use aliquots of 250 μl of either cells or plasma are stored at $-70°C$.

The MagNA Pure LC instrument (Roche Diagnostics, Indianapolis, Ind.) and Total Nucleic Acid Isolation Kit (Roche Diagnostics) are used for the automated extraction and isolation of HHV-6 DNA from 200 μl of purified white blood cells or plasma. The samples are dissolved and simultaneously stabilized by incubation with a buffer containing denaturing agents and proteinase K. Nucleic acids released from the samples are bound to the surface of magnetic glass particles, and unbound substances are removed by several washes. The purified nucleic acids are then eluted in a low-salt buffer. Isolated total nucleic acids are diluted in a final volume of 66 μl of elution buffer and immediately processed for real-time PCR.

The primers used for the qualitative and quantitative HHV-6 DNA real-time PCR assays are from a portion of the HHV-6 DNA genome that carries the U65-U66 genes (13) and detect both variants; the generated DNA product is approximately 173 to 176 bp in length. To prepare standards for quantitative PCR, the 173- to 176-bp PCR product is produced using the High Fidelity PCR Master kit (Roche Applied Science, Indianapolis, Ind.) and is directly cloned into a pCRII-TOPO plasmid vector using the TOPO TA cloning kit (InVitrogen, Carlsbad, Calif.). The recombinant vector is then transformed into chemically competent cells of the DH5α-T1 strain of *Escherichia coli* using the rapid One Shot (InVitrogen) transformation procedure. Selected clones are amplified by overnight culture in LB broth containing 50 μg of ampicillin/ml and are then prescreened by PCR to confirm the size of the insert; the insert is also sequenced for verification. Plasmid DNA from the transformed clones is isolated in bulk using a Qiagen midi kit (Qiagen, Inc., Valencia, Calif.). The standards made from the plasmid are calibrated using a reference standard containing 1.4×10^{10} viral particles of HHV-6 strain U1102 variant A per ml (Advanced Biotechnologies, Inc., Columbia, Md.) as determined by electron microscopy. Serial 10-fold dilutions of this standard, ranging from 10^8 to 10^1 HHV-6 DNA copies per ml, are used to characterize the sensitivity, specificity, linearity, and precision of the quantitative assay. The standard curve is created automatically with software from an ABI Prism 7000 Sequence Detection System (Applied Biosystems, Foster City, Calif.) by plotting the threshold cycle (C_t) values against each standard of known concentration.

Both qualitative and quantitative HHV-6 DNA real-time PCR assays are performed in 50-μl volumes containing $1\times$ TaqMan Universal Master Mix (Applied Biosystems), 900 nM concentrations of forward and reverse primers, a 200 nM concentration of the fluorogenic probe labeled with FAM (6-carboxylfluorescein) at the 5′ end and TAMRA (tetramethylrhodamine) at the 3′ end, nuclease-free water with yeast tRNA (60 ng/ml; Roche Molecular Biochemicals, Indianapolis, Ind.), and 10 μl of islolated total nucleic acid. The mixtures are added to individual wells of 96-well reaction plates, and the plates are sealed with adhesive optical covers and then rotated on an orbital shaker for 30 s to thoroughly mix and remove air bubbles in the wells. The amplification and detection are completed using an ABI Prism 7000 Sequence Detection System. The thermal cycling parameters consist of 1 cycle for 2 min at 50°C, 1 cycle for 10 min at 95°C, and 45 two-step cycles of 15 s at 95°C and 60 s at 60°C. For the qualitative assay, one negative control (HHV-6-negative purified human white blood cells) and one positive control of HHV-6 strain Z-29 variant B at a concentration of 2×10^7 viral particles/ml (Advanced Biotechnologies, Inc.) are processed with each batch of clinical specimens from extraction of nucleic acids through the detection of amplified product. For the negative controls, cells are counted using a hemocytometer and the concentration of cells is adjusted to 2.0×10^6 cells/ml by dilution in PBS. Single-use aliquots of 250 μl of suspended material from each control are stored at $-70°C$. For the quantitative assay, the above controls are processed as well as a set of five standards ranging from 10^4 to 10^8 HHV-6 DNA copies/ml. Specimens and controls are tested singly for the qualitative assay and in triplicate when quantifying the amount of HHV-6 DNA. Specimens or controls are considered positive in the qualitative assay when the generated fluorescence signal at the C_t value exceeds a defined threshold limit. In the quantitative assay, the quantity of HHV-6 DNA in each specimen or control is determined from the generated standard curve. The quantitative real-time PCR can quantitate over a range of 140 to 140 million copies of HHV-6 DNA/ml at a 95% detection rate. Reliable results can be obtained

below 140 copies/ml, but the detection rate diminishes as the DNA input drops below this value. A human albumin gene primer and probe set is used in separate PCRs as an internal positive control to ensure that samples contain nucleic acid and to exclude the presence of inhibitors.

Interpretation of Results

The ubiquitous distribution of HHV-6 throughout the world complicates the interpretation of laboratory studies, and a combination of methods may be required to confirm the relationship of HHV-6 infection with various diseases. Also, most diagnostic methods for HHV-6 are in the early stages of development; the sensitivity and specificity of each assay have not been systematically evaluated in controlled, prospective studies, and reagents have only recently been made available to diagnostic laboratories through commercial sources.

Serologic testing is most useful for diagnosing primary infections with HHV-6 in children with acute illnesses and for studies of the epidemiology, clinical pathology, and natural history of the virus. For interpretation of serologic tests, a history of seroconversion from a negative to a positive IgG antibody response to HHV-6 between acute- and convalescent-phase sera or the presence of IgM in a single serum sample during a primary infection helps establish HHV-6 as the causative agent. If a serum sample from early in an illness contains HHV-6 antibodies and a fourfold or greater rise in titer is demonstrated in a second specimen taken several weeks later, a diagnosis of recent infection due to reactivation or reinfection can be made. If acute- and convalescent-phase sera are both positive for HHV-6 antibody but the antibody titer is unchanged, the result is interpreted as HHV-6 infection at some time in the past. Screening a single serum specimen for IgG antibody to HHV-6 can also provide evidence of previous exposure to the virus and assists in identifying individuals at risk for HHV-6 infection.

The use of serologic techniques to establish the presence of active HHV-6 infection can be problematic; the detection of HHV-6-specific IgG or IgM antibodies may not always indicate primary infection, and in the setting of reactivation or latent infection, conventional serologic studies have a limited value in establishing an association with disease. Increased titers of IgG to HHV-6 may occur during infections with other herpesviruses, such as CMV, EBV, or HHV-7, and the relative importance of each virus in producing disease may be difficult to determine. Variations in the detection of HHV-6-specific antibodies have been observed and may be related to the methods and reagents used. The use of insensitive assays may inappropriately indicate that HHV-6 infection has been excluded or that a positive seroconversion had occurred when, in fact, this may represent an inability to detect low levels of antibody during reactivation. Assays should also be extensively evaluated for specificity to detect potential cross-reactivity with other herpesviruses. Results of serologic tests for IgM antibody should be interpreted with caution; IgM antibody can appear in both primary and reactivated HHV-6 infections and can persist for extended periods after a primary infection. Also, some children may not develop detectable IgM responses during primary infection. A recognized technical problem with HHV-6 IgM assays is the occurrence of false-positive and false-negative reactions due to high levels of competing rheumatoid factor and HHV-6-specific IgG.

The appropriate selection of methods for the diagnosis and monitoring of HHV-6 disease is a challenge. The lack of well-defined, commercially available reagents and standardized methods and controls has made the interpretation of laboratory results more difficult. Whenever possible, serologic diagnoses of HHV-6 infection should be confirmed by virus isolation or suitable direct detection methods. To implicate HHV-6 as the cause of certain diseases, it may also be necessary to use methods that measure active virus replication, since the qualitative detection of virus or viral DNA may simply indicate the presence of the virus in a latent state. A more accurate assessment of the involvement of HHV-6 in a given disease may be provided by the detection of cell-free viral DNA in serum or plasma by PCR, by qualitative amplification of specific HHV-6 mRNA transcripts, by detection of viral antigen expression in tissues or PBMC by immunohistochemistry or in situ hybridization, or by quantitative assessment of the viral load by DNA PCR.

HHV-7

Introduction

HHV-7 was first isolated in 1989 from PBMC of a healthy individual (12). In contrast to HHV-6, little is known about the prevalence, biology, and pathogenesis of this virus. HHV-7 is morphologically identical to other herpesviruses but, like HHV-6, is characterized by having a tropism for CD4$^+$ T lymphocytes, by causing infection early in life, and by being ubiquitous, with a seroprevalence rate of more than 85% in U.S. and European populations (see reference 1 for a review). Lower rates of seropositivity in Japan have been reported. After primary infection, HHV-7 can persist in the host in a latent state and reactivation can occur. Primary infection in children is thought to occur somewhat later in life than primary infection by HHV-6, usually after 24 months of age and by 5 years of age, although higher rates of seropositivity have been reported at a younger age (6). Salivary glands appear to be a main site of viral replication for HHV-7, and transmission is likely to occur from contact with respiratory secretions. Seroconversion to HHV-7 antibody positivity is a separate and distinct event from production of antibody to HHV-6. The virus can be grown in PBMC or CBC and shows a characteristic cytopathic effect of large, refractile cells indistinguishable from the cytopathic effect of HHV-6. A single continuous T-cell line (Sup-T1) can support the growth of HHV-7 with variable success. The virus is closely related to HHV-6 but has been shown to be genetically and immunologically distinct. Unlike for HHV-6, genetic variants have not been described for HHV-7. The DNA of HHV-7 has no homology to that of EBV, herpes simplex virus, or varicella-zoster virus and has limited homology to that of CMV. Therefore, HHV-7 has been classified as a member of the betaherpesviruses with HHV-6 and CMV. Western immunoblot analyses of viral proteins reveal different patterns for HHV-6- and HHV-7-infected cells, although monoclonal antibodies to HHV-6 can cross-react with HHV-7-infected cells. Several viral proteins have been identified for HHV-7, ranging in size from 30 to 136 kDa. The virus is frequently and consistently isolated from the saliva of infected individuals and can be detected in specimens such as peripheral blood, cervical secretions, and cerebrospinal fluid.

The clinical spectrum of disease caused by HHV-7 is poorly understood. HHV-7 has been associated with up to 10% of roseola cases and, as with HHV-6, is thought to be responsible for seizures and other neurologic events in children (see reference 20 for a review). The virus also has been isolated from two patients with a chronic viral syndrome and

a child with a nonspecific febrile syndrome without rash. No viruses other than HHV-7 were isolated in these cases, and a seroconversion to HHV-7 but not HHV-6 positivity was documented. There is some evidence to suggest that HHV-7 also may play an etiologic role in pityriasis rosea. Little is known about disease caused by HHV-7 in immunocompromised patients, although reactivation of the virus in bone marrow and solid-organ transplant recipients is common (see reference 10 for a review). The glycoprotein CD4 is a critical component of the receptor on the surface of T lymphocytes for HHV-7; it has been shown that a selective and progressive downregulation of the expression of CD4 in HHV-7-infected T cells leads to a marked reciprocal interference of HIV infection. Infection of PBMC with HHV-7 enhances NK cell cytotoxicity by induction of IL-15. HHV-7 also may interact with other herpesviruses, leading to the reactivation of HHV-6 and CMV. Reactivation of HHV-7 has been reported to be a cofactor for the progression of CMV disease in renal transplant patients infected with CMV.

Immunologic and Molecular Diagnosis

The methods for laboratory diagnosis of HHV-7 are essentially identical to those for diagnosis of HHV-6 and currently include the direct examination of clinical specimens for viral antigens by immunohistochemistry (15) or viral nucleic acids by in situ hybridization and PCR (3, 28), virus identification in cell culture (12), and detection of antibodies against the virus (6). An HHV-7 antigenemia assay similar to that described above for HHV-6 has been developed for the detection of HHV-7 early and late antigens in PBMC isolated from recipients of liver and allogeneic stem cell transplants (19). The serodiagnosis of HHV-7 infection can be made by IFA, EIA, and Western immunoblot assays, using HHV-7-infected cells as an antigen source. Seroconversion to HHV-7 positivity, as determined by IFA, is independent of that to HHV-6 positivity and is diagnostic for primary infection. An antibody response to HHV-7 is induced only by HHV-7 infection, since neither seroconversion nor a significant rise in the titer of antibody to HHV-7 can be detected following primary infection with HHV-6. Conversely, seroconversion to HHV-7 positivity can cause a simultaneous rise in the titer of antibody to HHV-6. This is thought to be due to the ability of HHV-7 to induce a response of memory B cells against HHV-6 cross-reactive antigens or to be due to reactivation of HHV-6 during infection with HHV-7. HHV-6 antibodies are not protective against HHV-7 infection, since seroconversion to HHV-7 positivity can occur in the presence of high titers of antibody to HHV-6. The presence of antigenic cross-reactivity between HHV-6 and HHV-7 should be considered when performing serologic assays; it may be necessary to preadsorb patient sera to infected cells for specific determination of titers of antibody to each virus. An HHV-7 antibody avidity assay has recently been developed and validated and used in conjunction with the HHV-6 avidity test described above to detect and distinguish primary from past infections with either HHV-6 or HHV-7. In addition, dual primary HHV-6 and HHV-7 infections have been confirmed by using these assays.

Both conventional and real-time PCR assays have been described for the detection of HHV-7 DNA from clinical specimens. As with HHV-6, qualitative PCR assays are not able to differentiate active disease from asymptomatic infection or latency, and HHV-7 DNA is frequently found in saliva and PBMC of healthy individuals. To this end, PCR assays for quantitating HHV-7 DNA in infected individuals have been developed and are being evaluated for the ability

to correlate the viral load of HHV-7 with clinical disease and response to antiviral therapy, and to facilitate studies of the epidemiology of the virus (11, 28, 36).

The interpretation of laboratory results for HHV-7 is confounded by a paucity of commercially available reagents and, as with HHV-6, by the ubiquitous nature of this virus. In addition, caution is needed in interpreting the results of serologic studies because of the cross-reactivity of HHV-7 with HHV-6 and because of the ability of HHV-7 to reactivate other members of the herpesvirus family. With serologic evidence of dual infection, it may be difficult to determine the relative importance of each virus in causing disease. Virologic methods, including viral culture, rapid direct detection of antigens and/or nucleic acids, and serology, must be combined with a clinical assessment of the patient to provide a reliable determination of HHV-7 infection and to establish a clear relationship between infection and human disease. It may also be necessary to monitor viral load or other measures of active virus replication to help in our understanding of the natural history and pathogenesis of this virus.

HHV-8

Introduction

Using the molecular technique of representational difference analysis, HHV-8, also termed Kaposi's sarcoma (KS)-associated herpesvirus, was first identified by Chang et al. (5) in 1994 in more than 90% of KS tissues obtained from patients with AIDS. Subsequently, HHV-8 has been detected in patients with all forms of KS from all parts of the world, including AIDS-associated KS and classical KS in Mediterranean and Eastern European adults, HIV-1-negative African endemic KS of adults and children, and KS in persons with iatrogenic immunosuppression, most often organ transplant recipients (see references 2 and 26 for reviews). HHV-8 also has been detected in AIDS-related primary effusion lymphomas (formerly called body cavity-based lymphomas) and multicentric Castleman disease. In addition, HHV-8 has been implicated in the pathogenesis of other diseases, including multiple myeloma, sarcoidosis, angiosarcoma, non-KS skin lesions (including squamous and basal cell carcinomas) of immunocompromised patients, and multiple sclerosis. However, numerous follow-up studies using PCR-based and serologic assays have failed to corroborate the original findings, making it unlikely that HHV-8 is associated with these disorders. Little is known about primary HHV-8 infection in healthy individuals, and the diseases associated with this virus are thought to be more probably due to viral reactivation.

The biology, epidemiology, and pathogenesis of this virus are still not well understood (extensively reviewed in references 2 and 26). HHV-8 is classified as a gammaherpesvirus in the genus *Rhadinovirus* and has sequence homology to the simian virus herpesvirus saimiri and EBV. These viruses establish persistent, latent infection and are associated with immortalization and transformation of cells. The replicative form of the HHV-8 genome is approximately 165 kb in length, and 97 genes have been identified. Several genes have homology to human genes, such as those encoding cyclin D (a cell cycle inducer), various cytokines, and Bcl-2 (a blocker of apoptosis). Expression of these genes may help explain the association of HHV-8 with cell transformation and the development of tumors. Viral replication may be affected by interaction with other viruses such as HIV-1 and EBV, since body cavity lymphoma cells are frequently coinfected with EBV and tumors associated with HHV-8 are

often seen in persons infected with HIV-1. It also has been demonstrated that HIV-1 can increase HHV-8 replication in a body cavity lymphoma cell line. Genetic diversity exists among viral isolates of HHV-8, resulting in the identification of strains A, B, and C; strain A has been found mainly in patients with AIDS-associated or classical KS, while strains B and C are seen more often among African patients. The virus has a cell tropism for CD19$^+$ B lymphocytes, the flat endothelial cells lining vascular spaces, and the perivascular spindle cells of KS lesions. Its distribution is worldwide, although it is not ubiquitous in most populations and there is considerable variation in its prevalence, which is related to the geographic and demographic distribution of KS. The precise modes of transmission are unknown. Based on the epidemiology of HHV-8, however, it is thought to be transmitted through sexual contact, predominantly among homosexual and bisexual HIV-1-positive males or their sexual partners. Likely sources of infection for sexual transmission are semen and possibly female genital secretions; HHV-8 DNA has been found in the semen of male AIDS patients and cervicovaginal specimens from HHV-8-seropositive women. Although HHV-8 DNA has yet to be found in feces, sexual practices involving oral-anal contact may be a risk factor for homosexual transmission. HHV-8 also has been detected in oral secretions and PBMC of HIV-1-infected males and in the blood of an apparently healthy blood donor following multiple donations. Widespread horizontal transmission from oral secretions may be responsible for the high rate of HHV-8 infection in areas where KS is hyperendemic. However, the transmission of HHV-8 by blood or the respiratory route in populations at low risk for KS is likely to be uncommon. Transmission through organ transplantation has been documented and is of concern for this patient population.

Immunologic and Molecular Diagnosis

The laboratory diagnosis of HHV-8 infection is possible using molecular methods such as PCR or using serologic assays (see reference 32 for a review), although the clinical need for testing has not been defined. These methods have been used mainly to study the epidemiology of HHV-8 and to investigate the relationship between HHV-8 and the pathogenesis of various diseases. Assays are currently available only in research laboratories, and there are few commercial sources of reagents.

PCR is the primary method used for the direct detection of HHV-8 from tissues; body fluids such as serum, plasma, urine, saliva, bone marrow, and semen; and PBMC from infected individuals. The most widely used primers are those originally described by Chang et al. (5) and are specific for the highly conserved 233-bp region of the KS330Bam fragment (open reading frame [ORF] 26). Other useful primer sets have been evaluated and include those that amplify gene sequences of ORFs 8, 25, 37, 65, 72, 73, 75, K5, and K6. Quantitative conventional (8) and real-time (18, 31) PCR assays recently have been developed to measure the HHV-8 viral load in PBMC, plasma, or tissues of individuals with AIDS-associated KS, classical KS, AIDS-related primary effusion lymphomas, and multicentric Castleman disease and in organ transplant recipients. These assays may be useful to determine the exact mode(s) of transmission of the virus, to assist in the diagnosis of KS and other diseases associated with HHV-8 infection, to identify those individuals at highest risk of disease, to predict the progression to and development of KS, and to assess the efficacy of different therapeutic regimens. It has been shown that individuals with HHV-8-related diseases have more HHV-8 DNA in either plasma or PBMC than do persons without disease, but the level of HHV-8 DNA in plasma is significantly higher than that in PBMC. Quantitation of HHV-8 in plasma, therefore, may be more accurate for evaluating the risk of HHV-8 disease progression and the efficacy of therapy.

Attempts to culture HHV-8 have met with great difficulty, and current methods are labor-intensive and impractical for diagnostic use. Nevertheless, CD19$^+$ B cells, the human papillomavirus-transformed endothelial cell line BB19, and the adenovirus-transformed human kidney epithelial cell line 293 have been used to grow virus from KS spindle cells, fluids from body cavity lymphomas, and filtered cell culture fluids from CD19$^+$ cells positive for HHV-8. However, continual replication in these cell lines has not been successful. Monoclonal antibodies specific to HHV-8 have been described and are currently being used to localize HHV-8 in infected cells and tissue by immunocytochemistry and flow cytometry. These antibodies are not widely available for diagnostic use.

Serologic testing for HHV-8 can be done by a variety of formats, including IFA, EIA, and immunoblot assays. Similar to serologic tests for EBV, these assays have been designed to detect antibody responses to HHV-8-specific antigens expressed during latency or lytic infection. Antigens currently used in HHV-8 serologic assays include purified viral particles, whole cells, or isolated nuclei prepared from HHV-8-infected cell lines derived from body cavity-based lymphomas, whole-cell lysates, recombinant viral proteins, and synthetic peptides.

IFAs for measuring HHV-8-specific antibody responses from patient sera are usually done with HHV-8-infected whole cells fixed onto slides as the substrate. The cell lines BC-1 and HBL-6, which are latently infected with HHV-8 and coinfected with EBV, were originally used to develop some of the first IFAs for the detection of HHV-8 antibodies against nonstructural latent antigens of the virus, particularly the latency-associated nuclear antigen (LANA). Antibody cross-reactivity is of primary concern with assays that use cells infected with both HHV-8 and EBV; cell lines such as BCP-1 and BCBL-1, which are infected with HHV-8 alone, are now being used in most whole-cell IFAs to minimize cross-reactions with antibodies to other herpesviruses. For measurement of antibodies to lytic antigens by IFA, HHV-8-infected cell lines are treated with phorbol esters or sodium butyrate. This results in the chemical induction of a lytic cycle of viral replication and the expression of lytic antigens that usually correspond to structural viral proteins. When using IFA, the presence of stippled immunofluorescence in the nuclei of uninduced cells is representative of an antibody response to LANA, while antibodies against HHV-8 lytic antigens are measured by observing fluorescence as diffuse cytoplasmic staining, spots in the nucleus, or localized to the membrane of the induced cells. A monoclonal antibody-enhanced IFA (mIFA) has been described and uses a mouse monoclonal antibody and induced or uninduced BCBL-1 cells for detecting antibodies to latent and lytic HHV-8 antigens. Although IFAs can be used to detect a range of antibody responses to various latent and lytic proteins of HHV-8, the procedures are labor-intensive and subjective, requiring considerable experience and critical evaluation to ensure reliable results. Extensive quality control is also needed to monitor the appropriate expression of lytic antigens in induced cells and to prepare the substrate slides.

EIAs have been developed that use whole viral lysates as antigens for detecting HHV-8 antibodies. The whole-virus EIA is designed to detect IgG antibodies to nonstructural and most structural HHV-8 antigens; it uses a viral lysate

prepared from sucrose gradient-purified whole virions obtained from the cell line KS-1. More recently, recombinant proteins of the lytic viral capsid antigen from ORF 65 or peptides corresponding to a fragment of the minor capsid protein from ORF 26 have been used in the development of HHV-8 serologic EIAs.

Immunogenic latent (encoded by ORF 73 [LANA]) and lytic (encoded by ORFs 65, K8.1, K8.1A, and K8.1B) proteins have also been recombinantly expressed and used in immunoblot assays (37). Reactions to LANA on immunoblot assays are seen as a high-molecular-mass doublet of 226 and 234 kDa. The ORFs corresponding to K8.1 encode HHV-8-specific envelope glycoproteins of 35 to 40 kDa.

With most of the available serologic assays, HHV-8-specific antibodies have been detected in the majority of individuals with KS, AIDS-related primary effusion lymphomas, or multicentric Castleman disease. Among persons infected with HIV-1, the seroprevalence for HHV-8 is highest in HIV-1-infected homosexual males, indeterminate in intravenous drug users and persons infected through heterosexual contact, and lowest in hemophiliacs, women, and children. It also has been shown that seroconversion to HHV-8 positivity precedes the progression to KS and predicts the subsequent appearance of KS lesions in HIV-1-infected individuals. In the general population, the highest seroprevalence rates for HHV-8 are seen in sub-Saharan Africa and Mediterranean countries, while rates in northern European, North American, and southeast Asian countries are relatively low.

In several studies done to compare the various HHV-8 antibody assays (24, 30, 37), good assay correlation was obtained when testing sera from individuals with KS. The most significant discrepancies between assays were observed when determining the seroprevalence of HHV-8 in high-risk groups without KS or groups at minimal risk for HHV-8 infection, such as blood donors. While the different methods showed similar antibody trends within the various epidemiological and population groups, they did not always agree. Considerable variation in sensitivity and specificity was observed from one assay to another when testing individual serum specimens within defined panels of sera from different populations. This appears to be related to the choice of assays, the use of different serum dilutions and cutoff values, the selection and preparation of antigen(s) used, and the lack of standardized methods and reagents. In general, the mIFA using lytic antigens identifies the highest number of individuals with HHV-8-specific antibodies, while assays based on latent antigens or individual HHV-8 proteins and peptides are less sensitive. The specificity of the lytic mIFA has been questioned because this assay detects HHV-8 antibodies in a much higher percentage of healthy blood donors and the results have not been corroborated by other assays. However, it is still unknown whether the lytic mIFA is just more sensitive or truly detects cross-reactive antibodies. In general, nonspecific reactions have been found to occur when IFAs are performed with sera at dilutions of <1:40, particularly if the cells used as an antigen source were chemically induced. Dilutions as high as 1:100 or 1:160 have been recommended to avoid such reactions, but such dilutions also may lead to false-negative results. Single-antigen assays do not appear to detect all antibody responses to infection with HHV-8, but use of these tests has demonstrated that individuals may differ in their abilities to recognize different HHV-8 proteins and that different antibody profiles can develop during the course of HHV-8 infection (30). It is clear that no one assay is completely sensitive and specific, and that combinations of several assays or combination of several antigens in a single

assay may be required to accurately determine the seropositivity to HHV-8, particularly in the general population (30). Zhu et al. (37) have recently shown that IFA positivity with both latent and lytic antigens followed by confirmation with an immunoblot assay using a panel of latent and lytic immunogenic recombinant antigens provides a reliable, sensitive, and specific measure of HHV-8 antibodies.

Until serologic assays are extensively evaluated and better standardized, their utility for diagnosing HHV-8 infection and for determining the immune status of an individual is limited and the interpretation of results is difficult. As with HHV-6 and HHV-7, it may be necessary to correlate serologic results with direct antigen and/or nucleic acid detection and to quantify the HHV-8 viral load to reliably detect infection and to establish a clear relationship between infection and human disease.

Papillomaviruses and Polyomaviruses

KEERTI V. SHAH AND EUGENE O. MAJOR

75

Until recently, papillomaviruses and polyomaviruses were grouped together as papovaviruses, but they are now classified as two distinct families. The viruses of the two families are unrelated genetically and immunologically, and their genetic organizations and biology are quite dissimilar (12). Papillomaviruses infect only surface epithelia and are not transported to internal organs in the course of their infections. They are etiologically linked to a number of naturally occurring human and animal cancers. In contrast, polyomaviruses have a viremic phase during which they infect internal organs such as the kidneys and lymphoid cells.

PAPILLOMAVIRUSES

Papillomaviruses are widely distributed in nature and probably infect all higher vertebrates. They cannot be propagated in cell cultures. Therefore, rapid advances in our knowledge about papillomaviruses were possible only after molecular cloning became available in the 1970s. To date, over 100 human papillomaviruses (HPVs) have been characterized. Phylogenetic analyses of papillomaviruses reveal groupings that are consistent with the observed phenotypes, including species of origin, tissue tropism, and association with benign versus malignant lesions.

Papillomaviruses are nonenveloped viruses with a circular, covalently closed, double-stranded DNA genome of about 8,000 bp. All of the genomic information is carried on one strand. The genome is divided into an early region (E) that contains eight open reading frames (ORFs), a late region (L) that contains two ORFs, and a noncoding long control region in which the regulatory elements for viral DNA replication and transcription are located. The L1 and L2 genes code for, respectively, the major and minor capsid proteins of the virion. The E6 and E7 genes of high-risk HPV code for the transforming proteins that bind cellular tumor suppressor genes, p53 and Rb, respectively, and lead to dysregulation of the cell cycle and genetic instability. The E4 gene is expressed in the late stage of the virus cycle, even though it is located in the early region. The E1 gene is required for viral DNA replication, and the E2 gene modulates transcription of viral genes. No functions are known for the E3 and E8 ORFs.

HPVs are strictly epitheliotropic viruses that infect squamous epithelia of the skin and mucous membranes. Infection is initiated when the basal cells of the epithelium are exposed to infectious viral particles after minor trauma,

e.g., during sexual intercourse or after skin abrasions. The expression of viral genes is tightly linked to the stages of cellular differentiation. In the basal and parabasal cells of the epithelium, only the early viral genes are expressed and the viral DNA is replicated in low copy numbers. In the upper, more differentiated layers of the epithelium, all viral genes are expressed, leading to extensive replication of viral DNA and the production of infectious viral particles. The presence of infectious virus in the most superficial cells of the infected epithelium, which are shed constantly, facilitates transmission. The relative lack of cells of the immune system in the epithelium, the site for the entire life cycle of HPV, probably accounts for the low immune responses seen in HPV infections.

HPVs fall naturally into two groups, mucosal HPVs and cutaneous HPVs. The genital tract is the main reservoir for mucosal HPVs, but two mucosal HPVs (types 13 and 32) exclusively infect the oral cavity. The clinical conditions associated with HPV infections are listed in Table 1.

Mucosal HPV

About 40 HPV types infect the genital tract. Genital HPV types are the most common sexually transmitted pathogens. In sexually active U.S. women, HPV prevalence, as measured by detection of viral sequences by PCR, may exceed 30%. HPV prevalence reaches its peak in young adults and declines in older age groups. Less than 10% of the women with HPV DNA in the genital tract have abnormal cervical cytology. Infections last for 1 to 2 years, and most individuals clear their infections completely. Immunodeficient women, e.g., women infected with the human immunodeficiency virus (HIV), have a high prevalence of HPV infections and of cervical cytological abnormalities.

Cervical Cancer

About 500,000 cases of cervical cancer occur annually worldwide. A large majority of these cases occur in developing countries, where cervical cancer is the most frequent malignancy among women. Epidemiologically, cervical cancer has long been known as having all the risk factors of a sexually transmitted disease. Studies over the past two decades have established that sexually transmitted HPV infections are etiologically linked to cervical cancer (3, 30) and that they initiate the multistep process that leads to cervical cancer (13). Invasive cervical cancer is preceded by

TABLE 1 Major clinical associations of HPV infections

Disease	Main HPV types	Mode of transmission
Mucosal HPV		
Anogenital warts	6, 11	Sexual contact
Juvenile-onset respiratory papillomas	6, 11	Mother to child, at birth
Cervical cancer	16, 18, 31, 45, and others	Sexual contact
Vulvar, penile and anal cancer	16 and others	Sexual contact
Focal epithelial hyperplasia (oral cavity)	13, 32	Nonsexual contact
Oropharynx cancer	16 and others	Unclear
Cutaneous HPV		
Cutaneous warts	1 to 4, 10, and others	Nonsexual contact
EV	5, 8, and others	Nonsexual contact
Skin cancers	EV-associated types and novel HPV types	Transmission and pathogenesis not clear

low-grade and high-grade squamous intraepithelial lesions (SIL), which are precursors of cervical cancer. The time interval between low-grade SIL and invasive cancer may span several decades. HPVs are found in a large majority of SIL and of cervical cancers. HPV infection precedes cervical SIL in prospective studies of cytologically negative women (13). Some HPV types, e.g., HPV-16 and HPV-18, are preferentially associated with invasive cancer, whereas some, e.g., HPV-6 and HPV-11, are almost never found in invasive cancers. In a large international study, HPV-16, HPV-18, HPV-45, and HPV-31 accounted for, respectively, 50, 14, 8, and 5% of cases of invasive cervical cancers (3). The viral genome is integrated into tumor cell DNA in a majority of women with cervical cancer but is present as free copies in women who are cytologically normal.

Laboratory studies strongly support the epidemiologic evidence in favor of the HPV etiology of cervical cancer (13). In phylogenetic analyses, high-risk and low-risk HPVs cluster in separate branches. The genomic DNAs of HPV-16 and HPV-18 can immortalize human keratinocytes and can produce lesions resembling high-grade SIL in organotypic cultures of cervical epithelium, but the genomic DNAs of HPV-6 and HPV-11 cannot do so.

In the United States, tens of millions of HPV infections occur annually, resulting in about 13,000 new cases of invasive cervical cancer. Most of the HPV infections, including infections with high-risk HPVs, are resolved on their own. The cervical SIL that may result from HPV infections can be detected in Pap smear screening programs and treated effectively. A history of inadequate Pap smear screening is the strongest risk factor for cervical cancer in the United States. In countries where cervical cancer incidence is high and effective Pap smear screening programs are not available, sexual promiscuity of the male population often accounts for the high rates of cervical cancer.

The evidence linking HPV with cervical cancer is as persuasive as that for any other human carcinogen. HPV infections account for 100% of cervical cancers and provide a unique example of a major human cancer that has a single etiology.

Cancers at Other Genital and Nongenital Sites

The high-risk HPV types, especially HPV-16, are etiologically linked to at least a proportion of anal, vaginal, and vulvar cancers. Among nongenital sites, HPV infections are linked to cancers of the oropharynx, especially tonsillar cancer (7).

Anogenital Warts (Condylomata)

Condylomata are benign tumors and are the best-known and most common clinical manifestation of genital HPV infections. It is estimated that in the United States, several million cases of condylomata occur annually. Infections with HPV-6 and HPV-11, types that are almost never associated with invasive cancer, are responsible for 90% of anogenital warts. Condylomata are transmitted to about 70% of sexual partners and have an incubation period of 3 weeks to 8 months.

RRP

Genital tract HPV-6 and HPV-11 are also responsible for recurrent respiratory papillomatosis (RRP), which may have onset in early childhood (juvenile-onset RRP) or in adult life (adult-onset RRP). Juvenile-onset RRP is most often caused by transmission of HPV-6 and HPV-11 at birth, during fetal passage through an infected birth canal. Cesarean delivery offers some protection against juvenile-onset RRP. Most cases of juvenile-onset RRP occur in the first 2 years of life. Patients with adult-onset RRP acquire HPV infection after birth.

Although infection of the genital tract with HPV-6 and HPV-11 is not uncommon, RRP is a rare disease, an indication that virus transmission from mother to child is inefficient. In the United States, the annual number of new cases of RRP is estimated to be about 1,000. Vocal cords in the larynx are the most frequent site of RRP. The tumors, although they are benign, may cause life-threatening respiratory obstruction.

HPV in the Oral Cavity

Two HPV types, HPV-13 and HPV-32, produce focal epithelial hyperplasia, a benign oral condition found frequently in some indigenous populations but only rarely in other groups. These types are not recovered from the genital tract. Genital HPVs, especially HPV-6 and HPV-11, may also infect the oral cavity, probably as a result of oral sex.

Cutaneous HPVs

Skin Warts

Skin warts are most prevalent in school-age children and young adults. They are transmitted by direct contact with infected tissue or by contact with virus-contaminated objects. There is a correlation between the site and morphology of a wart and the infecting HPV type. HPV-1 is strongly correlated with plantar warts, HPV-2 is correlated with common warts, and HPV-3 and -10 are correlated with flat warts. Skin warts almost never undergo malignant change.

Epidermodysplasia Verruciformis

Epidermodysplasia verruciformis (EV) is a very rare disease in which an extensive, lifelong, wart virus infection of the skin is never resolved (14). The disease is often familial. Clinically the warts are flat or are in the form of reddish-brown macular plaques. The disease generally has onset in infancy or childhood, with multiple, disseminated, wart-like lesions on the face, trunk and extremities, which tend to become confluent. In about one-third of the cases, malignant transformation occurs in the reddish-brown plaques in areas exposed to sunlight.

The flat warts of EV patients often have the same HPV types (e.g., HPV-3 and HPV-10) that are found in the flat warts of individuals without EV. However, the EV patients also harbor about 20 additional types (HPV-5, HPV-8, and other EV-associated HPV types) that are recovered predominantly from the macular plaques. The skin cancers of EV patients provide a model in which specific viral types (especially HPV-5 and HPV-8), host factors (genetic immunological defect), and environmental factors (sunlight) act together in the genesis of the malignant lesions.

Skin Cancers

Knowledge about HPVs in the skin is changing rapidly (22). With the use of highly sensitive assays, DNA sequences of many HPV types are easily recovered from plucked hairs of completely normal skin. Up to 50% of normal skin samples from immunocompetent individuals and nearly 100% of normal skin samples from immunodeficient individuals yield HPV sequences. HPV DNA is acquired early in life. The amount of viral DNA in the tissue is estimated to be very low, about one copy per hundreds of cells. The prevalence of HPV DNA is somewhat higher in nonmelanoma skin cancers than in normal skin. Most of the sequences belong to HPV types in the subgenus of EV-associated HPVs. Cutaneous HPVs have a weak transforming activity. Whether cutaneous HPVs contribute to the development of nonmelanoma skin cancers is unclear.

Role of Immunologic Assays

Diagnosis of Infections

Immunologic testing has played a relatively small role in diagnosis of HPV infections, but serologic assays are valuable in epidemiologic studies. Viral diagnosis is routinely made by nucleic acid hybridization tests, and most of the information acquired to date on HPV biology has been obtained on the basis of detection of HPV genomic sequences in tissues. Type-specific reagents are not commercially available for HPVs. Several factors have combined to limit the role of immunologic tests in viral diagnosis. (i) Because the viruses cannot be grown in culture, it has been difficult to develop immunologic reagents. (ii) As the cervical disease progresses from low-grade SIL to invasive cancer, synthesis of viral capsid proteins and of infectious particles is completely shut down. Therefore, serologic reagents that detect the capsid L1 and L2 proteins are of little value for the diagnosis of HPV types in cancer tissues. (iii) Other proteins of interest, e.g., the transforming E6 and E7 proteins, are expressed in such small amounts in affected tissues that their detection is very cumbersome.

As described below, assays have been developed for detection of antibodies to L1 proteins and to E6 and E7 proteins.

VLP Serology

Large numbers of sera have been tested for antibodies to HPV-16 in enzyme-linked immunosorbent assay (ELISA) with use of virus-like particles (VLPs) as the antigen (see Methods). A detectable antibody response occurs in a proportion of individuals with documented infection (Fig. 1). Antibody titers in positive sera are low. Higher rates of HPV seropositivity are associated with (i) persistent infection, (ii) infections that have a high viral burden, (iii) infection with HPV-related pathology, and (iv) residence in areas of high HPV endemicity.

Serology for HPV-16 E6 and E7 Proteins

Antibodies to the E6 and E7 proteins are markers of HPV-associated invasive cervical cancer (Fig. 2). These antibodies can be detected by ELISA with E6 and E7 peptides, by Western blot assays with E6 and E7 fusion proteins, and by radioimmunoprecipitation assays with in vitro-transcribed and -translated full-length E6 and E7 proteins. In a case-control study of cervical cancer, serum antibodies to E6 or E7 protein were detected in 63% of cases and 10% of controls. Elevated levels of antibodies to the E6 or E7 protein were found in 41% of cases but in only 0.5% of controls. The antibody response may reflect the tumor burden in invasive cervical cancer.

Cell-Mediated Immunity

It is very probable that a cell-mediated immune response to HPV is required for clearance of infection and for control of disease. Conditions that depress cell-mediated immunity (e.g., HIV infection, organ transplantation) exacerbate HPV-associated diseases. However, reagents to assess any measure of cell-mediated immune response to HPV infections are not yet routinely available.

HPV Vaccines

Attempts to develop prophylactic vaccines against HPV infections, employing the major capsid protein L1 as an antigen, have been remarkably successful in clinical trials. The L1 protein, when expressed by recombinant DNA technology, has the intrinsic ability to assemble into VLPs which are conformationally identical to authentic virions (27). Immunization of humans by intramuscular injection with VLPs results in a robust antibody response, with antibody titers far exceeding those resulting from natural infections. In a recent study, a vaccine based on HPV-16 VLPs administered as three intramuscular injections was tested in a placebo-controlled proof-of-principle trial in young U.S. women (17). The vaccine was found to prevent 100% of incident persistent HPV-16 infections and HPV-16-associated cervical intraepithelial neoplasia. The vaccine was genotype specific and it did not prevent cervical pathology due to types other than HPV-16. Studies in progress are examining the effectiveness of the vaccine in men and in HIV-infected individuals and are attempting to formulate vaccines that can be employed more easily in the developing world.

Methods

Detection of Viral Capsid Antigen

All HPV types have common antigenic determinants, some of which are located internal to the virion surface. Immunization of rabbits with detergent-disrupted virus capsids of an HPV, or of an animal papillomavirus, results in a broadly cross-reactive

antiserum that can detect capsid antigens of any HPV in infected tissues. An antiserum prepared by immunization of rabbits with disrupted bovine papillomavirus capsids, and capable of detecting HPV capsid proteins, is commercially available (DAKO Corp., Carpinteria, Calif.).

The antigen can be detected by indirect fluorescent-antibody tests on frozen tissues or by an immunoperoxidase test on paraffin sections of formalin-fixed tissues. The specific staining is confined to the nuclei of infected epithelial cells. In positive tissues, the staining is most marked in the superficial layers of the epithelium, where viral capsids are synthesized. The proportion of cells in an infected tissue that contains the capsid antigen is highly variable; for example, capsid antigen is readily detected in plantar warts but may be present in only a very few cells in respiratory papillomas. Tissues that display viral cytopathic effect (koilocytosis) are likely to be capsid antigen positive, but the antigen is not detected in all koilocytotic cells in a tissue.

A positive test indicates productive infection with any of the HPVs. The infecting HPV type cannot be specifically diagnosed by the test because type-specific antisera are not available. A negative test does not imply that the lesion is not HPV associated. The test would be negative for capsid antigen in HPV-associated high-grade SIL and invasive cancers because viral particles are not synthesized in these lesions.

ELISA To Detect Antibody Response to HPV Infections

A serum antibody response to HPV infections can be detected with the use of antigens that maintain the conformational epitopes of native virions. HPV capsid proteins (L1) expressed in baculovirus or vaccinia virus have served satisfactorily as antigens. VLPs have been prepared for nearly all the medically important HPVs. This ELISA is not commercially available.

Conclusion

Although few immunologic tests for HPV are commercially available for use in clinical laboratories, this situation may change. Development of HPV-based vaccines against cervical cancer is a major goal of current research. Therefore, it is anticipated that standardized tests to measure HPV immune response will become available.

POLYOMAVIRUSES

Polyomaviruses consist of a double-stranded, circular DNA genome surrounded by a nonenveloped, icosahedral capsid that is approximately 45 nm in diameter, approximately 10 nm smaller than the papillomaviruses. The genomic organization of the polyomaviruses differs significantly from that of the papillomaviruses. This disparity, along with differences in biology, prompted the establishment of polyomaviruses into a separate family, *Polyomaviridae*. The genomic organization among the different polyomavirus family members is remarkably similar. The genome, which is approximately 5,000 bp, is functionally divided into an early region (2.4 kb), which is transcribed prior to DNA replication, and a late region (2.3 kb). Clockwise transcription from the origin of replication on one DNA strand yields the large, middle, and small T proteins for the mouse polyomavirus and the large and small T proteins for the primate polyomavirus. These early genes are necessary for subsequent transcription of the late region, which occurs in a counterclockwise direction and on the opposite strand of DNA. This late region codes for the structural proteins and the agnoprotein, which has been implicated in intracellular trafficking of viral proteins. In addition, there is a small noncoding region (0.4 kb) that contains the regulatory elements

for viral replication and transcription. Structural differences in the regulatory region of the human polyomavirus JC virus (JCV) can be used as a basis for subtype classification. Furthermore, differences in transcription factor binding in this region have been strongly implicated in the regulation of the host range of these particular viruses (15, 19).

The polyomaviruses are broadly distributed in nature, with hosts including humans, rodents, birds, and rhesus macaques (Table 2). In humans, JCV is the etiologic agent for the fatal demyelinating disease progressive multifocal leukoencephalopathy (PML), while BK virus (BKV) infection is associated with urinary tract infections and nephropathy. Within the normal, healthy human population, JCV and BKV appear to circulate independently, with a vast majority of individuals exhibiting antibodies to these viruses. Initial infection and seroconversion appear to occur early in childhood and in the absence of any clinical symptoms. In the United States, approximately 50% of children develop antibodies to BKV by 3 years of age and antibodies to JCV by 12 to 14 years of age. Although the initial route of infection is unknown, it is likely that entry is via a commonly accessible route such as respiratory inhalation. The virus is then trafficked to the internal organs by viremia, where it can remain in a latent state. Both JCV and BKV are excreted in the urine during acute infections as well as after reactivation, which suggests that at least one site of latency is in kidney tissue. During periods of severe immune deficiency, reactivation of the virus eventually leads to pathology and clinical symptoms of the associated diseases. In the case of PML, it has been hypothesized that virus travels across the blood-brain barrier via circulating B lymphocytes (11), implicating lymphatic tissues as a site of latency as well.

Disease Associations

Progressive Multifocal Leukoencephalopathy

PML is the only demyelinating disease of the human central nervous system (CNS) for which the etiologic agent is a well-characterized virus, JCV. It was initially described in 1958 as a set of clinical symptoms and pathology in two patients with chronic lymphocytic leukemia (1), but it was not until 1971 that viral particles were isolated from the brain of a patient with non-Hodgkin's lymphoma who had died from PML (21). Early diagnosed cases were very few and were seen usually in conjunction with lymphoproliferative disorders. Presentation of clinical symptoms occurred later in life, in the fifth or sixth decade. However, since then, the disease has become much more common in association with HIV-1 infection and a rapidly growing population of immunosuppressed individuals. Although transplant recipients with acquired immunedeficiencies also comprise a small but significant percentage of PML patients, the number of PML cases with HIV-1 infection as the underlying immunosuppressive disorder is far greater than the combined total number of PML cases in all other patients. It has been estimated that 0.72% of all patients with AIDS have PML and that up to 5% will eventually develop the disease (2). PML is also an AIDS-defining illness in HIV-1-seropositive individuals, accounting for 1% of all diagnosed AIDS cases.

The clinical symptoms of PML have continued to evolve, particularly with the advent of highly active antiretroviral therapy in AIDS patients. Potent antiretroviral drugs have effectively reduced plasma HIV viral loads and increased CD4 cell counts, which could potentially lead to a decreased susceptibility to opportunistic infections such as PML. Studies have shown that in PML patients treated with highly active antiretroviral therapy, the course of PML may halt or go into remission in 50% of patients, with prolonged survival (5). The early signs of PML are sometimes difficult to diagnose, since they can present in a wide variety of neurological disturbances consistent with subcortical white matter involvement. Motor weakness, visual disturbances, and cognitive impairments are the three most common initial manifestations of PML, and they have been described as the classic "triad" of presenting symptoms (18). Diagnosis of PML currently tends to rely on a combination of radiographic findings and clinical history. The demonstration of viral particles or DNA from lesions within the brain had been the definitive evidence for PML but has now been replaced by JCV DNA levels in the cerebrospinal fluid (CSF).

TABLE 2 Polyomaviruses

Virus	Host species	Disease in natural host
BKV	Human	Acute hemorrhagic cystitis; acute respiratory tract disease; ureteral stenosis; nephropathy
JCV	Human	PML
SV40	Rhesus monkey	Natural infection of macaques; interstitial pneumonia; renal tubular necrosis; PML-like lesions in immuno-compromised macaques
African green monkey polyomavirus (AGMPyV)	African green monkey	Natural infection; multiplies in B lymphoblasts
Baboon polyomavirus 2 (BPyV)	Baboon	Natural infection
Simian virus 12 (SV12)	Baboon	Natural infection; may persist in kidneys
Mouse polyomavirus (MPyV)	Mouse	Natural infection of wild mice; persists in kidneys; tumorigenesis
Murine pneumotropic virus (MPtV)	Mouse	Natural infection of mice; infects lung endothelium
Hamster polyomavirus (HaPV)	Hamster	Subcutaneous tumorigenesis
Rabbit kidney vacuolating virus (RKV)	Rabbit	Natural infection of cottontail rabbits
Budgerigar fledgling disease virus (BFDV-1)	Parakeet	Highly infectious; multisystemic disease
Goose hemorrhagic polyomavirus (GHPV)	Goose	Hemorrhagic nephritis and enteritis
Bovine polyomavirus (BPyV)	Cattle	Natural infection of cattle; persists in kidneys

Infection appears to propagate by cell-to-cell contact, since viral particles are concentrated in cells at the periphery of the lesion. Furthermore, infected cells are often found near blood vessels in the brain, a finding that supports the theory of viral entry into the CNS via a hematogenous route, such as infected B lymphocytes (5). Within the lesioned area, lytically infected oligodendrocytes and reactive, enlarged astrocytes can be found, as well as macrophages that help to clear cellular debris. Neurons and axons are largely spared, since the virus rarely infects cells of neuronal lineage. However, there have been isolated reports of viral particles in cerebellar granule cells (6). Although the lytic infection of oligodendrocytes is the main event leading to the pathology of PML, it has been demonstrated that astrocytes and, more recently, human CNS progenitor cells in culture are also susceptible to JCV infection (19). The latter finding is of particular interest in regard to the pathogenesis of this disease. Since progenitor cells are responsible for repopulating various cell types in the brain, infection of this population of cells, as demonstrated in cell culture, could not only interfere with normal recovery after injury but also serve as a potential reservoir for virus during periods of latency.

Urinary Tract Diseases

The human polyomavirus BKV was first isolated in 1971 from the urine of a renal transplant recipient. Both of the human polyomaviruses, JCV and BKV, are excreted in the urine of healthy and immunocompromised individuals. Interestingly, there can also be an increased incidence of viruria in pregnant women, which may be indicative of the paradoxical immune suppression experienced by the body during pregnancy. Occasional cases of cystitis in healthy children have also been reported and have been associated with primary BKV infection. In both adult and pediatric patients with acquired immune deficiencies during the course of organ transplants, there is a particularly high risk of BKV reactivation and productive infection in the cells of the tubular epithelium, which could ultimately lead to allograft rejection. The incidence is indeed high enough to necessitate management of polyomavirus infections in transplant recipients, as well as potential screening of organ donors. Particularly in recent years, there has been a rapid increase in reported complications due to polyomavirus infections in renal and bone marrow transplant recipients. Because BKV remains latent in the kidneys, organ transplantation from seropositive donors to seronegative recipients may lead to BKV nephropathy in the setting of immunosuppressive regimens.

The hallmark of BKV nephropathy following transplantation has been considered to be the presence of "decoy" cells in the urine, which are infected cells with visible viral inclusion bodies that have been shed from the epithelium (9). However, urine analysis is best used as a screening process, since the definitive histologic signs of BKV nephropathy include viral inclusions or DNA in renal tubular cells and glomerular epithelial cells, as well as enlarged, irregular nuclei. Inflammatory infiltrates may be involved in persisting nephropathy, a condition that has been termed interstitial nephritis. End-stage disease is marked by fibrosis and tubular necrosis.

Human Malignancies

Much attention has been focused recently on the potential association between polyomavirus infection and the development of tumors in humans. Polyomaviruses are oncogenic in laboratory animals and can transform human cell lines. Indeed, "T" in simian virus 40 (SV40) large T was so named due to its transforming capability. During the period from 1955 through early 1963, millions of people worldwide were inadvertently exposed to SV40 via contaminated polio vaccines prepared using primary rhesus monkey cells. The accidental introduction of SV40 to humans and the demonstrated oncogenicity in human cells raised concerns about long-term effects of SV40 exposure (4). Similarly, DNA sequences from the human polyomaviruses JCV and BKV have been found in a variety of tumors, including those of the CNS (23). However, a recently completed study of the presence of JCV, BKV, and SV40 viral nucleotide sequences in a large sampling of human brain tumors did not reveal any association (25). As yet, a direct causal relationship has not yet been established (24), and the significance of these observations with respect to etiology remains mainly descriptive and unclear in relevance.

Detection of Viral Antigens

Immunostaining

Viral antigens can be identified in infected cells or tissues by use of antibody-based assays such as indirect immunofluorescence or immunoperoxidase staining. In the past, antisera made by immunizing rabbits with disrupted viral capsids and cross-reactive to JCV, BKV, and other polyomaviruses were utilized. However, there are now more specific polyclonal and monoclonal antibodies in existence that can identify either early or late proteins of specific polyomaviruses. In paraffin-embedded tissue or biopsy specimens, viral protein staining is usually confined to the nucleus.

ELISA of Urine Supernatants

JCV or BKV viral particles in urine specimens can be detected efficiently by a standard antigen capture ELISA protocol. Hyperimmune rabbit serum is used to coat the wells of microtiter plates as capture antibody. Urine supernatants are then added to the wells. Human sera having high titers to BKV or JCV are used as the detector antibody, and signal generation is obtained with an alkaline phosphatase-conjugated anti-human immunoglobulin G linked to an appropriate substrate. In this manner, relatively low levels of viruria can be rapidly detected to screen for potential reactivation in transplant recipients. However, PCR techniques have largely replaced ELISAs for the detection of viral nucleotide sequences in the urine and are increasingly directed toward the determination of viral copy numbers.

Hemagglutination Assay

The human polyomaviruses have the ability to agglutinate human type O erythrocytes (20). The antigen responsible for the hemagglutinating activity is located on the Vp1 capsid protein. Serial dilutions of samples are typically made in a microtiter plate in Alsever's solution, after which purified human type O erythrocytes are added to the wells. After a 6- to 12-h incubation at 4°C, an approximate virus titer in hemagglutination units can be read as the reciprocal of the highest dilution of sample that results in hemagglutination.

Detection of Viral DNA Sequences

In Situ DNA Hybridization

A definitive diagnosis of PML requires the demonstration of JCV virions or DNA in biopsy specimens taken from lesions in the brain or the presence of JCV DNA in the CSF. The

most specific and reliable assay for detecting replicating viral DNA is in situ DNA hybridization using a JCV-specific, biotinylated DNA probe (10). After overnight hybridization, the probe is detected using a streptavidin-biotin-horseradish peroxidase signal-generating system and diaminobenzidine. If viral DNA is present, the nuclei stain light to dark brown. Unlike immunofluorescent staining, which uses cross-reactive antibodies, in situ DNA hybridization can be performed using very specific probes that can selectively identify JCV, BKV, or SV40. Furthermore, since the sensitivity of this assay is in the range of approximately 100 genome copies, a positive result is indicative of replicating viral DNA and active infection.

PCR Analysis

Polyomavirus DNA sequences can be detected from a number of tissues and fluids by PCR, which makes it a very powerful tool in helping to diagnose infection and pathogenesis of associated diseases. Specific primers can be designed to selectively amplify viral DNA from each of the polyomaviruses. Of more recent interest is the concept of quantifying viral copy numbers from CSF as a potential marker for disease progression in PML patients. Similarly, rising BKV copy numbers in the urine could be an indicator of reactivation in transplant recipients. To this end, real-time quantitative PCR protocols have been established for the human polyomaviruses by using serial dilutions of plasmid containing whole viral genomes to generate the standard curve (26). This technique is very sensitive and efficient and can detect down to one viral copy with reproducibility. In terms of clinical use, the presence of polyomavirus DNA sequences in CSF or urine provides support for a differential diagnosis.

Serology

Hemagglutination Inhibition Assay

To determine antibody titers against the human polyomaviruses, a hemagglutination inhibition assay can be performed using viral antigen to coat the wells of microtiter plates and then adding serial dilutions of human serum. Human type O erythrocytes are then used for hemagglutination. An antibody titer can be read as the reciprocal of the highest dilution that inhibits hemagglutination. Polyomavirus VLPs have been developed by self-assembly of purified Vp1 proteins. For assay purposes, VLPs have replaced the use of infected-cell culture supernatants as the source of antigen (29). Hemagglutination inhibition assays were heavily employed in the past in early serological studies to examine the worldwide distribution of these viruses.

ELISA

A more rapid and reproducible measurement of antibody titers is obtained by ELISA (8). Just as in hemagglutination inhibition, the polyomavirus VLP of interest is used to coat microtiter plate wells and serial dilutions of sera are layered on top. Labeled anti-human secondary antibodies are added to detect the antipolyomavirus antibodies bound to the antigen. Colorimetric detection and readings at specified wavelengths are then used to determine end-point dilutions. Alternatively, readings can be compared to a standard curve. Using either BKV or JCV VLPs, it has been demonstrated that antibodies against these viruses are very specific and do not cross-react. Furthermore, titers to JCV and BKV generally demonstrate a reciprocal relationship, indicating that individuals most probably experienced independent infections by the two viruses.

Conclusion

Immunologic assays are generally not helpful in diagnosing disease, since seroconversion occurs very early in life and persists throughout adulthood. High antibody titers to JCV have not been associated with an increased incidence of PML, although there is some evidence that a link may exist between BKV antibody titers in renal transplant donors and recipients and the risk for allograft rejection. Furthermore, serological data do not show a correlation of JCV and BKV antibody titers with an increased incidence of tumor formation in humans. Diagnostic testing at present relies heavily on DNA-based technologies such as in situ DNA hybridization and quantitative PCR.

Adenoviruses

LETA K. CRAWFORD-MIKSZA

76

The accidental discovery in 1953 of "spontaneous" cytopathic degeneration in cell cultures of human adenoid tissue led to the discovery of a new family of viruses. The original name proposed for this phenomenon was "adenoid degeneration agent" (36). Observation of this type of cytopathology in cell cultures inoculated with specimens from a number of clinical syndromes quickly followed, leading to the designation adenoidal-pharyngeal-conjunctival agents in 1954 (25), replaced by the less cumbersome adenovirus (Ad) within 2 years. Since then, it has become clear that Ads are ubiquitous microorganisms, isolated from every mammalian, marsupial, bird, and reptile species that has been studied, yet they are host specific, even among primates. They share a nonenveloped, icosahedral capsid structure and a linear double-stranded DNA genome of approximately 36 kbp. There are three capsid proteins on the surface of the virus. The icosahedral faces are covered with 240 hexon capsomers, each composed of a trimer of the hexon protein. The 12 vertex capsomers are composed of the penton base, containing five copies of the penton protein, and the protruding fiber attachment complex with one or two fibers, each carrying a trimer of the fiber protein (49). Ads are classified into serotypes with immunological reagents that delineate (i) type-specific neutralization, defined by epitopes on the hexon protein, and (ii) type-specific hemagglutination-inhibition (HI), defined by epitopes on the fiber attachment protein (46). To date, the human adenoviruses (HAds) number 51 serotypes that are subdivided into six species (A through F) on the basis of fiber protein characteristics, DNA homology, and biological properties (15, 23, 40). Among adults, transmission occurs by respiratory droplet, but among young children fecal-oral spread predominates. Even in overt respiratory disease, HAds are shed in stools in greater numbers for a longer period than from the respiratory tract, and asymptomatic persistent shedding of virus for weeks to months is common (17).

Within the viral genome, the hexon capsid protein contains regions with both the greatest degree of conservation and the highest degree of mutability. The hexon protein elicits two types of immunological response in HAd infection. Type-specific neutralizing antibody is directed against epitopes on the exposed surfaces of the hexon that are unique to each serotype (12), and nonneutralizing, broadly cross-reactive antibody that is directed against conserved genus-specific regions of this protein is shared by all known HAds.

Early studies showed that neutralizing antibody appeared within 2 weeks of primary infection, at relatively low titers of 8 to 80, and then declined to undetectable levels over a 2-year period if reexposure did not occur (25). Seroprevalence of any given serotype therefore depends on the levels of that virus circulating in the community. Seroprevalence of endemic serotypes associated with respiratory infections, such as HAd type 2 (HAd2) and HAd7a, has been found in 25 to 100% of the populations studied, consistent with continuous reexposure, while antibodies to the serotypes involved in sporadic outbreaks of keratoconjunctivitis were found in 0 to 6% (44). The presence of neutralizing antibody does not affect persistence or protect against subsequent colonization with the same serotype but does protect against development of clinical disease (17). The level of nonneutralizing cross-reactive antibody also rises and declines within the same time frame, but there is a low-level anamnestic boost with each subsequent HAd infection (20). The levels of nonspecific indicators of inflammation, C-reactive protein and interleukin-6, are also substantially elevated during HAd infection (3, 26).

Apart from their role as human pathogens, there is currently enormous interest in the development of Ads as vectors for both gene delivery and chemotherapeutic agents. The majority of these are recombinant, engineered, replication-deficient variants of HAd5. This intense focus on Ad biology has resulted in a large and detailed body of information on the interactions between virus and host cell that may soon have therapeutic applications for clinical infections.

Laboratory diagnosis of HAd infections can be accomplished by three standard approaches. The first approach, isolation of the agent in cell culture followed by confirmation with a group-specific immunofluorescent reagent, is the usual method employed in most clinical settings. With the exception of the enteric serotypes HAd40 and -41, HAds are regarded as relatively easy to culture in several human heteroploid cell lines derived from carcinomas of the respiratory tract (HEp-2, A549, or KB). Diploid lung fibroblasts, used by most clinical virology laboratories for culture of cytomegalovirus and herpes simplex viruses, are also sensitive to most HAds but may be slower to display typical cytopathology. Serotype identification can be accomplished with neutralization tests in cell culture employing standardized immune serum pools, type-specific antisera, or molecular

techniques. Although culture of an agent from a specimen collected from the site of pathology may constitute the definitive diagnosis, it may require 1 to 2 weeks, even with the improvements of shell vial culture and monoclonal antibodies for detection.

The second approach, using rapid methods of detection involving direct detection of viral antigens or nucleic acid in clinical materials, has improved the speed of diagnosis. Since the number and efficacies of antiviral chemotherapeutics are increasing, this is of direct benefit to the patient. At present, the only readily available methods of diagnosing gastroenteritis caused by HAd40 or -41 are direct detection of viral antigens in stool specimens by antigen capture, latex agglutination, or electron microscopy.

The third approach to diagnosis is through serologic tests. Serologic tests for HAd infections detect anti-HAd immunoglobulin M (IgM) in an acute-phase specimen and measure rises in group- or type-specific antibodies in paired serum specimens. Detection of IgM is now one of the earliest laboratory indicators of infection, often preceding culture results. Serologic diagnosis is particularly important when viral culture is delayed or not available and for confirmation of an etiologic relationship when a virus is isolated from a peripheral site. Virus isolation, identification, and antigen detection methods are discussed elsewhere (43). This chapter concentrates on serologic methods for diagnosis of HAd infections and recent advances in molecular detection of viral nucleic acid.

The most widely used methods for measuring HAd cross-reactive, genus-specific antibodies of both the IgG and the IgM classes are enzyme immunoassay (EIA) and indirect immunofluorescence (IIF) assay (also called indirect fluorescent-antibody assay). Complement fixation (CF), once used extensively, is the most standardized serologic test for diagnosis of HAd infection. However, by comparison with EIA and IIF, CF is cumbersome and much less sensitive, and its use is now limited to reference laboratories that still maintain CF capability for antigens for which there is no other suitable method. The EIA and IIF methods appear to have equivalent sensitivities, so the choice of one versus the other is more a matter of convenience, depending on the format and equipment being used for other serologies in the laboratory and personnel expertise. Laboratories may elect to use one method routinely and use the other as confirmation for problem specimens that are difficult to interpret, for example, when antinuclear antibody, rheumatoid factor, or other nonspecific reactions are present.

For some cases, in which an HAd is isolated from a peripheral site not directly involved in pathology, it is desirable to confirm an etiologic relationship by documenting a rise in the titer of type-specific neutralizing antibody between acute- and convalescent-phase specimens with that isolate. This can be accomplished by serum neutralization (SN) or HI tests. SN tests are also used extensively in serosurveys for the presence of neutralizing antibody to a specific serotype in defined populations, such as military recruits tested for serostatus to HAd4 and HAd7a (30), or to quantify preexisting antibody in those who are candidates to receive an adenoviral vector as a chemotherapeutic or gene transfer agent.

Specimen requirements for HAd serodiagnosis are standard: collection of whole blood that is allowed to clot and then separated. Care must be taken to collect the acute-phase specimen in the first few days of illness in order to detect the presence of IgM and avoid the anamnestic rise in group-specific antibody. Convalescent-phase specimens can be collected within 2 to 4 weeks after onset.

CLINICAL FEATURES

HAds are associated with a broad spectrum of clinical pathology (Table 1). Severity of infection may vary from asymptomatic subclinical infection to fulminant disseminated disease, but the individual contributions of viral virulence factors and host factors to pathogenesis are, as yet, poorly understood. In recent years, HAds have emerged as significant pathogens in fatal outbreaks in Malaysia, the United States, Israel, Japan, Korea, and Argentina, which may reflect an increase in the pathogenic potential of the strains involved (9, 48). While there are at least 51 human serotypes, the majority of clinical disease manifestations involve approximately one-fourth of them.

TABLE 1 Illnesses commonly associated with HAd infections

Disease(s)	Population at risk	Associated serotype(s)[a]
Acute febrile pharyngitis	Infants, young children	1, 2, 3, 5, 6, 7, and 7a
Pharyngoconjunctival fever	School-age children	3, 7, and 14
ARD	Military recruits, residential communities	4, 7, and 7a (3, 11, and 21)[b]
Pertussis-like syndrome	Infants, young children	5
Pneumonia	Any age group	1, 2, 3, 4, 5, 7, 7a, and 21
Epidemic keratoconjunctivitis	Any age group	8, 19, and 37 (3)
Acute hemorrhagic cystitis	Infants, young children, immunocompromised individuals	11 and 21 (7)
Gastroenteritis	Infants, young children	40 and 41
Intussusception	Infants, young children	Species C
Meningitis, encephalitis	Infants, young children	3, 5, 6, 7, 7a, and 12
Myocarditis, pericarditis	Infants, young children	1, 2, 3, 7, 7a, and 21
Disseminated disease, multiple organ involvement	Immunocompromised individuals	All, including many species D

[a]We have included the serotype designations for HAd7 and -7a. Early serology (36a) and recent genetic evidence (14) indicate that they are distinct strains, but most of the literature does not distinguish between them. Available sequence data for HAd7 genotypes determined by restriction enzyme profiles as 7b and 7d denote that they are of the 7a serotype (14).

[b]Serotypes in parentheses are less frequently associated with the syndrome.

Respiratory Diseases

The greatest numbers of clinical HAd infections involve the respiratory tract. It has been estimated that HAd infections account for 7% of all respiratory disease in children, including pneumonia, pneumonitis, bronchiolitis, croup, pharyngitis, bronchitis, and upper respiratory infections (8). HAds are responsible for serious and sometimes fatal outbreaks of acute respiratory disease (ARD) in closed residential communities, such as military barracks, orphanages, summer camps, chronic care facilities, and schools (10). Historically, epidemics of ARD in military personnel were the most significant cause of morbidity, hospitalizations, and work-time loss in new recruits and trainees until introduction of vaccines for HAd4 and HAd7a in the early 1970s. In 1996, the manufacturer of the vaccines discontinued production, and stocks of the vaccines were exhausted in 1998. Multiple military training centers have since experienced large outbreaks of HAd-induced ARD, and many more outbreaks are anticipated before a new vaccine can be produced and approved (19). Progression of HAd respiratory infections to pneumonia occurs in both adults and children and can be fatal even among immunocompetent individuals.

Diseases of the Eye

HAds are the etiologic agent of 20% of acute conjunctivitis in children (18) and 5% of epithelial keratitis in adults and children (11). Species D serotypes HAd8, -19, and -37 are well documented in numerous outbreaks of epidemic keratoconjunctivitis in adults and children in both community and institutional settings, including nosocomial infections in ophthalmology clinics.

Gastroenteritis

HAds account for 3 to 10% of pediatric gastroenteritis worldwide (6). The enteric HAds, HAd40 and HAd41, account for the majority of outbreaks, but many other serotypes have been associated with sporadic cases in children and adults, as well as gastrointestinal symptoms concomitant with respiratory disease.

Myocarditis and Pericarditis

A growing number of reports have linked HAds and acute myocarditis, with and without pericarditis, in infants and young children (31); sudden infant death associated with myocarditis (41); and idiopathic left ventricular dysfunction in adults (32). For the most part, diagnosis has been made by inference from throat or rectal cultures because isolation from heart tissue has not been productive. The difficulty in establishing a causal relationship through peripheral site culture has been resolved by the recent molecular characterization of HAds directly from heart tissue.

Infections in Immunocompromised Individuals

The rapid expansion of transplantation procedures and the longer survival times of persons with AIDS have contributed to an increasing population whose immune systems have been compromised by disease, chemotherapy, or genetics and who are particularly susceptible to viruses that establish latent and persistent infections. A wide range of pathology involving almost every organ system has been associated with HAd infection in this population, including fulminant hepatitis, encephalitis, cystitis, nephritis, and renal failure. HAds account for approximately 10% of the chronic diarrhea and colitis that are among the earliest manifestations of human immunodeficiency virus (HIV) infection (27). Since the introduction of effective chemotherapeutics for herpesviruses,

HAds have emerged as one of the most significant causes of fatal infections in organ and bone marrow transplant patients, particularly allogeneic bone marrow and stem cell transplant recipients (27). HAd infection is also a significant risk factor for decreased survival time in persons with AIDS (37). This has led to recognition of the need for rapid and quantitative molecular assays to monitor adenoviral load during antiviral therapy, similar to those used for HIV (21, 22, 28).

In addition to the major disease syndromes, HAds have been linked to sporadic cases of more unusual presentations, including toxic shock-like syndrome, meningoencephalitis with and without flaccid paralysis, Reye's syndrome, venereal disease, hemorrhagic fever-like syndrome, and intussusception and mesenteric lymphadenopathy in young children. As with myocarditis, molecular detection of an HAd genome in the affected organs is moving us closer to establishing an etiologic relationship.

HAd serology is rarely requested alone but is usually requested as part of the differential diagnosis for the syndromes listed above. A respiratory agent battery may include HAd, influenza viruses A and B, *Mycoplasma pneumoniae*, respiratory syncytial virus, and *Chlamydia pneumoniae*. HAd serology may also be included in panels for conjunctivitis, gastroenteritis, meningitis, childhood rashes, myocarditis, and lymphadenopathy.

TEST PROCEDURES

EIA

EIA is now one of the most automated tests in the clinical laboratory and, for the most part, uses the 96-well microplate format, automated plate washers, and readers that define experimental parameters and interpret results. It is adaptable to any number of antigens, with a variety of anti-immunoglobulin enzyme conjugates and substrates. A recent innovation is the use of single-row microwell strips, or modules, that obviate the need for a whole 96-well plate, conserving antigen, reagents, and operator time. The availability of commercially prepared HAd antigen for EIA is currently unpredictable, but antigen can be prepared in-house if there are cell culture facilities.

EIA for both IgG and IgM detects genus-specific cross-reactive antibody so that, theoretically, any serotype may be used as an antigen. It is common practice to use one of the low-numbered endemic serotypes that grow to high titers in any of the cell cultures described above, i.e., HAd2, -3, -4, -5, or -7a. Flasks of cells that have just reached confluence are changed to maintenance medium of 98% Eagle's minimal essential medium in Hanks' balanced salt solution with 2% fetal bovine serum. A virus inoculum that induces a 4+ cytopathic effect in 3 to 5 days is used. Cells and fluids are harvested, subjected to three freeze-thaw cycles, and clarified of cell debris by centrifugation at $1,000 \times g$ for 10 min at 4°C. Whole virus is recovered by ultracentrifugation of the supernatant at $40,000 \times g$ for 4 h. The virus pellet is resuspended and disrupted in a small amount of solubilizing alkaline buffer (pH 9.0) containing 10 mM Tris, 0.14 M NaCl, 4 mM EDTA, 0.1% sodium desoxycholate, and 0.1% NP-40. Viral lysate is titrated and then diluted in 5 mM phosphate-buffered saline (PBS) (pH 7.2 to 7.4), usually diluted 1:50 to 1:200. This working dilution of antigen is used to coat 96-well plates or strip wells by evaporation to dryness at 37°C. Plates and strips specifically treated for antigen absorption are commercially available. Stored in airtight plastic bags with desiccant at 4°C, this antigen is stable for 1 year.

Uninfected cell cultures are treated exactly the same for use as negative cell controls.

The commercial conjugates for EIA that are currently available are anti-human immunoglobulins labeled with one of two types of enzyme, either horseradish peroxidase or alkaline phosphatase. The choices of substrate, stop solution, and detection wavelength are determined by the enzyme used. Substrate and stop solutions are commercially available as well. For horseradish peroxidase, the substrate may be o-phenylenediamine or tetramethylbenzidene with hydrogen peroxide, the reaction may be stopped with acid (1 N HCl or 2 M phosphoric acid), and the results may be read at A_{492} or A_{450}, respectively. For alkaline phosphatase, the substrate is usually p-nitrophenyl phosphate for EIA applications, the reaction is stopped with alkaline solutions (50 mM trisodium phosphate, pH 12.6), and the results are read at A_{405}. The optimal dilution of conjugate should be determined in each laboratory according to the manufacturer's guidelines.

Specimens to be tested for IgM are first treated with a commercially available anti-human IgG according to the manufacturer's recommendations. The wash buffer is 5 mM PBS (pH 7.2 to 7.4) with 0.05% Tween 20. The diluent for both sera and conjugates is wash buffer with 1% casein blocking agent. Sodium azide (0.01%) may be added to the wash and diluent buffers as a preservative. Plates or strip wells are removed from 4°C storage and washed three times, drained, and blotted. Serial dilutions of test sera, beginning at 1:200, are added to antigen and control wells, and the plates are incubated at 37°C for 1 h in a moist chamber or sealed. After the plates are washed five times, drained, and blotted, diluted anti-IgG or -IgM conjugates are added and the plates are incubated at 37°C for 1 h. The plates are washed five times, substrate is added, and the plates are incubated for 15 to 30 min. Stop solution is added, and the plates are read in an automated plate reader at the required wavelength. Each EIA run should contain negative cell controls, reagent controls, and positive-control sera. The optical density of the substrate solution alone should be <0.6 U, and for other negative controls it should be <1.0 U.

IIF

IIF detects genus-specific, cross-reactive anti-HAd antibodies of both the IgG and the IgM classes, depending on the conjugates used. It provides a good alternative to EIA when relatively few samples are being tested or when results are needed as quickly as possible. It does require a good-quality epifluorescence microscope and experienced laboratory personnel. Antigen slides with HAd grown in cell culture, normal cell controls, anti-human immunoglobulins conjugated with fluorescein isothiocyanate with counterstain, and control sera are currently available commercially from several sources. Optimal working dilutions of conjugates must be determined with each new lot according to the manufacturer's guidelines. It is also possible to prepare antigen slides in-house, if desired. Preprinted glass slides with 8, 10, or 12 wells are used. As in the case of EIA, the choice of HAd serotype is not critical, and the same viruses and cells listed above may be used. Cell culture flasks are infected with an inoculum that produces cytopathic effect in 50 to 75% of the cells (2+ to 3+) in 2 to 3 days. Uninfected cell cultures are maintained at the same time. Infected and uninfected cells are harvested by gentle trypsinization and resuspended in a small volume of PBS. Uninfected cells are pooled with infected cells at a 1:2 ratio so that an optimal 25 to 30% of cells will stain with control sera. Uninfected cells are used to make cell control spots on the same or separate glass slides. Infected and uninfected cell suspensions are dotted onto printed slides, allowed to air dry, and fixed in cold fresh acetone for 10 min. Stored at −70°C, they are stable for >1 year. Each new lot of antigen must be validated with the conjugates for sensitivity and specificity.

Specimens tested for anti-HAd IgM are absorbed with anti-IgG as described above. Test sera are diluted fourfold in PBS (pH 7.2 to 7.4), beginning at 1:8 for IgG determinations and 1:10 for absorbed sera for IgM determinations. A 1:8 or 1:10 dilution of each test serum is added to a negative control well, and PBS alone is added to infected and uninfected wells as a conjugate control. Slides are incubated in a moist chamber at 35 to 37°C for 20 min. Sera are decanted, and the slides are washed in fresh PBS for 5 min. Working dilution of conjugate is added, and the slides are incubated and washed as described above and then allowed to air dry. A preservative mounting medium of 10% polyvinyl alcohol (crystalline, type II)–20% glycerol in 50 mM Tris buffer (pH 8.5) is applied, and a coverslip is applied. The slides are examined for the degree and location of fluorescence. HAd antigen is located primarily in the nucleus, where viral replication takes place, but also may be seen in the cytoplasm. The degree of fluorescence is calibrated as for any other immunofluorescent procedure, from 1+ to 4+, with 1+ as the cutoff for positivity. When paired sera are tested and the rise in titer is greater than fourfold, no further testing is required. However, if endpoints fall relatively close together, the test may need to be repeated with serial twofold dilutions bracketing the endpoints.

SN

Rarely, a type-specific immune response must be determined, and SN is the test of choice. Several microplate formats that facilitate the use of multichannel pipettors, plate washers, and even automated plate readers have been described (13, 24). In a clinical setting, the virus used is usually the patient isolate or stock virus culture of the serotype of interest. There are a few species D serotypes that do not grow to high enough titers to be tested in a microplate format and require testing in a tube format, but they are not often encountered. A colorimetric microneutralization procedure using a spectrophotometer capable of reading an A_{550} is the simplest and most automated of the microtiter formats (13). The tube format is described elsewhere (43).

HI

HAds are able to hemagglutinate several types of mammalian erythrocytes in vitro. They were originally grouped by their hemagglutination properties, which are based on fiber protein characteristics (Table 2). The immune response to HAd infection includes type-specific antibody directed against the fiber protein, which inhibits hemagglutination. HI was originally used to serotype an HAd isolate with standardized antisera and was evaluated as a diagnostic test for serologic diagnosis of HAd infection. Its utility as a diagnostic test is limited by the requirements for the patient's own virus isolate, fresh sources of rat and rhesus erythrocytes, and pretreatment of test sera to remove nonspecific inhibitors of hemagglutination. While it is still the means to characterize the fiber protein for new and untypeable HAd strains, even this has been complicated by the increasing emergence of naturally occurring recombinant HAd strains that express the hexon protein of one serotype and fiber protein of another. A description of the test is given in a previous edition of this manual (15a).

TABLE 2 Ad serotypes grouped into species by hemagglutination and DNA homology

Species	Serotype(s)	Hemagglutination pattern
A	12, 18, and 31	Rat, incomplete[a]
B	B1 (3, 7, 7a, 16, 21, and 50) and B2 (11, 14, 34, and 35)	Rhesus, complete
C	1, 2, 5, and 6	Rat, incomplete[a]
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, and 51	Rat, complete
E	4	Rat, incomplete[a]
F	40 and 41	Rat, incomplete[a]

[a]Requires the presence of 1% heterotypic antiserum in diluent for complete agglutination.

MOLECULAR TECHNIQUES FOR DIAGNOSIS

Detection of viral nucleic acid in clinical materials is the most rapidly expanding diagnostic methodology in medicine, overtaking culture as the "gold standard" for diagnosis of infectious disease. Several different strategies have been developed for both target and signal amplification and incorporated into commercially prepared kits and detection systems for a variety of microorganisms. Of these, PCR amplification of viral nucleic acid has demonstrated the greatest versatility and applicability. The obvious advantages of PCR include speed and increased sensitivity in situations in which virus isolation is unproductive or impossible. Outcome studies have documented the clinical and financial advantages of rapid diagnosis (5, 35). The disadvantages include the lack of a viable isolate to characterize biologically, the limited information available from conserved regions when consensus primers are used, and the problems associated with PCR contamination. Despite these difficulties, PCR is the most thoroughly studied and most widely used amplification tool today. The refinements of real-time PCR, multiplexing, and nested protocols have only increased its utility.

PCR

Nucleic Acid Extraction

Nucleic acid extraction is the limiting step in all amplification protocols. In a clinical setting, the identity of the microbial agent of infection is rarely known prior to testing, so that DNA and RNA viruses, as well as bacteria, yeasts, and parasites, may be part of the differential diagnosis. For this reason, we recommend an extraction procedure that isolates total nucleic acid, so that both PCR and reverse transcriptase-mediated PCR may be performed from the same extract. The all-purpose extraction method of Boom et al. (7), in which guanidinium isothiocyanate (GuSCN) is used with silica adsorbent, has been used successfully for bacteria and RNA and DNA viruses. Briefly, 100 μl of body fluids or 100 mg of tissue is dissolved for 20 min in 0.9 ml of lysis buffer (5 M GuSCN in 50 mM Tris-HCl [pH 6.4]–20 mM EDTA–1.5% [vol/vol] Triton X-100), with disposable microtube pestles used for homogenization if necessary. Large fragments of debris are removed by centrifugation. Powdered silica is added to adsorb nucleic acid, which is then washed sequentially in wash buffer (lysis buffer without EDTA or Triton X-100), 70% ethanol, and acetone to dry, and finally eluted in 100 μl of RNase-free 10 mM Tris (pH 7.5).

Automated nucleic acid extraction machines, using this or other chemistry, are available from several vendors, as are numerous commercially available cartridges, columns, and reagents, which work well with some clinical specimens but not others, especially tissue.

Formalin-fixed, paraffin-embedded tissues present different but not insurmountable extraction problems. Several protocols have been described elsewhere (1, 45). Again, we recommend a procedure that extracts total nucleic acid for the reasons given above. In our laboratory, we have adapted a method for extraction that provides total nucleic acid using phenol-chloroform-isoamyl alcohol at pH 8.0 (42).

Amplification

A number of PCR protocols have been devised for HAd amplification, and many target conserved genes in one of two ways. Conservation among Ads is a relative term: while protein sequence may be conserved in a given region, DNA sequence may be extremely degenerate, and therefore the primers used must contain some level of degeneracy. The hexon gene carries regions of maximum protein conservation, and several assays target short sequences within these regions with degenerate consensus primers (4). The drawback is that the serotype or genotype cannot be deduced from these amplicons, merely the presence or absence of HAd. Other assays target regions of type specificity with type-specific primers when a limited number of serotypes are suspected, as in gastroenteritis outbreaks or ARD in military recruits (14). Real-time PCR assays use this approach because real-time assays cannot tolerate degeneracy in primers or probes (16). The drawback of this approach is the limitation in detectable serotypes, which is not optimal for community-acquired infections or infections in the immunocompromised. More recently, nested PCR protocols that increase the sensitivity of detection as well as increase the size of the amplicon so that further characterization is possible by restriction fragment length polymorphism analysis or sequencing have been described (2, 29, 38, 39). Our laboratory and others now routinely use a nested protocol to amplify six of the type-specific hypervariable regions of the hexon protein so that serotype identification is possible by sequencing (2, 39). Others use multiplex formats to determine species, if not serotype (33, 47). Appropriate controls are critical for PCR. As in all laboratory tests, there is an element of risk for cross-contamination of specimens and reagents, but this appears to be even greater with molecular biology-based techniques. There should be sufficient negative controls to rule out PCR contamination and internal controls to assess the quality of nucleic acid present.

The choice of any given format for a laboratory depends on a number of considerations, particularly the patient population to which it will be applied. Military hospitals do not have the same needs as a tertiary-care teaching hospital with a large transplant population. Logistics within the laboratory itself, in terms of equipment, trained personnel, and cost-benefit analysis, play an equally important role.

INTERPRETATION

The classical fourfold or greater rise in titer of either group- or type-specific antibody between acute-phase and convalescent-phase specimens is considered diagnostic of HAd infections. The difficulty with this is that after 2 to 4 weeks postonset the clinical relevance may be lost. There are also difficulties in documenting a fourfold rise when the acute-phase specimen is not collected early enough. The increased sensitivity of EIA and IIF for the detection of genus-specific antibody,

compared with that of CF, usually means that there is some level of antibody in the population due to constant exposure to endemic serotypes. The heterotypic anamnestic rise that occurs early in infection may obscure a fourfold rise in titer of antibody to the infecting serotype when the acute-phase specimen is not collected in the first few days.

The presence or absence of IgM may be determined in the acute phase and therefore be more clinically relevant. IgM determinations by EIA or IIF are well standardized procedures for a number of infectious agents. However, the clinical significance of IgM in HAd infection has not been well studied. Most of the serologic surveys that defined the immunological response to HAd infection predate our ability to distinguish the IgM component. This is certainly a subject that requires further study.

However, serologic tests for HAd infections are only one part of the total laboratory diagnostic workup that may include culture and antigen or nucleic acid detection. Each of these approaches confirms and validates the others, and diagnosis is rarely made by just one approach. A recent comparison of six methods for ARD diagnosis showed that traditional viral culture, PCR, and serology had almost equivalent sensitivities but that each of these three methods detected a slightly different segment of the cohort (34). It is therefore desirable to augment serologic diagnosis with one or more additional approaches.

The significance of a PCR result, i.e., the presence or absence of the viral genome in a given specimen, should be interpreted in the same way that a positive or negative culture result is interpreted. HAds are capable of persistent and latent infection, and various factors must be taken into account, including the site from which the specimen is taken (peripheral versus site of pathology), the timing and integrity of specimen collection, the sensitivity of the assay employed, and consistency with clinical presentation. The possibility of PCR contamination must also be evaluated. As with interpretation of serological test results, it is better to have the corroboration of additional methods of diagnosis if possible.

Parvovirus B19

STANLEY J. NAIDES

<div style="text-align:center">77</div>

Autonomous parvoviruses capable of helper virus-independent replication have been isolated from many animal species. Human parvovirus-like particles were first isolated from stools of a patient with enteritis, but their classification remains controversial. The human serum parvovirus B19 was accidentally discovered in 1975 in healthy donor blood used in the development of hepatitis B virus surface antigen diagnostic tests. To date, three genotypes have been described: types 1 (B19), 2 (A6/K71), and 3 (V9). Genotype-specific disease variation has not been reported (8, 19). Clinical disease was historically attributed to B19 before recognition of the A6/K71 and V9 genotypes. The most frequent clinical presentation of B19 infection is erythema infectiosum, or fifth disease, a common childhood exanthem. Application of sensitive molecular biological and immunological methods to viral diagnosis has allowed recognition of the ever-expanding spectrum of clinical presentation (28).

BIOLOGICAL, CLINICAL, AND EPIDEMIOLOGICAL FEATURES

Physicobiochemical Characteristics

B19 and its variants are members of the *Erythrovirus* genus, subfamily *Parvovirinae*, family *Parvoviridae*; the genus contains members of the family that infect mammalian hosts and are autonomous in their ability to replicate in host erythroid precursors. Parvovirus B19 is the smallest (18 to 26 nm in diameter) DNA virus known to infect humans. It forms nonenveloped icosahedral virions. The single-stranded genome contains approximately 5,600 nucleotides (37). B19 encapsidates a single copy of genome. Progeny virus populations are represented by equal numbers of virions containing positive- or negative-sense DNA.

B19 employs a simple coding strategy. A single strong promoter at map unit 6 initiates transcription for both a left-handed nonstructural protein region and a right-handed structural protein region (5). The nonstructural protein, NS1, is approximately 74,000 Da and is encoded between nucleotides 435 and 2448. NS1 is a helicase that provides the "nickase" activity for reduction of replicative DNA forms to progeny virus DNA that can be packaged into the virion and may also play a role in the assembly of viral DNA into mature capsids during viral replication. Recently, studies have shown that NS1 causes apoptosis in its erythroid precursor cell target as well as in nonpermissive cells, e.g., hepatocytes (26, 36).

Both structural proteins, VP1 and VP2, are encoded in the same open reading frame by nucleotides at positions 2444 to 4786 and 3125 to 4786 and are 84,000 and 58,000 Da, respectively. VP2 transcription is initiated at an alternate start site at nucleotide 3125 (6).

Pathogenesis and Pathology

Experiments on healthy volunteers provided a detailed picture of the natural history of B19 infection in the normal host. When B19 viremic plasma was inoculated into the nostrils of previously seronegative individuals, B19 was first detected in recipient serum by day 6 postinoculation. Viremia lasted up to 7 days, with the peak occurring on days 8 and 9 postinoculation. During this period, B19 DNA appeared in nasal and oropharyngeal secretions but virus was not detected in urine or stool. Approximately 11 days postinoculation, high-titer anti-B19 immunoglobulin M (IgM) antibody developed, followed by the appearance of anti-B19 IgG antibody. Volunteers with a significant level of preexistent anti-B19 antibody did not show any evidence of viremia or anti-B19 IgM response. During the viremic phase, some of the subjects had a flu-like illness with malaise, myalgia, and transient fever. Coincident with the onset of viremia, reticulocytosis was absent and remained so for up to 10 days. Viremia was cleared with the onset of the anti-B19 IgM antibody response, which was associated with the second phase of clinical illness, characterized by rash, arthralgia, and arthritis (2). The cell receptors for B19 were reported to be neutral glycosphingolipids, including globoside, which are widely distributed in various cell types (12, 13). $\alpha_5\beta_1$-Integrins may serve as coreceptors (43).

During natural infection, the incubation period may vary from 6 to 18 days, with a maximum of 28 days. By the time most patients present, usually with rash, polyarthralgia, and/or polyarthritis, an anti-B19 IgM response has begun and the patients are not infectious. An exception is the patient with aplastic crisis, who typically presents during the viremic phase. Usually, anti-B19 IgM is present for up to 2 to 3 months postinfection, after which its level may wane. Specific IgG response to B19 is long-lived. Approximately 50% of the adult population have anti-B19 IgG antibodies (14).

Clinical Manifestations

The clinical spectrum of parvovirus B19 infection may be classified by common (Table 1) and uncommon (Table 2) manifestations.

Nearly half of infected children and adults have subclinical or asymptomatic infection. Erythema infectiosum, or fifth disease of childhood, is the best-known manifestation of B19 infection. Children aged 4 to 7 years are typically infected as they enter school, but children as young as 1 year of age and adolescents may present with fifth disease. Prodromal symptoms are often mild. The majority of the children have the hallmark rash characterized by bright red "slapped cheeks." The rash may also appear on the torso and extremities. It may recur after sun exposure, hot bath, or physical activity. Usually the exanthem is a lacy, reticular, "fish net," or blotchy macular or maculopapular eruption, but occasionally it is vesicular or hemorrhagic. Other symptoms usually are mild and include sore throat, headache, fever, cough, anorexia, vomiting, diarrhea, and arthralgia. Children presenting with rash usually have serum anti-B19 IgM antibody present at presentation. Uncommon dermatological manifestations include vesiculopustular eruption, purpura with or without thrombocytopenia, and a "socks-and-gloves" erythema. Erythema infectiosum may also be encountered in adults in whom the rash tends to be more subtle and the bright red slapped-cheeks symptom is often absent; the flu-like symptoms tend to be more severe in adults.

Approximately 10% of children with erythema infectiosum have associated arthritis and arthralgia. In adults, the polyarthralgia and joint swelling tend to be more prominent (27, 31). The arthropathy typically appears as an acute, moderately severe, symmetric, peripheral polyarthritis. The joints most frequently affected include the metacarpophalangeal joints, proximal interphalangeal joints, knees, wrists, and ankles. The duration of these symptoms is usually brief (approximately 10 days), but one-third of patients continue to have persistent joint symptoms 2 to 3 months after onset of the disease. About half of patients who have chronic parvovirus arthropathy meet the criteria of the American Rheumatism Association for a diagnosis of rheumatoid arthritis (31). Patients may have transient expression of autoantibodies, usually in low to moderate titer, including rheumatoid factor, anti-DNA, antilymphocyte, antinuclear, anticardiolipin, and antiphospholipid antibodies (25). Initial studies of major histocompatibility predisposition suggested an association between chronic B19 arthropathy and HLA DR4, but subsequent studies by the same authors failed to substantiate this association (22, 44). The pathogenesis of B19 arthropathy has not been fully elucidated. In patients with chronic B19 arthropathy, B19 DNA may be found in bone marrow aspirates and in synovial biopsy specimens, suggesting B19 viral persistence in apparently immunocompetent individuals (15, 27). B19 DNA has been detected

TABLE 1 Common clinical manifestations of parvovirus B19 infection

Asymptomatic infection
Aplastic crisis
Erythema infectiosum (fifth disease)
Hydrops fetalis
Arthropathy, acute and/or chronic
Chronic or recurrent bone marrow suppression in
   immunocompromised individuals

TABLE 2 Less common clinical manifestations of parvovirus B19 infection

Skin
  Vesiculopustular eruption
  Henoch-Schönlein purpura
  Thrombotic thrombocytopenic purpura
  Socks-and-gloves syndrome

Hematological
  Anemia
  Thrombocytopenia
  Leukopenia
  Benign acute lymphadenopathy
  Hemophagocytic syndrome

Vasculitis
  Polyarteritis nodosa
  Wegener's granulomatosis

Liver
  Hepatocellular enzyme elevations
  Non-A, non-B, non-C, non-E, non-G fulminant liver failure

Nervous system
  Paresthesias
  Meningitis
  Sensorineural hearing loss

in the normal synovium of young adults by using sensitive PCR techniques (38). One group reported B19 DNA and capsid protein in rheumatoid synovium (40). Coculture of B19-positive rheumatoid synovium with normal cells increased tumor necrosis factor alpha production, a finding typical of rheumatoid arthritis. The group suggested that B19 may be a causative agent of rheumatoid arthritis, a provocative suggestion that remains to be confirmed (41). Transgenic mice expressing B19 nonstructural protein, NS1, are prone to developing polyarthritis (42).

Fetal parvovirus B19 infection presents as fetal or congenital anemia, hydrops fetalis, spontaneous abortion, or stillbirth. In some cases, fetal infection is asymptomatic and self-limited. During B19 infection in utero, virus infects fetal erythroid progenitor cells, causing maturation arrest and severe anemia. The resulting hypoxia causes high-output cardiac failure with fluid accumulation in body cavities and generalized edema of the fetus. B19 may also infect the fetal liver, spleen, kidneys, heart, lungs, thymus, adrenal glands, skeletal muscle, eyes, and placental tissue (27).

Individuals with inherited or acquired conditions causing a decrease in reticulocyte production or abnormal destruction of erythrocytes may develop aplastic crisis during an acute B19 infection. These predisposing conditions include iron deficiency; congenital dyserythropoietic anemia; α- and β-thalassemias; hereditary spherocytosis, stomatocytosis, or elliptocytosis; deficiencies in the production of erythrocyte enzymes such as glucose-6-phosphate dehydrogenase, pyruvate kinase, pyrimidine-5′-nucleotidase; sickle cell disease; chronic autoimmune hemolytic anemia; antibody-mediated autoimmune hemolytic anemia; paroxysmal nocturnal hemoglobinuria; virus-associated hemophagocytosis; and blood loss. In healthy individuals, B19 causes transiently decreased reticulocyte production, but this is not usually clinically evident (29).

Chronic or recurrent bone marrow suppression with anemia, thrombocytopenia, and/or leukopenia has been found in

patients with immune compromise including Nezelof's syndrome; those who had undergone prior chemotherapy for lymphoproliferative disorders including acute lymphocytic leukemia, chronic myeloid leukemia, Burkitt's lymphoma, acute lymphoblastic lymphoma, myelodysplastic syndrome, astrocytoma, and Wilms' tumor; those with human immunodeficiency virus infection and AIDS; and those who were receiving immunosuppressive therapy for bone marrow or organ transplantation. In immunocompetent hosts, anti-B19 IgM and acute-phase IgG antibody recognize antigenic determinants on VP2 and may last for 2 months or more. Convalescent-phase anti-B19 IgG antibody recognizes determinants on VP1 (23). VP1 differs from VP2 by containing unique N-terminal determinants absent from the shorter VP2 (37). Patients with congenital or acquired immunodeficiencies fail to produce convalescent-phase IgG antibodies to VP1, and their serum is unable to neutralize B19 in vitro (29). Since IgG seroprevalence in the adult population is approximately 50%, it was not surprising that neutralizing activity to B19 was detected in commercially available pooled immunoglobulin. Administration of commercial immunoglobulin with anti-B19 activity to patients with immunodeficiency who have chronic B19 infection and cytopenias is effective in clearing B19 infection and allowing bone marrow recovery (16).

Recently, several uncommon manifestations of B19 infection have been described, including idiopathic thrombocytopenia purpura, transient erythroblastopenia of childhood, Diamond-Blackfan anemia, encephalitis, aseptic meningitis, brachial plexus neuropathy, paresthesias, neuralgic amyotrophy, and motor weakness. Unusual rheumatologic presentations attributed to B19 infection include systematic vasculitis, Henoch-Schönlein purpura, Kawasaki's disease, polyarteritis nodosa, adult Still's disease, fibromyalgia, and systemic lupus erythematosus. Parvovirus B19 has also been associated with acute fulminant liver failure, myocarditis, mononucleosis-like syndrome, Koplik's spots, and pneumonia (21, 24, 29, 36, 39, 40).

Epidemiology

Parvovirus B19, genotype 1, has a worldwide distribution. Genotypes 2 and 3 tend to be found in Europe and Africa (8, 19). B19 infection occurs in all age groups throughout the year in epidemics or as sporadic cases. The peak incidence is seasonal, occurring predominantly in late winter and early spring. Serological studies show that B19 has usually infected 2 to 15% of children under the age of 5 years, 15 to 60% of school age children (5 to 19 years old), and 30 to 60% of adults. A total of 20% of children and 26% of adults found to be seropositive had experienced a previous asymptomatic infection. The highest rates of natural infection (50 to 60%) were observed during outbreaks of erythema infectiosum or B19-induced aplastic crisis (3, 9).

Natural transmission of B19 occurs mostly via respiratory secretions or vertically from mother to fetus. Recently, transmission via transfusion of blood and blood products was reported. The frequency of contamination of blood obtained from single donors usually ranges from 1 in 30,000 to 1 in 50,000 donations. However, the frequency of contamination of pooled clotting-factor concentrates can be much higher (45).

LABORATORY DIAGNOSIS

Cell Culture

A major limitation in studies of B19 has been the absence of appropriate cell lines permissive for the virus. Attempts to detect B19 virus in standard cell cultures have not been successful. Several investigators use cell cultures of erythroid origin for B19 propagation. B19 infection of primary cell cultures of erythroid precursors derived from human fetal liver and bone marrow or of human megakaryocytic leukemic cell lines has been successful. However, cultivation of B19 in these cell cultures is not routine, and the viral yield tends to be low. Attempts to use animals, including anthropoid primates, for modeling B19 infection have been unsuccessful.

Electron Microscopy

Standard electron microscopy methods of negative staining allow the examination of a liquid sample dried on an electron microscopy grid that had been previously coated with a thin layer of plastic, followed by staining with phosphotungstic acid or uranyl acetate. Electron-dense material accumulates around viral particles, giving a bas relief appearance or negative-contrast image (Fig. 1).

Specific viral identification may be confirmed by immunoaggregation with polyclonal or monoclonal anti-B19 antibodies (immunoelectron microscopy [IEM]), or by immunogold labeling. However, successful IEM requires the absence of excess endogenous anti-B19 antibody in the sample. In serum samples, "bare" virions are present only in the very early stages of infection before specific antibody develops. IEM may be useful when used with nonserum body fluids or tissues in which anti-B19 antibody is not present in high titer. After incubation of the sample with specific antiserum or anti-B19 monoclonal antibody, centrifugation, and negative staining, the aggregated virions can be seen by electron microscopic examination.

Combined pseudoreplica-immunochemical staining may be more useful, even in the presence of endogenous anti-B19 antibody, since even a few antigenic sites may be adequate to allow the labeling of B19 by specific anti-B19 monoclonal antibodies. Virus can be detected in various body fluids by this method (32). In the pseudoreplica technique, a sample is absorbed into an agarose block, leaving viral particles on the surface. The agarose is then overlaid with a plastic film, which, after hardening, is floated off of the agarose, inverted, applied to a support grid, and negatively stained. Combined pseudoreplica-immunochemical staining uses second-stage gold-conjugated labeling antibodies to detect first-stage anti-B19 monoclonal antibody before negative staining. Examination of viral particles with specific colloidal-gold-conjugated antibodies permits species identification. Otherwise, it may be difficult to discriminate B19 virions from other nonenveloped icosahedral viruses of a similar size, such as enteroviruses, on the basis of morphology alone. B19 may be present as "full" particles with the contrast stain excluded, or stain may enter the capsid, giving the appearance of an "empty" shell (Fig. 1). Although these methods have high specificity, they require special equipment and experienced examiners and are labor-intensive, rendering them suboptimal for routine diagnosis (32).

Immunoassays

Immunofluorescence assay, radioimmunoassay (RIA), and enzyme-linked immunosorbent assay (ELISA) have been used to detect both B19 antigen and specific anti-B19 antibody. The indirect immunofluorescence assay was successfully applied to the cellular localization of B19 antigen in tissue and cell culture samples but has not found wide clinical application. Several RIA and ELISA systems were developed for detecting B19 antigen and anti-B19 IgM and IgG antibody. They can be divided into two major groups. The
FIGURE 1 Electron micrograph of serum from a patient with sickle cell disease and aplastic crisis, showing full (white arrow) and empty (black arrow) nonenveloped, icosahedral viral particles measuring ~23 nm in diameter, visualized by negative staining with uranyl acetate. Bar, 100 nm (original magnification, × 196,000). Reprinted from reference 31 with permission of the publisher.

first system developed consisted of tests using native virus from viremic patients as an antigen source (Fig. 2A) (11). Briefly, for antibody capture RIA or ELISA to detect anti-B19 IgM or anti-B19 IgG, microtiter plates (solid phase) are

coated with anti-human IgM (μ-chain specific) or anti-human IgG (γ-chain specific) antibody diluted in carbonate-bicarbonate buffer during an overnight incubation. After the plates have been washed with phosphate-buffered saline
FIGURE 2 ELISA-based tests showing antibody capture ELISA for anti-B19 IgM antibody (A), antibody capture ELISA for anti-B19 IgG antibody (B), antigen capture ELISA for B19 virus (C), and recombinant or synthetic B19 antigen-based ELISA for detection of B19 antibody (D).

containing a low concentration of nonionic detergent to prevent nonspecific aggregation, the serum to be tested for antibody is added; if the RIA or ELISA is used for detection of antigen, a defined serum with high-titer anti-B19 IgM is added instead. After incubation and washing with buffer, a high-titer B19 viremic serum without endogenous anti-B19 specific antibodies is added as an antigen source; if the RIA or ELISA is used for detection of antigen, the serum to be tested for virus is added instead. In the antibody capture assay, an antigen-negative control serum may be added to parallel wells at the antigen step to detect nonspecific reagent cross-reactivity. Detection of such cross-reactivity may be necessary to avoid false-positive results for patients presenting with autoantibodies such as rheumatoid factor (30). In the antigen capture assay, parallel wells with an anti-B19 IgM negative control capture serum and parallel wells with appropriate virus negative control sample (e.g., normal serum, body fluid, and cell lysate) must be added to detect nonspecific reagent cross-reactivity.

After overnight incubation and washing with buffer, monoclonal antibody with anti-B19 activity is added. After nonadherent anti-B19 murine monoclonal antibody is washed off, anti-mouse class-specific antibody labeled with ^{125}I (RIA) or peroxidase (ELISA) is added. After incubation and washing, radioactivity is counted or color developer in the presence of H_2O_2 is added to each well. The reaction is stopped with 2 M H_2SO_4. We considered an antibody capture assay positive when the absorbance of the sample incubated with the virus was greater than 3 standard deviations above the mean value of background controls (i.e., all serum samples in an assay incubated with nonviremic serum at the antigen step) and the difference between the mean of test well values and the mean of background well values for a given sample was greater than 3 standard deviations of the mean of the background wells for all sera tested (4).

Identification of a stock of high-titer viremic serum without endogenous anti-B19 antibody for use as antigen in immunoassays (Fig. 2A and B) may require significant effort. B19 virus in a panel of candidate antigen sources may be detected by screening antigen capture RIA or ELISA (Fig. 2C) and confirmed by direct DNA hybridization. Alternatively, PCR with B19-specific primers followed by hybridization of the amplified product with B19-specific probes may be used. Antigen detection by ELISA is usually not as sensitive as direct DNA hybridization or PCR amplification (1), but it is useful in screening for high-titer viremic sera. Candidate antigen sources then need to be screened by an antibody capture assay to eliminate those with endogenous antibody.

To overcome the problem of limited access to antigen for diagnostic testing, a second group of solid-phase immunoassays were developed based on recombinant protein or synthetic peptides representing B19 antigenic structures (Fig. 2D). Initially, Chinese hamster ovary cells were transfected with a plasmid containing the B19 nucleotide sequence allowing the expression of both VP1 and VP2 viral proteins that self-assembled into empty capsids (20). These proteins were subsequently expressed using bacterial or baculovirus vectors and form the basis of commercially available diagnostic kits. Several groups have synthesized peptides based on published B19 DNA sequences for use as antigen in immunoassays. For antibody assays, synthetic protein or peptide with B19 antigenic activity is absorbed onto the solid phase. Recent comparison of several commercial kits to each other and to indirect antibody capture ELISA addressed their sensitivity and specificity (7, 34, 35).

Antibodies to genotypes 1 and 3 may be detected equally well by using ELISAs targeting B19 or V9, respectively (17).

Methods for Detection of B19 Nucleic Acid

B19 DNA may be detected by hybridization with cDNA probes, riboprobes (synthetic RNA), or synthetic oligonucleotide probes. Hybridization may be performed directly on tissue or cells by in situ hybridization allowing localization of viral DNA. Disrupted virus-containing sample or extracted DNA may be blotted onto a nitrocellulose or nylon membrane before being hybridized with B19-specific probe. Recently, numerous modifications of this basic approach have been used to detect B19 in body fluids, blood products, tissue, and cell culture extracts. Nonradioactive labels for probes may be used for safety and long shelf life. B19 DNA has been detected in serum by using a digoxigenin-labeled RNA probe to hybridize with target DNA, followed by capture of the hybrid onto a solid phase (microtiter wells) previously coated with a second anti-B19 oligonucleotide probe to an unhybridized portion of the B19 target DNA; an alkaline phosphatase-conjugated anti-digoxigenin antibody and chemiluminescent substrate allow the detection of B19 DNA on a scintillation counter.

PCR-based technologies offer exquisite sensitivity and the ability to detect B19 DNA in different types of clinical specimens. Various oligonucleotide primers directed against sequences in both the nonstructural and viral capsid protein genes have been used (10). PCR is more sensitive than traditional dot blot hybridization; the use of an internal radiolabeled probe to detect amplification product by Southern analysis is still more sensitive than dot blot hybridization. Many investigators have now reported the use of PCR to detect B19 in fetal and adult tissues, body fluids, blood products, and cell cultures. However, PCR detection of B19 DNA in clinical samples is not problem free. The most common problem is the presence in clinical samples of inhibitors of *Taq* polymerase (18). Different approaches to avoid this problem have been used, including controlled heating of the sample, detergent extraction of DNA, and the use of a second round of amplification with nested primers. In antigen capture or immunoadherence PCR, virus is adhered to PCR tubes precoated with anti-B19 monoclonal antibody, and after incubation and washing, the PCR mixture (containing primers, deoxynucleoside triphosphates, and *Taq* polymerase) is added, virions are disrupted by heating, and viral DNA is amplified. This approach avoids nonspecific inhibition and provides high sensitivity and specificity (21, 24). PCR primers may be chosen to preferentially amplify genotypes 2 and 3, although the practical impact of differentiating B19 (genotype 1) from genotypes 2 (K71/A6) or 3 (V9) has not been defined (19, 33).

DISEASE PREVENTION AND THERAPY

Parvovirus B19 infection is widespread in the community. It is therefore difficult to prevent exposure and to control the spread of infection. Community and household contacts are frequently asymptomatic. Hospital exposures may occur. However, isolation of viremic patients may decrease the level of exposure (29).

Specific antiviral therapy has not been identified. In general, patient management is symptomatic and supportive. Patients with acute aplastic crisis may require blood transfusion. Adults with chronic B19 arthropathy are managed with nonsteroidal anti-inflammatory drugs (31). Fetal transfusion in utero may be required to support the fetus during

B19 infection complicated by severe anemia; fetuses transfused in utero and surviving the aplastic crisis have been born without apparent long-term sequelae (29). Immunocompromised patients who lack neutralizing anti-B19 antibodies and who present with manifestations of persistent B19 infection benefit from commercial intravenous immunoglobulin (16). Intramuscular immunoglobulin for prophylaxis following B19 exposure has not yet been adequately evaluated. Specific antiviral chemotherapy for parvovirus B19 has not been demonstrated.

Influenza Viruses

JACQUELINE M. KATZ, ALEXANDER I. KLIMOV,
STEPHEN E. LINDSTROM, AND NANCY J. COX

78

Epidemics caused by influenza viruses may be identified by their explosive onset in a given population, their seasonal characteristics in regions of temperate climate, the respiratory and systemic symptoms associated with illness, and the high attack rate among susceptible individuals. Based on these distinct features, influenza epidemics have been tracked through history, well before the first isolation of the virus in 1933 and the availability of laboratory methods for their identification.

The influenza virus types A, B, and C belong to the family *Orthomyxoviridae.* Antigenic properties of the two major structural internal proteins of influenza viruses, the matrix protein (M1) and the nucleoprotein (NP), allow for differentiation between the virus types. Orthomyxoviruses are enveloped and pleomorphic to spherical, with a diameter of approximately 80 to 120 nm, and contain a segmented RNA of negative sense. Influenza A viruses are further classified into subtypes according to the antigenic characteristics of their two major surface glycoproteins, the hemagglutinin (HA) and the neuraminidase (NA). Sixteen distinct HA and 9 NA subtypes have been identified thus far (14, 27, 46). At present, only influenza A viruses bearing the H1 or H3 HA and N1 or N2 NA cocirculate with influenza B viruses in the human population. All subtypes of influenza A viruses are maintained in wild aquatic birds, the reservoir from which certain subtypes have (i) infrequently crossed species to establish stable lineages in humans, swine, and horses; (ii) more frequently crossed species to circulate widely in domestic poultry; and (iii) been transmitted sporadically to aquatic or other mammalian species. Influenza B viruses have also been isolated from seals (34). In recent years, wholly avian influenza viruses of the H5, H9, and H7 subtypes have been transmitted directly from domestic poultry to humans and caused a spectrum of illness, from mild to severe and fatal disease (7, 27, 35, 43).

The nomenclature of influenza viruses includes the type, the geographic location where the virus was isolated, a laboratory identification number, and the year of isolation, followed by the subtype, e.g., A/New Caledonia/20/99 (H1N1). The species is included for viruses of animal origin, e.g., A/Seal/Massachusetts/133/82 (H4N5).

CLINICAL ASPECTS

Influenza epidemics are caused by influenza A and/or B viruses almost every year. Influenza C viruses usually cause mild to inapparent disease, primarily in children. Therefore, routine diagnosis of influenza C is not commonly undertaken. Influenza epidemics are often associated with excess morbidity and mortality, although the latter is to some extent dependent on the virus type and the age of the affected population (39).

Influenza viruses replicate predominantly in the ciliated columnar epithelium of the respiratory tract. Early in infection, large amounts of virus are shed into respiratory secretions which when expelled through sneezing and coughing can be transmitted to close contacts. Spread by direct contact with contaminated hands or surfaces is also possible. An incubation period of 1 to 4 days is typical but may extend to 7 days. The typical clinical picture of influenza virus infection is sudden onset of fever of >38°C of 3 to 4 days' duration and is often associated with headache, myalgia, and malaise as well as respiratory symptoms, including sore throat, cough, rhinorrhea, nasal congestion, and/or tracheobronchitis. However, there is a great deal of variation in the clinical presentation of laboratory-confirmed cases, which may depend on the age of the patients. Fever and cough are the most common symptoms in all age groups and are often the only clinical manifestations in the elderly, whereas vomiting and diarrhea occur more often in children than in adults (1, 9, 33). Data from epidemiological studies indicate that influenza A viruses of the H3N2 subtype cause more severe illness than influenza B viruses, which in turn are more severe than H1N1 infections. While all age groups are affected by influenza A infections, influenza B viruses predominantly cause illness in children. Certain chronic medical conditions, such as diabetes, asthma, chronic heart and lung diseases, and immunosuppression, predispose individuals to severe complications from influenza. The incidences of influenza-related hospitalizations and deaths are highest among those over 64 years of age. Complications from influenza often present as lower respiratory tract problems. Complications requiring hospitalization include primary viral or, more commonly, secondary bacterial pneumonia with fatal outcome. Otitis media is a common complication of influenza virus infection seen in young children. A large proportion of influenza patients have abnormal electrocardiograms, yet myocarditis and arrhythmia with fatal outcome are relatively rare events (32).

Relatively little is known about the epidemiology and the clinical significance of influenza C viruses. These viruses cause upper respiratory infection predominantly in children, adolescents, and young adults, and they occasionally have

been associated with outbreaks, but they show no particular seasonality. Fever and cough are the predominant symptoms, but in rare instances, influenza C virus has been isolated from patients with lower respiratory tract infections (32). The focus of this chapter is diagnosis of influenza A and B viruses since these types are the major human pathogens.

INFLUENZA VIRUS GENE PRODUCTS AND REPLICATION

The replication and molecular biology of influenza viruses have been extensively reviewed elsewhere (19, 28) and are summarized only briefly here. Influenza A and B viruses possess eight segments of negative-sense RNA which encode at least 10 proteins. Contact between the virus and cell surface is mediated by the HA, which binds to terminal residues of *N*-acetylneuraminic (sialic) acid linked to cell surface glycoproteins or glycolipids. The virus enters the cell through receptor-mediated endocytosis via clathrin-coated pits. In the reduced pH of the endosome, the HA molecule undergoes structural changes that promote the fusion of the HA with the endosomal membrane. The low pH of the late endosome activates the transmembrane M2 ion channel protein, allowing a flow of H^+ to the inner part of the virion, which leads to the dissociation of the M1 protein, the major structural protein of the virus, from the ribonucleoprotein (RNP) complexes. The RNP complex, which is composed of three polymerase proteins surrounded by the NP, is released into the cytoplasm and is rapidly transported into the nucleus. In the nucleus of the host cell, viral RNAs are transcribed into mRNAs, from which viral proteins are synthesized, and into complementary RNAs, which serve as templates for the synthesis of viral progeny RNA segments. The three viral polymerases, PA, PB1, and PB2, catalyze this process. PA is involved in viral RNA replication, while PB1 and PB2 are essential for mRNA synthesis. The nonstructural protein (NS1) inhibits processing of host mRNA, thus allowing the preferential translation of viral mRNA in the cytoplasm, using the host cell's ribosomal machinery. Newly synthesized viral polymerases, NP, and nuclear export protein are transported to the nucleus and complexed with viral RNA segments to form RNPs that under the influence of M1 and nuclear export protein are exported to the cytoplasm. The viral membrane proteins, i.e., the HA and NA of influenza A and B viruses, as well as the transmembrane proteins M2 of influenza A and the NB and BM2 proteins of influenza B, undergo posttranslational modifications in the endoplasmic reticulum and, after transport through the Golgi complex, are inserted into specific areas of the cellular membrane. The M1 protein lines the inner leaflet of the plasma membrane and associates the RNP with the transmembrane proteins. Finally the assembled virions bud from the membrane of the host cell. The NA cleaves sialic acid moieties on the host cell membrane to facilitate release of the HA and the mature virus particles into the extracellular space.

INFLUENZA VIRUS VARIATION

The virus-encoded RNA polymerases do not exhibit proofreading activities. Therefore, point mutations in the viral genome occur at a frequency of approximately one per 10^4 nucleotides. Such point mutations may lead to the emergence of variant viruses that are antigenically distinct from previously circulating strains of the same subtype. Amino acid changes in the globular distal part of the HA molecule are of particular importance, because neutralizing antibodies to antigenic sites in this region provide protection from reinfection with identical or closely related virus strains. Thus, amino acid changes in the HA and NA surface glycoproteins frequently give rise to new epidemic strains to which immunity acquired through previous infection with a homologous type or subtype or by vaccination offers only limited protection. Such new antigenic variants are responsible for the almost yearly epidemics of influenza A and B. Genetic reassortment, i.e., the exchange of gene segments between two viruses, provides an additional evolutionary pathway for influenza A viruses. During simultaneous infection of a host cell with two viruses of different subtypes, gene segments from the two parent viruses can reassort, producing progeny containing segments from both viruses. A virus that has acquired a novel HA from the reservoir of influenza viruses circulating among wild aquatic birds, with or without a novel NA, may be able to infect individuals lacking immunity to the novel HA. If the virus also has the ability to spread from human to human, it may give rise to a pandemic, i.e., a global epidemic caused by a virus in a susceptible population (46).

In the 20th century, pandemics occurred after the appearance of the H1N1 subtype during the "Spanish Flu" in 1918, the emergence of the H2N2 subtype during the "Asian" pandemic in 1957, and the H3N2 viruses during the "Hong Kong" pandemic in 1968. The viruses that caused the last two pandemics were reassortant viruses that had acquired a novel HA and one or two other genes from an avian influenza virus along with the ability to be transmitted efficiently from human to human. Since swine are susceptible to both avian and human influenza viruses, they have been proposed to be an intermediate mammalian host in which reassortment may take place. However, it is now established that influenza A viruses from other species may also be transmitted directly to humans, and so it is also possible that a reassortant virus with pandemic potential may arise in humans without the need for an intermediate host.

IMMUNITY TO INFLUENZA VIRUSES

Strain-specific virus-neutralizing antibody directed against the HA is the primary immune mediator of protection against infection and clinical illness, while antibody directed against the NA may reduce the severity of disease through enhancing viral clearance (16). Antibodies to NP and M1 are of diagnostic importance. Significant rises in antibody directed against the abundant internal structural proteins NP and M1 can be detected after primary infection and reinfection with viruses of the homologous type and are of diagnostic significance. Antibodies to the transmembrane M2 protein may also be produced after repeated influenza virus infections. Antibody to the ectodomain of the protein has been shown to play a role in viral clearance in mice, but the contribution of anti-M2 antibodies to viral clearance in human influenza infection is unknown. $CD4^+$ and $CD8^+$ T cells also play an important role in immunity to influenza and, in contrast to the strain-specific response of antibodies, tend to be more cross-reactive among subtypes, recognizing more conserved epitopes on the surface proteins and/or internal viral proteins. $CD4^+$ T cells provide help for the antibody response and the induction of $CD8^+$ T cells, whereas $CD8^+$ T cells have been associated with accelerated clearance of virus and recovery from infection (41). The ability to recognize a given T-cell epitope is dependent on the HLA phenotype of an individual.

Upon primary infection with influenza viruses, strain-specific immunoglobulin M (IgM), IgG, and IgA antibodies to the HA are detected in serum and in respiratory secretions.

As seen in infections with other viruses, IgM and IgA serum antibodies peak approximately 2 weeks after onset of symptoms and then decline, whereas anti-HA IgG antibodies reach maximum levels a few weeks after infection and persist for many years. The durability of the IgG response to influenza was demonstrated during the 1977 reemergence of H1N1 viruses, when individuals with immunologic memory of H1N1 strains circulating before 1957 were to a large extent protected against reinfection. Antibodies to NA generally reach detectable levels in serum only after repeated infections with related strains. In primed individuals, infection with related viruses results in serum IgG and IgA and mucosal (nasal) IgA antibodies in most cases. Antibody-secreting cells of all three immunoglobulin classes may be detected in local lymphatic tissues and peripheral blood as early as 2 days after vaccination of primed individuals (4, 11). The level of the IgM response in primed individuals is most likely dependent on the antigenic relatedness of the infecting virus to previously encountered influenza viruses.

A number of cytokines and chemokines, such as interleukins 6 and 10, tumor necrosis factor alpha, and gamma interferon, can be detected in nasal washes of individuals experimentally infected with influenza viruses. The levels and kinetics of production of some of these cytokines can be correlated with those of clinical symptoms of influenza virus infection (15).

INFLUENZA SURVEILLANCE

Because of the major medical and socioeconomic impact of influenza and because of the constant threat of the emergence of new epidemic or pandemic strains, the World Health Organization established an international network for the global surveillance of influenza as one of its first activities in 1947 (18). The primary goals of this network are to monitor influenza activity worldwide, to identify new epidemic or pandemic strains in a timely manner, to make recommendations for the formulation of the annually updated vaccine, and to make new virus strains available for vaccine production.

PREVENTION AND CONTROL OF INFLUENZA

Vaccination is the primary means to reduce the impact of influenza viruses and the disease they cause. In the United States, annual immunization with influenza vaccine is recommended for individuals and their caregivers who are at increased risk for influenza-related complications (6). Inactivated intramuscular vaccines are licensed for individuals aged >6 months, while live attenuated cold-adapted intranasal vaccines are currently licensed for individuals 5 to 49 years of age (6). Due to the rapid evolution of influenza viruses, the composition of the vaccine has to be updated annually. The response to influenza vaccines is dependent on age, risk status, and immune status of an individual. Influenza vaccine is 70 to 90% effective in preventing influenza illness in younger, healthy adults when the vaccine strain is well matched antigenically with the circulating virus (6).

In addition to vaccine, antiviral agents can be used for prevention and treatment of influenza virus infections. In the United States, amantadine and rimantadine have been licensed for prophylactic and therapeutic use for several years. The prophylactic efficacy of these two compounds is comparable to that of vaccination. Their selective action against influenza A viruses, their side effects (particularly in the case of amantadine), and the rapid emergence of drug-resistant viruses in treated individuals have each contributed to the limited use of these compounds. Drug-resistant viruses can be spread to close contacts and can cause typical influenza (20). Recently a high proportion of amantadine- or rimantadine-resistant viruses were found in several countries (3, 38).

Another class of antivirals against influenza, the NA inhibitors zanamivir and oseltamivir, have been licensed for therapeutic use (17, 21, 22). One major advantage of these two drugs is their activity against both influenza A and influenza B. In clinical studies, NA inhibitors have been shown to reduce complications from influenza (8, 24). Viruses resistant to both zanamivir and oseltamivir were generated in vitro (20, 31). However, no resistant mutants have been isolated so far from immunocompetent patients treated with zanamivir. It was shown that resistant mutants can be isolated from approximately 1% of adults and from 5 to 18% of pediatric patients treated with oseltamivir (26, 36). However, the infectivity of mutant viruses tested has generally been compromised (23, 31).

DIAGNOSIS OF INFLUENZA VIRUS INFECTIONS

Identification of the illness-causing agent, assistance in the selection of optimal treatment, genetic and antigenic characterization of an influenza virus isolate, determination of vaccine immungenicity and efficacy, screening for drug-resistant isolates, providing epidemiological data, and contributing clinical isolates for the selection of vaccine strains are some of the functions performed by laboratories engaged in influenza virus diagnosis. Virus cultivation in cell culture or embryonated hens' eggs, detection of viral antigens or nucleic acids in clinical specimens, or measuring virus-specific antibodies in serum and other specimens are the techniques commonly applied. The reliability and the clinical impact of laboratory diagnosis are greatly influenced by the quality of the clinical specimens and the timing of the specimens' collection, the conditions for transport from the patient to the laboratory, the selection of appropriate methods and reagents, the expertise of the laboratory staff, and quality assurance of the laboratory services.

Specimens for the isolation of viruses or for the direct detection of viral antigens or nucleic acids should be taken early during the course of illness, i.e., during the first 4 days after onset of symptoms. Nose and throat swabs (collected by using a cotton applicator and placed in a suitable transport medium), nasopharyngeal aspirates, and nasal washes are all suitable specimens. The primary goal when collecting such samples should be to obtain as many virus-infected epithelial cells as possible. To avoid inactivation of virus, the specimen should be shipped to the laboratory without delay, preferably refrigerated. If the elapsed time between specimen collection and processing in the laboratory exceeds 72 h, the specimen should be stored frozen at temperatures well below −40°C. Paired serum samples collected during the acute phase and 2 to 4 weeks later are required for a serological diagnosis of influenza.

Point-of Care Tests

Although virus isolation is still considered the "gold standard" for diagnosis of influenza, results of virus culturing become available only in several days. The availability of NA inhibitors (see above) stimulated development of rapid diagnostic tests that can be used at the point of care, allowing physicians to prescribe available drugs in a timely manner and reduce unnecessary use of antibiotics (2).

TABLE 1 Rapid diagnostic tests for influenza

Test	CLIA[a] waived	Antigen detected[b]	Specimen type[c,d]	Specimen storage[c]
Directigen Flu A (Becton Dickinson)	No	A	NP wash/aspirate/swab, throat swab	2–8°C, 72 h
Directigen Flu A+B (Becton Dickinson)	No	A+B	NP wash/aspirate/swab, nasal wash, throat swab, BAL	2–8°C, 72 h
Flu OIA (Thermo Electron)	No	A/B	Nasal aspirate/swab, throat swab, sputum	2–8°C, 24 h
Flu OIA A/B (Thermo Electron)	No	A+B	Nasal aspirate/swab, throat swab, sputum	2–8°C, 24 h
Xpect Flu A & B (Remel)	No	A+B	Nasal wash/swab, throat swab	2–8°C, 72 h, or −20°C, 6 mo
NOW Influenza A & B (Binax)	No	A+B	Nasal wash/aspirate, NP swab	2–8°C, 24 h
QuickVue Influenza (Quidel)	Yes	A/B	Nasal wash/aspirate/swab	2–8°C, 8 h, or 15–30°C, 8 h
QuickVue Influenza A+B (Quidel)	Yes	A+B	Nasal wash/aspirate/swab	2–8°C, 8 h, or 15–30°C, 8 h
SAS Influenza A, SAS Influenza B	No	A+B	NP wash/aspirate	4–8°C, 24 h
Clearview Flu A/B (Wampole)	No	A+B	Nasal wash/swab, throat swab	2–8°C, 72 h, or −20°C, 6 mo
ZstatFlu (ZymTx)	Yes	A/B	Throat swab	0–40°C, 24 h

[a]CLIA, Clinical Laboratory Improvement Amendments.
[b]A+B, test differentiates between influenza A and B viruses; A/B, test does not differentiate between A and B viruses.
[c]Per manufacturer test inserts.
[d]NP, nasopharyngeal; BAL, bronchoalveolar lavage.

Most of the point-of-care tests are based on immunoassay detection of viral antigens in clinical samples, while one of them detects virus NA activity (Table 1). These tests require minimal expertise and can be completed within only 10 to 30 min. They are widely available now, although more sensitive and less expensive tests are highly desired. More than 10 rapid diagnostic tests are licensed in the United States (http://www.cdc.gov/flu). Directigen A can identify influenza A only, while some other tests do not distinguish between influenza A or B (Flu OIA, Quick Vue Influenza, and ZstatFlu). Certain tests were designed to differentiate between these two types of influenza (Directigen Flu A+B, Flu OIA A/B, NOW Influenza A & B, QuickVue Influenza A+B, SAS Influenza A and Influenza B, Clearview Flu A/B, and Xpect Flu A & B). Nasopharyngeal washes, nasopharyngeal swabs, nasal aspirates, and nasal swabs are the most common specimens used, although bronchial lavage fluid, throat swabs, and sputum are also mentioned as appropriate specimens in inserts accompanying some rapid diagnostic tests.

Appropriate use of rapid diagnostic tests requires a clear understanding of the predictive value of the tests, which depends on their sensitivity and specificity as well as on the level of influenza activity in the tested population (Table 2). Sensitivity is defined as the percentage of true influenza cases among true-positive (TP) plus false-negative (FN) test results, while specificity is the percentage of true-negative (TN) influenza cases among TN plus FP test results. Variable sensitivity and specificity have been demonstrated for the different rapid diagnostic tests. For example, compared with those of viral culture, the median sensitivity and the median specificity for the Directigen Flu A + B test were shown to be 89.8% (86.6 to 100%) and 98.7% (95.5 to 100%), respectively, in detecting influenza A viruses and 87.5% (62.5 to 88.9%) and 96.8% (88.1 to 100%), respectively, in detecting influenza B viruses (44). Recent study of more than 4,000 respiratory samples revealed that the sensitivity of the Directigen Flu A+B test was 43 to 45% for detection of both influenza A and B viruses in patients with respiratory symptoms, while the test specificity was more than 99% (5). The median sensitivity and the median specificity of the ZstatFlu test were 68.8% (48.1 to 96%) and 83% (62.7 to 92.4%), respectively, in several studies combined (44).

The positive predictive value (PPV) of a test is equal to the percentage of the value obtained by the equation TP/(TP + FP). The negative predictive value (NPV) of a test is defined as the percentage of the value obtained by the equation TN/(TN + FN). PPV and NPV are important characteristics of a rapid test, since even highly sensitive and specific tests can have low PPVs and high NPVs if the prevalence of influenza in the community is low and, therefore, FP results are most likely to be obtained. When the activity of influenza in the community is low, it is important to confirm positive test results by virus culture or other methods (immunofluorescence or PCR). Accordingly, FN results are more likely during the influenza season.

Rapid diagnostic tests are becoming widely used by many clinics and physicians. However, the accuracy of currently available tests is less than optimal, and these tests have the further limitation of not providing virus isolates for further characterization.

Direct Detection Using FA

The detection by fluorescent antibody (FA) staining of viral antigens in exfoliated epithelial cells of the respiratory tract is a sensitive method that can produce results within 2 to 3 h.

TABLE 2 Sensitivity, specificity, and predictive values of tests[a]

Test result	Disease	
	Present	Absent
Positive	TP	FP
Negative	FN	TN

[a]Determined as described in the text.

Specific monoclonal antibodies for some of the clinically most relevant respiratory viruses can be purchased from several suppliers.

For a successful application of this technique it is essential that the specimen is processed in the laboratory within hours after collection. Briefly, epithelial cells are freed from contaminating mucus, fixed on microscope slides, stained by FA staining methods, and, finally, identified by fluorescence microscopy. Adequate controls, i.e., cell culture-grown preparations, known positive clinical specimens, and monoclonal antibodies with different specificities, should be included in each test run.

1. Dilute the specimen 1:2 to 1:5 in phosphate-buffered saline (PBS), pH 7.4, containing 10 mM dithiothreitol to partly solubilize mucus. Transfer the specimen to a centrifuge tube, add half the volume of 45% Percoll, mix gently with a pipette, and centrifuge at $700 \times g$ for 5 min. Carefully remove the supernatant and resuspend the cell pellet in 3 ml of PBS by gentle pipetting. Underlay the suspension with a 1- to 2-ml cushion of 20% Percoll, and centrifuge at $700 \times g$ for 5 min. Remove the supernatant and resuspend the cells in 0.1 to 1.0 ml of PBS. Add a drop of cell suspension (20 to 50 μl) to marked areas on clean microscope slides. Make an appropriate number of spots for the identification of influenza A and B and eventually other viruses. (Note: The optimal cell density should be determined using microscopic examination; dilute cells sufficiently to avoid overlapping of cells.) Allow slides to dry completely in a fume hood or in a laminar-flow hood and then fix using cold acetone for 5 min.

2. Apply 20 to 50 μl of appropriately diluted monoclonal antibody to each cell spot, place the slide in a moist chamber, and incubate at 37°C for 30 min. Rinse slide thoroughly with washing solution. Add 20 to 50 μl of fluorescein isothiocyanate-conjugated antibodies to mouse immunoglobulins (monoclonal antibodies) to each spot, place the slide in a moist chamber, and incubate at 37°C for 30 min. Rinse the slide thoroughly with washing solution. Drain excess washing solution, tap the slide dry on soft tissue, add mounting medium, and place a coverslip over the cells.

3. Examine the slide by fluorescence microscope at a magnification of ×250 to ×400. Virus-positive cells are identified by intracellular appearance of bright, apple-green fluorescence. A cell spot stained with a virus-negative (control) monoclonal antibody should not contain any fluorescing cells.

With optimal specimens, adequate handling, high-quality reagents, and experienced laboratory personnel, this technique reaches a sensitivity of 80 to 90% compared to standard virus isolation. However, the speed by which a result is obtained outweighs in many cases the reduced sensitivity.

Virus Isolation

Virus isolation in embryonated hens' eggs or in cell cultures continues to be the gold standard in the laboratory diagnosis of influenza virus infections. Days to weeks are required to obtain a conclusive result by virus isolation; therefore, this technique has limited utility in a clinical setting. Yet virus isolation is an invaluable method, because it provides an isolate for antigenic and genetic characterization, which is of utmost importance for the surveillance of influenza and for vaccine production. The continuous line of Madin-Darby canine kidney cells (MDCK) is the cell line of choice for the cultivation of influenza viruses. Trypsin, preferably 1-tosylamide-2-phenylethyl chloromethyl ketone-treated trypsin, at a concentration of 2 μg/ml must be added to the cell culture medium to allow for a continued replication of

influenza viruses in these cells. Primary monkey kidney cells have a wider virus spectrum than MDCK cells, and they do not require addition of trypsin to the medium. However, high cost and occasional contamination with endogenous viruses limit their use in many laboratories. Identification of influenza viruses must be done by hemadsorption, HA titration, or FA staining (25).

Rapid culture, i.e., a combination of virus isolation with detection of viral antigens in the cultured cells by immunoperoxidase staining before changes in the cell morphology can be identified, combines the sensitivity of standard virus isolation with the speed of some culture-independent methods. Protocols have been designed for a type- and subtype-specific identification of influenza viruses 16 to 24 h after inoculation (49).

RT-PCR

Reverse transcriptase PCR (RT-PCR) offers a rapid and highly sensitive method for the identification of influenza and other respiratory viruses in clinical specimens (10, 47). Although this method does not produce an isolate for further analysis, genetic variation of epidemic strains can be identified by nucleic acid sequencing, and with appropriate selection of primers, amino acid changes in the antigenic sites on the HA can be identified.

RT-PCR can be used for the detection of influenza viruses in original respiratory samples from patients, or for the characterization of viruses grown in tissue culture or embryonated eggs. Isolated virus RNA is first reverse transcribed into a cDNA copy using RT. The cDNA is then subjected to a repeated thermal cyclic reaction causing template denaturation (95°C), primer annealing (45 to 60°C), and product extension (72°C). RT-PCR requires an RNA template, a pair of oligonucleotides (or forward and reverse primers) that are complementary to the template, four deoxyribonucleoside triphosphates RT, and a thermostable DNA polymerase, such as *Taq* or *Tth*, that is not inactivated at 95°C. Since products of one round of amplification serve as templates for the next, each cycle of PCR doubles the amount of copied DNA. One-step RT-PCR reagent kits that combine reverse transcription and PCR reagents in one tube are available as well. Because it is not necessary to open the reaction tube to add PCR reagents following the reverse transcription reaction, one-step RT-PCR makes the amplification procedure simpler and less susceptible to contamination.

Nested or seminested RT-PCRs can significantly increase the sensitivity and specificity of PCR by further amplification of DNA using another set of forward and/or reverse primers. These secondary primers are complementary to regions located within the DNA copy amplified during the first round of PCR. The sensitivity of nested PCR in detection of influenza A(H1N1), A(H3N2), and B viruses can be as high as one to four target gene copies per reaction (45).

Recently, PCR strategies have been designed that utilize fluorescent probes for detection and/or quantitation of amplified DNA in real time (30). The most common real-time PCR strategy utilizes a dually labeled oligonucleotide probe (e.g., Taqman probe) that is labeled with a fluorescent dye, or fluorophore, and a quencher dye. Because the probe binds to the specific target and does not bind to nonspecific products, fluorescence is only observed if the desired DNA is amplified. A number of other real-time formats for detection of specific targets have been designed. Nevertheless, the sensitivity and specificity of real-time PCR as well as conventional RT-PCR depend on the quality of clinical samples and their storage

(42) as well as on the quality of the oligonucleotide primers and probes used for amplification.

Because of genetic diversity among influenza viruses, it is possible to design PCR primers and probes that will specifically detect only one influenza type or subtype. On the other hand, the M gene is the most conserved influenza virus gene and is widely used as a target for the detection of all influenza A type viruses. Specific primers that amplify the HA and NA genes are used for detection of influenza A virus subtypes. In addition, a number of protocols have been designed for the detection of influenza B viruses based on their NS genes (13, 29, 40, 45).

In order to avoid contamination and to protect the integrity of the sample RNA, it is important to comply with certain conditions during PCR performance:

- Work surfaces, pipettes, and centrifuges should be cleaned routinely to minimize the risk of contamination from DNA or RNA as well as RNase. Gloves should be used and changed as needed.
- All reagents should be kept on ice during assay setup.
- Negative ("water") controls and viral RNA-positive controls should be included in each run.
- Viral RNA controls should be added as the final step after all reagents, primers, and sample RNAs are sealed.
- When original clinical materials are used for detection of influenza virus genes, a primer and probe set to a host gene mRNA such as the human RNase P gene can be used as a positive control (12). Amplification of this RNA by conventional or real-time RT-PCR serves to validate the quality of the clinical sample. Failure to detect RNase P RNA in any of the clinical samples may be the result of an insufficient number of human cells in the sample, of improper extraction (loss) of RNA from clinical materials, or of the presence of RT-PCR inhibitors in a clinical specimen.
- Excessive amounts of RNA or DNA in the specimen may result in FN results. If a high level of nucleic acid is suspected, the sample may be tested at several dilutions to verify the negative results.

Serological Detection of Infection

Serodiagnosis of influenza virus infection can be established by a >4-fold increase of antibody titers between serum samples collected during the acute and convalescent phases of the illness. Acute-phase sera should be collected as soon as possible but no more than 7 days from the onset of illness. The convalescent-phase sera should be collected 2 to 3 weeks after the acute-phase sera. Because of the possibility of detection of antibody induced by prior infection or vaccination with influenza, single serum samples generally cannot be used for serodiagnosis of recent influenza virus infection, regardless of the type of assay to be used. Due to the need for paired sera, serodiagnosis of infection is necessarily retrospective in nature and is therefore not useful for patient management. Nevertheless, serodiagnosis may be useful to determine the etiology of a respiratory illness when virus isolation has not been successful or possible. The gold standard for serodiagnosis of infection or response to vaccination with human influenza viruses is the hemagglutination inhibition (HAI) assay (25). The microneutralization test is an alternative method for the detection of strain-specific antibodies to influenza viruses and in some cases may be more sensitive than the HAI test (37). This is particularly important for the detection of antibodies to avian influenza viruses in human sera, for

which the microneutralization assay should be used due to the fact that the HAI test is not sensitive enough to detect these antibodies. Although rarely used, the complement fixation test can be performed using unconcentrated virus in tissue culture supernatants or allantoic fluid, and it predominantly detects antibodies directed against the influenza virus NP and thus does not allow for a subtype- or strain-specific diagnosis. Although the complement fixation test is less specific than tests mentioned below, it may be useful during periods when antigens prepared from currently circulating viruses are not yet available. Enzyme immunoassays are typically performed to measure virus-specific IgG, IgM, or IgA antibodies in paired samples, e.g., acute- and convalescent-phase sera or pre- and postvaccination serum or respiratory samples. Such immunoassays perform optimally when concentrated and/or purified preparations of viral antigen are used to detect antibodies.

HAI Test

The HAI test is the standard method for characterizing the antigenic properties of influenza virus isolates, for serodiagnosis of influenza virus infections as well as for seroepidemiological studies detecting human influenza virus infection (25, 48). The HAI test measures strain-specific antibodies (Table 3); thus, the identity of the infecting strain can be established or the response to single components of the trivalent vaccine can be precisely determined. The quality of results obtained by the HAI test can be influenced by several factors. First, inhibitors present in some sera must be removed before testing. Treatment of sera with receptor-destroying enzyme from *Vibrio cholerae* is the usual method of choice, but trypsin-periodate treatment with heat may also effectively remove inhibitors from sera. Second, the source and quality of the red blood cells, which may be turkey, guinea pig, or human type O red blood cells, can greatly influence the test result. Third, the growth substrate of the antigen and the treatment of the antigen may also influence the test results. Because of the instability of the HA, the working dilution of antigen must be precisely determined and titered each time the HAI assay is performed. Well-characterized standard positive and negative reference sera must be included in each test (47). A detailed protocol is available on the World Health Organization website (http://www.who.org).

Microneutralization Test

The microneutralization test is a highly sensitive assay applicable to the identification of virus-specific antibody in human sera. The neutralization test has several additional advantages for detecting antibody to influenza virus. First, the assay primarily detects antibodies to the influenza virus HA and thus can identify functional, strain-specific antibodies in human serum. Second, since infectious virus is used, the assay can be developed quickly upon recognition of a novel virus and is available before suitable purified viral proteins become available for use in other assays. The microneutralization test is a sensitive and specific assay for detecting virus-specific antibody to avian influenza A viruses in human serum. The microneutralization test could detect H5-specific antibody in human serum at titers that could not be detected by the HAI assay, the traditional test used for the detection of antibodies to human influenza A and B viruses (37).

The microneutralization test has been designed to be a more rapid neutralization test in that it can yield results within 2 days, compared with other neutralization assays that take 3 to 4 days. The neutralization test is performed in two stages. The first is a virus-antibody reaction step in which serially diluted serum is preincubated with a standardized

TABLE 3 Antigenic drift of H3N2 viruses between 1968 and 2004 as demonstrated by their cross-reactivities in HAI tests using postinfection ferret sera

amount of virus and then inoculated into MDCK cell culture. After an overnight incubation, the cells are fixed and the presence of influenza A virus NP in infected cells is detected by enzyme-linked immunosorbent assay. The absence of infectivity constitutes a positive neutralization reaction and indicates the presence of virus-specific antibodies capable of neutralizing virus infectivity in human or animal sera prior to the addition of MDCK cells. As with other serological assays, well-characterized standard positive and negative reference sera must be included in each test. A protocol for a microneutralization test-enzyme immunoassay has been described previously (37). A detailed protocol for this assay will soon be available on the World Health Organization website (http://www.who.org).

CONCLUSIONS

Although influenza is often identified by its clinical presentation, multicenter studies using well-trained clinicians have shown that clinical diagnosis of influenza has an accuracy of 50 to 75% (21). Laboratory diagnostic services are therefore essential for several reasons. Early during the influenza season, the presence of influenza viruses in the community should be verified and the antigenic match between the circulating epidemic strains and the vaccine viruses should be determined. Laboratory diagnosis should be considered for atypical cases presenting during the influenza season and in cases where treatment with antiviral agents may be of benefit for the patient. In these instances, a rapid method such as detection of viral antigens in clinical specimens is the method of choice. Virus isolation and detection of virus antigens or nucleic acids in clinical specimens become more difficult a few days after onset of illness, when the amount of virus shed by the patient typically is decreasing. If a laboratory diagnosis is required during this stage, serological methods may provide the answer. It is often during the late part of an epidemic that new antigenic variants emerge. These variants are of particular interest because they may possess antigenic characteristics that will be predominant in viruses of the following season. For this reason, it is desirable to collect a representative number of isolates for antigenic characterization at the end of the season. Virus isolation should also be attempted when suspected cases occur outside the typical influenza season. With the availability of effective drugs for the prevention and treatment of influenza, the need for rapid diagnostic services is increasing. Some of these tests can be performed in a doctor's office or on a hospital ward, and they are of great importance for the appropriate use of antiviral medications and antibiotics. However, specialized laboratories must continue to use more sophisticated techniques such as virus isolation, RT-PCR, and serological methods in order to monitor the antigenic and genetic characteristics of influenza viruses circulating worldwide.

Respiratory Syncytial Virus, Human Metapneumovirus, and the Parainfluenza Viruses

PEDRO A. PIEDRA AND GUY BOIVIN

79

Respiratory syncytial virus (RSV), human metapneumovirus (HMPV), and the parainfluenza viruses (PIVs) are the major viral causes of acute respiratory tract disease in infants and children (32, 37). RSV is the single most important cause of bronchiolitis and pneumonia among young children. It is the major virus associated with hospitalization for acute lower respiratory tract disease in children younger than 5 years of age. Most of the hospitalizations occur in children younger than 12 months of age (32). HMPV is a recently recognized paramyxovirus that causes respiratory tract disease similar to that due to RSV (20, 37). It appears to be the second most common cause of bronchiolitis and pneumonia among young children. HMPV is often detected in children with underlying chronic conditions. Coinfection with RSV and HMPV may cause a more severe illness than infection with RSV or HMPV alone (19). PIVs regularly cause pneumonia, bronchiolitis, and croup among infants and children. Like RSV and HMPV, PIVs are associated mostly with acute upper respiratory tract illnesses in children. Among adults, RSV and PIVs cause a modest number of community-acquired pneumonias, especially in immunocompromised and elderly persons (9, 18). HMPV appears also to be a cause of community-acquired pneumonias in elderly adults (37). Limited information is available on the impact of HMPV in the immunocompromised host. RSV has been documented to cause outbreaks among elderly persons in semiclosed institutions, such as nursing homes, and is associated with high attack rates of pneumonia and significant case fatality rates (14). Nosocomial RSV, HMPV, and PIV infections occur among infants, children, and adults.

RSV, HMPV, and PIVs belong to the *Paramyxoviridae* family of respiratory viruses. The *Pneumovirnae* subfamily contains the *Pneumovirus* and *Metapneumovirus* genera. RSV is a pneumovirus that comprises two subgroups, A and B; HMPV is a metapneumovirus that also consists of two subgroups, A and B. The PIVs, members of the paramyxovirus group, include four serotypes, 1, 2, 3, and 4A and 4B. RSV, HMPV, and PIV are transmitted mainly by direct contact and uncommonly by aerosols. Epidemics of RSV and HMPV occur annually in the fall, winter, and spring in temperate climates. RSV epidemics last for approximately 20 weeks starting in October or November and ending in March or April. There are geographic differences with respect to the onset, peak, and end of the RSV epidemics. In the United States, RSV outbreak arrives earlier in the southern and midwestern states than in the northern and western states. Subgroups A and B circulate together in epidemics; however, subgroup A occurs about three times as often as subgroup B and may cause somewhat more severe illness. HMPV subgroups A and B cocirculate during the outbreak. The severity of HMPV disease has yet to be associated with a particular subgroup. PIVs exhibit differing epidemiological patterns: PIV type 3 occurs endemically with outbreaks in early spring, PIV type 2 occurs sporadically, and PIV type 1 occurs mainly in epidemics during the fall of alternate years.

Rapid diagnosis of RSV infection is very important because of the availability of effective treatment modalities for children with serious infections and for reduction of nosocomial infection. These are ribavirin, an established anti-RSV drug, and a new humanized monoclonal antibody for prophylaxis, designated palivizumab (32). Although ribavirin is an approved drug for the treatment of RSV disease, its use remains controversial because of its expense and limited benefit in shortening the duration of hospitalization. A potential long-term benefit of ribavirin treatment of RSV illness in children free of underlying disease may be a reduction in the frequency of reactive airway disease later in life (11). Ribavirin administered as an aerosol provides some therapeutic benefit in the treatment of RSV infection in infants with underlying cardiopulmonary diseases. Its current use is restricted primarily to children and adults who are immunocompromised. Palivizumab is directed against the fusion (F) protein of RSV and is effective in the prevention of hospital-related RSV infections in preterm infants, children with bronchopulmonary dysplasia, and children with hemodynamically unstable congenital heart disease (16, 21, 36). Vaccines for RSV, HMPV, and PIV remain in the developmental stage despite substantial research and clinical testing of various candidate vaccines.

LABORATORY DIAGNOSTIC TESTS

Rapid laboratory diagnosis of RSV, HMPV, and PIV infections, using sensitive and specific procedures that are cost-effective, can lead to a decrease in diagnostic evaluation tests, avoids indiscriminate use of antibiotics, reduces the number of nosocomial infections, and allows a rational use for specific anti-RSV treatment measures. A number of major approaches to the laboratory diagnosis of these virus infections are available: (i) tissue culture for virus isolation

from respiratory secretions of the upper and lower respiratory tract, (ii) rapid detection of viral antigen in respiratory secretions or middle ear effusions (in otitis media), (iii) viral RNA detection in respiratory secretions, and (iv) determination of specific antibody responses by serological assays.

Common Diagnostic Tests in a Hospital Laboratory

RSV and PIV infections can be rapidly diagnosed by the demonstration of viral antigen in exfoliated respiratory tract epithelial cells present in respiratory tract secretions, including nasal wash specimens. The "gold standard" for the diagnosis of RSV and PIV infection is virus isolation from respiratory tract specimens; however, this requires several days until virus growth in tissue cultures can be identified, often after the acute phase of illness subsides. Also, attention to transport and processing of the specimen is required because of virus lability. A shell vial technique reduces the time for virus isolation and identification to 24 to 48 h. Most hospital laboratories are not able to isolate HMPV in tissue culture because frequently the optimal cell line is not used, serum-free medium containing trypsin is needed, and the detection of viral cytopathic effect (CPE) requires a long incubation. Reverse transcription-PCR (RT-PCR) is currently the preferred test for the detection of HMPV (8, 37).

RSV and PIV infection can be rapidly diagnosed by demonstrating viral antigens in exfoliated respiratory tract mucosal cells. Several sensitive and specific assays have been described for identifying viruses in exfoliated cells, including immunofluoresence (IF), enzyme linked immunosorbent assay (ELISA), time-resolved fluoroimmunoassay, and RT-PCR (6, 7, 24, 35, 40). These procedures employ monoclonal antibodies directed against one of the major structural proteins of the virus or DNA primers to cDNA of the specific viruses. Diagnostic kits based on ELISA procedures contain all reagents and provide "self-contained" reasonably sensitive and specific assays for routine diagnosis in the hospital laboratory. Antigen detection diagnostic kits are routinely used for RSV. IF for identifying RSV and PIV antigens in exfoliated cells is used in some hospital laboratories, but this test requires well-trained technicians. In general, antigen tests are not very sensitive or useful in testing adults because the reduced viral loads in adults are frequently below the lower limits of detection of the tests. Commercial reagents for HMPV are currently not available. Multiplex PCR or RT-PCR is used in some hospital laboratories as the preferred method for rapid detection of common childhood respiratory viruses including RSV, HMPV, and PIVs. With the emphasis on the rapidity of diagnostic information and cost, procedures such as the antigen detection diagnostic kits and IF are often preferred in the hospital laboratory.

Common Serologic Tests in a Research Laboratory

Serologic assays are infrequently used in the hospital laboratory for the detection of RSV, HMPV and PIVs; however, these assays are frequently used for research purposes. They include the detection of RSV-specific immunoglobulin A (IgA), IgG, and IgM antibody in secretions, breast milk, and serum and the detection of diagnostic (fourfold) antibody rises between acute-phase and convalescent-phase serum specimens ("paired" serums). The Western blot (WB) test is useful in identifying RSV infection, in particular, in persons who have received an investigational RSV subunit vaccine (33). Antibody to RSV, HMPV, and PIV can be assayed by ELISA, virus neutralization (NT), direct or indirect IF, complement fixation (CF), and, for PIV, hemagglutination inhibition (HI). ELISA is a sensitive and specific procedure and

is the mainstay of serologic procedures for the diagnosis of RSV, HMPV, and PIV. A shortcoming of ELISA is that it measures the amount of binding antibody, which does not always correlate with protection against disease. NT assays such as the microneutralization and plaque reduction assays are similar to ELISA in sensitivity and specificity. The advantage of an NT assay is that it measures the neutralizing-antibody activity of serum, which is a better correlate of immunity than is binding antibody (34). NT assays, however, are more labor-intensive and require longer for completion.

The levels of antibody to RSV, HMPV, and PIV in large groups of infants, children, and adults can be measured in epidemiologic surveys by ELISA, including immunoglobulin-specific ELISA, as well as IF and NT tests that detect serum IgG antibody (or "protective" antibody) and reflect the immune status. Since HI antibody to PIV correlates well with the level of NT antibody, HI provides a sensitive, reliable, and rapid method for the survey of type-specific PIV antibody. The NT tests provide an excellent means of detecting protective antibody to RSV, HMPV, and PIV, but these procedures are labor-intensive and are generally performed only in research laboratories. Immunoglobulin-specific ELISA provides a highly specific and sensitive method of measuring individual serum IgA, IgG, and IgM responses. Infants younger than 6 months respond less than half the time with a brisk and high-titer IgG or NT antibody response because they all possess maternal antibody to RSV, HMPV, and PIV and because of their immature immunological systems (4, 18). In this age group, determination of antibody responses to infection with RSV, HMPV, and PIV should include several different assays to increase the likelihood of detecting an antibody response (5).

A site-specific ELISA employing as antigen one or more synthetic peptides of the reactive site of the large glycoprotein (G) and F protein of RSV provides an additional means of detecting antibody to RSV, mainly in research studies (2). A single peptide comprising 15 amino acids (peptide 12) of the G protein of RSV selectively reacts with monoclonal antibodies generated against the G protein. Use of peptides from subgroup A and B strains of RSV provides a means of measuring subgroup-specific antibody responses. This approach does not appear to be as sensitive as ELISA procedures employing whole virus antigen (3).

CLINICAL INDICATIONS FOR SEROLOGIC STUDIES

The choice of an assay for measuring antibody to RSV, HMPV, and PIV depends on several factors, including the objective of the test, information needed concerning current or past infection, the immunological status and age of the person being tested, and the sensitivity, specificity, rapidity, and complexity of the test employed. ELISA, HI, IF, NT, and WB procedures provide highly specific and especially reliable means for the determination of antibody to RSV, HMPV, and PIV. The HI test applies only to PIVs. The IgM ELISAs give serologic evidence of an acute infection even if only a single specimen of respiratory tract secretions or a single serum specimen, obtained soon after the onset of illness, is used. The WB test for RSV also provides serologic evidence of a recent infection even if a single serum specimen is used (33). It is likely that a WB profile for recent infection also can be developed for HMPV and PIVs. ELISA seems the best assay for antibody detection in the hospital diagnostic laboratory because it is highly sensitive, specific, and easy to use and provides the most practical method for detecting

antibody to RSV, HMPV, and PIV in persons of all ages, including infants and children younger than 6 months.

Paired serum specimens can be used for the diagnosis of RSV, HMPV, and PIV infection in patients with an acute illness; a wait of usually 18 to 21 days, but preferably not later than 35 days, is necessary before the convalescent-phase (second) serum specimen can be collected. This approach does not seem practical for acutely ill patients, because by this time the patient has recovered. Recent infection is signaled by detection of a fourfold or greater rise in antibody level in the convalescent-phase serum compared to the acute-phase serum. A diagnostic rise in antibody titer that is temporally associated with illness provides serologic evidence that the illness resulted from infection with that virus. However, when mitigating circumstances exist, the convalescent-phase serum can be obtained earlier, between 10 and 17 days after the acute-phase serum is collected. Importantly, use of a convalescent-phase serum specimen drawn too soon after the acute-phase serum specimen or an acute-phase serum drawn too late after onset of disease diminishes the opportunity of detecting a diagnostic antibody rise.

INTERPRETATION

The detection of a high level of RSV IgM or PIV IgM in a single specimen of respiratory secretions or serum or a fourfold or greater increase in antibody titer during convalescence indicates acute infection. Most infants, children, and adults infected with RSV, HMPV, or PIV develop IgA-, IgM-, and IgG-specific ELISA antibody. Site-directed ELISAs employing synthetic peptides of subgroups A and B of RSV as antigen (which allow the detection of antibody responses to linear epitopes) also detect subgroup-specific diagnostic rises in titer during RSV infection. WB test using sucrose gradient-purified RSV antigen detects RSV infection with similar sensitivity and specificity to those of ELISA and NT. HI tests provide similar sensitivity for infections with the serotypes of PIV. Although much less sensitive than either ELISA or the HI test, CF detects diagnostic rises in titer of paired serum specimens in less than half of infections among adults.

At birth all children possess maternal neutralizing antibody to RSV that wanes during the first 6 months of life; the presence of maternal antibody precludes the detection of antibody responses to RSV by most techniques (5). The WB test can detect most RSV infections because it measures not only responses to the surface G and F glycoproteins but also to the internal viral proteins (nucleoprotein [NP], phosphoprotein [P], and matrix protein [M]). The ELISA procedure can detect fourfold or greater rises in the titer of antibody to RSV in 50% of infected children in this age group. The ELISA that measures IgA anti-RSV antibody is more sensitive than the ELISA that measures IgG anti-RSV antibody in infants younger than 6 months of age. The NT test, WB assay, and ELISA are equally efficient in detecting antibody responses to RSV infection in children older than 6 months. CF fails to detect antibody responses in children younger than 6 months (5).

Heterotypic antibody responses detected by HI and CF tests frequently occur in patients with PIV infections. Increases in the PIV antibody titer occur after mumps virus infections. It is difficult to identify the infecting PIV serotype based solely on serologic procedures. The serotype may be identified by virus isolation with subsequent serotyping of the isolate by hemadsorption inhibition (HadI) or HI or by demonstration of antigen in exfoliated nasal epithelium by IF with a panel of monospecific antibodies or by RT-PCR.

REAGENTS

Selected Vendors for Reagents

Immunological, RT-PCR and tissue culture reagents can be purchased readily from many sources. Selected commercial sources include the following.

BioWhittaker, Inc. (www.biowhittaker.com), 8830 Biggs Ford Rd., Walkersville, MD 21793; 1-800-638-8174

DAKO Corp. (www.dakousa.com), 6392 Via Real, Carpinteria, CA 93103; 1-800-235-5673

GIBCO BRL Life Technologies (www.lifetech.com), 3175 Stanley Rd., Grand Island, NY 14072-0068; 1-800-828-6686

ICN Biomedicals, Inc. (www.icnbiomed.com), 3300 Hyland Ave., Costa Mesa, CA 92626; 1-800-854-0530

Intracel Corporation (www.intracel.com), 93 Monocacy Blvd A-8, Frederick, MD 21701; 1-877-289-5476

Labsystems, Inc. (www.labsystems.fi), P.O. Box 3655, Boston, MA 02241-3635; 1-800-522-7763

Midland Certified Reagent Company (www.mcrc.com), 3112-A West Cuthbert Ave., Midland, TX 79701-5511; 1-800-247-8766

TEST PROCEDURES

Tissue Culture Cell Methods for Isolation of RSV, HMPV, and PIVs

Isolation of RSV and PIVs by tissue culture technique has been the gold standard by which all other diagnostic tests are compared. The isolation of current wild-type virus strains is important for molecular epidemiology, evaluation of antiviral drugs, identification of escape mutants to antiviral therapy and immune prophylaxis, selection of viral strain for vaccine development, production of antigens or virus strains for serologic assays, use in evaluation of disease pathogenesis, correlates of immunity, development of vaccine with animal models, development of human virus challenge pools, and evaluation of diagnostic tests. These are just some examples of how current wild-type virus strains benefit

research and the practice of medicine. To optimize the isolation of RSV, HMPV, and PIVs, a good-quality specimen (nasal wash is preferred over throat swab or nose swab), timely transport of a specimen on ice to the laboratory, and use of cell lines permissive to RSV, HMPV, and PIVs are required. A transport medium such as 40% sucrose in Eagle minimal essential medium (EMEM) or 15% plant glycerol (Fisher Scientific, catalogue no. G-33-500) in Iscove's medium (BioWhittaker, Inc., catalog no. 12-722Q) stabilizes RSV, HMPV, and PIVs and improves the recovery of virus during prolonged transportation of the specimen. The nasal wash specimen is combined with the transport medium in a 1:1 ratio. Normally 2 ml of nasal wash is added to 2 ml of transport medium. Transport media should not contain fetal bovine proteins, an important issue for vaccine development. A disadvantage for sucrose-containing transport media is that at concentrations above 5%, sucrose is toxic to the cell monolayer and a final sucrose concentration of 15% or greater is required to stabilize RSV. Nasopharyngeal aspirates can be sent undiluted to the laboratory if they are transported rapidly on ice and processed within 4 h of collection.

A cell culture tube is the conventional cell culture method for growing respiratory viruses. It is a simple and inexpensive procedure, but RSV and PIV can take 3 to 14 days to grow, depending on the concentration of viable virus in the specimen. A shell vial method can identify RSV or PIV in 24 to 48 h but is more complicated and expensive and at times less sensitive. The shell vial method uses low-speed centrifugation to inoculate the specimen onto the cell monolayer which is growing on a glass coverslip. At 24 to 48 h, the monolayer is fixed and an IF assay is used to detect RSV or PIVs. Antibody against HMPV is not currently commercially available. A hospital or diagnostic laboratory is able to isolate and easily identify RSV and PIVs; however, HMPV is not isolated unless special growth conditions are used. The procedure described in this section has been published previously (18, 33, 41), but more detail is included here.

Materials

A HEp-2 cell culture tube (BioWhittaker, Inc., catalog no. 71-136D) is used for isolation of RSV; an LLC-MK2 cell culture tube (a monkey kidney cell line; BioWhittaker, Inc., catalog no. 71-197D) is used for isolation of HMPV; and a rhesus monkey kidney (Rh MK) cell culture tube (BioWhittaker, Inc., catalog no. 70-103D) is used for isolation of PIVs. These cell lines are most permissive to the above-mentioned viruses; however, any of the viruses can at times be isolated from most cell lines. The cell culture tubes, EMEM, antibiotics, antifungal, and trypsin are commercially available.

Identification of RSV or PIV Antigens in Epithelial Cells Shed in Nasal Secretions

Rapid diagnosis of either RSV or PIV infection can be confirmed in a few minutes to a few hours by demonstration of viral antigen in exfoliated cells in respiratory secretions or nasal wash specimens. In the past decade, a number of ELISA-based commercial tests have been developed for this purpose, each of reasonably high sensitivity and specificity for use in diagnosis of children, as an alternative to the more tedious IF procedures for detecting virus in exfoliated cells. They use proprietary reagents formulated on a matrix (e.g., a tablet or membrane) that forms the substrate on which an aliquot of respiratory secretions is layered. The matrix develops a color reaction when the secretions contain a sufficient amount of virus to react in a positive manner. Several direct enzyme immunoassays for RSV are available (DAKO Directigen RSV; Abbott TestPack RSV). The choice of commercial kit depends on the sensitivity and specificity and the rapidity of the color reaction (29, 40). Also, several IF kits have been developed to simplify this procedure, including a monoclonal antibody-based IF test (Imagen RSV; DAKO) to facilitate the detection of viral antigen in exfoliated cells (15, 22). IF kits are available that incorporate monoclonal antibodies to several respiratory viruses, including RSV and PIV, and provide a rapid screening procedure to identify these infections in clinical samples of respiratory secretions (22).

RT-PCR for Detection of Viral RNA Sequences of RSV, HMPV, and PIVs

RT-PCR is a technique for in vitro amplification of specific viral RNA sequences. It can identify infections missed by cell culture, IF assays, and rapid diagnostic test kits. It is ideally suited for the detection of viruses that are difficult to isolate by cell culture. RT-PCR is currently the best available method for detecting HMPV and frequently enhances the ability to diagnose infection, particularly in adults (4). RT-PCR can be applied to the detection of viral nucleic acid in cell culture harvest of specimens positive for CPE or Had, clinical samples of respiratory secretions and middle ear effusions, and other sites of virus infection. RT-PCR is being increasingly used in some hospital laboratories. There is growing interest in its use as a screening procedure for detecting viral RNA of several respiratory viruses simultaneously in clinical specimens (multiplex RT-PCR), for detecting viruses that are difficult to cultivate, and for detecting viruses for which commercial diagnostic reagents are lacking. It is highly sensitive and specific. A limitation of RT-PCR is the expense and meticulous attention required to prevent carryover contamination. Prevention of carryover contamination requires a separate room for sample preparation, a separate area for RT-PCR setup, and a separate room for post-PCR analysis. In addition, there is the need for traffic control from clean or pre-PCR to dirty or post-PCR areas. Use of dedicated lab coats and plugged pipette tips also helps reduce carryover contamination.

RT-PCR is divided into three major procedures: nucleic acid extraction, cDNA synthesis and amplification, and detection of cDNA product. An additional procedure for the confirmation of the virus-specific amplicon by Southern hybridization can be performed and is often desirable for research. Significant advancements have been made in facilitating the use of RT-PCR assays in hospital and research laboratories. Commercially available reagents and kits such as the viral RNA extraction kits (Q1Amp viral RNA mini kit; Qiagen Inc., Valencia, Calif.), the One Step Qiagen kit (Qiagen Inc.) for cDNA synthesis and amplification, primers, and the affordability of thermocyclers have made it feasible for RT-PCR to become a common and invaluable laboratory assay. The development of real-time PCR utilizing a LightCycler platform, a combined thermocycler and fluorimeter, has added to the speed, reproducibility, specificity, and sensitivity of the assay compared to conventional RT-PCR (25). An additional benefit of real-time PCR is the use of a single closed reaction vessel for nucleic acid amplification and detection, thus reducing the risk for environmental contamination from the amplicons.

RT-PCR is used for specific detection of RSV, HMPV, and PIV genomes in clinical specimens (1, 4, 7, 10, 13, 29). Advances in the technical aspects of this technique now allow both RT and PCR to be carried out in the same tube.

The amplified DNA PCR products are analyzed by agarose gel electrophoresis, in which DNA of known size is visualized by ethidium bromide staining of the gel when viewed under UV light (and photographed for a permanent copy) or by hybridization with a specific probe (Southern hybridization). Alternatively, fluorescent adjacent or TaqMan probes are used in the real-time PCR format. Depending on the virus, different genes are targets of amplification. The genes encoding the NP, F (note that G is very variable and mainly used for epidemiological studies), and SH proteins of RSV, the NP, L, F, and M proteins of HMPV, and the M and hemagglutinin-neuraminidase (HN) genes of PIV are often targeted for amplification. Selection of amplification primers aims at the sequences of the conserved regions of these genes and is based on analyses of these known sequences from several strains of the virus as available in published databases such as GenBank (10). The success of the amplification depends on the quality of the primer sets and on whether more than one set, called nested primers, are needed for amplification. Various RT-PCR procedures including real-time PCR for detection of RSV, HMPV, and PIV, using different primers and genes, have been developed and provide a starting point for applying this procedure to the diagnosis of RSV, HMPV, and PIV in clinical specimens (1, 4, 7, 8, 10, 13, 15, 17, 28, 29). Antigenic and genetic heterogeneities exist within the two major antigenic groups of RSV and HMPV and can be differentiated by PCR-based assays and restriction fragment analysis. Methods for the rapid analysis of samples of RSV using PCR followed by restriction mapping have been described (6). Clinical samples or tissue culture-grown RSV and HMPV can readily be divided into subgroups and then further classified into lineages. These methods enable the examination of large numbers of isolates by molecular biology-based techniques, thereby facilitating research into the molecular epidemiology of the virus. A description of a conventional RT-PCR procedure used in our laboratory for the identification of HMPV from infected LLC-MK2 cell culture can be found in reference 4.

A partial list of primers for RSV, HMPV, and PIVs is given in Table 1. Most of the primers listed are for HMPV because RT-PCR is currently the principal method for the detection of HMPV. In general, primers targeting the L, N, and F genes of HMPV provide the greatest sensitivity for detecting clinical HMPV isolates. Each set of primers listed below will require different thermocycling times according to its reference. It is important to use quality control procedures to ensure the accuracy of the RT-PCR test and to reduce carryover contamination.

COMMON SEROLOGIC TESTS

There are a number of substrates that work well for ELISA. Appropriate substrates for individual enzymes are available from several commercial sources. 5-AS forms a vivid purple color when acted upon by peroxidase, but other substrates of horseradish peroxidase can be used equally well.

ELISA for Measurement of RSV Antibodies
Several ELISA procedures for whole virus or viral proteins have been devised for the measurement of binding antibodies to RSV in serum, breast milk, and respiratory tract specimens from persons of all ages (12, 26, 27, 33, 34, 38, 39). Examples of some of these procedures can be found in the above references.

IF Test for Determination of RSV Antibodies
IF procedures for determination of RSV antibodies in human serum have been used for at least two decades. The procedure is easy to perform but not easily adapted to the evaluation of large numbers of specimens (23).

WB Test for Detection of Antibodies to Surface and Internal RSV Proteins
WB analysis has been used to help discriminate immune responses associated with subunit RSV vaccine from those associated with natural RSV infection (33). The WB assay is used to detect antibody binding to internal and surface

proteins of RSV. The antigen used is sucrose-purified RSV. Color development of bands with molecular masses 76, 50, 42, 35, and 28 kDa corresponded to RSV proteins G, F_1, NP, P, and M, respectively. The identities of the RSV proteins are confirmed using purified monoclonal antibodies to the proteins. Significant antibody detection occurs if there is an increase in the intensity of a preexisting band or the identification of one or more new bands that correspond to RSV proteins.

HI Test for Determination of PIV Antibody

Antigen consisting of untreated virus harvested from cell culture can be prepared by low-multiplicity infection of rhesus monkey kidney cells and harvesting of the virus at maximal hemagglutination activity. A sample of culture medium is tested daily for the presence of viral antigen and virus is harvested on the day of high-titer antigen, usually after 5 days of incubation. The untreated virus is then frozen in small aliquots at −70°C, incorporating bovine serum albumin (BSA) at a final concentration of 0.5% for antigen stabilization. A 0.1-ml volume of a 10% suspension of sterile BSA is added to each 1.9 ml of virus antigen, and the solution is adjusted to pH 7 with 1 or 2 drops of 1 N NaOH.

Treatment of Cell Culture-Grown Virus with Tween 80 and Ether Increases the Hemagglutinin Titer

Tween 80 at a final concentration of 0.01% is added to the virus harvested from cell culture. Ether is added to increase the total volume by one-third. Hemagglutination antigens can be purchased from commercial sources also (e.g., BioWhittaker, Inc.). For the microtiter procedure, U-well plastic disposable plates are preferred, since the hemagglutination patterns in U-shaped wells are interpreted readily. Initially, antigen lots must be titrated, and a dilution of antigen containing 1 hemagglutinin unit per unit volume should be determined. Antigen is used at 4 U per unit volume in the HI test.

NT Test for Determination of RSV Antibody

Neutralizing antibody to RSV can be measured by plaque reduction, by tube NT procedures, or in microtiter plates. The plaque reduction and microneutralization assays provide an especially sensitive measurement of neutralizing antibody to RSV subgroups A and B. The use and interpretation of these assays are facilitated by techniques which produce either large, clear plaques (1 to 2 mm in diameter [plaque reduction assay]) or tissue destruction (microneutralization assay) in susceptible cell monolayers (HEp-2 or Vero cells). The sensitivity of HEp-2 cells for replication of RSV varies with the source of the cells, and several lines may have to be tested before a sensitive one is detected. Several plaque reduction and microneutralization procedures for RSV neutralizing-antibody measurement have been described, each with slight but modest variations in test procedures. The microneutralization procedure provides end points in 6 to 7 days (33, 34). The microneutralization assay is performed on HEp-2 cells in 96-well tissue culture plates. Plaque-purified RSV is frequently used. Serial twofold dilutions of heat-inactivated sera are made in duplicate, often starting at 3 $\log_2$ dilution. The last serum dilution at which a ≥50% reduction in viral CPE is observed is defined as the neutralizing-antibody titer.

HMPV Microneutralization Protocol

HMPV microneutralization is similar to the RSV microneutralization assay except for some key points. A 48-well microtiter plate works best for this assay. The medium consists of EMEM with trypsin, glutamine, and antibiotics but without fetal calf serum (as described earlier in Tissue Culture Cell Methods). A complete cell monolayer of LLC-MK2 cells rather than trypsinized cells is used for the assay. Serial twofold dilutions of heat-inactivated sera are incubated with HMPV before being transferred onto wells with complete LLC-MK2 monolayers (41).

Measurement of NT Antibody for PIV

For the measurement of the level of antibodies to the four PIVs, individual tests must be carried out with the specific virus type as the test virus in the NT test. Since PIVs do not usually produce CPE in cell culture but do exhibit hemadsorption, the end point of the NT procedure is the demonstration of HadI.

Measles and Mumps

DIANE S. LELAND

80

Measles virus, also called rubeola, and mumps virus are both RNA viruses of the family *Paramyxoviridae*, subfamily *Paramyxovirinae*; measles virus is in the *Morbillivirus* genus, and mumps virus is in the *Rubulavirus* genus. These viruses cause classic 7-day measles and mumps, respectively. Both were included among the expected illnesses of childhood in the United States prior to the introduction of vaccination programs in the late 1960s. Measles epidemics involving 500,000 to 700,000 cases occurred every 2 years (4), and approximately 150,000 cases of mumps were reported annually (7). Measles continues to be a major concern globally, ranking as the fifth leading cause of mortality worldwide for children younger than 5 years. Of 777,000 childhood deaths attributed to measles in 2000, most occurred in Africa (58%) and Southeast Asia (26%) (9).

In measles virus infection, after 1 to 2 weeks of incubation, fever, rhinorrhea, cough, and conjunctivitis appear, followed by a maculopapular rash and Koplik spots (1- to 3-mm-diameter red spots with a bluish-white speck in the center located on the buccal mucosa—pathognomonic for measles). The rash usually lasts 7 days, and recovery is rapid and complete. The complications of measles may include otitis media, lower respiratory infections, confusion, and seizures. Subacute sclerosing panencephalitis (SSPE) is believed to be a persistent measles infection of the central nervous system. Onset is 4 to 7 years after the initial measles episode and is characterized by personality changes, mental deterioration, involuntary movements, and muscular rigidity, invariably ending in death (4).

Mumps, which is clinically inapparent in 25 to 30% of cases, is typically mild and characterized by slightly elevated temperature and enlargement of one or both parotid glands. Complications of mumps include meningoencephalitis (up to 15% of cases) and, in postpubertal individuals, orchitis (20 to 30% of males) and oophoritis (7% of females) (7). Mumps remains common throughout much of the world.

The epidemiology of both measles and mumps, along with that of rubella virus (3-day or German measles), changed dramatically with the aggressive vaccination programs implemented in the United States in the 1960s. The number of measles and mumps cases in the United States decreased rapidly throughout the 1970s and 1980s. In 1986 to 1987, there was a brief resurgence of mumps cases that peaked at 8,000 to 12,000 cases. A similar resurgence in the number of measles cases occurred in 1989 to 1991, peaking

at nearly 30,000 cases. Resurgences were attributed to susceptible populations of children under 5 years of age residing in urban settings and to an accumulation of underimmunized children born between 1967 and 1977 (4).

Following the resurgences mentioned above, a two-dose schedule was implemented for the combination measles, mumps, and rubella (MMR) vaccine in the United States. The first dose is given between 12 and 15 months, and the second dose is given between 4 and 6 or 11 to 13 years. The protective value of the second dose of vaccine is reflected in the current low numbers of measles and mumps cases. The United States experienced a record low of 44 confirmed cases of measles in 2002. Eighteen of these cases were internationally imported; 15 additional cases resulted from exposure to the imported cases, and 3 additional cases were caused by measles viruses with genotypes consistent with imported sources (8). SSPE has been largely eliminated in countries like the United States in which measles has been reduced to low levels for more than a decade. Only 231 mumps cases were reported in the United States in 2002 (8), but isolated outbreaks continue to occur.

Transplacental transfer of antibodies traditionally provided protection from measles and mumps infections for infants for 6 months or longer after birth. Currently, the level of transplacental antibody is lower at birth and infants are more susceptible because the level of protection is lower in infants born to mothers whose measles and mumps immunity is vaccine induced. By 6 months of age, only 18% of infants born to vaccinated mothers were shown to have protective levels of measles antibodies; this is in contrast to the 50% of infants born to naturally infected mothers (24). Premature infants (<32 weeks gestation and weighing <1,000 g) may demonstrate seronegativity of 45% for measles and 55% for mumps, with further deterioration of immunity over the next 3 months, resulting in seronegativity of 94% for measles and 100% for mumps (13).

Interestingly, despite the lower levels of measles-specific antibody following vaccination compared to those after natural infection, antibody in vaccinated individuals has been shown to persist (12). Measles antibody has been detected in two-dose MMR vaccine recipients 26 to 33 years after vaccine administration, with 92% of these individuals showing antibody at protective levels.

With the decrease in incidence of both measles and mumps, the demand for diagnostic services has changed.

Although previously diagnosed on clinical grounds alone, both infections are now so rare that they are not readily recognized by physicians. Likewise, they may occur in underimmunized individuals or in immunocompromised individuals, in whom typical clinical signs and symptoms are absent. Due to the low incidence of measles in the United States, the clinical case definition, which included generalized maculopapular rash, fever, and either a cough, coryza, or conjunctivitis, currently has a low positive predictive value. Serological (or other laboratory-defined) confirmation is essential to ensure an accurate diagnosis (16).

DIAGNOSTIC STRATEGIES

Although both measles virus and mumps virus can be isolated in cell culture, isolation may be difficult due to the need to collect specimens very early in the infection process and to the slow proliferation and weak to absent production of cytopathogenic effect by these viruses in traditional tube cell cultures. Newer modified cell culture techniques involving detection of viral antigen in shell vial cultures have improved the sensitivity and speed of measles and mumps virus isolation. However, for both viruses, cell lines optimal for virus isolation and the specialized reagents needed for confirmation may not be kept on hand at many diagnostic laboratories. Virus isolation, although desirable because of the yield of a viral product that can be used in additional studies such as genotyping, may be unsuccessful even in confirmed cases.

Molecular techniques, which do not rely on the presence of viable virus, can be used to detect viral RNA directly in clinical samples. Molecular testing by reverse transcriptase PCR (RT-PCR) may yield positive results in instances when virus culture is unsuccessful. Measles virus RNA has been detected in many types of clinical samples at various time intervals. Measles virus RNA has been detected in throat samples of 93% of patients during the period of 5 days before until 12 days after onset of symptoms, and 88% of patients may secrete measles virus RNA in their urine until 5 weeks after onset of symptoms (25). In a study of nearly 30 measles virus-infected patients, measles virus RNA was detected by RT-PCR within 3 days of appearance of the rash in plasma of 100% of the patients and in nasopharyngeal samples and peripheral blood mononuclear cells of 96% of the patients (20). Shedding of measles virus RNA in urine, nasopharyngeal samples, and peripheral blood mononuclear cells has been documented for 30 to 60 days after the onset of rash, with shedding more frequently prolonged in human immunodeficiency virus-infected children (21). Likewise, mumps virus RNA has been detected by RT-PCR in oral fluids, cerebrospinal fluid (CSF) (22), saliva or throat specimens, and urine specimens (1). Molecular methods are more expensive than virus isolation but may provide a viable approach for confirming the presence of measles or mumps virus.

The serologic approach, relying on detection of antibodies for confirmation of infection, has long been the most accessible and reliable diagnostic tool for confirming measles and mumps virus infections. In natural infection by both measles and mumps viruses, the antibody response upon infection is predictable and consistent. Immunoglobulin M (IgM) is detectable initially within 3 to 4 days of appearance of clinical symptoms and persists for 8 to 12 weeks. IgG is detectable within 7 to 10 days of the onset of symptoms, is maintained at high levels for years, and remains detectable for life. After vaccination, measles virus-specific IgM positivity

rates have been reported as follows: 2% at 1 week, 61% at 2 weeks, 79% at 3 weeks, and 60% at 4 weeks. IgM may persist for 8 weeks or longer. After vaccination, measles IgG positivity rates are as follows: 0% at 1 week, 14% at 2 weeks, 81% at 3 weeks, and 85% at 4 weeks (15).

Although antibodies against various viral proteins are produced, protection is most closely correlated with antibodies to the measles virus hemagglutinin (H) protein and the mumps virus hemagglutinin-neuraminidase (HN) protein. Most assays use whole virus or viral extract antigens that will detect antibodies of various specificities, but most detect antibodies against the measles H and mumps HN proteins effectively.

The most widely used methods in measles and/or mumps antibody detection are enzyme immunoassay (EIA) and indirect immunofluorescence assay (IFA). Complement fixation (CF), hemagglutination inhibition (HI), neutralization (NT), and plaque reduction neutralization (PRN) are seldom used in diagnostic laboratories but may be available at reference or research facilities. A brief description of each of these methods is presented later in this chapter. EIAs and IFAs can be designed to detect either IgG or IgM, and PRN can be modified to allow a comparison of IgM and IgG levels, as well as to measure the total (IgG and IgM) response. The other methods detect total response and do not distinguish between IgG and IgM. Commercial kits for EIA and IFA are readily available, and testing is not difficult to perform. The other assays are more complicated, requiring a variety of reagents and considerable expertise on the part of the technologist.

Acute infection or vaccination with either measles or mumps virus is confirmed when virus-specific IgM, regardless of level, is detected in a sample collected 4 days to 6 weeks after the virus exposure or onset of symptoms. EIA, IFA, and PRN are suitable methods for detecting IgM, but these assays may be available only at reference or state health laboratories. Acute infections can also be confirmed with IgG-specific EIA and IFA or by total antibody detection by CF, HI, NT, or PRN, if the antibody level in the second of two samples collected 2 weeks apart can be shown to be significantly higher than that of the first sample. With assays performed in serial twofold dilutions, a fourfold increase in antibody level between acute- and convalescent-phase samples confirms infection. For methods such as EIA that are not performed with serial dilutions, the manufacturer must provide guidelines for defining significant differences in antibody level. No standardized interpretation is available.

The laboratory confirmation of SSPE is less straightforward. Measles virus often cannot be isolated, due to its defective nature, and antibodies are detectable but in abnormally high quantities. A comparison of levels of antibody in serum and CSF shows greater elevations in the CSF than in the serum (5).

Most measles and mumps antibody testing in the United States is conducted to determine the immune status of health care workers or to assess vaccine effectiveness. Commercially available EIAs and IFAs have shown acceptable sensitivity and specificity for this purpose. EIA endpoints, however, are usually set to maximize confidence in positive results, causing these methods to yield false-negative results in low-titered immunity (5). In situations where very low levels of antibody are suspected, the NT and HI assays for measles and mumps antibodies and the PRN assay (for measles) may need to be requested.

TECHNOLOGY

Molecular Methods

Reagents and procedures for molecular methods for measles and mumps virus RNA detection are not well standardized, so protocols for these assays will not be presented here. RT-PCR, which is described elsewhere in this volume, is the approach of choice and has been applied for detection of measles and mumps virus RNA in infected cell cultures as well as in clinical samples. Simple detection as well as genotyping may be accomplished with this approach. Various gene targets on the viruses, primer and probe compositions, amplification methods, and visualization protocols have been employed. Sources cited below present procedural details for RT-PCR as reported in individual studies.

A one-step RT-PCR for measles virus RNA performed directly on plasma, nasopharyngeal samples, and peripheral blood mononuclear cells has been described elsewhere (20). A new multiplex nested RT-PCR has been shown to simultaneously detect and identify measles and rubella viruses, along with human parvovirus B19, in using pharyngeal exudates, CSF, and serum (18). As a result of the current lack of standardization, comparison of various in-house RT-PCR assays for measles virus RNA has shown that laboratories could differ in sensitivity by as much as 1,000-fold in their ability to detect measles virus (2).

A nested RT-PCR assay has been used to detect mumps virus RNA (1). RT-PCR has also been applied after enrichment of viral template RNAs by overnight culture of the virus in Vero cells and the substitution of polyacrylamide gel analysis for agarose gel electrophoresis (6). These modifications enhanced sensitivity, providing for detection of 1 to 20 infectious units of virus or an equivalent of 1 to 10 pg of mumps virus-specific plasmid DNA. A TaqMan-based one-step real-time RT-PCR for detection and quantification of mumps virus RNA was able to quantify concentrations of a mumps virus gene ranging from 10^1 to 10^8 copies per reaction (17).

Serologic Methods

(Note: the basic principles underlying many of the following assays are described elsewhere in this volume.)

The specimen collection guidelines are similar for most serologic assays: collect whole blood, separate serum, store the serum in the refrigerator (2 to 8°C) for up to 48 h, and freeze the serum (−20°C) if testing will be performed after 48 h. For most methods, heat inactivation of the serum (incubation at 56°C for 30 min) is not required. Some methods specify that heat-inactivated samples cannot be used. In general, contaminated, hemolyzed, lipemic, or icteric specimens should not be used.

An alternative to serum collected by venipuncture is whole blood obtained by fingerstick or heel prick, spotted on Whatman filter paper, air dried, sealed in air-tight packets, and stored at 2 to 8°C. Venous blood collected by venipuncture may also be spotted on filter paper and stored. Following elution and dilution of the dried blood sample, commercial EIAs may be used to test the sample. Results of EIA testing for measles (3, 10, 11, 14, 19) and mumps (11) virus IgG and IgM from dried blood spots have shown excellent correlation with those of fresh serum or plasma testing. Storage of blood spots for up to 24 months without significant change in antibody testing results has been demonstrated, although storage for 6 months or less is recommended (23). Prior to testing, the dried blood is eluted from the filter paper by using phosphate-buffered saline (PBS) with Tween 20 at room temperature for 30 min. The eluted sample is then diluted in PBS containing 5% fat-free milk powder before being tested by EIA (11).

EIA

Most diagnostic laboratories use commercially supplied measles and mumps antibody EIA systems. Protocols provided and validated by the manufacturer must be followed without modification if results are to be of the expected quality. The typical configuration involves an antigen-coated solid phase (often microwells). The antigen may be an extract of cells infected with virus (often Edmonston strain for measles and Enders strain for mumps) or a recombinant protein. Testing is performed either manually or with an automated system. All controls are supplied by the manufacturer to ensure accuracy and reproducibility. Most EIAs detect only IgG, but IgM-specific EIAs are available. These may include an "IgM capture" step featuring microwells coated with antibodies against human IgM. In the first step of the assay, the patient's serum is added to the antibody-coated microwell, and any IgM present in the sample is bound, or captured. In subsequent steps, reagents are added to confirm that the captured IgM is indeed specific for the virus. Most large reference laboratories list measles- and mumps-specific IgM testing in their menus.

IFA

IFA is used for both measles and mumps antibody detection. Written procedures, along with proper reagents and controls, are included with each commercial product, and manufacturers' guidelines must be followed. Like the EIAs, most IFAs are designed to detect IgG antibodies, but they can be used for IgM detection. Usually, IgM-specific IFA testing is preceded by an IgM separation step (column separation or addition of anti-IgG) to separate IgM from IgG.

CF

CF depends on the binding of antibodies to the viral antigen to make antigen-antibody complexes that bind complement. CF is a lengthy and cumbersome method of antibody detection. Few diagnostic laboratories currently use this method for measles or mumps antibody determinations because the EIAs and IFAs are more sensitive and so much easier to perform.

NT

Virus NT measures the capacity of serum antibody to neutralize live virus, thus preventing it from infecting susceptible cell cultures. NT testing requires laboratory facilities suitable for management of live, infectious viruses and cell cultures. The virus must be quantitated prior to the start of the assay, and cell cultures are observed to determine the result. This method is sometimes considered the reference method against which other assays should be compared because neutralizing antibodies considered protective for infection are measured.

HI

An overview of the HI test for measles and mumps antibodies is presented below. A detailed procedure is available in previous editions of this manual (23a, 23b).

Antigens

Commercially purchased measles and mumps virus hemagglutinating antigens are used. Antigen suspensions must be

treated to break up antigenic particles and titrated to determine a challenge dose of 2 50% hemagglutinating units.

Erythrocytes

For measles virus antibody testing, use African green, Patas, or rhesus monkey erythrocytes. For mumps virus antibody testing, use chick, goose, or monkey cells.

Specimen Preparation

Serum, plasma, or CSF may be used. Nonspecific inhibitors of agglutination must be removed from serum or plasma by treatment with saturated ammonium sulfate, and nonspecific agglutinins must also be removed by mixing inhibitor-free sample with packed erythrocytes. CSF is usually free of nonspecific inhibitors and agglutinins.

Performance of the Test

A U-bottom microwell plate may be used to prepare serial twofold dilutions from 1:2 to 1:2,048 for each sample for the measles virus test and from 1:10 to 1:640 for the mumps virus test. Add prepared, titrated hemagglutinating antigen to serum dilutions, incubate the mixture, and add a 0.5% erythrocyte suspension to all wells. Allow erythrocytes to settle. Read for hemagglutination.

IgG and IgM titers can be determined separately in a series of three titrations. The first is carried out as described above. The second titration uses serum that has been extracted with *Staphylococcus aureus* protein A, and the third titration is conducted on sera that have been further treated for 30 min with 0.2 volume of 1 M 2-mercaptoethanol. The IgG level is the difference between the arithmetic titers of the first two tests, and the IgM level is the difference between those of the second and third tests. IgG3 and IgA remain in the third test.

PRN (Measles Only)

An overview of the PRN test is presented below. A detailed procedure is available in previous editions of this manual (23a, 23b).

Challenge Virus

Use a line of virus that has been through a plaque passage fewer than five cycles previously.

Cell Cultures

Use Vero cells grown to confluence in 24-well (16-mm-diameter) plates.

Performance of the Test

Mix portions of serial dilutions of inactivated serum with an equal volume of virus containing 125 PFU. Incubate the mixtures for 1 h at 37°C. Use this mixture to inoculate cell cultures drained of their medium. Incubate the cultures for 1 h at 37°C. Replace the inoculum with agarose overlay. Incubate for 4 to 7 days (with timing determined by plaque formation). Remove the overlay, stain the cells with neutral red diluted in cell culture medium, and count the plaques. A 50% reduction in plaque count, relative to controls, is considered the endpoint.

INTERPRETATION

Measles

The presence of measles virus RNA in clinical samples is evidence for current or very recent infection or vaccination. The interpretation of measles serologic testing results is gen-

erally uncomplicated, with the presence of IgM indicating current or recent experience with the virus, either through infection or vaccination. However, interpretation of a positive IgM result from a person with suspected measles can be difficult if the person has recently received measles vaccine. Because measles virus-specific IgM may appear as early as 8 days after vaccination and persists for at least 8 weeks after primary vaccination, IgM-positive results obtained during this time should not be assumed to confirm infection (15). IgM is not produced routinely upon revaccination of previously immunized persons but may be detected following clinical measles in these individuals (4). An absence of IgM does not rule out measles virus infection. Samples collected within 72 h after onset of rash may not yet contain detectable IgM, and IgM may not be produced in infection of those previously immunized (4).

A significant increase in IgG level between acute- and convalescent-phase samples is also indicative of infection or vaccination but may be seen in individuals with a history of natural infection or vaccination when they are again exposed to the virus. Failure to detect a significant increase between acute- and convalescent-phase samples in infection may occur if the samples are collected too long after the onset of symptoms.

Mumps

As with measles virus infection, the presence of mumps virus RNA in clinical samples is evidence for current or very recent infection or vaccination. However, the interpretation of mumps antibody testing results is less straightforward than that of measles. Mumps IgM may be detected, along with significant increases in IgG, in patients infected with related viruses, such as the paramyxoviruses. In general, cross-reactivity with related viruses can be ruled out by testing for these antibodies in parallel with mumps antibody testing. The greatest increase in antibody level should identify the true infection. Virus isolation is the most accurate method for resolving this issue. Interpretation of mumps serology, like that of measles, can be obscured in patients who were previously vaccinated. Various therapeutic treatment regimens such as chemotherapy may result in a decrease in seropositivity for measles and mumps.

Interpretation and Applications of Laboratory Results in Diseases of Low Prevalence

Even assays of high specificity will have a low positive predictive value in populations with low prevalence (<1%) of infection, making a high percentage of positive results false positives (3). This precautionary note fits well with the current status of measles and mumps infections in the United States, suggesting that a single positive laboratory value should be carefully scrutinized. Thorough clinical histories and confirmatory laboratory testing are warranted in order to differentiate true-positive from false-positive laboratory findings. For example, a single positive measles IgM result should be supported or confirmed with follow-up measles IgG testing to demonstrate serconversion from negative to positive or a significant increase in IgG titer. Also, in this case, detection of measles virus RNA in clinical samples would give the necessary confirmation and would do so more quickly than monitoring of the IgG level.

Rubella Virus

JAMES B. MAHONY

81

For most virology laboratories in North America, rubella virus has all but dropped off the radar screen, with few diagnostic requests. This is in part due to the World Health Organization's effort to reduce congenital rubella syndrome (CRS) from its current level of over 100,000 cases annually via the introduction of mass vaccination programs in resource-poor countries. Live attenuated vaccines, introduced in the late 1960s, are currently in use in roughly half of the countries in the world. National immunization programs for rubella have increased from 78 countries in 1996 to 123 by the end of 2002 (2). Despite the introduction of new vaccination programs, rubella outbreaks continue to occur in many countries around the world, and babies diagnosed with CRS have recently been reported in Italy, Greece, China, Australia, and Japan (17). Recent surveys of rubella virus antibody titers in women of child-bearing age (20) indicate that vaccination programs are not reaching all populations and that the risk of CRS remains. A recent case of a congenitally infected baby born to a vaccinated woman with detectable rubella antibody has raised concern about the efficacy of the measles, mumps, and rubella (MMR) vaccine (22). The efficacy and safety of the MMR vaccination have been under intense scrutiny over the past 2 years, with links between MMR vaccine and autism (15). In the wake of recent discussions about the safety of live vaccines in patients with DiGeorge syndrome/velocardiofacial syndrome (14), novel approaches to immunization have been initiated, including the development of a recombinant rubella virus E1 glycoprotein vaccine.

Rubella virus is a single-stranded RNA virus with 9,762 nucleotides and is classified as a member of the *Togaviridae* family. Rubella virus possesses three major structural proteins: two envelope glycoproteins, E1 and E2 (58 and 42 to 47 kDa, respectively), and a nucleocapsid protein, C (33 kDa). Morphologically, rubella virus is spherical (diameter, 60 to 70 nm) and possesses a dense nucleoprotein core surrounded by a lipid bilayer that contains glycoproteins E1 and E2. Rubella virus is destroyed by proteinases and lipid solvents but is relatively resistant to freezing and thawing or sonication. Viral RNA and protein are synthesized in the cytoplasm and combine to form nucleoprotein cores, which are then assembled into mature virions at marginal cytoplasmic membranes by joining with viral glycoproteins previously compartmentalized in the Golgi network. Although this mechanism of virus replication is similar to that of other togaviruses, rubella virus is unique and immunologically distinct from all other togaviruses. Rubella virus is antigenically stable, and antigenic variation has so far not been an issue for vaccination or serological diagnosis; the significance of the possible emergence of new international subgenotypes of rubella virus is unknown (24). Rubella virus is found only in human populations and as far as we know has no counterpart in the animal kingdom. It is for this reason that rubella virus has been placed as the only member in the separate genus *Rubivirus*.

Postnatal rubella (German measles) is transmitted chiefly through direct or droplet contact from nasopharyngeal secretions. The peak incidence of infection is in the late winter and early spring. Subclinical infection is common. The period of maximum communicability appears to be a few days before and 5 to 7 days after onset of the rash. Volunteer studies indicate the presence of rubella virus in nasopharyngeal secretions from 7 days before to 14 days after the onset of the rash. Infants with congenital rubella may continue to shed virus in nasopharyngeal secretions and urine for 1 year or more and may transmit infection to susceptible contacts. Virus can be isolated from the nasopharynx at 6 months of age in approximately 10 to 20% of these patients.

Prior to the widespread use of rubella virus vaccine, rubella was an epidemic disease with 6- to 9-year cycles; the majority of cases occurred in children. Currently, in North America, the incidence of rubella has declined by more than 99% in comparison with the prevaccine era. In North America, the risk of acquiring rubella has declined sharply in all age groups, with a greater percentage of the cases now occurring in young, unvaccinated adults. Recent serological surveys in the developed world have indicated that 10 to 20% of young adults are susceptible to rubella. This degree of susceptibility in young adults is due predominantly to underutilization of vaccine in this population, not to waning immunity in immunized persons. In developing countries where mass vaccination programs have not been initiated, significantly larger proportions of the population are susceptible to rubella virus infection. For this reason, most infections seen in North America occur in immigrants from countries where immunization has not reached.

The incubation period for postnatal rubella ranges from 10 to 21 days, averaging 16 to 18 days. It is usually a mild disease characterized by an erythematous maculopapular discrete rash, postauricular and suboccipital lymphadenopathy, and slight fever. Some 25 to 50% of infections are asymptomatic.

Transient polyarthralgia and polyarthritis that occasionally occur in children are extremely common in older individuals. Encephalitis and thrombocytopenia are rare complications.

Antibodies to the virus appear as the rash fades (Fig. 1), and initially, both immunoglobulin G (IgG) and IgM antibodies can be detected. Antibodies of the IgM class generally do not persist beyond 4 to 5 weeks after onset of illness (13), while IgG antibodies usually persist for life. Reinfection with the virus can occur, but it is almost always asymptomatic and can be detected by a rise in IgG antibodies. The risk of fetal damage resulting from reinfection during pregnancy is low, but a recent case of CRS in a woman who seroconverted following vaccination has been reported (22). The attenuated virus vaccines induce production of IgM and IgG antibodies similar to that observed with natural infections except that the titers are generally lower. Reinfection rates with wild-type virus are greater among vaccinees than among persons previously infected under natural conditions.

LABORATORY DIAGNOSIS

Clinical laboratories are called upon to diagnose rubella virus infections and to perform rubella immunity screening. Because virus isolation procedures are slow and expensive and host antibody responses are rapid and specific, serological procedures are usually performed for disease diagnosis (the exception would be virus isolation from a congenitally infected newborn). Reliable and sensitive laboratory technology has been developed for the measurement of rubella antibodies of the IgM and IgG classes. These serological tests are used to diagnose congenital rubella and postnatal rubella infections (usually in children or young adults) and to determine the immune status for rubella. In the past, various techniques have been used to measure rubella antibodies, including hemagglutination inhibition (HI), passive hemagglutination (PHA), hemolysis in gel, latex agglutination (LA), enzyme immunoassay (EIA), fluorescence immunoassay, radioimmunoassay, complement fixation (CF), and a variety of rubella virus-specific IgM antibody assays. However, laboratories now generally use commercially available EIAs for IgG and IgM detection. An international standard serum is now available,

and an antibody concentration of 10 IU/ml is generally accepted as the level conferring immunity.

Investigation of rubella virus infection in pregnancy presents a special challenge demanding a rapid and accurate diagnosis. If the patient develops clinical signs, a serum specimen should be collected immediately and tested for the presence of rubella virus-specific IgM by EIA (1, 3). Alternatively, it may be paired with a second serum sample collected 5 days later. The two samples should be investigated in parallel in the same test on the same day. A fourfold or greater rise in HI, CF, or neutralization antibodies, together with clinical symptoms, is diagnostic for recent infection, as is a significant change in optical densities or binding ratios in a solid-phase immunoassay (SPIA). A seroconversion in any patient indicates recent rubella virus infection. Patients without clinical symptoms but with diagnostic serology pose a special problem. They may have a primary infection or reinfection with an anamnestic antibody boost. The absence of late-rising PHA or CF antibodies in the first serum sample in this type of patient would provide evidence that the infection was primary (Fig. 1). Measurement of rubella IgG avidity by EIA may also help to differentiate primary infection from reinfection. The third type of case involves the patient whose serum samples are collected several days after the infection, when all serological tests are in plateau (Fig. 1); in this situation, testing for IgM may be helpful. If time is available, a third serum sample collected several weeks later and run in parallel with the others may demonstrate a fourfold decline in titer, which would be diagnostic. Serological examination of the suspected contacts may also be helpful in this situation.

Investigation of a suspected case of congenital rubella could include several approaches. One approach is to demonstrate rubella virus-specific IgM antibody in the infant's serum, which would be diagnostic of congenital rubella. A second approach is to perform serial serum antibody titrations (HI or SPIA) during the first 6 months of life; a persistence of a high titer in the infant during this time (Fig. 2) is highly suggestive of congenital rubella. A third approach is to perform immunoblotting and peptide EIA on sera collected during the neonatal period, looking for
FIGURE 1 Antibody response after rubella virus infection. FIA, fluorescence immunoassay (FIAX); N, neutralization; NSP, nonstructural protein.
FIGURE 2 Antibody responses in an infant congenitally infected with rubella virus.

reduced bands for E1 and E2 proteins (10). Nonserological approaches for diagnosis include virus isolation and nucleic acid detection by PCR.

TESTING PROCEDURES

Specimens

For details of procedures for the collection and storage of serum, urine, nasopharyngeal, throat, or cerebrospinal fluid specimens, see reference 8. Testing of oral fluid samples as an alternative to serum offers many advantages. These specimens have been positive for rubella virus-specific IgM or rubella virus RNA in a large proportion of CRS cases (10).

PHA

PHA is a rapid, inexpensive way of screening for rubella immunity. PHA antibody in response to nonstructural proteins (Fig. 1) parallels CF and neutralization responses after infection, whereas PHA to structural protein is more closely aligned with HI and SPIA. Both antibodies remain measurable for years after infection or immunization and indicate immunity. PHA employs human type O erythrocytes, stabilized with formaldehyde-pyruvic aldehyde and sensitized with rubella virus antigen. The erythrocytes agglutinate in the presence of specific rubella antibody. In the test, phosphate buffer is added to V-bottom microwells. Specimens, as well as positive and negative controls, are added and then mixed before the addition of the sensitized cells. A row of erythrocytes without rubella antigen is used as a control and allows more objective scoring of results. A button of erythrocytes signifies the absence of antibody (susceptibility to rubella), whereas disperse settling of erythrocytes indicates a positive reaction (immunity to rubella).

Radial Hemolysis

Radial hemolysis can be used to screen large numbers of serum samples by preparing plates in advance and storing them at 4°C. We have successfully used the method of Russell et al. (18). Freshly drawn sheep erythrocytes are washed with dextrose-gelatin-Veronal buffer, treated with 2.5 mg of trypsin (Difco, Detroit, Mich.) per ml in dextrose-gelatin-Veronal for

1 h at room temperature, and sensitized with rubella HA antigen (Flow Laboratories, McLean, Va.) (240 hemagglutination units [HAU] per ml) in HEPES-saline-albumin-gelatin buffer (HSAG; pH 6.2) for 1 h at 4°C. Sensitized erythrocytes (0.15 ml of a 50% suspension) are mixed with 0.4 ml of guinea pig complement (Behringwerke, Marburg, Germany) and added to 10 ml of 0.8% agarose preheated to 43°C, and the mixture is poured into a square petri dish (100 by 15 mm). The plates can be stored at 4°C and used for up to 14 days. Prepoured radial hemolysis plates are available from Orion Diagnostics, Helsinki, Finland. Sera are inactivated at 56°C for 30 min, pipetted into 3-mm-diameter wells punched in the agarose, and allowed to diffuse overnight at 4°C in a humidified atmosphere. The plates are then incubated for 2 h at 37°C. Plates with incomplete hemolysis are flooded with 4 ml of guinea pig complement (diluted 1:3) and reincubated. All sera are also tested in control plates containing unsensitized erythrocytes to monitor nonspecific hemolysis. Zones of hemolysis in control plates range from 3.5 to 5 mm in diameter. Zone diameters of >5 mm on antigen-containing test plates indicate immunity.

LA

Rapid LA tests are used predominantly for immunity screening. The tests incorporate antigen-coated latex particles and may be performed on a card or in a tray. Agglutination lends itself to processing small numbers of specimens.

EIA

EIA kits are commercially available from a number of North American and European suppliers and have been developed for rubella virus-specific IgG and IgM antibody. All of the commercially available EIAs are solid-phase capture assays using either microplate wells, beads, or filters and measure antibodies to envelope and/or capsid proteins. Most are performed in a couple of hours and are low in cost. Automation is built into some EIAs, whereas others are manual. Most of the tests are quantitative or semiquantitative and incorporate both positive and negative controls. At the present time, we are using a microparticle EIA which is automated for detection of IgG or IgM on the solid phase. The antibodies are detected by use of anti-human IgG or IgM antibody

coupled to alkaline phosphatase followed by methylumbel-liferyl phosphate substrate (1). The assay is performed with IMX or AXSYM analyzers (Abbott Laboratories, North Chicago, Ill.), providing test results in 1 h.

HI

Although different laboratories use modifications of the standard rubella HI test, the following is a description of the test that we have consistently found to give good results. The test is conveniently performed in disposable plastic or vinyl V-bottom microtiter plates. The rubella HA antigen is titrated each time the test is performed. Serial twofold dilutions of the antigen are made in 0.025 ml of HSAG (pH 6.2) to which 0.05 ml of a 0.25% washed suspension of pigeon erythrocytes is added. Control cups containing no antigen are included. The plates are sealed and placed at 4°C for 1 h, after which they are placed at room temperature for 15 min before the results are read. The highest dilution that produces a pattern of complete hemagglutination is considered 1 HAU; 4 HAU is used in the HI test. Before the HI test is performed, nonspecific inhibitors of hemagglutination and nonspecific agglutinins must be removed from sera. Test serum (0.1 ml) is added to 0.1 ml of HSAG and 0.6 ml of a 25% suspension of kaolin. The suspension is mixed and allowed to sit at room temperature for 20 min with frequent agitation. The kaolin is pelleted in a clinical centrifuge, and the supernatant fluid is transferred to a clean tube containing 0.05 ml of a 50% suspension of pigeon erythrocytes. After 60 min of incubation at 4°C the erythrocytes are centrifuged, and the supernatant fluid is removed and heated at 56°C for 30 min. This final sample, which represents a dilution of 1:8, is now ready to be incorporated into the test. Alternatively, nonspecific inhibitors may be removed by precipitation with heparin and manganous chloride. The serum sample is diluted 1:4 with 0.15 M NaCl. To each 0.8 ml of diluted serum are added 0.03 ml of sodium heparin (200 U) and 0.04 ml of 1 M manganous chloride. The sample is held at 4°C for 20 min, and the precipitate which forms is pelleted by centrifugation. The supernatant fluid is then absorbed with pigeon erythrocytes as described above.

Known positive and negative control sera are treated similarly. Further serial twofold dilutions of each serum are made in 0.025-ml volumes of HSAG. An area of the plate is reserved for duplication of the first three dilutions of each serum. These receive HSAG in place of antigen and serve as serum controls. To each other dilution of serum is added 4 HAU of antigen in a volume of 0.025 ml. The antigen is back-titrated in a separate section of the plate by doubling dilutions in 0.025 ml of HSAG to represent 4, 2, 1, and 0.5 HAU. The plates are incubated for 1 h at room temperature, after which 0.05 ml of a 0.25% suspension of pigeon erythrocytes is added to each well and the plates are mixed on a plate vibrator. The hemagglutination pattern is read after 1 h at 4°C. The reciprocal of the highest dilution of serum which completely inhibits hemagglutination is taken as the endpoint or rubella titer.

Since the original description of the HI test for rubella (21), several modifications have been introduced. These include the choice of indicator erythrocytes (5), optimal pH of reagents (6), methods for removal of nonspecific inhibitors from sera (7), methods for preparation of the antigen (19), and duration of incubation of antigen with the sera (16). The widely used commercial HI tests available in the 1980s and 1990s, including Rubindex (Ortho Diagnostics, Raritan, N.J.) and Rubatech (Abbott), are no longer available in North America.

CF

The CF test is performed by a standard technique (23).

IFA

The indirect fluorescent-antibody (IFA) test for rubella antibody, first described in 1964, used chronically infected LLC-MK$_2$ cell cultures as the solid-phase antigen. Other acutely infected cell systems or even purified rubella antigens have since been used for the rubella IFA test. For the classic IFA test, acutely infected cells are grown either on Leighton tube coverslips or in culture flasks, and they are then trypsinized and deposited on slides as cell smears. The cytoplasm of cells infected with rubella virus contains rubella antigens. These antigens are used to detect specific antibodies by the indirect method in which an anti-human globulin conjugated with fluorescein isothiocyanate is employed. The technique is rapid and relatively inexpensive and allows detection of IgG and IgM antibodies; however, IFA test results are read visually with a fluorescence microscope and are open to subjective interpretation.

A soluble rubella antigen immobilized on an opaque plastic surface has also been used in an IFA test. In the FIAX test, the antigen-sensitized surface is allowed to react in a two-step procedure with the serum and the fluorescein-labeled conjugate, and the resulting fluorescence signal is measured objectively in a fluorometer. The intensity of the fluorescence signal correlates with the titer of rubella antibody. The sensitivity and specificity of this assay method correlate well with those of the HI test.

Other assays for detecting rubella antibody include mixed hemadsorption and time-resolved fluoroimmunoassay. These tests have their own characteristics and have not gained widespread usage.

Rubella IgM Assays

Commercial EIAs are available for testing whole sera for rubella virus-specific IgM. These EIAs usually employ a pretreatment step or use anti-IgM capture antibody on the solid phase to isolate IgM from IgG and Fab antibody fragments in the indicator reagent to eliminate rheumatoid factor false-positive results. They possess a high level of sensitivity and specificity (3, 4).

Rubella virus-specific IgM antibodies can be separated from IgG by sucrose density gradient fractionation and then detected by HI, EIA, or IFA test. Density gradient centrifugation entails diluting the test serum 1:3 in phosphate-buffered saline and adsorbing it with pigeon erythrocytes. After removal of the erythrocytes, the serum is placed on a discontinuous sucrose gradient that is constructed by layering sucrose solutions in phosphate-buffered saline in a 5-ml cellulose nitrate tube (37, 33, 28, 24, 18, and 12% [wt/vol], as determined by refractometer readings). Before the test serum is layered, the gradient is allowed to equilibrate by overnight diffusions at 4°C. The specimen is carefully laid on top, and the tube is centrifuged for 16 to 18 h at 150,000 × g. The bottom of the tube is carefully punctured with a needle-type fraction collector, and 10 to 12 fractions are collected (0.3 ml per fraction; about 20 drops). Fractions 2 to 4 usually contain IgM; fractions 6 to 9 contain IgG, and the top two fractions contain nonspecific inhibitors of hemagglutination. Alternatively, other immunoglobulin separation techniques such as gel filtration, staphylococcal protein A absorption, quaternary aminoethyl-Sephadex chromatography, and 2-mercaptoethanol destruction have been used with variable success. Density gradient centrifugation for IgM purification has been replaced with affinity chromatography using immobilized IgG.

Virus Isolation

Few laboratories have the techniques or expertise to culture rubella virus, and when virus detection is clinically important, laboratories may want to consider detection of rubella virus RNA by PCR. A wide variety of cell types are susceptible to infection by rubella virus. For primary isolation from clinical specimens, primary African green monkey kidney (AGMK), Vero, or RK-13 cell cultures are commonly used (21). Rubella virus is detected by interference with the cytopathic effects (CPE) of a challenge virus. For virus isolation in AGMK cells, four tubes containing cell monolayers are drained of medium; 0.2 ml of the specimen is used to inoculate each tube and allowed to absorb for 1 h at 35 to 36°C for 10 days. Uninoculated AGMK cell cultures serve as controls. At the end of the incubation period, the tubes are examined for any CPE. If none is found, two inoculated and two control tubes are challenged with 100 to 1,000 50% tissue culture infectious doses ($TCID_{50}$) of a challenge virus. The challenge viruses most commonly used for rubella virus isolation in AGMK cells are echovirus 11 and coxsackievirus A9. Challenged tubes are read 3 to 4 days after challenge. The presence of rubella virus is indicated by little or no CPE in the inoculated tubes and complete destruction of the control cells infected with challenge virus in the absence of rubella virus. Confirmation of the presence of rubella virus requires specific neutralization of the interference with rubella antibody.

Specimens with low concentrations of rubella virus may produce little or partial interference in the culture tubes initially inoculated. The culture fluids may have to be passaged to demonstrate the virus. Fluid from the cultures that were not challenged should be used to inoculate an additional four tubes of AGMK cells. Additional control tubes are also included. These tubes should be incubated for a further 7 to 8 days. Two inoculated tubes and two control tubes are then challenged with echovirus 11 and observed for CPE. The absence of rubella virus interference with the echovirus cytopathogenicity on passage of fluid from tubes that did not demonstrate interference initially confirms the absence of rubella virus in the original tube. If virus is not found after such a passage, it is rarely found by further passages.

Some laboratories use RK-13 or Vero cells for isolation of rubella virus. In these cell systems, rubella virus produces CPE; however, the CPE is not always clear on primary isolation, and cell culture fluids may need to be passaged several times for full detection of virus. These cell systems, however, do offer the advantage of direct neutralization for identification of an isolate. An indirect immunofluorescence staining method has also been shown to be specific and sensitive for identifying rubella virus isolates in these cells.

Fresh unfrozen tissue specimens may be of particular value in attempts to isolate virus from fetal tissues and organs. A convenient method is to explant minced tissue fragments with growth medium and allow sufficient time for the outgrowth of cells. When the cells have formed monolayers, the extracellular fluids can be harvested and tested for the presence of an interfering agent, as described above. This is a more sensitive method for rubella virus isolation than the method in which tissue extracts or homogenates of ground tissue are used.

Rubella virus can be neutralized specifically with rubella antiserum prepared in rabbits. Such antisera are available from several commercial sources. Immune rabbit serum is diluted to contain 4 U of neutralizing antibody. A normal preimmune (rubella antibody-free) rabbit serum is diluted similarly for the control titration. The media from the two

companion, unchallenged cultures containing the interfering agent are pooled, and serial 10-fold dilutions are made in maintenance medium (undiluted to 10^{-6}); 0.1-ml samples of each dilution are used to inoculate three culture tubes. The 10^{-1}, 10^{-2}, and 10^{-3} dilutions are also combined with an equal volume of the prediluted rubella antiserum and of the prediluted normal rabbit serum. After 1 h of incubation at 35°C, 0.2 ml of each of the mixtures is used to inoculate three tubes of AGMK cells. The tubes are incubated at 35 to 36°C for 7 to 8 days, challenged with echovirus 11, and observed for the development of enterovirus CPE. Destruction of the AGMK monolayers inoculated with the isolate dilution containing between 10 and 100 $TCID_{50}$ plus the immune rabbit serum, but not of those with the normal rabbit serum, indicates that the isolate is rubella virus.

Nucleic Acid Detection

PCR has been used to detect rubella virus RNA in amniotic fluid specimens or from biopsies of chorionic villi from the fetus in utero (9, 16). Reverse transcriptase PCR first uses reverse transcriptase to make a cDNA copy of genomic RNA and then PCR amplification using rubella virus-specific oligonucleotides in either a one- or a two-step reaction. The product is detected by Southern blotting. Compared to those of rubella IgM antibody for diagnosing congenital rubella, the sensitivity and specificity of PCR in a recent study were 95 and 100%, respectively (9).

Lymphocyte Transformation Assay

A rubella-specific lymphocyte transformation assay, using cryopreserved mononuclear cells, has been developed (12). A negative rubella-specific lymphocyte transformation response in a seropositive child 3 years of age or younger was highly suggestive of congenitally acquired rubella.

MATERIALS AND REAGENTS

Erythrocytes for PHA are sensitized with rubella antigen by the standard tannic acid treatment. The reagents come standardized in a kit (Rubacell; Abbott).

HA antigen is prepared by infecting monolayers of BHK-21 cells in 32-oz (960-ml) bottles with 5 to 10 ml of rubella virus stock containing 10^4 or more $TCID_{50}$/ml. After the virus has adsorbed for 2 h at 37°C, the monolayers are covered with Eagle's medium containing 2% fetal bovine serum that has previously been adsorbed with kaolin (to remove nonspecific agglutinins). The medium is changed after 24 h, and then HA antigen is harvested after 5 and 7 days of incubation. High-titered antigen can be extracted from the monolayers by extracting the cell-associated antigen with alkaline buffers. The cell-associated antigen preparations have CF activity and can be used as the antigen source in the CF test. We have found that good-quality CF and HI antigens in lyophilized form can be purchased from commercial sources such as BioWhittaker Inc. (Walkerville, Md.) and Ortho Diagnostics.

Red blood cells for HI are prepared by collecting blood from a wing vein of a pigeon into modified Alsever's solution. The erythrocytes are washed three times in HSAG buffer, and the packed cells are suspended in an equal volume of HSAG to make a 50% suspension; part of this suspension is used to absorb nonspecific agglutinins from the test sera. A 10% working suspension is made in HSAG, from which the 0.25% suspension to be used in the test is prepared.

Acid-washed kaolin powder to be used in an HI test can be purchased from most scientific supply companies. A 25-g

amount of kaolin is washed with Tris buffer until a pH of 7.0 or greater is achieved. The Tris buffer is made by mixing 12.1 g of Trizma base (Sigma Chemical Co., St. Louis, Mo.), 80 ml of 1 N HCl, and 0.85 g of NaCl and bringing the volume to 1 liter. This solution is then further diluted 1:10 in distilled water for washing the kaolin. After the final wash in Tris buffer, the kaolin pellet is suspended in 100 ml of Tris-bovine albumin buffer (Tris-BSA). This buffer is made by adding to 96.67 ml of Tris buffer the following ingredients: 0.33 ml of a 35% sterile solution of BSA (Nutritional Biochemicals Corp., Cleveland, Ohio), 1 ml of a 0.5% $MgCl_2 \cdot 6H_2O$ solution, 1 ml of an 8% NaN_3 solution, and 1 ml of a 0.5% $CaCl_2$ solution.

HSAG is made from three different stock solutions: (i) 5×HEPES-saline, (ii) 2×BSA, and (iii) 100×gelatin. HEPES-saline is made by adding 29.8 g of HEPES powder, 40.95 g of NaCl, and 0.74 g of $CaCl_2 \cdot 2H_2O$ to 1 liter of water and adjusting the pH to 6.2. BSA is made by adding 20 g of BSA powder to 1 liter of water. Gelatin is made by adding 25 mg of gelatin to 2 liters of water. All solutions are filtered. A working solution of HSAG is made by adding 200 ml of HEPES-saline to 500 ml of BSA solution and 100 ml of gelatin stock solution. The volume is made up to 1 liter by adding 200 ml of sterile distilled water. The pH of the working solution should be 6.25. The solution can be stored for 2 months if it remains sterile. HSAG may be purchased from several commercial sources (Flow Laboratories; GIBCO Laboratories, Grand Island, N.Y.; or M. A. Bioproducts).

QUALITY CONTROL AND INTERPRETATION

Confirmation of clinical rubella requires the demonstration of a fourfold rise in antibody titers in paired sera, the presence of rubella virus-specific IgM, or the detection of rubella virus RNA by PCR in the case of congenital rubella. There is considerable variability in the antibody titers maintained during life, and a firm diagnosis cannot be made on the absolute titer of a single serum sample. Because of day-to-day variations in the results of tests, paired sera must be tested in parallel. Differences in titers of paired sera tested on different days may reflect test-to-test variation and not a true change in antibody concentration. This observation is especially important when paired sera are collected from pregnant women who have not experienced clinical illness. Judgments regarding therapy should be withheld until the sera have been retested in parallel on the same day. False-positive IgM results are more likely to occur with indirect assays than capture IgM assays and might also occur with rheumatoid factor-positive sera or with sera containing cross-reacting IgM antibody. For this reason, a second IgM assay using a different format should be done to confirm maternal rubella during the first trimester, before patients make a decision to terminate the pregnancy in jurisdictions where it is legal.

EIA titers should be converted to HI antibody equivalence since the latter expressed as international units has been routinely used to determine immunity. Currently, advisory groups suggest that between 10 and 15 IU represents immunity to rubella in the majority of cases, where a dilution of 1:8 in the HI test is equivalent to 15 IU.

PHA or radial-hemolysis tests are used to detect "late" antibody indicative of a convalescent phase or immunity. When these tests are negative and sera test positive by tests that pick up "early" rubella antibody (EIA and HI), the combination of a negative late antibody and positive early antibody result indicates a recent infection. Sera giving this pattern of antibody results are invariably rubella IgM antibody positive.

Patients without detectable antibodies are usually susceptible to infection by rubella virus; however, a small percentage of adults may not have detectable antibodies and yet are immune. Neutralizing antibodies at low dilutions can usually be detected in the sera of these patients. The lack of serological responses to rubella virus vaccine in women who do not have detectable antibodies is often due to low levels of neutralizing antibodies. With the HI test described here, the first dilution in the test is 1:8. A patient's serum that is positive only at 1:8 should be retitrated to rule out a possible false-positive reaction.

Enteroviruses

DAVID SCHNURR

82

Poliovirus, the prototype for the enterovirus group, is of current and historic interest as the agent of paralytic poliomyelitis. Polio has been known for centuries and occurred in epidemic fashion until the development and application of poliovirus vaccines starting in the 1950s. A goal of the World Health Organization (WHO) was the complete eradication of naturally transmitted poliovirus by the year 2000 (references 15 and 16 and this manual provide an excellent review of the enteroviruses). While eradication has not been achieved, transmission of wild-type poliovirus has been restricted to a few areas in the world, and complete eradication remains the goal. However, recent complications involving the spread of wild-type poliovirus have provided new challenges (18).

The search for other agents causing poliomyelitis-like syndromes resulted in the discovery of the group A and B coxsackieviruses from human specimens cultured in mice. The use of cell cultures for viral isolation resulted in the discovery of a number of related viruses, named the echoviruses (for enteric cytopathogenic human orphan virus). Poliovirus, coxsackie A and B viruses, and echoviruses make up the *Enterovirus* genus. Current taxonomy based on sequence analysis divides the human enteroviruses into five species, poliovirus and human enteroviruses A to D, containing 65 serotypes (6).

More recently, the application of molecular techniques has contributed to enterovirus diagnostics and taxonomy. Application of molecular methods, especially PCR, has resulted in more rapid and sensitive diagnostic assays and molecular biology-based taxonomy.

THE AGENTS

The *Enterovirus* genus belongs to the family of *Picornaviridae*, viruses with a single-stranded, positive-sense RNA genome. The virions are unenveloped, 28 to 30 nm in diameter, and composed of 60 subunits, named protomers, each composed of the four viral proteins. The genus was created in 1957 in order to group together agents with similar properties that inhabit the alimentary tract. The enteroviruses are currently composed of 65 serotypes: poliovirus types 1 to 3, 23 serotypes of group A coxsackieviruses, 6 serotypes of group B coxsackieviruses, 29 serotypes of echoviruses, and enteroviruses 68 to 71. These are classified into five species: poliovirus (3 serotypes) and human enteroviruses A (12 serotypes), B (37 serotypes), C (11 serotypes), and D (2 serotypes) (6).

The 5′ end of the genome is untranslated and highly conserved. These conserved sequences are the targets for primers of the PCR, which recognizes all or almost all of the enteroviruses, and thus provide for group detection and identification. Enterovirus-specific PCR primers do not amplify the RNA of echovirus 22 or 23, now classified as members of the genus *Parechovirus*.

The enteroviruses are extremely stable in the environment. They retain viability indefinitely at −70°C and for years at −20°C and are not inactivated by ether or chloroform. Infectivity is lost when they are heated at 50°C for 2 min or more. Virions are protected from heat inactivation by addition of divalent cations. UV light, formaldehyde treatment, or sodium hypochlorite (0.3 to 0.5 ppm of chlorine) treatment inactivates infectivity.

Serotypes are defined by the lack of cross protection with hyperimmune serum in the neutralization assay. Type-specific determinants reside on the surface of the virion and have been defined by use of monoclonal antibodies (MAbs) (16). Taxonomy based on the nucleotide sequences of the structural proteins correlates closely with the results of typing with hyperimmune sera (12).

Heating or UV light converts the infectious N particle to the noninfectious H form. The conversion exposes epitopes, which cross-react among enteroviruses. MAbs, which react with all human enteroviruses and presumably react with these epitopes, have been described elsewhere (23, 25).

Various types of antigenic variants occur among the enteroviruses. MAbs have been used to show the range of antigenic variants within a serotype (23). A prime strain is an antigenic variant not neutralized by antiserum to the parental virus, while antiserum to a prime strain neutralizes the prime strain virus and parental virus alike.

CLINICAL INDICATIONS

Enteroviral infections range from asymptomatic to severe and sometimes cause fatal diseases. Certain serotypes are more likely to be involved in a given syndrome than others, but there is considerable overlap between the syndromes caused by the various enteroviruses.

The central nervous system is a major target for enteroviral infections. Paralytic poliomyelitis, due to poliovirus types 1

to 3, is among the most serious of all the enteroviral syndromes. The incidence has decreased sharply due to the use of the poliovirus vaccine and concerted efforts to vaccinate as many susceptible persons as possible. Enhanced surveillance has been maintained in order to ensure that all new cases are detected. Poliomyelitis-like disease is occasionally associated with vaccine virus reverting to virulence in immunocompromised persons or infection by other enteroviruses, particularly enterovirus 71. Enterovirus 71 has been described as the cause of brain stem encephalitis with up to 10% mortality in Taiwanese children (22). A more frequent but less severe disease is aseptic meningitis, for which enteroviruses are the major cause. Rapid diagnosis of enterovirus infection by PCR has direct, important benefits, reducing antibiotic treatment and allowing for earlier discharge of children from the hospital. Chronic enteroviral meningoencephalitis in agammaglobulinemic patients is a rare disease caused by persistent infection of the central nervous system, usually by an echovirus or occasionally by a group A or B coxsackievirus.

Coxsackie A virus infections frequently result in skin rashes or respiratory infections. Herpangina, characterized by fever, mouth lesions, and sore throat, is caused by several of the coxsackie A viruses. Coxsackie A16 virus and enterovirus 71 are the most common causes of hand, foot, and mouth disease and a syndrome that can occur in large epidemics (2). A number of coxsackie A serotypes are also associated with respiratory infections, especially in children.

Coxsackievirus A24 and enterovirus 70 are associated with epidemic conjunctivitis and acute hemorrhagic fever. Enterovirus 70 infections can also result in severe neurologic complications. The coxsackie B viruses cause viral myocarditis and pancreatitis and are important agents in the etiology of neonatal disease.

Echovirus infections result in a variety of syndromes. Large outbreaks of echovirus 30-associated aseptic meningitis occur periodically, most recently in 1991 to 1993 and again in the late 1990s (13).

LABORATORY DIAGNOSIS

Enterovirus infections are protean in their expression, ranging from asymptomatic to presenting a wide range of symptoms and syndromes. A definitive diagnosis depends on laboratory detection of infection. Although particular serotypes are associated with certain syndromes, an etiologic association cannot be established on clinical grounds alone. Laboratory diagnosis is done by isolation and identification of the agent, serology, or direct detection. In many situations, direct detection by PCR is the method of choice because it is rapid and sensitive.

For best results, specimens for viral culture or direct detection should be collected as early in the course of the illness as possible. Specimens that should be collected include a respiratory sample, a stool or rectal swab, and cerebrospinal fluid (CSF) for aseptic meningitis.

Isolation and Identification

Culture of the agent from host material in cell culture or newborn mice has been the standard for diagnosis of enteroviral infection. Although no one cell type supports growth of all enteroviruses, all members of the group, except for coxsackie A viruses 1, 19, and 22, can be grown in cell cultures. All of the group A and B coxsackieviruses can be grown in mice.

Since no single cell type supports the replication of all the enteroviruses, more than one cell type should be inoculated

for optimal recovery. A human fetal diploid line such as WI-38 or MRC-5, primary monkey kidney cells, and BGMK and RD are cell lines sensitive to a variety of enteroviruses. The range of viruses that will grow in any cell type can be enhanced or selected by introducing specific cell surface molecules that act as viral receptors by genetic engineering. For instance, cells expressing CD155 are targeted to polioviruses (3), and BGMK cells expressing decay-accelerating factor are reported to be sensitive to a broader range of serotypes than the parental BGMK cells (4). Another innovation designed to broaden the sensitivity of cell culture has been to combine two cell types, such as engineered BGMK and CaCo cells, in a single culture (4).

Enterovirus growth in cell culture is recognized by observation of the characteristic cytopathic effect (CPE). Depending on the dose of the inoculum, cell type inoculated, and the strain of virus, CPE may take up to several days to develop. The shell vial technique is a method for making the results of cell culture isolation available in 24 to 72 h (20). Inoculated cultures are stained with group-reactive MAbs, frequently allowing detection of virus before CPE has developed.

Although a presumptive identification of an enterovirus can be made, based on knowledge of host symptoms, the specimen, type and progression of CPE, and the cell type in which the virus grows, confirmation that the isolate is an enterovirus requires a specific immunological or molecular test.

MAbs which react with most or all enteroviruses (group-reactive MAbs) may be used in indirect immunofluorescence assays for confirmation. The MAb described by Yousef et al. (25) has high specificity and low sensitivity, while the MAbs described by Yagi et al. (23) are more sensitive but less specific. Confirmation that an enterovirus has been grown in culture can also be achieved by PCR amplification of the viral genome from the tissue culture fluids.

Another approach to confirm that an isolate is an enterovirus is neutralization with type-specific immune sera. This technique confirms that the isolate is an enterovirus and identifies the serotype in the same test. For most purposes, identification of an isolate as an enterovirus without knowing the serotype is sufficient. However, for enterovirus epidemiology and practical questions such as tracing the circulation of poliovirus, serotyping is of importance.

On the basis of epidemiological information, a particular serotype may be targeted by attempting to neutralize the isolate with one or a few specific immune sera. However, because of the large number of serotypes and the inability to reliably associate particular serotypes with a given syndrome or symptoms, pools of immune sera have been used for typing. The widely used Lim-Benesch Melnick (LBM) immune serum pools are available from the WHO. Typing results are subject to error (21), perhaps because with the LBM pools the serotype is determined by neutralization with one, two, or three of the pools. Confirmation of the pool results by neutralization with a single, type-specific immune serum provides for the most reliable serotyping. More rapid and economical typing may be done by indirect immunofluorescent staining using type-specific MAbs, which are commercially available for the most frequently isolated serotypes (17).

Confirmation that an isolate is an enterovirus can be done by enterovirus-specific PCR (see the PCR discussion below ["Direct Detection"]). A real-time PCR assay which can reliably differentiate between entero- and rhinoviruses has been described elsewhere (5).

Due to a variety of factors associated with serotyping, including antigenic variation and drift, viral aggregation,

expense, and the time required to complete the characterization, there is a great interest and need for development and application of molecular methods for typing enteroviruses (1, 7, 8, 11, 12). Molecular methods such as restriction fragment length polymorphism of PCR amplicons and nucleotide sequencing of different regions of the genome have been evaluated for their use in typing. The type as determined by sequencing from the VP1 region correlates almost exactly with the type determined serologically (12). Even isolates that cannot be serotyped by using standard WHO and Centers for Disease Control and Prevention immune sera were typed by VP1 sequence data, and the type as indicated by sequencing was confirmed by neutralization with type-specific immune sera (11).

Enterovirus isolates that were not typeable by sequencing of the VP1 region were further characterized by sequencing of the remainder of the genome. On the basis of molecular and biologic data, these untypeable enteroviruses are now proposed as new enterovirus serotypes (14).

Serology

Serology has not been used extensively for diagnosis of enteroviral infections because the serotype-specific nature of the neutralization assay makes it difficult to select which virus should be used as the target in the test. Neutralization tests on a single serum are generally not useful because many individuals have antibody from previous infections. However, a fourfold rise in neutralizing titer between acute- and convalescent-phase sera is of value when there is interest in only a few serotypes, as in the case of paralytic poliomyelitis. Use of a single antigen is also possible when epidemic outbreaks with a particular serotype occur, such as with enterovirus 71 in Taiwan (2) or echovirus 30 (13). Broadly cross-reactive immunoglobulin M (IgM) antibodies detected by enzyme-linked immunosorbent assay are useful in detecting recent infection. The IgM assay can be group or serotype specific, depending on the treatment of the antigen. Heating exposes cross-reactive antigens, while capture with type-specific antibodies results in preservation of type specificity. Reactivity in the IgM assay depends on the selection of the test antigen and the individual host response.

Direct Detection

Direct detection of a virus in clinical material provides the most rapid and therefore clinically most useful information. Nucleic acid amplification by PCR is sensitive and specific and is the method of choice for direct detection of enteroviruses. Highly conserved, panenterovirus, group-reactive sequences located in the 5′ noncoding region of the genome are targets for primers and probes for detection of enterovirus RNA. Enteroviruses from various specimens have been successfully amplified and detected by use of these primers and probes. The 5′ end of the genome contains sufficient sequence homology with rhinoviruses that cross-reactivity between the enteroviruses and rhinoviruses occurs. Depending on the specimen and goals of the assay, this cross-reactivity can be used as a screen for both entero- and rhinoviruses (5), or enterovirus-specific primers may be used (10).

A variety of specimens such as blood, respiratory, stool, CSF, and paraffin-embedded or fresh myocardial tissue samples have been successfully used as the source of enterovirus RNA for molecular detection. Molecular testing of CSF for enterovirus has been especially beneficial in reducing hospital stay and antibiotic use in pediatric patients with neurologic symptoms. Detection of the viral genome in the CSF is positive evidence of invasion, is more sensitive than culture, and provides results in a clinically useful time frame.

The specimen should be collected as early in the acute phase of illness as possible and transported to the laboratory for processing within 48 h or frozen at −70°C until tested. Care must be taken not to cross contaminate specimens. Guanidine thiocyanate-based RNA extraction methods work well with specimens likely to yield enteroviruses, and false negatives are reported not to be a problem with this method (9). The RNA is copied into cDNA by reverse transcription (RT) using *Tth* polymerase (19) or reverse transcriptase. The *Tth* enzyme has both RT and thermostable DNA polymerase activity in a single molecule. When an RT enzyme is used, the thermostable DNA polymerase must be added separately to the reaction mix.

PCR results in a many-fold increase of amplicons, doubling in number for each round of amplification. The basic principle of PCR technology has remained relatively unchanged, while methods for detection of the amplified product have evolved.

The products of the PCR can be detected and sized by electrophoresis and staining of the gel with ethidium bromide. The size of amplicons is estimated by comparing the positions of nucleic acid bands in the stained gel with those of known molecular weight standards. If a band is of the expected size for the enterovirus amplicon, that is presumptive evidence that the amplicon is enterovirus specific. However, the size of the amplicon does not guarantee specificity; hybridization of the amplicon with an oligonucleotide probe complimentary to the amplified sequence provides confirmation that the amplicon is enterovirus specific. The hybridization reaction can be done following Southern blotting from the gel, by plate or liquid hybridization. Southern blotting of the PCR products onto a solid-phase surface is followed by hybridization to a probe labeled with a radioactive element, biotin, or some other tracer molecule. For plate hybridization, the probe is bound to the plate and the products of the PCR are hybridized to the bound probe. Plate and blot hybridization can be measured by enzyme immunoassay using primers labeled with biotin (19) that are incorporated into the amplicon during amplification or by use of a MAb that reacts with the double-stranded DNA probe and amplicon hybrid (24). The enzyme is conjugated to avidin, which binds strongly to biotin or to an antibody directed against the species type of the primary antibody.

More recently, real-time detection methods have reduced the time for obtaining a diagnosis (5, 10). Real-time formats provide results in hours from the setup of the assay.

Standards for reporting results on human specimens are set by the Clinical Laboratory Improvement Amendments (CLIA) and can be found in the *Federal Register* 1992 and 24 January 2003 issues. PCR methods for enterovirus detection are home brew assays and therefore require a verification protocol that addresses criteria set by the CLIA regulations. This protocol must be completed and documented before the assay results can be reported. The criteria are accuracy, precision, sensitivity, specificity, reportable range of test results, and normal values. Determination of sensitivity and specificity for clinical specimens is difficult because culture, the "gold standard" for enterovirus detection, is less sensitive than molecular methods. Establishing the sensitivity and specificity for an assay that is more sensitive than the gold standard is a special problem. One approach to resolve discrepant results between molecular methods and culture is to sequence amplification products from PCR-positive, culture-negative specimens. Knowledge of the amplicon sequence

can be used to determine if it was copied from an enterovirus template. Sequence analysis also provides information on the similarity of the amplicon to positive-control RNA that is used in the assay. The amplicons should be of enteroviral origin but should differ from each other and from the positive-control nucleic acid. One caveat is that the sequences may be very similar or perhaps identical in cases where outbreaks with a single serotype of closely related strains occurs. Clinical diagnosis of enteroviral infection can be used to establish sensitivity in cases where the PCR is positive and there is strong epidemiological evidence of an enterovirus infection in the absence of positive viral culture.

A reportable assay must include the proper controls. For each assay, there must be a positive and negative control. For specimens for which the extract may inhibit the PCR and as a positive control for the extraction, a PCR for an RNA that should be present, that is, a housekeeping gene, should also be included. The housekeeping gene is not required if it can be demonstrated that the particular specimen type does not contain inhibitory substances.

Proficiency testing is an important quality control issue and is required by CLIA. Proficiency testing for molecular detection of enterovirus is not available through the regular providers of proficiency panels in the United States. Options are to share specimens between laboratories or to set up an internal proficiency testing program within a laboratory. There is a European source for enterovirus proficiency test specimens through Quality Control for Molecular Diagnostics (http://www.qcmd.org).

One current difficulty with PCR is that virtually all tests are developed for use at individual laboratories. Until reagents and protocols are standardized and proficiency testing is made available, it is difficult to compare results between laboratories, and the sensitivity and specificity of any given test must be carefully evaluated. Although work remains to be done, for many purposes nucleic acid amplification methods are rapidly becoming the tests of choice for enterovirus detection.

INTERPRETATION

Isolation and identification remain an important standard for enterovirus diagnosis. However, because of their sensitivity and rapid turnaround, nucleic acid amplification methods are becoming more prominent and are preferable for testing where results may yield clinically useful information. If an enterovirus is identified, the significance of the detection depends on the known association of the agent with the syndrome and the site from which the virus was detected. For example, a positive result for CSF is more significant than a positive test for a stool or respiratory specimen in evaluating the etiology of aseptic meningitis.

Direct detection, especially in aseptic meningitis, is a valuable diagnostic aid allowing the discontinuation of antibiotic therapy and hospital discharge for children. Direct detection by PCR or other sensitive methods is likely to be the highest priority for clinical diagnostic virology laboratories.

The role of enteroviruses, especially group B coxsackieviruses, in the etiology of myocarditis is a question that has been extensively investigated. A viral isolate from the heart is highly significant compared to one from the stool. There have been a number of studies using PCR to detect enteroviral RNA in myocardial tissue of humans. Persistence of enteroviral RNA in the absence of infectious virus does occur. However, the significance of this persistence has not been adequately explained. In any situation, failure to detect a virus does not rule out a viral etiology.

A fourfold or greater rise in neutralizing antibody titer is the strongest serologic evidence for recent infection. The presence of enterovirus-specific IgM is evidence of a recent infection but does not establish proof of etiology. A high titer of neutralizing antibody in a single serum is of questionable significance.

Enterovirus infections will remain an important clinical entity, and diagnostic tools and their applications for these agents will continue to evolve. The use of molecular methods, particularly PCR, is an important advance that will contribute greatly to more rapid and sensitive diagnostics for enteroviruses.

Viral Hepatitis

MAURO BENDINELLI, MAURO PISTELLO, GIULIA FREER,
MARIALINDA VATTERONI, AND FABRIZIO MAGGI

83

In recent decades, the importance of viruses as causative agents of liver parenchymal inflammation has been fully appreciated, with the discovery of five major hepatitis-inducing viruses and the development of sensitive diagnostic tools for each of them. In addition, two more viruses with still uncertain liver tropism and pathogenicity have been identified in patients suffering from hepatitis of unknown origin (Table 1). By convention, hepatitis is labeled acute when it lasts less than 6 months and chronic when it persists longer. In spite of extensive use of vaccines against hepatitis A and B in many countries and despite considerable underreporting, acute or chronic viral hepatitis still ranks among the most frequent reportable infectious diseases throughout the world. In particular, hepatitis B virus (HBV) and hepatitis C virus (HCV) are known to infect several hundred million people worldwide. Diagnostic laboratories are therefore frequently confronted with the need to confirm clinical diagnosis of acute or chronic hepatitis, identify the causative virus, and evaluate disease progression and therapy outcome.

Diagnosis of hepatitis and assessment of its severity rely largely on the biochemical analysis of liver integrity and function (Table 2). Aspartate-aminotransferase and especially alanine-aminotransferase (ALT) are of utmost importance, since their levels in serum are highly sensitive indicators of hepatocellular damage and provide simple means of monitoring liver inflammation. Liver endoscopy and especially liver biopsy (when indicated) are essential for accurate determination of the stage and outcome of chronic hepatitis and for deciding the optimal therapeutic strategy. However, clinical features and biochemical, imaging, and histopathological changes are of little help in differentiating the responsible virus. Thus, etiological diagnosis of acute and chronic hepatitis depends extensively on laboratory tests that are specific for each individual virus and are generally used in a stepwise fashion (see below). A feature common to all hepatitis-inducing viruses is that they are poorly cultivable in vitro, if at all, and, with the exception of hepatitis E virus (HEV), they do not infect small laboratory animals. Laboratory diagnosis has therefore always relied on the use of immunoassays that measure viral antigens or antibodies. The more recently introduced molecular tests that detect and quantify viral genomes complement the information obtained immunologically and, due to rapid turnaround times and the availability of user-friendly commercial kits, have acquired a key position in both the diagnosis and the

follow-up of viral hepatitis. On the other hand, in the near future, molecular assays are likely to prove useful also in assessing host factors predictive of hepatitis virus infection outcome. Polymorphisms in human cytokine genes or their promoter sequences are beginning to be associated with infectious disease severity and may ultimately become criteria for optimizing therapeutic regimens for individual patients.

HEPATITIS-INDUCING VIRUSES

The vast majority of acute forms of hepatitis are the result of primary infection by the hepatitis viruses designated A to E (Table 1). These viruses differ greatly both genetically and structurally but have in common marked hepatotropism and the ability to trigger variable degrees of liver damage. Primary infection is often nonsymptomatic or accompanied by mild influenza-like manifestations and minimal aberrations of biochemical liver tests. When symptoms of liver damage are clinically evident, these symptoms are essentially uncharacteristic of the causative virus and range from those associated with mild, anicteric or icteric hepatitis (low-grade fever, malaise, anorexia, blunting of taste, nausea, easy fatiguability, and myalgia) to those associated with rare but frequently fatal fulminant hepatitis.

A major difference between A and E hepatitis and the other forms of viral hepatitis is that, whereas hepatitis A and E are constantly self-limiting and resolve in very few weeks or months, variable proportions of HBV, HCV, and hepatitis D virus (HDV) infections do not resolve but tend to persist for protracted periods, frequently for the life span of the infected patient. The clinical consequences of chronic infection by HBV, HCV, and HDV vary greatly both in pattern and severity; thus, patients may remain relatively asymptomatic for extended periods or indefinitely (healthy carriers) or present jaundice and other liver inflammation symptoms of varying severity, with either a stable or a remittent course. Eventually, after variable but generally long intervals, chronicity may result in progressive hepatic failure (decompensated hepatitis) and cirrhosis. Chronically infected patients also are at highly increased risk (20- to 300-fold, depending on the specific populations considered) of developing hepatocellular carcinoma (HCC), and they may suffer from a number of extrahepatic manifestations, including arthralgias, glomerulonephritis, the vasculitis known as

TABLE 1 Viruses discussed in this chapter

Virus	Type of infection	Main route(s) of transmission
Viruses with marked hepatotropism		
HAV	Self-limiting	Oral-fecal
HBV	Self-limiting or persistent	Parenteral
HCV	Self-limiting or persistent	Parenteral
HDV	Self-limiting or persistent	Parenteral
HEV	Self-limiting	Oral-fecal
Viruses with uncertain hepatotropism[a]		
GBV-C or HGV	Self-limiting or persistent	Parenteral
TTV	Self-limiting or persistent	Oral-fecal/parenteral/ respiratory/others

[a]The existence of the putative hepatitis F virus has never been confirmed.

polyarteritis nodosa (especially HBV), and cryoglobulinemia (especially HCV). The proposed association with other diseases, such as Sjögren's syndrome and porphyria cutanea tarda, is much less well established.

Acute hepatitis can also be observed during the course of systemic infections by many other viruses that are not primarily hepatotropic but occasionally produce clinically significant liver damage. These include Epstein-Barr virus, cytomegalovirus, and, less frequently, certain adenoviruses and enteroviruses, parvovirus B19, yellow fever virus, and others. In these infections, liver involvement is usually a minor component of overall pathobiology, and the coexistence of symptoms other than those of hepatitis is an important guide for etiologic diagnosis. The laboratory tests used for diagnosis are discussed in the specific chapters dealing with these viruses.

In addition to the above forms, a relatively small number of cases of acute and chronic hepatitis that cannot be ascribed to any currently known virus also occur. The search for agents that might be responsible for these cryptogenetic forms by modern molecular approaches has led to the discovery of other candidate hepatitis-inducing viruses (Table 1). GB virus type C (GBV-C, also called hepatitis G virus [HGV]) and torquetenovirus (TTV), the prototype of the novel genus *Anellovirus*, are widespread, but their hepatopathogenic potential is much less pronounced than originally proposed or may even be nonexistent. These viruses are considered here because they were discovered in hepatitis patients and because for some of them the ability to injure the liver, alone or in association with other agents, is still under scrutiny.

TABLE 2 Serum parameters useful for the biochemical evaluation of liver necrosis and function

Test	Information provided
ALT and aspartate-aminotransferase . .	Degree of hepatocellular injury and necrosis
γ-Glutamyl transferase	Marker of cholestasis
Alkaline phosphastase	Confirmation of cholestasis
Direct bilirubin	Degree of cholestasis
Albumin, cholinesterase, ... total cholesterol, prothrombin time, etc.	Degree of damage to liver protein synthetic activity
Ferritin	Degree of damage to liver storage activity
Immunoglobulin profile	Immune system activation

The mechanisms by which viruses damage the liver are only partially understood, but, at least in the viral systems most thoroughly investigated, data converge to indicate that tissue injury is mainly mediated by the host's immune attack on viral antigen-expressing hepatocytes, while the direct effects produced by viral replication itself are of marginal importance, if any. Indeed, when cell-mediated immune responses are feeble, as typically occurs in individuals infected perinatally or those undergoing immunosuppressive treatments, the manifestations of hepatitis B and C are usually less severe than when the immune system is mature and uncompromised. Conversely, in patients chronically infected with HBV or HCV, abrupt withdrawal of immunosuppressive treatments is often followed by worsening of the clinical and biochemical picture, although viral replication declines. On the other hand, chronic HBV and HCV infections of immunocompromised individuals, primarily those who are coinfected with human immunodeficiency virus type 1 (HIV-1), are particularly difficult to treat with some success.

HCC develops in 2 to 4% of chronic hepatitis patients, mostly those with a background of liver cirrhosis. It is generally accepted that the extensive cell death and regeneration that occur in the chronically infected liver, together with the resulting persistent inflammation, are major driving forces in tumorigenesis; however, the fine mechanisms of hepatocyte transformation remain unclear. The HCCs developed in patients chronically infected with HBV almost universally carry, integrated in their cells, fragments of the viral genome. The role played by these fragments, however, remains essentially unresolved. The pathogenetic mechanisms of the extrahepatic manifestations associated with hepatitis viruses are also poorly understood.

HBV, HCV, and HDV produce long-lasting viremias and are frequently transmitted parenterally through infected blood (blood-borne hepatitis) or sexually. In contrast, hepatitis A and E viruses, which are abundantly excreted with the feces and can be found only briefly in blood, follow epidemiological patterns typical of classical infections transmitted via the oral-fecal route. Most epidemiological features of GBV-C and anelloviruses are still poorly defined, but current evidence indicates that the usual route of transmission is parenteral for HGV and enteric or respiratory for anelloviruses. HBV and HCV infections observed in neonates are generally acquired during parturition or postnatally.

The viruses considered in this chapter are examined separately because of their distinctive properties. For each virus, a concise summary of the most relevant biopathological features is provided, and the approaches used for diagnosis and follow-up are discussed. Regarding the latter aspect, special

emphasis is given to the methods that are most widely used, have entered the clinical laboratory most recently, or have only been proposed but appear suitable for routine use in the near future. For assays that are no longer in common usage, the reader is referred to previous editions of this manual. The procedures for commercial assays are accurately described in the manufacturers' accompanying leaflets and should be strictly followed, while those for in-house methods are too varied to be detailed here. Guidelines for the correct selection of tests in different clinical situations are given at the end of the chapter.

HAV

Hepatitis A virus (HAV) is a 27- to 32-nm, nonenveloped icosahedral virus with a linear, single-stranded, positive-sense RNA genome. The RNA is approximately 7.5 kb in length and encompasses a single open reading frame (ORF), two untranslated regions (UTRs) at the 5′ and 3′ ends, and a poly(A) tail. The 5′-UTR contains an extensive secondary structure required for cap-independent translation and is covalently linked to a 2.4-kDa protein (VPg protein). The ORF is translated into a whole polyprotein that is sequentially cleaved, mostly by a viral protease, into precursor and then mature structural (VP) and nonstructural (NS) proteins. Three capsid proteins (VP1, VP2, and VP3) are found in mature virions, while a small VP4 protein is released during morphogenesis. End products also include the protease, an RNA-dependent RNA polymerase, and other NS proteins. Several of these features are common to the *Enterovirus* genus within the family *Picornaviridae*. However, the genomic organization of HAV is partially different, and the degree of genetic homology to enteroviruses is very low. Also, HAV does not react with enterovirus-specific monoclonal antibodies, is not cytopathic in culture, and is highly resistant to physicochemical agents. For these and other reasons, HAV is classified in a picornavirus genus of its own, *Hepatovirus*. Although the degree of heterogeneity is high (at least nine variants between genotypes and subtypes and three antigenic variants have been distinguished), only one serotype is known (8). Adaptation of wild-type HAV to culture conditions is slow and troublesome, but some laboratory strains grow readily in primate cells. The main protective antigenic site is conformational and contributed to by both VP1 and VP3. Therefore, a significant neutralizing antibody response is elicited only by whole-virus preparations, while disrupted virions and recombinant proteins have not been proven effective in inducing protective immunity (17).

Exposure to HAV is usually enteric. The virus invades the liver, possibly following a phase of gastrointestinal amplification, and replicates extensively in hepatocytes, from where it is shed into the bloodstream and bile. Viremia, which was traditionally considered more short-lived, has been shown to start roughly 15 days before peak liver enzyme levels and to last between a month and a year (5). Fecal shedding is also significantly longer than previously believed. The antibody response is considered a key element in elimination of infectious HAV in both blood and feces, while cell-mediated mechanisms are probably most important in pathogenesis and clearance of virus from the liver. An immunoglobulin M (IgM) antibody response is invariably detected, usually in concomitance with the disappearance of viral antigen from the bloodstream. Anti-HAV IgG follows and persists for years, conferring lifelong protection (Fig. 1).

HAV infection is clinically silent in over 90% of children under 5 years old and in 70 to 80% of adults. Overt forms range in severity from a mild, short-lived anicteric illness to more protracted severe icteric hepatitis. Fatal liver failure is rare and usually occurs in patients with preexisting chronic hepatitis B or C or other forms of liver damage. Signs and symptoms, often preceded by a nonspecific prodromic phase, develop after an incubation period of 10 to 50 days and are typical of acute liver inflammation. Biochemical and clinical abnormalities usually resolve in 4 to 6 weeks, albeit liver enzymes may take longer to normalize. HAV does not cause chronic disease, but some patients may experience generally mild relapses weeks after recovery from the primary disease.

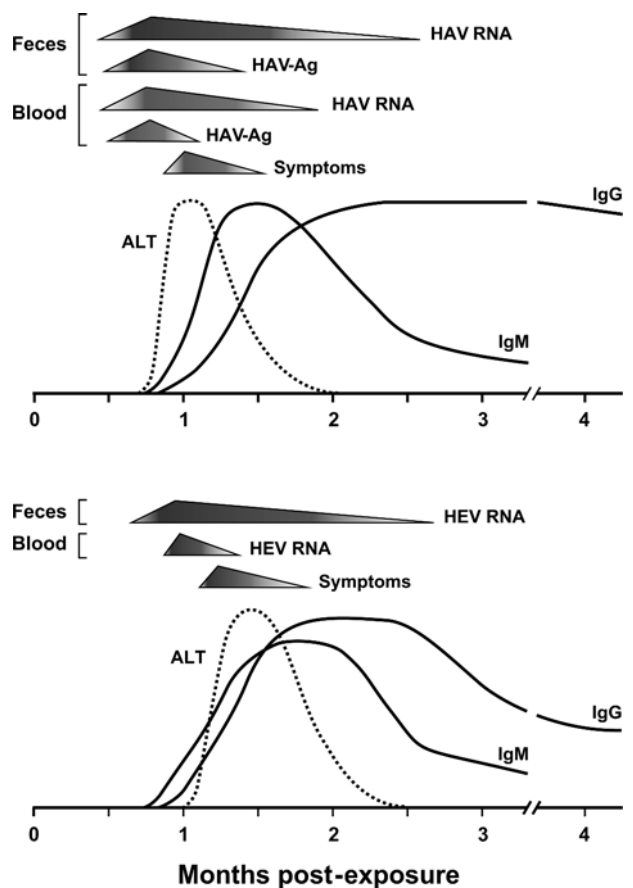
Primates are the only hosts. HAV is transmitted mainly through person-to-person contact by the fecal-oral route and, due to its remarkable resistance in the environment, may give rise to massive water- and food-borne epidemic dissemination. In developing countries, 10-year-old children are almost invariably anti-HAV positive. In industrialized countries, the circulation of HAV has been declining for several decades, leading to increased proportions of susceptible adolescents and adults. However, HAV remains the most common cause of hepatitis in the United States and elsewhere. In industrialized countries, epidemics still occur from time to time, and clinical severity increases with age, leading to the paradoxical effect of greater morbidity and


FIGURE 1 Typical course of immunovirological events and manifestations of liver damage in symptomatic infection by the enterically transmitted HAV (top) and HEV (bottom). Both viruses produce many more inapparent than symptomatic infections, but the immunovirological events are similar to the ones depicted. Neither virus produces chronic infections.

mortality in older age groups and increasing economic costs (14). Small outbreaks take place primarily among infants in preschool day care centers and their contacts and among people living in poor neighborhoods, while sporadic cases are generally traced to the consumption of raw bivalve shellfish and to travel to countries with poor sanitation. Parenteral transmission is suspected in hemophiliacs and injecting drug users (IDUs). Tissue culturing of some HAV strains has greatly facilitated the development of inactivated and attenuated vaccines, but only the former have been licensed and extensively employed, either alone or in combination with anti-HBV vaccine. Administration of immune serum globulins to contacts and targeted vaccination campaigns are highly effective at reducing infection severity and incidence, respectively.

Assay Systems for HAV

An algorithm for use and interpretation of laboratory tests for HAV infection is provided in Fig. 2.

Testing for Antiviral Antibody

The first choice for diagnosis of ongoing HAV infection is to search for anti-HAV IgM. This marker is almost invariably present from onset of clinical symptoms and remains detectable for 3 to 6 months in approximately 80 to 90% of patients and for up to 1 year in the remaining patients (Fig. 1). Commercial tests are generally both sensitive and specific. Currently, testing is generally carried out by enzyme immunoassays (EIAs). The most convenient and widely used tests are in the solid-phase antibody capture format, using μ-chain-specific antibody to bind any IgM present in the test serum, the addition of HAV grown in culture and purified to trace specific IgM, and an enzyme-conjugated anti-HAV IgG to reveal bound antigen.

Because there is virtually no temporal lag between the appearance of anti-HAV IgM, IgG, and IgA, comparison of the titers of these classes of antibody has no diagnostic value. Total anti-HAV antibody (both IgG and IgM) is measured to determine whether individuals have been exposed to HAV, either by natural infection or vaccination, and to assess the need for or the efficacy of immunoprophylaxis in contacts and in persons at risk of infection because of their profession, travel to areas of high endemicity, or contact with infected persons. Commercial kits generally use solid-phase competitive inhibition EIAs with purified HAV as the test antigen. While the original anti-HAV assays were designed for use with serum, other types of specimen, such as urine, have been investigated because they are more convenient for diagnostic and epidemiological purposes. Appositely modified EIAs have been proposed. Results can be expressed as international units (IU) for comparison with appropriate reference standards. Discrimination between past infection and past vaccination is rarely necessary but can be achieved by testing sera for antibodies to NS proteins, which are not elicited by the inactivated vaccines currently in use. The use of HAV neutralization tests is restricted to the biologic control of vaccine manufacturing.

Testing for Viral Antigen

Direct detection of the infectious agent has an ancillary role in the laboratory diagnosis of hepatitis A due to the reliability and ease of anti-HAV IgM testing. Even now, although sensitive and easy genome amplification assays are available, the greatest utility of virus detection lies in the identification of individuals who spread the virus in the course of outbreaks and the infection fomites. In clinical settings, detection of HAV antigen is generally carried out by EIA methods.

Testing for Viral RNA

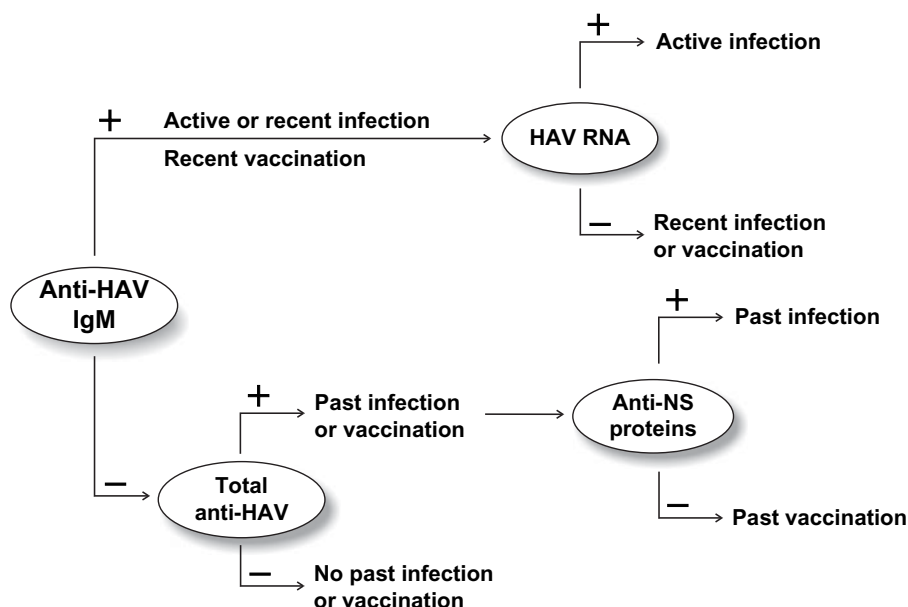
Viral RNA is tested for mainly by reverse transcriptase PCR (RT-PCR). Studies have demonstrated that real-time RT-PCR detects HAV in serum for up to >1 year after clinical onset, with peaks in the order of magnitude of 10^5 viral copies/ml at the time of diagnosis (5). Stool samples are found HAV RNA positive for months, i.e., for much longer periods than detectable by the most sensitive immunoassays (Fig. 1). However, only stool samples containing detectable


FIGURE 2 Algorithm for use and interpretation of laboratory tests for HAV infection. HAV RNA detection is usually carried out with stool samples.

HAV antigen proved infectious when used to inoculate primates (33). RT-PCR detection of HAV RNA in serum before seroconversion has been recommended for early diagnosis of hepatitis A during outbreaks (9). RT-PCR is also particularly suitable for detecting virus in wastewater and shellfish, where its concentration can be particularly low. In addition, molecular techniques can be designed to permit subsequent evaluation of the genetic relatedness of different clinical or environmental isolates, which can be epidemiologically useful.

HBV

HBV is classified within the family *Hepadnaviridae*, together with related viruses of animals. Virions are double-shelled particles, 40 to 42 nm in diameter, with a tight outer lipoprotein envelope that contains three forms of a virus-encoded glycoprotein (designated surface antigen [HBsAg]). Inside the envelope is the 27-nm icosahedral capsid, or core, composed of approximately 200 copies of a single phosphoprotein (core antigen [HBcAg]). This encloses a relaxed-circular, partially duplex DNA genome of 3.2 kb and the polymerase, which performs the synthesis of viral DNA as well as other functions. Among the smallest of all known animal virus genomes, the HBV genome has four extensively overlapping primary ORFs: the *S* gene, coding for the HBsAg proteins; the *C* gene, coding for the HBcAg and hepatitis B e antigen (HBeAg); the *P* gene, coding for the DNA polymerase; and the *X* gene, coding for a multifunctional regulatory protein with transactivating properties essential for replication. The virus is relatively heat stable but is rapidly destroyed by acids and lipid solvents.

The only cells that have proved susceptible to HBV infection in vitro are primary hepatocytes of humans and chimpanzees (the only susceptible species); all attempts to grow the virus in more readily available systems have failed. Mice transgenic for all or part of the viral genome are therefore used extensively to explore aspects of HBV molecular biology and pathogenesis. In vivo, the virus replicates predominantly in hepatocytes, although some viral DNA is also found at extrahepatic sites, including kidney, pancreas, and mononuclear cells. A key feature of HBV replication is that the genome is synthesized via an RNA intermediate. Following cell entry through a still-undefined receptor(s), the partially double-stranded DNA genome is released from the core, transported to the nucleus, and converted into a covalently closed circular DNA molecule which serves as a template for the synthesis of genomic and subgenomic RNAs by host RNA polymerase II. Assembly takes place in the cytosol; here, genomic RNA and viral proteins encoded by the subgenomic RNAs associate to form the nucleocapsid. After encapsidation, genomic RNA is reverse-transcribed into a strand of DNA, which is then transformed into the partially duplex molecule found in mature virions. Subsequently, the nucleocapsids acquire the envelope by budding through intracellular membranes at sites where viral glycoproteins have accumulated and are released extracellularly, with no evident direct cytopathology. However, in the context of laboratory diagnosis, the most noteworthy features of HBV replication are as follows. (i) Virion release by hepatocytes is sustained and long-lasting. (ii) The envelope glycoproteins are produced in great excess relative to what is needed for virion morphogenesis and are released as spherical and tubular subvirion aggregates as well as intact virions; in the bloodstream, the former typically outnumber virions by 3 to 5 orders of magnitude, thus representing a

large part of the HBsAg. (iii) A fraction of C gene products is not incorporated into virions but reaches the Golgi apparatus, where it is cleaved to form HBeAg by cellular proteases; HBeAg is then released as such by infected cells and circulates freely in blood, where it is detectable as a distinct antigen.

HBV has been classified into immunotypes and genotypes, based on distinctive antigenic determinants in the HBsAg and genetic relatedness, respectively. One antigenic determinant (designated *a*) is cross-reactive among all immunotypes, whereas the others tend to be present in one of two allelic forms (e.g., *d-y* and *w-r*). This results in different antigenic formulas, of which the most frequent worldwide are *adw*, *adr*, and *ayw*. Due to the presence of an important cross-protective moiety in the universal *a* determinant, however, there is only a single serotype of HBV, and the usefulness of immunotypes is solely epidemiological. Of the eight genotypes currently recognized, genotype A is pandemic, whereas the others are more geographically restricted (genotypes B and C prevail in Asia, genotype D prevails in southern Europe, E in Africa, F in the Americas, and G in the United States and France, and genotype H has been recently identified in Central America). In recent studies, Caucasian patients infected with genotype A were found to be more likely to resolve the infection than Caucasian genotype D patients, and Asians with genotype B developed milder forms of hepatitis and responded better to therapies than Asian genotype C patients (15, 53). Certainly more important for laboratory diagnosis and disease management, however, are the so-called HBeAg-minus core or precore mutants of the virus, which are unable to express HBeAg due to a stop codon in the C gene, and the drug-resistant variants that are commonly found in patients undergoing therapy (see below). The clinical significance, if any, of mutations increasingly found in the S gene of HBV isolates obtained from vaccinated children is still unclear.

Most primary HBV infections evolve with moderately altered liver enzymes but no appreciable symptoms. Clinically evident acute hepatitis is observed only in <5% of perinatal HBV infections and in 20 to 30% of adult infections. Symptoms of acute hepatitis B develop after a longer incubation period (usually 1.5 to 3 months) and tend to be more severe and longer-lasting than in other forms of acute viral hepatitis (Fig. 3). Acute-phase HBV-infected patients normally contain large numbers of virions in their blood (10^9 per ml or greater), although viremia usually undergoes a slight decline when the symptoms of acute hepatitis develop, most likely as a result of the mounting immune responses. The viral components detectable in viremic blood include HBsAg (present both as whole virions and subvirion aggregates), HBeAg, HBV DNA, and the virion-associated DNA polymerase. HBcAg instead usually remains hidden within intact virions or complexed with antibodies. Serologically, during this stage the host's immune response is revealed only by the presence of antibodies to the internal capsid protein (anti-HBc).

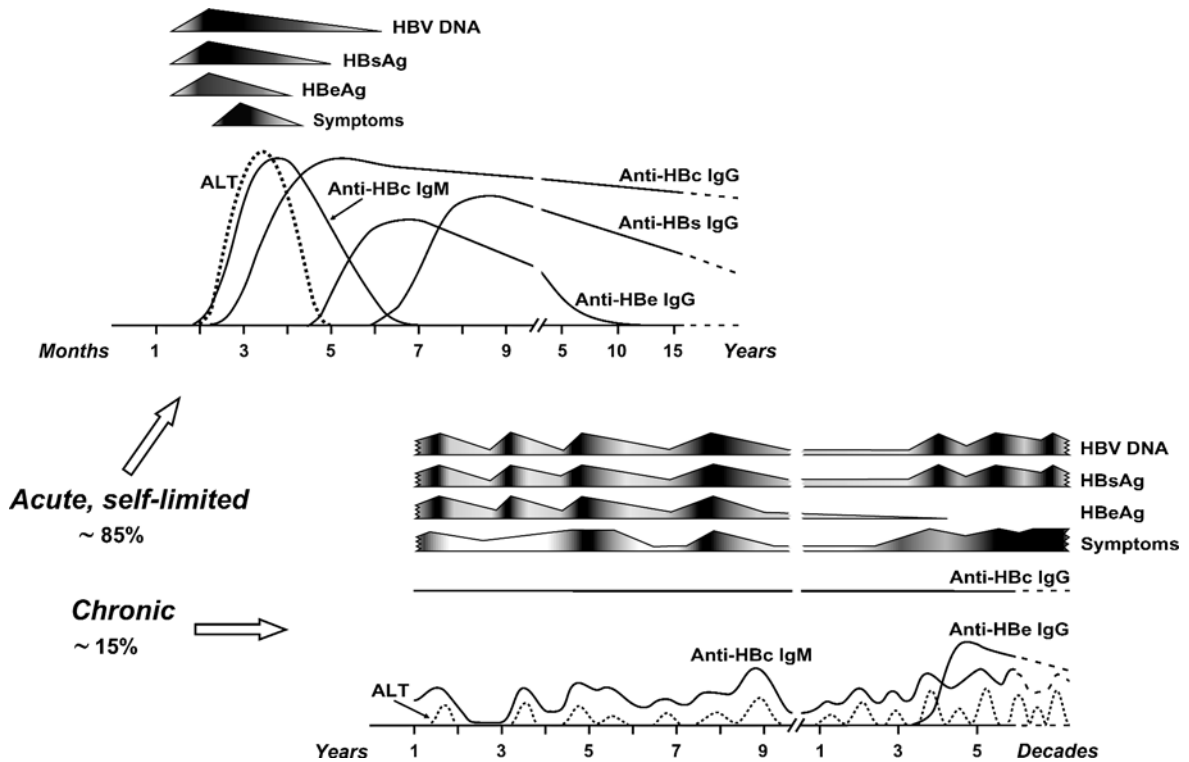
In the absence of complications, clinical resolution of acute hepatitis B occurs within 2 to 6 months from onset and is generally paralleled by the clearance of viral antigen and DNA from blood and followed by the development of antibodies to HBsAg (anti-HBs). Anti-HBs possess virus-neutralizing activity and confer lifelong immunity. Recovery, however, is believed to be mediated mainly by cytokines and cytotoxic T lymphocytes. Self-limited HBV infections are characterized by a progressive decline of viremia (Fig. 3). For example, a >40% reduction of HBsAg concentration is


FIGURE 3 Typical course of immunovirological events and manifestations of liver damage in symptomatic acute, self-limiting, and chronic HBV infection. The proportion of infections that chronicize is indicated as 15% but in fact varies widely, depending on the patient's age and other variables (see text). The initial, acute phases are essentially the same, regardless of whether the infection resolves or becomes chronic. The vast majority of HBV infections do not produce overt disease or do so after many years of persistence; however, the immunovirological events are similar to the ones depicted.

considered suggestive of a favorable prognosis. Importantly, resolution of infection is usually preceded by the disappearance of HBeAg from blood and appearance of detectable antibodies to this antigen (anti-HBe). Concomitantly or subsequently to these changes, hepatic histology, biochemical parameters, and clinical conditions normalize. Thus, by all classical criteria, both acute hepatitis B and the underlying infection are resolved.

Recently, however, sensitive genome amplification assays (typically, nested PCR) have revealed that 30 to 80% of patients who have apparently resolved an acute hepatitis B infection may continue to harbor low levels of HBV DNA in the serum, blood mononuclear cells, and liver for years. This condition, which is often referred to as occult HBV infection and is especially frequent in patients coinfected with HCV and HIV-1, needs to be better understood because it is not even known whether the viral DNA detected is full-length genomes and whether it is enclosed within potentially infectious virions. Helping to obscure the picture, a similar status has been observed also in individuals lacking any other marker of ongoing or past HBV infection, including anti-HBc (2).

As mentioned above, a proportion of acutely infected individuals, regardless of whether they are symptomatic or not (in fact, the forms of hepatitis with mild or no symptoms have an increased tendency to persist), fail to clear the virus, do not develop readily detectable anti-HBs, and progress to chronicity. Of several variables which affect the frequency of

this occurrence, the patient's age is by far the most important. Indeed, perinatal infections become chronic in more than 90% of cases, compared with 15 to 30% of cases in childhood and fewer than 5% in adulthood. The behavior of infection markers is clearly distinct from the one described for self-limiting transient infections. The picture is dominated by the persistence of variably high levels of HBsAg and other markers of viremia in serum usually for life, while clinical manifestations vary from alternating periods of remission (chronic hepatitis B) to no symptoms at all (healthy HBV carriers). Chronic viremia may remain essentially stable over time but more often fluctuates somewhat, with peaks in concomitance with elevated levels of ALT and of anti-HBc IgM and a deteriorated clinical picture (Fig. 3). It has been calculated that chronically infected patients release as many as 10^{11} or more virions per day in the bloodstream and that the daily turnover of circulating virions is about 50% (35). At any rate, with passing years, the levels of infectious virus in blood tend to slowly decline, as revealed by decreasing concentrations of HBeAg and HBV DNA. Ultimately, generally after many years of persistence, HBeAg becomes undetectable, and this is generally followed by seroconversion to anti-HBe. Nonetheless, HBsAg and HBV DNA continue to be readily detectable in the circulation (Fig. 3).

During chronic hepatitis B, liver damage accumulates and in approximately 20% of cases ultimately leads to cirrhosis. In turn, cirrhosis determines a 100-fold or more

increased risk of developing HCC. Importantly, chronically infected individuals with no detectable HBeAg have a mild disease course, exhibit a relatively low risk for progression to cirrhosis and HCC, and transmit the virus with reduced efficiency. However, it is imperative to consider that, particularly in Asia and southern Europe, failure to demonstrate HBeAg can not only represent an indicator of low infection activity but also be the consequence of active infection by HBeAg-minus variants of the virus.

Spontaneous resolution of persistent HBV infection is rare, occurring annually in less than 1% of subjects. The few cases of chronic infection which do eventually completely resolve exhibit an evolution of infection markers similar to the one discussed for resolution of self-limiting acute infections, albeit much slower in pace. Recently, these similarities have been seen to include the long-term detectability of minute amounts of viral DNA in plasma and liver by sensitive amplification methods, in spite of consistently negative HBsAg tests (2, 15, 44).

The prevalence rates of chronic HBV infection vary widely throughout the world, from as high as 25% in certain areas of sub-Saharan Africa, China, and Southeast Asia to as low as 0.1 to 0.5% in western Europe and North America. Niches of especially high endemicity, however, can be found within specific ethnic, behavioral, and professional groups of any geographical region. Infected humans shed HBV with body fluids, including saliva, urine, semen, vaginal and menstrual fluids, tears, and breast milk. Vertical transmission from infected mothers to babies during parturition or postnatally is a major mechanism of virus diffusion especially in areas where HBV is hyperendemic, where intrafamilial spread with no other apparent form of exposure also occurs and seems to be especially important for young children. Sexual transmission is also frequent, as shown by high rates of infection among sexually active young adults living in areas of low endemicity, with peaks among male homosexuals. However, IDUs show the highest rates of infection in these areas. Recognized fomites include toilet articles and contaminated medical instruments. Transmission by blood transfusions and clotting factor replacement therapy is currently uncommon as a result of donor screening, virucidal treatment of blood derivatives, and other measures. Several intervention strategies have been implemented to limit HBV dissemination, but vaccination of newborns with recombinant HBsAg is by far the most powerful and is used extensively in many parts of the world. Indeed, increasing implementation of vaccination is rapidly modifying HBV epidemiology in many countries.

Natural and recombinant alpha interferon (IFN-α) and, more recently, its pegylated form pegIFN-α have shown limited utility for treatment of chronic HBV infection. The recent advent of nucleoside or nucleotide analogs that target the viral polymerase has, however, started a new therapeutic era. Lamivudine and adefovir dipivoxil have proved efficacious and generally well tolerated and have consequently been elevated to the rank of first-line therapies. Several other antiviral compounds currently under scrutiny are showing promise and might become therapeutically available in the near future. Current treatments often lead to sustained improvement of clinical symptoms, ALT level normalization, and reduction or clearance of viremia. However, total eradication of infection is infrequent. In any case, due to the rapid emergence of resistant P gene mutants, most patients relapse after withdrawal of therapy. Liver transplantation remains the only treatment for decompensated cirrhosis and HCC. Unfortunately, recurrence of HBV infection in the grafted liver is common and shows a particularly aggressive course, in spite of recent pharmacological attempts. For more comprehensive reviews of HBV pathobiology, consult references 11, 15, 24, and 44.

Assay Systems for HBV

Customarily, the laboratory diagnosis of HBV infection has been carried out by using commercial immunoassays that detect the viral antigens or the corresponding antibodies and provide most of the information needed at relatively low cost. The kits currently used to this purpose exploit various principles and formats (including dipsticks), are generally characterized by good to excellent specificity and sensitivity, and have often been automated to deal with large numbers of samples. HBV DNA detection and quantitation, however, are being increasingly used for assessment and management of hepatitis B. Commercially available molecular assays also have different formats and are generally reliable, standardized, and simple to use or automated but remain relatively expensive. Criteria for use and interpretation of HBV test systems are provided in Fig. 4 and Table 3.

Testing for HBsAg

HBsAg becomes detectable in serum 2 to 10 weeks after initiation of infection (i.e., 2 to 6 weeks before ALT abnormalities and 2 to 5 weeks before clinical onset) and reaches peak concentrations of 50 to 300 μg per ml in the late incubation or early acute phase. The capture EIAs and other immunoassays currently in use for HBsAg detection and quantitation have a lower limit of sensitivity in the range of 0.1 to 2 ng of HBsAg per ml of serum, corresponding to roughly 3×10^7 viral particles. Given this high sensitivity, a negative test implies that no active HBV replication is ongoing or, more rarely, that the virus produced is too scarce for consistent HBsAg detectability, as occasionally is observed during acute infections accompanied with massive liver necrosis (fulminant hepatitis) and in neonatal infections. Mutations in the a determinant may also affect the performance of HBsAg immunoassays. Importantly, since sporadic false positives do occur (due to accidental contamination, insufficient washing of microwells or beads, or the presence of anticoagulants in test samples), a first positive HBsAg result should always be confirmed with the same test or a different type of test, such as specific inhibition with unlabeled anti-HBs or, more conveniently, by assaying for other markers of infection. Before molecular assays became routine, the customary confirmatory marker was total anti-HBc. Since anti-HBc is the first antibody to appear and the most persistent, a positive HBsAg test in the absence of a corroborating positive anti-HBc test always had to be interpreted with great caution. Currently, testing for HBV DNA should be considered the confirmation method of choice.

By itself, a confirmed positive HBsAg test proves that an HBV infection is ongoing but does not distinguish between acute self-limiting infection, acute infection with no tendency to resolve, and chronic infection with moderate or exuberant virus replication. Accurate investigation of the patient is required to distinguish among these possibilities, including direct measurement of viremia levels, testing for HBeAg, and testing for the presence and concentration of anti-HBc IgM, anti-HBe, and anti-HBs.

Testing for Viral DNA

Since the tests currently in use may have detection limits as low as 10^2 viral genomes per ml, to date, HBV DNAemia is the most accurate marker of ongoing HBV replication.

Figure 4 flowchart text:

Suspected infection → Total anti-HBc or HBV DNA

− → False positive HBsAg
+ → Confirmed infection → Anti-HBc IgM
  + → Recent infection or reactivation of chronic infection

Determination of HBV DNA also circumvents the problem of demonstrating and staging infections sustained by genetic variants of HBV, such as the HBeAg-minus mutants.

HBV DNA assays usually target the C gene and can be both qualitative and quantitative. However, the qualitative tests are being rapidly replaced by quantitative methods that perform equally well and are of greater utility in the follow-up of patients, especially when the patients are undergoing antiviral treatments. The commercially available tests have different sensitivities and linear ranges, but their precision

TABLE 3 Interpretation of immunovirological profiles for HBV

Genome (HBV DNA)	HBsAg	HBeAg[a]	Anti-HBe	Anti-HBc IgM	Anti-HBc IgG	Anti-HBs	Interpretation
							Acute infection
+	+	+	−	−	−	−	Very early stages
+	+	+	−	+	−	−	Early stages
+	+	+	−	−	+	−	Late stages
−	−	−	+	±	+	+	Resolution
							Chronic infection
+	+	±	−	−	+	−	Typical profile
+	+	±	±	+	+	−	Reactivation

+	−	−	−	−	±	±	Occult infection
−	−	−	±	−	±	±	Remote infection
−	−	−	−	−	−	+	Past vaccination
−	+	−	−	−	−	−	Likely false positive
−	−	−	−	−	+	−	False positive, passively acquired antibody, resolved infection with loss of detectable anti-HBs
−	−	−	−	−	−	−	No infection

[a]In infections by HBeAg-minus virus variants, HBeAg may test negative and anti-HBe may test positive in spite of active HBV replication.

and reproducibility characteristics are generally good. Among the assays, the so-called real-time methods, which quantify the viral nucleic acids in test samples by measuring the amplicons while they form during the exponential phase of amplification, have reached the diagnostic laboratory only recently but thanks to their excellent characteristics (linearity of up to 7 logs versus the 3 to 4 logs of conventional PCR assay, sensitivity up to 50 to 100 copies/ml, high throughputs, cost-effectiveness) are setting a new standard for quantitative assays. A plethora of in-house single-round and nested quantitative PCR assays have also been described, with reported sensitivities ranging from 5 to 10 viral particles/ml (nested PCR) to 600 copies/ml (single-round PCR), but many suffer from small linearity ranges and other limitations. Additional innovative technologies, such as DNA chips and other microarray technologies, have the potential to simultaneously quantitate the virus and characterize its genetic features but have yet to reach the clinical virology laboratory.

The wide array and decreasing costs of available quantitation methods have led to consideration of periodic measurement of HBV DNA as the key parameter for the management of HBV patients. However, uncertainties still exist with regard to what levels of HBV DNAemia can be associated with a lack of clinically significant liver damage and what levels instead demand antiviral intervention (7, 22). Recently, a viremia of 10^5 HBV DNA copies per ml of serum was proposed as the cutoff level for distinguishing healthy carriers from chronic hepatitis patients (20), but further studies are clearly warranted.

Testing for Anti-HBc

Typically, anti-HBc IgM develops at the same time as ALT changes in acute infection (i.e., 1 to 2 weeks after HBsAg) and rapidly reaches considerable titers. The presence of high-titer anti-HBc IgM is therefore diagnostic for acute or recent HBV infection and, together with HBV DNA, may be the only marker present in neonatal infections or when the amount of HBsAg produced remains under the threshold of test sensitivity, as occasionally occurs in fulminant hepatitis. In the subsequent 4 to 6 months, IgM predominates but then slowly declines and is overwhelmed by increasing titers of anti-HBc IgG. In self-limiting infections, anti-HBc IgM becomes undetectable in a few months, although low titers are sometimes found for up to 2 years. In chronic low-grade infections, anti-HBc IgM is either undetectable or low in titer but usually reappears or increases (>10 IU/ml) when viral replication exacerbates, thus representing an indicator of infection activity. Tests for total anti-HBc (IgM and IgG) remain positive after complete eradication of infection, and the antibodies persist for life in >90% patients.

Testing for HBeAg, Anti-HBe, and Anti-HBs

As mentioned above, HBeAg appears in blood at the same time as HBsAg and is detectable whenever the virus is actively replicating. Conversely, disappearance of HBeAg is indicative of reduced viral replication. Note, however, that anti-HBe can coexist with active virus replication in patients infected by HBeAg-minus variants. For example, in patients undergoing antiviral treatment, the emergence of an HBeAg-minus mutant should always be suspected when elevated ALT levels persist despite HBeAg clearance.

In acute infection, conversion from HBeAg positivity to anti-HBe positivity is prognostic for resolution since it is usually followed by the disappearance of HBsAg (but, as discussed above, not always of HBV DNA) from serum and by the appearance of anti-HBs within weeks or months. In chronic infection, loss of HBeAg and acquisition of anti-HBe tend to be associated with biochemical and histological improvement.

Anti-HBs become measurable just before or, more typically, a few weeks after HBsAg clearance and, being virus neutralizing, are a marker for complete clinical recovery and acquired immunity. Anti-HBs are usually permanent but, many years after infection resolution, they have a somewhat higher tendency than anti-HBc to become undetectable.

Determining Viral Genotype or Immunotype

HBV can be immunotyped with monoclonal antibodies and genotyped by characterization of amplified segments of the viral DNA by sequence analysis, restriction pattern analysis, or inverse hybridization. To date, HBV typing has generally remained restricted to epidemiological studies. If confirmed, the recent indications that HBV genotype might affect disease severity and responsiveness to therapies (15) might render HBV genotyping a routine laboratory test, similar to what already occurs with HCV. Although no standard HBV genotyping method has yet been established, sequence analysis will most likely become the method of reference, in analogy to what happens with other viruses.

Testing for HBeAg-Minus and Drug-Resistant Mutants

As discussed above, some HBV mutants are of clinical interest. Determination of whether HBV has evolved clinically significant mutations is becoming increasingly important. Patients with undetectable HBeAg but high HBV DNA levels and severe liver damage can carry mutants altered in the precore or core region of the C gene of the virus that are unable or impaired in the ability to produce HBeAg. These mutants can be identified by sequencing the region of the viral genome involved (the most frequent has a stop codon at codon 28 of the precore region). Less cumbersome methods have also been proposed but still need to be properly evaluated.

Breakthroughs in the response of HBV to therapies are often the result of the emergence of mutations in the target site of the drug being used. For example, during long-term therapy with lamivudine, the frequency of lamivudine-resistant mutants has been seen to rise from between 15 and 30% in the first year to 60% or more by the fourth year of treatment. As there are no phenotypic resistance assays available, HBV drug resistance is monitored by genotypic analysis. Most lamivudine-resistant mutants have an exchange of the methionine at codon 552 within the YMDD amino acid motif of the catalytic site of the DNA polymerase to either valine or isoleucine, which narrows the active site pocket and blocks drug binding. Direct sequencing of selected regions of ORF *P* (approximately 600 nucleotides) is the method of choice; however, more rapid assays similar in principle to the ones developed for HIV-1 drug resistance analysis have been developed and are commercially available.

HCV

HCV, the major agent of parenterally transmitted non-A, non-B hepatitis, remained elusive until the late 1980s, when its genome was molecularly cloned from experimentally infected chimpanzees. The genome is a linear molecule of single-stranded, positive-sense RNA approximately 9.5 kb in length. It contains one large ORF and two relatively short

UTRs at the 5′ and 3′ ends that play essential roles in genome expression and replication. The ORF is translated into a large polyprotein precursor of approximately 3,000 amino acids which is cleaved post- and cotranslationally into a dozen mature proteins. Of these, three are essentially structural (the capsid, or C, protein and the envelope glycoproteins E1 and E2) while the others (p7, NS2, NS3, NS4A and -B, and NS5A and -B) have enzyme activity (an RNA-dependent RNA polymerase, two proteases, and a helicase) and other poorly defined functions. Recent studies have shown that p7 has ion channel activity. A new protein with undetermined functions (protein F) encoded by an ORF overlapping the C region has also been identified. The virion, which has proved hard to visualize, is round, 55 to 65 nm in diameter, and consists of a 30- to 35-nm icosahedral nucleocapsid formed by numerous copies of the C protein and an outer lipoprotein envelope with small projections containing the E1 and E2 glycoproteins. Its infectivity is relatively unstable. On the basis of genomic organization and other criteria, HCV is classified within the family *Flaviviridae*, genus *Hepacivirus*.

Diversity among HCV isolates is minimal in the 5′-UTR and maximal in the E2 glycoprotein, where a stretch of 31 amino acids (hypervariable region 1) has been proposed to function as a decoy for immune escape, similarly to the V3 loop of HIV. Analyses have distinguished six major genotypes, designated 1 through 6, each one divided into subtypes designated by lowercase letters. A few recombinants have been reported from Russia and Peru (subtypes 2k/1b and 1a/1b, respectively). As discussed below, it is generally accepted that the infecting genotype of HCV may influence the likelihood of a patient's response to therapies. The impact of genetic heterogeneity in cross-protective immunity and pathogenic potential is instead poorly understood, although evidence has recently been obtained for multiply exposed IDUs and experimentally infected chimpanzees for the existence of at least some intra- and intergenotype protection (16) and of limited between-genotype differences in disease progression (29).

Dissection of HCV-host cell interactions lags far behind, mainly due to the lack of suitable tissue culture systems, while information about the dynamics of infection in the organism is derived mainly from posttransfusion hepatitis and chimpanzees. HCV shows a distinct tropism for hepatocytes but also replicates in lymphoid cells, circulating plasmocytoid dendritic cells, and other cell types, although much less productively. In typical primary infections, the virus becomes detectable in blood within 1 to 3 weeks and peaks a few weeks later; then it gradually declines over the following months. Just before and shortly after seroconversion, the load of HCV in plasma can fluctuate extensively and drop to very low levels. In this phase, spontaneous clearance of primary infection has been observed in a proportion of cases that has varied between 15 and 50% in different reports and appears to be most frequent in female and young patients (25). However, in the majority of subjects, the infection becomes persistent. Modulation and clearance (when it occurs) of acute-phase viremia are believed to result from the host's immune response, which is vigorous but tends to be slower than in most other systemic viral infections. In particular, the window period between the appearance of virus in plasma and that of antiviral antibodies (anti-HCV) usually lasts 7 to 9 weeks and, occasionally, as long as 9 months (Fig. 5). However, there are no established immunological or virological markers that can be used to reliably predict whether acute HCV infection will be cleared or become chronic, although an association of certain major histocompatibility complex class II alleles with infection outcome has been reported.

In untreated chronically infected patients, the number of virions produced and cleared per day is on the order of 10^{10} to 10^{12}; the levels of circulating HCV remain essentially stable or slowly increase over time, with fluctuations that do not usually exceed $1 \log_{10}$, hardly ever falling below the level of detection. For these patients, concentrations and spectra of anti-HCV are approximately the same as observed in advanced acute infection (Fig. 5). Complete spontaneous resolutions of chronic infections have hardly been reported. On the contrary, recently, by use of very sensitive detection methods, HCV RNA has been detected in the blood of patients who have apparently undergone a well-documented spontaneous or therapy-induced resolution of infection. Reportedly, the peripheral blood mononuclear cells of these patients also harbor the negative, replicative strand of the viral genome, suggesting that HCV can be even more difficult to eradicate than previously believed (30). Also, a recent report has suggested that hard-to-detect (occult) HCV infection might be responsible for abnormal liver function in patients with no anti-HCV antibodies and no other known causes of hepatitis (6).

More than 70% of acute infections are symptom-free or present with nonspecific manifestations. When clinical hepatitis is present, it develops after an incubation period of 4 to 20 weeks and is generally mild and brief. Fulminant hepatic failure is very rare. ALT concentrations may exhibit different elevation patterns (single or multiple peaks, plateaus, etc.) but infrequently exceed 1,000 IU/liter, generally reflecting moderate liver damage, and usually progressively normalize within a few weeks. As a matter of fact, because acute infections are so inconspicuous, they frequently go undiagnosed, and many people are discovered to be HCV infected during chronicity as a fortuitous finding of blood testing for unrelated reasons. In accord with the concept that acute liver damage by HCV is essentially immune system mediated, self-limited infections appear to be more frequent among symptomatic than asymptomatic patients (42).

The clinical importance of HCV is due mainly to its long-term persistence and to the consequent accumulation of hepatocellular damage, which progresses more slowly but possibly more severely than during chronic hepatitis B. In about a third of chronic infections, ALT levels remain normal for prolonged periods. Most patients start to show intermittently or persistently elevated levels of ALT and progressively deteriorated liver functions after 2 or 3 decades of infection, and up to 20% go on to develop cirrhosis. HCC can develop in 10% of cirrhotic livers. Male gender, old age at the time of infection, alcohol intake, elevated ALT levels, and coinfection with HBV and/or HIV-1 are all factors that negatively affect prognosis (12, 54).

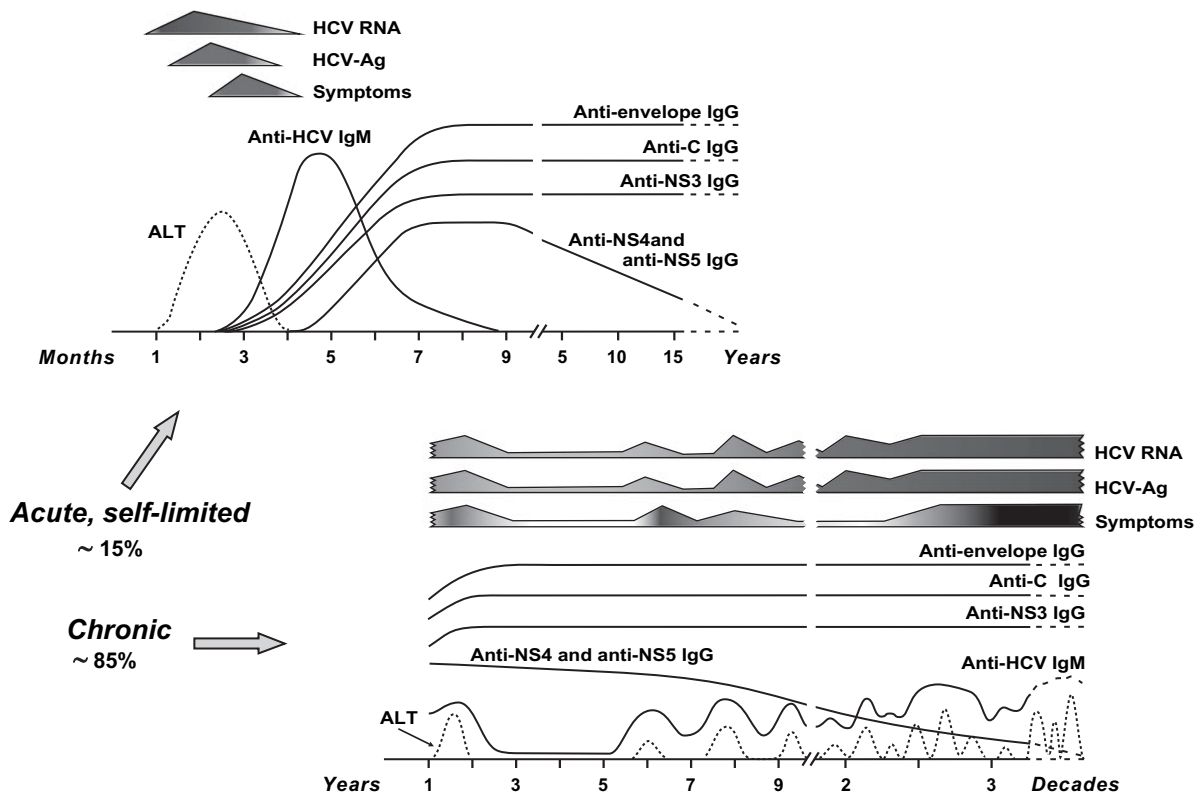
Humans are the only known natural reservoir for HCV. About 3% of the world population is estimated to be infected, with prevalence rates ranging around 2% in North America and western Europe and >10% in some Asian and African countries. Because many infected people may be clinically healthy and unaware of their infections, apparent prevalence is likely to increase in future years. The National Institutes of Health has estimated that the prevalence of chronic infection in the United States will keep increasing at least until the year 2015 (25). Thanks to much-improved blood screening, the risk of acquiring HCV infection as a result of blood transfusions or treatments with blood derivatives is currently extremely low. Nevertheless, iatrogenic


FIGURE 5 Typical course of immunovirological events and manifestations of liver damage in symptomatic, acute self-limiting and chronic HCV infection. The initial, acute phases are essentially the same, regardless of whether infection resolves or becomes chronic. HCV has a greater tendency to persist than HBV. The vast majority of both acute and chronic infections do not produce overt disease or do so after many years of persistence; however, the immunovirological events are similar to the ones depicted.

transmission is still observed in dialysis units, and there are also sporadic reports of HCV transmission from infected health care personnel to patients. In low-prevalence developed countries, intravenous drug abuse accounts for most new infections. Tattooing, acupuncture, body piercing, and any practice that may cause exposure to contaminated blood also contribute to dissemination. Mother-to-baby and sexual transmission are relatively ineffective, unless conditions that favor high viral loads, such as concurrent HIV-1 infection, coexist. Transmission to household contacts is infrequent, and there is no evidence for insect vectors. A significant proportion of HCV infections, designated community acquired or sporadic, occur apparently in the total absence of risk factors. Surveys have shown that HCV subtype 1a is predominant in North America, subtype 1b is predominant in western Europe and Japan, and types 4 and 5 are predominant in Africa, while type 6 appears to be restricted to Southeast Asia. Subtype 2c, previously considered a rare genotype, was found to be the second most frequent genotype in Italian patients with community-acquired infection (31). Differences in genotype distribution have also been observed, depending on the mode of infection.

Primary and secondary prevention activities are similar to those for HBV, except that no vaccine is available. Attempts to develop vaccines against HCV are under way but are encountering considerable hurdles. The efficacy of postexposure prophylaxis with immunoglobulins is probably only marginal. Treatment has improved significantly in recent

years, and currently pegIFN-α in combination with ribavirin is the standard of care for chronically infected patients. This combination therapy produces sustained virological responses in a much higher proportion of cases than monotherapy with IFN-α alone: up to 80% in infections by genotype 2 and 3 HCV and around 50% in infections by the other genotypes. A variety of other compounds, mostly targeting the viral enzymes, are being evaluated for possible clinical use, and hopefully some will became therapeutically exploitable in the near future. At least 25% of liver transplants worldwide are carried out in patients with HCV cirrhosis and HCC. Nearly all recipients relapse with hepatitis C in the grafted organ: this is usually a very precocious event, which leads to severe hepatitis and cirrhosis in up to 30% of patients (26).

Assay Systems for HCV

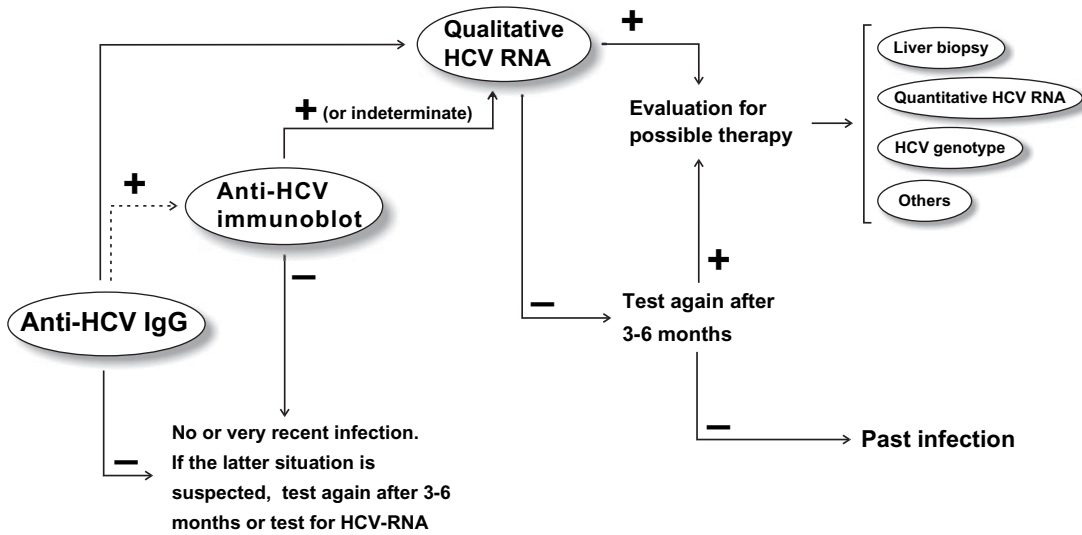
The first approach to diagnosis of HCV infection is detection of anti-HCV IgG (Fig. 6). In the context of first diagnosis, testing for the presence of virus in blood by either nucleic acid or antigen is useful for (i) identifying patients and blood or tissue donors who are still in the preserological phase (as discussed above, with HCV the window period is particularly extended), (ii) resolving indeterminate serological results, (iii) recognizing the relatively few patients who still possess anti-HCV but have spontaneously resolved the infection, and (iv) sorting vertically infected newborns from those who have merely received transplacental anti-HCV


FIGURE 6 Algorithm for use and interpretation of laboratory tests for HCV infection. Under selected circumstances, HCV-Ag detection and measurement can be used in place of HCV RNA detection. Immunoblotting as a means to confirm positive EIA results is currently skipped by many laboratories, which proceed directly to HCV RNA detection and use confirmation by immunoblotting only for the patients who test HCV RNA negative.

from their mothers. On the other hand, detection and especially quantitation of viremia are invaluable for correct clinical management of infected patients, since they provide an evaluation of HCV replicative activity in the liver (which should not be equated with severity of liver damage; see below).

Testing for Antiviral Antibodies

Commercial kits for anti-HCV IgG screening have been redesigned several times to shorten the duration of the window period and to augment sensitivity and specificity, thus meeting the needs of blood banks as well as of diagnostic laboratories. The ones in use at present (third generation) have reduced the window period by 4 to 6 weeks and consist of EIAs and other immunoassays using optimized combinations of recombinant and synthetic antigens representing conserved domains of the C, NS3, NS4, and NS5 proteins. Their specificity is generally excellent. The very few false-positive results observed have been attributed to hypergammaglobulinemia, aged serum samples, and rheumatoid factors or have remained unexplained.

For patients at high risk of infection with increased ALT levels and high anti-HCV reactivity, supplemental anti-HCV testing can be skipped, since correlation between a positive screening test and infection is essentially 100%, and it is less costly to proceed directly to testing for viremia (Fig. 6). In all other circumstances and especially when ALT levels are normal, certain laboratories validate positive results with a second immunoassay, possibly different from the one used for screening, while others prefer to proceed directly to testing for viremia. Serological validation is most often carried out by immunoblotting, which permits a dissection of antibodies directed to different viral determinants. Sera that react with products derived from at least two viral genes are considered positive and indeterminate when reactive with a single protein; reactivity to the carrier polypeptide fused to recombinant antigens (usually human superoxide dismutase)

shows that the positivity might be nonspecific. Indeterminate immunoblot results may be indicative of false positivity, especially for low-risk individuals, but they are frequent also for HCV-infected immunocompromised patients, whose reactivity is often restricted to C and NS3 antigens. It should also be kept in mind that IgG antibodies tend to be produced later in response to NS4 and NS5 than to other viral proteins and to wane earlier following spontaneous or posttreatment resolution of infection; therefore, absence of reactivity to envelope, C, and NS3 proteins may be indicative of recent infection, in patients still seroconverting, or of a resolved infection. Since the avidity of anti-HCV IgG increases significantly with duration of infection, tests that measure this parameter can help to sort out recent from remote infection, but they have not become routine.

The first anti-HCV antibody detected in infected patients is usually IgM. This class of antibody, however, cannot be used as a marker of acute-phase infection because it is also found in 50 to 70% of chronic infections. In the latter, the detection of anti-HCV IgM is frequently discontinuous, and some investigators consider this marker an indicator of increased virus activity, since it correlates nicely with ALT and viremia levels (Fig. 5). Unfortunately, the sensitivity and specificity of currently available commercial kits for anti-HCV IgM are far from perfect. Thus, even the optimized anti-HCV assays in use at present provide no reliable clues to discriminate resolved from ongoing infection and to evaluate the extent of viral replication. As mentioned above, this can be achieved by testing and measuring viremia.

Testing for Viral RNA

Detection and measurement of HCV RNA in plasma or serum are most frequently carried out with commercial assays that exploit RT-PCR and other gene amplification techniques similar to those discussed for HBV. The sensitivity, specificity, and hands-on requirements of most current

commercial assays are highly satisfactory; the lower detection limits are as low as 25 to 50 IU per ml, and intra- and interassay variabilities are small. Due to the wide genetic variability of HCV, correct selection of the genome segment targeted by amplification methods is critical. The preferred target is the 5′-UTR, but even in this highly conserved region only some segments are sufficiently homogeneous to permit an equal efficiency with all viral genotypes. This explains why early commercial quantitative kits underestimated the titers of certain HCV genotypes by approximately 1 log, a shortcoming virtually eliminated in current versions. The availability of automated devices for nucleic acid extraction, detection, and quantitation has markedly increased throughputs and reduced (although not eliminated) the risks of specimen contamination. False negatives are usually the result of carelessness in the preanalytical phase.

Qualitative nucleic acid-based tests are most useful in assessing the safety of blood donations but prove useful also when a suspicion of active infection based on serological grounds needs to be confirmed. In this case, it is advisable to retest negative patients several times at intervals of several weeks in order to identify the ones who might have intermittent viremia, as is frequently observed in the course of spontaneous resolution or antiviral therapy.

Quantification of HCV RNA in serum or plasma probably has its greatest utility in aiding in the decision of whether and when to start treating patients and in monitoring their responsiveness to antivirals, but, given that the costs and accuracies of the test methods are similar, they are also increasingly used as an alternative to simple HCV RNA detection. Viral loads may reach peaks of 10^7 IU per ml or more during primary infection but in untreated chronic infections usually range around 10^5 to 10^6 IU per ml, with considerable variations in individual patients. A positive correlation between HCV RNA levels in plasma and viral replication in the liver has been documented, but it is generally recognized that viral loads are of limited relevance for prognosis at the level of single patients. Despite partially different dynamic ranges and analytical sensitivities, most current commercial tests quantify HCV with similar efficiencies. The introduction of IU to express viral loads has greatly facilitated the comparison of results obtained with different methods, but it is nevertheless recommended that individual patients be monitored for viremia level by consistent use of the same assay throughout their follow-up. This is especially important if the patient is undergoing treatment (23).

Testing for Viral Antigen

Immunoassays for direct demonstration and quantitation of HCV antigen in serum have become commercially available more recently than genome-targeted molecular methods. The assays currently on the market target the core antigen and generally use classical EIAs. They are highly specific and perform equally well regardless of the infecting HCV genotype, with a lower limit of sensitivity of 1.5 pg (reportedly, 1 pg of HCV antigen corresponds to 8,000 to 8,500 IU of HCV RNA per ml, as detected by molecular methods). Reports have argued that, despite its low sensitivity, HCV antigenemia quantitation could be a relatively inexpensive alternative to molecular assays as a means of monitoring the efficiency of antiviral treatments. However, it is important to note that the test becomes positive a few days after the appearance of HCV RNA and is rather insensitive when the viral load is <10,000 IU/ml (45).

Determining Viral Genotype

The major indication for HCV genotyping is the need to obtain all the information for customizing treatment protocols. In fact, it is generally accepted that successful treatment of genotype 1 and 4 HCV infection with combined pegIFN-α and ribavirin therapy requires higher doses of ribavirin (1,000 to 1,200 mg daily versus 800 mg) and longer durations (48 versus 24 weeks) than treatment of infection by other genotypes (42). Sequence analysis of the viral genome is the "gold standard" for any genotype determination, and in the case of HCV sequencing, carefully selected short segments of the 5′-UTR, NS5B, or E1 are sufficient for practical purposes. In particular, analysis within the 5′-UTR permits an accurate definition of genotype, while assignment to subtypes is generally achieved by analyzing the NS5B region. Sequencing of the HVR1 and NS5B regions is indicated solely to trace epidemiological linkages when suspected transmission events need to be confirmed.

Automated sequencers have become increasingly available in recent years, yet genome sequencing is still expensive, time-consuming, and feasible only in laboratories with skilled expertise. Alternative easier-to-perform methods include type- or subtype-specific RT-PCR, restriction fragment length polymorphism analysis of RT-PCR amplicons obtained from informative domains of the viral genome, and other techniques. A frequently used commercial test exploits the ability of 5′-UTR amplicons to hybridize to type-specific probes immobilized on nitrocellulose strips (line probe assay). Assessment of the reactivity of a patient's antiviral antibodies against genotype-specific synthetic peptides deduced from the C and NS4 regions of the genome (improperly called "serotyping") does not distinguish subtypes and is less accurate. A commercial direct-sequencing kit targeting the 5′-UTR and NS5B regions and incorporating all the machinery needed to achieve a report—from RNA extraction to the database of reference strains—is also announced. It is likely, however, that genotyping will soon be based on real-time techniques capable of differentiating types and subtypes by melting curve analysis or hybridization with type-specific probes labeled with different fluorescent dyes.

Viral Quasispecies Analysis

Similarly to many other viruses, HCV is present in infected hosts in the form of a variably complex mix of genetic variants, generally known as quasispecies. Several investigations have addressed the issue of whether the complexity and diversity of the viral quasispecies may represent useful parameters in decision making about the management of HCV-infected patients, but no firm conclusions have been reached. In any case, the methods currently in use for quasispecies analysis (cloning followed by sequencing, single-strand polymorphism analysis, etc.) are too laborious for routine use.

HDV OR DELTA VIRUS

HDV is a satellite infectious agent that was first identified while an unusual antigen (delta antigen, or HDAg) found in certain HBV-infected patients was investigated and was subsequently found to resemble certain subviral agents of plants. HDV derives its outer envelope protein from HBV, and hence it grows only in HBV-infected hosts. The virion, a slightly pleomorphic 36-nm-diameter sphere, consists of (i) the above-mentioned external envelope composed of HBsAg and lipids; (ii) a circular, negative-sense single-stranded RNA of approximately 1.7 kb, which is the smallest genome

of any known animal virus; and (iii) a poorly defined capsid made of numerous copies of HDAg, the only known protein it encodes. The single-stranded RNA forms a rod-shaped imperfect duplex due to pairing of roughly 70% of its nucleotides and has well-characterized ribozyme activities. Self-cleavage and self-ligation are essential for processing the RNA intermediates generated by a rolling-circle mechanism of replication that uses cellular RNA polymerases. In virions and infected cells, the HDAg is present in two isoforms (small, or S-HDAg, of 195 amino acids, and large, or L-HDAg, which has 19 more terminal amino acids), which result from differential posttranscriptional RNA editing and have distinct regulatory functions during viral replication. Being unique among animal viruses, HDV is classified as the only member of the free-standing genus *Deltavirus*.

Unlike for HBV, extrahepatic replication of HDV has never been detected. Experimentally, HDV replicates only in HBV-infected chimpanzees (with more severe consequences than other human hepatitis viruses), in mice engrafted with HBV-infected primary human hepatocytes, and in eastern woodchucks infected by the respective hepadnavirus. Cells exposed to HDV alone can replicate the viral genome in the absence of any HBV gene product but with no production of complete virions and, with the exception of a subtle growth disadvantage, no consequences for the cells (46). Thus, there is no practical cell culture system for in vivo isolation.

HDV infection may occur either as coinfection in patients who are concomitantly infected with HBV or as superinfection of already HBV-infected patients, and the course and consequences of infection differ considerably in the two situations (Fig. 7). In coinfection, HDV replication is slowed by the scarce HBsAg available and generally peaks at low levels 1 week after HBV and evokes feeble immune responses. On the other hand, the dynamics of HBV replication and HBV-specific immune responses are scarcely affected relative to those of single HBV infection. Both viruses are generally cleared in a few months, and only 1 to 3% of coinfections become chronic. Clinical manifestations, when present, are indistinguishable from those caused by HBV alone except that they tend to be more severe and biphasic. The natural history of the few coinfection cases that fail to resolve is also similar to that of chronic hepatitis B alone, but bouts of HDV replication may occur. These are usually associated with transient reductions of HBV viremia due to competition for HBsAg.

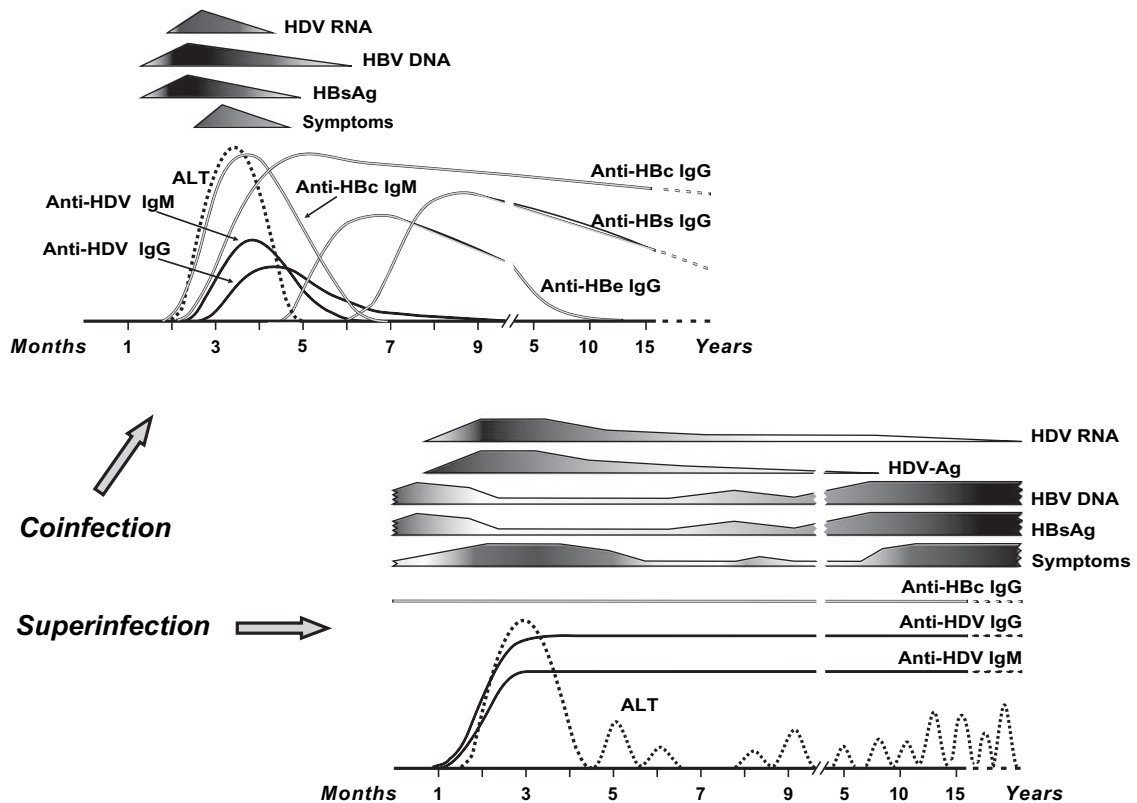
During superinfection, because HBsAg is already abundant in hepatocytes, HDV replication is more prompt and florid than in coinfection and causes a more profound suppression of preexisting HBV viremia. Immune responses to HDV also mount rapidly but, in spite of persistent high titers of anti-HDV antibodies (anti-HDs), over 70% of superinfected patients continue to circulate HDV indefinitely, although at lower levels than in earlier stages (Fig. 7). In


FIGURE 7 Typical course of immunovirological events and manifestations of liver damage in symptomatic HDV infection. In concomitant infection (coinfection) of naive individuals with HBV and HDV, HBV markers are affected very little by concurrent HDV replication, and HDV markers may escape detection due to their transient nature. In superinfection of individuals already infected with HBV, HDV replication is particularly florid and may produce transient reductions or undetectability of HBV DNA and HBsAg (see text).

patients who eventually succeed in resolving HDV infection, anti-HD IgG usually persists for the remainder of life. The acute phase of superinfection often, though not invariably, causes exacerbation of liver damage and a significant rate of fulminant hepatitis. The manifestations and outcome of chronic dual infection are also usually severe, with accelerated evolution toward cirrhosis, liver decompensation, and HCC.

Roughly 20 million people are believed to be HDV infected worldwide. The prevalence of HDV is uneven, however, ranging from 0.5 to 2% of HBV-infected individuals in North America and northern Europe, where HDV is virtually confined to IDUs, to 20 to 60% in South America and central and east Asia. The fact that the nucleotide sequences of different isolates may vary by 30% or more has led to distinguishing of three unevenly distributed HDV genotypes and two subtypes: type I is present worldwide, type II is present in Japan and Taiwan, and type III is present in northern South America, where acute infection is associated with particularly severe disease. Although HDV transmission routes are poorly understood, it is generally accepted that they are the same as for HBV.

As may be obvious in the light of HDV dependence on HBV, anti-HBV therapies (especially IFN-α) have been seen to significantly improve the long-term clinical outcome and survival of patients with chronic hepatitis D, even if they already have cirrhosis before treatment is initiated. Most importantly, HDV endemicity has considerably decreased where HBV vaccination is extensively used. Nevertheless, HDV is still an important cause of severe and fulminant hepatitis in developing countries (for recent reviews, see references 40 and 43).

Assay Systems for HDV

The possible coexistence of HDV infection is an important consideration in the management of hepatitis B, especially in areas of high HDV endemicity and in IDUs worldwide. In particular, it should be suspected in all cases of fulminant hepatitis B and in individuals with chronic HBV infections that undergo a sudden deterioration of symptoms which remains unexplained on the basis of parameters of HBV infection and other possible hepatotoxic events or do not improve as a result of lamivudine treatment. Traditionally, diagnosis used to rely mainly on assays for anti-HD, but HDV RNA detection methods have now become of great importance. Figure 8 provides a scheme for using and interpreting these tests.

Testing for Viral RNA

Detection of HDV RNA in the serum of HBV-infected patients is a particularly useful marker, as it indicates ongoing active HDV replication and is almost invariably positive in all types of HDV infection (13). Currently, HDV RNA is assayed mostly by RT-PCR assays, which especially in the real-time format have shown high sensitivity (lower detection limit, 10^2 to 10^3 genomes/ml) and specificity. HDV RNA quantitation is especially useful for patient follow-up in the course of therapy and often correlates with extent of liver injury (51). Liver biopsy can be complemented with the demonstration of HDV RNA located primarily in the nuclei of hepatocytes.

Testing for Viral Antigen

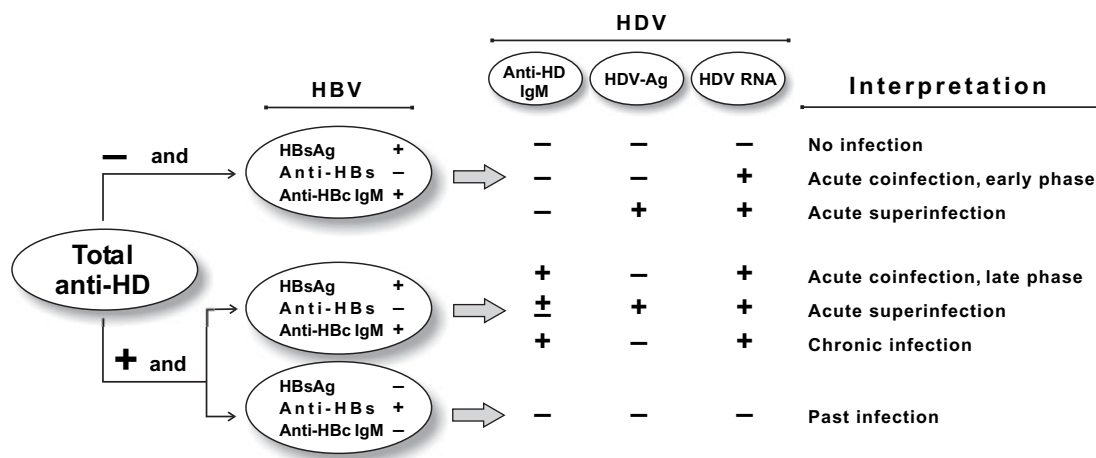
Although the presence of HDAg in serum is also a marker of ongoing active HDV replication, its clinical utility is very limited, as it is readily detectable only during the acute stages of superinfection, when HDV replicates extensively and reaches titers of up to 10^{11} infectious doses/ml of serum in 2 weeks (often causing a transient reduction of HBV viremia down to undetectable HBsAg). In contrast, most individuals with coinfections and chronic infections test HDAg negative because virus replication is moderate and/or the patients' anti-HDs interfere with HDAg detection in current assays (Fig. 7). Western blotting suffers less from the latter limitation and has the additional advantage of allowing separate visualization of S-HDAg and L-HDAg, but it is labor-intensive and commercially unavailable. In the past, immunohistological identification of HDAg in liver biopsy specimens has also been widely used.


FIGURE 8 Algorithm for use and interpretation of laboratory tests for HDV infection. A prerequisite for HDV testing is that the patient is infected with HBV. In regions of high HDV endemicity, HDV testing should be carried out every second or third year or whenever there is an unexplained aggravation of hepatitis. In regions of low endemicity, HDV testing should essentially be limited to IDUs or people returning from areas of endemicity.

Testing for Antiviral Antibodies

Assays for anti-HD use ex vivo-derived or recombinant HDAg. However, it is important to note that anti-HDs can be missed in self-limited coinfection because they develop late, remain low in titer, are mostly IgM, and persist briefly. In chronic infection, the presence of anti-HD IgM and high titers of total anti-HD are indicators of poor prognosis, though the correlation is far from absolute (13). Finding high titers of anti-HBc IgM is also useful in defining management and prognosis, since they indicate recent HBV infection and thus ongoing coinfection.

Determining Viral Genotype

HDV typing can be carried out by restriction fragment length polymorphism analysis or sequencing of selected amplicons, but currently its utility is limited to epidemiological surveys (50).

HEV

Hepatitis E, a major form of enterically transmitted hepatitis, is widespread in many developing countries but is currently considered an emerging threat also for other areas. HEV is nonenveloped, spherical, and roughly 30 to 34 nm in diameter. The genome is a capped, positive-sense, single-stranded, linear RNA of approximately 7.2 kb and is organized into three potential ORFs, two terminal short UTRs, and a poly(A) tail at the 3′ end. ORF1 has motifs characteristic for RNA-dependent RNA polymerase, RNA helicase, and other enzymes; ORF2 encodes the putative capsid protein; and ORF3 overlaps with the other ORFs and encodes a small immunogenic, cytoskeleton-associated phosphoprotein of unknown functions. HEV was classified within the family *Caliciviridae* until recently, but it is currently considered a genus of its own, the *hepatitis E-like viruses*. Several isolates have been entirely sequenced and, albeit phylogenetic analysis is still incomplete, at least three genotypes have been recognized: types I (Burma strain; Asia and Africa), II (Mexico), and III (United States). Genetic heterogeneity observed among different isolates is moderate except in a segment of ORF1. Only one serotype appears to exist, on the basis of serological cross-reactivity and cross-protection studies in experimental animals. HEV was definitively identified by inoculation into nonhuman primates soon after HCV was recognized as the principal cause of parenteral non-A, non-B hepatitis and was subsequently shown to infect other mammals as well. However, to date, HEV has not been reproducibly propagated in simple cell culture systems. Evidence indicates that HEV is a labile virus; therefore, storage of infected fecal extracts in liquid nitrogen is recommended for preservation (for a comprehensive review, see reference 49).

In several hepatitis E outbreaks, young adults 15 to 40 years of age were most at risk of developing overt illness. Lower disease rates for younger individuals were attributed to subclinical infection. The disease has an incubation period that ranges from 15 to 60 days (average, 40 days) and resembles hepatitis A but tends to be more severe (Fig. 1). In different epidemics, fatalities due to fulminant liver failure have usually been around 0.5 to 2% in hospitalized patients and are observed almost exclusively among third-trimester pregnant women and/or their unborn babies.

Antibodies are already present at clinical onset and peak by 1 month. Antiviral IgM is detected in >90% of patients and persists for at least 3 months in half of them, while IgG declines more gradually (Fig. 1). Anti-HEV antibody has been detected as long as 14 years after infection in roughly half of the patients. Reports of patients who have become seronegative much earlier may be due to improper choice of the antigens used in the assays for anti-HEV detection. Viremia and fecal excretion are short-lived and generally over soon after biochemical resolution of hepatitis in most patients (1).

HEV is present primarily in the Indian subcontinent, central and Southeast Asia, the Middle East, Mexico, and other developing countries with inadequate environmental sanitation, where it causes >50% of all cases of acute hepatitis. It is usually transmitted by fecally contaminated drinking water, and extensive waterborne epidemics are not infrequent. In highly developed countries, the infection is mostly imported by immigrants and travelers (and possibly infected animals as well) and shows little or no tendency to spread to contacts; however, cases with no risk factors in the medical history also occur. In such areas, anti-HEV is found in roughly 2% of healthy blood donors, but a certain number of false-positive results cannot be excluded. Chronic infection has never been detected in humans. Sporadic infection may be responsible for virus survival during interepidemic periods, but a role of nonhuman reservoirs is also very likely, since HEV or HEV-like agents are widespread in rodents, pigs, and other animals. Additional evidence indicating that HEV infection might be a zoonosis derives from sequence comparison of human and animal virus isolates (47). At the time of writing, no commercial vaccine against HEV infection is available; however, vaccination with recombinant HEV capsid protein has conferred protection in rhesus macaques, and a promising phase II clinical trial of this vaccine is ongoing in Nepal (34).

Assay Systems for HEV

Testing for Antiviral Antibodies

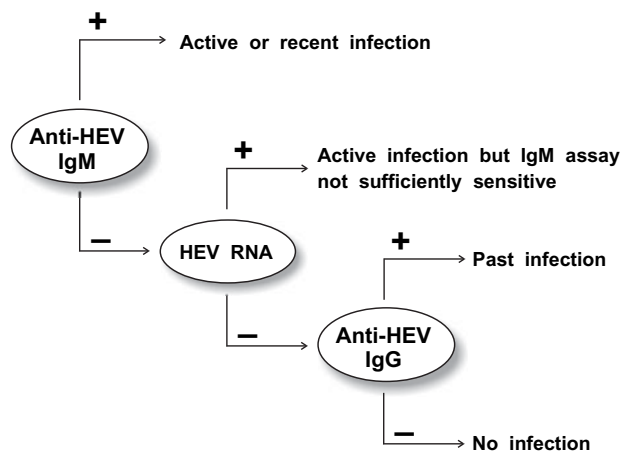
Detection of anti-HEV IgM is a well-recognized marker of recent infection and the most convenient one for diagnosis during the acute phase. Anti-HEV IgG antibodies are measured to discriminate remote from recent infections (Fig. 9). Since HEV cannot be cultivated or purified in large quantities, serology relies essentially on immunoassays using


FIGURE 9 Algorithm for use and interpretation of laboratory tests for HEV infection. HEV RNA assays should be performed only when there are solid reasons for suspecting HEV infection (see text), on stool samples collected within 2 to 3 weeks from clinical onset.

recombinant or synthetic ORF2 and/or ORF3 peptides of variable length (49). Recent comparisons have indicated that ORF2-based serological assays are more reliable than ORF3-based ones, possibly because the former contain epitopes more conserved among viral isolates. Thanks to considerable improvements, currently available commercial kits perform significantly better than previous ones (52). Western blotting has been used in small-scale studies to validate serological results.

Testing for Viral RNA

Because viremia frequently subsides before symptoms arise, feces (possibly collected within 1 week of symptoms) is a more appropriate specimen than blood for direct demonstration of the virus. RT-PCR assays using primers targeted to conserved segments of ORF1 or ORF2 generally perform well and detect the full range of clinical isolates. However, a negative result does not exclude infection, and the detection of anti-HEV IgM should be considered more informative.

GBV-C OR HGV

In the mid-1990s, two independent groups characterized two novel viral agents in the blood of patients with cryptogenetic hepatitis by the use of molecular approaches similar to the ones used for identifying HCV (18, 39). The viruses were called GBV-C and HGV, but sequence data soon showed that they were different isolates of the same species. The virion is an enveloped sphere, 40 to 60 nm in diameter. The genome is single-stranded, positive-sense linear 9.4-kb RNA, consisting of a single, long ORF and two UTRs located at the 5′ and 3′ termini. The ORF encodes a large polyprotein that is posttranslationally cleaved into mature structural proteins (namely, envelope glycoproteins E1 and E2) and NS proteins (NS2 to NS5, with motifs typical of an RNA-dependent RNA polymerase, two proteases, and a helicase). Notably, location of the gene for the nucleocapsid or C protein is still debated. It might be within the genomic RNA, possibly in a reading frame different from that of the major ORF, or within negative-sense RNA where a second ORF with no known functions has been described. Apart from this, the genomic organization of GBV-C is similar to that of HCV and other flaviviruses. The degree of nucleotide homology with HCV, however, is low (<30%). Overall genetic diversity among isolates is limited, but at least five major genotypes, some of which are further divided into subtypes, have been demonstrated and have different geographic distributions.

The immunobiology and pathogenic potential of GBV-C are poorly understood. Most acute infections resolve within a few weeks, but approximately 25% persist. In self-limiting infection, the disappearance of viremia is preceded by the development of antibodies to the E2 protein (anti-E2). In infections that become chronic, anti-E2 instead remains undetectable, and the virus continues to circulate in blood for many months or years, apparently bound to low-density lipoproteins but not to antibody. While this strongly suggests that anti-E2 is important for virus eradication, antibodies to the nucleocapsid protein have no apparent role in virus clearance.

To date, an unequivocal demonstration that GBV-C is implicated in any pathology is lacking. There are numerous reports of acute and chronic GBV-C infections in individuals with no evidence of hepatitis or other disease. In the few patients infected with GBV-C alone with otherwise unexplained elevated ALT levels, biochemical alterations were usually modest and temporally unrelated to GBV-C viremia fluctuations. Sites of GBV-C replication and persistence are poorly defined, but the liver does not appear to be a major one. Even in HBV- and HCV-infected patients, concomitant GBV-C infection did not seem to affect the severity of liver damage or outcome of therapy. However, the possibility that GBV-C may occasionally induce hepatitis, similarly to other viruses which may occasionally become hepatotropic, cannot be totally excluded. Interestingly, recent reports have indicated that HIV-1 patients coinfected with GBV-C by several years have lower HIV loads, progress to AIDS more slowly, and tend to survive longer than singly HIV-1-infected patients, suggesting that GBV-C might inhibit HIV-1 replication through mechanisms that remain to be elucidated (48).

Epidemiological surveys have shown that 2 to 20% of healthy people worldwide have antibodies against GBV-C, with the lowest rates found in Asia and North America and the highest rates found in Africa and South America. The prevalence rates of viremia are lower, varying between 1 and 4% in the general populations of different countries but with peaks of 25 to 75% in IDUs and other subjects at risk for parenteral infection in general. The high frequency of GBV-C infection in HCV- and HBV-infected patients (10 to 19%) demonstrates that these infections disseminate through similar routes. Mother-to-child transmission has been documented, while sexual transmission is considered likely (for a comprehensive review, see reference 41).

Assay Systems for GBV-C

Because there is growing consensus that GBV-C is an orphan virus in search of a disease, diagnostic tests are performed almost exclusively for research purposes. Nonetheless, laboratory diagnosis of infection may still be indicated for those forms of acute or chronic hepatitis that appear to be viral in origin but in which no other known virus can be implicated.

Testing for Viral RNA

Methods for isolating GBV-C in tissue culture and for detecting GBV-C antigen are currently unavailable. The diagnosis of active GBV-C infection is therefore carried out by molecular methods. Serum is the specimen of choice, although saliva, semen, and numerous tissues including liver, bone marrow, spleen, and white blood cells have been shown to contain small concentrations of virus. Conversion from detectable to undetectable viral RNA, especially if this occurs in concomitance with the development of anti-E2, shows a strong correlation with recovery from infection. However, intermittent viremia has also been observed in persistently infected individuals. RT-PCR assays that target the 5′UTR are preferable, since those targeting the coding regions NS3 and NS5 lead to some false-negative results, apparently due to a low level of homology. Use of the latter should be limited to confirmation of results for samples that have had a positive reaction by use of the 5′-UTR. More standardization is clearly needed. Several RT-PCR kits are commercially available and appear to have comparable sensitivities. Quantitative assays exploiting real-time or competitive PCR and genotyping methods using restriction fragment length polymorphism analysis, genotype-specific primers, or sequencing have also been described but at this time have no demonstrated clinical utility.

Testing for Antiviral Antibodies

Several distinct strongly reactive epitopes have been detected in the NS proteins. Since they appear to be conformation sensitive, the procedure used for their production is

critical for antigenicity. The only antibody detection approach fairly well validated to date is EIA using E2 protein expressed in CHO cells as a test antigen (commercial kits available). On the basis of the evidence discussed above, anti-E2 is considered a marker of clearance of infection. However, considerable uncertainty still exists about the correct interpretation of test results for individual patients. This is due to the facts that the assay can remain negative for months after exposure to the virus and that anti-E2-positive individuals may undergo reactivations of the infecting virus as well as reinfections with a different GBV-C genotype. Moreover, despite considerable improvements, current tests still yield a significant proportion of false-positive and false-negative results. Testing for NS3 antibodies has been proposed but has not yet been fully validated as a means of improving the reliability of GBV-C serology. Confirmatory tests proposed include a line probe assay based on recombinant structural and NS proteins, a radioimmunoprecipitation assay using E2 protein expressed in BHK-21 cells, and a sandwich EIA using E2 protein expressed in CHO cells, but all of these tests must be validated, and at least some are clearly impractical for routine use. Anti-E2 IgG lasts for >3 years at fairly constant titers, while attempts to develop reliable specific IgM assays have been frustrating so far. Thus, no serologic test that may provide information on the duration of GBV-C infection is available.

TTV AND OTHER ANELLOVIRUSES

The free-standing genus *Anellovirus* was created recently to accommodate a large group of viruses that are often highly divergent from each other in sequence but have in common a remarkably small circular single-stranded DNA genome of negative polarity. Torquetenovirus (from the Latin torques, necklace, and tenuis, thin) (TTV), the prototype of the group, was first identified in 1997 in the serum of a patient with cryptogenetic posttransfusion hepatitis (27). Subsequent studies revealed the existence of numerous clearly related additional viruses, some of which were classified in the separate species mini-torquetenovirus (TTMV), due to their even smaller genome. SEN virus (SENV), thus named for the HIV-positive patient in whose blood it was first identified, was initially considered an independent entity but is now classified within the 5 genogroups and over 30 genotypes in which TTV is currently subdivided as a result of its extreme genetic diversity.

TTV has not yet been visualized with certainty by electron microscopy or grown in tissue culture. As determined by examining infected plasma, the viral particle has a diameter of 30 to 50 nm, is nonenveloped, and appears to be very stable in the environment. About two-thirds of the 3.8-kb genome is made up of a large ORF (ORF1, coding capacity for approximately 770 amino acids) and several partially or totally overlapping smaller ones. The rest (UTR) of the viral genome is noncoding and contains various regulatory elements probably involved in replication. Although the natural history of infection is poorly understood, it is well documented that TTV is extremely prevalent worldwide (80% or more of healthy subjects are viremic at titers ranging from 10^3 to 10^8 DNA copies per ml), frequently if not invariably establishes chronic productive infections, and shows replication dynamics as active as those of other chronic viremia-producing viruses, such as HBV, HCV, and HIV. Cases of seemingly self-limited acute infection have also been described; however, it is unclear whether they reflect true virus eradication. On the other hand, mixed infections by multiple TTV genogroups

and genotypes are quite common, thus suggesting that immune responses are inefficient at eradicating the virus and provide no significant cross-protection. Transmission is believed to occur by the oral-fecal route and parenterally and transplacentally, but the upper respiratory tract also is an important route by which abundant virus can be shed into the environment. The discovery that TTV viremia is so widespread among the general population rendered early data on its high prevalence in hepatitis patients meaningless. Also, reports that infection with certain TTV genotypes, such as SENV, may be specifically associated with self-limited non-A non-E hepatitis have not been clearly substantiated (37). To date, therefore, TTV does not appear to be a significant agent of hepatitis and should actually be considered a virus in search of a disease since no other clinical involvement has been demonstrated with reasonable certainty (3). Interestingly, the loads of TTV in nasal samples of infants hospitalized for acute respiratory infections were recently seen to correlate with disease severity. Indications that TTV might be immunomodulatory in young children have also been reported (19).

Assay Systems for TTV
As long as the pathological implications of TTV remain undefined, diagnosis of infection will be of uncertain clinical utility.

Testing for Viral DNA
Because of the lack of sensitive in vitro culture systems and viral antigen detection methods, the only described approach for demonstrating TTV is by PCR amplification. The virus can be easily detected in serum and other specimens such as stools, saliva, nasopharyngeal and genital fluids, and breast milk. Due to the great genetic diversity of TTV, "universal" PCR methods are targeted to a small, highly conserved segment of the UTR. Use of these methods has greatly increased the rates of TTV-positive samples and revealed viremia titers 10- to 100-fold higher than those determined by ORF1-based PCR assays. None of the PCR protocols proposed, however, has been validated for detection of the entire spectrum of TTV variants. Typing of TTV has most frequently been carried out by sequencing of ORF1 segments; however, genogroup-specific PCR assays have recently been designed for appropriately selected UTR or ORF1 regions. PCR primers have also been designed for selective detection of SENV or other TTV genotypes and are targeted mainly to the ORF1. Quantitative assays based on microwell hybridization of amplicons obtained with primers specific for SENV isolates have also been described.

Testing for Antiviral Antibody
To date, there are no validated immunoassays of practical use in the clinical laboratory. The only reports on the presence of anti-TTV antibody in infected patients involved PCR-assisted immunoprecipitation of whole virus extracted from fecal samples, Western blotting with a truncated ORF1 recombinant protein, and an EIA against ORF1 synthetic peptides. These and other studies have shown that anti-TTV IgG is present in most viremic and nonviremic subjects and that a large proportion of the TTV found in blood is immunocomplexed.

CHOOSING TESTS ACCORDING TO DIAGNOSTIC PURPOSE

The sections above have described the complete range of diagnostic tests available for each virus discussed. However, testing should be modulated depending on the information

sought, the characteristics of the specific patient under scrutiny (e.g., age, clinical features, risk factors, etc.), and epidemiological circumstances. This planning avoids needless costs in terms of reagents, equipment, technical time, and expertise. The following considerations are meant to assist in choosing the optimal testing protocol in different situations.

Etiologic Diagnosis of Hepatitis

The existence of risk factors for parenteral transmission (e.g., abuse of injecting drugs, transfusions of blood or blood derivatives, recent major surgery, promiscuous sex life, etc.) should immediately raise the suspicion that acute hepatitis is due to HBV or HCV. By contrast, a history of risky behavior for enteric transmission (e.g., recent visit of unvaccinated individuals to areas of HAV endemicity, ingestion of raw bivalve shellfish, etc.) should orient the clinician toward hepatitis A or E diagnosis. The diagnostician should also keep in mind that hepatitis A and E tend to occur in outbreaks of variable size, while hepatitis B and C are usually sporadic. Clinical presentation may also provide some guidance. Abrupt initiation of symptoms with a fever of >38.5°C and a sharp elevation of ALT levels above 1,000 IU/liter are usually indicative of HAV infection. In contrast, insidious onset of symptoms and moderately elevated ALT levels are more typical of hepatitis B and C. Cholestasis is especially prominent in hepatitis E.

In practice, however, in order to shorten diagnostic times and recognize possible mixed infections—which are not uncommon, especially in IDUs and other high-risk groups—clinicians investigating the origin of a recently diagnosed hepatitis usually request simultaneous testing for HAV, HBV, and HCV. A standard protocol for diagnosing acute viral hepatitis includes determination of anti-HAV IgM, HBsAg, anti-HBc IgM, and anti-HCV. A single testing for anti-HAV IgM and HBsAg is usually sufficient to confirm or exclude infection by HAV or HBV, respectively. As discussed in the appropriate section, anti-HAV IgM is a reliable marker of recent infection. If HBsAg is found in serum, it is customary to proceed to test for total anti-HBc, which is confirmatory for diagnosis, and for anti-HBc IgM, which is present at high titers in acute infection and in exacerbated chronic infection. It is also worth recalling that testing for anti-HBc IgM is usually enough to identify the few cases of fulminant or neonatal HBV hepatitis that test HBsAg negative (see above). In any case, testing for HBV DNA will help solve any diagnostic doubt that might persist. The presence of anti-HCV is evidence of active infection in approximately 80% of cases and warrants further assessment. In contrast, the absence of anti-HCV does not exclude acute hepatitis C because 30 to 50% of patients are not reactive at clinical onset. It is thus necessary to further assay seronegative patients for HCV RNA, which circulates in blood well before any biochemical or clinical change, and/or retest these patients for anti-HCV after 3 months or more. The possibility that antiviral antibodies are passively acquired should also be considered when dealing with neonates or persons treated with serum immunoglobulins. Outside areas of endemicity, testing for HDV should be reserved for HBV-infected patients who have traveled to such areas or who abuse injecting drugs. Testing for HEV should be limited primarily to patients living in or recently arrived from areas where the virus is endemic and, in the absence of such risk factors, when all other causes of hepatitis have been excluded. Finally, if all of the above viruses have been ruled out, the patient may be assayed for viremia by HGV or TTV

and other anelloviruses, although the clinical significance of positive tests remains generally unclear.

Follow-Up of Hepatitis after Etiology Has Been Established

Accurate follow-up of patients infected by hepatitis viruses that may give persistent infection (HBV, HCV, and HDV) is important. Because primary infection is often clinically silent, the ex novo appearance of symptoms of hepatitis may result from recrudescence of unrecognized chronic infection as well as from primary infection. Distinguishing between these possibilities requires additional tests, as schematically indicated in Table 3 and Fig. 4, 6, and 8. Moreover, the ALT levels of patients with HBV, HCV, and HDV infection should be monitored at relatively close intervals. Parameters that provide a direct evaluation of virus replication are also of great utility, but, unless the clinical picture undergoes significant changes, they can be examined at longer intervals. Because the liver is by far the major body site of HBV and HCV replication, viremia levels are a dependable measure of virus replication within this organ, although not of liver damage progression. Measurement of HBsAg in paired serum samples obtained 4 to 6 weeks apart can help in distinguishing acute HBV infections that have no tendency to recovery, because in this case antigenemia shows no appreciable decline. The presence of circulating HBeAg is also an important marker of vigorous HBV replication, while its disappearance followed by the development of anti-HBe usually precedes, by weeks or months, the disappearance of HBsAg and the development of anti-HBs, which are hallmarks of resolution. Anti-HBc IgM levels are useful for diagnosis of reactivation of chronic infection, as well as acute infections. Currently, however, quantification of HBV DNA levels in blood circulation is commonly used, since this test provides the most direct and accurate indication of HBV replicative activity and also detects the HBeAg-minus mutants that persist despite the presence of anti-HBe. Also, patients with persistently high HBV DNA loads should be carefully monitored for HCC. HBV-infected individuals who abuse illicit drugs or live in areas where HDV is highly prevalent should also be tested for markers of superinfection by HDV every 2 to 3 years and, in any case, whenever symptoms deteriorate abruptly or persist in spite of HBeAg unreactivity. HDV superinfection is an important element in decisions about patient management.

Hepatitis C has much less propensity to spontaneously resolve than hepatitis B. Serology is of little or no value for staging HCV infection because current anti-HCV IgM assays perform poorly, and the humoral profiles show very slow, if any, change in the course of persistence, even after virus clearance. Follow-up is carried out by periodically measuring HCV RNA or, less frequently, HCV antigen loads. Over 95% of viremic patients test positive for HCV antigen at levels that generally but not invariably correlate with the viral loads determined by molecular assays (38, 45). HCV viremia values vary extensively for individual patients but, except in the acute phase of infection, tend to remain stable over time. Direct visualization of necroinflammatory liver changes is currently irreplaceable for prognosis and management of chronic hepatitis. Biopsy should preferably be carried out during periods of relatively low hepatitis activity.

Predicting and Evaluating the Outcome of Antiviral Therapy

As discussed above, the options currently available for treatment of viral hepatitis are limited. In particular, although

numerous new drugs are under evaluation or development, there are no antiviral drugs approved for hepatitis A and E, and those that can be used to contain and possibly eradicate HBV and HCV are still few. The decisions regarding antiviral therapy of chronic hepatitis B and C are generally made on clinical, histopathological, and immunovirological grounds and should be carefully weighed against side effects and cost. The goals are a sustained virological response (virus undetectable in blood) or at least a sustained biochemical response (normalization of ALT levels for >12 months) and improved histopathology. Once the decision to initiate therapy is made, the dynamic changes of viremia during treatment are an important guide, together with parameters of disease progression such as ALT levels, in deciding whether the therapy should be continued, discontinued, or adjusted.

Treatment of chronic hepatitis B has improved greatly in recent years, thanks to the development of new antiviral drugs which, alone or in combination with IFN-α, effectively inhibit HBV replication and improve disease status and prognosis. The best noninvasive approach for monitoring the response of chronic HBV infection to therapy is measurement of the markers of virus activity, including HBsAg, HBeAg, and HBV DNA, as well as ALT values at intervals. Initially, the response to therapy in terms of viral load is generally very sustained, but relapses are almost the rule due to the selection of drug-resistant virus mutants. How drug-resistant HBV mutants can be identified has been described in a previous section. Since HDV replicates only if HBV is also present, treatments that cure HBV also eradicate HDV. Evidence, however, indicates that concurrent infections by two or more hepatitis viruses are difficult to treat. Also extremely difficult to treat are HBV and HCV infections in HIV-1-positive patients. These dual or triple infections have recently emerged as major causes of morbidity and mortality, with liver damage that progresses more rapidly than in singly infected individuals, and they may significantly decrease tolerance to highly active antiretroviral therapy (28, 36).

With regard to chronic hepatitis C, there is wide consensus that all patients with persistently elevated ALT levels, high viremia levels, and portal and bridging liver fibrosis should be treated because their risk of developing cirrhosis is prominent. It is also generally agreed that patients with consistently normal levels of ALT and patients with advanced cirrhosis should be managed on an individual basis or in the context of clinical trials. A decrease of liver fibrosis in some treated HCV-infected patients has recently been described (32). Features that correlate with poor response of chronic hepatitis C to therapy include the following: viral genotypes 1 and 4; high viremia loads; highly complex viral quasispecies; and, in Asian type 1b isolates, the amino acid composition of a specific segment of the NS5A protein as well as patients' old age, male gender, African-American ethnicity, and presence of advanced liver fibrosis (54). Thus, therapeutic strategies and regimens need to be customized on the basis of numerous variables, among which the viral ones are of utmost importance (10). Current guidelines suggest that genotype 1 or 4 HCV-infected patients should be administered a 48-week course of pegIFN-α and ribavirin, whereas patients infected by genotype 2 or 3 should be treated for 24 weeks only and with lower dosages of ribavirin. Pretreatment viral burdens are also very relevant: baseline viral loads higher than 800,000 IU per ml have been seen to correlate with reduced rates of sustained responses, especially in genotype 1 HCV-infected subjects. The early effects of treatment on viral load are considered useful for predicting

the eventual response to therapy and adjusting the therapeutic protocol accordingly, since a sustained virological response is most likely in patients whose plasma HCV RNA drops to undetectable levels or shows a 2-$\log_{10}$ decrease by 12 weeks of treatment (early responders). Contrariwise, HCV RNA titers above 450,000 and 30,000 IU per ml at 4 and 12 weeks of therapy, respectively, have been reported to correlate with failure to undergo a sustained virological response (4). In this context, measuring the level of HCV antigen in blood has also shown utility: a negative antigenemia by 1 month of therapy was reported to be highly predictive of favorable response (21). With the therapies in use at present, many HCV-infected patients who initially appear to respond well relapse, as documented by the return to abnormal ALT levels and high virus levels in serum. The causes of hepatitis C relapses are poorly understood.

Guidelines for treatment of acute hepatitis C are still poorly defined. It has been suggested that therapy should begin as early as possible for asymptomatic patients but start only 2 to 4 months after acute onset for those with symptoms, since they are more likely to clear the infection spontaneously (42).

Evaluation of Immune Status

Evaluation of immune status is generally needed to decide whether persons scheduled for vaccination are already immune as a result of past infection and to evaluate the immunizing effect of vaccination. For HAV, total anti-HAV is the test of choice. For hepatitis B, anti-HBs is usually sufficient, and total anti-HBc may be used to discriminate previous infection from vaccination. A low level of anti-HBs alone in the absence of a history of vaccination might be a false-positive result.

Epidemiological Surveys

Because evaluation of the prevalence rates of viruses in selected populations or groups requires the examination of large numbers of samples, a compromise between the sensitivity/specificity and the cost of a test(s) is usually sought. Total anti-HAV persists long after infection or vaccination; thus, serosurveys are of limited value in the determination of the extent of actual HAV circulation in a population at the time of testing. Examination of sewage samples for the presence of HAV by molecular methods is more informative and relatively simple. This method is proving useful also for monitoring HEV infection in areas of endemicity, while serosurveys are of value for surveillance of HEV penetration in areas of low or no endemicity. Anti-HCV positivity rates provide a valid estimate of actual HCV prevalence because approximately 80% of seropositive individuals are also virus carriers. Similarly, tests for HBsAg provide an accurate estimate of HBV carrier prevalence. Sensitive molecular assays have shown that a number of patients continue to harbor minute copy numbers of HBV DNA long after HBsAg is no longer detectable, but the significance of these subjects in epidemiology is unknown. Because antibody detection tests for GBV-C and anelloviruses are under validation or not yet available, respectively, epidemiological investigations for these viruses have used molecular assays. In general, these are more expensive than immunoassays but can be designed in such a way as to provide information also about prevailing virus genotypes.

Screening of Blood, Tissue, and Organ Donors

In most countries, donor screening for hepatitis viruses is still limited to testing of sera for HBsAg and anti-HCV.

A small number of cases of HCV infection still occur in recipients, due to the fact that anti-HCV tests do not reveal donors in the window period. Since these cases can be further reduced by tests that detect HCV RNA, the blood banks of several countries have introduced them in their routine. The so-called surrogate markers for non-A, non-B hepatitis, such as ALT and anti-HBc, have lost impact after the development of HCV tests, but they still help to exclude risky donors. Testing of donors for other blood-borne viruses, including GBV-C and TTV and other anelloviruses, is instead generally viewed as an additional burden, totally unproductive in terms of blood and organ supply safety.

Rotaviruses and Noroviruses

NINGGUO FENG AND SUZANNE M. MATSUI

84

ROTAVIRUS

Group A rotavirus, a member of the family *Reoviridae*, is a major cause of infectious gastroenteritis in infants and young children throughout the world. This pathogen alone accounts for 20 to 70% of hospitalizations due to diarrhea and 400,000 to 500,000 deaths per year in developing countries (34). The impact of rotavirus diarrhea is also substantial in industrialized countries, where nearly all children experience a rotavirus infection by the time they are 5 years old. In the United States each year, rotavirus diarrhea results in 500,000 physician visits and 50,000 hospitalizations (33, 39). Given the magnitude of the global public health problem associated with rotavirus infection and the observation that natural infection ameliorates the rate and severity of reinfection, strategies to develop effective vaccines have been pursued intensively.

Rotavirus was first identified by electron microscopy (EM) of duodenal biopsy specimens from children with diarrhea (2). Viral particles were found to be 70 nm in diameter, with a distinctive appearance. Ultrastructural analysis by electron cryomicroscopy disclosed that the viral capsid is formed by three concentric protein layers with external spikes. Within the innermost layer is the viral genome, composed of 11 segments of double-stranded RNA. The antigenic capsid proteins important for rotavirus detection are VP6 (encoded by gene segment 6), the middle-layer protein that specifies the subgroup; VP7 (encoded by gene segment 7, 8, or 9, depending on the strain), the glycoprotein that forms the lunar-like surface of the outer capsid shell and determines G serotype; and VP4 (encoded by gene segment 4), the protease-sensitive spike protein of the outer capsid that determines the P serotype (reviewed in reference 8).

The ability to detect rotavirus infection is essential in epidemiologic surveys, vaccine studies, and investigations of outbreaks of gastroenteritis. A variety of methods are available to facilitate the diagnosis of rotavirus infection, from imaging the virus directly to detecting viral antigens immunologically to detecting viral nucleic acid. EM is a highly sensitive and specific method that allows direct visualization of the virus and has the potential to identify other enteric viruses within a sample as well, but it requires expert operators and specialized equipment that are not readily available in all settings and cannot process large numbers of samples rapidly. Diagnostic methods based on immunologic detection of rotavirus antigens have been developed to circumvent some of these problems (46). Enzyme immunoassay (EIA), in particular, has been used extensively to establish the incidence and prevalence of rotavirus infection and to define antigenic characteristics of the virus. The simplicity and high sensitivity and specificity of the assay, along with its ability to handle large numbers of samples efficiently, are distinct advantages of EIA.

EIA

Two EIA formats have been developed to detect rotavirus antigen. In the direct assay (Fig. 1), the anti-rotavirus antibody is labeled with enzyme. The capture antibody (Ab_1 in Fig. 1) and rotavirus antibody conjugated with an enzyme (Ab–Enzyme) may be derived from the same host. Once the Ab–Enzyme is produced and its characteristics are defined, the assay can be performed rapidly and without difficulty. In the indirect assay (Fig. 2), an unlabeled antiviral antibody is bound to a solid phase and enzyme-labeled antiglobulin is used to quantify the amount of antigen bound (Fig. 2). The capture antibody (Ab_1 in Fig. 2) and the detector antibody (Ab_2) must be derived from two different animal species. This format is well suited to a laboratory that performs a number of different EIAs, since a single, commercially available enzyme-labeled immunoglobulin can be used for any EIA. In addition, the relatively higher degree of sensitivity attainable with the indirect EIA is advantageous in evaluating samples from large epidemiological surveys.

Modification of the EIA by incorporating a high-affinity marker-antimarker combination yields rapid and reproducible results (46). One strategy is to label the liquid-phase antibody with biotin and then allow it to react with avidin. In EIA systems, the assay can be completed by reaction with avidin that has been covalently coupled to an enzyme or complexed with biotin-substituted enzyme. The latter format yields signal-to-noise ratios that are superior to those encountered when enzyme-linked avidin derivatives are used. If avidin directly labeled with enzyme is used, avidin derived from avidin-producing strains of streptomycetes or egg white avidin which has been modified to minimize the extent of nonspecific reactions is preferable to unmodified egg white avidin.

A distinct advantage of the biotin EIA method is that virtually all of the immunological and enzymatic activities

1. Rotavirus antibody (Ab₁) is adhered to the well of a microtiter plate.

Wash

2. The test material is added. If it is rotavirus (●) positive it will adhere to the rotavirus antibody precoat. Rotavirus negative material (⋯) will be washed away in the following washing.

Wash

3. Rotavirus antibody (Ab) conjugated with an enzyme is added. This antibody can be derived from the same host as Ab₁. This will react with rotavirus antigen that is adhered to Ab₁.

Wash

4. A substrate is added. The enzyme adhered to the well will convert the substrate to a visible form. The amount of color is proportional to the amount of rotavirus antigen in the test material.

of the reagents are maintained throughout the immunoassay procedure, since the enzyme is not directly linked to immunoglobulin. In addition, the fact that a single molecule of avidin can react with up to four molecules of biotin offers the potential for increased sensitivity due to magnification at the level of avidin-biotin interactions. On the other hand, since avidin-biotin systems do not utilize anti-immunoglobulins, they are less subject to nonspecific interactions with other anti-immunoglobulin materials often present in clinical specimens. EIA systems that use biotin are often more specific than equivalent systems that involve unlabeled antibodies and enzyme-labeled immunoglobulins.

The EIA can also be designed to detect rotavirus antibody in one of two ways. In the binding assay, rotavirus antigen is bound to the solid phase either directly or through an antibody. Dilutions of test specimen are added, and the amount of bound immunoglubulins is determined by the addition of the appropriate enzyme-labeled anti-immunoglobulin and, after incubation, the appropriate substrate. By using class-specific anti-immunoglobulins, immunoglobulin G (IgG), IgM, and IgA can be specifically quantified. In practice, the ability to measure anti-rotavirus IgM levels in serum can be greatly improved by first removing serum IgG with staphylococcal protein A or streptococcal protein G or by ion-exchange chromatography (47). Alternatively, IgM (an indicator of recent infection) can be measured by a reverse-capture system, in which IgM is bound to a solid phase by means of anti-human IgM and then IgM directed at

rotavirus is quantified by the addition of rotavirus antigen and labeled anti-rotavirus antibody. The measurement of anti-rotavirus IgA is important in the measurement of anti-rotavirus antibody in human body secretions such as intestinal fluids and milk (49). One problem with the binding method is that a different antiglobulin is required for each species of animal in which antibody is to be measured. When antibody from a number of animal species is to be tested, a blocking assay can be used. Such assays simply involve the mixing of the test specimen with a known amount of rotaviral antigen and, after a suitable incubation period, the measurement of antigen not neutralized by the serum. Such blocking tests are simple to perform and use the same reagents as do the antigen detection tests. However, they do not provide information about the immunoglobulin subclass of the rotavirus antibody.

General Considerations

Solid Phase

All of the EIAs described above require the initial binding of a reactant to a solid phase. The most widely used and versatile is the microtiter plate, from which results can be obtained rapidly with a microplate spectrophotometer. In preparation for screening a large number of samples, a large number of plates can be coated at once. If the coated plates are carefully sealed with plastic film and stored at 4°C in a moist chamber, they display minimal loss of activity for up to 4 months of storage.

1. Rotavirus antibody (Ab₁) is adhered to the well of a microtiter plate.

Wash

2. The test material is added. Rotavirus antigen (●) will adhere to the rotavirus antibody precoat. Rotavirus negative material (∴) will be washed away in the following washing.

Wash

3. Unconjugated rotavirus antibody (Ab₂) from a different animal than Ab₁ is added. This will react with rotavirus antigen that is adhered to Ab₁.

Wash

4. Enzyme-labelled antibody directed against the IgG globulin subclass of the animal source of Ab₂ is added.

Wash

5. A substrate is added. The enzyme adhered to the well will convert the substrate to a visible form. The amount of color is proportional to the amount of antigen in the test material.

Washing

Washing facilitates the separation of reactants bound to the solid phase from unreacted reagents that could yield false-positive results. This is best accomplished by adding a non-ionic detergent such as Tween 20 to the wash fluid and washing with at least 200 μl of wash fluid in each well. To avoid incomplete removal of reactants and sporadic mixing of reagents between wells, aspiration of wash fluid with a suction device (e.g., a suction manifold or a Pasteur pipette attached to a vacuum) is recommended over simple inversion of the microtiter plate.

Enzymes

Although a number of enzymes can form active conjugates with immunoglobulin, most EIAs use either peroxidase or alkaline phosphatase. Conjugates prepared with either enzyme can be used for rotavirus EIAs, and the choice of enzyme depends on the particular needs of the investigator. Peroxidase has the advantage of being relatively inexpensive and having substrates which form a dark color and thus are easy to read visually. Peroxidase conjugates are stable at 4°C,

but their action is largely destroyed by bacteriostatic agents such as sodium azide. Sodium azide is commonly added to fecal specimens to deter bacterial overgrowth, but it should not be used in the steps immediately preceding and during the use of the peroxidase. Alkaline phosphatase, on the other hand, is not sensitive to bacteriostatic agents and thus is more stable under field conditions. In addition, the reaction between alkaline phosphatase and the substrate can be completely stopped by raising the pH above 12, and alkaline phosphatase has a large number of substrates (see below). Both alkaline phosphatase- and peroxidase-conjugated anti-immunoglubulin antibodies are available from a number of commercial sources; alkaline phosphatase is somewhat more expensive than peroxidase. An overview of enzyme-antibody conjugates is found elsewhere in this manual (chapter 2).

Substrates

The simplest substrates for use in EIAs are those which yield a visible product on interaction with the bound enzyme. The amount of color can be estimated visually or quantified with

a spectrophotometer. There are a number of such substrates available, including p-nitrophenyl phosphate for alkaline phosphatase and o-phenylenediamine, 5-aminosalicylic acid, and diaminobenzidine (in conjunction with peroxide) for peroxidase.

Reagents

The sensitivity of EIAs makes it necessary to use highly specific reagents to minimize undesired cross-reactivity. Specific reagents are best prepared from rotavirus strains that have been adapted to tissue culture systems. While numerous strains can be used, the simian strain SA11 is well suited for use in immunoassay systems since it can be grown to high titer in a number of different tissue culture cell lines. Antigen obtained from tissue culture cells should be purified by multiple sedimentation on sucrose and cesium chloride gradients, using standard ultracentrifugation techniques, before being used to immunize animals; this avoids the problem of nonspecific interactions due to the generation of antibodies to nonviral tissue culture components. Antigens cloned and expressed in recombinant forms or synthetic peptides may also serve as antigens for solid-phase immunoassays (25). However, care should be taken to exclude the possibility of reaction to vector-derived proteins or to cross-reacting peptides; the use of molecular sources of antigen does not remove the need for performance of careful control reactions to ensure assay specificity.

Purified antigen can be used to immunize a variety of laboratory animals, most commonly mice, guinea pigs, rabbits, goats, and sheep. Antiserum is collected from the animals by bleeding at multiple intervals after immunization and is monitored by the immunoassays described above. Rotavirus reagents are also available from commercial and nonprofit sources. Reagents obtained from these sources should be carefully evaluated for sensitivity and specificity prior to use. Rotavirus antigen can also be used to prepare monoclonal antibodies by means of mouse immunization and standard hybridoma techniques. The availability of enzyme-labeled anti-immunoglobulins which have been affinity purified to remove nonspecific reactivity has greatly improved the specificity and reduced the background activity of indirect immunoassays. The use of highly specific anti-immunoglobulins is recommended in all assay formats.

It should be noted that although there are antigenic differences among human and animal rotaviruses, all group A rotaviruses share sufficient common antigenic determinants to allow detection by reagents to one strain. On the other hand, if highly specific or monoclonal reagents are used, quantitative determinations can be performed to determine the subgroup and serotype of rotavirus isolates by the comparison of homotypic and heterotypic reactions (26). Different reagents may be required to detect rotaviruses that do not share the rotavirus common antigen. Since reagents vary in potency according to their source and method of preparation, optimal dilutions for use in the EIA should be determined by titration.

Nonspecific Reactions

Positive reactions that are not due to the presence of rotavirus antigen or antibody can occur by a variety of mechanisms. Nonspecific interactions among the antisera can cause high background in the absence of any added specimen. This problem can be overcome by the use of purified reagents as described above and, in the indirect assay, by the use of enzyme-labeled conjugates prepared from antiglobulins of high specificity. In addition, some stool specimens contain material that can react nonspecifically with an animal immunoglobulin. These specimens can be identified by the fact that they react with wells coated with normal serum as well as with those coated with specific anti-rotavirus serum; the exact nature of this cross-reacting material is not known. Nonspecific activity is detected by processing each specimen in wells coated with serum that does not contain antibody to rotavirus as well as in wells coated with anti-rotavirus antiserum. Specific rotavirus activity is defined as the difference between the activity in the specimen processed in wells coated with the anti-rotavirus serum and that in the same specimen processed in wells coated with the nonimmune serum (Fig. 3).
